Table 1: Real-world resource allocation problems in recent literature.

resources or demands, e.g., if a job attains higher throughput when it has exclusive access to a GPU compared with when sharing it with other jobs.

- *Non-separable constraints.* A constraint is non-separable when it spans multiple resources and multiple demands simultaneously. For example, this occurs when the jobs submitted by each user are collectively limited by a user-specific GPU hour quota. To restore decomposability, DeDe has to treat all jobs (the original demands) from the same user as a single aggregated demand. However, this aggregation reduces the granularity of parallelism, from the job level to the user level.

Suboptimal solutions. DeDe may fail to reach the optimal solution when the allocation problem deviates from the assumptions underlying standard ADMM.

- *Non-convex problems.* Although ADMM has demonstrated empirical success on various non-convex problems [54, 64, 70], its theoretical convergence is guaranteed only under specific conditions [39, 57, 61]. Consequently, DeDe may converge to suboptimal solutions in non-convex settings.
- *Nonlinear constraints.* When a constraint is nonlinear, DeDe has to reformulate it with an indicator function in the augmented Lagrangian. The indicator function returns zero if the constraint is satisfied and infinity otherwise. However, this approach destroys the convexity of the objective, resulting in the aforementioned non-convex problems.
- *Higher allocation dimension.* DeDe assumes a two-dimensional allocation matrix that maps resources to demands, leading to a two-block ADMM formulation. Introducing additional dimensions such as a temporal dimension [37] will increase the number of variable blocks in ADMM and thus might lead to convergence issues [11].

5 Case Studies

In this section, we present case studies of DeDe applied to three representative resource allocation problems [44]: cluster scheduling, traffic engineering, and load balancing.

5.1 Cluster Scheduling

Cluster scheduling problems [43–45, 63] involve allocating computing jobs to different resource types in heterogeneous clusters. The job scheduling example introduced earlier is a simplified version of this problem.

Max-min allocation. This variant aims to distribute the heterogeneous cluster resources fairly among jobs such that the minimum throughput is maximized.

- *Variables.* Jobs can be time-sliced across available resource types [44, 45]. Thus, the allocation plan is a matrix $x \in [0,1]^{n\times m}$, where x_{ij} is the fraction of time (optimization interval) that each job j spends on each resource type i.
- *Objective.* Given an allocation matrix x, we adopt a normalized effective throughput of job j from POP [42], which is a linear function of x_{*j}. The objective is to maximize the minimum normalized effective throughput:

$$\underset{x}{\text{Maximize}} \ \min_{j} \ \text{throughput}(j, x_{*j}).$$

- *Resource constraints.* For each computing resource type i, the total amount of resources requested by all jobs cannot exceed the corresponding capacity:

$$\sum_j x_{ij} z_j \le \text{capacity}_i, \quad \forall i,$$

where z_j is the amount of resources requested by job j.

- *Demand constraints.* For each job j, the sum of all fractions of time must not exceed 1 naturally:

$$\sum_i x_{ij} \le 1, \quad \forall j.$$

Proportional fairness. The second variant of cluster scheduling maximizes the overall resource utilization while ensuring minimum service for each job. This variant shares the same variables and constraints as above, except for the objective:

- *Objective.* Proportional fairness aims to maximize the sum of log utilities of each job:

$$\underset{x}{\text{Maximize}} \sum_j \log(\text{throughput}(j, x_{*j})).$$

Applying DEDE. Both variants of cluster scheduling exhibit the separable structure required by DEDE. Their objectives to maximize are a sum or min of utilities for allocating each job, and a linear constraint is applied to each job and each computing resource. Thus, DEDE can decompose the problem into n per-job allocations and m per-demand allocations.

5.2 Traffic Engineering

Traffic engineering problems [24,43,44,55,65] allocate traffic demands between datacenters onto the network links in a wide-area network (WAN) topology.

Maximizing total flow. This problem variant focuses on maximizing the total flow allocation.

- *Variables.* Let $x_{(u,v)(s,t)} \geq 0$ denote the amount of flow from a datacenter pair (s,t) assigned to a network link (u,v). In common path-based traffic engineering, flows between each node pair (s,t) are allocated only over links along pre-configured paths $P_{(s,t)}$.
- *Objective.* For each node pair (s,t), the inflow it incurs to node v is computed as: $\text{inflow}(v,(s,t)) = \sum_{(u,v)\in P_{s,t}} x_{(u,v)(s,t)}$, and outflow as: $\text{outflow}(v,(s,t)) = \sum_{(v,u)\in P_{s,t}} x_{(v,u)(s,t)}$. Consequently, the total flow allocated for the node pair (s,t) is captured by $\text{inflow}(t,(s,t))$, the total inflow toward the destination t. Therefore, the objective of maximizing the total flow between all node pairs can be expressed as:

$$\underset{x}{\text{Maximize}} \sum_{(s,t)} \text{inflow}(t,(s,t)).$$

- *Resource constraints.* For each link (u,v), the cumulative flow from all node pairs traversing it must not exceed its link capacity $c_{u,v}$:

$$\sum_{(s,t)} x_{(u,v)(s,t)} \leq c_{u,v}, \quad \forall (u,v) \in E.$$

- *Demand constraints.* For each node pair (s,t), the total flow allocated cannot exceed the total demand. Additionally, for all nodes other than s and t, the inflow and outflow must be equal, ensuring no flow "black hole" along the paths:

$$\begin{aligned} &0 \leq \text{inflow}(t,(s,t)) \leq d_{s,t}, \\ &\text{inflow}(v,(s,t)) = \text{outflow}(v,(s,t)), \forall v \neq s,t, \end{aligned} \quad \forall (s,t).$$

Minimizing max link utilization. This variant aims to evenly distribute traffic demands across network links to avoid overloading any single link. The utilization of link is commonly defined as the (uncapped) ratio of total flow assigned to a link to the link's capacity, although it cannot actually exceed 100% in practice. This formulation shares the same variables and constraints as above, with a revised objective:

- *Objective.* The goal is to minimize the max link utilization across the network:

$$\underset{x}{\text{Minimize}} \max_{(u,v)\in E} \frac{\sum_{(s,t)} x_{(u,v)(s,t)}}{c_{u,v}}.$$

Applying DEDE. The traffic engineering problem aligns with the separable structure of DEDE: the objectives are expressed as either a sum over per-demand utilities or as a maximum over per-link utilities, and linear constraints are applied to each demand and each link. Therefore, DEDE can decompose the problem into $|E|$ per-link allocations and $|V|^2$ per-demand allocations for parallelism. In practice, due to the large overhead of maintaining $|V|^2$ per-demand subproblems, we group these subproblems by their sources, reducing the total number of subproblems to just $|V|$.

5.3 Load Balancing

Load balancing problems [14,44,49,53] allocate data shards among storage servers to scale out query loads in a distributed store. Load balancing is a non-convex problem with integer variables, wherein DEDE can provide a high-quality solution empirically, as discussed in §4.2.

Minimizing shard movements. This problem aims to minimize shard movements across servers during load changes while keeping the load nearly balanced on each server.

- *Variables.* The allocation plan is encoded in a matrix $x \in [0,1]^{n\times m}$, where x_{ij} is the fraction of data shard j assigned to server i. Additionally, a binary matrix x' captures shard placement, where $x'_{ij} = 1$ if the data shard j is located on server i (i.e., when $x_{ij} > 0$); otherwise, $x'_{ij} = 0$.
- *Objective.* The movement of data shard j allocated to server i can be represent as $(1 - T_{ij})x'_{ij}f_i$, where T_{ij} denotes the initial shard placement, and f_j denotes the memory footprint of data shard j. The objective of minimizing total shard movement can be expressed as:

$$\underset{x}{\text{Minimize}} \sum_j \sum_i (1 - T_{ij})x'_{ij}f_i.$$

- *Resource constraints.* For each server i, the total query load must be close to the average query load L. Meanwhile, the total memory usage must be within the memory capacity:

$$\begin{aligned} &L - \varepsilon \leq \textstyle\sum_j x_{ij}l_j \leq L + \varepsilon, \\ &\textstyle\sum_j x'_{ij}f_j \leq \text{memory}_i, \end{aligned} \quad \forall i,$$

  where l_j is the query load on data shard j.

- *Demand constraints.* Each data shard j must be entirely allocated across servers:

$$\sum_i x_{ij} = 1, \quad \forall j.$$

Applying DEDE. The load balancing problem also demonstrates a separable structure: the objective is the sum of allocation quality per data shard, while linear constraints are applied independently to each server and each shard. This allows DEDE to decompose the problem into n per-server allocations and m per-shard allocations.

6 Implementation of DEDE

We have implemented DEDE as a Python package and uploaded it to PyPI for easy installation: `pip install dede`.

Listing 1 showcases a basic resource allocation example using DEDE. Line 5 creates an $N \times M$ non-negative allocation matrix `x`, where `x[i,j]` represents the fraction of time that demand `j` runs on resource `i`. Lines 12–13 define a constraint for each resource using parameters, and Lines 14–15 define a constraint for each demand. The objective, defined in Line 18, is to maximize the sum of entries in `x`. Finally, the problem is constructed in Lines 21–22 and solved in Line 23.

Built on top of the popular optimization modeling language `cvxpy` [3, 15], DEDE inherits most of its syntax and APIs, such as `Variable()`, `Parameter()`, and `Maximize()`. A notable distinction is that DEDE requires users to explicitly separate resource constraints and demands constraints when initializing a problem (Line 22). As a parallel optimization tool, DEDE allows users to configure the number of CPUs (Line 23); by default, all available cores are used.

Internally, DEDE solves the optimization in three stages:

- *Problem parsing.* DEDE transforms all inequality constraints into equivalent equality constraints through non-negative slack variables. E.g., `x[:,j].sum() <= 1` is converted to `x[:,j].sum() + sj == 1` with a slack variable `sj`. Then slack variables are treated just like other variables.
- *Problem building.* DEDE organizes resource constraints into disjoint per-resource groups and demand constraints into disjoint per-demand groups. For each group, a per-resource or per-demand subproblem is constructed with `cvxpy` following Equations 8 and 9.
- *Problem solving.* DEDE solves these subproblems in parallel using multiple CPU cores. During ADMM iterations, only the parameters are updated, avoiding the overhead of rebuilding problems in `cvxpy`. Similarly, for the same problem with varying resources and demands, only the relevant parameters are updated.

We use Ray [41] to parallelize our computation across multiple cores, as Python's native multithreading model is constrained by the (notorious) global interpreter lock (GIL). Ray circumvents this issue by managing multiple Python interpreter processes, effectively bypassing the GIL. Moreover, Ray offers robust support for inter-process communication, sparing us from manually implementing such mechanisms using Python's lower-level multiprocessing primitives.

```
1  import numpy as np
2  import dede as dd
3
4  # Create allocation variables
5  x = dd.Variable((N, M), nonneg=True)
6
7  # Create parameters
8  param = dd.Parameter(
9      N, value=np.random.uniform(0, 1, N))
10
11 # Create constraints
12 resource_constrs = [
13     x[i,:].sum() <= param[i] for i in range(N)]
14 demand_constrs = [
15     x[:,j].sum() <= 1 for j in range(M)]
16
17 # Create an objective
18 obj = dd.Maximize(x.sum())
19
20 # Construct and solve the problem
21 prob = dd.Problem(
22     obj, resource_constrs, demand_constrs)
23 prob.solve(num_cpus=64, solver=dd.ECOS)
```

Listing 1: Resource allocation example with DEDE package.

7 Evaluation

We answer the following questions in the evaluation:

1. How does DEDE compare with state-of-the-art approaches in allocation quality and computation time? (§7.1)
2. How do DEDE and baseline approaches react to changes in problem granularity, temporal fluctuation, spatial redistribution, and link failures? (§7.2)
3. What is the individual contribution of each design component in DEDE? (§7.3)

Our evaluation compares four approaches:

- *Exact sol.* This baseline solves the original resource allocation problem using commercial solvers. We adopt the implementation from POP, which utilizes `cvxpy` [3, 15], Gurobi [22], and CPLEX [25] for cluster engineering, traffic engineering, and load balancing, respectively.
- *POP.* POP-k [44] randomly splits the problem into k smaller subproblems, applies commercial solvers to each, and coalesces the resulting k sub-allocations into a global allocation. However, POP only *simulates* the parallel execution by solving subproblems sequentially and calculating the parallel solving time mathematically.
- DEDE. DEDE is our truly parallel implementation (§6). By default, the solution from the previous optimization interval is used to warm-start the subsequent interval.
- DEDE*. For a fair comparison with POP, we create a variant of DEDE, denoted as DEDE*, following POP's simulation methodology. DEDE* solves subproblems sequentially and estimates the parallel solving time mathematically.

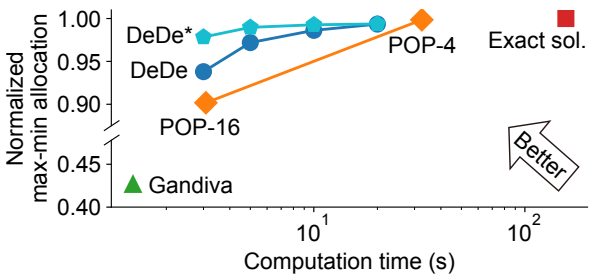

Figure 4: Results of the cluster scheduling variant that maximizes the minimum job throughput (max-min allocation).

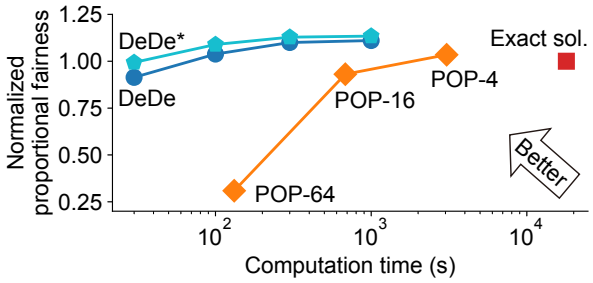

Figure 5: Results of the cluster scheduling variant that maximizes proportional fairness among job throughputs.

We also consider domain-specific approaches apart from these four approaches. In cluster scheduling and load balancing, we evaluate the greedy heuristic algorithms, Gandiva [63] and E-Store [53], respectively. In traffic engineering, we evaluate a demand-pinning approach ("Pinning") similar to a prior work [42], where the top 10% of demands are allocated using optimization engines and the rest are assigned to shortest paths. We also evaluate Teal [65], a learning-accelerated traffic engineering approach that achieves massive parallelism using a GPU.

All approaches are evaluated in terms of allocation quality and computation time. The computation time is measured using 64 CPU cores (2× Intel Xeon Gold 6142), with an additional GPU (Nvidia Titan RTX) available for Teal.

7.1 DeDe vs. the State of the Art

In this section, we compare DeDe against state-of-the-art approaches on resource allocation problems from §5.

7.1.1 Cluster Scheduling

We stress-test DeDe's scalability in a large, heterogeneous cluster scheduling environment, where jobs are allocated in a time-sliced manner across 456 different types of compute resources, e.g., GPU/CPU instances that vary in vendor, generation, memory capacity, and other specifications. The quantity of each resource type is randomly drawn from $\{8, 16, 24, \ldots, 64\}$, resulting in a total of 16,520 instances. We utilize the simulator in Gavel [45] and model job arrivals as a Poisson process with an average inter-arrival of 100 seconds. We update job allocation decisions every 6 minutes, repeating this process for 200 scheduling rounds (20 hours). For each job, the number of requested resource instances per type is drawn from $\{1, 2, 4, 8, 16, 32\}$, and following prior work [59], 33% of the jobs are restricted to specific resource types. Job throughput is derived from relevant benchmarks [19, 26, 36]. Please refer to Appendix A for more details on this setup.

Max-min allocation. Figure 4 compares DeDe against other approaches in terms of max-min allocation. DeDe quickly attains a near-optimal max-min allocation of 0.94 in just 3 seconds and 0.99 within 10 seconds, demonstrating a better balance between max-min allocation and computation time compared with Exact sol., Gandiva, and POP. In contrast, Exact sol. experiences a significantly slower computation time of 156 seconds due to its sequential nature. The greedy heuristic, Gandiva, performs poorly, achieving only a max-min allocation of 0.43 (in 1.4 seconds). POP-4 provides a comparable tradeoff between time and accuracy to DeDe, but is 1.6× slower. The faster variant, POP-16, splits the problem into 16 smaller subproblems and achieves a lower max-min allocation of 0.9 (in 3.1 seconds), since smaller subproblems limit the ability to select optimal GPU/CPU assignments.

DeDe*, representing the same algorithm under idealized conditions similar to POP's simulation, achieves a normalized max-min allocation of 0.99 and is 3.3× faster than DeDe in Figure 4. The reason is that DeDe* executes each iteration more quickly and completes more iterations within a given time. The discrepancy in iteration time between DeDe and DeDe* arises from three factors: (1) DeDe measures the end-to-end time, including problem solving, compilation, solution unpacking, and other associated tasks, while DeDe* only accounts for the core solving time; (2) DeDe's parallel implementation incurs overhead from cache contention, which slows computation; (3) In DeDe, each subproblem is statically pre-assigned to one of the processes, making it susceptible to straggler delays. In contrast, DeDe* assumes perfect dynamic scheduling.

Proportional fairness. Figure 5 compares DeDe against other approaches in maximizing proportional fairness. This problem is particularly challenging due to the logarithmic form of the objective function. Exact sol., which uses the SCS solver in `cvxpy`, fails to reach optimality even after 5 hours of computation. As a result, several methods report normalized fairness scores that exceed 1 when normalized relative to Exact sol. Both DeDe and DeDe* achieve greater speedups than POP by effectively breaking the problem into smaller and easier subproblems. Notably, DeDe and DeDe* both reach a normalized proportional fairness of over 1 within 100 seconds. In contrast, POP-4 and POP-16 require 3,053 seconds and 682 seconds, respectively, to achieve comparable allocation quality, while POP-64 yields a significantly lower

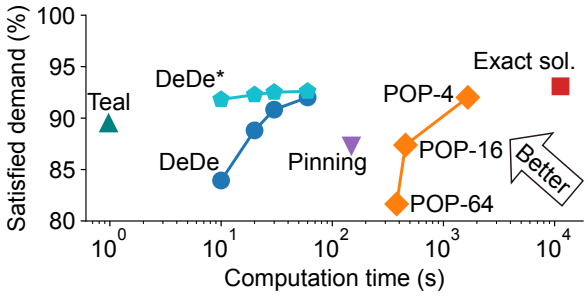

Figure 6: Results of the traffic engineering problem variant that maximizes the total flow.

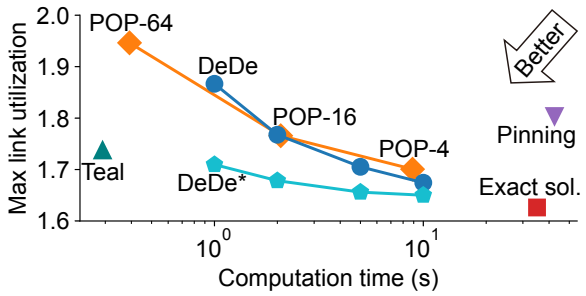

Figure 7: Results of the traffic engineering problem variant that minimizes the max link utilization.

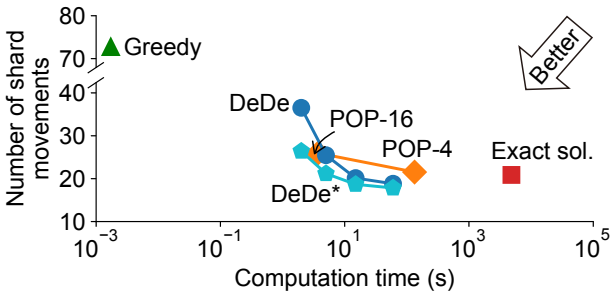

Figure 8: Results of the load balancing problem where the objective is to minimize shard movements.

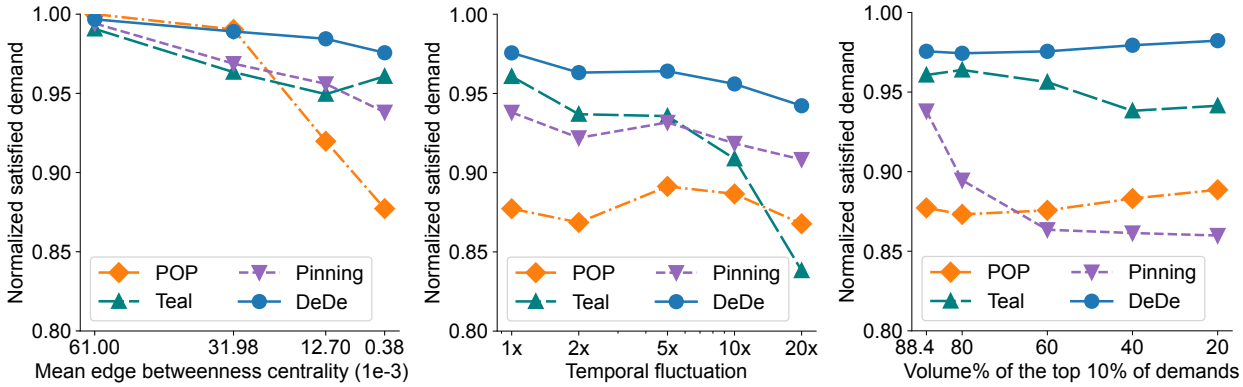
fairness score of only 0.31.

7.1.2 Traffic Engineering

We adopt the evaluation setup in Teal [65], with a focus on its largest topology—a 1,739-node network adapted from an internet topology for WAN purposes. The traffic matrices are collected from the production WAN of a global cloud provider and mapped onto the above topology.



Maximize total flow. Figure 6 compares DEDE to the baselines in maximizing total flow. DEDE achieves 90.8% satisfied demand within 30 seconds and 92% within 60 seconds, showing a superior trade-off between satisfied demand and computation time compared with Exact sol., POP, and Pinning. Its idealized variant, DEDE*, achieves a satisfied demand that is 8% higher than DEDE within 10 seconds. While POP-4 also reaches 92% satisfied demand, its average computation time is significantly longer, at 1,658 seconds. POP-16 and POP-64 improve parallelism by dividing the workload into more subproblems, reducing computation times to 456 seconds and 380 seconds, respectively. Note that the speedup of POP-64 is limited compared with POP-16 as the number of cores per subproblem drops from 4 to 1. This increased parallelism also comes at a cost, with satisfied demand decreasing to 87.4% for POP-16 and 81.6% for POP-64. Pinning focuses on top demands to reduce problem size but remains constrained by the sequential nature of its optimization solvers. As a result, it achieves a modest speedup, requiring 149 seconds to reach 87.3% satisfied demand. Teal, a learning-accelerated approach, leverages massive GPU parallelism to achieve 89% satisfied demand in only 1 second. However, it relies on a highly customized machine-learning framework, demanding significant human effort for design and training.

Min-max link utilization. Figure 7 compares DEDE with other approaches in minimizing maximum link utilization. Here, the link utilization metric serves as proxy for network congestion and is allowed to exceed 100% during optimization. DEDE attains a maximum link utilization of 1.67 within 10 seconds and 1.71 within 5 seconds. Exact sol. reaches 1.63 with a longer computation time of 35 seconds. This is faster than maximizing total flow because minimizing max link utilization is computationally less challenging and thus requires fewer iterations. Pinning takes 42.5 seconds, making it slower than DEDE and slightly slower than Exact sol., as it requires additional time to rebuild the problem when the top 10% of node pairs change. POP's variants, POP-4, POP-16, and POP-64, achieve a maximum link utilization of 1.70, 1.77, and 1.95 within 9, 2, and 0.4 seconds on average, respectively. Although POP-16 is faster than DEDE, a fairer comparison between POP-16 and DEDE*, both simulating parallelism, reveals that DEDE* achieves a comparable computation time to POP-16. The domain-customized Teal takes only 0.3 seconds on a GPU to attain a maximum link utilization of 1.74.

7.1.3 Load Balancing

We follow the load balancing settings in POP [44], except for increasing the scale to 2,048 data shards distributed across 256 servers. In each round, a new shard-to-server allocation is computed based on updated query loads. We simulate for 100 rounds, using the first 20 as a warm-up. To ensure the problem's feasibility, we set the tolerance parameter ϵ to 0.1.

Minimize shard movements. Figure 8 compares DEDE with baselines in minimizing shard movements. DEDE achieves an average of 20.1 shard movements in 15 seconds, better than POP-4's 21.5 shard movements within 133 seconds. In faster scenarios, DEDE achieves 25.4 shard movements in 5 seconds, while POP-16 achieves an average movement of 26 in a slighter less time of 3.7 seconds. For a fair comparison,

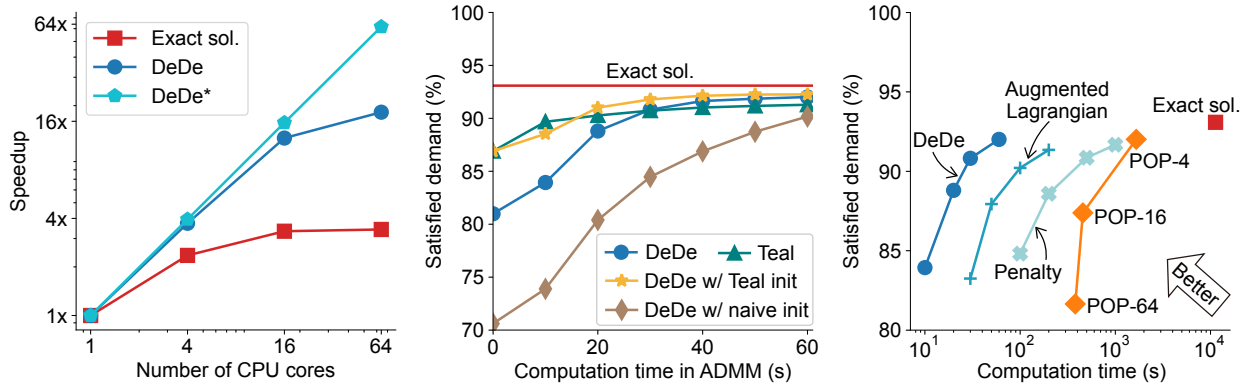
(a) Granularity changes. (b) Temporal fluctuation. (c) Spatial redistribution.

Figure 9: Normalized satisfied demand in traffic engineering against granularity, temporal, and spatial changes.

DeDe* consistently achieves around 16% fewer shard movements than POP, given a similar time limit. Exact sol. requires 20.9 shard movements on average, but is significantly slower with an average of 4,820 seconds. This slower computation is due to the NP-hard nature of solving the mixed-integer linear program underlying load balancing. Notably, Exact sol. does not produce the minimum possible shard movements because optimizing each scheduling round independently does not guarantee an optimal solution across the entire series. At the opposite end of the time-accuracy trade-off, the greedy heuristic provides a rapid but less accurate solution, completing in just 2 milliseconds but averaging 73 shard movements after naively fixing its constraint violations.

7.2 Robustness

Using traffic engineering as an example, we evaluate the robustness of DeDe and other baselines against changes in problem granularity, temporal dynamics, spatial redistribution, and link failures. In these experiments, DeDe is run for 30 seconds, and we normalize the satisfied traffic demand by the optimal one achieved by Exact sol.



Changes of problem granularity. The granular problem structure required by POP, where each demand only requests a small fraction of *interchangeable* resources, can be impractical. In traffic engineering, for example, demands are constrained by the link capacity on specific pre-configured paths. Similarly, in cluster scheduling, 33% of GPU tasks in production clusters are limited to specific GPU types [59]. In Figure 9a, we present results on varying levels of problem granularity using traffic engineering as an example. To quantify resource interchangeability, we use the mean edge betweenness centrality [9, 10], which measures the average percentage of demands served by a given edge.

As the mean edge betweenness centrality decreases, all approaches experience a decline in normalized satisfied demand, ranging from 0.8–2.1% for DeDe, 2.8–4.2% for Teal, 2.5–5.6% for Pinning, and 1–12.3% for POP. However, the maximum decrease in POP is 5.9× greater than DeDe because POP's subproblems struggle to find alternative resources within their restricted subsets, whereas DeDe's subproblems retain access to the full set of resources. Teal exhibits a slight 1.3% increase in satisfied demand when the mean edge betweenness centrality is minimal. This is because the reduced edge selection simplifies allocation decisions.

Temporal dynamics. Next, we introduce temporal fluctuations [65] to the traffic matrices for robustness assessment. For each demand, we calculate the variance σ^2 in its changes between consecutive time slots and create a new normal distribution $N(0, k\sigma^2)$. We choose the values of k to be 2, 5, 10, and 20. Next, we randomly draw a sample from the newly created normal distribution and add it to each demand in every time slot, simulating temporal fluctuations.

Figure 9b demonstrates that DeDe effectively manages temporal fluctuations, with changes in normalized satisfied demand limited to 1.3–3.5%. In contrast, Teal suffers a significant decrease of 12.8%, as it lacks prior exposure to the distribution of these fluctuating demands during training. Pinning and POP experience variations in normalized satisfied demand ranging from 0.6–3% and 1–1.6%, respectively. This is because randomness may occasionally favor splitting a problem into subproblems or focusing on top demands exclusively, while at other times, it does not.

Spatial redistribution. To evaluate robustness against spatial redistribution, we reassign traffic demands among node pairs. Specifically, we adjust the top 10% of demands, which initially account for 88.4% of the total volume, so that they take up 80%, 60%, 40%, and 20% of the total volume instead. Figure 9c shows that DeDe consistently fulfills the highest demand across all spatial distributions. Pinning's performance decreases by 8.3%, as its strategy of focusing only on top demands relies on the presence of a heavy-tailed demand distribution. Teal has a slight decrease of up to 2.4% due to unseen demand distribution in training. This is a relatively

(a) Speedup when varying CPU cores. (b) Convergence rate. (c) Comparing different optimization methods.

Figure 10: Micro-benchmarks with the objective of maximizing total flow in traffic engineering.

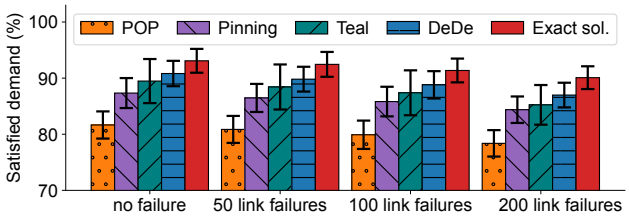


Figure 11: Satisfied demand of traffic engineering under zero, 50, 100, or 200 link failures after recomputing flow allocation.

smaller decrease than the temporal fluctuation, because Teal can still handle simple, evenly distributed traffic demands. POP has a slight increase of 1.4% as demands are more granular, where no demand requires a significant fraction of the total resources.

Link failures. Widespread failures across inter-datacenter links are relatively rare in real-world operations unless triggered by physical fiber cuts [52]. However, we simulate severe failure scenarios, introducing 50, 100, and 200 simultaneous link failures. As shown in Figure 11, the satisfied demand declines consistently across all methods. Specifically, all approaches drop by 0.6–1.1% under 50 link failures, 1.5–2.1% under 100 link failures, and 3–4.2% under 200 link failures. These drops stem from the fact that the failed links represent only a small portion of the total 8,558 links, allowing all approaches to recompute flow allocation given adequate time.

7.3 Micro-benchmarks

We conduct micro-benchmarks to evaluate the impact of DEDE's design components, with all experiments performed in maximizing total flow in traffic engineering.

Speedup when varying CPU cores. Figure 10a evaluates the speedup of DEDE, DEDE*, and Exact sol. with 1, 4, 16, and 64 CPU cores. DEDE* achieves 61.7× speedup under 64 cores, where the slight gap occurs as we cannot exactly divide the total computation time evenly across 64 cores. DEDE also achieves an almost linear speedup when the number of CPU cores grows from 1 to 16. However, this linearity diminishes with 64 cores, where DEDE only achieves 18.2× speedup. This is because utilizing all 64 cores for parallelism incurs overhead from cache contention and stragglers, as discussed in §7.1.1. In contrast to the linear speedup of DEDE* and DEDE, the speedup of Exact sol. is sublinear and marginal, achieving only 3.4× speeds with 64 CPU cores. This is because of commercial solvers' sequential nature, e.g., the simplex method [46] in linear programming requires thousands to millions of small steps to reach the optimal solution.

Convergence rate. Teal generates a coarse, initial solution to traffic engineering using neural networks and fine-tunes it through ADMM. While Teal also "decouples" constraints, it does not further "decompose" the problem as DEDE does. Instead, it analytically and approximately minimizes a problem-specific augmented Lagrangian, directly projecting the result onto the non-negative feasible region. As a specialized method, Teal converges rapidly, achieving 90% satisfied demand within 10 seconds, as shown in Figure 10b. In comparison, DEDE requires ∼30 seconds to attain comparable performance. In each optimization interval, DEDE is warm-started using the previous solution by default. When initialized instead with Teal's neural network output, DEDE converges at a similar rate. In contrast, employing a naive initialization—where each demand is equally split across available paths—reduces DEDE's convergence speed by nearly half.

Alternative optimization methods. Figure 10c evaluates alternative constrained optimization techniques for maximizing total flow in traffic engineering—the penalty method [4] and the augmented Lagrangian method [23], comparing them with the ADMM-based approach used by DEDE. Both methods aim to solve the reformulated optimization problem in Equation 4 by jointly (and naively) optimizing variables x and z, but they differ in how they enforce constraints. The penalty method introduces penalty terms into the objective function to discourage constraint violations. It starts with a

small penalty coefficient and gradually increases it toward infinity, thereby driving the solution toward feasibility. However, this process typically involves solving a series of increasingly ill-conditioned problems, resulting in slow convergence. In our evaluation, it was more than 30× slower than DeDe in achieving a satisfied demand of over 90%. The augmented Lagrangian method improves upon the penalty method by combining both penalty terms and Lagrange multipliers. This helps enhance convergence stability and typically reduces the number of required iterations. However, unlike the ADMM approach used in DeDe, it lacks the benefit of decomposition and parallelism. As a result, despite its faster convergence over the basic penalty method, it remains over 3× slower than DeDe in reaching a satisfied demand of over 90%.

8 Related Work

Resource allocation problems. Multi-tenant systems often address resource allocation challenges. Section 5 examines three prominent examples: cluster scheduling [28, 45, 47, 63, 66] allocates jobs to CPUs or GPUs in heterogeneous clusters, traffic engineering [1, 24, 32, 51, 69] allocates traffic demands to network link capacities in wide-area networks, and load balancing [14, 49, 53] allocates query loads to servers in distributed databases. Beyond these problems, Skyplane [27] allocates cloud resources (e.g., bandwidth and TCP connections) to overlay paths that traverse intermediate cloud regions, minimizing the cost of inter-region bulk transfers. Zeta [67] allocates traffic forwarding capability from gateway clusters to virtual private clouds for scalable and robust east-west communication in large-scale clouds. Shoofly [52] allocates light wavelengths of optical fiber to network shortcuts abstracted from optical bypasses, in order to minimize the hardware costs of provisioning long-haul capacity. By leveraging the commonly observed separable structure of real-world resource allocation problems, DeDe is applicable to the aforementioned cases as well as a broad range of others.

Optimization algorithms. Various constrained optimization algorithms have been employed to solve resource allocation problems, depending on the variable types, objectives, and constraints. For linear programming problems like traffic engineering, the Gurobi solver [22] utilizes two primary methods. The simplex method [46] iteratively progresses along the boundaries of the feasible region toward the optimal solution, while the barrier method [31] iteratively approaches the optimal solution from within the feasible region. In mixed-integer linear programming like load balancing, the branch-and-bound method [7] divides the problem into smaller subproblems, or branches, and then eliminates certain branches based on bounds on the optimal solution at each iteration. For more complex optimization problems, such as cone programming when maximizing proportional fairness in cluster scheduling, the ECOS algorithm [16] adopts a similar iterative process as the barrier methods, with search directions found by a symmetric indefinite KKT (Karush-Kuhn-Tuck) system. All these constrained optimization algorithms operate sequentially and iteratively, and thus introduce bottlenecks in solving time. In contrast, DeDe decouples and decomposes the problem into many parallel subproblems, and thus allows faster problem solving.

Decomposition for scalability. As resource allocation problems grow, efforts have been made to parallelize the iterative process in optimization algorithms for better scalability. NCFlow [1] accelerates traffic engineering by partitioning the network into clusters and concurrently solving the flow allocation problem in each cluster. POP [44] targets "granular" allocation problems where resources are interchangeable. It randomly splits resources and demands into subsets and allocates each subset in parallel. Soroush [43] generalizes the classical waterfilling algorithm for max-min fair allocation and presents parallelizable combinatorial algorithms with fairness guarantees. Teal [65] models traffic engineering with neural networks to benefit from the massive parallelism in GPU. Eason et al. [17] employ the Benders decomposition algorithm to parallelize the design of a specialized cross-layer backbone network, offering performance guarantees for a particular allocation problem. While these prior decompositions rely on restrictive assumptions or problem-specific designs, DeDe offers a general and theoretically grounded approach solution for diverse resource allocation problems.

9 Conclusion

In this paper, we scale real-world resource allocation problems from a different lens, observing that the vast majority of them exhibit an inherent separable structure. This key insight allows us to systematically decouple resource and demand constraints and decompose the original optimization problem into independent and parallel subproblems for allocating individual resources and demands. We implement this approach, DeDe, as a Python package, offering a push-button solution that accelerates large-scale resource allocation. Through extensive evaluation across diverse resource allocation tasks, we demonstrate that DeDe significantly improves scalability while closely approximating the quality of exact solutions.

Appendix

A Evaluation Setup of Cluster Scheduling

We detail the experimental setup for the large-scale cluster scheduling evaluation described in §7.1.1.

Computing resources. We collect 456 distinct GPU/CPU resource types from three benchmark sources [19, 26, 36]. These resource types differ along multiple dimensions such as vendor, interconnect, memory configuration, deployment platform, etc. While it is unlikely today for any single cluster to host all 456 types, recent trends in distributed ML workloads [62, 66] suggest the possibility of scheduling ML jobs across global-scale clusters in the future. For each resource type, the number of available instances is randomly drawn from the set $\{8, 16, 24, \ldots, 64\}$, reflecting common modern hardware configurations where nodes are provisioned with GPU/CPUs in multiples of eight. This setup results in a total of 16,520 GPU/CPU instances in our simulated environment.

Jobs. We generate 2,588 types of ML jobs based on the Notable AI Models dataset [18]. For each ML model, we synthesize multiple job types encompassing both training and inference tasks under various numerical precisions. The number of compute instances requested by each job is sampled from $\{1, 2, 4, 8, 16, 32\}$, in line with common practices in data and model parallelism. Job throughput values are either taken directly from ML benchmarks [19, 26, 36] or, when unavailable, estimated based on each job's FLOP requirements and the computational capacity of the respective hardware.

Scheduling Simulator. Our evaluation employs Gavel's ML scheduling simulator [45], with several adjustments. Jobs are time-sliced across available resource types but are not co-located, due to the increased size and resource demands of modern ML workloads. To ensure that jobs do not grow beyond cluster capacity, we set the average job inter-arrival time to 100 seconds in the Poisson process. We begin the simulation from a steady state, maintaining approximately 1,500 to 2,000 active jobs at any given time. Job allocation decisions are made every 6 minutes, consistent with Gavel's default settings, and the simulation runs for 200 scheduling rounds, or 20 hours.

Quantum Virtual Machines

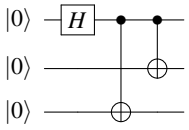
Abstract

Cloud computing services offer time on quantum computers, but users are forced to each use the entire quantum computer to run their programs as there is no way to multiplex a quantum computer among multiple programs at the same time. We present HyperQ, a system that introduces virtual machines for quantum computers to provide fault isolation, better resource utilization, and lower latency for quantum cloud computing. A quantum virtual machine is defined in terms of quantum computer hardware, specifically its quantum gates and qubits arranged in a hardware-specific topology. HyperQ enables quantum virtual machines to be simultaneously executed together on a quantum computer by multiplexing them in time and space on the hardware and ensuring that they are isolated from one another. HyperQ works with existing quantum programs and compiler frameworks; programs are simply compiled to run in virtual machines without the programs or compilers needing to know what else might be executed at the same time. We have implemented HyperQ for the IBM quantum computing service, the largest quantum computing fleet in the world. Our experimental results running quantum programs in virtual machines using the IBM service demonstrate that HyperQ can increase utilization and throughput while reducing program latency, by up to an order of magnitude, without sacrificing, and in some cases improving, fidelity in the results of quantum program execution.

1 Introduction

Quantum cloud computing now makes it possible to obtain on-demand access to quantum computers through cloud-based platforms. These first-generation quantum computers from cloud providers in the form of Noisy Intermediate-Scale Quantum (NISQ) [49] devices heralds the initial shift from classical to quantum computing and the potential realization of practical quantum applications [23]. While classical computers consist of circuits made up of gates that process bits, NISQ devices consist of quantum circuits made up of quantum gates that process quantum bits (qubits). Given their high cost and complexity, cloud computing providers typically only have a few quantum computers available. Nevertheless, they are in high demand by users and IBM recently ran its 3 trillionth quantum program [35].

While cloud computing provides robust software infrastructure that leverages virtual machines (VM) to enable efficient, scalable, and flexible multi-tenant utilization of classical computing resources, the software infrastructure for quantum cloud computing is primitive at best. Users of cloud-based quantum computers submit the quantum programs they want to run to as batch processing jobs, and the cloud service runs the quantum programs on the quantum computer one after another and returns the results. There is no virtualization of quantum computing resources, so each program, no matter how big or small, runs by itself on the quantum computer until it completes, at which point another program is run. This is extremely inefficient given that most programs can only utilize a small number of the qubits available on existing NISQ devices, leaving much of the quantum computer unused. Programs can only utilize a small number of qubits because as the number of qubits used increases, the complexity of the underlying quantum circuit being executed also increases, leading to propagation errors due to hardware noise and loss of fidelity in the results. The utilization problem is exacerbated by the limited number of quantum computers available. Users can end up waiting days for a quantum computing service to return the results of their programs given the high demand for quantum computing resources and the inability of the quantum computer to run more than one program at a time. Cloud services often further limit the number of outstanding program submissions from a user at any given time to only a few, adding further delays to obtaining results from running multiple quantum programs.



Addressing this inefficiency requires enabling multiple quantum programs to share the underlying hardware. While some research efforts have proposed methods for quantum multiprogramming, they rely on custom quantum compilers to combine multiple programs at compile time [15,34,43–45]. This *static* approach requires knowing precisely which programs will execute together during compilation, preventing independent compilation and execution–a stark contrast to the flexibility enjoyed in classical computing. Many existing techniques struggle with scalability, either limiting the number of co-executing programs or relying on algorithms

with poor complexity for larger machines. Furthermore, these specialized compilers often lack the optimizations found in standard compilation tools like Qiskit.

Inspired by the success of VMs in improving the utilization of classical cloud computing services, we present HyperQ, a run-time management system for cloud-based quantum computing based on a new quantum virtual machine (qVM) abstraction for quantum computers. It virtualizes quantum hardware, i.e., exposes the same interface as a standalone quantum computer, supports multiprogramming *dynamically* and enables fault isolation. It significantly improves resource utilization and reduces latency while mitigating the impact of hardware noise to preserve, and even improve, the fidelity of program execution, all with minimal virtualization overhead.

HyperQ defines a qVM in terms of quantum computing hardware as a quantum circuit abstraction for running quantum programs with a well-defined set of quantum gates and a fixed number of qubits arranged in a specific topology. To enable direct execution of qVMs, the qVM qubit topology must be matched to the qubit topology of the underlying quantum computer hardware. However, qubits can in theory be connected in arbitrary topologies, making it difficult to match the topology of a qVM with that of the quantum computer. Our insight is that we observe that all real quantum computers define a qubit region in which qubits are connected together in a fixed topology, and that region is replicated in a grid-like manner to constitute the overall quantum computer. We leverage this insight to define qVMs in a architecture-specific manner such that the qVMs for a quantum computer are some fixed multiple of its qubit region and thus can be easily mapped to the computer to execute. HyperQ also leverages the natural separation of qubits in the hardware topology to isolate different qVMs and mitigate crosstalk noise when multiple quantum programs are executed simultaneously.

HyperQ virtualizes and manages quantum hardware in a manner that is compatible with existing quantum cloud computing services. Since quantum computer hardware does not yet have quantum memory (QRAM), it lacks context switching capabilities. To support qVMs without being able to save and restore quantum execution state, HyperQ interposes on how quantum programs are submitted to cloud computing services. Users locally compile their quantum programs and submit them in the same manner as they do with existing infrastructure, but the compiler backend transparently targets a qVM instead of a quantum computer. HyperQ encapsulates the compiled executables in their respective qVMs, then schedules qVMs for execution by binpacking them into composite quantum circuits, each of which fits into the qubits of the actual quantum computer. Each composite quantum circuit appears to the cloud service like any other other job, and hence can be submitted to, and executed by, existing quantum computing cloud services. Running a composite quantum circuit enables its qVMs to execute in parallel and in isolation on different qubits of the quantum computer.

To construct the composite quantum circuits, HyperQ optimizes the allocation of quantum hardware resources and partitions resources among qVMs to provide fault isolation. HyperQ uses a simple scheduling algorithm that can guarantee better resource utilization and lower latency for every quantum program compared to the service it would receive without HyperQ on an existing quantum cloud computing service. The algorithm solves a three-dimensional binpacking problem across both space and time while accounting for quantum-specific resource constraints including noise and measurement. It can further tradeoff utilization for improved fidelity of results of quantum program execution.

HyperQ is compatible with existing quantum compilers such as Qiskit [22], enabling quantum programs to leverage its many compiler optimizations. A qVM appears as a backend compilation target similar to actual quantum hardware. Quantum compilers need not know what else will run with the program being compiled, but can simply compile quantum programs to their respective qVMs independently of one another. This is in contrast to existing quantum multiprogramming methods [15, 34, 43–45] that require custom compilers and knowing the exact circuits to be co-executed to combine them at compile time. Since programs are compiled to qVMs instead of the larger underlying quantum computer, they compile faster as compilation time is proportional to the number of qubits of the compilation target, irrespective of whether the program actually uses the number of qubits available.

We have implemented HyperQ and demonstrate that it can be easily used by existing quantum programs and compiler infrastructure, and deployed with existing quantum cloud computing services. Our experimental results with the IBM Quantum cloud computing service and its 127-qubit Eagle quantum computer [50] show that, compared to IBM Quantum, HyperQ can increase resource utilization and reduce latency in obtaining results by up to an order of magnitude for a wide range of quantum programs. We show that qVMs are isolated from one another during execution so that these performance gains can be achieved without compromising fidelity in the program results. Surprisingly, we also show that HyperQ can schedule qVMs in a noise-aware manner that can even improve fidelity in the program results compared to IBM Quantum, while still providing much better utilization and latency.

2 Background

We first provide some background about quantum programs, computers and compilers. For further details, see [21, 42].

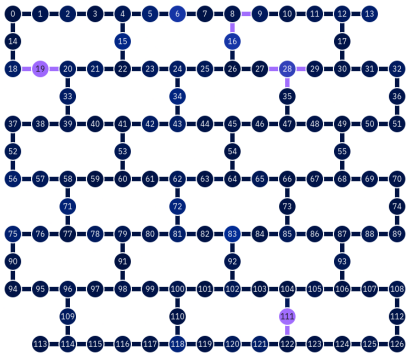

Figure 2: IBM 127-qubit Eagle machine [50].

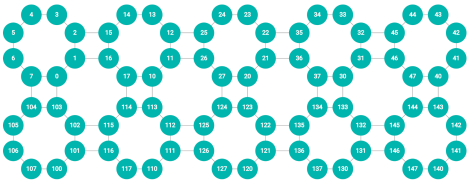

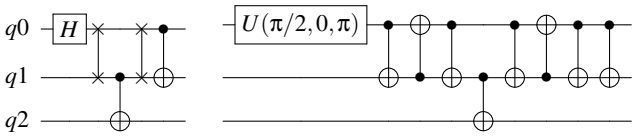

Figure 3: Rigetti 80-qubit Aspen M-3 machine [1].

Qubits, quantum gates and quantum programs In quantum computing, each quantum program is represented as a quantum circuit. The basic unit of a quantum circuit is a qubit, analogous to a register in classical computing. While a bit in classical computing can only be 0 or 1, a qubit can have many more states, specifically any state that is a superposition of 0 and 1. The basic operation on qubits is through a quantum gate, analogous to an instruction in classical computing. A typical quantum gate operates on either one or two qubits. On a quantum machine, two single-qubit gates can run simultaneously on two qubits, as can two two-qubit gates on two disjoint pairs of qubits. Quantum gates manipulate qubits to cause interference, whereby certain qubit states constructively combine and others are eliminated, and entanglement, whereby a qubit's state is correlated with other qubits. Qubits can be measured to get classical bits as result, where the result of a measurement is probabilistic and will collapse the qubit to the state that agrees with the measurement, which will be either 0 or 1. A typical quantum program will perform measurements at the end to produce output of the same number of classical bits as it has qubits. Figure 1 shows a simple GHZ circuit [20] represented by graph and by code.

Quantum computers A quantum computer has a quantum processing unit (QPU) that supports a fixed set of quantum gates, known as its gate set, and arranges its qubits in a particular topology, the latter being described by a coupling map. Similar to classical logic where a set of AND, OR, and NOT gates are sufficient, in quantum computing, there is also a universal gate set. A common universal gate set is the single qubit rotation and an entangled two-qubit gate such as the Controlled-NOT (CX) gate, shown in Figure 1. Different quantum computers may support different gate sets, or instruction sets, and qubit topologies. For example, Figures 2 and 3 shows the coupling maps of the IBM Eagle and AWS Rigetti Aspen M-3, which are quite different. Quantum computers are also equipped with classical registers to store the results of measurements. Note that quantum computers currently lack QRAM, so there is no mechanism to save qubit states outside of the QPU. The only option is to reduce qubits to classical bits by measuring them so the results can stored in classical RAM, with the resulting loss of quantum superposition.

(a) After routing. **(b)** After nativization.

Figure 4: Compilation of GHZ circuit. In the routing stage, if qubit $q0$ is not connected to $q2$ in the coupling map, it is not possible to have a CX gate between them. Instead, two SWAP gates between $q0$ and $q1$ will be inserted and the CX gate will be applied between $q1$ and $q2$. In the nativization stage, with the instruction set $\{\texttt{U},\texttt{CX}\}$, H is translated into $\mathrm{U}(\pi/2,0,\pi)$ and SWAP is expanded into three CX gates.

Quantum compilation Quantum compilation transforms a quantum program into a quantum circuit that satisfies the topology and gate constraints specified by a quantum computer. This includes mapping the qubits used by the program to actual qubits available in the quantum computer. A routing stage [26, 36, 57] inserts SWAP gates into the circuit, to swap qubits, so that two-qubit gates are only applied to qubit pairs that are actually connected in the coupling map. A nativization stage [33] decomposes all quantum gates into those in the instruction set of the target quantum hardware. Figure 4 shows an example for compiling the GHZ circuit. Because compilation is based on the constraints of the target quantum hardware, the resulting compiled quantum circuit is only for the target hardware and is generally incompatible with other hardware with different instruction sets and qubit topologies. For example, a quantum program compiled for the IBM Eagle will not run on the AWS Rigetti.

Noise A significant challenge in near-term quantum computing is the presence of noise. Noise arises from unwanted interactions between the qubits and their surrounding environment, such as thermal fluctuations or electromagnetic interference when performing quantum operations and measurements. Noise introduces errors into quantum operations, leading to a decrease in the fidelity of quantum states and ultimately causing the execution of quantum programs to yield incorrect results. Noise can occur from quantum gates and measurements, as well as crosstalk between qubits. Crosstalk occurs when operations on one qubit unintentionally affect the states of neighboring qubits. It is typically caused by unintended electromagnetic coupling or leakage of control signals be-

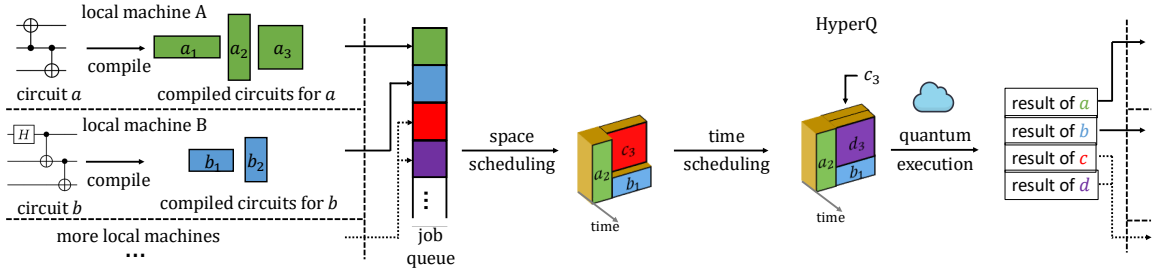

Figure 5: HyperQ workflow.

tween nearby qubits on the quantum chip, and its effects are strongest between qubits that are directly connected with one another. Crosstalk is a major source of noise for NISQ devices and its impact can be an order of magnitude greater than gate errors; mitigating crosstalk is critical to achieve reliable and accurate quantum computation on NISQ devices [37, 45].

3 Design

HyperQ is designed to be compatible with existing quantum programs, computers, and compilers. It accomplishes this based on the observation that quantum computers are structured using a basic repeating region of qubits. For example, the IBM Eagle in Figure 2 is structured around a repeating I-shaped region of qubits, while the Rigetti in Figure 3 is structured around a repeating octagonal-shaped region of qubits. By leveraging this repeating structure, HyperQ can provide qVMs such that programs can be independently compiled to run in qVMs, which are in turn placed into these regions on the machine and executed correctly because the topology and gate set of the qVM matches that of the real machine.

Figure 5 shows the workflow of HyperQ. First, users write and compile their quantum programs on their local machines, where the compiler target is a qVM instead of the actual quantum hardware. Second, the resulting compiled quantum circuits are sent to HyperQ to schedule and run in qVMs on the actual quantum computer. Because current quantum computers do not support context switching, HyperQ schedules and multiplexes qVMs on the hardware by binpacking them in space and time into batch jobs of some estimated execution duration. Each job is created by composing the qVMs in the batch together into one big composite quantum circuit. The batch jobs are then submitted to the cloud quantum computing service to be executed on the quantum machine. After a batch job is completed, HyperQ will receive the measurement result of the combined quantum circuit, which contains results for all qVMs. HyperQ will postprocess the measurement result to identify the part that belongs to each qVM, and return the separated results to the users.

Like VMs on classical computers as originally described by Popek and Goldberg [47], HyperQ ensures that qVMs meet three virtualization properties of interest whenever a quantum program is run in a qVM: efficiency, resource control, and equivalence. The efficiency property states that all innocuous instructions of the program are executed by the hardware directly, where an innocuous instruction is one that does not depend on its location in physical memory or the privilege mode of the CPU running the instruction. This implies that HyperQ ensures that the execution speed of a quantum program in a qVM is at worst a modest decrease versus running directly on the underlying hardware. Furthermore, since quantum computers lack QRAM and QPUs lack privilege modes, all quantum instructions are innocuous. The resource control property states that the program cannot affect the system resources available to it. This means that HyperQ retains control of the hardware and ensures that qVMs are isolated from one another. The equivalence property states that any program executing in a virtualized environment should exhibit the same behavior as if the program had run directly on the underlying hardware, with the possible exception of differences caused by timing or availability of resources. This implies that HyperQ retains compatibility with existing hardware and software so that it can run unmodified quantum programs in qVMs and have them execute correctly.

qVMs have other similarities and differences with VMs on modern classical computers. For example, qVMs are architecture-specific, such that a qVM for an IBM Eagle will not work on a Rigetti quantum computer, just as an x86 VM will not run an Arm VM. A key difference is that given the absence of quantum context switching capabilities, HyperQ does not rely on trap-and-emulate virtualization or hardware virtualization extensions to support it.

3.1 qVM Interface

HyperQ provides a qVM interface that is the same as that provided by a quantum machine backend such as IBM Quantum or Amazon Braket. A qVM provides a virtual coupling map and instruction set, much like a quantum machine provides a coupling map and instruction set, also known as its gate set. It is architecture-specific, just like classical VMs. For example, just like a VM for an x86 machine will not run directly on an Arm machine, a qVM for an IBM Eagle machine will not run on an AWS Rigetti machine. Users can construct their quantum programs using any quantum programming frameworks like Qiskit. A user can then compile the developed program

into an executable that can run in a qVM, which means it conforms to the topology constraint of the given coupling map of the qVM and only uses the gates provided by the gate set. The compiled executable for the qVM will include information regarding how the program's qubits map to the virtual qubits of the qVM, and identification of the set of classical bits the program uses for output.

Basic qVM configuration A basic qVM is defined based on the repeating structure of a specific physical machine. Its coupling map is a shape that is repeated in horizontal and vertical directions in the target physical machine. For example, for the IBM's Eagle machine, we define the basic qVM's coupling map to be an I-shape with seven qubits, which is not only the repeating region for the Eagle machine, but also serves as the entire machine configuration for IBM's smaller 7-qubit Falcon machine, shown in Figure 6. In other words, the I-shape is an architecture-specific region for this family of IBM quantum machines. For the Rigetti Aspen M-3, the coupling map is defined as an octagon shape.

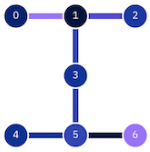

Figure 6: IBM's 7-Qubit Falcon machine [50].

HyperQ splits the physical machine's coupling map into a grid of regions, with each region in the grid have the same shape of the coupling map of a basic qVM, together with some optional connecting qubits between two adjacent regions. For example, the I-shaped region pattern appears in the Eagle machine multiple times. We can split the machine into 9 non-overlapping "Falcons", which form a 3×3 grid, as shown in Figure 7. The instruction set of a qVM is the same as that of the physical machine that will be used to execute the qVM. This is similar to how classical VMs reflect the instruction set of the hardware that they virtualize, except that the qVM instruction set is defined in terms of quantum gates. For the family of IBM quantum machines, the qVM interface is identical to that of the IBM Falcon, and therefore the qVMs can run quantum programs compiled for the IBM Falcon without modification, satisfying the equivalence property. Furthermore, an IBM Eagle machine can run the same qVMs as an IBM Falcon since they have a common architecture that is being virtualized in terms of their instruction set and repeating structure.

Fault isolation HyperQ ensures that qVMs are isolated from one another by also leveraging the structure of the physical machine being virtualized. A key issue that HyperQ must address in this context is that quantum hardware has crosstalk noise, where the state of one qubit can be affected by an instruction applied simultaneously on an adjacent qubit. Crosstalk noise could potentially result in the execution of one qVM affecting the execution of another. HyperQ isolates qVMs from one another by enforcing that qubits from different qVMs are not directly connected to each other. An easy way of doing that is including unused qubits between qVMs to mitigate crosstalk noise. For example, Figure 7 shows that the 9 non-overlapping qVMs have unused qubits between them so that no qVM has a qubit that is directly connected to the qubit of another qVM. As discussed in Section 4.2, our experimental results demonstrate that this simple approach is effective in ensuring fault isolation.

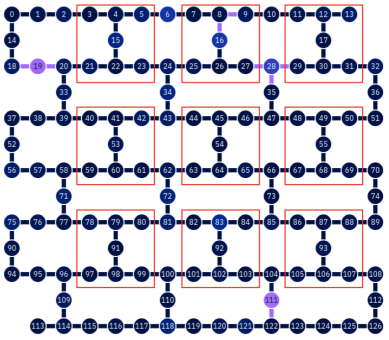

Figure 7: qVM basic unit mapping grid.

Scaled qVM sizes HyperQ provides different sizes of qVMs so that quantum computing resources can be elastically allocated according to computation needs. All the qVM sizes are a multiple of the basic qVM, which we refer to as scaled qVMs. Specifically, HyperQ provides $m \times n$ qVMs, which have the same instruction set as that of the basic qVM, and a coupling map with the shape of an $m \times n$ array of basic qVM shape, together with all the connecting qubits connecting adjacent basic shapes. For example, a 1×2 qVM on the IBM Eagle has 16 qubits and a coupling map of two I-shapes connected horizontally with two connecting qubits.

There are two principles to choose connections for scaled qVMs. First, they need to have the same shape so that we can easily assign the scaled qVMs anywhere on the real machine. For example, we would like to assign scaled qVMs anywhere within the 3×3 grid for the IBM Eagle. Unfortunately, the coupling map is not 90-degree rotational symmetric so we cannot make all connections to be the same. To work around this issue, we define horizontal and vertical connections separately, as shown in Figure 8 for the IBM Eagle. By making sure all horizontal connections and all vertical ones have the same shape respectively, we can still achieve the grid abstraction. We just need to be careful that now a n×m VM and m×n VM are different when n≠m. Second, connections within a scaled qVM should not overlap with connections that can possibly be used by other scaled qVMs. In other words, if we remove a scaled qVM from the grid of regions, adjacent basic regions in the remaining grid should still be able to connect. This does not mean all connections must be completely distinct. We can have overlapping connections within a scaled qVM.

Each scaled qVM of a different size also needs a defined coupling map, built from the basic I-shaped unit, horizontal, and vertical connections. For a connection, we use negative qubit number and add corresponding edges, as shown in Fig-

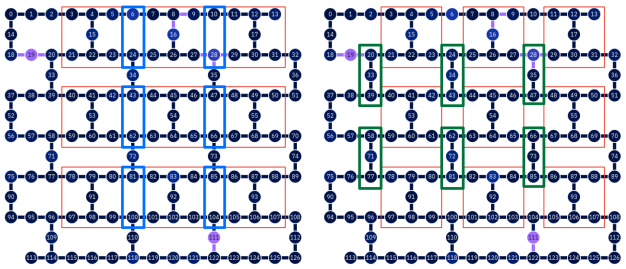

Figure 8: Physical connections for scaled qVMs.

ure 9b. Negative numbered qubits represents qubits inside of connection and positive numbered qubits represent the qubit in the adjacent basic unit. For example, qubit -2 in a horizontal connection should connect to qubit 0 of the basic block on its right, and qubit 2 of the basic block on its left. Each qubit in a scaled qVM needs its own unique number in the coupling map, which we provide by translating the numberings in Figures 6 and 9b based on their relative position. Basic units, horizontal connections and vertical connections are added in row-major order which each component having an assigned qubit number offset. The numbering of a qubit is its component offset plus its number within the component. We ensure that we avoid renumbering the same qubit if horizontal and vertical connections overlap.

HyperQ also scales using fractional multiples of a basic qVM, which we refer to as a fractional qVM. For example, a half qVM for the IBM Eagle would be top or bottom 3-qubit shape in the I-formation, dividing the basic 7-qubit qVM into two fractional 3-qubit qVMs. Fractional qVMs allow multiple small quantum programs to be executed simultaneously in isolation in a region normally taken up by one basic qVM.

For scaled qVMs, HyperQ maintains fault isolation in a similar manner as for basic qVMs. Scaled qVMs that are larger than basic qVMs inherent the same unused qubits between basic qVMs for fault isolation. Fractional qVMs utilizes the unused qubit in the middle of the I-formation between the top and bottom 3-qubit shapes to provide a similar fault isolation mechanism.

Adaptive qVM size selection Unlike classical VMs, a qVM does not have an operating system to multiplex multiple quantum programs because such operating systems are not available, so each qVM runs a single quantum program. Instead of manually selecting the size of a qVM, HyperQ automatically adapts the qVM size to the needs of the quantum program it will run, starting with the compilation process. Quantum programs define the number of qubits used in its quantum circuit, so it is straightforward for HyperQ to rightsize the qVM required. There is no reason to choose a smaller qVM because it will not be able to run the program, and there is no reason to choose a larger qVM because it will occupy additional qubits that it does not need.

For a given qVM size, multiple shapes may be possible.

(a) Horizontal connection **(b)** Vertical connection

Figure 9: VM connection coupling map for scaled qVMs.

For example, a 4 basic unit qVM could be a 1×4 qVM, a 2×2 qVM, or a 4×1 qVM. HyperQ aims to choose the shape that uses the minimal number of basic regions and the best connectivity. By default, HyperQ iterates through all possible (m, n) combinations and chooses the one that can satisfy desired qubit count with the smallest m×n. When multiple configurations have the same m×n, HyperQ chooses the ones with the smallest $|m-n|$. For example, HyperQ would prefer 2×2 over 1×4 since the former has better connectivity. In the default case, HyperQ generates at most 2 versions of qVMs, which can occur when there are two qVMs with the smallest $|m-n|$. For example HyperQ would generate both 1×3 and 3×1 qVMs if 3 basic units are required. In the scheduling step, HyperQ can adaptively select the best qVM shape to use given real-time traffic on the system.

3.2 Compilation

Users compile their quantum programs for qVMs in the same manner as they do for real hardware. There is no difference from the perspective of the user's workflow. Like classical computers, there is no need for the compiler to know what else will be running on the quantum computer as part of compilation. HyperQ works with existing quantum compiler frameworks to automatically select the right size qVM for the program based on the number of required qubits defined in the program. However, a compiler requires a backend to target for compilation. From the perspective of the compiler, each qVM of different dimension is considered a different backend with its own coupling map, just like IBM Falcon and Eagle machines are also considered different backends for existing quantum compilers. To utilize existing compilers, we provide a virtual backend object matched to the respective qVM's coupling map. When compiling a quantum program for a qVM, HyperQ determines the right size qVM based on program information, then selects that virtual backend for the compiler to use to generate the executable quantum circuit. A virtual backend appears just like a backend for real hardware, so existing compilers can work with qVMs without modification. For example, the compiler can perform optimizations on the virtual backend just like it does for a hardware backend. Although this provides broad compatibility with existing compilers, one limitation can be if the virtual backend does not provide the same degree of hardware specificity. In this case, certain highly specialized hardware-specific optimizations that rely on the full knowledge of the physical machine's low-level properties might not be fully exploited during compilation targeting a qVM.

We implemented virtual backends for the Qiskit compiler framework, which is widely used and is the default compiler infrastructure for the IBM Quantum Platform. A Qiskit backend also includes `run` instructions for how to run the compiled executable. In the case of qVMs, the `run` instruction calls HyperQ, which in turn performs scheduling before submitting the qVM to quantum hardware for execution. The virtual backend interface has equivalent behavior as real backends provided by IBM.

3.3 Scheduling

Users submit their qVMs with compiled executables to HyperQ. They are analogous to classical virtual appliances, which are VMs prepopulated with the program they will execute. HyperQ provides hypervisor-like functionality by scheduling when to run the qVM, allocating the necessary quantum hardware resources, and isolating qVMs from one another. To be compatible with existing quantum cloud computing services, HyperQ introduces a scheduling algorithm that is guaranteed to perform at least as good as the current approach of running programs sequentially one after another in FIFO order. The idea for HyperQ's scheduler is to consider qVMs for scheduling in FIFO order, but group qVMs in batches where they can run simultaneously by space and time multiplexing the quantum hardware. Each batch is then sent to the real hardware for real execution.

The scheduling algorithm solves a three-dimensional binpacking problem of how to pack qVMs in space and time to run on a quantum machine. An important constraint with existing cloud quantum computing services is that each program runs to completion and is not preemptible. To fit into this framework, HyperQ essentially packs qVMs together in a batch so the batch appears to the cloud service as one big quantum program that uses some number of qubits and runs for some amount of time.

The scheduling algorithm divides this binpacking problem into two stages. First, HyperQ performs a space scheduling algorithm that partitions the quantum hardware resources into basic regions and assigns those regions to qVMs so they can run at the same time. Second, HyperQ performs a time scheduling algorithm that appends some qVMs into the batch created by space scheduling to even out the amount of execution time required across basic regions. Once a batch is completed and sent to the hardware, the scheduling algorithm will repeat the process again on the remaining qVMs that have been queued but not yet scheduled for execution.

Space scheduling Without HyperQ, a single quantum program running on the physical machine will occupy the whole machine, even if it only uses a small portion of qubits in the machine. HyperQ solves this problem via space multiplexing by dynamically partitioning the machine into multiple regions matched to the sizes of the qVMs that need to be executed. The scheduling algorithm selects a set of qVMs from the job queue and assigns them to regions on the real hardware.

Algorithm 1: Space Scheduling

```
Input: L: a list of executables
Output: a list of compiled circuits with their location
selection ← {}
occupied[r][c] ← false, ∀ 0 ≤ r < maxrow, 0 ≤ c < maxcol
for e in L do
    for v in all versions of e do
        for (r, c) in all positions do
            if regions in [r, r+v.width) × [c, c+v.height) are
              all unoccupied then
                add (v, r, c) into selection
                mark all regions used by v occupied
                if all regions occupied then
                    return selection
                break
return selection
```

Algorithm 1 shows the spatial scheduling algorithm. It employs a greedy approach. The algorithm scans through the job queue of qVMs in arrival order. For each qVM, the algorithm checks whether it is possible to assign that qVM to one (or an array of) unoccupied regions on the hardware. If so, the qVM is assigned to those regions and removed from the job queue. Otherwise, the qVM is left unchanged and will be considered for the next batch. If there are multiple possible assignments, the algorithm will always use the topmost leftmost assignment. If there are multiple shapes of qVMs for a given quantum program, the algorithm will try them in order.

A key feature of HyperQ's approach is that the regions assigned have the same shape as the coupling map of the qVM. This enables mapping a qVM and its compiled executable to run on the real machine without the need for the program to be recompiled. Recall that compilation assigns program qubits to qubits for the target machine, which in the case of a qVM, are virtual qubits of the qVM. Once a qVM is scheduled to a specific region of the real machine, each virtual qubit of the qVM is assigned to a physical qubit of the real machine. HyperQ simply replaces the virtual qubits in the instructions of the executable with the physical qubits that will be actually used for execution. This can be thought of as just changing the qubit labels. This process is easy and fast, and allows a qVM to be placed in any region on the real machine.

Noise-aware scheduling In addition to space scheduling, HyperQ offers a noise-aware variant of its scheduling algorithm, designed to leverage up-to-date machine noise information and improve the fidelity of program execution. For instance, on IBM Quantum's Eagle device, noise calibration data for each pair of qubits is refreshed daily as their noise characteristics vary over time. HyperQ aggregates this data to compute an average noise level for each basic qVM region. It then ranks these regions by noise quality and designates the worst n as "low-quality." By avoiding these low-quality regions during scheduling, HyperQ can improve the fidelity of quantum program results. The parameter n is tunable, allowing

the system to balance throughput against fidelity; our experiments show that excluding the three lowest-quality regions yields a measurable fidelity improvement while sustaining good performance.

Beyond machine-level noise considerations, HyperQ also estimates the noise sensitivity of a qVM based on the program it will run. This could be done in several ways. One approach would be for the qVM to have a configuration option that its user can set to indicate whether its program is noise resilient. For example, a user that is using a qVM could indicate that it is noise resilient if it is running a variational quantum algorithm which can handle high levels of noise versus a Fourier transform which is more brittle to noise. Another approach would be to designate certain qVMs as not noise sensitive using a simple heuristic of their gate count exceeding some threshold because then they are likely to have highly noisy results. During scheduling, these high-noise or noise-resilient qVMs are preferentially placed onto the low-quality regions, thus conserving the high-quality ones for more noise-sensitive workloads. To enable this, we add a single condition to the space scheduling algorithm: if the next job in the queue is a normal qVM, it is assigned to regions of higher quality, whereas a high-noise or noise-resilient qVM is placed in low-quality regions. As with basic space scheduling, the jobs are processed in FIFO order, ensuring fairness while accommodating varying noise characteristics.

Time scheduling Besides space-multiplexing to run multiple quantum programs in parallel, HyperQ also uses time-multiplexing to fill in gaps caused by differences in how long different qVMs need to run, which would otherwise leave machine resources idle. When a qVM with a long running program runs in parallel with a qVM with a shorter program, the time scheduling algorithm appends another qVM to the end of the qVM with the shorter program. After executing the qVM with the shorter program, the qubits it used do not need to stay idle while waiting for the qVM with the longer program to finish, but can be used by another qVM.

Algorithm 2 shows the time scheduling algorithm. It starts from the job batch created by space scheduling. It scans the job queue of qVMs by arrival order. For each qVM, the algorithm will try to append it to a region after an already scheduled qVM, or to an array of regions with qVMs of similar execution time. This appending is valid only when the total execution times of qVMs on that region does not exceed the qVM with the longest execution time scheduled in the previous space scheduling step. If there are multiple possible assignments, the algorithm uses the topmost leftmost assignment. After time scheduling, the overall execution time of the whole batch will remain the same.

A requirement of the time scheduling algorithm is estimating how long each qVM needs to run. While in classical computing, estimating the execution time of arbitrary programs is problematic, this is much easier to do accurately for quantum programs. Near-term quantum programs have no loops and no variable memory access times due to caching behavior. Their execution time is entirely determined by the instructions used, which are the quantum gates. Each quantum gate has a known processing time, so HyperQ uses the circuit critical path length to estimate execution time, where path length is weighted by each gate's processing time. Since quantum compilers such as Qiskit account for gate delay as part of compiler optimization, we can obtain gate processing times from Qiskit's backend properties interface. For example, we found that on the IBM Eagle, a single-qubit gate takes 6e-8 seconds (s) and a two-qubit ECR gate takes about 6e-7 s. HyperQ then uses this information to binpack qVMs in time. Future quantum hardware supporting newer dynamic circuits that can incorporate conditional gate execution may make estimating running time harder; we leave this as future work.

Algorithm 2: Time Scheduling

```
Input: L: a list of executables
S: a list of compiled circuits with their location selected by
space scheduling
Output: a list of selected compiled circuits with their
        location
selection ← S
length[r][c] ← 0, reuse[r][c] ← 0,
 ∀ 0 ≤ r < maxrow, 0 ≤ c < maxcol
for v in S do
    for (r, c) in positions used by v do
        length[r][c] ← v.length
for e in L do
    for (r, c) in all positions do
        for v in all versions of e do
            if putting v at [r, r+v.width) × [c, c+v.height)
              does not increase max length and does not
              exceed reuse limit then
                add (v, r, c) into selection
                update length and reuse of all regions used
                  by v
                break
return selection
```

Appending a qVM after another qVM to time multiplex the same set of physical qubits requires first resetting the state of the qubits so that the appended qVM can be executed without being entangled with the state of the previous qVM. Before the reset, the previous qVM needs to perform a measurement of the qubits to obtain its results. The time scheduling algorithm accounts for the potential delay caused by mid-circuit measurement and reset and will leave gaps unfilled if the costs of measurement and reset in the middle of the execution of some circuits would outweigh the benefit of running another qVM. We use Qiskit's backend properties interface to obtain measurement and reset operation execution times. For the IBM Eagle, the measurement and reset operation times are 1.3e-6s and 1.8e-6 s, respectively.

HyperQ's scheduling provides performance guarantees with respect to the serialized FIFO approach used currently by

cloud quantum computing services. That serialized approach runs programs to completion in arrival order and has each program take up the entire machine when it runs. We refer to the time interval in which a program is executed as a time quantum, and can view the operation of a quantum computer as executing programs in sequentially numbered time quanta. HyperQ guarantees that it will always run a quantum program in a time quanta numbered no higher than the time quanta from using the serialized approach. In other words, any quantum program will be scheduled for execution at least as early as the serialized approach. Furthermore, by enabling multiple quantum programs to run in qVMs simultaneously, HyperQ guarantees that the overall utilization of the quantum machine is always at least as good as the serialized approach.

3.4 Executing with Quantum Hardware

After grouping qVMs into batches, HyperQ submits the batches to the actual quantum hardware for execution. Since current cloud services provide no direct instructional-level support for qVMs, we use existing interfaces to run qVMs by aggregating all qVMs in a batch into a big program that can directly run on real hardware. Then, HyperQ submits the big job to cloud platforms, and gets the measurement result which contains results of all qVMs in the batch. Finally, HyperQ splits the result into results of each program. Note that HyperQ is designed to be a fully dynamic runtime system, so the qVM abstraction can be dynamically supported once online runtime control of quantum hardware becomes available.

qVM aggregation To aggregate the qVMs into a big job, HyperQ combines them all into a single composite quantum circuit. This preprocessing involves qubit translation, gate direction adjustment, and insertion of reset instructions.

For space multiplexing, HyperQ translates all instructions on virtual qubits in the programs compiled to qVMs into instructions on physical qubits. HyperQ maintains a qubit mapping between qVM qubits and physical qubits for all shapes of qVMs and all possible allocation positions of the qVMs onto the hardware. Because qVMs map to the hardware in rectangular grid regions, it is straightforward to maintain this mapping by translating qVM grid coordinates. HyperQ uses this mapping to translate all programs in qVMs by changing their virtual qubits into hardware qubits according to the qubit mapping. For example, if a program is using a virtual qubit 1 which is mapped by scheduling to physical qubit 20, HyperQ will translate the instructions with virtual qubit 1 to instructions with physical qubit 20. Using the mapping, translation is quick and easy to do as a linear scan of the compiled executable. The translated instructions will be executed by the hardware directly and have the same execution speed as the original instructions, because the same instruction has the same execution time on different qubits. HyperQ's use of direct execution ensures that it satisfies the efficiency property.

HyperQ must also perform gate direction adjustment. Qubits are connected by edges, and edges can be directional on real hardware. In a two-qubit gate, the two qubits perform different roles. For instance, in a CX gate, one qubit is the control bit and the other is the operand bit. If the edge between the qubits is directed, one qubit can only be the control bit and the other can only be the operand bit. The IBM Eagle machine uses ECR gates as qubit links and they are directed. Even though it uses a repeating I-shaped region, the gate direction for different I-shaped regions may be different. To account for this, HyperQ uses a qVM coupling map with undirected edges. Once a qVM has been scheduled to an actual region on the hardware, HyperQ translates all instructions with undirected edges to directed edges matching the actual regions. Like qubit translation, this is straightforward to do via a simple linear scan of the compiled executable.

For time multiplexing, HyperQ inserts reset instructions and a barrier at the start of each qVM that follows another qVM using the same qubits. The resets occur in parallel, and the barrier ensures they begin simultaneously, helping to minimize reset latency.

As part of its linear scanning, HyperQ detects any mid-circuit measurement or reset operations and flags any qVMs with programs in which the number of such operations exceeds a defined threshold. This rarely if ever occurs. Such qVMs are removed and placed into separate quantum circuits to ensure that they cannot affect the execution of other qVMs.

Finally, HyperQ concatenates all the preprocessed programs into a big quantum circuit, which contains the execution of all the programs in the batch and is ready to run on the cloud. HyperQ's big quantum circuit is designed to successfully execute on NISQ hardware devices even though other large quantum circuits compiled from quantum programs cannot run successfully due to noise. The reason for this is that HyperQ's combined qVM circuit does not perform quantum operations across the qubits in different qVMs whereas quantum circuits from quantum programs generally do and expect their results to be from the entanglement of all of the qubits being used. As a result, HyperQ's combined circuit does not have the high noise behavior resulting from entanglement across all of the qubits.

HyperQ retains control of the hardware so that any program failures cannot corrupt the hardware or affect later executions of other programs. Before submitting the batch to cloud platforms, HyperQ estimates the running time of the batch by adding up the estimated gate time provided by IBM along the longest gate sequence in the batch. HyperQ submits the big job to the cloud with a timeout limit $1.5\times$ of the estimated running time. If the job fails to finish, it will timeout and control of the hardware will return to HyperQ. The combination of timeouts and unused qubits for fault isolation among qVMs ensures that HyperQ satisfies the resource control property.

Result post-processing After executing the aggregated circuit, HyperQ extracts each qVM's results using a maintained

mapping between qVM classical bits and their positions in the big circuit's output. This linear mapping allows HyperQ to split the cloud's returned results into separate outputs for each qVM.

4 Evaluation

To demonstrate the effectiveness of HyperQ, we have implemented it for the IBM Quantum Platform cloud service and evaluated its performance. From the cloud provider's perspective, we evaluate how much HyperQ can improve both throughput and utilization of quantum computing resources. From the user's perspective, we evaluate how much HyperQ can improve latency by reducing delay in program execution, including accounting for any extra virtualization overhead from the offline processing required to schedule and use qVMs. We also evaluate how HyperQ affects fidelity in program execution, including how much noise HyperQ introduces from multiplexing quantum hardware among qVMs and how it compares to the current single execution approach employed by IBM and other cloud services.

4.1 Experimental Design

We use a subset of QASMBench [25], which covers most types of typical quantum workloads in different sizes. There are three categories of workloads in QASMBench: small, medium and large. The number of qubits in each circuit ranges from 2 to 10 in the small category, and 11 to 27 in the medium category. Within the small category's range, today's NISQ machines can compute correct results with relatively high probability. We do not use the large category, because the circuits either require hundreds of qubits or millions of gates, and therefore are not runnable on near-term quantum computers.

#	Name_#qubits	Description
30	sat_n11	Boolean satisfiability problem
31	seca_n11	Shor's error correction for teleportation
32	gcm_n13	Generator coordinate method
33	multiply_n13	Perform 3×5 in a quantum circuit

48	ising_n26	Ising model simulation via QC
49	wstate_n27	W-state preparation and assessment

Table 2: Quantum program workloads in the medium category.

We construct two benchmark sets from QASMBench: small-only and small&med. The small-only benchmark contains circuits from the small category, as listed in Table 1. This benchmark is particularly useful to evaluate fidelity because the expected perfect results of the circuits from the small category can be computed by classical simulators. Therefore, we ensure that all circuits in the benchmark contain actual measurements at the end of execution so that we can approximately reconstruct the resulting statevectors to compare with the expected ones. The small&med benchmark contains circuits from both Table 1 and the medium category, as listed in Table 2. This benchmark better evaluates scheduling performance in the presence of more varied qVM sizes and showcases the elasticity of our HyperQ implementation; it is used for throughput, utilization, and latency measurements.

To use the QASMBench programs to provide an approximation of a real-world workload, we construct an arrival order among the programs by randomly putting each program workload into a queue some fixed number of times. Using the same number of repetitions for each workload facilitates later average fidelity calculations. For the small-only benchmark, there are 29 program workloads and each is repeated 5 times resulting in a job queue of 145 program workloads. For the small&med benchmark, there are 49 program workloads and each is repeated 4 times, resulting in a job queue of 196 program workloads.

We run the benchmarks using four platform configurations:

job arrival	configuration	small-only	small&med
all-at-once	IBM Quantum	456 s	683 s
	HyperQ	54 s	178 s
	improvement factor	8.4x	3.8x
	HyperQ space+time	47 s	139 s
	improvement factor	9.7x	4.9x
	HyperQ noise aware	64 s	176s
	improvement factor	7.1x	3.9x
poisson	IBM Quantum	456 s	683 s
	HyperQ	143 s	230 s
	improvement factor	3.2x	3.0x
	HyperQ space+time	143 s	203 s
	improvement factor	3.2x	3.4x
	HyperQ noise aware	152 s	223 s
	improvement factor	3.0x	3.1x

Table 3: Throughput for HyperQ versus IBM Quantum.

job arrival	configuration	small-only	small&med
all-at-once	IBM Quantum	3.3%	7.8%
	HyperQ	28%	35%
	improvement factor	8.6x	4.4x
	HyperQ space+time	35%	46%

	improvement factor	3.2x	3.6x
	HyperQ noise aware	9.7%	26%
	improvement factor	3.0x	3.4x

Table 4: Utilization for HyperQ versus IBM Quantum.

IBM Quantum The current approach used by the IBM Quantum Platform, and other quantum cloud providers, to run each program individually on the entire machine.

HyperQ Use HyperQ to run programs in qVMs with space scheduling.

HyperQ space+time Use HyperQ to run programs in qVMs with both space and time scheduling.

HyperQ noise aware Use HyperQ to run programs in qVMs with space and noise-aware scheduling.

To evaluate performance with different submission queues, we run all experiments using two different arrival models: 1) all jobs arrive at the start in an infinite job queue (all-at-once); 2) jobs arrive as a Poisson process with rate of 1 job per second (poisson).

All experiments run on the IBM Quantum Platform, where each user is limited to at most three jobs in queue. We used IBM's Brisbane quantum computer, which features the 127-qubit Eagle chip and is available for the public. When a program is executed on the hardware, it is run 4000 times by default to get the resulting state distribution. We used a desktop PC with a 3.2 GHz Intel Core i9-12900K CPU and 32 GB of RAM to compile the programs, schedule and aggregate qVMs into big job quantum circuits, and postprocess results. Compilation was done using Qiskit v1.0 with default settings.

4.2 Results

Throughput We measured the throughput when running the benchmarks. This can be quantified by obtaining the actual run time for each job on the quantum hardware, which is reported by the IBM platform, then obtaining the total run time for each configuration by summing the actual run times. We can then compute the throughput by dividing the number of programs executed by the total run time. Since the number of programs executed for each platform is the same, we can report the total run time as an indirect measure of throughput.

Table 3 shows the throughput results. HyperQ significantly outperforms the baseline IBM Quantum Platform by up to almost an order of magnitude. With jobs arriving all at once, HyperQ has a higher throughput improvement factor for the small-only benchmark because it can run more qVMs simultaneously since the programs require smaller qVMs. Even when running larger programs in the small&med benchmark, HyperQ can provide almost five times better throughput than the baseline IBM Quantum Platform. HyperQ provides better throughput when using both space and time scheduling than using only space scheduling or noise-aware scheduling, but all HyperQ configurations significantly outperform IBM Quantum. With a Poisson job arrival, HyperQ's improvement over IBM Quantum is less significant than with the jobs all arriving at once because there are fewer qVMs in the queue that can be scheduled together. However, HyperQ still provides 3 times or more improvement over IBM Quantum for all configurations. Note that HyperQ and HyperQ space+time are the same for the small-only benchmark with Poisson job arrival because there are not enough additional jobs in the queue to use time scheduling. HyperQ noise aware only has 6% lower throughput than HyperQ space+time with a Poisson job arrival because when there are fewer qVMs to schedule, there are a sufficient number of good regions to run the qVMs.

Utilization We measured the utilization rate when running the benchmarks. Traditionally, utilization is defined as the ratio between the number of active qubit seconds and the total number of qubit seconds. Ideally, the total number of active qubit seconds should be the sum of the active seconds of each qubit, however, the IBM platform provides no reporting of how long each qubit is actually performing operations. We approximate this measure by assuming that for each program, all qubits that are used by the program are active for the whole time the program runs on the quantum hardware. As a result, we can approximate utilization using the running time of each program. We estimate that amount by running each program alone and recording the total time IBM reports. For a HyperQ generated job, the number of active qubit seconds is calculated

job arrival	configuration	small-only						small&med					
		compile	schedule	queue	run	total	improve	compile	schedule	queue	run	total	improve
all-at-once	IBM Quantum	0.04	N/A	226	3.2	229	N/A	0.22	N/A	338	3.5	342	N/A
	HyperQ	0.04	0.14	26	3.6	30	7.6x	0.16	0.40	96	5.1	101	3.4x
	HyperQ space+time	0.04	0.26	22	5.2	28	8.2x	0.16	0.70	76	6.6	83	4.1x
	HyperQ noise aware	0.04	0.14	33	3.6	37	6.2x	0.16	0.49	96	5.0	101	3.4x
poisson	IBM Quantum	0.04	N/A	156	3.2	159	N/A	0.22	N/A	244	3.5	248	N/A
	HyperQ	0.04	0.04	1.2	2.5	3.7	43x	0.16	0.29	7.0	5.0	12	20x
	HyperQ space+time	0.04	0.04	1.2	2.5	3.7	43x	0.16	0.34	4.4	5.0	9.7	26x
	HyperQ noise aware	0.04	0.04	1.4	2.6	4.0	40x	0.16	0.34	9.6	4.7	15	17x

Table 5: Average latency for HyperQ versus IBM Quantum (seconds).

as the sum of the qubit seconds for all qVMs.

Table 4 shows the utilization results. Similar to the throughput results, HyperQ far outperforms the baseline IBM Quantum Platform, by up to an order of magnitude. With jobs arriving all at once, HyperQ has a higher utilization improvement for the small-only benchmark than the small&med benchmark because it is easier to pack more qVMs together when they are mostly of similar size. Nevertheless, HyperQ achieves relatively high utilization for both benchmarks, demonstrating its ability to maintain good utilization independent of what workloads are executed. With a Poisson job arrival, HyperQ's improvement over IBM Quantum is less significant than with the jobs all arriving at once because there are fewer qVMs in the queue that can be scheduled together. However, HyperQ still provides over 3 times improvement over IBM Quantum.

While HyperQ's utilization is many times higher than current practice, its utilization is limited by external fragmentation: the number of qVM qubits that can be used out of the total number of qubits on the machine. At most 85 of the 127 qubits are used for the 127 qubit IBM Eagle when all 9 qVM regions are in use. If the number of jobs is small, not all qVMs are used. For example, for the small&med benchmark, external fragmentation is 59% for all-at-once and 33% for Poisson arrival.

Latency We measured the latency for running the benchmarks with each platform configuration. In the baseline IBM Quantum case, users need to compile the program, submit it to the cloud service, wait in queue, and finally the program can be executed. With HyperQ, there is also the added step of scheduling qVMs and aggregating them into a job that can be submitted to the cloud service. Time spent waiting in queue is the most variable component of latency, and depends on how much work has been submitted to the cloud service across all users. To provide a conservative measure of queue waiting time that ignores jobs from other users, we assume that the queue is initially empty and there are no jobs from other users. The resulting queue waiting time for a job is then only due to the latency of running other jobs in the benchmark before it. With HyperQ, because all programs in a batch job do not have their results returned by the cloud service until the entire batch is complete, we use the run time of the entire batch job as the measure of run time for each program that is run simultaneously in the batch.

Table 5 shows the latency results on average across all programs. HyperQ significantly reduces the average latency of program execution by up to forty times. The key reason for this is because it reduces the queue waiting time because of faster consumption of the program workloads for execution by running them simultaneously. The queue waiting time is the dominant factor in latency, even with the assumption that the queue is initially empty, so that is the most crucial component of latency to reduce. HyperQ adds scheduling overhead from having an extra scheduling step, but it is negligible. HyperQ also increases average run time because short programs running in a batch need to wait for the longer programs in the same batch to finish. However, our results show that the increased scheduling and running time are negligible compared to the queue waiting time.

In practice, the waiting time for running the benchmarks also depends on jobs submitted by other users as well, further increasing queue waiting time. This waiting time for other users depends on the highly varying amount of workload being serviced by the IBM Quantum Platform. There is a real qualitatively different usage experience with HyperQ versus directly using IBM Quantum because of waiting time. With IBM Quantum, running either benchmark takes anywhere from a day or two to an entire week. In contrast, with HyperQ, running the benchmarks typically takes a few hours. Specifically, running the small-only and small&med benchmarks directly with IBM Quantum took 19 and 40 hours, respectively, while using HyperQ typically took 2-3 hours for either benchmark, though sometimes it took as little as 5 minutes.

Fidelity We measured the fidelity of results for running the benchmarks with each platform configuration. It is crucial that HyperQ does not negatively impact fidelity as a result of multiplexing program execution together such that hardware noise from nearby qubit usage for one qVM ends up corrupting the results of another qVM. The result of a quantum circuit can be seen as a probability distribution over states described by binary strings. We use the L1 distance between the distribution given by results of the 4000 runs and the ideal probability distribution on a classically-simulated ideal quantum computer. We calculate the ideal distribution using

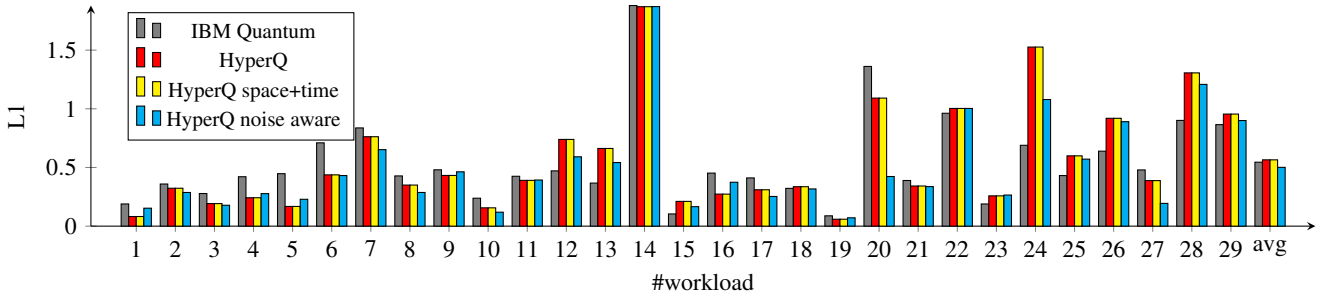

Figure 10: Fidelity for HyperQ versus IBM Quantum per workload with Poisson job arrival.

Qiskit's Aer simulator. The L1 distance is defined as

$$L1 = \sum_{s \in ES} |p_{ideal}(s) - p_{real}(s)| \quad (1)$$

where ES is the set of possible results, $p_{ideal}(s)$ is the probability of result s in the ideal distribution, and $p_{real}(s)$ is the probability of result s in the real result. The value of $L1$ ranges from 0 to 2. $L1 = 2$ means the result is completely corrupted by noise, while $L1 = 1$ means the result has more than half of the perfect result. If a quantum program generates a deterministic result, such as Grover's algorithm or a quantum adder, then $L1 = 1$ is sufficient fidelity to ensure that correct results are generated by the program. We can therefore use this threshold as a rough measure of good fidelity.

Table 6 reports the average fidelity results for the small benchmark. Figure 10 shows the results on a per workload basis for Poisson job arrival. HyperQ provides similar fidelity as the baseline IBM Quantum case of running each program in isolation on the entire machine, adding negligible noise on average for both the space only and noise-aware scheduling. However, HyperQ with time scheduling does incur higher noise for jobs arriving all at once. This is caused by additional mid-circuit measurement and reset operations introduced by time scheduling. These relatively new operations are still noisy on current hardware, though they are expected to improve in future hardware [19, 38] which will make time scheduling more beneficial. Nevertheless, in all cases, HyperQ provides average fidelity that is much better than $L1 = 1$. Overall, HyperQ effectively isolates program execution in qVMs such that space multiplexing them on quantum hardware does not compromise the fidelity of program execution.

Moreover, HyperQ noise-aware scheduling can provide better average fidelity results than IBM Quantum, improving averaging fidelity by roughly 10% over IBM Quantum for Poisson job arrivals. HyperQ noise-aware scheduling does better for Poisson job arrivals than jobs arriving all at once because when there are fewer qVMs to schedule together, there are a sufficient number of good regions to run the qVMs. In contrast, HyperQ space only scheduling does slightly worse for Poisson arrivals than jobs arriving all at once because when not all regions need to be used, inadvertently using a bad region and leaving out good regions to run qVMs worsens average fidelity. Figure 10 also shows various workloads in which HyperQ provides substantially better fidelity results for certain workloads. A closer investigation finds that, for a fixed quantum program, the Qiskit compiler will by default always select the same set of qubits to run the program. If this selection is bad, the result will have bad fidelity. In contrast, HyperQ's space scheduler can assign the program to different regions, averaging out bad choices, while its noise-aware scheduler only puts high noise workloads on qVMs running in noisy regions. Given the degree of isolation that is already provided by qVMs, the region selection can have a more significant impact on fidelity than any potential crosstalk from concurrent execution of qVMs. As a result, HyperQ noise-aware scheduling can surprisingly provide better fidelity results than directly using IBM Quantum.

configuration	all-at-once avg L1	poisson avg L1
IBM Quantum	0.55	0.55
HyperQ	0.55	0.57
HyperQ space+time	0.64	0.57
HyperQ noise aware	0.54	0.50

Table 6: Average fidelity for HyperQ versus IBM Quantum.

HyperQ's ability to provide good fidelity is due in part to ensuring that qVMs are not directly connected to one another. To quantify the impact of using qVMs with no direct connections, we ran a simple experiment with five two-qubit quantum programs, each of which consisted of 100 random quantum X and CX gates. We use two-qubit programs because they are simple but enough to represent the difference between interactions between qubits within a program versus crosstalk between programs. We use 100 gates to have programs that have deep enough circuits to show the impact of propagation errors due to noise. We use X and CX gates because they are deterministic, instead of having their results based on a probability distribution, so that it is easy to simulate such a program on a classical computer to determine its correct result without noise. For each program, we ran it in three configurations on a line-shaped area of the IBM Eagle: 1) single program by itself (qubits 4+5), 2) two copies of the program running on adjacent qubits (qubits 4+5 and 6+7), and 3) two copies of the program running in regions that are separated from one another by one qubit (qubits 4+5 and 7+8). The average success rate of the three configurations in computing the correct

result was 85%, 81%, and 85%, respectively. In other words, having concurrently executing quantum programs on directly connected qubits results in worse fidelity, while using individual unused qubits between such programs maintains the same level of fidelity as when running the program by itself. This result further demonstrates that including individual unused qubits between qVMs is helpful to maintain fault isolation.

5 Related Work

VMs have been used for classical computing since the 1960s, directly following the development of multiprogramming, aiming to ensure noninterference among processes, reduce system complexity for developers, and make software portable across different hardware models [2, 8, 39]. VMs experienced a rebirth in the late 1990s and are widely used on classical computers today [3–6, 9–14, 24, 27–32, 40, 41, 48, 54]. The need to effectively utilize quantum computing hardware and manage multiple circuits running on one machine draws parallels to the desire for VMs after multiprogramming, which inspired our work. HyperQ is the first to introduce qVMs to run on and multiplex quantum computers. While VMs on classical computers benefit from hardware support for virtualization [6], HyperQ enables virtualization of quantum computers and the use of qVMs without additional hardware virtualization features. Although the term "Quantum Virtual Machine" has been used previously for classical simulation of quantum computers [7, 18, 51], that usage does not support any virtualized abstraction on quantum hardware.

The evolving landscape of quantum computing has spurred significant research into quantum software [16, 46, 52, 53], including various custom quantum compilers to support multiprogramming for small-scale quantum machines [15, 34, 43–45]. These custom compilers combine multiple quantum circuits at *compile time* and therefore require knowing at compile time which quantum programs will be executed together. Unlike standard practice on classical computers, they do not allow programs to be compiled independently and later executed in arbitrary combinations. Furthermore, the specialized compilers are usually less optimized compared to using standardized compiler tools like Qiskit. Some of the approaches do not scale to larger quantum machines because they only allow two circuits to run in parallel [15]. None of them improve the fidelity of program execution or consider time multiplexing. HyperQ takes a fundamentally different approach by introducing a powerful virtualization abstraction and manage actual multiprogramming at *run time* by a scheduling algorithm. This preserves independent compilation of programs while enabling scalable multiprogramming, fault isolation, efficient resource utilization, and even improved fidelity of quantum program execution. Furthermore, unlike previous approaches, HyperQ is seamlessly compatible with existing quantum cloud services.

Kernel fusion [17, 55, 56] and program merging [58] have been proposed to improve the utilization of GPUs and programmable network switches by using a custom *compiler* to merge multiple CUDA or P4 programs into one big program. In contrast, HyperQ employs a simple scheduler to combine multiple programs for execution at *run time*. At compile time, each program is compiled individually by users with a standard compiler.

6 Conclusions and Future Work

HyperQ is the first system to introduce quantum virtual machines and use them to enable better resource utilization and lower latency for quantum cloud computing. By leveraging the repeating qubit regions of real quantum machines, HyperQ can define quantum virtual machines in terms of an architecture-specific quantum instruction set and virtual qubit topology, then map them to directly execute on real hardware with no runtime virtualization overhead. Quantum programs can be compiled for specific-sized virtual machines, and HyperQ will binpack them together in batches in both space and time then translate them to aggregated machine-sized quantum circuits so they can be simultaneously executed on a quantum computer. We have implemented HyperQ for the IBM Quantum Platform in a manner that is compatible with the existing cloud service and compilation tools. Our experimental results on real quantum hardware show that HyperQ can reduce program latency as well as increase utilization and throughput by an order of magnitude without sacrificing fidelity in the results of quantum program execution.

HyperQ is designed to virtualize existing quantum computers, but new generations of quantum computers are being developed that are radically different from previous generations as quantum hardware technologies improve. We are exploring how HyperQ can be extended to take advantage of these advances in quantum hardware for diverse qubit technologies like ion traps and neutral atoms, and across different hardware architectures. We also plan to leverage enhanced mid-circuit measurement and control flow for more flexible time-multiplexing. These developments will enable HyperQ to continue to evolve with hardware to provide the system software and virtualization foundations for future quantum cloud computing infrastructure.

A Artifact Appendix

Abstract

This artifact provides the source code and scripts to reproduce the experimental results for HyperQ. The artifact contains Python scripts to implement the core HyperQ hypervisor, run

benchmarks against both a baseline IBM Qiskit configuration and various HyperQ scheduling policies, and scripts to retrieve and analyze the performance data, including throughput, utilization, and fidelity. It allows for a comprehensive validation of the claims made in this paper.

Scope

This artifact is designed to validate the performance claims of the HyperQ system. Specifically, it allows for the reproduction of the results in table 3, 4, 6, and figure 10. README.md provides instructions to run the baseline benchmarks using the default IBM scheduler and HyperQ benchmarks with three distinct scheduling policies.

Contents

The artifact consists of Python scripts for core HyperQ functionalities (such as `HypervisorBackend.py`) and for executing the various benchmarks. Scripts dedicated to data retrieval and result analysis are organized into the `getdata/` and `analysis/` directories, respectively. The `benchmark_result/` directory is used for storing benchmark workload files and experimental outcomes, and includes the `result_ideal.txt` file which provides pre-computed ideal state vectors.

Hosting

The artifact is hosted on GitHub https://github.com/1640675651/HyperQ with branch `main` and commit hash `a1c7460`. Future updates will be pushed to the `main` branch, and we encourage you to use the latest version available.

Requirements

The artifact was developed and tested on a standard Linux environment. It requires several software dependencies for its operation: Qiskit, the Qiskit Aer simulator, and the QASMBench benchmark suite. Additionally, a valid IBM Quantum Account with an API token is essential for submitting jobs to IBM's quantum hardware and retrieving results. For complete and detailed instructions on how to set up these dependencies and configure the necessary environment, please consult the `README.md` file provided in the artifact's GitHub repository.

QOS: Quantum Operating System

Emmanouil Giortamis Francisco Romão Nathaniel Tornow Pramod Bhatotia
Technical University of Munich

Abstract

Quantum computers face challenges due to hardware constraints, noise errors, and heterogeneity, and face fundamental design tradeoffs between key performance metrics such as *quantum fidelity* and system utilization. This substantially complicates managing quantum resources to scale the size and number of quantum algorithms that can be executed reliably in a given time.

We introduce QOS, a modular quantum operating system that holistically addresses the challenges of quantum resource management by systematically exploring key design tradeoffs across the stack. QOS exposes a hardware-agnostic API for transparent quantum job execution, mitigates hardware errors, and systematically multi-programs and schedules the jobs across space and time to achieve high quantum fidelity in a resource-efficient manner. QOS's modular design enables synergistic cross- and intra-layer optimizations, while introducing new concepts such as compatibility-based multi-programming and effective utilization.

We evaluate QOS on real quantum devices hosted by IBM, using 7000 real quantum runs of more than 70.000 benchmark instances. We show that the QOS achieves 2.6–456.5× higher fidelity, increases resource utilization by up to 9.6×, and reduces waiting times by up to 5× while sacrificing only 1–3% fidelity, on average, compared to the baselines.

1 Introduction

Quantum computing promises to solve computationally intractable problems with classical computers [2, 12, 25, 68]. Thanks to remarkable technological advances in materials science and engineering, quantum hardware has become a reality in the form of quantum processing units (QPUs) [19, 27, 69]. Interestingly, QPUs are now readily available in a quantum-as-a-service fashion offered by all major cloud providers [3, 5, 24, 32].

However, QPUs present fundamentally unique hardware-level challenges that cannot be directly mapped to classical accelerator-oriented computing (we empirically detail these hardware challenges in § 3). In particular, QPUs operate in the NISQ-fashion (Noisy Intermediate-Scale Quantum [57]), leading to strict *hardware constraints* and a *non-deterministic* computing platform [50, 61].

More specifically, QPUs are inherently noisy and small in computational capacity, which limits the size of the problems they can solve [57]. Second, the degree of noise differs across QPUs and time, even of identical architecture and model, making it difficult to decide which QPUs should execute a quantum program with good performance [61]. In addition, we can not trivially multi-program multiple quantum jobs on the same QPU to increase utilization without them interfering with each other in undesirable and unpredictable ways [45], severely degrading performance [40]. Last, scheduling quantum jobs on heterogeneous noisy QPUs exhibits a fundamental tension between quantum performance metrics, such as *fidelity* [21], and classical performance metrics, such as utilization and load balance (i.e., resource efficiency).

Unfortunately, these problems are amplified by the current state of software, where QPUs are managed through rudimentary interfaces, despite the ever-increasing demand for these scarce resources [1, 50, 61]. Researchers have proposed specialized approaches to address some of the aforementioned OS and QPU challenges individually, for instance, fidelity without runtime support [4], basic multi-programming via FIFO or random job selection [16], or heuristics-based scheduling [62]. Unfortunately, these systems are designed in isolation, are tightly coupled to specific policies, and lack the architectural flexibility and interoperability needed for cross-stack coordination.

At the same time, in industry platforms like IBM Cloud [32] and AWS Braket [3], multi-programming is not supported, and users must improve fidelity and select QPUs *manually*. However, the noisy, scarce, and heterogeneous nature of QPUs naturally motivates users to select the best-performing QPUs, further amplifying the already high QPU load imbalance and queue waiting times [50, 61].

In total, there is still no operating system that addresses quantum job and resource management in a unified and systematic way, i.e., an architecture that supports composable, cross-layer mechanisms designed specifically for the constraints of quantum computing. Such a system must integrate error mitigation techniques to improve fidelity, fidelity-aware performance estimation to handle the spatiotemporal variability of QPUs, multi-programming to increase utilization through compatibility-aware co-location of quantum jobs, and a scheduler that balances QPU load and reduces queue times—all under a single, unified stack.

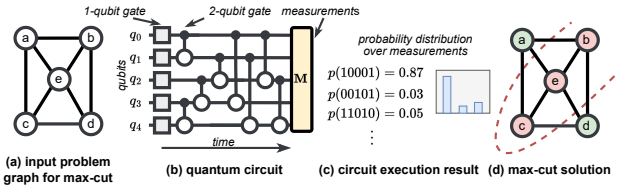

Figure 1: Foundational example (§ 2.1). **(a)** *Input graph to max-cut.* **(b)** *A quantum circuit encoding the max-cut formulation for the graph.* **(c)** *The execution result is a probability distribution of bitstrings.* **(d)** *The result is interpreted as a max-cut between vertices* $\{a,d\}$ *and* $\{b,c,e\}$.

To fill this gap, we propose QOS, a quantum operating system for holistically tackling quantum computing challenges through a modular, cross-layer architecture. At the core of QOS lies the *Qernel* abstraction—the common denominator that enables the seamless composition of diverse system mechanisms and facilitates cross-layer optimizations.

QOS abstracts away the underlying complexity of quantum resource management and systematically explores the associated tradeoffs of quantum computing. To achieve this, QOS exposes hardware-agnostic APIs and comprises four main components: (1) the *error mitigator*, a component that composes complementary techniques to increase fidelity by mitigating hardware noise, (2) the *estimator*, which predicts fidelity performance across heterogeneous QPUs to guide scheduling decisions, (3) the *multi-programmer* that bundles compatible jobs on the same QPU to improve QPU utilization while minimizing fidelity loss, and (4), the *scheduler*, which performs fidelity-aware, multi-objective job scheduling to reduce queueing latency and balance QPU load.

We implement QOS in Python by building on the Qiskit framework [33]. We evaluate QOS on IBM's 27-qubit QPUs [32], using a dataset of more than 7000 quantum runs and 70.000 state-of-the-art quantum benchmark instances used in popular quantum algorithms [38, 60, 76]. Our evaluation shows that the error mitigator improves execution fidelity by 2.6–456.5× on average, depending on the problem size (§ 9.2), the estimator correctly identifies high-fidelity QPUs (§ 9.3), the multi-programmer fidelity by 1.15–9.6× for a target utilization (§ 9.4), and the scheduler reduces the waiting times by 5× while sacrificing at most 3% of fidelity (§ 9.6).

Contributions. Our main contributions include:

1. QOS is the first quantum operating system to holistically address the challenges of quantum computing. Its modular architecture and the introduction of the Qernel abstraction enable a clean separation of mechanism and policy, enabling flexible integration of evolving techniques without modifying system interfaces.
2. QOS enables both cross-layer and intra-layer optimizations through its end-to-end system design. QOS's components synergistically optimize fidelity and resource efficiency while supporting composable techniques within individual layers.
3. QOS systematically explores and manages key quantum computing tradeoffs, including: (i) fidelity vs. runtime overheads in error mitigation and performance estimation; and (ii) fidelity vs. QPU utilization, as well as job waiting times, in multi-programming and scheduling.
4. QOS introduces technical novelties across the quantum software stack: (i) the *Qernel* abstraction as a unifying execution unit, (ii) the composable error mitigation pipeline that is the first to combine circuit cutting, qubit reuse, and qubit freezing—techniques that amplify each other when composed non-trivially, (iii) a multi-programming model introducing the concepts of *compatibility scoring* and *effective utilization*, enabling higher-fidelity circuit co-location, and (iv) the first multi-objective, fidelity-aware scheduler that jointly considers fidelity and waiting times.

2 Background

2.1 Quantum Computing 101

Quantum computers solve *specific* computationally hard problems exponentially faster than classical computers by leveraging the quantum mechanics principles of *superposition* and *entanglement*. Specifically, the basic units of quantum computation are *qubits*, which during quantum computation are both 0 and 1 at the same time (recall Schrodinger's cat experiment [65]), and when entangled, they can interact with each other even over large distances [41].

To solve NP-hard problems (e.g., maximum-cut) with quantum computers, we use algorithms such as the Quantum Approximate Optimization Algorithm (QAOA) [20]. This algorithm is considered practical for today's quantum hardware capabilities and influential towards achieving quantum advantage [63].

Foundational example. Figure 1 shows how QAOA solves an example max-cut problem for an input graph **(a)**. First, the graph is encoded as a *quantum circuit*. Quantum circuits comprise qubits and quantum gates, akin to logical gates in classical circuits (e.g. NOT, XOR), which are applied over time (from left to right). In the max-cut case, each graph vertex corresponds to a qubit and each edge to a 2-qubit gate in the circuit **(b)**. At the end of the circuit, we measure each qubit to read its value, which gives bitstrings as output. Notably,

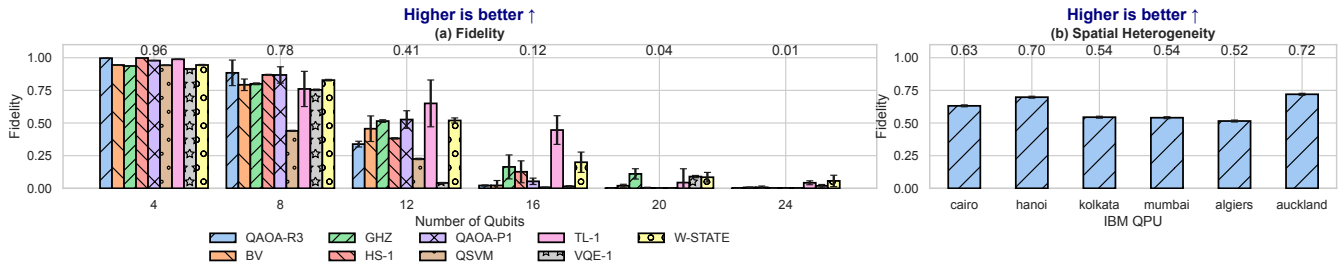

Figure 3: **(a)** Challenge #1, Fidelity (§ 3.1). *Impact of the number of qubits (circuit size) on fidelity. There is an average 98.9% reduction in fidelity from 4 to 24 qubits.* **(b)** Challenge #2, Spatial heterogeneity (§ 3.2). *Fidelity of a 12-qubit GHZ circuit on different IBM QPUs. There is a 38% fidelity difference from best to worst QPU.*

measurements collapse the superposition state to a definite binary value.

Since quantum mechanics is inherently probabilistic, the bitstring we get is truly random, but due to the algorithm structure, it follows a *probability distribution*, which ultimately renders quantum computers useful. Thus, we execute the circuit in many trials (*"shots"*), with each trial providing a specific bitstring from the qubit measurements. The solution of the quantum calculation is, therefore, a probability distribution over all possible bitstrings of the measured qubits, where high probability maps to the solution, while low (~ 0) does not represent a solution **(c)**. In our example, the bitstring `10001` represents the max-cut solution that contains the partitions {a, d} and {b, c, e} **(d)**.

2.2 Technical Foundations

Execution Model. The technology and engineering required to build QPUs renders them an expensive resource, i.e., there are less than 100 QPUs globally offered in the cloud in a quantum-as-a-service fashion [3, 5, 24, 32]. To run quantum programs, users typically write circuit-level code (Figure 2 (a)), which then *transpile* on the QPU to make it executable, send it to the cloud for execution, and finally get the results back. Specifically, the transpilation process performs three key steps: (1) converting the gates of the circuit to the native gate set of the QPU, (2) mapping the logical qubits of the circuit to the physical qubits of the QPU, (3) routing the qubits to the physical qubits with restrictive connectivity by inserting additional costly gates. Figure 2 (b) shows the physical layout of an IBM Falcon QPU. Vertices are the physical qubits, and the edges capture their connectivity, i.e., between which qubits we can apply 2-qubit gates. Figure 2 (c) shows the physical circuit after transpilation with the QPU's noise characteristics, which we detail next.

QPU characteristics. Today's QPUs are described as noisy intermediate-scale quantum (NISQ) devices [57] since they exhibit low qubit numbers (e.g., up to a few 100s [32]) and are susceptible to hardware and environmental noise. Specifically, when measuring a qubit, there is a chance to read the opposite value, and when applying gates, there is a chance the gate performs a wrong operation [23]. On top of that, when qubits are left idle (no gates applied) for more than a few hundred microseconds, the superposition *decoheres* to the $|0\rangle$ state [35], similar to resetting a register to 0. Lastly, qubits destructively interfere with each other via *crosstalk* effects [45]. Figure 2 (c) shows qubits Q_0 and Q_3 that influence each other via crosstalk, noisy gates, qubit Q_0 that is left idle for long enough to decohere, and noisy measurements.

QPU heterogeneity. Additionally, QPUs are vastly *heterogeneous* across space and time, unlike classical accelerators. Across space, QPUs vary in terms of technology, e.g., superconducting qubits [19, 69] or trapped ions [30], architectures of the same technology, e.g., Falcon or Osprey superconducting QPUs [32], and noise properties (formally called `noisemodel`) even for the same architecture [23], e.g., two identical QPUs exhibit different noise errors, etc. Across time, the QPUs are *calibrated* regularly to maintain their performance [31, 77, 82], a process that generates *calibration data*. These data quantify the noise errors and change unpredictably after each calibration cycle.

Performance metric. To measure the quality of a circuit execution on NISQ QPUs, we use the **fidelity** metric [21], which measures the similarity between the noisy probability distribution and the ideal probability distribution that noiseless, ideal QPUs can obtain. Given two probability distributions over measurement outcomes, the ideal P_{ideal} and the noisy P_{noisy} distributions, fidelity is computed as: $F(P_{ideal}, P_{noisy}) = (\sum_i \sqrt{P_{ideal}(i) \cdot P_{noisy}(i)})^2$. Fidelity is a number in the $[0, 1]$ range, where a higher fidelity means a better quality result.

Circuit properties. Execution fidelity is impacted by the aforementioned QPU noise model and the *circuit properties* that describe the circuit's complexity and, thus, susceptibility to errors. Circuit *width* refers to the number of logical qubits involved in the circuit and typically also the physical (H/W) qubits required to execute it. Circuit *depth* denotes the largest number of layers of gates applied to the qubits and quantifies the circuit runtime. A larger depth typically indicates a higher chance for decoherence errors. Last, the number of *non-local gates* refers to the gates that act on non-adjacent qubits, which are particularly susceptible to errors in NISQ devices. *Generally, larger circuits (larger width, depth, or number of*

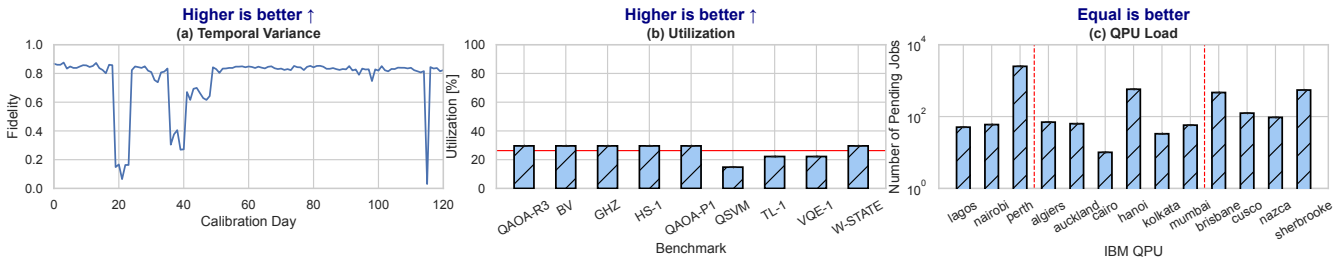

Figure 4: **(a)** Challenge #2, Temporal variance (§ 3.2). *Fidelity of a 6-qubit GHZ circuit on IBM Perth, across 120 calibration days. There are 20 pairs of days with more than 5% difference in fidelity.* **(b)** Challenge #3, Utilization (§ 3.3). *Maximum utilization achieved on a 27-qubit QPU for nine benchmarks while maintaining at least 0.75 fidelity. The average utilization is* 26.3%*, and the max is* 29.6%*.* **(c)** Challenge #4, QPU Load (§ 3.4). *Number of pending jobs on different IBM QPUs. The groups separated by vertical red lines indicate QPUs of the same size. There is up to 57× difference in number of jobs between QPUs of the same size.*

non-local gates) equals lower fidelity.

Circuit feature vectors. While circuit properties are useful, sometimes they fail to characterize the structural and computational properties of quantum circuits. Thus, we can use the Supermarq feature vectors, a set of six metrics proposed by Tomesh et al. [76] with the initial goal of quantifying quantum benchmark coverage. These features quantify the parallelism and speedup potential, the lower bound on execution time, QPU connectivity requirements, entanglement (i.e. complexity), and susceptibility to decoherence and measurement errors.

3 Motivation and Key Ideas

To motivate QOS, we present a set of *unique* challenges that distinguish QPUs from classical accelerators. We categorize our findings into four challenges that must be addressed to improve the practicality of quantum computing: fidelity, utilization, spatial and temporal heterogeneities, and load imbalance. The experimental methodology used is the same for the final system evaluation and is explained in detail in § 9.1.

3.1 Fidelity

Executing quantum programs with high fidelity is challenging since QPUs are characterized by relatively small numbers of qubits and noise, which leads to computation errors (§ 2.2). As the number of qubits and gates in a quantum circuit increases, the noise errors accumulate and the overall fidelity decreases.

Results. Our results are highlighted in Figure 3 (a). The *x* axis shows the circuit size as the number of qubits while the *y* axis shows the fidelity, where higher is better. The experiment is run on the IBM Kolkata 27-qubit QPU. For each increase in qubits, the average fidelity decreases, up to 98.9% from 4 to 24 qubits. Moreover, it is physically impossible to run circuits with a size larger than 27 qubits, since we cannot map them.

Implication. NISQ devices are limited due to size and noise and, therefore, cannot be practically used for large quantum circuits, either logically because the circuit doesn't fit in the device or the execution results would be degraded from noise-induced errors, which translates to low fidelity.

3.2 Spatial and Temporal Heterogeneity

In the classical domain, two identical CPUs perform similarly for all applications at each point in time. In contrast, QPUs exhibit differences in the layout and connectivity of qubits [26] and variations in noise errors even for QPUs of the same model, which leads to spatial performance variance. Moreover, QPUs are calibrated regularly (§ 2.2), and after each calibration, the noise properties change [61]. As a result, the execution fidelity can vary across different calibration cycles, leading to temporal performance variance.

Results. Figure 3 (b) shows a 12-qubit GHZ circuit's fidelity on different IBM QPUs. Fidelity varies across the QPUs, with a maximum difference of 38% from best to worst. Notably, all six QPUs are of the same model (Falcon r5.11).

Figure 4 (a) shows a 6-qubit GHZ circuit's fidelity over 120 calibration days executed on the IBM Perth 7-qubit QPU, where each data point represents a single day's fidelity. The largest single-day difference in fidelity is 96.5%, and there are 20 instances of a single-day fidelity drop of more than 5%. Note that there is no way to predict a QPU's future calibration data to expect such performance differences.

Implications. Due to structural differences across QPUs, quantum circuits perform differently across them. Additionally, there is a high degree of temporal performance variance across calibration cycles, as the fidelity might change significantly from day to day with no discernible pattern.

3.3 Utilization

The fidelity of circuits decreases as their size increases (§ 3.1), and as a result, it becomes more challenging to utilize a QPU effectively. In contrast to the classical domain, where a CPU can be fully utilized, to get high-fidelity results in the quantum domain, we necessarily under-utilize QPUs.

Results. Figure 4 (b) shows the maximum utilization of the IBM Kolkata 27-qubit QPU for nine benchmarks while

targeting at least 0.75 fidelity. No benchmark exceeds 30% utilization, while the average is 26.3%. Higher fidelity targets would yield even lower utilization and vice-versa.

Implications. There is a tradeoff between QPU utilization and fidelity. In general, the lower utilization, the higher fidelity, and vice-versa. In contrast to the classical domain, the tension between these metrics is vastly larger.

3.4 QPU Load Imbalance

The quantum cloud faces QPU load imbalance. The root cause is spatiotemporal heterogeneity (§ 3.2), combined with the manual QPU selection offered by the current quantum cloud model [32]. These naturally motivate users to select the highest fidelity QPU(s) for that calibration cycle [61].

Results. Figure 4 (c) shows the average number of pending jobs for different IBM QPUs across October 2023. The groups of QPUs (separated by the red dashed line) have a size of 7, 27, and 127 qubits, respectively. There is a 49×, 57×, and 5.7× maximum load difference across the groups, respectively.

Implications. Load imbalance leads to long waiting times for the users and thus, low quality of service. However, the performance difference does not always justify the load differences between QPUs. For instance, the 12-qubit GHZ circuit in Figure 3 (b) performs 1.1× better on IBM Hanoi than IBM Cairo, yet the former exhibits 57× higher load.

4 Overview

We propose QOS, an operating system for quantum computing. In this context, we define a quantum operating system as a software layer that transparently manages quantum jobs and resources efficiently with respect to job fidelity and waiting times (user's goals) and QPU utilization and load-balance (cloud operator's goals). Therefore, QOS strives for three design goals: (1) QOS's architecture should be general and modular, cleanly separating mechanism from policy while enabling both cross-layer coordination and within-layer optimizations. (2) QOS should enable the execution of large quantum jobs with high fidelity. (3) QOS should be resource efficient by achieving high QPU utilization and balancing QPU load to minimize queue waiting times.

4.1 The QOS Architecture

Figure 5 shows the overview of our system's design. QOS comprises a layered architecture that consists of an API and four main components: the error mitigator, the estimator, the multi-programmer, and the scheduler, which we detail next.

Qernel abstraction. QOS implements a wide range of mechanisms with different abstraction requirements, from error mitigation to scheduling level. To enable the composability of these mechanisms in a unified architecture,

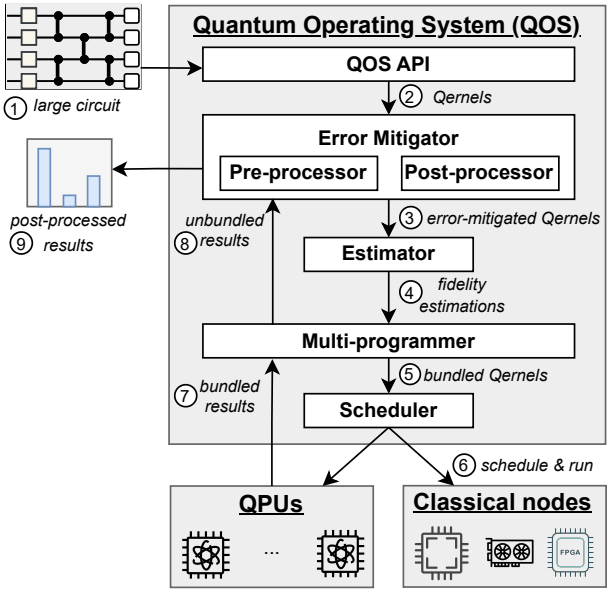

Figure 5: QOS overview (§ 4): *QOS consists of four main components: the error mitigator, estimator, multi-programmer, and scheduler.*

we propose the *Qernel* abstraction that acts as a common denominator for the QOS mechanisms to apply their policies.

QOS API. The QOS API abstracts away the underlying complexity of the noisy and heterogeneous quantum resources by exposing hardware-agnostic functions for configurable quantum job execution. The API transforms the user's input circuits into Qernels for QOS to apply its mechanisms.

Error mitigator. To increase the fidelity of quantum programs, the error mitigator applies pre- and post-processing error mitigation techniques. However, there exists an abundance of such techniques, and they typically incur high runtime overheads that scale with the amount of error mitigation used. Thus, the error mitigator automatically selects and composes a subset of techniques given budget constraints to limit the associated runtime costs.

Estimator. To make informed scheduling decisions in the landscape of QPU spatiotemporal performance variance, we require accurate fidelity estimations that do not depend on expensive simulations or trial runs. The estimator leverages analytical models to predict the execution fidelity on the underlying QPUs in a scalable manner.

Multi-programmer. There is an inherent tradeoff between QPU utilization (proxy of program size) and fidelity. To increase QPU utilization without significantly compromising fidelity, the multi-programmer spatially multiplexes multiple quantum programs on a single QPU with careful consideration for fidelity performance loss.

Scheduler. There is a fundamental tradeoff between job waiting times and fidelity that arises from the underlying spatial performance variance. The scheduler trades minimal fidelity for significant waiting time improvement by optimizing for this conflicting objective.

Table 1: QOS programming API.

QOS API	Description
`run(circ, cnfgs)`	Run circuit with config. options.
`results(jID)`	Retrieve the job results.
`status(jID)`	Retrieve the job status.
`backends()`	Retrieve the available backends.
`backend_props(bID)`	Retrieve the backend properties.

4.2 QOS Programming Model

We introduce the QOS programming model designed to abstract away the underlying complexity of managing heterogeneous and noisy quantum resources. QOS exposes hardware-agnostic APIs and leverages the Qernel unified abstraction that acts as a common denominator across its components to enable the application of its diverse mechanisms.

QOS APIs. Table 1 shows the QOS APIs that abstract away quantum job execution and resource management. To run a quantum circuit, users simply call `run` with the circuit and configuration options, such as the error mitigation budget, which controls the runtime overheads and thus cost (in $). This function returns a unique job id, *jID*. Users can call `result` and `status` with the returned *jID* to retrieve the execution results and status, respectively. Last, users call `backends` and `backend_props` to retrieve the available QPUs and their properties.

The Qernel abstraction. The Qernel implements data structures that store the static and dynamic properties of the quantum job. Specifically, to apply error mitigation techniques optimally, we must leverage the characteristics of the quantum circuit, such as the circuit's size (number of qubits), depth, number and types of 2-qubit gates, the number of measurements, etc. Additionally, we include the six Supermarq features vectors [76] since they are potentially useful for heuristic-based optimizations or regression-based prediction models [59]. This information is described as the static properties of the Qernel. The dynamic properties include the Qernel's execution status (`done`, `failed`, `running`, `scheduled`), the estimator's output, i.e., fidelity estimations (§ 6), and the final post-processed results.

System workflow. Users submit a large circuit using the QOS API ①. Then, QOS transforms the circuit into a Qernel, the common denominator of QOS, and submits it to the error mitigator ②. This component outputs error-mitigated Qernels and submits them to the estimator ③. The estimator predicts the fidelity of running the Qernel(s) on the QPUs to guide scheduling ④. Next, the multi-programmer bundles Qernels with low utilization and sends them to the scheduler ⑥, who schedules and runs the bundled Qernels, optimizing for maximal fidelity and minimal waiting times ⑥. After the execution, the bundled results are unbundled by the multi-programmer into separate results and are sent to the error mitigator for post-processing ⑧. Finally, the post-processor synthesizes the final results and returns them to the user ⑨.

5 Error Mitigator

Quantum computers are characterized by hardware and environmental noise errors, which hinder their practicality and scalability (§ 3). The error mitigator applies pre- and post-processing to the Qernels and execution results, respectively, to mitigate these noise errors.

Challenges. Currently, there is a plethora of individual error mitigation techniques that require their own sub-systems to operate, with no common infrastructure to compose them. However, composability is essential for fidelity improvement since error mitigation techniques can complement each other, if stacked together in the correct order, to further improve performance [9, 11]. Additionally, some techniques spawn an exponential number of sub-circuits and, after execution, require post-processing using classical resources [44, 55]. There are two main challenges in efficiently leveraging error mitigation: (1) Which error mitigation techniques must be used and in which order? (2) How to balance the tradeoff between fidelity improvement and exponential overheads with respect to runtime and resources?

Key ideas. The error mitigator automatically applies error mitigation techniques, abstracting this complexity away from the user. The key idea is that not all gates and qubits are equal; some of them are noise *hotspots*, lowering the fidelity significantly more than others. We constrain the exponential overheads by (1) setting an error mitigation budget b to be spent, and (2) greedily applying error mitigation techniques on the hotspots in the order that maximizes fidelity improvement with the least added overheads.

5.1 Pre-Processor

The pre-processor first analyzes the Qernel to generate important metadata, identifies the error mitigation opportunities, and then prepares the Qernel for the respective techniques.

Qernel analysis. Qernel analysis generates two main pieces of information that guide the application of error mitigation techniques: (1) Qernel metadata and (2) optimization opportunities such as *hotspot* qubits or gates, i.e., qubits and gates that can be removed to reduce noise errors significantly. Specifically, we generate the key Qernel static properties and the six SupermarQ feature vectors as stated in § 4.2.

Error mitigation techniques. We focus on two existing error mitigation techniques: circuit divide-and-conquer and qubit reuse, since these techniques increase fidelity and enable the execution of large quantum jobs on small(er) QPUs. However, QOS supports any technique that achieves the same goals [10, 15, 43, 75].

At a high level, techniques in the former category divide (large) circuits into smaller fragments that can be executed on small QPUs, and the fragmented execution results are post-processed back to a single value. The advantages are two-fold: (1) We can scale the size of circuits that are

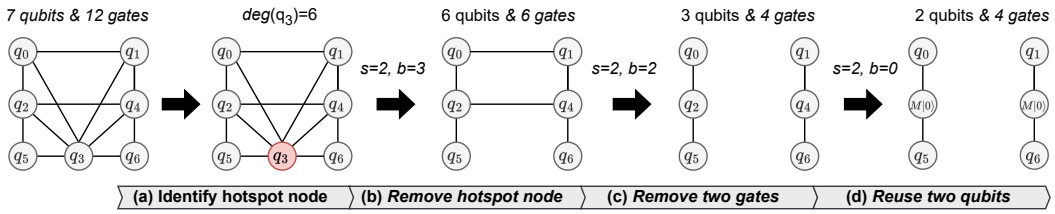

Figure 6: Error mitigator pre-processor workflow (§ 5.1). *The initial Qernel has 7 qubits and 12 gates, and budget $b=3$.* **(a)** *We identify q_3 as a hotspot node with a degree of 6.* **(b)** *We remove this node, which reduces the qubit and gate counts to 6.* **(c)** *We remove two gates, giving two fragments of 3 qubits each.* **(d)** *The budget is depleted, so we use qubit reuse to further reduce the qubits by two.*

executable on the current small QPUs beyond the H/W qubit limit, and (2) we can improve fidelity since smaller and less complex circuits achieve higher fidelity (§ 2.2, § 3.1). Unfortunately, these techniques incur *exponential* quantum and/or classical overheads with respect to the number of divisions; therefore, they must be used conservatively.

More specifically, circuit divide-and-conquer comprises *circuit cutting and knitting* [44, 55] and *qubit freezing* [4]. Circuit cutting can simplify the circuit's structure by virtualizing noisy non-local gates into (less noisy) local gates [44] or cutting a qubit (wire) in the temporal dimension to shorten its runtime [55]. Thus, circuit cutting can improve the circuit's width, depth, and number of non-local gates at once (§ 2.2). During knitting, the original (full) circuit results are reconstructed through classical post-processing of the subcircuit results. We refer interested readers to CutQC [73] and QVM [78] for details on how circuit cutting works in practice. Comparably, qubit freezing identifies qubits with significantly more connections to other qubits (hotspots) and partitions the circuit by replacing the hotspot qubits with binary values, effectively dropping their noisy non-local gates. Since every qubit can be replaced by a binary value, this process generates 2^m smaller circuits for m frozen qubits.

In both cases, we automatically find the cut locations that achieve the smallest sub-circuits possible with the fewest cuts possible. To maximize the synergy between techniques, we first apply qubit freezing to remove multiple non-local gates at once with a relatively small cost, and then we greedily apply circuit cutting. To restrict the exponential overheads that scale exponentially with the number of cuts, we use the budget b to cut up to b times. Typically, we set the budget $b=3$ by default, and the overheads scale as $O(2^b)-O(8^b)$, depending on the divide-and-conquer technique.

On the other hand, qubit reuse (also referred to as recycling) reduces qubit requirements by reusing physical qubits after resetting them [18, 29, 34]. Once a qubit's role in computation is complete, it is measured, reset to a known state (typically $|0\rangle$), and reassigned to another logical qubit later in the circuit. This approach enables more efficient use of limited hardware resources and allows execution of larger circuits than the QPU's qubit limit. This method, however, increases the circuit depth (i.e., execution duration), which can lead to quantum decoherence errors (§ 2.2); therefore, the tradeoff, in this case, is between circuit size and runtime. To restrict the runtime increase, we use qubit reuse as a last resort to render the Qernel executable by at least one QPU in the system (i.e., the optimized Qernel fits at least one QPU's size constraints).

Workflow example. Figure 6 shows the pre-processing workflow for a QAOA circuit (§ 2.1) with 7 qubits and 12 gates. The pre-processor aims to achieve a maximum Qernel size of two qubits with a budget of $b=3$. To achieve this, it takes the following steps:

Step 1: The pre-processor applies analysis to identify a hotspot node; in this case, q_3 is a hotspot with a degree of 6 gates (Figure 6, (a)).

Step 2: Then, the pre-processor removes q_3 and its gates with qubit freezing. The new Qernel size is 6 qubits with 6 gates. Then, it updates the budget to $b=b-m$, where $m=1$ is the number of qubits frozen (Figure 6, (b)).

Step 3: Next, the pre-processor applies circuit cutting on two gates and updates the budget to $b=0$. The new Qernel consists of two fragments, each with a size of 3 qubits and 4 gates (Figure 6, (c)).

Step 4: Since $b=0$, the pre-processor applies qubit reuse to achieve a size of 2 qubits and identifies qubits q_0, q_1 as reusable. Here, $M|0\rangle$ denotes measurement and reset to the $|0\rangle$ state. The final Qernel now has two fragments of 2 qubits and 4 gates (Figure 6, (d)).

The final output is a Qernel with a 42.8% smaller size and 66% less noisy gates. Notably, this result is only attainable through the synergy of techniques, as no individual method alone can achieve comparable improvements.

5.2 Post-Processor

The post-processor reconstructs the final error-mitigated results by classically stitching together intermediate outcomes from sub-Qernel executions. In circuit knitting, each virtualized gate (i.e., cut) is expanded into a linear combination of basis gates with associated coefficients. When multiple such gates are virtualized, the global coefficient vector becomes the tensor product of the individual gate vectors, resulting in an exponentially large space of up to 8^k bitstring-weight pairs for k virtualized gates. The post-processing then requires computing a weighted sum over all 8^k combinations, with each term involving a product of subcircuit results. As such, this

process requires a scalable post-processing infrastructure.

The map phase. To efficiently process the large number of results, we follow a divide-and-conquer approach. Specifically, we split the results into k equal sizes and distribute them to k classical nodes to be processed in parallel. We parallelize across k to increase data locality and reduce communication overheads since all results for each of the k cuts will be in the memory of the same node. Locally, each node performs tensor product ($\otimes$) operations on the probability distributions, which are parallelizable across the node's threads. If available in the node, QOS leverages GPUs or TPUs to accelerate the tensor products. Following this process, the k nodes output k intermediate results, ready to be reduced into a single result.

The reduce phase. QOS selects any of the k nodes to perform the reduce step. The rest of the nodes send the intermediate results to this node, which performs a thread-parallel sum of k results. Equivalent to the map phase, the parallel sum can also be executed on GPUs. This produces the final output to be returned to the user.

6 Estimator

The estimator is responsible for predicting the fidelity performance of a given Qernel on the underlying QPUs without executing the Qernel, which would be extremely costly. This prediction will be the leading decision factor for the scheduler when assigning the Qernel to a QPU.

Challenges. Estimating fidelity a priori faces three key challenges: (1) Fidelity is a non-deterministic metric affected by the hardware's probabilities of errors, which change across QPUs and time unpredictably (§ 3). (2) Simulating a Qernel to obtain fidelity estimates is intractable since the complexity of simulating quantum systems scales exponentially with the number of qubits [22]. (3) Fidelity can be approximated numerically [47]; however, there is an accuracy-cost tradeoff. The more complex the analytical model becomes, the higher the runtime overhead of estimation.

Key idea. The estimator leverages analytical and regression models that do not require real execution or simulation of the Qernel. Specifically, the estimator's models compute a *score* for each Qernel-QPU assignment that captures the potential fidelity of that assignment, and the estimator supports configurable scoring policies with different runtime-cost tradeoffs. These policies consider (1) the Qernels' properties generated from the error mitigator, (2) the QPUs' calibration data (i.e., noise model), which are available to quantum cloud providers since they perform the calibration cycles.

For (1), important properties include the number and types of gates, depth, and the number of measurements (§ 4.2). For (2), recall that QPUs are characterized by calibration data that describe the exact error rates of the QPU for that calibration cycle (§ 2.2), specifically, the individual qubit readout errors, the individual gate errors, and the $T2$ coherence times. In this work, we implement two scoring policies: a numerical approach for fine-grained control over the estimations and a regression model approach for abstracting away the complexity of estimation.

Numerical cost policy. This policy estimates execution fidelity by transpiling the circuit for the target QPU (§ 2.2). Target transpilation enables fine-grained fidelity estimation by producing the mapping between logical and physical qubits and the gate (instruction) schedule. The mapping captures the expected readout and gate errors, while the gate schedule captures the order and exact timing that the gates will be applied on the qubits, which reveals the hardware decoherence and crosstalk errors, as explained in § 2.2. This method has been explored before, and there are multiple variants, but we base our implementation on Mapomatic [47].

To compute the score, we need the following information: (1) The readout/measurement error probabilities that describe the probability of a bit-flip during measurement, (2) the gate error probabilities, (3) the T2 time, which measures for how long a qubit can stay in an excited state (i.e., $|1\rangle$), thus quantifying the decoherence error probability, and (4) the crosstalk error which is measured through crosstalk characterization [45]. With this information, we can multiply the probabilities of the respective sources of errors to get an estimate of the total error/fidelity.

Formally, for each qubit q_i the readout error is $e_{r(i)}$, for each gate g_j the error is $e_{g(j)}$, and the decoherence error is $e_{d(t)} = 1 - e^{-t/T2_i}$, where t is the idle time of the qubit q_i (no gates act on it [14]) and $T2$ is the decoherence time of q_i. The crosstalk error between gates g_k and g_l is $e_{ct(k,l)}$. Putting it all together, the final fidelity score is computed as follows: $fid = 1 - \prod_{i=0}^{N} e_{r(i)} e_{d(i)} \prod_{j=0}^{M} e_{g(j)} \prod_{j=0,k=0}^{M \times M} e_{ct(j,k)}$, where N is the circuit's number of qubits and M is the number of gates. Since all hardware error information is known a priori, and quantum errors accumulate multiplicatively, this policy produces high-accuracy estimations, as we show in § 9.3.

Regression model policy. Since the impact of noise errors on fidelity during quantum computation can be described numerically, we can train a regression model to predict the fidelity of a transpiled Qernel on a possible QPU using the QPU's calibration data and the Qernel's static properties as features. Specifically, we use the aforementioned errors we defined in the numerical cost policy as QPU features and the static properties (§ 4.2) as Qernel features. Even simple regression models such as linear regression achieve high prediction accuracy, up to 99%. Although this policy is simple to use without detailed knowledge of the relationship between errors, in QOS, we use the numerical cost policy by default for estimation to have a clear understanding and full control of the process.

7 Multi-programmer

The size of quantum programs that run with high fidelity is small, leading to QPU underutilization (§ 3.3). To increase QPU utilization, QOS *multi-programs* two or more Qernels, potentially from different users, to run on the same QPU. We refer

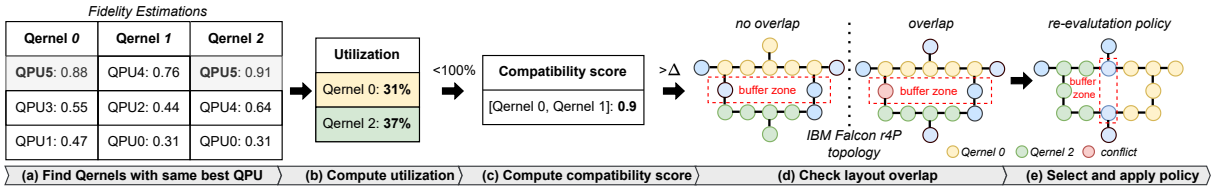

Figure 7: QOS multi-programmer example workflow (§ 7). **(a)** *We use the estimator's output to find Qernels with the same best QPU.* **(b)** *We compute their independent utilization, and* **(c)** *their compatibility score. If compatible,* **(d)** *we check for layout overlap, and* **(e)** *apply the appropriate multi-programming policy.*

to this multi-programming as *bundling* the Qernels together.

Challenges. Bundling Qernels faces three distinct challenges: (1) Trivially bundling Qernels together will deteriorate fidelity because qubits interfere with each other via crosstalk errors (§ 2.2). (2) On top of that, bundled Qernels with unequal runtimes do not optimally increase utilization since *effective* utilization is measured in space and time (number of QPU qubits used and duration that they are non-idle). (3) Qernel compilation involves several NP-hard processes [70], so we need to minimize it.

Key ideas. To tackle these challenges, we introduce new ideas unexplored by prior multi-programming work [16, 40]. First, we define a new utilization metric, namely *effective* utilization, that captures the temporal dimension of utilization, i.e., H/W qubit usage during computation time. Next, we compute Qernel *compatibility functions* that quantify how well-suited any two Qernels are to run together, to minimize fidelity loss and re-compilation times. Last, we create *buffer zones* between two bundled Qernels to minimize crosstalk errors.

7.1 Qernel Compatibility

Qernel compatibility quantifies crosstalk errors and the effective utilization of bundled Qernels by considering the Qernels' static properties (§ 4.2).

Effective utilization. The trivial way to compute utilization in the case of bundled Qernels is by dividing their total number of qubits over the QPU's number of qubits, N_{total}/N_{QPU}. However, this is not accurate when the bundled Qernels have unequal runtimes. In order to accurately quantify QPU usage in the context of multi-programming, we define effective utilization as *spatial* plus *temporal* utilization. To quantify spatial utilization, it suffices to compute the ratio of allocated QPU qubits (of the longest Qernel in terms of depth) over the QPU's number of qubits.

To quantify temporal utilization, we scale the spatial utilization of each allocated Qernel with a weight that is the ratio of the Qernel's duration over the longest Qernel's duration. Recall that, to measure the Qernels' durations, we use the depth property that reflects the longest sequence of gates the Qernel consists of (§ 2.2).

More technically, we define effective utilization as $u_{eff} = \frac{N_{C_{max}}}{N_{QPU}} \cdot 100 + \sum_{k=1}^{n} \frac{D_k}{D_{max}} \cdot \frac{N_{C_k}}{N_{QPU}} \cdot 100$, where $N_{C_{max}}, N_{QPU}$ are the number of qubits of the longest Qernel and the QPU, respectively, k is the number bundled Qernels excluding the longest Qernel, and D is the depth of the Qernel. The first term, $\frac{N_{C_{max}}}{N_{QPU}} * 100$, captures the spatial utilization. The right term (sum) captures the temporal dimension, and $\frac{D_n}{D_{max}}$ is the relative depth of Qernel k compared to the longest Qernel, and $\frac{N_{C_k}}{N_{QPU}}$ is the fraction of QPU qubits used by Qernel k.

For example, a 10-qubit Qernel Q_0 spatially utilizes 50% of a 20-qubit QPU. Now assume that Q_0 runs $3\times$ longer than a 10-qubit Qernel Q_1. During $\frac{2}{3}$ of Q_0's runtime, the qubits allocated to Q_1 will be idle, decreasing the effective utilization to only 66%.

Quantifying crosstalk. To quantify crosstalk without running the bundled Qernels, we use the *entanglement ratio* and *parallelism* Qernel feature vectors of [76], where higher values indicate a higher chance for crosstalk errors (§ 2.2). Intuitively, the entanglement ratio captures the proportion of 2-qubit gates over all gates, and parallelism captures how many gates run in parallel per time unit. Thus, more parallel 2-qubit gates equal a higher chance of crosstalk errors [45].

Compatibility formula. To quantify the compatibility of two candidate Qernels, we consider their effective utilization, as well as their joint entanglement ratio and parallelism scores. This is because we ideally want high effective utilization (not just higher spatial) and fewer crosstalk-induced errors.

Formally, we score a possible Qernel pair as follows: $qc = \alpha\, u_{eff} + \beta\, ER_b + \gamma\, PA_b \mapsto [0,1]$. Higher score is better, $\alpha+\beta+\gamma = 1$ (the weights add up to one), u_{eff} is effective utilization, ER is entanglement ratio, PA is parallelism, and b denotes *bundled*, i.e., E_b is the entanglement ratio of the bundled Qernels. The four variables are tunable to give priorities on different objectives, e.g., prioritize effective utilization or minimize crosstalk. After experimenting and fine-tuning, we found that $\alpha = 0.25, \beta = 0.25, \gamma = 0.5$, and $qc \geq 0.75$ gives balanced results, as we show in § 9.4.

Buffer zone. Crosstalk characterization studies on real machines have shown that the probability of crosstalk errors drops exponentially with the distance between any two qubits [45]. We leverage this to minimize crosstalk errors by creating a *buffer zone* between any two bundled Qernels, i.e., at least one hardware qubit between the two sets of allocated qubits must be free. Given the hardware constraints and limited number of available qubits, we limit the buffer size to up to two qubits of distance.

7.2 Multi-programming Policies

In this work, we implement two multi-programming policies; the first is the *fast path* multi-programming while the second requires re-compilation and re-estimation.

Restrict policy. The restrict policy checks if there is no overlap in the Qernel mappings on the QPU, including the buffer zone. For example, in Figure 7 (d) in the left case, the logical qubits of the Qernels are mapped to disjoint sets of physical qubits on the QPU, and there is a buffer zone between the two sets. In that case, the policy simply bundles the Qernels together, and fidelity loss is minimized through the aforementioned compatibility score.

Re-evaluation policy. This policy is the fallback of the restrict policy. If the Qernel mappings overlap, the two Qernels are transpiled again for the target QPU, and their new fidelity is estimated. If the new fidelity is lower up to a fixed $\varepsilon > 0$ value compared to the original independent fidelities, the bundling is kept. Otherwise, the multi-programmer selects the next most compatible Qernel pair.

Example. Figure 7 shows an example where the multi-programmer receives three Qernels with three estimations each and identifies *Qernel* 0 and *Qernel* 2 as a possible pair since their best QPU is the same (*QPU*5) (a). It computes their independent utilization (31% and 37%, respectively), and the combined utilization is under 100% (b). It computes the compatibility score that surpasses the threshold ($0.9 > 0.75$) (c). In (d), the right case shows an overlap in the buffer zone (the red qubit), so we apply the re-evaluation policy.

Unbundling. To unbundle the results, the multi-programmer keeps a record that maps the initial (solo) Qernel IDs to the new, bundled Qernel ID, as well as the Qernels' sizes. Therefore, when receiving a new result from a Qernel with an ID i, it scans the record to find an entry i, and if found, it splits the probability distribution bitstrings (§ 2.1) into two parts: the left-most and the right-most bits based on the Qernel sizes.

8 Scheduler

Scheduling quantum programs involves fundamental tradeoffs between conflicting objectives; specifically, users ideally want the fidelity of *the best fidelity QPU* and the waiting time of *least busy QPU*.

Challenges. Scheduling quantum tasks faces three key challenges: (1) To maximize fidelity, most programs must be scheduled on the same subset of best-performing QPUs (§ 3.2), forming hotspots and necessarily increasing user waiting times. (2) The scheduler must at least know estimates of the quantum task durations. However, similar to fidelity estimation (§ 6), quantum execution time estimation must be fast, without real execution or simulation. (3) Job scheduling is a well-known NP-hard problem; therefore, every heuristic or greedy solution will present a tradeoff between optimality and performance.

Key ideas. Our scheduler leverages an analytical model to estimate the Qernel execution time quickly. Then, based on the fidelity predictions from the estimator, it assigns and runs Qernels across space (which QPUs) and time (when). Last, our scheduler supports configurable policies for managing the aforementioned tradeoffs, prioritizing maximal fidelity, minimal waiting times, or a balanced approach. Our two main policies are a fast heuristic algorithm, similar to [62], and the first genetic-based multi-objective optimization algorithm.

Execution time estimation. To optimize for minimal waiting times, the scheduler must first estimate each Qernel's execution time and then aggregate the execution time estimations in each QPU's queue to compute the total waiting times. To estimate the execution time, we iterate the longest path (depth) of a Qernel (§ 4.2) that corresponds to the longest-duration gate chain and thus defines the Qernel's execution time. By summing the gate durations of each node in the longest path, we get the Qernel's total execution time.

Formula-based policy. Optimizing for conflicting objectives involves comparing two possible solutions (e.g., maximal fidelity vs. minimal waiting times). In the formula-based policy, we use the following scoring formula to compare and select between two possible assignments: $score = c\frac{f_2 - f_1}{f_1} - (1-c)\frac{t_2 - t_1}{t_1} + \beta\frac{u_2 - u_2}{u_1}$. This formula factors fidelity, waiting time, and utilization to determine which assignment is better, given priorities. The parameters are as follows: f_i: fidelity of the estimation result i, t_i: waiting time for the QPU from estimation result i, u_i: utilization of the QPU for estimation result i, $c \in (0,1)$: a system-defined constant that weighs the fidelity difference between estimations and finally, β: a system-defined constant acting as a weighting factor for utilization difference, balancing system throughput and fidelity. By selecting higher c, the system prioritizes fidelity over waiting times, and vice versa, and by selecting higher β the system prioritizes utilization over fidelity, and vice versa. By default, $c = \beta = 0.5$, which aims for balanced fidelity, waiting times, and utilization. Notably, prior work does not include utilization in the scheduling decisions [62].

Genetic algorithm policy. Genetic algorithms excel at optimizing for conflicting objectives by efficiently searching over vast search spaces, and for that, they can be used in the context of QOS. We formulate a multi-objective optimization problem with the conflicting objectives of fidelity vs. waiting times and use the NSGA-II genetic algorithm [17] to solve it. The algorithm creates a Pareto front of possible solutions (schedules), each achieving a different combination of average fidelity and average waiting times. Then, to select one of those schedules, we use the aforementioned formula to score each schedule and select the schedule with the highest score.

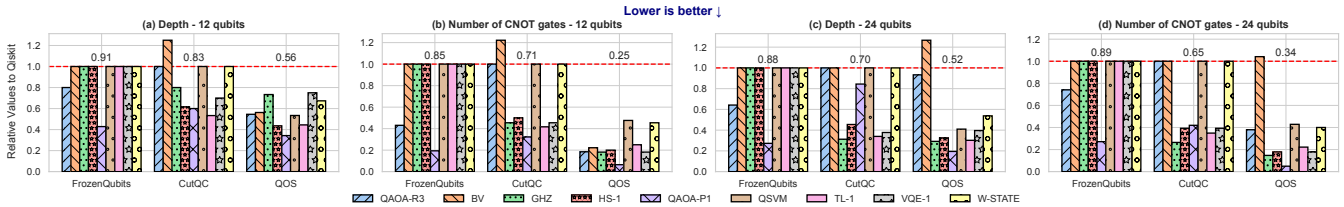

Figure 8: Error mitigator (§ 9.2). *Impact of the error mitigator on the circuit depth and the number of CNOTs. The circuits are optimized using budget $b=3$, and we compare against Qiskit (red horizontal line), FrozenQubits [4] and CutQC [73]. There is an average 46%, 38.6%, and 29.4% reduction in circuit depth, and 70.5%, 66% and 56.6% reduction in the number of CNOTs, respectively.*

9 Evaluation

9.1 Experimental Methodology

Experimental setup. We conduct two types of experiments: (1) classical tasks, such as circuit transpilation and trace-based simulations, and quantum tasks (2), which run on ***real*** QPUs for measuring the circuits' fidelities.

For (1), we use a server with a 64-core AMD EPYC 7713P processor and 512 GB ECC memory. For (2), we conduct our experiments on IBM Falcon r5.11 QPUs. Unless otherwise noted, we use the ***real*** Kolkata 27-qubit QPU hosted by IBM.

Framework and configuration. We use the *Qiskit* [33] Python SDK for compiling quantum circuits and running simulations. We compile quantum circuits with the highest optimization level (3) and run with 8192 shots. Each data point presented in the figures is the median of five runs.

Benchmarks. We study QOS on a set of circuits used in state-of-the-art NISQ algorithms, adopted from the 3 benchmark suits of Supermarq [76], MQT-Bench [60] and QASM-Bench [39]. The algorithms' circuits can be scaled by the number of qubits and depth. Specifically. We study 9 benchmarks: GHZ, W-State, Bernstein Vazirani (BV), Hamiltonian Simulation (HS-t), Quantum-enhanced Support Vector Machine (QSVM), Two Local Ansatz (TL-n), Variational Quantum Eigensolver (VQE-n), and Approximate Optimization Algorithm (QAOA-R/P), these benchmarks cover a wide range of relevant criteria for evaluating QOS.

For the TL and VQE circuits, we use circular and linear entanglement, respectively. The HS, VQE, and TL benchmarks are scalable by their circuit depth with the number of time-steps t and layers in the *ansatz* n. The QAOA-R/P circuits are initialized using regular/power-law graphs, respectively, with degree $d \in \{1,3\}$.

Metrics. We evaluate the following metrics: **(1) Hellinger Fidelity**. As defined in [21], where it ranges in $[0,1]$ and higher is better. **(2) Static Properties**. Number of *CNOT* gates and *depth* (§ 2.2). **(3) Utilization.** The effective QPU utilization (§ 7). **(4) Waiting Time**. The time a Qernel spends in a QPU's queue, waiting for execution, in seconds. **(5) Classical Overhead**. The error mitigation classical overheads as a factor of runtime increase (×). **(6) Quantum Overhead**. The error mitigation quantum overheads as a factor of numbers of circuits increase (×).

Baselines. We evaluate the error mitigator against the standalone fidelity-improving frameworks Qiskit v0.41, CutQC [73] and FrozenQubits [4]. We evaluate QOS's multi-programmer against [16], and we evaluate the synergy between the error mitigator, estimator, and multi-programmer vs. CutQC and [16] as a single baseline. Regarding QOS scheduler, to the best of your knowledge, [62] is the only peer-reviewed quantum scheduler, but it doesn't provide source code or enough technical details to faithfully implement it.

9.2 Error Mitigator

RQ1: *How well does the error mitigator improve the fidelity of circuits that run on NISQ QPUs?* We evaluate the performance of the error mitigator w.r.t the post-mitigation properties and fidelity of the circuits while also analyzing the classical and quantum costs of our approach.

Effect on the circuit depth and number of CNOTs. In Figure 8, we show the performance of the error mitigator on the circuits' depth and number of CNOTs, where we plot the relative difference in post-optimization circuit depth and the number of CNOTs between Qiskit (the red horizontal line) and FrozenQubits [4], CutQC [73], and our error mitigator. Figures 8 (a) and (c) show that the circuit depth decreases by 46%, 38.6%, and 29.4%, respectively. Figures 8 (b) and (d) show that the number of CNOTs decreases by 70.5%, 66%, and 56.6%, respectively. The improvement in both metrics against the baselines is attributed to the composability of our error mitigator, where the combined techniques achieve better results than any standalone technique. In cases where QOS under-performs compared to the baselines (e.g., BV benchmark for 24 qubits), it is because the error mitigator achieved the desired circuit size with the qubit reuse technique, which incurs additional costs (§5.1).

Impact on fidelity. Figure 9 shows the error-mitigated circuits' fidelity against Qiskit [58], CutQC [73], and FrozenQubits [4]. The results show a mean 2.6×, 1.6×, and 1.11× improvement for 12-qubit circuits, respectively, and a 456.5×, 7.6×, and 1.67× improvement for circuits of 24 qubits, respectively. The fidelity improvement is a consequence of lower circuit depths and fewer CNOTs, as shown in Figure 8.

Classical and quantum overheads. Figure 10 (a) shows the average classical and quantum overheads of the error

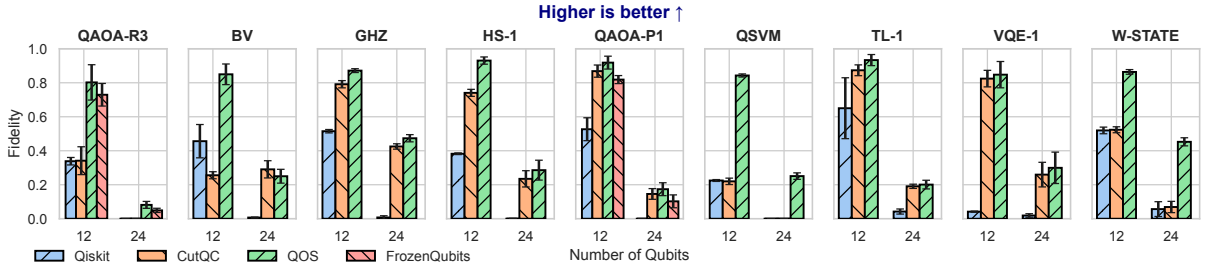

Figure 9: Error mitigator (§ 9.2). *Impact of the error mitigator on the circuit fidelity against Qiskit [58], CutQC [73], and FrozenQubits [4]. The circuits are optimized using budget $b=3$. There is a mean $2.6\times$, $1.6\times$, and $1.11\times$ improvement for 12-qubit circuits, respectively. There is a $456.5\times$, $7.6\times$, and $1.67\times$ improvement for circuits of 24 qubits, respectively.*

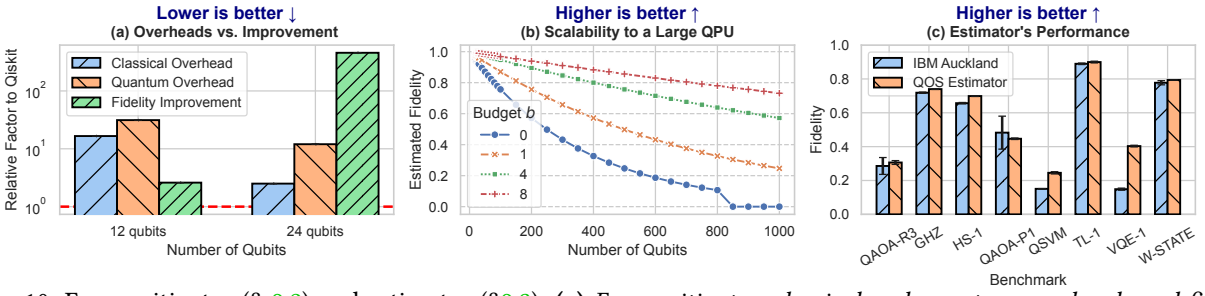

Figure 10: Error mitigator (§ 9.2) and estimator (§9.3). **(a)** *Error mitigator: classical and quantum overheads and fidelity improvement as a relative factor to Qiskit. For 24 qubits, the improvement outweighs the overheads.* **(b)** *Error mitigator: scalability to a large, hypothetical 1000-qubit QPU. Any budget $b>0$ achieves higher quality results than using no optimizations.* **(c)** *Estimator's performance: fidelity of IBM Auckland vs. the QPU automatically selected by the estimator.*

mitigator. The classical overhead is $16.6\times$ and $2.5\times$ for 12 and 24 qubits, respectively, and the quantum overhead is $31.3\times$ and $12\times$ for 12 and 24 qubits, respectively. However, fidelity improves by $2.6\times$ and $456.5\times$ for 12 and 24 qubits, respectively; therefore, for larger circuits, the fidelity improvement is worth the cost.

Scalability. To demonstrate that the error mitigator is scalable, we run the VQE-1 benchmark on a hypothetical 1000-qubit QPU with one-qubit gate errors of 10^{-4}, two-qubit gate errors of 10^{-3}, and measurement errors of 10^{-2}. We optimize with budget $b\in\{0,1,4,8\}$ and report the estimated fidelity. Figure 10 (b) shows that all budget b values improve the estimated fidelity, where higher b equals higher fidelity.

RQ1 takeaway. The error mitigator improves the properties of quantum circuits by 51% on average, leading to an improvement in fidelity of 2.6–$456.5\times$, while incurring justifiable classical and quantum overheads.

9.3 Estimator

RQ2: *How well does QOS's estimator address spatial and temporal heterogeneities?* We evaluate the estimator's precision in selecting the top-performing QPU for each benchmark. We establish a baseline using the on-average best-performing machine every calibration day. On the day of the experiment, IBM Auckland was the best-performing machine (also with the highest number of pending jobs).

Estimator's accuracy. Figure 10 (c) shows the fidelity of the eight benchmarks when run on QPUs selected by the estimator versus when run on the IBM Auckland QPU. The QPU selected for the BV benchmark is Auckland; therefore, we omit this result. For the rest of the benchmarks, the IBM Sherbrooke and Brisbane QPUs were automatically selected. Interestingly, the fidelity is on par or even higher than IBM Auckland, except for only one benchmark, the QAOA-P1, possibly because of its unique, power-law connectivity structure.

RQ2 takeaway. QOS's estimator automatically identifies QPUs with higher fidelity than the current standard practice.

9.4 Multi-programmer

RQ3: *How well does QOS's multi-programmer increase QPU utilization with minimum fidelity penalties?* We evaluate the impact of the multi-programmer on the fidelity of co-scheduled circuits for certain utilization thresholds.

Utilization vs. fidelity. Figure 11 (a) shows the average fidelity of nine benchmarks with utilization of 30%, 60%, and 88%. The three bars represent: no multi-programming *(No M/P)* refers to large circuits that run solo, baseline multi-programming *(Baseline M/P)* refers to [16], and QOS's multi-programming approach *(QOS M/P)*. There is an average $9.6\times$ improvement in fidelity compared to solo execution and an average 15% ($1.15\times$) improvement compared to the baseline.

Effective utilization. The results in Figure 11 (b) show that QOS achieves, on average, a 7.2% higher effective utilization (§ 7), with a maximum improvement of 10.1%. We attribute

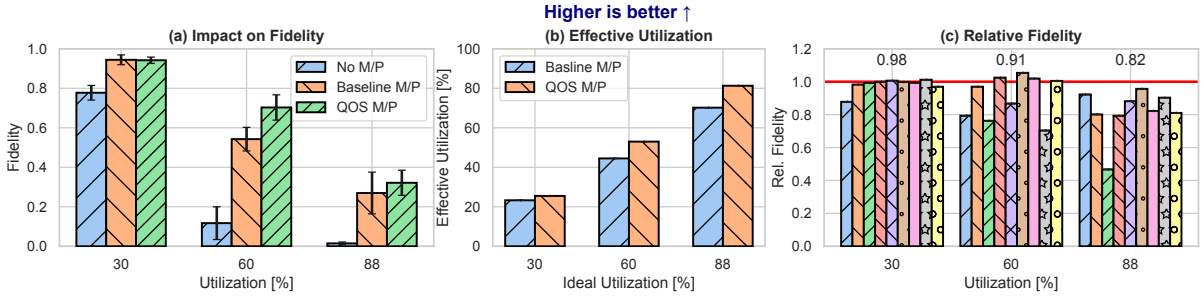

Figure 11: Multi-programmer (§ 9.4). **(a)** *Impact of multi-programming on fidelity. There is a 9.6× and 1.15× improvement compared to no multi-programming and the baseline, respectively.* **(b)** *Effective utilization. There is 7.2% higher effective utilization on average.* **(c)** *Relative fidelity w.r.t. solo circuit execution. There is an average 9.6% drop in fidelity due to QOS's multi-programming.*

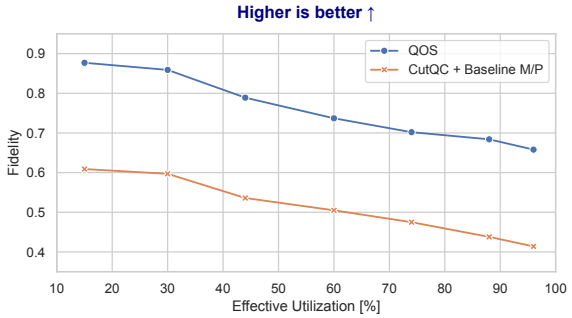

Figure 12: QOS error mitigator, estimator, and multi-programmer vs. CutQC [73] and the baseline multi-programming framework [16]. *QOS achieves* 48% *higher fidelity for the same utilization, on average.*

this improvement to the inclusion of temporal utilization.

Fidelity penalty vs. solo execution. In Figure 11 (c), we evaluate the fidelity penalty of multiprogramming vs. solo circuit execution for utilization of 30%, 60%, and 88%. The fidelity loss is 2%, 9%, and 18%, respectively. The average fidelity loss is 9.6% compared to solo execution, which is in line with previous studies [16, 40]. In the worst case (18%), the fidelity loss is caused by the restrictions in high-quality qubit allocations and the crosstalk errors.

RQ3 takeaway. The QOS multi-programmer improves fidelity by 1.15–9.6× and effective utilization by 7.2% compared to the baselines while incurring an acceptable fidelity penalty ($<10\%$) compared to solo execution.

9.5 QOS vs. Combined Baseline

RQ4: *What is the performance of the within- and cross-layer optimizations of QOS's error mitigator, estimator, and multi-programmer?* We evaluate the impact of QOS's components (without the scheduler) on the fidelity and utilization of the co-scheduled circuits for certain utilization thresholds.

Figure 12 shows the fidelity performance of QOS vs. CutQC [73] and the baseline multi-programming [16]. Here, we use a 27-qubit QPU, and a workload of all nine evaluation benchmarks with initial circuit sizes of 8-, 16-, and 24-qubits. We configure the error mitigator and CutQC to achieve a circuit size half of the original (i.e., 4, 8, and 12-qubit circuits). QOS achieves 48% higher fidelity than the baselines for the same utilization, on average. There are two main reasons for this: (1) the QOS components perform better individually as previously shown (§ 9.2, § 9.4) and (2) the synergy between the QOS components enables better (w.r.t. fidelity) co-scheduling decisions compared to standalone systems [16].

9.6 Scheduler

RQ5: *How well does QOS's scheduler balance fidelity vs. waiting times and balance the load across QPUs?* We evaluate our scheduler by generating a representative workload consisting of a dataset we collected during the development of QOS.

Dataset collection. During our exploration of the motivational challenges (§ 3) and experimentation and evaluation of the QOS components and their policies, we collected a dataset of 70.000 benchmark circuits and more than 7000 job runs in the quantum cloud. We use this dataset to simulate representative workloads, as we detail next.

Workload generation. To generate realistic workloads, we monitored all available QPUs on the IBM Quantum Cloud [32] for ten days in November 2023 to estimate the hourly job arrival rate. The average hourly rate is 1500 jobs per hour and is the baseline system workload for our evaluation.

Fidelity vs. waiting time. Figure 13 (a) shows the performance of the formula-based scheduling policy. We show the average fidelity and waiting time as the fidelity weight, c, changes (§ 8). A weight of 0.7 achieves $\sim$5× lower waiting times than full priority of fidelity while sacrificing only $\sim$2% fidelity. Figure 13 (b) shows the Pareto front of scheduling solutions generated by the genetic algorithm policy. A weight $c=0.5$ achieves 2× lower waiting times with 4% lower fidelity.

QPU load balancing. Figure 13 (c) shows the QPU load as the total runtime each QPU was active, in seconds, for the formula-based policy. All QPUs handle similar loads, with a maximum difference of 15.2%.

RQ5 takeaway. QOS scheduler balances the trade-off between waiting times and fidelity by reducing them 5× and only 2%, respectively while balancing the load across QPUs.

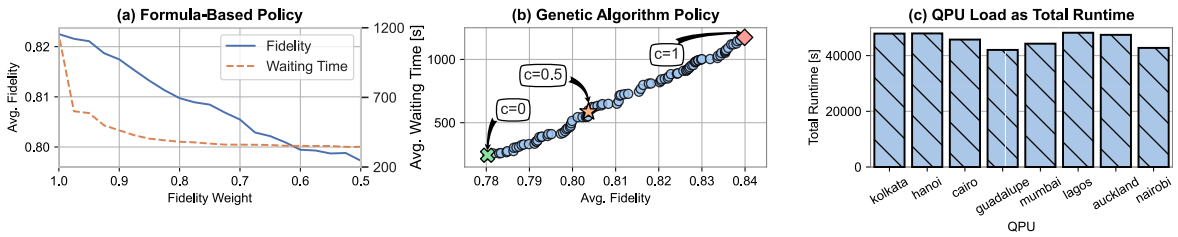

Figure 13: Scheduler (§ 9.6). **(a)** *Formula-based scheduling policy: Average fidelity vs. average waiting times. A fidelity weight* $c = 0.7$ *achieves* $\sim 5\times$ *lower waiting time for only* $\sim 2\%$ *lower fidelity.* **(b)** *Genetic algorithm policy: it creates a Pareto front of schedules, where a fidelity weight* $c = 0.5$ *achieves* $2\times$ *lower waiting times for* $\sim 4\%$ *fidelity decrease.* **(c)** QPU load as the total runtime of each QPU for the formula-based policy. The maximum load difference between any two QPUs is 15.2%.

10 Related work

Quantum error mitigation. Error mitigation techniques can be categorized as (1) execution pre- and post-processing [13–15, 42, 51–54, 71, 74, 75], (2) circuit divide-and-conquer [4, 6, 54, 73], and (3) qubit reuse [8, 29, 34, 48, 48, 49]. Unfortunately, all these techniques are implemented standalone without any infrastructure to compose them. Instead, QOS integrates and composes at least one technique per category in a single software stack, achieving higher fidelity and abstracting away the complexity from the programmer.

Quantum performance estimation. Prior work on quantum performance estimation has focused on resource estimation—predicting required physical qubits under fixed fidelity assumptions [7, 59]—and fidelity estimation using analytical models [47]. In contrast, QOS estimates fidelity under hardware constraints and supports both analytical and ML-based approaches.

Quantum multi-programming. Quantum multi-programming work [16, 40] focuses solely on mapping *two* circuits on a single QPU while providing similar fidelity to both (allocation fairness). However, they lack a systematic strategy for selecting compatible jobs to co-locate, and do not consider temporal utilization. Furthermore, neither work supports buffer zones to reduce crosstalk noise between co-located circuits. The delayed instruction scheduling optimization proposed by [16] is already available in the Qiskit transpiler via the ALAP scheduling pass [58], and thus is inherently used by QOS. Finally, [40] introduces a cross-program SWAP optimization technique, which tightly couples its multi-programming and scheduling logic; this makes it incompatible with any separate, system-level scheduler like QOS's, as relocating the bundled circuits to another QPU invalidates its core optimization technique.

Quantum job scheduling. Current quantum scheduling methods [62, 64, 72, 81] are limited because they (1) only perform single-to-many scheduling, (2) do not account for QPU utilization, (3) lack fine control over the fundamental design tradeoffs (§ 3.4), or (4) require manual input for final scheduling decisions. In contrast, QOS multiplexes circuits across space and time in a many-to-many fashion, increases QPU utilization, balances the inherent tradeoffs of quantum, and abstracts away the underlying resource management.

Cloud OSes, resource management, and job scheduling. Classical cloud operating, resource management, and job scheduling systems have been extensively researched in the past decades [28, 36, 37, 46, 56, 66, 67, 79, 80, 83, 84]. However, the classical domain, even when addressing accelerator heterogeneity, does not face the unique challenges of quantum computing (§ 3) and, as such, cannot be trivially adapted to accommodate its needs.

11 Conclusion and Discussion

We presented QOS, the first quantum operating system to (1) holistically address quantum computing challenges through a modular, policy-mechanism-separated architecture, (2) enable cross- and intra-layer optimizations via end-to-end co-design, (3) systematically explore key tradeoffs between fidelity, utilization, and waiting times, and (4) introduce novel abstractions and techniques across the stack, including the Qernel, composable error mitigation, compatibility-based multi-programming, and multi-objective scheduling.

QOS establishes foundational principles for quantum operating systems that remain relevant as QPU technology evolves. While hardware will improve, core challenges like noise, heterogeneity, and resource scarcity will persist, requiring tradeoffs between fidelity, utilization, and latency. These principles naturally extend to fault-tolerant quantum computing, where QOS's fidelity-aware scheduler and compatibility-based multi-programmer can guide logical qubit placement and error-corrected resource allocation.

Abstract

The rapid growth of data-intensive applications has created a demand for high-density storage systems. Data-Processing-Unit-based (DPU-based) Just a Bunch of Flash (JBOF) solutions provide an energy-efficient and cost-effective architecture to meet this need. However, existing JBOF solutions struggle with scalability when handling an increasing number of attached SSDs, due to their heavy reliance on the DPU's CPU for SSD I/O operations.

In this paper, we introduce Scalio, a scalable disaggregated key-value store designed to address the limitations of current DPU-based JBOF systems. Scalio offloads as many SSD I/O operations as possible to the DPU's network I/O capabilities, including traditional RDMA verbs and a recent hardware optimization, NVMe over Fabrics Target Offload. Additionally, Scalio incorporates a two-layer design with compact in-memory data structures to handle hot read traffic and manage bursty writes. One of the key challenges in this design is ensuring consistency between the DRAM states in the DPU and the SSD states, which, unlike CPU L1/L2 caches, are not automatically synchronized through hardware cache coherence protocols. To address this, Scalio introduces an RDMA-based cache consistency protocol that guarantees linearizability across the system, despite the disaggregated nature of the architecture.

Our experiments show that Scalio significantly improves both scalability and throughput, achieving up to 3.3× higher throughput compared to existing systems, especially in high-density SSD configurations.

1 Introduction

1.1 Motivation

The demand for high-density storage solutions has rapidly increased with the growth of data-intensive applications [8, 21, 27, 30, 36]. To address this need, Data-Processing-Unit-based (DPU-based) Just a Bunch of Flash (JBOF) storage systems (Figure 1) have emerged as cost-effective and energy-efficient solutions, drawing significant attention from both academia [12, 13, 15, 16, 23, 24, 35, 55, 56, 62] and industry [6, 33, 34, 38, 39, 42, 43]. As they are designed specifically for network and storage acceleration, DPUs typically consume far less power and cost compared to traditional storage servers [4, 5, 48]. For instance, even high-end DPUs like NVIDIA's BlueField-3 use only 75–150 watts [44], significantly less than a typical Xeon CPU, which consumes 300–500 watts [19].

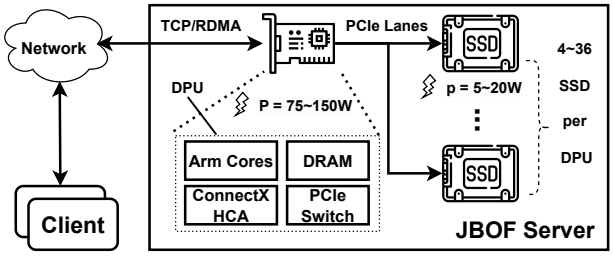

Figure 1: DPU-based JBOF systems' architecture [6, 33].

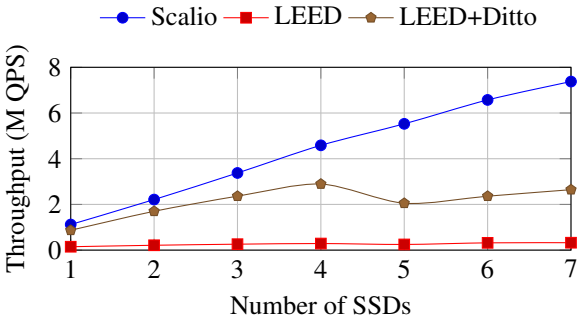

Figure 2: The throughput of Scalio with different number of SSDs attached to each DPU under YCSB [11] workload C. Scalio is compared to: 1) SOTA JBOF SSD key-value store LEED [16]; and 2) LEED combined with SOTA disaggregated DRAM key-value store Ditto [52] as its in-memory cache.

To maximize these benefits, increasing storage density by connecting more SSDs per DPU is a promising strategy. Theoretically, if each SSD offers a throughput of t and consumes power p (typically 5–20W [47, 63]), and the control plane (mainly the DPU) consumes power P, then with n SSDs, the throughput per watt is $\frac{nt}{P+np}$. Since P is typically more than ten times larger than p, the potential maximum throughput per watt increases sharply as the number of SSDs per DPU grows. This vision is further reinforced by the recent emergence of

[1]Equal contribution
[2]Corresponding authors: zhang_mingxing@mail.tsinghua.edu.cn, wuyw@tsinghua.edu.cn

DPU-based JBOF servers from vendors like SuperMicro [33] (a 36-SSD JBOF) and AIC [1, 51] (a 26-SSD JBOF), indicating an urgent need for optimizations targeting scenario of high-density storage with energy-efficient cores.

However, current software stacks struggle to **scale up** effectively with higher SSD counts in JBOF systems. This issue is particularly evident in small key-value workloads, which are common in latency- and throughput-critical applications like social networks and e-commerce. Serving these scenarios with high-density JBOF platforms should ideally saturate the aggregated IOPS of the large bunch of SSDs, providing high throughput with low latency while being cost- and energy-efficient. Yet, as shown in Figure 2, the throughput of existing disaggregated JBOF key-value store systems like LEED [16] plateaus when more than four SSDs are connected per DPU, highlighting the need for optimization of small key-value workloads to fully exploit the storage potential of JBOF systems. Moreover, this focus aligns with the increasing demand for low-latency, small operations in cloud-native applications, which dominate modern distributed storage needs [3, 9, 11, 32, 53, 59]. By optimizing for small key-value workloads, Scalio not only enhances performance but also improves scalability in high-density, energy-efficient storage systems.

1.2 Our Contributions

Our analysis attributes the above scale-up limitation of JBOF key-value stores to its heavy reliance on the DPU's CPU for SSD I/O operations, which derives from the micro-benchmark results in § 2.1. While the small ARM cores in DPUs offer energy efficiency, they lack the processing power to handle the combined IOPS of multiple SSDs, making the DPU's CPU a critical bottleneck in high-density configurations [12, 25].

Interestingly, unlike the constrained CPU resources, we observe that network resources are largely underutilized in these IOPS-bound scenarios. Across all our experimental settings, less than 1% of the maximum network IOPS is utilized, which exists because there is a three-order-of-magnitude gap between the performance of SSD I/O operations and the DPU's RDMA read/write capabilities [18, 45].

Based on this observation, we aim to offload as many SSD I/O operations as possible to the network. We leverage a technique called NVMe over Fabrics (NVMe-oF) Target Offload, which implements the NVMe-oF standard directly on the server-side DPU's Host Channel Adapter (HCA) [14, 28, 58]. With this approach, clients can send NVMe commands directly to server-side SSDs over network, utilizing the network IOPS resources without burdening the DPU's CPU. The DPU's HCA processes all regular I/O requests using hardware logic, communicating directly with NVMe PCI devices via peer-to-peer PCI communications [40, 41]. As illustrated in Figure 3, this setup effectively bypasses the DPU's CPU. More details will be provided in §2.2.

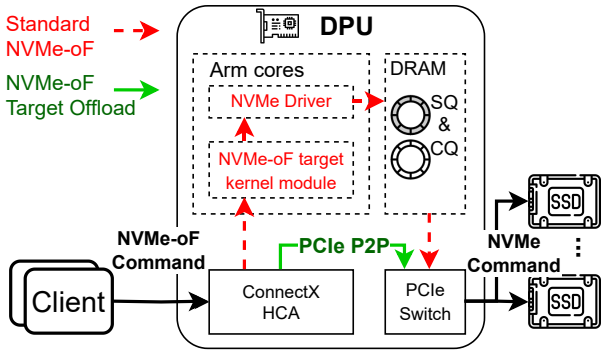

Figure 3: The data flow of the standard NVMe-oF and NVMe-oF Target Offload technology.

Moreover, our further experiments reveal that even when all SSD read operations are offloaded via NVMe-oF target offload, the DPU's CPU can still become a bottleneck in write-intensive workloads. This is primarily because CPU resources are heavily consumed by in-memory concurrency control mechanisms and handling random SSD writes. To overcome this challenge, we develop a **two-layer design** that employs succinct data structures residing in the DPU's DRAM. This design absorbs recent hot reads through offloaded RDMA reads and manages bursty writes via buffered group commits (§4.2). The in-memory data structure is shared between the DPU's CPU and clients' remote RDMA operations, allowing part of its maintenance overhead to be offloaded to clients.

However, while RDMA and NVMe-oF target offload reduce CPU burden by bypassing it, they introduce new consistency challenges. In a disaggregated architecture, clients operate independently without direct interconnection or synchronization. When read/write logic is partially or fully offloaded to clients' remote operations, concurrent accesses from multiple clients can corrupt data if there are no proper mechanisms to control access to shared resources.

The crux of the problem is that, unlike L1/L2 caches in CPUs, which are automatically maintained via hardware cache coherence protocols [20], **the DRAM states (e.g., indexes and caches for hot key-value pairs) residing in the DPU are not automatically consistent with the SSD states**. With NVMe-oF target offload, clients read data directly from the SSD, bypassing the DPU's CPU and DRAM. This necessitates explicit cache invalidation mechanisms initiated by remote clients. Without proper handling, this can lead to cache consistency issues that violate linearizability guarantees [46]. In § 5, we delve deeper into this problem and introduce our RDMA-driven cache consistency protocol.

This protocol effectively manages the flushing of buffered data and cache invalidations to maintain consistency and ensure linearizability. It also carefully partitions the roles between clients' offloaded operations and the DPU's server-

side operations, allowing us to reduce the excessive use of heavy RDMA Compare-and-Swap (CAS) operations for synchronization. This is crucial for performance as studies [7,10,22,31,57,61] have shown that the maximum IOPS of RDMA CAS is ten times less than that of RDMA read/write.

In this paper, we propose Scalio, the first disaggregated key-value store leveraging NVMe-oF target offload to achieve scalability in the DPU-based JBOF architecture. We evaluated Scalio against two baseline systems—LEED [16] and LEED with Ditto [52] as the in-memory cache—using YCSB [11] workloads A, B, C, D, and F. Through experiments varying the number of SSDs from 1 to 7, we demonstrated Scalio's scalability and verified its performance improvements. These improvements are a result of several key mechanisms: in-memory caching, offloaded reads, and batched writes, which reduce CPU usage and optimize SSD IOPS utilization. Sensitivity analysis further confirmed that Scalio's performance is robust to changes in key parameters. Our experiments show that Scalio achieves a 1.8× to 3.3× speedup over LEED with Ditto, and 2.5× to 17× over LEED, highlighting the solid performance improvements of Scalio.

2 Background and Motivation

2.1 JBOF based Key-value Store

DPU-based Just a Bunch of Flash (JBOF) architectures represent a promising evolution in storage systems, offering significant advantages in energy efficiency compared to traditional CPU-based storage servers [12, 16, 35, 55, 62]. Typically, a JBOF system combines multiple NVMe SSDs with one or two Data Processing Unit (DPU) into a compact 1U/2U high-density chassis [6, 33]. Rather than relying on the general-purpose CPUs and NICs of conventional systems, The DPU consolidates networking, data acceleration, and storage processing into a single, specialized ASIC (Application-Specific Integrated Circuit), providing both high performance and reduced energy consumption [5].

The energy efficiency and high-density storage capabilities of JBOF architecture make it an ideal platform for key-value storage systems, especially in environments requiring high performance and energy savings [27, 62]. As an illustration, LEED [16] is a key-value store specialized for the JBOF platform. It uses a log-based data structure on the SSDs for reducing random I/O and a small, hash-based index structure in memory for indexing. According to its experiements with one 8-core Broadcom Stingray PS1100R SmartNIC [5] and four Samsung DCT983 SSDs [50], LEED achieves near-full saturation of the SSD I/O capabilities.

However, we observed that CPU resourses remain a primary bottleneck in LEED. It allocates one core for control-plane tasks, three cores for RDMA requests, and four cores (i.e., one dedicated core for every SSD) to handle SSD I/O operations, **which inherently limits the scalability of LEED**.

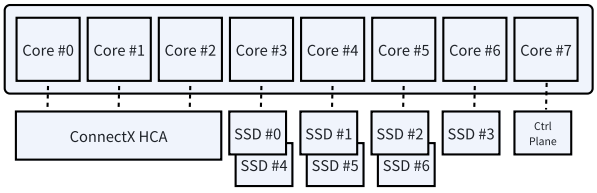

Figure 4: CPU allocation of the testbed.

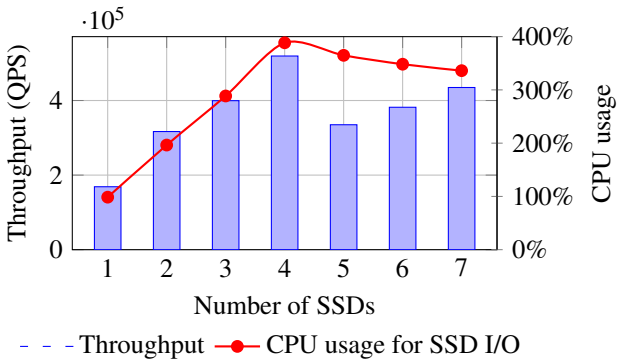

Figure 5: LEED's throughput and CPU usage for handling SSD I/O operations as the number of SSDs scale up.

In order to evaluate the system as the number of SSDs increases, we augment the SSD binding strategy by allocating the SSDs to the CPU cores in a round-robin approach, as in Figure 4. We vary the number of SSDs from 1 to 7, and plot the system throughput along with the CPU usage in handling SSD I/Os in YCSB C workload that exhibits a uniform request distribution, as in Figure 5.

As can be seen from the experiment result, the system throughput reaches a maximum when using 4 SSDs, whereas the CPU usage also approaches the limit (400% for handling SSD I/O in LEED's configuration)[1]. As the number of SSDs increases, the CPU usage gets saturated, causing the throughput unable to scale up.

Interestingly, we also measured LEED's network I/O utilization, and the results show that LEED's network I/O utilization remains less than 1%. In our tests, LEED achieved no more than 600K IOPS over the network, while the Mellanox ConnectX-6 Host Channel Adapter it uses is capable of handling up to 200M IOPS [45]. This underutilization of network I/O capabilities offers an opportunity for achieving better performance in a high-density setup, by offloading calculation from the DPU's CPU to the HCA and releasing burden on the DPU's CPU.

[1]We use perf to quantify the CPU usage of LEED in handling SSD I/Os, which derives from calling spdk_bdev_*, kv_* (functions of LEED kv store) and their corresponding callback functions.

2.2 NVMe over Fabrics Target Offload

NVMe over Fabrics (NVMe-oF) [12, 17, 37] extends the Non-Volatile Memory Express (NVMe) standard, which was originally designed for fast storage access over PCIe, to networked environments. It enables high-speed data transfer between host and remote NVMe devices across data center networks.

In standard CPU-based NVMe-oF implementations, the host system encapsulates NVMe commands into NVMe-oF requests and sends them over the network to the target storage device. The target server's CPU handles these requests through a kernel module or a userspace target process (typically implemented via SPDK [60]). These modules transform the incoming requests into block I/O structures, issues operations to the NVMe device, and replies to the client. Processing these I/O requests consumes significant CPU cycles on the target, especially when the IOPS is high.

With the increasing adoption of NVMe-oF in data centers, modern DPUs have introduced a specialized hardware optimization called NVMe-oF Target Offload [14, 28, 58]. As illustrated in Figure 3, this implementation delegates the handling of NVMe operations and SSD commands entirely to the Host Channel Adapter (HCA) hardware via PCIe P2P commands. By offloading these tasks, the CPU usage on the target side is minimized. This allows the system to scale more effectively, handling higher IOPS with lower latency without being limited by the CPU's processing power.

To demonstrate the benefits of NVMe-oF target offload, we conducted performance measurements comparing standard NVMe-oF and NVMe-oF target offload implementations. Using `fio` we measured the maximum read IOPS of both implementations as the number of SSDs increased. The results are presented in Figure 6.

Our experiments show that NVMe-oF target offload achieves similar IOPS performance to standard NVMe-oF implementations. In addition, NVMe-oF target offload offers great CPU savings. Compared with the standard NVMe-oF implementation that consumes 562% target CPU, the target offload implementation consumes 0 target CPU resource. Therefore, NVMe-oF target offload offers significant advantages for implementing scalable disaggregated storage systems. However, adopting NVMe-oF target offload requires careful coordination between the host and target to maintain data consistency and ensure efficient communication.

3 Overview

In our analysis of existing DPU-based JBOF disaggregated key-value stores, we identified excessive CPU consumption on the DPU as a key scalability limitation. To overcome this challenge, we redesigned the in-memory data structures and optimized the read and write workflows. Our approach aims to offload as many I/O operations as possible to clients through one-sided RDMA/NVMe-oF network operations while ensuring linearizability and consistency are maintained. Figure 7 compares the workflow of the current state-of-the-art system LEED with the workflow of our proposed solution.

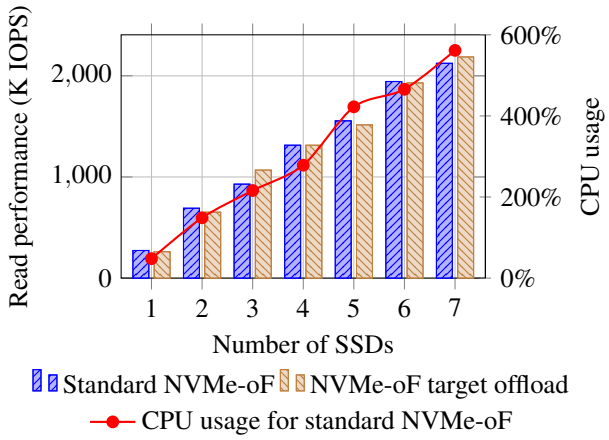

Figure 6: The read IOPS performance of the standard NVMe-oF implementation and the NVMe-oF target offload implementation under fio tests, along with the CPU usage of the standard NVMe-oF implementation as the number of SSDs scale up. The CPU usage of the NVMe-oF target offload implementation is zero.

3.1 Read Workflow

Existing systems, like LEED, rely on two-sided RDMA-based RPC calls for both read and write operations. In these systems, the DPU handles all queries and updates to the in-memory index along with data reads and writes from the SSD, resulting in high CPU usage on the DPU.

In contrast, Scalio, as shown in Figure 7 (b), introduce a multi-layer in-memory structure that integrates the SSD index with an in-memory cache. This allows direct RDMA-based queries and updates. When a client requests a key, the operation proceeds in two phases:

1. In-Memory Query Phase (Steps 1-3): The client uses RDMA read operations to fetch the hash block matching the hash value of the queried key. Each hash block contains multiple slots to hold several key-value pairs and a linear search is performed by the client to find the desired key. If the key is found in the block (cache hit), the value is returned immediately. Otherwise, a victim slot will be determined based on the oldest last_ts (modified in the background by clients finishing cache operations), and the client will evict the outdated data and lock the slot with an RDMA CAS operation on the complete field. Validation with a double-read is required during the process of locking in order to ensure atomicity, which will be further explained in § 5.2.

2. SSD Access and Cache Update Phase (Steps 4-5): If the key is not found in the cache (cache miss), the in-memory

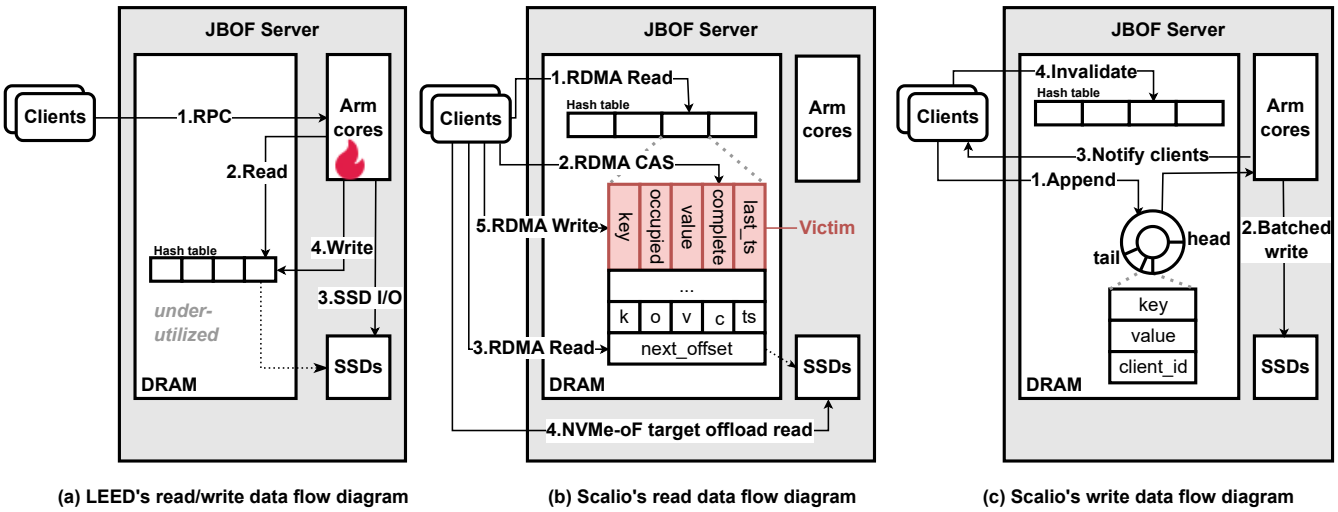

Figure 7: The workflows comparision between LEED's and Scalio.

structure provides the SSD location with the next_offset field. The client then performs a one-sided NVMe-oF target offload operation to read the data from the SSD. After retrieving the data, the same client updates the victim slot with RDMA write operations and frees the lock.

All of these operations fully utilize the network I/O capabilities with one-sided network primitives and hence bypass the DPU's CPU. To implement this workflow both efficiently and correctly, we face two main challenges that will be addressed in subsequent sections. First, we observe that RDMA network bandwidth remains under-utilized, particularly with small key-value pair workloads. To optimize this, we configure the capacity of each hash block to a larger value, accommodating more key-value pairs with the same key hash without compromising the network IOPS. Second, to handle concurrent updates to the in-memory structure by multiple clients and the DPU's CPU, we introduce two additional flags (occupied and complete) for each in-memory item and a cache consistency protocol to maintain linearizability (discussed in §5).

3.2 Write Workflow

Unlike the read workflow, which is entirely one-sided, the write workflow of Scalio involves both RDMA operations and processing by the DPU's CPU. In the original LEED implementation, each write involves two SSD write operations performed by the DPU's CPU, creating a bottleneck in write-heavy workloads. To address this, we implement a server-side batching method that enables group commits, reducing the number of SSD writes. The process involves:

1. Appending Request Data (Step 1): Clients append their write requests to an in-memory ring buffer on the DPU using RDMA operations.

2. Batched Writing (Step 2): The DPU's CPU continuously polls the ring buffer, flushes the write requests to the SSDs in batches and updates the next_offset field.

3. Client Notification (Step 3): After the updates are written to the SSDs and the new offsets are updated in-memory, the DPU's CPU notifies the clients of the successful write.

4. Cache Invalidation (Step 4): Clients invalidate outdated cache entries using RDMA write operations.

During the buffering period, the client's write operation is held until the DPU's CPU processes the batch, updates the next_offset and sends a notification. The write is considered committed when the corresponding next_offset field is updated and any oudated item is invalidated from the cache. More details are provided in §4.2.

By incorporating these optimizations, we reduce the CPU load on the DPU and enable the system to scale effectively as the number of SSDs increases. Our approach addresses the scalability bottlenecks of current systems, fully leveraging the capabilities of DPU-based JBOF architectures.

4 Scalio Implementation

In this section, we present the implementation details of Scalio, focusing on its mechanisms for efficient query and update operations. Scalio's design centers around two key aspects: (1) an in-memory index shared between the DPU and clients, which serves as cache and provides a consistent and synchronized view of system data; and (2) a batched write mechanism, leveraging group commits to improve write throughput while handling bursty workloads.

4.1 Index Structure

The index structure of Scalio includes an RDMA-accessible hash table for caching frequently accessed key-value pairs.

This design minimizes the need for DPU's CPU involvement by enabling clients to interact directly with the cache.

The hash table hashes keys to consecutively addressed blocks, each containing multiple slots for storing key-value pairs, as shown in Figure 7 (b). Given Scalio's focus on small key-value pairs, both the key and value are stored inline within each slot. Our prior observations suggest that network I/O capabilities have significant headroom for further utilization, allowing us to increase block size without saturating the network. Based on sensitivity analysis in § 6.5, we found that block sizes up to 1KB can be used without overloading the network bandwidth. This size is sufficient to cache small key-value pairs, with each block holding up to 10 key-value pairs of 100 bytes each, or more for smaller pairs. This design enables clients to fetch an entire block in a single round trip, reducing query latency for frequently accessed items by allowing quick access to the desired data.

Apart from the key and value, each slot in the hash table contains three additional fields: occupied, complete, and last_ts. The first two fields serve as flags to indicate the cache consistency state of the slot, as discussed in § 5. The last_ts field records the timestamp of the most recent access to the k-v pair, and victim slots are determined by the oldest last_ts.

When a client accesses a key-value pair, it updates the corresponding last_ts field via an RDMA write operation in the background. The use of timestamps for LRU eviction in disaggregated memory systems has been evaluated in previous works [52] and is shown to offer sufficient performance.

Each block in the hash table contains an offset to the SSD index, which points to the corresponding hash-based index region in the SSD that indexes key-value pairs with the same hash. The implementation of such data structure in the SSD has been thoroughly discussed in prior works such as LEED [16]. When a client fails to find the desired key in the cache, it will use the offset to initiate NVMe-oF target offload operations, retrieving the data directly from the SSD.

4.2 Batched Write Mechanism

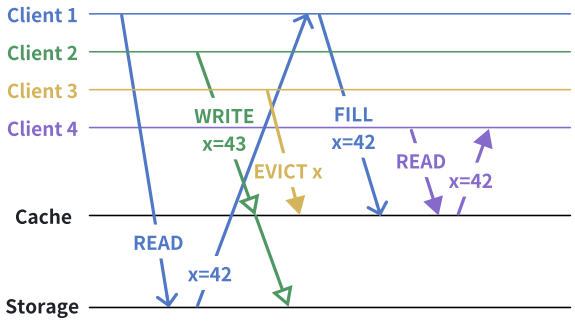
The batched write mechanism in Scalio consists of three main components: (1) a ring buffer for temporarily storing key-value updates with client IDs, (2) a batched write process for efficiently flushing updates to SSDs, and (3) a group commit mechanism to ensure the atomicity of batched operations.

The JBOF server handles incoming updates submitted by clients via RDMA send operations and appends these updates to the ring buffer, as shown in Figure 7 (c). It then polls it in a batched manner, accumulating updates for bulk flushing to SSDs. After writing to the SSDs, the server updates the corresponding next_offset field and then notifies clients of completion using their recorded client IDs. This batched write mechanism improves throughput by absorbing bursty write requests and reducing the DPU's CPU load through fewer SSD I/O operations.

A group commit process is triggered when the JBOF server accumulates a batch. The DPU flushes the batch to SSDs in a single deterministic operation (as long as the batch size is smaller than the SSD block granularity, such as 4KB). Afterward, the DPU updates the next_offset field in the in-memory data structures with the new SSD offsets, reflecting the locations of the written data. The group commit is completed when the DPU notifies all relevant clients that their updates have been successfully written. Scalio only acknowledges the write operations to the client when the update is successfully logged onto the SSDs, so that consistency is guaranteed in the event of server crashing.

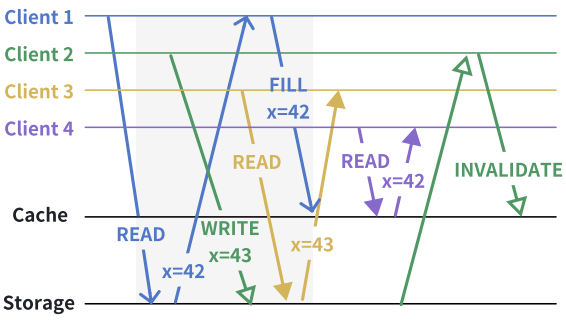
While these mechanisms improve throughput and reduce the DPU's CPU load, determining the precise linearization point of write operations remains a challenge. Specifically, maintaining consistency between cached data and the underlying SSD storage is crucial, especially in a disaggregated system where client-server interactions may occur asynchronously. This challenge will be addressed in § 5, where we explain how Scalio ensures correctness while optimizing performance through its cache consistency protocol.

5 Cache Consistency Protocol



In a disaggregated architecture, certain operations are offloaded to clients, allowing them to bypass the JBOF server and directly interact with the underlying storage. This design improves performance by reducing the DPU's workload but also creates a critical challenge: ensuring that the cached data in the in-memory data structures remains consistent with the actual data stored on the SSDs. Naive cache consistency protocols fail to ensure linearizability in the disaggregated architecture, which will be explained in § 5.1. Therefore, maintaining cache consistency becomes a key requirement for ensuring correctness in the system [46].

In this section, we will first define the problem in maintaining cache consistency within such a disaggregated system. We will then present our cache consistency protocol, designed to address these challenges, and demonstrate its correctness to ensure that the cached data remains consistent and up-to-date with the storage layer.



5.1 Problem Definition

To illustrate the problem with cache consistency, consider the time series diagrams shown in Figure 8, which illustrate how naive cache consistency protocols can violate the linearization guarantee.

Initially, the SSD holds the data $x = 42$, while the cache does not contain any record of x. Client 1 issues a read request for x, and since there is no cache hit, it fetches the data from the SSD and stores it in the cache. Meanwhile, Client 2 issues a write operation, updating the value of x to 43. Regarding write operations, two typical cache consistency protocols ex-

(a) The write-to-cache-first protocol violates linearizability.

(b) The write-to-SSD-first protocol violates linearizability.

Figure 8: The time series diagrams that demonstrate the naive cache protocols' violating the linearization guarantee.

ist, depending on the sequence of updating cache and the SSD storage: (1) writing to cache first and then updating the SSD; (2) writing to SSD first and then invalidating the cache item.

(1) The write-to-cache-first protocol may violate the linearizability guarantee, as illustrated in Figure 8 (a). Under this protocol, Client 2 will first update $x = 43$ to the cache. However, Client 1's later filling of $x = 42$ will overwrite the update, causing data loss.

Worse, suppose another Client 3 issues an eviction of x during the time difference, Client 1 will have no clue of Client 2's updating the cache item, remain unaware of the conflict, thus leading to data loss. As a consequence, when Client 4 finally reads x, it will get the previous value 42 rather than the latest value 43. The write-to-cache-first protocol cannot hold the linearizability guarantee.

(2) The write-to-SSD-first protocol also risks inconsistency in the event of cache refilling, as illustrated in Figure 8 (b). Under this protocol, Client 2 will first apply the update $x = 43$ to the SSD and later invalidate x from the cache. However, Client 3 performs a read operation for x after Client 2 updating the SSD but before Client 1 refilling the cache. At this point, Client 3 first accesses the cache, but since x is not present, it queries the SSD and retrieves the value $x = 43$ that was written by Client 2. This is then returned as the query result.

Then, suppose another Client 4 issues a read request for x after Client 1 has completed its operations. It reads from the cache and receives the value $x = 42$, which was cached earlier by Client 1. As we can see, this outcome violates the linearizability guarantee, as different clients observing the same key x at different times see inconsistent values.

The problem lies in the window of time during which the cached data has not been updated with the new value, while the SSD has already been updated with the new data. During this period, any client that attempts to query the cache may end up in an inconsistent state, leading to conflicting results. Specifically, the cache may not reflect the most recent updates on the SSD, causing clients to read stale data from the cache or the SSD, depending on the timing of their requests.

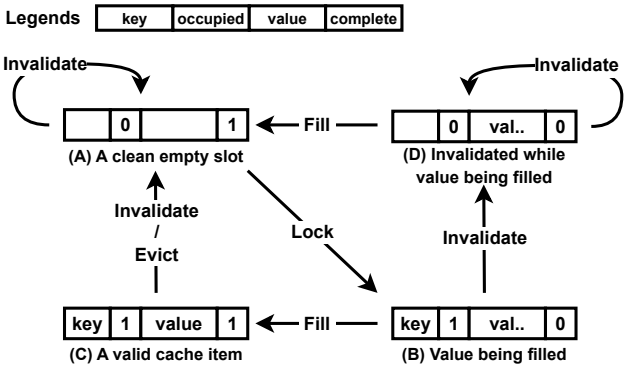


Figure 9: The states and transitions of Scalio's cache consistency protocol.

5.2 Protocol Design

To address the cache consistency issue, we propose a cache consistency protocol for Scalio. The core of this protocol is based on two flags — occupied and complete — which are added to each slot in the in-memory data structure, as shown in Figure 7 (b). The occupied flag indicates whether the slot contains a valid key, while the complete flag indicates whether the value in the slot is fully written.

These two flags result in four distinct states, as illustrated in Figure 9. Each state represents a specific condition of the cache slot:

State A: A slot is empty and safe to be reused when occupied is false and complete is true. In this state, the slot is not holding any valid data and can be safely reclaimed by other operations for filling new data.

State B: A slot is in the process of being filled. This indicates that the data in the cache is not yet fully valid and may lag behind the data in the SSD storage. If another client tries to access the same key while the slot is in State B, it must wait and retry, as the cache is not yet in a consistent state.

State C: A slot is valid and complete when both flags are true.

This state indicates that the key-value pair is fully written and consistent with the data in the SSD.

State D: A slot enters State D when the cache entry is invalidated by an update while the slot is still in State B. In this state, both flags are set to false, signifying that the slot is in an inconsistent state. Any other reader that attempts to query the item will treat the item as a miss, and any other write will be blocked until the client issuing the cache filling has completed writing the value (transiting to State A), thus avoiding potential collisions or torn reads/writes.

This state-based design is the foundation of our cache consistency protocol, ensuring that the data in the cache remains consistent with the SSD storage. The protocol's operation is integrated into the system workflow, and the detailed sequence of steps is outlined in the following paragraphs.

Read workflow. When a client initiates a read request, it starts by performing an RDMA read of the hash block (Step 1 in Figure 7 (b)). The client first searches for a slot containing the matching key. If the key is found in State C, the corresponding item is returned. If the key is in State B, the client will wait and retry later, as the cached item is not yet valid. If no match is found, a cache miss occurs, and the client proceeds with the following steps.

The client continues by selecting a victim slot according to the client-centric LRU eviction policy (§ 4.1). It issues an RDMA CAS operation to update the complete flag to 0 (Step 2 in Figure 7 (b)) and attempts to lock the slot. If the CAS operation succeeds, the client writes the key to the slot and sets the occupied flag to 1, transitioning the slot to State B.

Since clients perform cache-related operations independently, chances are that two clients may happen to choose two different slots as victim slots. To ensure atomicity and avoid key collisions, the client performs a double-read (Step 3 in Figure 7 (b)). A second RDMA read checks if any other slot in the hash block contains the same key and has the occupied flag set to 1. If a collision is detected, the client resets the slot's flags (occupied = 0, complete = 1) and reverts to Step 1, ensuring only one client is filling with the same key. If no collision occurs, the lock process is successfully completed, and the client proceeds to retrieve the offset of the SSD index from the block, moving on to Step 4.

After completing Step 4 and obtaining the data from the SSD, the client fills the value into the selected slot and updates the complete flag to 1 via RDMA write, transitioning the slot to State C.

To handle client failures, Scalio can opt in a lease mechanism that bounds how long a client may hold or update a cache slot. Each key-value slot maintains an additional timeout_timestamp alongside its state flags, representing the latest time the client's lease remains valid. When a client acquires a slot (entering State B), it writes the current timestamp plus a lease duration into timeout_timestamp. If that timestamp is exceeded—indicating the client has failed—other clients will see the expired lease, treat the slot as unlocked, and automatically evict it for reuse. This approach ensures that orphaned locks do not persist indefinitely and that resources are safely reclaimed without impacting Scalio's consistency guarantees.

Write workflow. For write requests, once the client receives confirmation of the successful write from the server (Step 3 in Figure 7 (c)), it invalidates any outdated cache entries. The client performs an RDMA read on the corresponding hash block and checks if any slot contains the same key with the occupied flag set to 1 (either State C or State B). The client then sets the occupied flag to 0, transitioning the slot to State A or State D, as appropriate.

Under our cache consistency protocol, the consistency problem is resolved as follows: Client 1, after reading the cache layer, encounters a cache miss and proceeds to lock a slot. We now focus on the gray-shaded section illustrated in Figure 8 (b). Since Client 1 has locked a slot, the slot will be in State B within this section. At this point, according to the protocol, Client 3 will attempt a read but will wait briefly and then retry. Eventually, the cache will have been updated by Client 1, turning the slot to state C, and it will read the value $x = 42$ written by Client 1, which will be returned as the result of the query. We can then linearly order the clients as Client 1, 3, 4, 2 and ensure that the operations behave in a way that respects the order in which the clients perform their actions.

5.3 Correctness

We now demonstrate the correctness of Scalio's cache consistency protocol, by two steps: (1) define the linearization points of the read and write operations; (2) show that such definition can linearize all operations.

We begin with the definition of the linearization points. The linearization point of a read operation is defined as: (1) on cache hit, the moment when the RDMA read reaches the cache and gets the hash block (i.e., when Step 1 is done in Figure 7 (b)), or (2) on cache miss, when the victim slot has been locked and successfully validated by the double-read check (i.e., when Step 3 is done in Figure 7 (b)). The linearization point of a write operation is defined as the earliest moment when no cache slot in State B or State C exists with the same key after the update is applied to the SSD. It is easy to verify that by this definition, the linearization points are between the the start and the end of each operation.

In order to prove linearizability, the key is to demonstrate that all operations appear to behave in the sequence specified by the definition. Since the operations are all key-value read and write operations, it is equivalent to showing that every read operation is guaranteed to read **exactly** the value updated by the closest write before, as illustrated in Figure 10.

Part 1: every read operation will never read values earlier than its closest-write-before's update. At the linearization point of the closest-write-before, the corresponding cache slot should be in either State A or State D, by the definition of the linearization point. If the read operation is a cache hit,

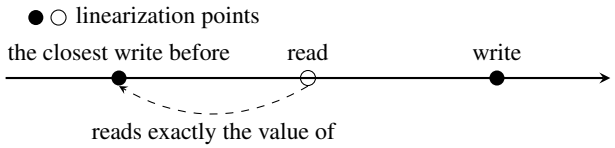

Figure 10: Illustration of the proof objective.

the cache slot must have been transitted to State C at the time of the cache hit. The only possible path of the transition is by another client that locks the slot, and refills the slot with the SSD data at the time of locking. The whole process of transition happens after the writer's linearization point, so the data read by the cache hit must be no earlier than the data written by the closest-write-before. On the other hand, if the read operation is a cache miss, by definition, it will read the closest-write-before's already applied update on the SSD.

Part 2: every read operation will never read values later than its closest-write-before's update. This is guaranteed by the definition of the write operations' linearization point, because at any moment before a subsequent write operation's linearization point, the subsequent update is either not on the SSD or masked by an existing cache slot with the same key but a previous value. Therefore, the read operation will never read newer values that have not been linearized yet.

By combining the two parts, it can be assured that all read and write operations happen in the sequence by the definition of their linearization point. Since each linearization point happens between the corresponding operation's invoke and return, it can be further concluded that if an operation ends before another operation begins, the linearization point of the latter operation must be later than the other. In other words, the linearization point definition respects real time ordering.

In conclusion, the linearization property of Scalio's cache consistency protocol is demonstrated.

6 Evaluation

6.1 Experimental Methodology

Testbed. We configured our testbed to resemble a DPU-based JBOF storage environment, consisting of one storage node and five client nodes (with up to 160 client threads) interconnected via a high-speed RDMA network. The storage node includes seven Samsung 970 PRO SSDs [49], each offering 500K IOPS under 4KB blocks, connected to a ConnectX-6 HCA. We emulated a DPU-based JBOF configuration by limiting the available Intel Xeon Gold CPU cores to 8 and memory to 8 GB, which aligns with the configuration of commodity DPU-based JBOF platforms [6, 16, 35, 39].

Implementation details. Our system environment is based on Linux kernel version 5.15.0, which includes native support for NVMe-oF targets. We installed the MLNX_OFED driver (version 24.04-0.7.0) and set up the NVMe target subsystem (nvmet) to handle NVMe-oF requests, configuring it to use RDMA as the transport protocol. Additionally, we enabled the `attr_offload` parameter within the NVMe target setup to support the offloading implementation for NVMe-oF, which allows for scalable handling of I/O operations by bypassing traditional CPU processing [40, 41]. For the software stack, we further maintained fairness by porting LEED's code using the same SPDK stack and employed the same SSD storage data structures as LEED. The source code is available at https://github.com/madsys-dev/scalio-osdi25-ae.

Workloads. For workload evaluation, we employed the Yahoo! Cloud Serving Benchmark (YCSB) [11], focusing on five specific workload types: YCSB A, YCSB B, YCSB C, YCSB D and YCSB F. YCSB E is omitted as other systems because it requires range query. We generated 20 million key-value pairs, each with a maximum key length of 16 bytes and a maximum value length of 64 bytes, distributed with a Zipfian distribution and a Zipfian constant of 0.99. The cache can hold approximately 2 million key-value pairs.

Baselines. We compared Scalio with two setups: (1) the LEED [16] JBOF key-value storage system (denoted as LEED) and (2) the LEED storage system combined with the Ditto [52] disaggregated key-value caching system (denoted as LEED+Ditto). For fairness, we apply the same Arm-core-allocation strategy as LEED, accompanied with the round-robin SSD binding strategy as illustrated in Figure 4. The cache size is set to 1 GB for both Scalio and the LEED+Ditto baseline.

6.2 Performance Improvements

We evaluated the performance of Scalio along with the baseline systems by varying the number of SSDs from 1 to 7 and measuring throughput under YCSB workloads A, B, C, D, and F. The results, shown in Figure 11, highlight Scalio's superior throughput and scalability across all workloads as the number of SSDs increases.

Scalio demonstrates superior scalability compared to the baselines, as the baseline systems experience throughput saturation when the number of SSDs reaches 4, while continues to scale efficiently as more SSDs are added. Under read-intensive and read-only workloads (YCSB B, C, D), Scalio achieves up to 3× speedup, and under write-intensive workloads (YCSB A, F), it achieves up to 2× speedup.

The 3× speedup observed in read workloads is primarily due to the use of NVMe-oF target offload. This optimization frees the JBOF server's CPU from handling read operations, allowing it to fully utilize the SSDs' I/O capabilities, as shown in Figure 12. In contrast, the baseline systems struggle to fully utilize SSD IOPS because their JBOF servers become CPU-bound as the number of SSDs increases.

For write workloads, the 2× speedup is largely attributed to the batched write mechanism. By combining multiple value updates into a single SSD write operation, Scalio reduces CPU

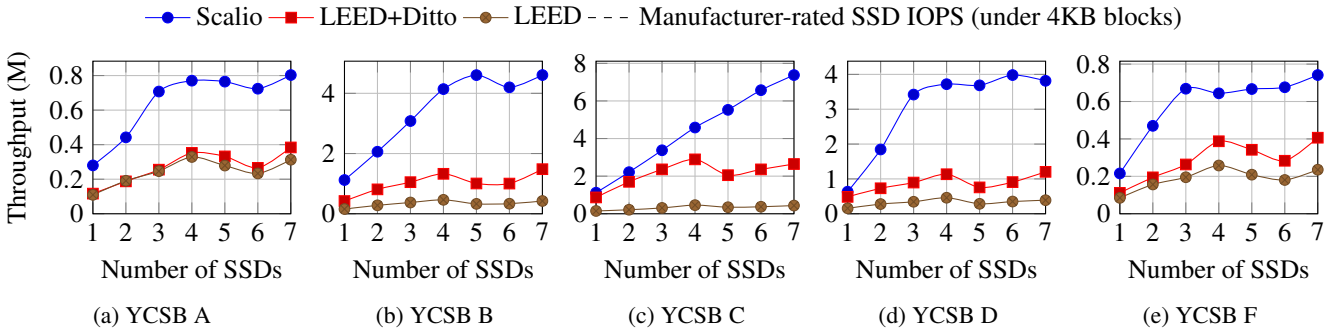

Figure 11: Throughput for YCSB workloads A,B,C,D and F as the number of SSDs scale up.

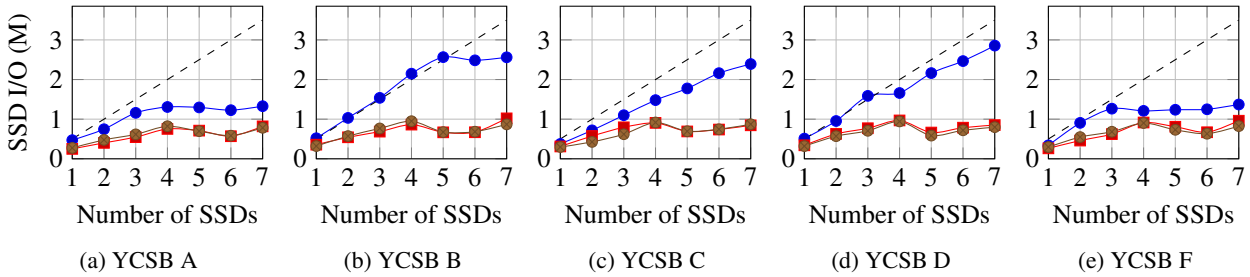

Figure 12: SSD I/O usage under YCSB workloads A,B,C,D and F as the number of SSDs scale up.

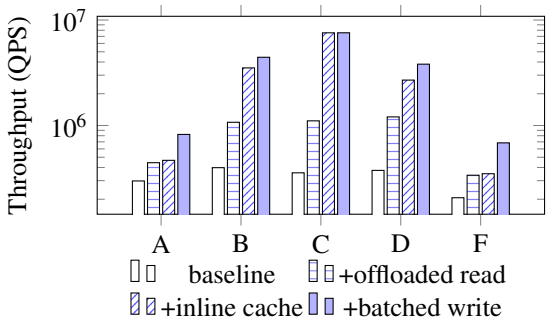

Figure 13: Throughput improvement breakdown under YCSB workloads A, B, C, D, and F. The Y-axis is log scale.

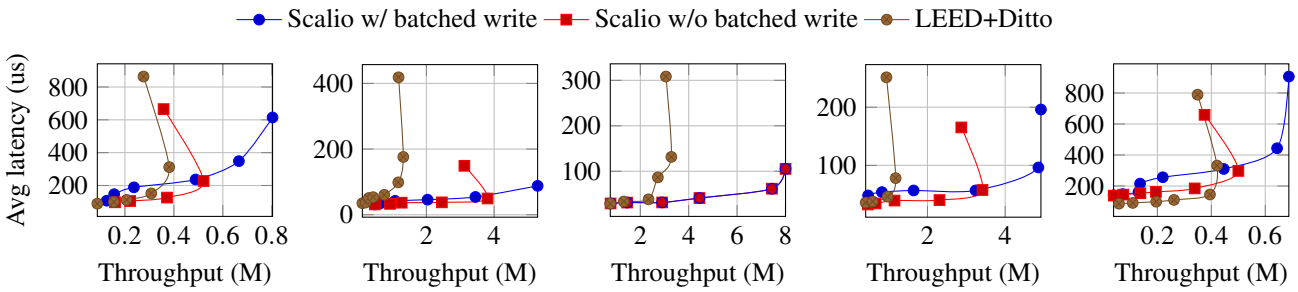
overhead, which improves SSD I/O efficiency. The batched write mechanism minimizes the number of write operations required, thus alleviating pressure on the JBOF server and enhancing throughput.

A more detailed breakdown of these improvements can be found in § 6.3, with performance impacts of each optimization evaluated and discussed.

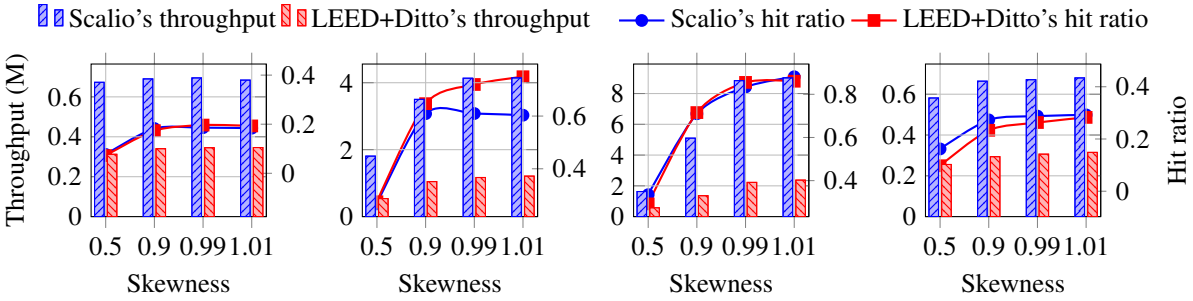
In conclusion, Scalio's optimizations—primarily inline cache, offloaded reads and batched writes—effectively reduce CPU overhead, maximize SSD IOPS utilization, and enhance scalability and throughput as the number of SSDs increases. These improvements enable Scalio to outperform baseline systems in both throughput and resource utilization.



6.3 Improvements Breakdown

To assess the impact of each individual optimization, we conducted a detailed analysis of Scalio's contributions under YCSB workloads A, B, C, D, and F, using a 7-SSD configuration. Figure 13 shows the breakdown of performance improvements as we incrementally enabled each optimization: (1) offloaded read, (2) inline cache, and (3) batched write. By evaluating the effects of these optimizations, we demonstrate how each one contributes to the overall system performance.

Offloaded read. Offloaded read provides a speedup of 1.5× to 3.2× across all workloads by offloading massive SSD I/O to the network, relieving the DPU's CPU. This increases SSD I/O utilization and bridges the gap between the SSD's I/O capabilities and the system's performance, as in Figure 12.



Inline cache. Inline caching is particularly effective under read-only and read-intensive workloads by absorbing hot reads. Our system statistics show that Scalio's in-memory caching layer absorbs 72.2%, 85.2%, and 62.6% of total read and write operations under YCSB B, C, and D, respectively. This absorption leads to throughput improvements of 3.6×, 6.7× and 2.7×, matching the observed speedup.

Batched write. Batched write provides a speedup of up to 1.96×, and its contribution is the most obvious in YCSB A and F, which belong to write-intensive workloads. According to our experiments, batched write can reduce the number of SSD writes per key-value update operation from 2 to approximately 1, which reduces the burden on the DPU's CPU, thus contributing to the speedup.

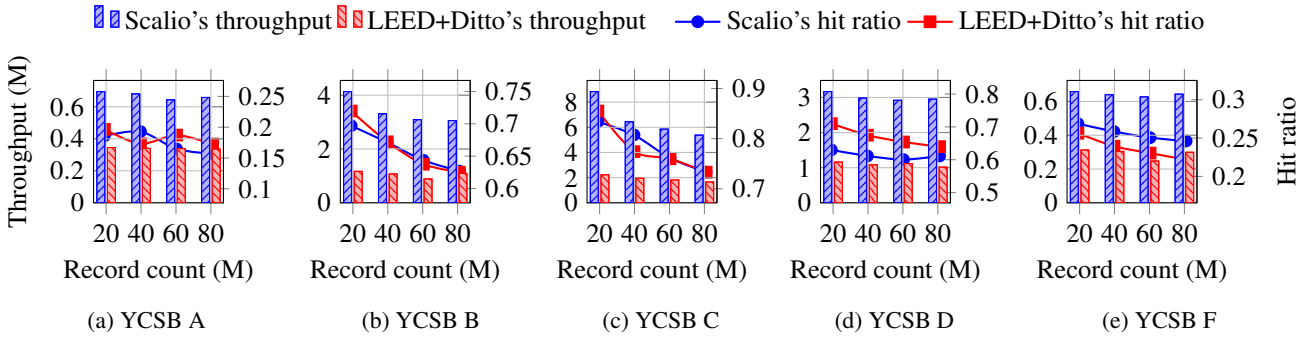
6.4 Latency

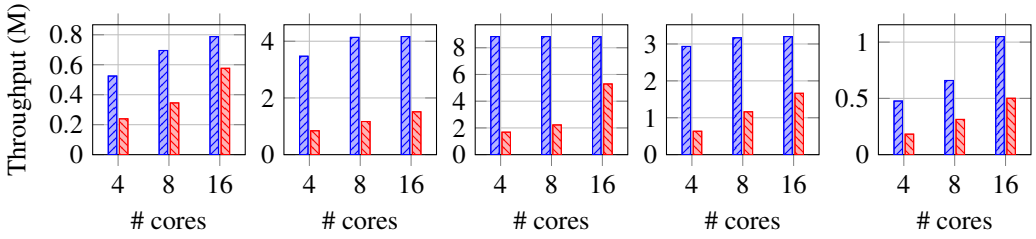
In this subsection, we compare the latency performance of Scalio with and without the batched write feature, alongside the LEED+Ditto baseline. The comparison highlights the trade-off between latency and throughput introduced by the batched write mechanism, where throughput is significantly improved at an acceptable cost of some latency. Our evaluation demonstrates two key findings: (1) Scalio without batched write delivers both lower latency and higher throughput compared to LEED+Ditto, and (2) Scalio with batched write achieves even higher throughput, with an acceptable latency trade-off. Users can choose between prioritizing low latency in latency-critical scenarios or enabling batched write for higher throughput.



Comparing Scalio without the batched write mechanism to the LEED+Ditto baseline, Scalio demonstrates a 20% to 30% reduction in average latencies across all workloads, while also achieving a 2× to 3× throughput improvement. Both the reduction in latency and the throughput improvement are due to two key optimizations: Scalio's inline caching, which reduces round-trip time on cache hits by using a compact inline data structure, and the bypassing of the JBOF server's CPU, which lowers network latency on cache miss paths. These optimizations not only alleviate the DPU's CPU load but also improve SSD I/O utilization, driving higher throughput with lower latency and enhancing system performance. Under the read-modify-write workload YCSB F, Scalio ensures cache consistency, which the baseline system fails to achieve, at slight expense of latency.

Comparing Scalio with the batched write mechanism to the LEED+Ditto baseline, we observe a trade-off where the group commit mechanism introduces significant throughput improvements in exchange for a tolerable increase in latency. For instance, in YCSB A, Scalio achieves 2.1× higher throughput (800 M IOPS) compared to the baseline, with only a 1.97× increase in latency (614 us). This shows that while there is a moderate latency penalty, it is well-compensated by the substantial gain in throughput, making the trade-off beneficial for overall system performance.

In conclusion, Scalio provides a well-balanced approach to system performance, effectively addressing the trade-offs between throughput and latency. When batched write is disabled, Scalio outperforms the baseline in both throughput and latency, providing lower latencies across all workloads. With batched write enabled, Scalio achieves much higher throughput with only a minimal increase in latency, allowing it to efficiently handle diverse workloads while maintaining an optimal balance between performance and responsiveness.



6.5 Sensitivity Analysis

In this subsection, we conduct a sensitivity analysis under the 7-SSD configuration by varying several key parameters. We

(a) YCSB A (b) YCSB B (c) YCSB C (d) YCSB D (e) YCSB F

Figure 16: Throughput and cache hit ratio when varying the total number of records under YCSB A, B, C, D, and F.

(a) YCSB A (b) YCSB B (c) YCSB C (d) YCSB D (e) YCSB F

Figure 17: Throughput when varying the number of cores under YCSB A, B, C, D, and F.

will present the results of four experiments: (1) varying the workloads' skewness , (2) varying the dataset size, (3) varying the number of CPU cores, and (4) varying the hash block size.

Skewness. We varied the Zipfian constant from 0.5 to 1.01 to evaluate the system performance under different workload skewnesses, as shown in Figure 15. (YCSB D is omitted as it does not follow the Zipfian distribution.) As observed, Scalio performs better as the skewness increases, particularly in read-only and read-intensive workloads, where higher skewness results in a higher hit ratio. For write-intensive workloads, while hot data may hinder performance, this affects both Scalio and the baseline similarly, with Scalio still outperforming the baseline. Overall, Scalio consistently outperforms the baseline system of 2× to 3× across all skewness levels and workloads, demonstrating its ability to handle varying workload distributions effectively.

Dataset size. We varied the total number of key-value pairs from 20 million to 80 million, testing the system's performance at each step, as shown in Figure 16. As the dataset size increases, the cache hit ratio slightly decreases and throughput marginally drops. However, Scalio consistently outperforms the baseline, demonstrating its robustness with larger datasets.

Number of CPU cores. We varied the number of CPU cores, testing configurations with 4, 8, and 16 cores. The 16-core configuration represents an ideal scenario, assessing the system's performance under ample CPU resources. The results are shown in Figure 17. Scalio is less sensitive to variations in the number of CPU cores, especially in read-only or read-intensive workloads, as it offloads operations to the network and hence requires fewer CPU resources. In contrast, the performance of LEED+Ditto degrades significantly as the number of CPU cores decreases. The performance gap between Scalio and the baseline widens from 1× to 2× (under the 16-core configuration) to 2× to 5× (under the 4-core configuration), highlighting Scalio's advantage in environments with limited CPU resources.

Capacity of hash block. We varied the hash block's capacity by adjusting the number of slots per block, testing configurations with 4, 8, and 16 slots. As shown in Figure 18, changes in block size have minimal impact on Scalio's performance. This suggests that the hash block size can be tuned according to specific cache requirements, offering flexibility in optimizing performance without significant trade-offs.

7 Discussion

Fairness of evaluation setup. While our evaluation uses an emulated DPU setup, it provides a conservative and fair estimate of real-world performance. We constrained the testbed to 8 cores and 8 GB memory to match typical DPU resource limits, and Scalio's core performance benefits stem from offloading CPU-intensive SSD I/O via NVMe-oF target offload—an advantage that holds regardless of the CPU power. We further ensured fairness by aligning our setup with LEED's, using the same SPDK stack, RDMA topology, and data structures. This setup realistically reflects Scalio's deployment scenario

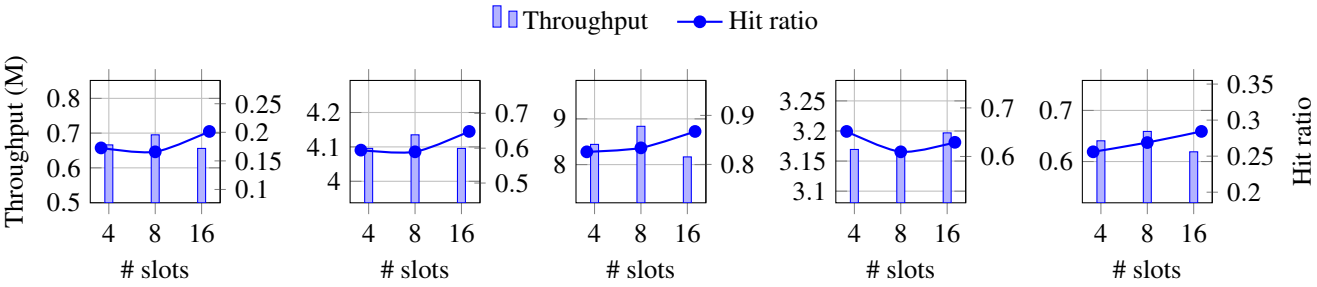


Figure 18: Throughput and cache hit ratio when varying the number of slots per hash block under YCSB A, B, C, D, and F.

and expected performance characteristics.

Energy efficiency of DPU-based design. Scalio's DPU-based approach leverages ASIC-accelerated NVMe I/O to achieve significantly higher energy efficiency than general-purpose CPUs. While increasing CPU power consumption might suggest potential performance gains, it does not guarantee linear scaling—especially for I/O-heavy workloads where overheads grow disproportionately. In contrast, DPU-based JBOF systems can already efficiently support 26 or more SSDs with lower power. Given these factors, Scalio's DPU-based design offers higher effective performance per watt and better scalability than simply scaling up CPU resources.

Server failure handling. Scalio ensures robustness against server-side failures by integrating with orthogonal redundancy techniques such as RAID or dual-DPU setups at the JBOF level. These mechanisms are widely adopted in disaggregated storage systems and can tolerate SSD or node failures without modifying Scalio's core protocol. For example, RAID-10 can preserve data availability and consistency even under partial disk failures, allowing Scalio to continue operating seamlessly. This integration enhances system reliability while preserving Scalio's scalability and performance benefits.

8 Related Work

Energy-efficient storage. Energy-efficient storage solutions are increasingly necessary as storage demands rise. LEED [16] uses DPU-based JBOF platforms for lower power consumption, but its performance is limited by the DPU's CPU load. FAWN [2] relies on low-power "wimpy" nodes, but its design is not well-suited for modern high-density JBOF architectures, which offer better energy efficiency. Gimbal [35] leverages DPU-based JBOFs for managing tenants with strong QoS guarantees, but its focus is on tenant isolation, not computational efficiency. TrickleKV [62], a key-value storage system built on JBOF, aims to alleviate network traffic contention rather than improving CPU efficiency. SKV [55] offloads replication to SmartNICs in disaggregated key-value systems but still relies on host servers for most operations. Scalio overcomes the limitations of these systems by increasing storage density and offloading tasks to reduce CPU load on the DPU, significantly enhancing overall power efficiency.

Storage over network. Storage over network technologies enable the separation of storage and computation by connecting devices via protocols such as iSCSI and NVMe-over-Fabrics (NVMe-oF). iSCSI [26] facilitates storage networking through TCP/IP, but it suffers from CPU inefficiencies due to single-queue structures, creating bottlenecks, particularly with multi-core CPUs. NVMe-oF improves upon iSCSI by utilizing protocols like RDMA for direct data transfer between SSDs and compute nodes, as explored in [17]. However, the standard NVMe-oF implementation still places a heavy load on target CPUs which limits scalability, and there has been few studies on the NVMe-oF target offload implementation.

Cache consistency/coherence protocols. Cache consistency/coherence protocols are well-studied in both monolithic and distributed systems. In monolithic systems, protocols like MESI [20] ensure consistency between L1/L2 caches and main memory. In distributed systems, various protocols ensure consistency between cached data and underlying storage. DistCache [29] partitions hot objects across cache nodes using independent hash functions and routes queries with a power-of-two-choices mechanism. Similarly, CliqueMap [54] uses a quorum-based approach, combining replication, client-based quoruming, and self-validating server responses. These protocols maintain consistency across distributed nodes. Scalio's protocol, on the other hand, is designed for DPU-based disaggregated systems, where RDMA reduces CPU overhead and ensures consistency through efficient cache management without full synchronization across all nodes.

Disaggregated in-memory key-value stores. High-performance, disaggregated in-memory key-value stores typically use one-sided RDMA to bypass the CPU, achieving efficient, direct data access. FORD [64] provides transaction support using RDMA atomic operations, but this design is more lock-heavy and less efficient in cases without transactional needs, such as in-memory index. Ditto [52] offers a more efficient solution in terms of in-memory caching, but it lacks integration with secondary storage layers like the SSD storage layer, and thus cannot be directly applied to systems

with both DRAM and SSD storage. Our work targets efficient serving of small key-value pairs, along with integration with SSD storage layers to provide high-performance key value storage service with linearizability guarantee.

9 Conclusion

In this paper, we propose Scalio, a scalable disaggregated key-value store designed for high-density JBOF systems. By leveraging NVMe-oF Target Offload, Scalio bypasses the DPU's CPU, reducing overhead, while its two-layer architecture and batched write mechanism efficiently handle bursty workloads. Our cache consistency protocol ensures data consistency across the system. Experimental results demonstrate Scalio's superior scalability and performance, particularly as the number of SSDs increases.

Low End-to-End Latency atop a Speculative Shared Log with Fix-Ante Ordering

Shreesha G. Bhat, Tony Hong, Xuhao Luo, Jiyu Hu, Aishwarya Ganesan, Ramnatthan Alagappan

University of Illinois Urbana-Champaign

Abstract. Today's shared logs incur expensive coordination to globally order records across storage shards before they can deliver records to applications. This makes them unsuitable for many modern applications that must process ingested data as early as possible and realize low *end-to-end* (e2e) latencies. We propose *SpecLog*, a new shared log abstraction that delivers records by speculating the global order, allowing the application's computation and shared-log coordination to be overlapped, thus reducing e2e latency. To enable accurate speculations, we introduce *fix-ante ordering*, a novel ordering mechanism that predetermines the global order and makes the shards adhere to the predetermined order. With fix-ante ordering, shards, except in rare cases, can accurately predict where their records will sit in the total order before global coordination. We build Belfast, an implementation of the SpecLog abstraction and fix-ante ordering. Our experiments show that Belfast offers lower e2e latencies than current shared logs while preserving their elasticity, flexibility, and scalability.

1 Introduction

Shared logs play a central role in many modern, data-driven applications like high-speed trading [27, 28], real-time search [54, 60], IoT analytics [24, 49], fraud detection [15, 46], and others [3, 59]. At a high level, in all these applications, a set of upstream components ingest data into the shared log, and a set of downstream tasks consume and process the data.

Shared logs ease the construction of the above applications by providing an abstraction of a durable and ordered sequence of records. Many shared logs [1, 4, 16, 29, 36, 61] provide this abstraction while storing records on multiple storage shards, i.e., they offer a *total order* of records across shards.

Early total-order logs like Corfu [16, 17] first obtain a position from a sequencer and then use a fixed position-to-shard mapping to write to the shard responsible for that position. This architecture fundamentally leads to three problems for applications [29, §2.2]: inability to seamlessly add or remove shards (to elastically adapt to demands), inflexible data placement, and limited scalability. Fortunately, a family of shared logs [29, 32, 36], starting from Scalog [29], address these problems by taking a *durability-first* approach. Here, clients first make records durable on the shards of their choice; the shards then periodically contact a sequencing layer to establish total order for a batch of records. This design enables one to add or remove shards without downtime, allows clients to choose the location of records, and enhances scalability [29].

Unfortunately, the design choices that enable these desirable properties in today's shared logs fundamentally lead to high *delivery* latency (§2). Delivery latency refers to the time between when upstream components produce records and the *earliest point* when the shared log can deliver these records to downstream tasks. The key reason for high delivery latency is the overhead to determine the global order and doing so in a batched manner. Specifically, the shards periodically batch and report the number of records made durable so far to the sequencing layer; the sequencing layer then determines a "global cut", which dictates how to assign positions to durable records across shards. Only after the shards coordinate with the sequencing layer and receive the global cut, can they assign positions to their records and serve them to downstream tasks, increasing delivery latency.

Such high delivery latency, in turn, leads to high application *end-to-end (e2e)* latency, which refers to the time between when records are produced and when the downstream task completes processing them. This is because only after the shared log orders and delivers records, can the application's downstream computations start, increasing e2e latency. Realizing low e2e latency, however, is critical for many real-world applications. Consider the following: a financial application that must flag fraudulent activity as soon as transactions are ingested [25, 62]; real-time analytics that must derive insights from new data as early as possible [6, 56]; high-speed trading that must trade quickly based on market feed [28, 34]. All these applications desire low e2e latency in addition to elasticity, flexible placement, and scalability from the shared log. Although today's shared logs like Scalog satisfy the latter needs, they cannot help realize low e2e latency.

SpecLog Abstraction and Fix-Ante Ordering. To enable applications atop shared logs realize low e2e latency, we identify an opportunity for speculative execution. Given that high delivery latency stems from global ordering, we observe that if a shared log can *speculate* the global order and deliver

records quickly, downstream computation can start based on the speculated order. Thus, the shared log's coordination and the downstream application's computation can be overlapped, reducing e2e latency. This approach suits real-world applications because they typically perform computation over the consumed records (e.g., computing aggregates [26], updating indexes [14, 19], performing analysis [31]).

Based on this observation, we propose SpecLog, a new shared-log abstraction (§3.1). SpecLog offers the same interface as current shared logs but with one difference. SpecLog first delivers records in a predicted order, and later confirms whether or not the prediction is correct. If correct, SpecLog enables low e2e latency; otherwise, SpecLog notifies applications to recompute based on the actual order, preserving correctness. While SpecLog's idea can benefit any shared-log design, our focus is on durability-first architectures that offer elasticity, flexibility, and scalability which are critical to applications in addition to low e2e latency. In such a durability-first SpecLog system, shards operate the same way as today's logs, periodically coordinating with the sequencing layer to determine the actual order. However, they predict the global order and deliver records earlier before coordination. Later, when the actual order arrives, shards confirm or fail the speculation.

Using speculation to reduce latency is *not* new; many prior distributed systems have done so [23, 33, 38, 39, 48, 65]. However, SpecLog is the first to offer a speculative interface for today's shared logs, helping applications realize low e2e latency while preserving the other properties of today's shared logs. Further, a key innovation in SpecLog is how it virtually eliminates misspeculations except in very rare cases via a novel ordering mechanism called *fix-ante* ordering.

To realize low e2e latency, SpecLog must be able to correctly predict record positions at the shards before global coordination. Such correct prediction in current logs like Scalog, however, is inherently difficult. This is because shards have the *free will* to make durable and report however many records they wish in each report to the sequencing layer. Because the positions assigned to records at a shard depend upon how many records *other* shards report, it is hard for the shard to predict where its local records will sit in the total order.

Fix-ante[†] ordering solves this problem (§3.2). The key idea behind fix-ante ordering is to *predetermine* beforehand the global order and try to enforce the shards to *adhere* to this order. Fix-ante order is specified as a series of predetermined global cuts. The shards adhere to each predetermined cut by making durable and reporting exactly the number of records as dictated by that cut (which we refer to as the shards' *quotas*). Because each shard knows that other shards will report precisely the number of records dictated by their quotas, each shard can accurately predict the positions of its local records in the total order without waiting for the actual global order (which is determined after coordinating with the sequencer).

[†]Fix-ante is derived from a Latin phrase "Praefixum ante" which roughly means to fix or predetermine beforehand (as opposed to having free-will).

Note that fix-ante ordering does *not* mean order is established before durability; rather, fix-ante ordering simply offers a way for predicting the global order in durability-first architectures.

As long as the shards adhere to their quotas, the actual global order will match the fix-ante one, ensuring that the positions speculated by the shards remain correct. Fortunately, SpecLog can ensure that shards can adhere to their quotas except in rare cases. Specifically, in failure-free cases, shards can adhere to their quotas even when they have fewer or more records than their quotas by filling in *no-op* records or by delaying records to subsequent reports, respectively. Even when a few shard replicas fail, quotas can be adhered to because shards are internally fault tolerant. Only in the rare case where an entire shard fails or if no shard replica can contact the sequencing layer, will the shard be unable to adhere to its quota, resulting in incorrect predictions. While SpecLog loses some performance under such rare cases, it still preserves correctness by failing the speculation.

Belfast System. We build Belfast, an implementation of the SpecLog abstraction and fix-ante ordering (§4). While fix-ante ordering provides a basic framework for accurate predictions, a real system must solve several performance challenges while still preventing misspeculations. First, Belfast must assign quota for a shard such that it is neither too high (which will add many no-ops) nor too low (which will delay records); Belfast achieves this by setting quotas based on ingestion rates. Second, even with the right quotas, Belfast must handle cases where shards experience bursts. Belfast handles bursts via a new *lag-fix* mechanism; without this, appends and confirmations will incur higher latencies. Third, Belfast must handle longer-term rate changes. Belfast does this by dynamically adjusting predetermined cuts and quotas. Importantly, it does so without misspeculations via a novel *speculation lease window* technique that ensures that all shards use the same predetermined cuts for predictions and that they uniformly move to the new cuts at the window boundaries. Belfast also adds or removes shards without downtime and misspeculations using the speculation lease windows. Finally, Belfast can dynamically exclude shards from some cuts to mitigate straggler shards and to maintain low latencies with many shards.

Results. Our experiments (§6) show that Belfast delivers records ∼3× earlier than Scalog, thereby reducing e2e latency by 1.6× over Scalog. Belfast offers significant benefits in e2e latency even with varying amounts of downstream computation. Belfast achieves low e2e latency while incurring minimal overhead in append latency over Scalog (5.8% with 10 shards). We also show that Belfast can effectively handle bursts, adjust to rate changes, mitigate straggler shards, and handle shard failures, all while maintaining low e2e latency. We show that, like Scalog, Belfast can add and remove shards without any downtime and scale throughput with shards while reducing e2e latencies. Finally, we build three applications (§5): intrusion detection, fraud monitoring, and high-frequency trading, and show that Belfast enables these applications to realize

1.4×-1.6× lower e2e latency than Scalog.

Contributions. This paper makes four contributions.

- We propose SpecLog, a shared-log abstraction that delivers records by predicting their order, overlapping global coordination and computation, thus reducing e2e latency.
- We introduce fix-ante ordering, a novel ordering approach that enables shards to accurately speculate global positions.
- We build Belfast, an implementation of SpecLog and fix-ante ordering. Belfast is the first shared log to offer elasticity, flexible placement, and scalability with low e2e latencies.
- We experimentally demonstrate Belfast's benefits.

2 Motivation

We explain why today's shared logs incur high delivery latencies, making them unsuitable for realizing low e2e latency.

2.1 State-of-the-Art Shared Logs: Background

Shared logs [16–18, 29] offer a powerful abstraction: a fault-tolerant, ordered record sequence that many clients can simultaneously append to and read from. Upon appends, the shared log makes records durable and linearizably [35] orders them: if an append *A* completes before another append *B* starts, then *A* will precede *B* in the log. Clients can read records at positions or subscribe to receive records in order.

With this abstraction and simple interface, shared logs ease building modern applications like real-time analytics [52, 54, 59, 60], high-frequency trading [27, 28], and many others [15, 31, 37, 46, 49, 51]. In all these applications, a set of upstream components ingest data into the shared log which provides strong durability and ordering guarantees. Downstream tasks then consume the records and compute over them.

Popular shared logs like Kafka [13] and others [5, 50] do not provide a total order across shards. Corfu [16, 17], an early shared log, offers total order. Corfu adopts an *order-first* approach, where clients first obtain a position from a sequencer. Then, using a fixed position-to-shard mapping, clients write the record to the shard responsible for the obtained position. As others have noted [29, §2.2], the order-first approach is harmful in three ways. First, it introduces holes because clients can fail after getting the position but before writing. Readers must fill such holes, which requires a system-wide mapping from positions to where records are stored, and clients and servers must agree upon this mapping. This means adding or removing shards requires agreeing upon the new mapping, which leads to system-wide unavailability. Second, the fixed mapping also means that clients cannot flexibly write records to shards of their choice. Finally, obtaining a position for every write makes the sequencer a scalability bottleneck.

State-of-the-art shared logs like Scalog [29] address these limitations. Scalog takes a *durability-first* approach, where clients first store records on a shard of their choice. After batching many records, the shards contact a sequencing layer which determines the total order of records across shards. By avoiding Corfu's fixed mapping, Scalog can add or remove

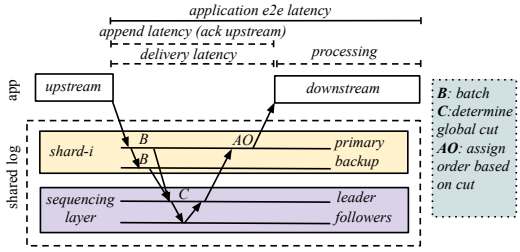

Figure 1: **Delivery and E2E Latency in Today's Shared Logs.**

shards without downtime, enabling it to elastically grow or shrink throughput and capacity [29, §6.1]; such seamless elasticity is important for applications to adapt to dynamic demands [29, 41]. Scalog also enables flexible data placement as clients can choose record locations; this is greatly useful because applications can assign records to shards based on application-level semantics (e.g., records of a particular user can go to one shard) or based on proximity. Finally, the batched communication with the sequencing layer allows Scalog to scale better than Corfu [29, §6.3]; such scalability is important for applications that must ingest and process data at high rates [29, 34]. Given these benefits, many systems like Boki [36] and FlexLog [32] adopt a Scalog-like design.

2.2 High Delivery Latency in Today's Shared Logs

Although today's shared logs offer desirable properties, the design choices that enable them to achieve these properties is fundamentally at odds with low *delivery* latency, which is the time between when records are produced into the log and the earliest point they can be delivered to downstream tasks.

Figure 1 shows this problem in Scalog. Clients first send records to the primary of a shard. The shard primary logs the records locally and replicates them to the shard backup. A record is durable once it has been logged by both the shard primary and backup. The shard servers then report their local log lengths to a sequencing layer. To amortize the cost of contacting the sequencing layer, the shards batch (***B*** in Figure 1) and only report log lengths periodically; such periodic reports incur a batching delay. The sequencing layer then assembles the local reports from shards and determines the number of durable records within each shard. It then computes a *global cut*: the global order of durable records across shards (***C***), and makes the cut fault-tolerant via Paxos [40]. The sequencer then sends the global cut to all shards, using which each shard assigns global positions to records in its local log (***AO***). Only after this point, in addition to acknowledging the appends, the shared log can deliver the records to downstream consumers, which then can start processing. Thus, between upstream ingestion and downstream consumption, applications incur batching delays and the cost of global ordering.

High delivery latencies are not merely a result of how today's shared logs are implemented, but rather a fundamental cost of the durability-first approach. This is because the design choice to have clients first write records to shards of their choice and then have the shards report to the sequencing layer

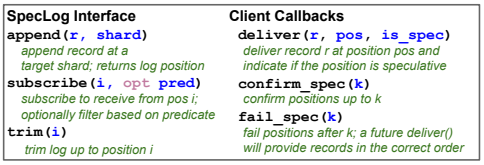

Figure 2: **SpecLog Interface.**

in a batched manner (which enables seamless elasticity, flexibility, and scalability) is what leads to high delivery latencies. Order-first shared logs like Corfu do not incur some of the above overheads like batching and coordination within the sequencing layer. However, they also deliver records only after the global order is established which takes multiple roundtrips [16, 43], thus still incurring high delivery latencies (besides suffering from other limitations for applications).

Unfortunately, high delivery latencies negatively impact application e2e latency. As shown in the figure, e2e latency includes the delivery latency and the time to process the records. Thus, to applications, the high delivery latencies of today's shared logs is a major obstacle to realizing low e2e latencies.

2.3 Demand for Low E2E Latency

Low e2e latencies are critical for many modern, data-driven applications. High-speed trading applications must execute trades in real-time based on incoming data feeds [27, 28, 34, 42], where shaving off even *milliseconds* of latency can save millions of dollars [9, 10]. Financial fraud detection systems need to flag suspicious transactions as quickly as possible [25, 55, 62], with every millisecond being crucial [2, 12]. Real-time analytics engines [52, 59] require rapid insights from fresh data, while real-time search systems must minimize the delay before new data appears in results [54, 60]. Similar low e2e latency requirements exist for event sourcing [37, 51], IoT analytics [24, 31, 49], and fleet management applications [58]. Unfortunately, current shared logs cannot meet these demanding latency requirements. Further, the importance of low e2e latency and thus the need for low delivery latency is evident from RedPanda's recent survey [11], where 100s of practitioners reported the vital metrics in their shared-log deployments. Among them, ∼35% cited delivery as the most critical latency metric.

3 SpecLog and Fix-Ante Ordering

We describe the SpecLog abstraction and explain how it uses fix-ante ordering to enable accurate speculations.

3.1 SpecLog Abstraction

Our goal is to design a shared log that enables low e2e latency. To this end, we first observe that in many modern, data-driven applications, downstream tasks typically perform computation over the consumed records. For example, IoT analytics performs aggregations, detects outliers, updates database views, or runs ML algorithms [20, 26, 49]. Real-time search platforms [54] incrementally update multiple indexes (e.g., document, columnar) as new data is ingested [14, 19]. Similarly, high-speed trading computes online aggregations and runs regression to predict expected profit and loss [42].

Current shared logs incur high delivery latencies and only after this delay, can downstream computations start, increasing e2e latencies. Given that high delivery latency stems from global ordering, we observe that if the shared log predicts global positions and delivers records earlier, downstream computation can start based on the speculated order. This allows the shared log's global coordination and downstream computation to be overlapped. That is, by the time the processing completes, the shared log could have determined the actual order after global coordination. If the predicted order matches the actual one, then applications realize low e2e latency.

Based on this observation, we propose the SpecLog abstraction. SpecLog offers a similar interface to today's shared logs [29] as shown in Figure 2. Applications can append records at a shard of their choice, subscribe[†] to records starting from a position (optionally filtering based on a predicate), and trim the log. The only difference is that when a record is delivered for a position, a bit indicates whether or not the position is speculative. If speculative, SpecLog will later confirm or fail the speculation. Applications require little changes to work with SpecLog's interface. First, applications must wait until they receive the confirmation before externalizing outputs (e.g., trigger alerts). Next, if downstream tasks perform state updates, they must roll them back if speculation fails.

SpecLog's idea can benefit any shared-log architecture, even order-first ones. However, our focus is on today's durability-first logs that offer elasticity, flexibility, and scalability because applications require these properties in addition to low e2e latency. Figure 3 shows how SpecLog would reduce e2e latencies in such durability-first shared logs. In SpecLog, once the records are durable, the shards predict their order (***P***) and deliver them to downstream tasks, which begin processing. Shards continue to process appends the same way as existing logs: they coordinate with the sequencing layer in a batched manner (***B***) to determine the actual order. Once the actual global cut is determined (***C***), SpecLog checks if the predicted order matches the actual one (***CO***). If the prediction is correct, SpecLog sends a confirmation; otherwise, the speculation fails and records are supplied in the correct order.

Properties. SpecLog reduces e2e latency compared to today's shared logs regardless of compute time. However, the extent of benefit depends upon how big or small the compute time is. Intuitively, SpecLog offers the most benefit when global ordering and computation effectively overlap; in other cases, SpecLog still offers lower e2e latencies. SpecLog preserves the seamless elasticity, flexibility, and scalability of today's shared logs. First, in SpecLog, clients still flexibly choose shards to write records. This, in turn, allows SpecLog to add or remove shards seamlessly without any downtime [29]. Finally,

[†]SpecLog can also support a read API, but the applications we target prefer subscribe because it enables them to consume records at the earliest.

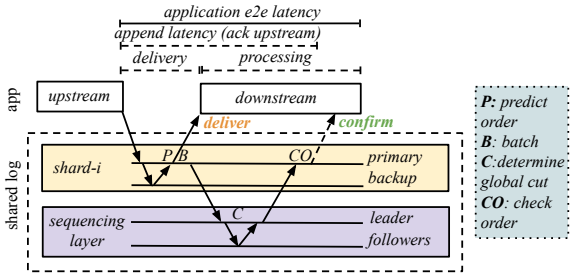

Figure 3: **Delivery and E2E Latency in SpecLog.**

because appends are batched at the shards which then contact the sequencing layer periodically, SpecLog would scale well.

3.2 Fix-Ante Ordering

SpecLog can lead to low e2e latencies only when the shards can correctly predict the position of their records. Unfortunately, making such correct predictions is difficult in durability-first shared-log designs. We observe that the *free-will* nature of reports is what makes correct predictions hard.

To understand this, consider Scalog with three shards S_1, S_2, and S_3. Suppose, initially, S_1, S_2, and S_3 report 2, 3, and 2 durable records to the sequencing layer, respectively. As a result, the sequencing layer would produce the global cut $\langle 2,3,2\rangle$. Scalog uses a deterministic, lexicographic scheme to assign order, where records in lower-numbered shards go before records in higher-numbered shards [29]. Thus, from the global cut, shards would assign positions to their local records as $S_1 : [1,2], S_2 : [3,4,5], S_3 : [6,7]$. One approach to predict the positions for subsequent records is to use the information from the previous cut (that S_1, S_2, and S_3 sent 2, 3, and 2 records, respectively). If such a scheme is used, S_2 would predict that its next local record would get position 10 (because it anticipates that S_1 would report 2 records and thus positions 8 and 9 would go to S_1). However, in the next report, S_1 *could* report 3 records (because it has the free-will to do so); thus, S_2's next local record will actually be assigned position 11 (not 10), making S_2's prediction incorrect.

Fix-ante Ordering Insight. Fix-ante ordering, in contrast, enables shards to accurately predict the positions of their records. The main idea behind fix-ante ordering is to *predetermine* in advance the global order and make the shards *adhere* to this order. Fix-ante order is a sequence of predetermined global cuts that the system is expected to produce. Each cut dictates how many records shards must include in their reports, which we refer to as the shards' quotas. Shards then adhere by exactly meeting their quotas in each report. The key insight is that, because each shard knows that the other shards will report precisely the number of records dictated by their quotas, each shard can accurately predict the positions of its records in the total order before global coordination. We make this idea more concrete below.

Predetermined Cuts, Quotas, and Predictions. The fix-ante order is specified as a sequence of predetermined global cuts $P_1, P_2, P_3, P_4 \ldots$ that the shards know beforehand. The i^{th} predetermined cut is given by $P_i : \langle d_{i1}, d_{i2}, d_{i3} \ldots d_{in}\rangle$, where d_{ij} is the expected number of durable records at shard j as of the i^{th} cut and n is the number of shards. The quota for a shard j to satisfy the i^{th} predetermined cut, q_{ij}, is the exact amount of new records that shard j must make durable and include in its i^{th} report. That is, $q_{ij} = d_{ij} - d_{(i-1)j}$.

Given this, the shards predict positions of their local records in the total order as follows. Intuitively, the positions for the j^{th} shard for the i^{th} cut will start after all the positions covered by the $(i-1)^{th}$ cut and the quotas for all the shards that precede j in the i^{th} cut[†]. Precisely, the predicted positions for the j^{th} shard for the i^{th} cut will be $[S+1, \ldots, E]$, where $S = \sum_{k=1}^{n} d_{(i-1)k} + \sum_{k<j} q_{ik}$ and $E = S + q_{ij}$.

As an example, consider the predetermined cuts for three shards S_1, S_2, and S_3 to be $\langle 1,2,2\rangle$, $\langle 2,4,4\rangle$, $\langle 3,6,6\rangle$ and so on. In this simple example, the quotas remain constant for all cuts with S_1, S_2, and S_3 having a quota of 1, 2, and 2, respectively. Given this, S_1, S_2, and S_3 would predict their record positions for the first cut to be $[1]$, $[2,3]$, and $[4,5]$, respectively. For the second cut, they would predict the positions of their subsequent records as $[6]$, $[7,8]$, and $[9,10]$, and so on.

Although SpecLog shards predict the positions based on fix-ante order, it does *not* mean that order comes before durability in fix-ante ordering. The system still determines the *actual* order by coordinating with the sequencing layer after durability. Determining the actual order is required because, in rare cases (as we describe below), shards may not be able to meet their quotas. To know the actual order, like in other durability-first logs, SpecLog shards periodically report to the sequencing layer the number of records they have made durable. The sequencing layer then sends the actual cut. As long as the shards adhere to their quotas, the actual cuts sent by the sequencing layer will match the predetermined cuts.

Adhering to Quotas and Fix-ante Order. Can shards always adhere to quotas? Fortunately, shards in SpecLog can adhere to their quotas except in rare cases. During normal operation, three cases are possible when a shard tries to meet its quota. First, the shard could have received from clients and made durable precisely the number of records as its quota; in this case, the shard naturally meets the quota and so simply reports all records. Second, a shard could have received and made durable fewer records than its quota. In this case, it adds *no-op* records to satisfy the quota; no-op records are ignored by downstream consumers. Third, a shard could have made durable more records than its quota. In this case, the shard delays the additional records to the next report.

Even when a few shard replicas fail, the shard can keeping meeting its quota; this is because shards are fault tolerant [16, 29, 43] as they internally use primary-backup replication [21] or Paxos [40]. Only in the very rare case where an entire shard fails or if no replica within the shard can contact the sequencing layer, the shard will not be able to adhere to

[†]This is because, SpecLog uses the same lexicographic procedure as Scalog to assign positions across shards from cuts.

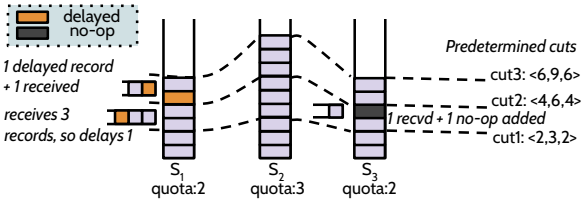

Figure 4: **Adhering to the Fix-ante Ordering.**

its quota and thus the actual cut will be different from the predetermined cut, making the predictions incorrect. While SpecLog loses some performance under such cases, it still preserves correctness by failing the speculation.

Figure 4 shows how shards can meet their quotas, which enables correct speculations. In this example, the predetermined cuts are $\langle 2,3,2\rangle$, $\langle 4,6,4\rangle$, $\langle 6,9,6\rangle$ and so on, and the shards S_1, S_2, and S_3 have a constant quota of 2, 3, and 2, respectively. As shown in the figure, initially, S_1, S_2, and S_3 have received and made durable 2, 3, and 2 records, respectively, allowing them to meet the quota by simply reporting all records. Next, S_1, S_2, and S_3 have received 3, 2, and 1 records, respectively. To meet its quota, S_1 delays one record to the next report (the orange record); similarly, S_3 adheres to its quota by adding one no-op record (the gray record). S_2 can thus accurately predict that its next local record will be assigned a global position of 10 because it knows that positions 8 and 9 would go to S_1 based on the predetermined cuts. This is in contrast to the free-will nature of reports in today's shared log, which makes correct predictions hard (as we described earlier).

While each shard adheres to its quota, the sequencing layer waits to receive reports from all the shards to ensure that the entire system followed the fix-ante order. Only when it knows that they have collectively adhered to the predetermined cut P_i; can the sequencer send the corresponding actual cut A_i. In the above example, suppose in the second report, the sequencer only received reports from S_1 and S_3 and has not heard from S_2. Then, it cannot send the second actual cut. If it sends the actual cut now, it would be $\langle 4,3,4\rangle$ instead of the predetermined cut $\langle 4,6,4\rangle$, which would make the predictions wrong. Thus, to match the predetermined cut, the sequencer waits until it knows that the shards have adhered to their quotas. Note that if any shards have a quota of 0 for a predetermined cut, then the sequencing layer does not wait for those shards. If the sequencer finds that it did not receive a report from a shard for a long duration (e.g., due to a failure), the sequencing layer will determine the actual cut based on the received reports; in such a case, the actual cut will be different from the predetermined one, which will be handled as a misspeculation.

Append Linearizability. With fix-ante order, although the cuts are predetermined, appends still *cannot* be acknowledged without coordinating with the sequencing layer; acknowledging appends before that will violate linearizability. Consider a scenario with two shards S_1 and S_2, and the first predetermined cut $\langle 1,1\rangle$. Suppose an append B happens at shard S_2

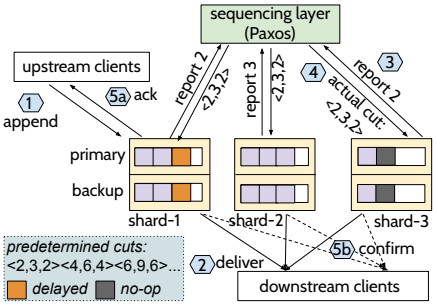

Figure 5: **Belfast Overview, Append and Delivery Path.**

(which will be assigned position 2 according to the predetermined cut). Assume that the system *incorrectly* acknowledges the append right away. Now, it is possible for another append A to start after this and be written to S_1, which will be assigned global position 1 (again according to the cut). Such ordering violates linearizability because A follows B in real time but is assigned a position before B in the total order. Thus, even with predetermined cuts, SpecLog waits for the actual cuts from the sequencing layer before acknowledging appends. In the above example, append B will be acknowledged only after receiving the actual global cut from the sequencing layer; the same cut will also cover append A, essentially making A and B concurrent, thus preserving linearizability.

Implication of Waiting to Satisfy Fix-ante Order. In Scalog, shards send however many records they have made durable at a fixed periodic interval. Also, Scalog's sequencing layer determines and sends the global cut at periodic intervals by including whichever shards have reported in that interval. Fix-ante ordering changes this behavior to keep the predictions correct. First, shards only report after they meet their quotas. Also, the sequencing layer sends the actual global cut after it waits for the shards to adhere to the corresponding predetermined cut. Thus, when shards do not report in a timely manner (e.g., because shards do not have enough records or are simply slow), it delays the actual global cut from the sequencing layer. Thus, fix-ante ordering in its original form (described thus far) will incur overhead in append latencies and the time to confirm the speculations. We next describe how with careful techniques, a system that uses fix-ante ordering, can alleviate this issue.

4 Belfast Design and Implementation

Belfast is an implementation of the SpecLog abstraction and fix-ante ordering. Although fix-ante ordering provides a basic framework for predictions, Belfast must ensure high performance under realistic settings, while enabling accurate predictions. We first describe Belfast's basic operation (§4.1), then how it addresses performance challenges (§4.2-§4.7), and finally how it handles failures (§4.8).

4.1 Basic Operation

Architecture. Figure 5 shows Belfast's architecture. Like Scalog, Belfast has a set of shards, a sequencing layer, and

clients. Each Belfast shard runs standard primary-backup replication [21] and is therefore fault-tolerant. The sequencing layer is a Paxos [40] group that determines actual global cuts and makes them fault-tolerant. Upstream clients can append records to shards of their choice and downstream clients subscribe to receive records from the shards.

Append Path. Figure 5 shows Belfast's append and record delivery path. The append path is similar to that of Scalog but has two differences. Like Scalog, clients first write records to shards, which then make the records durable (step-1). In Scalog, the shards contact the sequencer every *ordering interval* (T_{ord}), which enables them to batch and report many records. Belfast also does the same (step-3). The first difference is that Belfast shards adhere to quotas dictated by the predetermined cuts when reporting to the sequencer; the shards adhere by either reporting all new records, filling in no-ops, or delaying records. The second difference is how Belfast determines the *actual* global cut. In Scalog, the sequencer determines the global cut once roughly every T_{ord}, including the records of whichever shards have reported in that interval. In contrast, Belfast's sequencing layer sends the i^{th} actual global cut only when it knows that the shards have adhered up to the i^{th} predetermined cut (step-4). Finally, the upstream clients are acknowledged (step-5a).

Delivery Path. In Scalog, shards deliver records only after receiving the global cut (i.e., after step-4). In contrast, in Belfast, shards deliver records once they are durable by predicting their positions using the predetermined cuts without waiting to contact the sequencer (step-2). Once a shard receives the actual global cut (after steps 3 and 4), it checks if the actual cut matches the predetermined cut. If so, it sends a confirmation (step 5b); otherwise, it fails the speculation for the delivered records, after which the downstream clients would rollback and recompute based on the correct order.

4.2 Rate-based Quotas

A key factor that affects Belfast's performance is the shards' quotas. A shard's quota must be "right-sized". If too high, many no-ops will be added leading to extra work; if too low, many records will be delayed to subsequent reports, increasing the append and confirmation latencies for delayed records.

Belfast addresses this problem by predetermining cuts in such a way that the quotas match the shards' ingestion rates. With such rate-based quotas, each shard can naturally meet its quota in every report. That is, a shard will receive from clients and make durable roughly the same number of records as its quota every T_{ord}. However, even with a stable ingestion rate, there could be variations and thus the shard could have received and made durable more or fewer records than its quota. Belfast handles this by delaying records to subsequent reports or filling no-ops.

Rate-based quotas work well when rates are roughly stable and if shards are never added or removed. However, in reality, shards could experience bursts or drops in rates. The rates could also increase or decrease more permanently. Shards could be added or removed to meet dynamic application demands. Finally, a shard could be straggling, affecting the append and confirmation latencies for other shards. In the rest of this section, we describe how Belfast handles these problems, and importantly, how it does so without any misspeculation, preserving the e2e latency benefits of fix-ante ordering.

4.3 Handling Bursts and Drops via Lag Fix

When a shard experiences a burst, if the additional records in the burst are delayed to the subsequent ordering intervals, then it may take several intervals to drain the burst. This will increase the append and confirmation latencies for those records. Thus, instead of delaying additional records to subsequent intervals, Belfast shards report to the sequencing layer *immediately* once its quota is met. With this, in the normal case, when the rate is stable, a shard would report roughly once per T_{ord}. However, during a burst, the shard will send many reports in one ordering interval, draining the burst.

Such high-frequency reports alone, however, do not ensure that the requests in the burst can be acknowledged. This is because other shards would still be reporting once every T_{ord}, satisfying one predetermined cut every T_{ord}. Thus, the sequencing layer cannot send the actual cuts for the additional reports sent by the bursty shard. For example, if a bursty shard (say S_1) sends five reports while another shard (S_2) has sent one report, the sequencer can only send the first actual cut and cannot yet send the actual cuts for S_1's last four reports, delaying appends and confirmations of records in the burst.

To reduce the append and confirmation latencies, Belfast uses a *lag-fix* technique. Belfast first detects the burst at the sequencing layer by observing the high frequency of reports from a shard. It then realizes that the other shards are "lagging" and thus asks them to send more reports. The lagging shards then do so with client requests that they have and additionally filling no-ops as needed. This enables Belfast's sequencer to send the subsequent actual cuts. In the above example, once the sequencing layer informs S_2 about the lag and S_2 sends four additional reports, the next four actual cuts can be sent.

The lag-fix mechanism also helps Belfast handle sudden drops in ingestion rates. When a shard experiences a drop, it cannot meet its quota naturally. Although the shard will fill no-ops to meet the quota, doing so takes time because Belfast is conservative about filling no-ops (to minimize its overhead); this can result in delayed reports. Meanwhile, the other shards could have progressed more, causing this shard to lag behind. But fortunately, the lag-fix mechanism would instruct the shard to fill in no-ops immediately to satisfy many subsequent cuts and report them in one go; this helps the lagging shard quickly catch up with the rest of the system.

4.4 Speculation Lease Windows

The ingestion rate at a shard might change more permanently (for example, as clients join or leave). The mechanisms de-

scribed so far help Belfast handle slight variations and bursts. However, relying on them for long-term change will lead to performance overhead. In particular, if a long-term rate increase is handled by just high-frequency reports and lag fix, then it will introduce too many no-ops from the lagging shards; the sustained high frequency of reports will also increase the load on the sequencing layer. Similarly, a long-term rate decrease cannot just be handled by filling no-ops.

Thus, the system must periodically adjust predetermined cuts and quotas. Belfast's sequencing layer acts as a convenient place to do this because it can estimate the rates based on the frequency of reports. Further, since the shards periodically contact the sequencing layer, it can conveniently inform the shards of any changes in the cuts and quotas.

The key challenge is to change cuts without misspeculations. In particular, we must avoid cases where some shards use the old predetermined cuts, while others use the new cuts; if not misspeculations can arise. Suppose the current quotas for three shards S_1, S_2, and S_3 are 2, 3, and 2, respectively. Suppose the rate at S_1 increases, requiring a quota of 4. Assume the sequencer sets S_1's quota to 4 immediately after determining the first actual cut and sends the updated quota to the shards. However, based on the previous predetermined cuts, shard S_2 might have already delivered records for positions 10, 11, and 12 speculatively. But, with the new quota, S_1 would assign positions 8, 9, 10, and 11 to its records, which would lead to misspeculations in the predicted positions for S_2's records.

To avoid this problem, Belfast predetermines cuts and quotas for a *window*. All shards use the same predetermined cuts to make predictions within the window. Conceptually, the window is a *lease* on how long the shards can and must use the current predetermined cuts to make predictions. Belfast allows changes to predetermined cuts and quotas only at window boundaries. Thus, all shards uniformly use the new cuts and quotas after the current window ends.

Belfast realizes the speculation lease windows as follows. First, instead of time-based lease windows, Belfast measures windows in terms of number of predetermined cuts. That is, W cuts form a lease window. Shards can only speculate positions covered by W cuts. When the previous window nears completion, the sequencing layer informs shards of the predetermined cuts and quotas for the next window. In the previous example, S_1, S_2, and S_3, would move to the new cuts only when the current window ends. Thus, S_1 will not use the new quota of 4 in the current window and will do so only from the next window, preventing the above misspeculation.

Belfast determines the need for a quota change and the new quota as follows. When the ingestion rate increases (or decreases), a shard will report more (or less) frequently to the sequencing layer. The sequencing layer uses this change in frequency to detect the need for a quota change. Belfast decides the new quota in such a way that every shard, after the quota change, would report roughly once every T_{ord}.

4.5 Adding and Removing Shards Seamlessly

To meet the dynamic needs of applications, Belfast must be able to add and remove shards, and do so without misspeculations. The speculation window mechanism described above provides a good substrate to achieve this goal. The idea is that shards can be added or removed only at the speculation window boundaries. The sequencing layer decides the new quota assignments in the new window and the predetermined cuts will now include the newly added shard or exclude the removed shard. The only difference from Scalog's seamless elasticity is that shards must wait till the current speculation window to end to join or leave. However, window sizes are sufficiently small, such operations need not wait for long.

In Belfast, when a shard wishes to leave or join, it sends a request to the sequencing layer. A leaving shard waits until the current window is over and keeps meeting its quota until then. A joining shard can demand a quota, which the sequencing layer uses to determine the cuts for the new window with the shard included; eventually, the quota is adjusted appropriately.

4.6 Mitigating Straggler Shards

Belfast's mechanisms can help lagging shards catch up with the rest of the system. However, a shard could be slow for reasons other than it not being able to meet its quota. For example, the network could delay the reports or the reporting thread could be de-scheduled for a long time. Belfast must handle such straggler shards; otherwise appends and confirmations for records at other shards will be delayed.

Belfast mitigates straggler shards by first detecting them at the sequencer and then assigning their quotas to be zero in the next speculation window, similar to the quota-change mechanism. In the new window, the other shards can make progress without waiting for the straggler. In the next window, the straggler shard is given a small non-zero quota to see if it can meet it in a timely manner. If it is able to meet, the sequencer can ramp up the quota; otherwise, the shard is not given quotas for the subsequent windows.

4.7 Reducing Latencies with Many Shards

Rate-based quotas, no-op filling, and lag fixes help reduce append and confirmation latencies despite waiting for all shards to adhere to a predetermined cut. However, with a large number of shards, if Belfast assigns quotas for all shards in all cuts, then the possibility of actual cuts getting delayed because of a few slow shards becomes high.

However, the basic fix-ante ordering framework does *not* necessitate that all shards must report for all cuts. That is, the predetermined cuts could be set such that some shards don't have to report records for a cut to be satisfied (i.e., their quota can be 0 in that cut). The sequencer waits only for reports from those shards that have a non-zero quota before it sends the actual cut. Belfast leverages this fundamental property of fix-ante ordering to keep latencies lower with many shards. The idea is to "stagger" the cuts, where the sequencing layer

waits only for reports from a subset of shards to satisfy a cut and waits for different subsets in different cuts.

Belfast's current implementation realizes this idea via a simple strategy, where shards are grouped into g groups. The predetermined cuts are fixed such that the i^{th} cut waits for only shards in group $i \bmod g$. This enables the sequencer to send the actual cuts without waiting for all shards but only a subset for every cut, which reduces append and confirmation latencies. More sophisticated policies can be used to stagger the cuts (e.g., by assigning groups in a more dynamic manner); we leave such policies to future work.

4.8 Failure Handling

Belfast retains Scalog's behavior under sequencing-replica failures: the system is unaffected by follower failures but correctly remains unavailable until re-election if the primary fails. Each storage shard is internally replicated and thus can mask up to f failures. Belfast shards use primary-backup; a consensus group can also be used. Thus, Belfast remains unaffected in the presence of shard-internal failures as well.

Belfast's operation, however, is affected when the shard *as a whole* experiences a failure. This is a very rare scenario in practice, that can occur when more than f replicas within a shard crash or get partitioned, rendering the shard incapable of masking internal failures. Belfast handles whole-shard failures via a *view-change* protocol. Belfast's sequencing layer triggers a view change when it suspects a shard has failed (i.e., the shard is unresponsive to the sequencing layer's lag-fix instruction). During normal operation, Belfast stamps all speculatively delivered records, actual cuts, and confirmations with the view number. For correctness during whole-shard failures, any records speculatively delivered in the old view for which confirmations are pending must be failed.

We call the last position covered by the latest actual cut sent in the old view the *confirmed-gp*; intuitively, records for positions that precede confirmed-gp will not change. On a view change, Belfast fails speculations for all positions after confirmed-gp and informs the clients of the same. Clients rollback their computation up to the confirmed-gp and then re-consume records from the confirmed-gp and recompute.

To avoid re-sending the records from other alive shards or reassigning their positions, Belfast optimizes the above procedure. Instead of excluding a failed shard, S_F, immediately, Belfast fills the log slots that belong to S_F with no-ops for the remainder of the current window. The sequencer assigns this responsibility to an alive shard S_A. With this, speculations for all positions after *confirmed-gp* are failed and clients still rollback. The only change is that the earlier delivered records from other shards and their positions are retained at the clients' buffers; S_A then only delivers no-ops for positions belonging to S_F. S_A also makes durable and includes these no-ops in its reports. This helps all the shards make progress and eventually these positions will be confirmed. In the next window, S_F is excluded and S_A no longer needs to fill no-ops. Note that S_F will stop receiving actual cuts from the sequencing layer and so it will not be able to confirm or acknowledge records for the positions for which S_A filled no-ops. Shard S_A is also responsible for delivering failure notifications and mis-speculations to clients on behalf of S_F. Since all shards are made aware of S_F and S_A from the sequencer through the actual cuts, clients that were only connected to S_F will eventually timeout waiting for confirmations and get re-routed to shard S_A to receive the no-ops and confirmations. The client-side failure handling logic, including the timeout and re-routing, is hidden within the client library.

```
// compute thread state
var lastCompIdx uint64 // last computed log index

func HandleFailSpec(k uint64) {
    pauseCompute()
    for i := lastCompIdx; i > k; i-- {
        undoStateChange(i)
    }
    lastCompIdx = min(k, lastCompIdx)
    resumeCompute()
}
```

Figure 6: **Application Rollback**

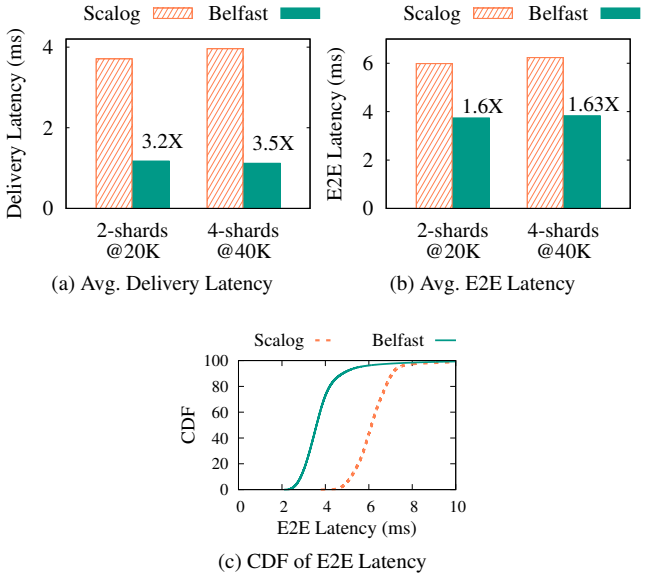
4.9 Implementation

We implemented Belfast by modifying open-source Scalog [7]. Our code is publicly available [8]. We introduce only one additional RPC for shards to register with the sequencer and join a Belfast cluster, while all other mechanisms, such as lag-fix and quota change, are realized by piggybacking onto existing RPCs (reports and cuts). Belfast makes all control information (e.g., quotas) also fault tolerant at the sequencer (without extra Paxos rounds). We set the window size to 100 cuts and ordering interval (T_{ord}) to 1ms. We turn on staggered cuts when we have more than 6 shards. To ensure progress, shards begin to fill no-ops to satisfy their quota after $1.5 \times T_{ord}$ since the last report. To minimize the overhead of no-ops, we coalesce consecutive no-ops in the shard-internal log into one on-disk entry and one message for replication; thus, shards can efficiently fill many no-ops.

5 Applications

We built three applications atop SpecLog to demonstrate its viability. These applications run atop conventional shared logs and can be ported to SpecLog's interface with minimal changes. The applications differ in sharding policies, downstream computations, and rollback actions.

IoT Intrusion Detection. Upstream sensors ingest readings into the shared log; different groups of sensors ingest values into different shards. There are many downstream tasks, one per shard. Each task calculates moving statistics, stores them in a local database, and raises alerts if they exceed a threshold value (hinting an intrusion). The cross-shard ordering helps establish the order of intrusion events across sensor groups. With Belfast, a downstream task speculatively calculates the statistics and writes them to a database, but waits for confir-



mation before it can raise an alert. If the speculation fails, tasks revert their database writes and reset statistic values.

Fraud Monitoring. This application analyzes users' transactions to detect fraudulent activity. Each transaction is tagged with the originating user's id. Upstream components can ingest transactions into any shard (e.g., the nearest one). There are several downstream tasks, each handling a subset of user-ids. Unlike the previous application, here, each downstream task consumes records from all shards but filters records based on a predicate (user-id). Each task examines if a transaction amount exceeds a threshold to raise alerts. The reader also updates a local database with the running statistics for each user and reverts this state if the speculation fails.

High-Frequency Trading. This application predicts the relationships between stocks based on their prices, which are then used to create pair-trading strategies. Upstream components update the real-time prices of stocks. Appenders can append to any shard or map stock-ids to shards. Downstream tasks subscribe to different stock-ids to receive live price data. Even if incoming data is sharded by stock-id, global ordering across shards is required, as downstream tasks must know the order of price changes across stocks. Downstream tasks predict price relationships via online linear regression. Stock prices are used to update the weights of the model in batches. These intermediate weights are stored in a database to create trading strategies. For rolling back, downstream tasks delete the stored weights, recompute them, and insert the new weights.

Porting Applications to Belfast. For porting applications, Belfast prescribes a few simple guidelines. Firstly, the application must wait for confirmation before externalizing outputs or taking actions. For example, the high-frequency trading application must not execute trades or take decisions based on unconfirmed results. Similarly, the fraud monitoring application cannot flag a transaction as fraudulent until it receives confirmations. Secondly, to deal with mis-speculations, applications have to maintain in-memory state of unconfirmed changes made to the application state in-order to correctly implement rollbacks. This in-memory state is small as there are only a few computed but unconfirmed records at any time. For example, in the fraud-monitoring application, each transaction updates a few rows of the user statistics database, therefore, for each unconfirmed application state change, the in-memory state contains the list of updated rows and their old states.

Implementing these guidelines require minimal changes to the application code for existing shared logs. This primarily includes a thread subscribing to the speculation confirmation or failure callbacks from Belfast and marking unconfirmed results as ready, or performing rollbacks respectively. On receiving a `fail_spec(k)`, the thread pauses compute, undoes the state changes for unconfirmed modifications beyond index `k` and instructs the compute thread to resume from that point onwards. The code snippet in Figure 6 shows how rollbacks are typically implemented with Belfast.

(c) CDF of E2E Latency

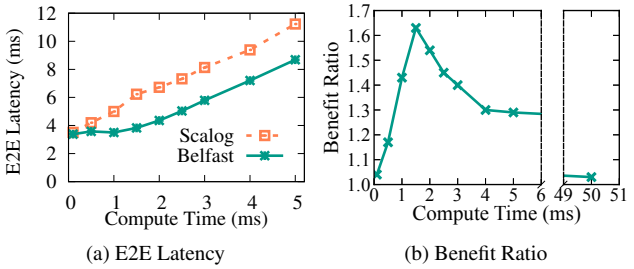

Figure 7: **Delivery and E2E Latency**

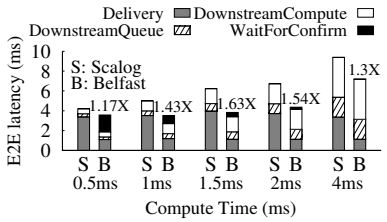
6 Evaluation



Our evaluation answers the following questions:

- What are the e2e latency benefits of Belfast? (§6.1)
- How do the benefits vary with computation time? (§6.2)
- What are the overheads in append latency? (§6.3)
- How does lag-fix help Belfast with bursts? (§6.4)
- How does Belfast adapt to rate changes? (§6.5)
- How does the speculation lease window size affect Belfast? (§6.6)
- Does Belfast enable seamless elasticity like Scalog? (§6.7)
- Does Belfast scale with shards while maintaining low latencies? (§6.8)
- Does Belfast effectively handle stragglers? (§6.9)
- Do real-world applications benefit from Belfast? (§6.10)
- What is the impact of failures on applications with Belfast? (§6.11)

Setup. We run our experiments on a CloudLab cluster. Each machine has an Intel 10-Core E5-2640v4 CPU, 64GB DRAM, a 25Gb ConnectX-4 NIC, and a SATA SSD. Belfast's sequencing layer has one leader and two followers. Each shard has one primary and one backup. Our main baseline is Scalog; in some experiments, we also compare against variants of Belfast. In Belfast, only the shard primary contacts the sequencer, reporting durable records; further, the reports adhere to the fix-ante ordering. In the original Scalog implementation, both the shard primary and backup contact the sequencer, which then determines which records are durable; also, the shard servers report in a free-will manner. To correctly compare fix-ante ordering and the free-will nature, we modify Scalog so that only the primary reports durable records to the sequencer. In all experiments, we use 4KB records and calculate Belfast's throughput by including only actual records (because clients don't have throughput benefit from no-ops).

(a) E2E Latency (b) Benefit Ratio

(c) Latency Breakdown

Figure 8: **Compute Time vs. E2E Latency Benefits**

6.1 E2E Latency Benefits

We first demonstrate the fundamental benefit of early speculative delivery and fix-ante ordering. We run a workload where upstream clients ingest records and downstream clients consume and compute over them. For a batch of consumed records, computation takes 1.5ms on average. We run with 2 and 4 shards and compare the delivery and e2e latencies of Belfast and Scalog. As shown in Figure 7(a), Belfast delivers records 3.2×-3.5× earlier than Scalog; downstream computation thus can speculatively start. Because of fix-ante ordering, the speculated and the actual order of the delivered records match. Thus, as shown in 7(b), Belfast reduces average e2e latency by 1.6×; we also note improvements in p99 e2e latencies (1.4× and 1.17× with 2 and 4 shards). Figure 7(c) shows the e2e latency CDFs for Scalog and Belfast for 4 shards. In contrast, Scalog delivers records only after global ordering, leading to high delivery and e2e latencies.

6.2 Compute Time vs. E2E Latency

We next examine how compute time impacts e2e latency. We run the same experiment as above with 4 shards but vary the compute time. First, as shown in Figure 8(a), for all compute times, Belfast offers lower e2e latency than Scalog. However, as shown in 8(b), the benefit varies with compute time (e.g., 1.17× with 0.5ms but 1.63× with 1.5ms compute).

We show why benefits vary with compute time by breaking down the e2e latency (8(c)). In Scalog, e2e latency comprises the time to deliver (Delivery), the time records wait in a downstream queue before they are picked for processing (DownstreamQueue), and the compute time (DownstreamCompute). In Belfast, additionally, tasks may have to wait for the order to be confirmed (WaitForConfirm). First, when computation and coordination effectively overlap (e.g., with 1.5ms compute), Belfast offers the most benefit. Second, with shorter compute (e.g., 0.5ms), the benefits decrease, because, although Belfast delivers earlier, once compute finishes, it waits for a while for the order to be confirmed. Next, as compute increases, the wait time for confirmation reduces. However, when the compute is long (4ms), compute exceeds ordering time, reducing benefits. With very high compute times (50ms), the benefit ratio approaches 1. Overall, with all compute times, Belfast offers lower e2e latencies than Scalog; the benefit is maximized when compute and coordination overlap effectively.

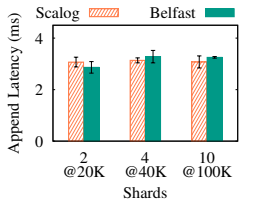
6.3 Append Latency

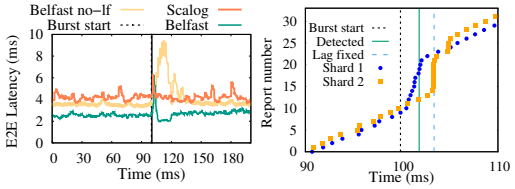
We now analyze Belfast's append latency. We run a workload with a few upstream clients and measure the append latency in Belfast and Scalog with 2, 4, and 10 shards. As shown in Figure 9, Belfast does incur an overhead compared to Scalog. This is due to the shards adhering to the quotas and the sequencing layer waiting to satisfy the predetermined cuts before it sends the actual cuts. However, mechanisms like rate-aware quotas, no-op filling, lag fix, and staggered cuts (for 10 shards as described in §4.9) help Belfast to keep this overhead to a minimum (5.8% with 10 shards). This is a small cost to pay for the significant reduction in e2e latencies, which is critical for many real-time applications (§2.3).

6.4 Handling Bursts with Lag-Fix

We now analyze how Belfast behaves under bursts and the efficacy of lag-fix. We run a workload with an average compute time of 0.8ms with two shards S_1 and S_2, and in the middle, introduce a burst of client requests on S_1 and measure e2e latencies. We compare Belfast against Scalog and a Belfast variant with lag-fix disabled (no-lf). As shown in Figure 10(a), first, Belfast's e2e latency is lower than Scalog throughout. Second, lag-fix generally helps maintain low e2e latencies by constantly fixing lagging shards. Third, lag-fix alleviates the effect of bursts notably. When the burst starts, in no-lf, even though S_1 reports more frequently, S_2 lags behind, delaying confirmations and thus leading to high e2e latencies. The lag persists even after the burst ends. In Belfast, while there is a small increase in latencies when the burst starts (which is also seen in Scalog), lag-fix kicks in, which helps S_2 to catch up and thus reduce latency. Figure 10(b) illustrates the lag-fix behavior by showing the timing of reports in Belfast. Once burst starts, S_1 reports more frequently (blue circles); Belfast detects S_2's lag and asks it to send more reports. S_2 does so (orange squares), resolving the lag.

Dealing with High Burstiness. As seen above, the lag-fix mechanism helps Belfast handle small bursts, drops and variability well. However, repeated bursts could cause many lag-fixes which can increase the load on the sequencing layer and affect client latencies. In such high-burstiness scenarios, Belfast can adopt a couple of techniques to remain performant. One approach is for the sequencing layer to detect such scenarios (based on the frequency of reports) and transition the system into a "high-burstiness" mode, where shards are





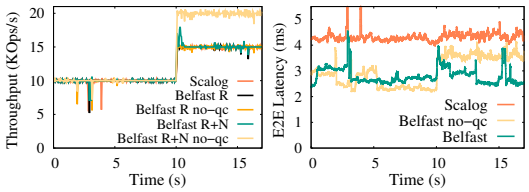


Figure 9: **Append Latencies**

(a) Throughput (b) E2E Latency

Figure 13: **Seamless Elasticity**

assigned quotas based on the peak of the bursts and are instructed to *proactively* fill no-ops to match the quota. Under extreme scenarios, Belfast could also dynamically turn-off fix-ante ordering and fall back to Scalog's mode of operation. We leave these approaches as an avenue for future work.

6.5 Changing Quotas Upon Rate Changes

We next examine Belfast's behavior under rate changes using the same setup as §6.4, but in the middle, we add sustained load to S_1, which increases its rate. We compare Belfast to Scalog and a variant with quota-changes disabled but lag-fix enabled (no-qc). Figure 11(a) shows the throughput. For Belfast and no-qc, R+N is the throughput that includes both actual records and no-ops, while R includes only actual records.

Initially, when the rates are stable, no-ops are minimal in both no-qc and Belfast, and they offer the same R and R+N throughput. However, when the rate increases at S_1, in no-qc, lag-fix kicks in, which makes S_2 fill in no-op records. In no-qc, S_1's quota is not changed and it keeps reporting more frequently to drain its "burst". As a result, S_2 keeps filling more no-ops (as can be seen from the higher R+N throughput for no-qc). In contrast, although initially Belfast fills no-ops (due to lag-fix), it quickly adjusts the quota for S_1 and thus S_2 doesn't fill many no-ops; thus, the no-op throughout comes down, keeping R+N close to R[†]. We also noted that in no-qc, the sequencer load was about 2× higher than in Belfast (because of its sustained high-frequency reports). Also, throughout, Belfast's throughput (R) matches Scalog's.

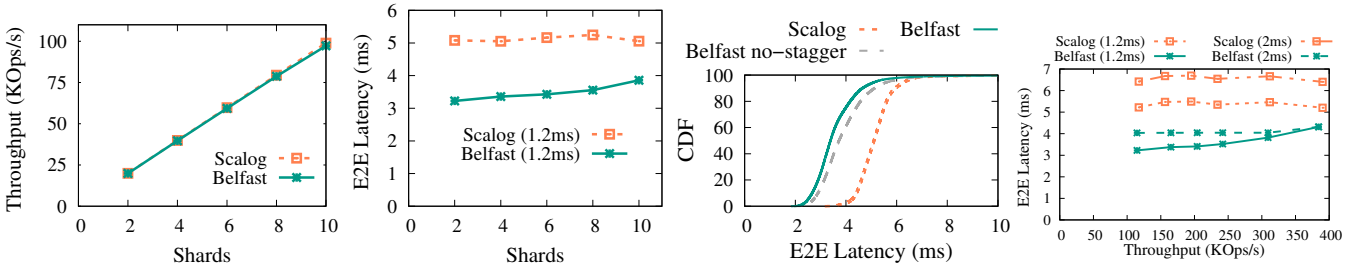

Figure 11(b) shows the e2e latency. Initially, both no-qc and Belfast offer the same e2e latency. However, after the rate change, no-qc suffers from higher e2e latencies because it takes a while to detect the lag and fill no-ops. In contrast, Belfast by changing the quota of S_1 to match its rate, avoids this overhead, leading to lower e2e latencies. Throughout, both Belfast and no-qc offer lower e2e latencies than Scalog.

[†]In all experiments, we noted no-ops added little overhead ($N/R < 5\%$).

6.6 Impact of Speculation Lease Window

We next examine the impact of the speculation lease window size on Belfast. We run a stable workload with 2 shards at 20K throughput at 1.5ms compute with varying sizes for the speculation lease window. As shown in Figure 12, very low window sizes impact both e2e and append latencies. With low window sizes, Belfast incurs frequent synchronization costs where the shards are blocked waiting for the sequencing layer to provide the quota for the next lease window. For instance, we observe that with a window size of 5, the shards spend about an entire ordering interval (T_{ord}) at the end of each lease window waiting for the next quota.

A large lease window size reduces the synchronization cost significantly (∼0.07% of T_{ord} at window size 100), however, Belfast is slower to react. For instance, at 10K throughput per shard, each shard reports 10 records on average every T_{ord}. Due to a transient drop, the ordering layer could assign a quota of 9 to a shard, leaving it in an undesirable state where the incoming rate exceeds the quota assigned for a very large window. This consequently affects client latencies. Furthermore, with a large lease window size, Belfast would also be slower to react to long term rate changes, incurring frequent lagfixes (approximating the behaviour of the no-qc variant in Figure 11). We see that a window size of 100 achieves a good balance and works well for us. In all cases, the e2e latency remains well under the 5.9ms value (see Figure 7(b)) for Scalog under the same workload.

(a) Throughput (b) E2E Latency (c) E2E CDF (10-shards) (d) Emulation Latency vs. Throughput

Figure 14: **Throughput and Latency vs. Shards**

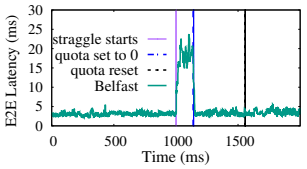

Figure 15: **Straggler Mitigation**

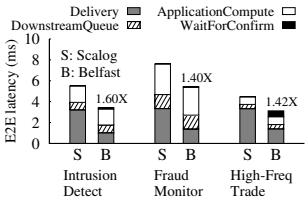

Figure 16: **Applications**

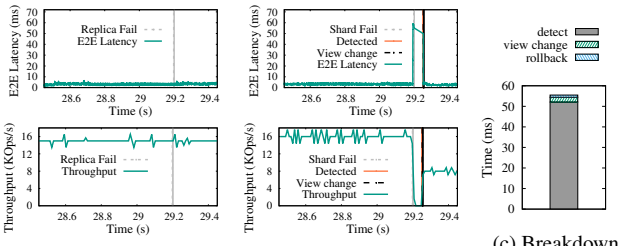
6.7 Seamless Elasticity

We next answer if Belfast offers elasticity without any downtime like Scalog. We also examine if Belfast can do so without causing misspeculations, thus continuing to offer low e2e latency as shards are added and removed. We run an experiment with two shards initially, add two shards on the fly, and then remove them. Figure 13 shows the throughput and e2e latency.

First, as shown in 13(a), when shards are added or removed, Belfast, like Scalog, has no downtime and no drop in throughput. The only difference is that records from the new shards are included only after the current speculation window ends, thus the throughput increase comes a bit late. The close-up shows this: Belfast's throughput increase is delayed but only slightly (< 100ms). Belfast also removes shards without downtime. Next, as shown in 13(b), Belfast offers lower e2e latency than Scalog even as shards are added and removed. This is because Belfast adds or removes shards at window boundaries, which prevents misspeculations, keeping e2e latencies low.

6.8 Throughput and Latency vs. Shards

We next analyze if Belfast can scale throughput with shards like Scalog while offering lower e2e latencies (with 1.2ms compute). As shown in Figure 14(a), Belfast, like Scalog, increases throughput with shards. Next, as shown in 14(b), it does so while offering lower e2e latencies than Scalog (1.66× and 1.4× with 2 and 10 shards). This is also evident from the e2e latency distribution for 10 shards in 14(c). 14(c) also shows the effect of staggered cuts, which helps Belfast to send actual cuts without waiting for all shards; as shown, staggered cuts improve latencies compared to the no-stagger variant.



To evaluate scalability beyond 10 shards, we build an emulation framework similar to Scalog [29]. The framework retains the sequencer and shard protocol, but the shards are emulated. Emulated shards report records at the same throughput and latency as real shards but do not receive actual records from clients. Client perceived latency is obtained by adding a delta measured from the real system to latencies measured at the emulated shards. To measure e2e latency, along with the compute, we add the time spent in the downstream queue as obtained in the real experiments. As seen in 14(d), Belfast's throughput scales similarly to Scalog's upto 40 shards. For compute of 1.2ms, Belfast's e2e latencies show a slope as they are limited by the confirmation latencies. For higher compute (2ms), Belfast is at a constant offset from Scalog. In all cases, e2e latency benefits are retained even at 40 shards.

6.9 Mitigating Straggler Shards

We now examine if Belfast can mitigate straggler shards effectively. In the middle of a workload, we inject delays into one shard, which significantly delays its reports. Figure 15 shows the e2e latency. When the shard starts to straggle, e2e latency temporarily goes high. Once the shard repeatedly sends significantly delayed reports, Belfast's sequencer sets the quota of the straggler shard to be zero for the next five windows, and therefore the actual cuts can be sent without waiting for the straggler, which reduces e2e latencies. Eventually, the straggler's quota is reset, and since we remove the injected delay at this point, low e2e latency is maintained.

6.10 Benefits for End Applications

We now evaluate the applications from §5. In all applications, several upstream components ingest data and downstream tasks subscribe to shards according to the application's sharding policy (described in §5) and compute over the consumed records. We run atop Scalog and Belfast, and measure application e2e latencies. As shown in Figure 16, IoT intrusion detection attains the maximum benefit. The breakdown shows that the average compute time for a batch of consumed records in this application is around 1.4ms, which enables almost the entire computation to be overlapped with shared log's coordination. The benefits are less pronounced in fraud monitoring and high-frequency trading which have an average compute time of 2.2ms and 800us, respectively. Thus, in fraud-monitoring, confirmation arrives before computation finishes,

(a) Shard Internal Failure (b) Shard Failure (c) Breakdown

Figure 17: **Application under Failure**

while, in HFT, downstream tasks wait for confirmation.

6.11 Application Behavior under Failures

Sequencing-replica failures do not change the behavior of Belfast compared to Scalog. We thus evaluate the fraud-monitoring application under two shard failure scenarios; shard-replica failures and whole shard failures. We run the shard-replica failure experiment with 3-way replicated shards ($f = 1$) and kill a shard replica in the middle of the run. Figure 17(a) shows that the throughput and e2e latency remain unaffected as the shard internally masks the failure. In the second experiment, we run 2-way replicated shards and fail the *entire shard* in the middle of the run. This scenario triggers misspeculations, which the application handles by performing rollbacks (see §5). As shown in Figure 17(a), e2e latency increases after the shard fails as misspeculations arise. However, once the view is changed and an alive shard fills no-ops on behalf of the failed shard (§4.8), the latency becomes low again. Similar behavior can also be seen with throughput. The breakdown in Figure 17(c) shows that detecting the failure takes up the most time between failure and recovery. More importantly, the time spent by the application to rollback, i.e., undo the state changes and resume is marginal.

7 Related Work

Shared Logs. Corfu [16, 17] cannot seamlessly reconfigure or flexibly place data, and has limited scalability. vCorfu [63] offers flexible placement for readers but still has the other problems. While Scalog [29], Boki [36], and FlexLog [32] address the above problems via a durability-first design, they do not enable low e2e latency, a critical need for applications. Our work is the first to build a shared log that enables low e2e latencies (while preserving the other properties). While we focus on durability-first logs given their desirable properties, Corfu-like logs also suffer from high e2e latencies. SpecLog's idea could enable such logs to offer low e2e latencies as well; specifically, such a system can allow clients to speculatively read ordered but non-durable records from the shard primary.

LazyLog [43], a recent shared log abstraction, reduces *append* latencies by avoiding eager ordering upon appends. However, LazyLog makes a crucial assumption that most reads are decoupled in time from the appends. For the class of applications we target, this assumption does not hold since records are consumed as soon as they are ingested. Furthermore, LazyLog enforces ordering before reads and therefore *does not* allow records to be delivered to downstream consumers before ordering completes. In contrast, SpecLog allows record delivery even before ordering is established and hides this cost by overlapping ordering with downstream computation. As a result, unlike SpecLog, the LazyLog abstraction does not fundamentally help reduce e2e latencies which will always include the cost of ordering.

Prior work [47] reduces subscription latency in pub-sub [30] systems; however, it does not build upon total-order shared logs or reduce e2e latencies.

Speculative Execution. Many distributed systems use speculation in other contexts like consensus [48], replicated stores [33], blockchains [23], BFT [39, 65], distributed file systems [45], transactions [57], atomic broadcast [38], and MapReduce [22]. However, our work is the first to offer a speculative interface for today's total-order shared logs to overlap their expensive coordination with application computation. More importantly, our work shows how to accurately speculate positions via a novel fix-ante ordering scheme.

Pre-partitioning in Consensus. Protocols like Mencius [44, 64] overcome Paxos' leader bottleneck by statically partitioning the consensus log across replicas. Each replica proposes client commands or special *skip* commands (i.e., no-ops) in its slots. While Belfast bears some similarity to these protocols (predetermining slots, filling no-ops), it differs in key ways. First, although Belfast's fix-ante cuts effectively pre-partition the shared log, these cuts are *speculative* in nature (unlike in Mencius). Second, Mencius's pre-partitioning is for replicas within a shard, whereas fix-ante ordering predetermines an expected total order across many shards. Our work also differs in context and purpose: Mencius-like systems pre-partition the log to overcome the leader bottleneck in consensus, whereas Belfast predetermines shared-log slots to enable speculative delivery for low e2e latency in durability-first shared logs.

8 Conclusion

Today's shared logs incur high delivery latency and thus cannot enable low e2e latency, a critical need for applications. SpecLog, a new shared-log abstraction, speculatively delivers records, thus overlapping computation and coordination. Fix-ante ordering enables SpecLog to accurately speculate positions before global ordering. We build Belfast based on these ideas and show that it enables low e2e latencies for applications without sacrificing today's shared logs' properties.

Abstract

Large language model (LLM) training is one of the most demanding distributed computations today, often requiring thousands of GPUs with frequent synchronization across machines. Such a workload pattern makes it susceptible to stragglers, where the training can be stalled by few slow workers. At ByteDance we find stragglers are not trivially always caused by hardware failures, but can arise from multiple complex factors. This work aims to present a comprehensive study on the straggler issues in LLM training, using a five-month trace collected from our ByteDance LLM training cluster. The core methodology is what-if analysis that simulates the scenario without any stragglers and contrasts with the actual case. We use this method to study the following questions: (1) how often do stragglers affect training jobs, and what effect do they have on job performance; (2) do stragglers exhibit temporal or spatial patterns; and (3) what are the potential root causes for stragglers?

1 Introduction

Large-language models (LLMs) have been widely adopted and are being used for a variety of tasks. In response to their adoption, many companies are focused on training ever-larger models because empirically an increase in model size has been shown to improve task accuracy. For example, in little more than a year, Meta has moved from the 65 billion parameter Llama-1 model to the 405 billion parameter Llama-3 model. Training these large models in a reasonable time requires using resources, including GPUs and memory, distributed across several thousand servers in a cluster. However, unlike previous distributed parallel data processing workloads such as MapReduce, distributed LLM training requires frequent synchronization and tighter coordination. Consequently, slow workers or *stragglers* can significantly hurt training time and resource efficiency. This paper seeks to answer the question *do stragglers actually pose a serious performance issue in real-world large-scale LLM training deployment?*

The impact of stragglers in LLM training is dictated by the parallelization strategy used to distribute LLM training across a cluster. A typical LLM training job uses a hybrid parallelism strategy that combines multiple parallism strategies, including pipeline parallelism (PP) [12, 19, 29] and data parallelism (DP) [32] to partition state and computation across servers. All of these strategies require frequent coordination to synchronize results across GPUs and servers, and are thus vulnerable to stragglers. A microbatch that is delayed due to a straggler in a PP stage can slow down the entire training batch in DP. Further, few approaches exist to mitigate the effect of stragglers in LLM training: traditional straggler-mitigation approaches [1–3] that rely on backup workers assume infrequent synchronization and would significantly hurt training performance and resource requirements for LLM training jobs. On the other hand, approaches that use asynchronous SGD [9] or drop updates from slow workers [15] change training behavior, and are not widely adopted due to concerns about their effect on model accuracy.

Given that LLM training jobs are vulnerable to stragglers, we set out to understand their effect on real-world LLM training clusters. To do so we analyzed traces collected from the LLM training cluster at ByteDance over a five-month period from January to May 2024 (§3.1). Our analysis seeks to address the following questions:

- How often do stragglers affect training jobs? What effect do they have on training job performance?
- Do stragglers exhibit temporal or spatial patterns? For example, do they appear in most or only a few steps of a training job? Are they confined to a few workers or more widespread across workers?
- What are the potential root causes for stragglers? What is the relative severity of different root causes?

We answer these questions using "what-if" analysis (§3.2): we estimate how a training job would perform if all (or a subset) of stragglers had not occurred. To do so, we identify the *dependency model* within a training job's traced operations, and then perform a simulation based on each operation's non-straggling execution time to quantify job-completion time in the absence of stragglers.

Our analysis revealed that stragglers are widespread and

have notable performance impacts on LLM training; 42.5% of the jobs are at least 10% slower due to stragglers. At the tail, stragglers can result in jobs wasting 45% of their allocated resources (§4.1). Most steps incur similar slowdowns within a straggling job, suggesting that they are often not caused by transient environmental issues but are rather caused by persistent problems (§4.2). Our analysis further shows that stragglers are more commonly caused by a slowdown in computation operations rather than communication operations (§4.3). We did not notice a positive correlation between job size and its straggler-related slowdown, suggesting factors other than job size play a dominant role in straggling (§4.4).

Coupling simulation-based analysis with manual inspection, we investigate several root causes for straggling. We found that hardware or software problems in a server were not a significant cause of the stragglers we observed (§5.1). On the other hand, imbalance in how work was partitioned across pipeline stages (§5.2), an imbalance in sequence lengths included in each microbatch (§5.3), and pauses induced by the garbage collector (§5.4) were responsible for many of the stragglers we observed. We summarize the key observations and their implications in §5.6.

Our analysis pipeline also suggests an approach to make it easier to detect and debug stragglers when a training job is running. As a result, we incorporated portions of our analysis pipeline into a monitoring system called *SMon* (§8) that is now deployed in the training cluster at ByteDance. SMon partially automates the manual analysis we report on in this paper, and is used by the on-call team at ByteDance to detect and address stragglers in important jobs.

2 Background

We start by providing background on distributed LLM training and sources of stragglers.

2.1 Hybrid-Parallel Training and Stragglers

Several different strategies have been developed to parallelize LLM training to overcome memory limitations and reduce training time. Each parallelization strategy is susceptible to stragglers. Below, we introduce the strategies used in our cluster and the sources of stragglers. We describe each strategy in terms of how computation and memory are partitioned across *workers*, a term we use to refer to a single GPU and a process (running on the CPU) that controls it.

Data parallelism (DP), ZeRO [32] and fully sharded data parallelism (FSDP [44]) DP partitions training data across multiple workers, each of which has a replica of the entire model. When DP is used, in each training step, a worker is assigned a training batch. The worker runs forward and backward computation for its assigned batch, and then all workers perform a gradient all-reduce step before moving to the next training step. The gradient all-reduce step requires synchronization between workers, and a slow worker can cause all workers to stall, leading to stragglers. ZeRO [32] and

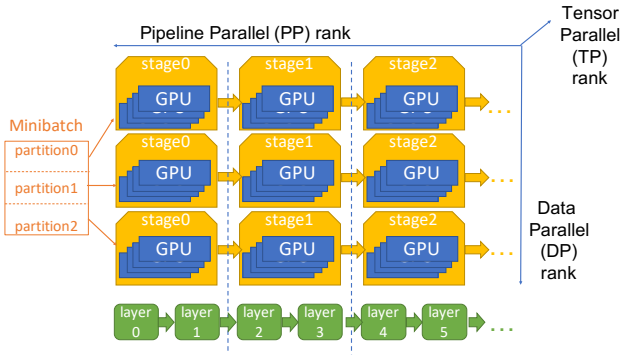

Figure 1: *Rank topology of a DP-PP-TP parallelism.*

FSDP [44] extend DP to reduce the per-GPU memory demand by partitioning the optimizer state, parameters, and/or gradients across workers. Instead of using a gradient all-reduce step, both ZeRO and FSDP require a reduce-scatter step that computes gradients, a device-local parameter update step, and an all-gather step to collect parameters for each training step. The reduce-scatter and all-gather steps require synchronization across workers, and are thus similarly susceptible to stragglers.

Pipeline parallelism (PP). PP partitions the model across multiple workers, each of which holds a disjoint set of consecutive model layers, referred to as a *pipeline stage*. PP reduces the per-GPU memory demand for model weights and activations. During training, a batch of data is split into several microbatches, and training is pipelined through PP stages. Several microbatch scheduling approaches have been proposed, including GPipe [19], 1F1B [12], and virtual pipeline parallelism (VPP) [29]. All of these scheduling approaches assume that computation is evenly partitioned across pipeline stages, and aim to minimize *pipeline bubbles*, *i.e.,* times when a pipeline stage is idle waiting for data from the previous stage. If PP stages are not evenly partitioned, the slowest stage stalls other stages and becomes a performance bottleneck. Thus, PP is susceptible to straggling due to uneven compute partitioning between PP stages. For ease of exposition, we do not explicitly discuss VPP, but our analysis does account for it.

Tensor parallelism (TP) and context parallelism (CP). In addition to PP, one can use Tensor (TP) [23, 29] and context (CP) [11, 26, 35] parallelism to further reduce the per-GPU memory demand. TP partitions each layer's weight between workers, and CP partitions each sequence's tokens across workers. Both require a synchronization step after each transformer layer so that partial results from all workers in the TP or CP group can be aggregated. As a slow device can stall progress during synchronization, both TP and CP are susceptible to stragglers. As we discuss in §7, we do not analyze systematic stragglers in the TP and CP groups.

Hybrid parallelism. In practice, LLM training uses a hybrid strategy that combines all of the parallelism strategies discussed above and provides better performance than any in-

dividual strategy.[1] When hybrid parallelism is used, workers can be organized into a hypercube, where each dimension corresponds to one parallelism strategy. A worker's coordinate provides its *rank* (*e.g.,* pipeline stage) in each parallelism dimension. Workers are also assigned a unique *global-rank* for identification. Figure 1 shows an example worker topology with DP-PP-TP parallel training.

Training with hybrid parallelism operates in a layered fashion. For example, when DP-PP-TP parallelism is used, workers with the same DP rank are grouped into a single PP group, which is responsible for computing gradients for a training batch. Inside each PP group, workers with the same PP rank are grouped into a TP group, each of which is responsible for a single PP stage. Finally, workers within the same TP group use TP parallelism to compute each layer in the PP stage.

The case of straggling for hybrid-parallelism. Hybrid-parallelism is affected by stragglers appearing in any of the parallelism strategies that it combines. For example, in the DP-PP-TP parallelism strategy, a slow TP worker will slow down the PP rank to which it belongs, leading to a PP bubble. This PP bubble, in turn, will slow down the entire DP rank to which the worker belongs, delaying gradient synchronization and stalling other DP ranks.

2.2 Goals and Challenges

Straggler definition. An LLM training job that uses hybrid parallelism is straggler-free if all workers take the same amount of time to complete their assigned work. This minimizes the time required for synchronization, resulting in an ideal straggler-free scenario that achieves the best possible performance. We also note that, by this fairly broad definition of straggling, a worker lagging behind others for any reason is considered a straggler. These reasons can include not only hardware issues that deterministically affect one single worker, but also unpredictable stalls that affect all workers uniformly (*e.g.,* garbage collection that prevents a task from making progress [22, 38]), as well as workload imbalance due to data skew [31, 43] or poor workload partitioning across weights (*e.g.,* PP stage) [11].

Our goal. In this paper, we want to investigate how straggling impacts real-world LLM training jobs and to unearth some of the underlying root causes. To do so, we seek to quantify *how much an actual LLM training job's speed differs from that of some ideal straggler-free case*. In keeping with our earlier definition, a straggling worker is one that completes its work more slowly than others. Thus, in the presence of stragglers, a job is delayed by its need to synchronize across groups of workers, resulting in a slower speed compared to the ideal straggler-free scenario.

Our study is based on analyzing traces from LLM training jobs collected over a five-month period. Although these traces capture each job's actual execution time, estimating the corresponding straggler-free completion time remains challenging. This is because it is tricky to assess straggling operations' impact on the overall job duration in the presence of overlapping execution. Traditional critical path analysis [5] falls short in this context, as highly parallel and homogeneous workloads like LLM training can exhibit many similarly critical paths. Focusing on a single path can lead to misleading conclusions, as shown in Coz [8]. To address this, we instead use trace-based simulation to "execute" each job on an alternative timeline where straggling operations are brought in line with their peers.

[1] Other parallelisms such as expert parallelism (EP) [24] also exist but are not used in the jobs that we analyze.

3 Methodology

In this section, we describe the traces used for our study and our methodology for analyzing them.

3.1 The LLM Training Job Traces

The cluster setup. The cluster on which the traces have been collected is dedicated for training and shared internally by multiple teams. The machines used in the cluster have a similar hardware configuration as NVIDIA's DGX servers: each server is equipped with eight GPUs interconnected with NVLink or PCIe links, four or eight NICs with hundreds of Gbps bandwidth, a separate NIC used for storage and management, a few hundred CPU cores and a few TBs of memory. Servers are interconnected through high-performance switches configured in a three-layer CLOS topology. The network is overprovisioned and carefully tuned [22] to ensure that there are no slowdowns due to network congestion.

Multiple jobs can be scheduled to run on the cluster at the same time, with each job having exclusive use of its allocated GPUs for the duration of the job. The scheduler ensures that each job uses homogeneous hardware by allocating it the same type of GPUs. Furthermore, the scheduler performs the GPU allocation in a best-effort manner to ensure a job's GPUs are close together in the network topology. Since large jobs request GPUs in multiples of eight, different large jobs do not share the same server machine. Combined with the lack of network congestion, this means we do not see stragglers due to resource contention despite jobs running on the same cluster.

Trace collection. The traces used in our study are collected from LLM pretraining jobs submitted during the time period from 2024/01/01 to 2024/05/31. As our study focuses on large jobs, we only use traces for jobs that use at least 128 GPUs. We also discard traces that are invalid or not suitable for analysis as detailed in §7. This produces 3079 jobs for our analysis. These jobs contain both dense and mixture-of-experts (MoE) models that are configured to train using either short or long context sequences. Of the 3079 jobs, 31.7% use $\geq$ 256 GPUs, 18.3% use $\geq$ 512 GPUs, and 3.6% use $\geq$ 5000 GPUs. In total, the analyzed jobs cover around half of the total GPU-hours among all LLM training jobs.

	Type of Operation	Description
Compute Op.	forward-compute	Forward computation done for a microbatch for a PP stage.
	backward-compute	Backward propagation done for a microbatch for a PP stage.
PP-specific communication Op.	forward-send, forward-recv	P2P communication between PP stages for a microbatch on the forward pass.
	backward-send, backward-recv	P2P communication between PP stages for a microbatch on the backward pass.
DP-specific communication Op.	params-sync	Collective communication (all-gather) among all DP ranks for a given PP stage to retrieve the stage's weights prior to the first microbatch's forward-compute.
	grads-sync	Collective communication (reduce-scatter) among all DB ranks for a given PP stage to aggregate the stage's gradients after the last microbatch's backward-compute.

Table 1: *Types of operations traced by NDTimeline and their description.*

All jobs in our traces are done using customized versions [22] of the open-source distributed LLM training system, Megatron-LM [28]. The jobs are configured to use different combinations of the parallelization strategies supported by Megatron-LM including DP, PP, TP and CP. [2]

The Megatron-LM based training system has been instrumented with our in-house profiling tool *NDTimeline* [20]. By default, it samples 10% of the training steps (aka iterations) of a job for profiling. For each profiled step, the tool records the start and end time of a set of operations that are deemed important, including those performing forward and backward computation as well as those performing communication. Table 1 gives all the profiled *operation types* and their description. A profiled forward or backward compute operation consists of many GPU kernels in order to reduce the cost of tracking many small computation kernels. NDTimeline periodically synchronizes the clocks of all machines for a job, thereby allowing us to align related operations across different machines for the purpose of what-if analysis (§3.2).

For each operation in the trace, its logged entry contains the operation type, its start and end timestamps as well as a set of metadata including the training step ID, the microbatch ID, the PP rank (within each PP group) and the DP rank (within the overall DP group). These metadata enable us to reconstruct the operation dependencies which are necessary in order to simulate an alternative timeline had stragglers not been present (§3.2).

3.2 Simulator for What-if Analysis

The goal of the what-if analysis is to assess the impact of stragglers by answering the following questions:

1. *how long would a job take if all stragglers were absent?*
2. *how long would a job take if all except for a certain group of stragglers were absent?*

To answer these questions, we simulate an alternative timeline without stragglers. The main insight is that comparable operations would have the same duration in the absence of stragglers. Based on this insight, we first try to estimate the duration of each operation in the alternative straggler-free scenario. Then, we simulate an alternative timeline in which operations launch according to their dependencies and complete within their estimated idealized durations. By comparing the simulated job completion time (JCT) to that of the actual trace, we can assess the impact of stragglers.

Estimate idealized operation durations for straggler-free scenarios. Conceptually, we can organize the traced operations into a multi-dimensional tensor with four dimensions: training step, microbatch, PP rank and DP rank. Let's refer to this tensor as an *OpDuration* tensor. We have one such tensor for each operation type in Table 1. For compute operations, the elements in the tensor are simply the corresponding operation duration in the trace. For communication, we calculate a sub-part of the traced duration called *transfer-duration*. As communication is done as part of a collective (or a P2P pair), the traced duration of an individual operation is affected by two factors: 1) the amount of time to transfer the data to another rank, aka the "transfer-duration". 2) the amount of time to wait for the other operations in the collective (or P2P pair) to start, aka the "blocking-duration". Of the two factors, "transfer-duration" is intrinsic to the collective operation while the "blocking-duration" is determined by operation scheduling. Therefore, we only store the "transfer-durations" in the *OpDuration* for a communication operation type, e.g. *params-sync*, *forward-send* etc. To estimate an operation's "transfer-duration", we take the maximum start time among all of its peer operations in the same collective (or the same P2P pair) and subtract it from its end time.

All operations of the same type handle the same workload, implying that, in the absence of stragglers, all elements of the idealized *OpDuration* tensor would be equal. To assess the impact of a particular group of stragglers—such as those specific to a machine with PP-rank p and DP-rank d—we selectively "fix" straggling on all other machines by overriding the duration of operations on those machines with their idealized values. For those elements belonging to the straggling machine (aka OpDuration[:,:,p,d]), we keep their original durations. We adopt a similar approach (in §5) to estimate the effect of only fixing some straggling elements: we use idealized operation times only for the elements that need to be fixed, and leave the others unchanged.

[2] CP in our traces uses an in-house implementation with a slightly different algorithm than the CP in open-source Megatron-LM.

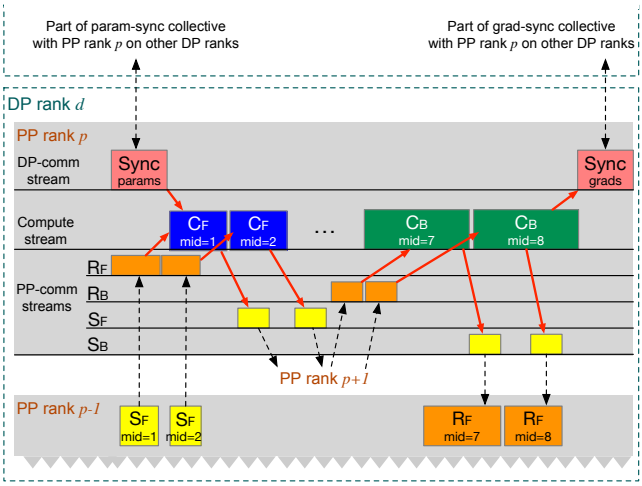

Figure 2: *The dependency model used in simulation. "mid" denotes microbatch ID. Operations within a stream execute sequentially. Across streams on the same rank, receive operations (e.g., R_F, $Sync_{params}$) precede the corresponding compute operation requiring the data. The opposite dependencies exist for compute and send operations. Across DP ranks, params-sync ($Sync_{params}$) and grads-sync ($Sync_{grads}$) on the same PP rank form a collective group. Across two adjacent PP ranks, their send and receive operations form a P2P pair.*

Once we determine the parts of *OpDuration* tensor that should have the same idealized values in a hypothetical straggler-free setup, the question remains what that value should be. We use different methods for computation and communication operations. For the computation operation, we use the average value across the group of elements to be equalized. For communication operations, we use median instead of average. Initially, we used average for both types of operations, but changed our solution after some manual root cause investigation. In particular, we observe that computational straggling arises predominantly due to workload partitioning imbalance. Therefore, taking the average makes sense as doing so amounts to workload re-balancing. On the other hand, communication operations have identical transfer volumes across different training steps, microbatches, PP ranks and DP ranks, but they straggle due to external issues like switch/NIC flapping. Furthermore, the affected operations tend to be very long, which significantly skews the average value and makes median a better choice.

Extract operation dependencies. Our simulator requires two pieces of input: the idealized operations durations and the operation dependency model. We have previously discussed how to estimate idealized operation duration. Next, we will explain the simulator's dependency model, which is derived from the Megatron-LM based training system in use.

In this dependency model, each worker runs several "streams" to execute its operations. All operations scheduled to run on a single stream execute sequentially, while operations across streams execute concurrently as long as their dependencies are satisfied. More concretely, each worker has a stream executing all forward and backward compute operations, a stream executing all DP-specific communication operations and four streams each executing a different type of PP-specific communication operations: forward-recv (R_F), backward-recv (R_B), forward-send (S_F) and backward-send (S_B), as shown in Figure 2. The dependencies among operations are as follows:

- *Same stream dependency:* Operations inside a stream are sorted according to their launch time in the trace. We assume an implicit dependency between adjacent operations since operations on the same stream execute sequentially.
- *DP communication and compute dependency:* The first microbatch's forward-compute operation at each PP stage should happen after the corresponding params-sync collective communication to fetch that stage's parameters, as shown in Figure 2 ($Sync_{params} \rightarrow C_{F,mid=1}$). The parameters are cached locally and used for subsequent microbatches. The gradients computed for different microbatches are locally accumulated and then aggregated across DP ranks. Thus, the last microbatch's backward-compute should happen before the grads-sync collective communication to aggregate the gradients of that PP stage across DP ranks, as shown in Figure 2 ($C_{B,mid=8} \rightarrow Sync_{grads}$).
- *PP communication and compute dependency:* Except for the first PP rank, the forward- and backward-compute operation of a microbatch on PP rank p must start after the completion of that microbatch's forward- and backward-receive communication operation on the same GPU, as shown in Figure 2 (e.g. $R_{F,mid=1} \rightarrow C_{F,mid=1}$, $R_{B,mid=7} \rightarrow C_{B,mid=7}$). Similarly, except for the last PP rank, the forward- and backward-send operation of a microbatch on PP rank p must start after the completion of that microbatch's forward- and backward-compute operation on the same GPU, as shown in Figure 2 (e.g. $C_{F,mid=1} \rightarrow S_{F,mid=1}$, $C_{B,mid=7} \rightarrow S_{B,mid=7}$).
- *Cross-rank communication dependencies:* The DP communication operations (aka params-sync, grads-sync) for a given microbatch form a collective group among all DP ranks with the same PP rank. Similarly, the PP send and receive operations for a given microbatch form a pair between adjacent PP ranks with the same DP rank. The dependency model for a group of collective (or P2P) operations is that no individual operation can start its data transfer until all operations have been launched.

Simulate an alternative timeline. Using the dependency model and idealized durations, we can simulate an alternative execution timeline using the following rules:

- The simulator launches an operation as soon as all of its dependent operations finish. In other words, an operation's start time is calculated as the maximum end time of its dependent operations.
- A computation operation after launch is immediately

marked as finished with end time calculated as the start time plus the corresponding operation duration in *OpDuration*.

- For each communication operation, the simulator waits for all its peer operations in the same collective group (or P2P pair) to launch. An operation's end time is calculated as the maximum launch time among the group plus the corresponding transfer-duration stored in *OpDuration*.

3.3 Metrics for Straggler-related Slowdown and GPU Waste

Now that we have designed a simulator to estimate a job's completion time in alternative straggler-free timelines, what metrics should we calculate to quantify the impact of stragglers? Let us use T_{ideal} to denote the JCT without stragglers. Similar to [31], to account for errors introduced from simulation, we also simulate the original timeline using unmodified operation durations and denote the resulting JCT as T. The simulation errors are relatively small and reported in §6. Furthermore, a small number of our traces had large simulation errors, and to ensure analysis fidelity, we discard traces with simulation error $\geq 5\%$ (§6). To quantify straggler-related performance slowdown, we calculate the slowdown metric S as a ratio:

$$S \triangleq T/T_{ideal}. \tag{1}$$

In addition to the overall straggler-related slowdown, we also want to quantify slowdowns due to straggling in different types of operations (Table 1). To do so, we first compute the *operation-type slowdown* S_t for each operation-type t as

$$S_t \triangleq T_{ideal}^{-t}/T_{ideal}. \tag{2}$$

where T_{ideal} is the ideal JCT computed as described above, and T_{ideal}^{-t} is the JCT when elements in *OpDuration* for operation-type t are not fixed.

In our cluster, a job has exclusive access to a GPU for its entire duration. As a result, an increase in job completion time (or a slowdown) can be directly translated to the amount of GPU-hours wasted by the job. Concretely, we estimate a job's *resource waste* as the percentage of GPU-hours wasted using the equation:

$$\frac{T - T_{ideal}}{T} = 1 - \frac{1}{S}. \tag{3}$$

Similarly, we can calculate wasted resources due to different operations types by computing $1 - 1/S_t$.

4 Impact of Stragglers

We perform simulation-based what-if analysis on the job traces and report the impacts of stragglers on our cluster.

4.1 Stragglers are prevalent and cause non-negligible resource waste.

Figure 3 plots the cumulative distribution function (CDF) of the resource waste percentage among all jobs. We observe that

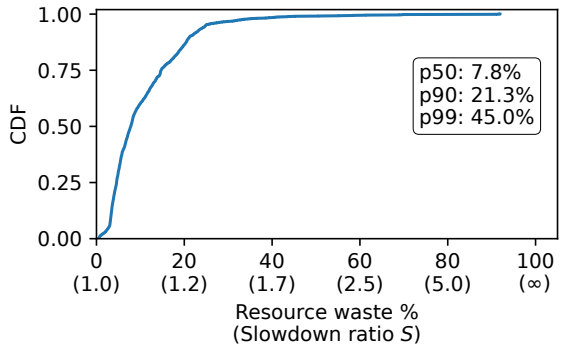

Figure 3: *CDF of resource waste among all jobs. A given waste percentage's corresponding slowdown ratio is shown in parentheses.*

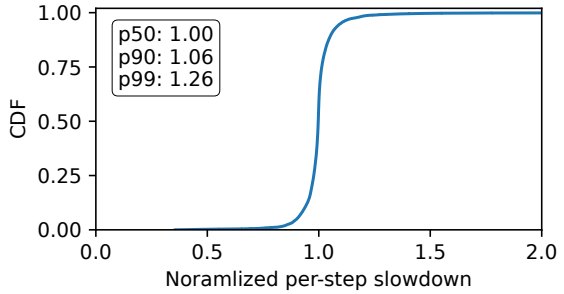

Figure 4: *CDF of per-step slowdowns normalized by job slowdown for 15 randomly selected steps from each straggling job.*

42.5% of the training jobs that we trace straggle. Furthermore, because of stragglers, $> 10\%$ of the jobs waste at least 21.3% of the GPU-hours it is allocated, while $\sim 1\%$ jobs waste at least 45.0% of its allocated GPUs. Across all our traces we found that 10.4% of the allocated GPU hours are wasted due to stragglers.

We also investigated jobs with large slowdowns ($S > 3$), and found that all of them were large jobs, where fewer than 3% of the workers were responsible for the problem. Furthermore, in most cases, the slow operations were performing computation, rather than communication. From this, we hypothesize that server problems (which could be problems with the hardware or misconfiguration) are generally to blame for these problems.

4.2 Steps have similar slowdowns in a straggling job.

Next, we investigate whether a few really slow steps or most steps contribute to a straggling job's slowdown. We refer to a job as straggling if it has a significant slowdown ratio $S > 1.1$. To do so, we define a step's slowdown as the ratio of the step's execution time to the ideal step execution time (*i.e.*, $\frac{T_{ideal}}{n}$ for a job with n training steps). Figure 4 shows the CDF of per-step slowdown normalized by the job's overall slowdown ratio. We observe that the median step has a normalized slowdown of 1.0, and even the 90th percentile step has a normalized slowdown of only 1.06. This indicates that most steps have a slowdown similar to the job's overall slowdown, suggesting

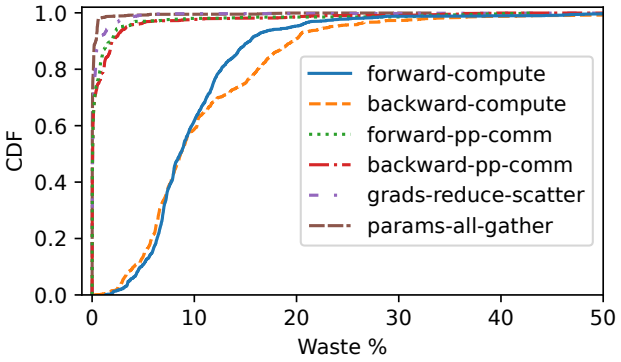

Figure 5: *Resource wasted due to the slowdown of a single type of operation. Computation slowdown caused the most resource waste, while communication had a minimal impact.*

that stragglers are not caused by temporary environmental factors but by more persistent problems. This result also implies that it is sufficient and cost-effective to sample a few training steps to profile stragglers.

4.3 Which operation types are to blame for straggling?

Figure 5 shows the fraction of resource waste by each operation type across all jobs in our traces. In our traces, communication time measures time spent transferring data, and thus a slowdown in send times produces a corresponding slowdown in receive times. As a result, we group both together in the figure. Contrary to the observation in FALCON [41] we find that most slowdowns are caused by computation operations, as opposed to communication. This is owing to our ample network bandwidth, the use of dedicated LLM-training clusters, and several in-house network optimizations and tunings [22].

Figure 5 also shows that PP-level communication has a slightly higher impact than the DP-level communication operations. This matches our expectation since DP-level communication is overlapped by a lot and can tolerate more slowdowns than PP-level communication kernels, many of which happen in the warmup and cooldown phases, which are on the critical path of a training step.

4.4 How does job size correlate with straggling?

Surprisingly, we do not observe an obvious positive correlation between the slowdown and job size. This suggests that job size is not the determining factor of straggling, and other factors like the model type or human factors may play a more important role. For instance, very large jobs are usually babysat by our on-call team and optimized better than others. Therefore, their slowdowns are not necessarily worse than those for smaller jobs. As another example, long-context jobs are observed to suffer more from stragglers (§5.3), but they typically have smaller job sizes, which when mixed with other models biased the result towards the opposite job size and slowdown correlation.

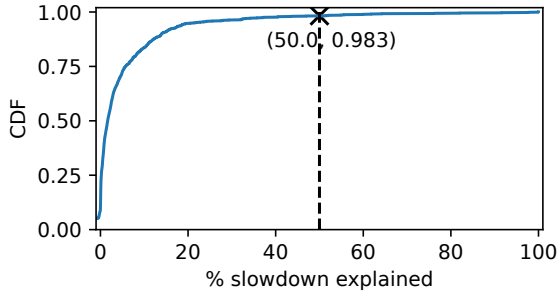

Figure 6: *CDF for M_W, the performance recovered after fixing the slowest 3% of workers, normalized by the performance recovered after fixing all workers. Observe that the slowest 3% of workers do not contribute significantly to the observed slowdown for most jobs.*

5 Root Causes

In this section, we analyze the traces to diagnose the root causes of stragglers. Our analysis focuses on straggling jobs, aka those with slowdown $S \geq 1.1$. Identifying the root cause of a job slowdown requires manual examination, and thus we cannot investigate all possible root causes. Instead, we focus on common root causes, i.e., ones that are either likely to cause stragglers or are commonly to blame in our setting. We start by looking at whether faulty hardware (or software) in one (or a few) workers is to blame (§5.1) Next, we discuss three common root causes in our cluster: imbalance in how computation is partitioned across pipeline stages (§5.2), imbalance in the length of sequences in each microbatch (§5.3), and stalls during garbage collection (§5.4). Finally, in §5.5, we briefly describe two interesting, but uncommon causes of stragglers.

5.1 Are individual workers to blame?

We first analyze how many of the stragglers are due to hardware or software problems with workers. Because we run health-checks, we expect that only a small fraction of workers should exhibit any problems. Consequently, if a job is slow because of problems with a few workers then fixing the execution time of operations running on the problematic workers (by changing them to the ideal execution time) should suffice to fix the entire job's completion time.[3] We use this observation to measure the impact of problematic workers on straggling jobs.

We start by computing the slowdown attributed to each worker, using the same technique that we used in the previous section to estimate an operation's slowdown percent. Specifically, we define the slowdown S_w for worker w as

$$S_w \triangleq T_{ideal}^{-w} / T_{ideal}. \quad (4)$$

where T_{ideal}^{-w} is the job completion time (obtained from the

[3]Though one faulty machine with a network issue affecting DP communication will affect additional $DP_degree - 1$ workers participating in the same DP-communication, as shown in §4.3 slowdown of DP communication is not a major contributor to straggling jobs, and consequently we do not consider it.

simulator) when we only fix operations that were not executed on worker w, and T_{ideal} is the execution time when all operations are fixed.

Next, for each job, we select the set of workers W whose slowdowns S_w are the highest 3% of the job. If a small number of workers are problematic due to hardware (or software) problems, then W would contain those workers. We then compute the fraction of the job's slowdown that can be attributed to these workers, M_W

$$M_W = \frac{T - T^W_{ideal}}{T - T_{ideal}}, \tag{5}$$

where T is the simulated original step duration (without any stragglers being fixed), T^W_{ideal} is the simulated step duration when only operations running on the selected workers are fixed, and T_{ideal} is the ideal simulated step duration after all stragglers are fixed.

Computing M_W for large jobs (with thousands of workers) is expensive because it requires running thousands of simulations to compute S_w for each worker w. Therefore, we use an approximation to scale our analysis: rather than computing a slowdown for individual workers, we measure a slowdown for whole DP ranks and PP ranks. We then assign each worker the smaller (*i.e.,* minimum) of the slowdowns for the DP and PP ranks to which it belongs (as a reminder, any worker must belong to one DP rank and one PP rank). This allows us to reduce the number of simulations from *DP degree* $\times$ *PP degree* to *DP degree* $+$ *PP degree*, making computation feasible.

Figure 6 shows a CDF of M_W for straggling jobs. We observe that worker problems contribute to more than 50% of the observed slowdown for only 1.7% of straggling jobs. This leads us to conclude that problematic workers are not the dominant factor for a majority of the straggling jobs in our traces.

We further investigated the few cases where problematic workers were primarily responsible for job slowdowns, and found that they resulted in a much larger slowdown: slowdown for jobs with problematic workers is 3.04 compared to the average slowdown of 1.28.

5.2 Stage Partitioning Imbalance

In our traces, we observed that an imbalance between the computation performed by the last pipeline stage and other pipeline stages was a common cause of stragglers. The last pipeline stage needs to execute a loss layer, and in most cases, the loss layer requires more compute cycles than transformer layers (and embedding layers, which take negligible compute time) [11, 39]. Thus, it is easy for users to accidentally partition the model (e.g., by evenly dividing layers over pipeline stages) in a way that leads to the last stage requiring significantly more computation, which in turn leads to stragglers.

To verify that the loss layer took longer than the transformer layers, we ran a job with four pipeline stages, where each pipeline stage runs 9 transformer layers, and the last stage runs an additional loss layer. The PyTorch trace for this job shows that logit computation (in the last layer) is over 9 times longer than a transformer layer, and that as a result, forward-compute (backward-compute) of the last stage is 2.07 (1.41) times slower than an average stage's computation.

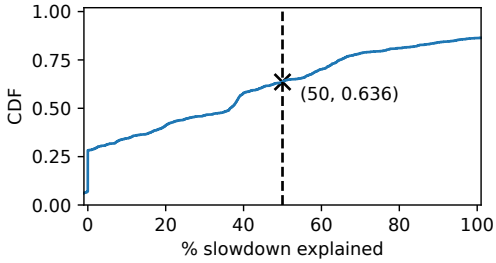

Figure 7: *CDF for M_S, the performance recovered after fixing all workers on the last PP stage, normalized by the performance recovered after fixing all workers. We set $M_S = 0$ for 21.1% of jobs not running PP. Observe that the last stage slowdown is a common straggler issue.*

We use a similar approach as in §5.1 to study the prevalence of this problem: we compute in simulation $T^{lastStage}_{ideal}$, the job's completion time if we only fix the execution time for operations in the last pipeline stage. Next, for each job that uses pipeline parallelism, we compute M_S, the contribution of the last stage as $M_S = (T - T^{lastStage}_{ideal})/(T - T_{ideal})$ (and we set $M_S = 0$ for the 21.1% of jobs that do not use pipeline parallelism).

Figure 7 shows the CDF of M_S's across jobs. We observe that for 39.3% of jobs, a majority of the job slowdown (*i.e.,* $M_S \geq 0.5$) is because of the last pipeline stage.

Next, we looked at whether this problem could be mitigated. We already use an approach similar to Llama 3 [11] to address this problem: we assign ε fewer layers to the last pipeline stage. However, we need to manually tune ε, and this has proven to be challenging for several reasons: First, when partitioning the model, we must assign an entire transformer layer to a pipeline stage, which limits how computation is split between pipeline stages; Second, the time taken by the loss layer (in proportion to the transformer layer) increases either if the vocabulary size grows, or if the maximum-sequence-length or the hidden layer size decreases. Larger ratios are likely to become more common as vocabulary size increases [34], and consequently, as others have also observed concurrently [42], this is going to increase the number of transformer layers that need to be executed in earlier pipeline stages to ensure that they take the same time as last stage. This in turn limits the number of pipeline stages that can be used for these models and leads to more layers in each virtual stage than desirable, limiting model parallelism. Consequently, even a good value of ε can result in suboptimal performance.

We also attempted to manually tune the number of layers in each pipeline stage for the job (with 9 transformer layers) that we discussed above, and we found that with manual partitioning we could get a speedup of 9.9%. However, even with

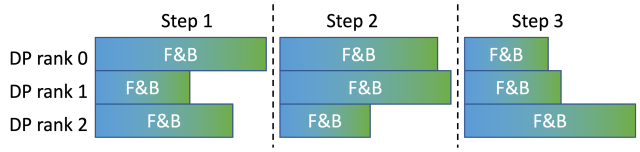

Figure 8: *A representative timeline for jobs with sequence length variance and using pure data-parallelism. Large variance exists in the computation operation times, causing stragglers to happen on some random DP rank(s) every step. "F&B" blocks denote the duration from when the first forward-compute launches to when the last backward-compute finishes.*

manual tuning, the computational load is not perfectly even across stages, *e.g.,* the forward-compute of the last stage is 1.55X of the other stages after tuning.

5.3 Sequence Length Imbalance

Next, we analyzed jobs whose slowdown is not explained by slow workers (§5.1) or imbalance in the computational load between pipeline stages (§5.2). Our inspection revealed that for long-context jobs, differences in sequence lengths between training data are a significant contributor to job slowdown. Recent studies [4, 14, 21] have shown that the datasets used to train long-context LLMs have a long-tailed sequence length distribution. We confirmed that this was also the case in our cluster: Figure 10 shows the sequence length distribution for the training data used in a long-context training job, where the *maximum-sequence-length* is set to 32K.

Variance in sequence length is a problem because the algorithmic complexity of the self-attention layer is quadratic [23]. Our system forms a training microbatch by collecting sequences (chosen at random) until the total length of the microbatch reaches a predefined maximum-sequence-length. However, the computation time for the microbatch depends not just on the maximum-sequence-length, but also on the length of each sequence s_i that is included in the microbatch because the computation time for a microbatch is $O(\sum s_i^2)$. For instance, a microbatch with one sequence of length 32K requires 32× more compute time than a microbatch containing 32 sequences of length 1K. The difference in computation time across microbatches results in bubbles in pipeline stages, and in DP ranks finishing at different times (shown in Figure 8). Both combine to produce stragglers.

Our reasoning above is based on the observation that computation time is proportional to $O(\sum s_i^2)$. In Figure 9, we empirically verify this assumption: we plot the duration and $\sum_i s_i^2$ of each microbatch in the first several training steps of a representative job, and find that indeed they are proportional.

Next, we quantified the fraction of jobs whose slowdown is due to sequence length imbalance. We cannot use the same metric as the previous two sections because our trace does not provide us with enough information to correct for sequence length imbalance. Instead, we measure the occurrence of slowdown due to sequence length imbalance using a *forward-backward correlation* metric. Our metric is based on the ob-

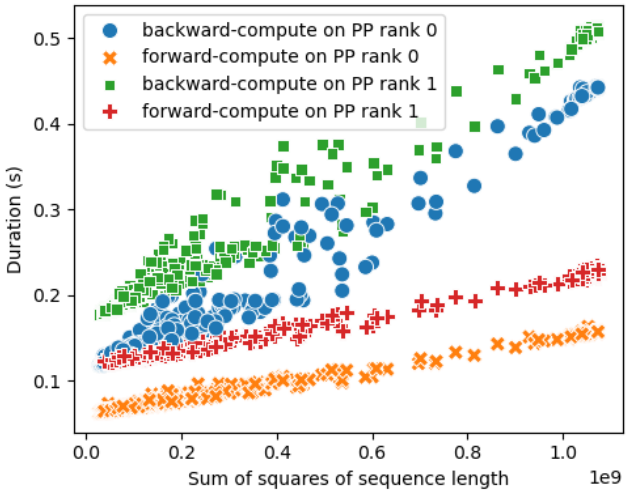

Figure 9: *Microbatch computation duration vs sum of sequence length squares, profiled over dozens of training steps on a job with maximum-sequence-length of 32K. Each data point represents a microbatch on the forward or backward pass on a specific PP rank.*

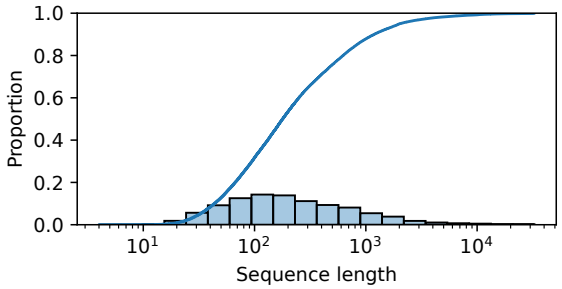

Figure 10: *Sequence length distribution, collected on a job with a maximum-sequence-length of 32K. The histogram is shown in bars, and the CDF is shown on the curve. Note the log scale on the x-axis.*

servation that if forward-compute for a microbatch is slow because of sequence length imbalance, then the backward-compute must also slow down by a similar amount, and the forward- and backward-compute times must be correlated. Figure 11 shows the Pearson correlation factor for a pipeline stage[4] in each straggling job (i.e., those with $S \geq 1.1$). Empirically, we found that jobs with a correlation coefficient ≥ 0.9 were most likely to have been slowed down because of sequence length imbalance. Using this threshold, we observe that 21.4% jobs are affected by sequence length imbalance. They have an average slowdown of 1.34.

Furthermore, in Figure 12 we analyzed how a change in the maximum-sequence-length affects job slowdown. We observed that sequence length imbalance has a larger effect as the maximum-sequence-length grows. But context lengths are growing, and thus addressing this scalability challenge is

[4]To avoid noise brought by microbatches computing loss and embedding layers, we only use microbatches on the second PP stage when *PP degree* ≥ 3. Otherwise, we use the first stage, and if VPP is used we also drop the first virtual stage to discard microbatches containing embedding layers.

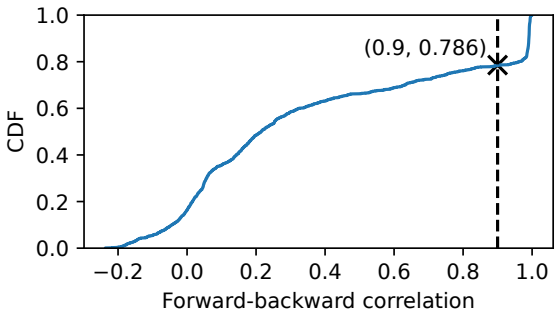

Figure 11: *CDF of forward-backward correlation of all straggling jobs in the solid line. The dashed line shows the proportion of overall resource waste by the jobs with correlation under the x values.*

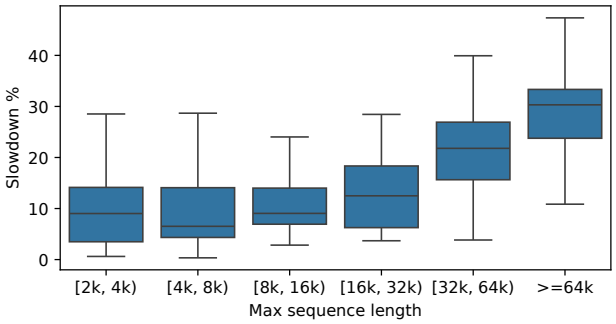

Figure 12: *Long context vs others.*

becoming increasingly important.

One approach to addressing this problem is to distribute sequences across microbatches so as to equalize the computation time for all microbatches. As we discussed above, microbatch computation times can be accurately predicted given sequence lengths (Figure 9). Thus, we prototyped a version of this approach where after a batch is formed, we use a linear model to redistribute sequences so that all DP ranks have a balanced computational load. We formulated the redistribution problem as a multiway number partitioning problem [40] and solved it using a greedy algorithm similar to the one used by DistTrain [43].[5] We used PyTorch's distributed KVStore [37] to exchange sequences between DP ranks. Next, each DP rank divides the assigned sequences into microbatches so that the sums of sequence lengths across microbatches are balanced, and we achieve this with a greedy algorithm. We tested this approach on a representative job with a maximum-sequence-length of 32K, and observed a 23.9% improvement in throughput.

Deploying such a fix in practice requires evaluating its effect at scale, and we leave this to future work. We expect that our proposed fix might increase memory requirements, because balancing computation in this manner results in sequence length sums varying across DP ranks, and might lead to increased memory requirements for some ranks. Furthermore, this fix only solves the imbalance at the DP level, but similar to DistTrain and DynaPipe [21], we also observed imbalance at the PP level (and a large number of PP bubbles) in jobs with large PP degrees and more microbatches. Other approaches to balancing computation across microbatches might be required to address PP-level imbalance.

[5] Except that we sort sequences in descending order since it gives a much better result in our case.

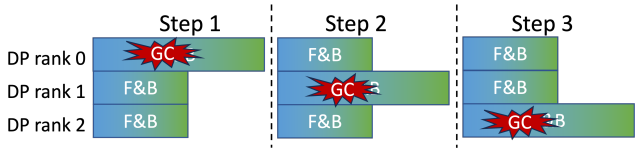

Figure 13: *Representative timeline for jobs suffering from the GC straggler. Different workers perform their GC at different steps, straggling each other.*

5.4 Python's Automatic Garbage Collection

Garbage collection (GC) is another significant cause of slowdowns. The jobs in our cluster are run using Python, whose runtime triggers GC when it is deemed necessary [36]. Once triggered, GC can take 100s of milliseconds, and during this period the user program is paused and new kernels cannot be started,[6] stalling forward-compute operations. Note that backward-compute operations are not affected because they are launched from C++.

This problem is further exacerbated because different Python processes trigger GC at different times. While the GC pauses a single worker, it blocks the entire training job as shown in Figure 13. The number of such pauses grows as the number of workers increases, and thus stragglers due to GC have become a more important concern as models have increased in scale.

Therefore, in 2023 our engineering team implemented a planned GC optimization to mitigate stragglers due to GCs. This optimization turns off Python's automatic GC mechanism, and instead manually schedules GC at a user-specified interval (that is specified in terms of training steps). This ensures that all workers run GC at the same time. This optimization is effective at preventing GC-related stragglers: on a job that uses 128 DP ranks, using this optimization so that GC is run every 500 training steps results in a 12.6% improvement.

While the planned GC optimization is effective, it is challenging to use in practice because choosing an appropriate GC-interval is hard. Picking too large a GC-interval can lead to the job running out of memory and crashing, while choosing too small a GC-interval can lead to worse performance. But the rate at which memory is allocated, and thus the appropriate GC-interval varies by job, and thus users need to tune the interval for each job. Therefore, we are conservative and do not enable planned GC by default: users can turn it on after they have analyzed previous runs of a job to determine an appropriate GC-interval. Consequently, this fix has not been widely adopted in our cluster.

[6] Python uses a stop-the-world garbage collector.

We also observed that the amount of time for which the GC pauses execution increases as the job progresses. This leads to a gradual decrease in training throughput, as has also been observed in the past [22, 38]. We suspect the slowdown is due to a memory leak, which increases heap size as the job runs longer and leads to longer GC pauses. Interestingly, we found that planned GC can mask the impact of this leak and leads to sustained training throughput.

5.5 Other Root Causes

As we stated previously, the set of root causes we have discussed is not exhaustive, and jobs in our traces might have been slowed down by other problems. Rather, our goal was to analyze some of the more obvious or common causes of stragglers. Below, we describe two uncommon but interesting root causes that appeared in our traces.

CUDA memory fragmentation. In a few cases, we observed that memory fragmentation slowed down PyTorch's CUDA memory allocator, and led to a significant increase in calls to `cudaFree` and `cudaMalloc`, which led to slower than usual forward- or backward-compute operations. In our traces, this appears as cases where TP communication kernels running on different TP ranks in the same TP group start at different times but finish roughly at the same time, suggesting that some of the communication kernels experience launch delays. We examined the PyTorch traces for these jobs to confirm that they did indeed make several `cudaFree` and `cudaMalloc` calls, and then we enabled allocator memory tracing and reran the job to further understand the problem. During rerun we observed many `segment_alloc` and `segment_free` calls, confirming that the PyTorch memory allocator was to blame. In future work, we plan to study both the prevalence of this problem and mitigation strategies.

False kernel dependency. When we first started training large MoE models, we found that reduce-scatter kernels (used to synchronize gradients) block other kernels (that do not depend on the reduce-scatter kernel) from being launched, and lead to significant job slowdown. We suspect that this is because of false dependencies [13, 30] caused by unrelated kernels sharing the same CUDA hardware queue. We found that increasing `CUDA_DEVICE_MAX_CONNECTIONS` alleviates the problem. However, we have also found that the problem seems to occur (and then disappear) as we evolve our model and framework, and we continue to investigate it to identify the cause.

5.6 Summary: Observations and Implications

Our root cause analysis yields the following key observations about our traces:

- Relatively few stragglers were due to machine problems (either due to hardware or software), implying that traditional health metrics are unlikely to aid in detecting or preventing most stragglers.
- The most prevalent causes for straggling are due to uneven pipeline stage partitioning, imbalance in sequence lengths in each microbatch, and pauses induced by the garbage collector. Our observations also led us to develop a new approach to address sequence length imbalance (§5.3).
- We observed two new but less prevalent causes for stragglers: PyTorch memory fragmentation and false kernel dependencies. While both issues had been reported before as potential performance problems, they were not known to lead to stragglers prior to our work.

6 Validation of Simulation Fidelity

Our analysis uses a simulator to estimate a job's execution time in the absence of stragglers, and also after fixing some stragglers. We validate the simulator's accuracy in two ways: 1) by comparing a job's average step time in the simulated original timeline to its average step time in the actual timeline; 2) by artificially injecting stragglers and comparing simulated and actual slowdowns.

Simulation inaccuracy and its sources. As we described in §3, not all types of operations are recorded in the trace: specifically, operations run on the CPU, including data loading, are omitted from the trace. In most cases, this limitation does not pose a problem because these CPU operations are overlapped with GPU ones, allowing their latency to be hidden. However, the overlap is not always perfect and delays the launch of the next operation. This *launch delay* is not simulated, constituting the main source of discrepancy in the simulation. To measure the discrepancy, we compute the average step run-time $\tau = T/n$ of the simulated original timeline (§3.3) for a job with n steps and compare it with the actual step run-time τ_{act}. In our experiments, the simulation discrepancy has a median of 1.3% and 90-percentile of 5.5%.

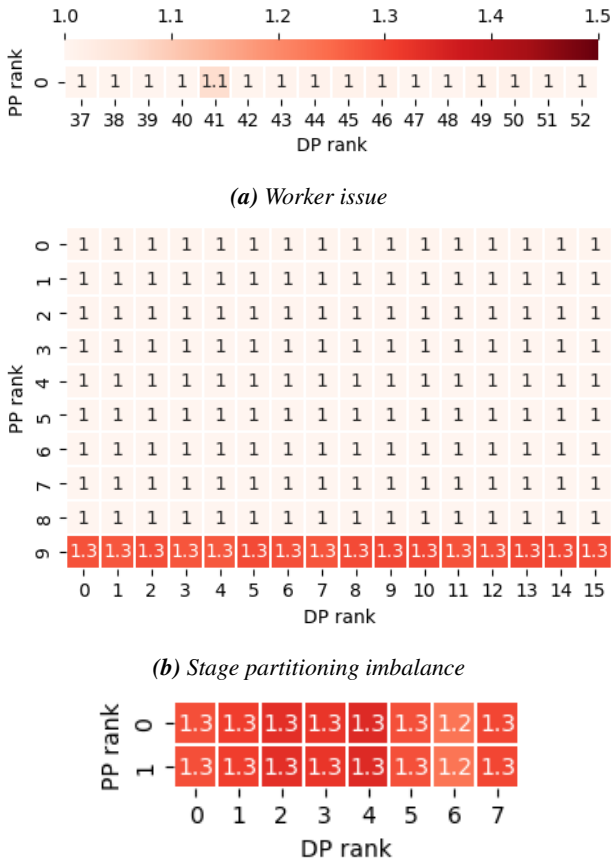
After examining the traces with large simulation discrepancies, we found three main causes: (a) As data is stored on a remote storage cluster using a separate, slower network, data loading is susceptible to network slowdown and time-out, leading to long launch delays for the first forward-compute operations of some training steps; (b) Long context jobs can have long delays before the launch of the first forward-compute operations of each step because, as part of batch preparation, samples are padded to the maximum sequence length, which is time-consuming; and (c) Early deployments of the planned GC optimization, where the GC was run every few training steps before gradient synchronization, slowed down the launch of those operations. We have resolved the latter two problems, but all three affect some of the traces that we captured. To ensure analysis fidelity, we dropped any traces where the simulation discrepancy is larger than 5%.

Validating the Accuracy of Slowdown Estimation. We validate the accuracy of slowdown estimation by running a job whose DP, PP, and TP degrees were 4, and CP degree was

1. We artificially slow down the first rank, *i.e.,* the worker with global-rank 0, by running a background process that periodically performs multiple matrix multiplications (MatMuls) of size 10K × 10K. By varying the time interval between MatMul launches, we create three levels of slowdown and measure the resulting slowdown. We also used the simulator to compute a simulated slowdown. Our measured slowdowns were 1.16, 1.40, and 2.03, respectively, which are close to the estimated slowdowns 1.21, 1.42, and 1.98.

7 Limitation

Next, we discuss the limitations of our analysis. Our limitations are due to the trace contents captured by NDTimeline, and we plan to address these limitations in future work.



Limitations due to data captured by NDTimeline. NDTimeline performs coarse-grained profiling and records time taken by a microbatch's forward and backward computation. It is challenging to use this information to analyze stragglers that occur within a TP or CP group, because TP and CP groups synchronize, and stragglers at the TP or CP granularity show up as slow microbatches in our traces. As a result, if the straggler slows down all microbatches, our method of estimating idealized microbatch durations will not allow us to compute the ideal straggler-free execution time, and thus we cannot analyze the effect of such stragglers.

A second limitation is due to a bug in NDTimeline which affects some of our traces. This bug caused NDTimeline to not record some operations, resulting in simulating the launch of some forward- and backward-compute operations earlier incorrectly. The bug was spotted after we had begun collecting traces, and we post-processed traces affected by this bug to fix this problem.

Job covered by our analysis. To ensure analysis fidelity, we had to discard a portion of the traces we collected from our cluster. Consequently, our analysis does not cover all the LLM training jobs run within the cluster, and may underestimate straggler prevalence and severity. The reasons for discarding are mostly due to problems with the trace and we outline them below.

First, we eliminated any jobs that repeatedly fail. Our cluster uses a system that automatically resubmits jobs that fail. However, software bugs result in cases where a single job might fail dozens of times or more, and we eliminate these jobs to avoid introducing bias into our analysis. In particular, we discard any job that is restarted more than 15 times, which results in us discarding 13.9% of the recorded jobs or 7.3% of the recorded GPU hours.

Second, we discarded jobs for which we could not successfully run the what-if analysis. This results in us discarding 50.0% of the remaining jobs, which amounts to 34.1% of the remaining GPU hours. Most of these are due to issues with the trace: 28% of the traces were discarded because we could not parse the job's command line to determine the degree of parallelism; 28% were discarded because the job had too few steps to allow analysis;[7] and 25% were due to corrupt traces.

(a) Worker issue

(b) Stage partitioning imbalance

(c) Sequence length imbalance

Figure 14: *Heatmap patterns with different root causes.*

Finally, as noted earlier (§3.3), we discard jobs with large simulation discrepancy (> 5%), which amounts to 11.2% and 7.7% of the remaining jobs and GPU hours, respectively. This results in total coverage of 38.2% jobs and 56.4% GPU hours.

8 Online Straggler Detection and Diagnostics with What-if Analysis

To make it easier for users to benefit from the analysis we have discussed so far, we built an online monitoring service called *SMon* that runs automatically after each NDTimeline profiling session (which records dozens of training steps). SMon estimates slowdown, per-step slowdown, and worker slowdown, and presents the results on a webpage. Similar to Pingmesh [18], we present worker slowdowns using a heatmap, where each cell represents a worker with its x- and y-coordinate as its DP and PP rank, respectively, and the color depth represents the worker's slowdown. Our use of such a heatmap serves two purposes: first, it makes finding straggling workers easier, and second, the pattern of slowdowns often

[7] We filter out steps that are doing batch size warmup, and in some cases this results in jobs with insufficient steps.

helps pinpoint the initial root cause for the slowdown, making it easier to address the problem. For instance, jobs with worker issues, stage partitioning imbalance and sequence length variance have distinct patterns as shown in Figure 14. SMon also presents a per-step heatmap using per-step duration instead of average in Equation (4) when computing worker slowdowns, to reflect only the straggling within each step.

We have configured SMon to alert our on-call team whenever important jobs experience significant slowdowns. When alerted, the on-call team checks the worker heatmap to identify a suspected root cause by seeing if it matches one of the known patterns. We then use the per-step slowdown and the per-step heatmap to locate the problematic step and ranks to further drill down and understand the problem.

Within a month of its deployment, SMon has helped us identify and address several stragglers: it allowed us to locate faulty machines in three cases where machine problems were responsible for stragglers, it helped identify a case where sequence length variance was leading to large job slowdown, and a separate case where imbalanced compute partitioning across pipeline stages was to blame.

9 Related Work

Straggler in big data. The straggler problem has been extensively studied in big data frameworks such as MapReduce [3, 10, 16, 31], predating the era of deep learning. Mantri [3] provided an empirical characterization of stragglers in large-scale MapReduce jobs, where they quantify the straggler prevalence and attribute the root causes to load-imbalance, cross-rack traffic, and bad machines. They propose a system that actively restarts or duplicates outlier tasks while optimizing task placement and scheduling to mitigate delays. Ousterhout et al [31] conducted a more in-depth analysis of the performance bottleneck of Spark using a what-if simulation similar to our method. They attribute stragglers to diverse causes, including Java GC and file system delays.

However, the simulation approaches and findings of [3, 31] are not applicable to LLM training. First, much of the complexity for simulating MapReduce jobs is due to dynamic task scheduling, *e.g.,* a reduce task is scheduled to a machine after its inputs become available at runtime. In contrast, LLM training uses simple static scheduling, *i.e.,* tasks are placed at the beginning of the job and never changed. Second, the complexity of simulating LLM training jobs lies in handling the complex dependency structure stemming from mixed parallelism. In particular, LLM jobs have to account for pipeline parallelism, tensor parallelism, and data parallelism, each of which occurs at different granularities and can involve only a subset of ranks. By contrast, dependencies of MapReduce jobs are much simpler, *i.e.,* all map tasks communicate with all reduce tasks. These differences limit the direct applicability of their approaches and conclusions to LLM training.

Straggler in deep learning training. Straggler problems have also been studied in the context of data-parallelism in the deep learning era. Many of these prior proposals have focused on developing straggler mitigation strategies: Ramamoorthy et al [33] suggest using redundant coded computations to mitigate stragglers; Downpour SGD [9] and Project Adam [7] use asynchronous SGD and stale gradient updates to mitigate stragglers; Hop [27], Tensorflow [1] and Chen et al [6] use backup workers to resolve stragglers; and DropCompute [15] suggests dropping updates from stragglers. By contrast, our work focuses on characterizing the effect of stragglers and their root cause.

Straggler in LLM training. Recent studies have begun to explore stragglers in LLM training. Malleus [25] mitigates the impact of stragglers using dynamic parallelism adjustments based on real-time device performance. MegaScale [22], Llama3 [11] and Imbue's report [38] discuss infrastructure challenges for LLM training and briefly mention how they debug stragglers, but do not provide in-depth analyses. Unlike these works, we focus on a detailed and comprehensive analysis of the straggler problem itself.

FALCON [41] presents a detailed characterization of stragglers and introduces several mitigation strategies. Our work differs in several ways. First, we analyze jobs on a dedicated cluster while FALCON's analysis is for a shared cluster. The difference in the settings lead to different results: unlike FALCON, we did not see stragglers due to resource contention. Second, FALCON's analysis of large jobs (512 to 1024 GPUs) is only limited to 27 job traces, while our analysis has a significantly larger scale: among the 3079 traces we analyzed, 562 jobs use $\geq$ 512 GPUs. With only a few dozen traces, FALCON relies on manual analysis to study stragglers and determine their root cause. By contrast, we use a semi-automated approach combining simulation-based what-if analysis and manual verification of hypothesized root causes. Furthermore, FALCON's analysis overlooks stragglers that affect most steps rather than only a small fraction of steps. As we show in §4.2, the former is more common than the latter in our traces.

10 Conclusion

We present an in-depth study of the straggler problem in LLM training on job traces collected from our cluster. We use what-if analysis as our core approach, which allows us to estimate slowdown caused by stragglers as well as attribute it to different workers or operation types. These measurements help us study the overall impact of stragglers, characterize straggler symptoms from various aspects, and preliminarily diagnose the root cause. Through extensive case studies, we find that stage partitioning imbalance, sequence length imbalance, and Python's automatic GC are the main root causes; machine issues are rarely observed to cause stragglers, but they tend to cause severe slowdown when happening.

We have implemented parts of the analysis pipeline in SMon, a monitoring tool that is deployed in the training cluster at ByteDance. SMon allows us to more accurately detect

stragglers in running jobs and improves the diagnostics efficiency.

A Artifact Appendix

Abstract

This artifact provides the core functionality of the simulator and the what-if analysis proposed in the paper, including:

- estimation of overall slowdown S (Eq. 1);
- estimation of slowdown S_t attributed to each operation type t (Eq. 2);
- estimation of slowdown S_w attributed to each worker w (Eq. 4);
- computation of characterization metrics M_W (Eq. 5) and M_S for individual worker issues and stage partitioning imbalance, respectively;
- heatmap visualization as in Figure 14; and
- timeline generation of the simulated ideal trace visualizable in Perfetto [17].

It also provides three sample traces to demonstrate the usage of the tool. More details can be found in "README.md".

Scope

The artifact allows readers to validate if the provided implementation of the simulator and the what-if analysis match the description in the paper and if the code is functional and sufficiently documented.

Contents

The artifact contains the source code of the simulator and a set of proposed what-if analysis, three sample traces and their expected analysis result. It also contains a README file with detailed documentation of the project and step-by-step instructions to run the analysis using the traces as examples.

Hosting

Our artifact is hosted on GitHub at `https://github.com/ByteDance-Seed/StragglerAnalysis` on the `artifact` branch. The commit version is `8efcd7f`.

Requirements

There is no special hardware or software requirement for this artifact, except a somewhat recent version of Python. The code has been tested with Python 3.11.

Fork in the Road: Reflections and Optimizations for Cold Start Latency in Production Serverless Systems

Abstract

Serverless computing has seen widespread adoption in public cloud environments. However, it continues to suffer from *long cold start latency*, which remains a key performance bottleneck. We have conducted an in-depth investigation of existing cold start optimizations and evaluated their effectiveness in large-scale industrial deployments. Our study reveals several common limitations in prior research: (1) reliance on simplified assumptions that overlook the complexities of large-scale systems; (2) a narrow focus on optimizing isolated components of the cold start process, while ignoring end-to-end workflow interactions; and (3) insufficient attention to the challenges introduced by concurrent execution environments. As a result, despite incorporating prior techniques, cold start latency on the Ant Group serverless platform remains in the range of hundreds of milliseconds to several seconds.

This paper identifies three previously overlooked sources of latency: (1) *control path latency*, stemming from interactions within the serverless runtime; (2) *resource contention latency*, arising under high concurrency and sustained execution; and (3) *user code initialization latency*, which reflects the trade-off between resource efficiency and startup performance. To address these challenges, we propose a suite of novel techniques that overcome key limitations in existing approaches. These techniques are designed to be both adaptable to real-world workloads and scalable to large deployments. Our system, ***AFaaS*** (short for Ant FaaS), reduces cold start latency to the millisecond level. AFaaS has been deployed in production for over 18 months and has consistently demonstrated stable performance at scale.

1 Introduction

Serverless computing is a cloud paradigm that has significantly transformed how applications are developed and deployed. By abstracting away infrastructure management, it enables developers to focus solely on application logic, while the serverless platform automatically handles resource allocation, scaling, and cost optimization. This paradigm has been widely adopted by major cloud providers, including AWS Lambda [10], Azure Functions [47], Google Cloud Serverless [36], Alibaba Serverless Application Engine [7], and Huawei Cloud Functions [39].

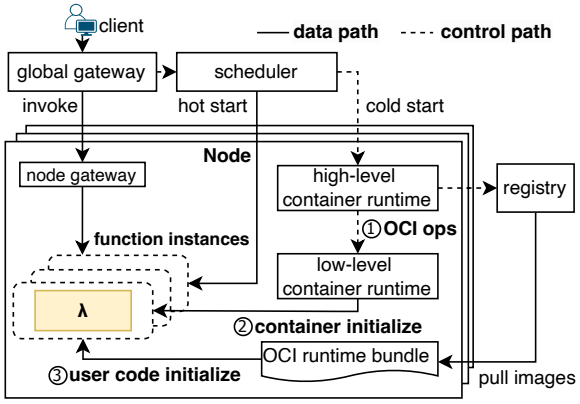

Figure 1: **Application start procedure in AFaaS.** This is simplified to show the key components of the OCI (Open Container Initiative) [41] specification.

However, the on-demand and pay-as-you-go nature of serverless computing introduces a persistent challenge: *cold start latency*. When a request arrives and no pre-warmed instance is available, the platform must initialize a new instance to run the target function—typically incurring a delay of over one second. Given that serverless functions often execute within just 50–100*ms*, such startup latency has become a well-known performance bottleneck in contemporary serverless platforms [6, 27, 28, 58, 96].

To address this challenge, researchers have proposed various optimizations. Checkpoint/restore techniques [12, 28, 89] and fork-based approaches [6, 27, 28, 68, 96] aim to bypass initialization by reusing state from pre-initialized templates. Caching-based methods [1, 2, 6, 11, 33] accelerate response time by reserving instances for frequently invoked ("hot") functions. Additionally, customized serverless runtimes [5, 58, 64] reduce cold start overhead by removing unnecessary features from the execution environments.

Figure 1 illustrates the current cold start procedure within

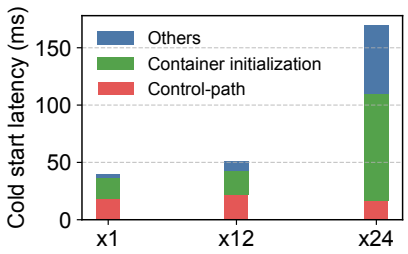

Figure 2: **Control-path costs.** Time spent on the control path when a function instance starts (excluding the initialization and execution of user code). $\times 1$, $\times 12$, and $\times 24$ represent different concurrency levels (*the number of functions that can be executed in parallel on a single serverless server*).

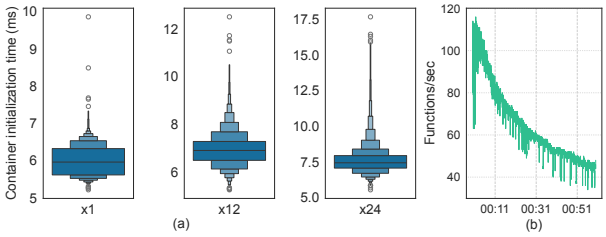

Figure 3: **Resource contention leads to unstable performance.** (a) Tail latency exhibits a clear positive correlation with concurrency levels, with ranges of $[5.21\text{ms}, 9.85\text{ms}]$ for $\times 1$, $[5.27\text{ms}, 12.49\text{ms}]$ for $\times 12$, and $[5.53\text{ms}, 17.67\text{ms}]$ for $\times 24$. (b) Under sustained high concurrency ($\times 24$ for 1 hour), throughput gradually decreased from an initial rate of 110 FPS (Functions Per Second) to 45 FPS.

a node, including three main phases: (1) *Control-path Interaction*: A high-level runtime (e.g., containerd) requests a low-level runtime (e.g., runc) to create a new instance, typically involving several binary calls and RPC operations based on the OCI (Open Container Initiative) [41] specification. (2) *Container Initialization*: The low-level runtime creates a function instance and completes its initialization — this has been the primary focus of previous research on cold starts in serverless computing. (3) *User Code Initialization*: After the function instance is ready, the instance must load and initialize the user code provided by the application developers.

Through real-world deployments, we identify three critical gaps in existing research on serverless cold starts. These factors significantly impact user-perceived latency but are widely overlooked. As a result, cold start latency on the Ant Group serverless platform remains in the range of hundreds of milliseconds to several seconds.

Gap-1: Control-path latency. The cold start involves more than just setting up the function instance itself; the control-path is equally critical. As shown in Figure 2, when the initialization of the function instance is optimized to a short duration, the latency on the control-path becomes prominent. Specifically, in our environment, the control-path latency takes 18*ms*–25*ms*, constituting approximately 30%–40% of the overall cold start period with Catalyzer [28]. The major source of these costs comes from the interaction between high-level and low-level runtimes, following the OCI specification [41]. For example, the shim-based invocation and binary call conventions (§2.2) incur overhead due to excessive interaction between multi-layer components.

Gap-2: Resource contention latency. Within the complex circumstances of the production environment, we witness performance instability. As illustrated in Figure 3, two scenarios are discerned: (1) Under high concurrency, the distribution of response time is significantly dispersed, presenting considerable tail latency. (2) During sustained execution, there is a marked decline in request throughput. Our profiling shows that the performance decline is primarily caused by resource contention within the host operating system during container startup. This issue has been largely overlooked in prior work and becomes especially critical under heavy workloads with intense contention.

Gap-3: User code initialization latency. Beyond initializing the container instance itself, the execution of user code introduces additional delays. For example, Just-In-Time (JIT) compilation or language runtime-specific code loading can significantly affect startup latency, especially when dealing with complex application frameworks or extensive dependencies (e.g., Spring [72], AngularJS [35]). User code initialization latency depends on user-specific behaviors. This makes it challenging for current optimization methods, such as provisioning [11] and SnapStart [12], to balance cost and efficiency.

Based on reflections from previous efforts and our experience in large-scale industrial environments, we develop a series of innovative techniques that overcome significant challenges to build a system, **AFaaS**, that adapts to real-world workloads and supports large-scale deployment.

First, we discover that the current cloud-native OCI [69] is not well-suited for serverless scenarios. Instead, we propose the Function Runtime Interface (FRI), which simplifies and optimizes the control path for function instances to reduce communication overhead between high-level and low-level components (§4.1).

Second, we identify bottlenecks caused by resource contention and conduct an in-depth analysis of the factors leading to performance instability. To address these issues, we propose strategies to mitigate contention. For inheritable and sharable resources, we integrate them into a ***seed*** (*sandbox template, a sandbox contains the initialized state to skip the initialization* [28]) to minimize redundant operations. For pre-allocatable resources, we use a pooling strategy to allocate them in advance, reducing concurrent conflicts. These strategies ensure consistent performance during concurrency and continuous execution (§4.2).

Finally, we extend the seed to include user code, preloading frequently invoked and time-consuming routines. To

optimize memory usage, seeds are managed using a hierarchical tree structure, where Copy-on-Write (CoW) is employed to efficiently create child nodes from the parent seed. This design reduces memory footprint while preserving fast startup performance (§4.3).

To our knowledge, AFaaS is the first commercial serverless system to achieve millisecond-level start latency. Our evaluation shows that AFaaS achieves a substantial reduction in end-to-end latency, ranging from 1.80× to 8.14× compared to the state-of-the-art Catalyzer in production scenarios, while maintaining a consistent start time between 5.45 ms and 9.41 ms. Under heavy workloads with high concurrency and sustained execution, AFaaS continues to deliver stable startup performance, with latencies between 6.97 ms and 14.55 ms, significantly outperforming Catalyzer's 38.39 ms to 74.05 ms. The system has been running reliably in production for over 18 months. All traces used in this paper are available at https://github.com/antgroup/AFaaS.

2 Characterizing Cold Start in Production Serverless Systems

2.1 Reflections for Cold Start in the Wild

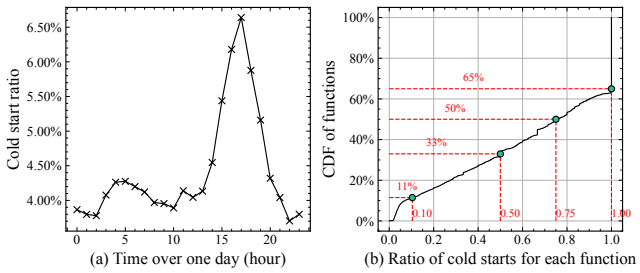

Figure 4: **Cold start pattern.** (a) The ratio of cold starts during a 24-hour period. (b) CDF of the cold start probability for each function.

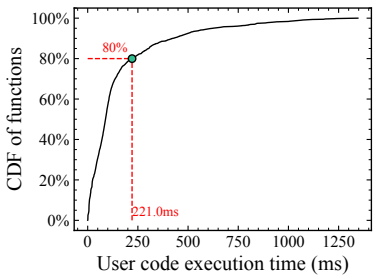

Figure 5: **User code execution time in Ant Group.**

Rapid Growth of FaaS in Ant Group. Currently, there are over 50,000 unique functions running on the public cloud in Ant Group, with approximately 100 million function calls per day. These functions are implemented in a variety of programming languages, including Node.js, PHP, Python, Java, and C++, and are executed on various runtime versions of each language. The scale is continuously growing.

Implication-1: Cold start is still significant as more than 50% of the functions exhibit a cold start probability exceeding 0.75. For security reasons, Ant Group deploys each function in a (micro) VM-based secure container [28,40]. Figure 4(a) illustrates the proportion of cold starts for a specific tenant over a given period in Ant Group. While over 95% of requests benefit from *hot start*, we observe that a significant portion of these *hot* requests are concentrated in a small number of frequently invoked functions (such disparities have also been observed in [44, 78]). As shown in Figure 4(b), more than 50% of the functions exhibit a cold start probability exceeding 0.75, while over 35% of the functions have a cold start probability of 1.

Implication-2: Caching-based hot start is insufficient to address the start latency issue (mainly) because of resource constraints. Like most cloud providers, to serve user requests more efficiently, Ant Group does not immediately destroy function instances after completing a request. Instead, these instances are retained for a period in the cache, enabling subsequent requests to be handled immediately if the function instances are still active. This process, known as a *hot start*, significantly enhances FaaS performance. AWS, Azure, and OpenWhisk keep containers alive for 10, 20, and 30 minutes, respectively, before terminating idle function instances [75,78]. However, caching infrequent functions would consume excessive memory. To achieve more flexible memory utilization, Ant Group limits hot instances to 1 minute, ensuring support for high-frequency functions. We still need to optimize the cold start performance, as over 60% of functions experience cold starts more frequently than hot starts.

Implication-3: Fork-based optimizations are essential but (still) insufficient to optimize end-to-end start latency. Figure 5 shows the user code execution time distribution in Ant Group— more than 80% of requests are processed within $221ms$, highlighting the importance of optimizing cold start latency. This observation differs from prior ones in [77]. To optimize cold start, we built secure container designs with the *sfork* (sandbox fork) mechanism of Catalyzer [28], which introduces optimizations to fork secure containers. This mechanism enables the creation of new function instances in $< 1ms$ under optimal conditions. Through long-term deployment and practical use of Catalyzer in production environments, several shortcomings have been identified. Firstly, Catalyzer primarily focuses on the fork operation of the sandbox process but overlooks key steps in the end-to-end container cold start sequence. These missing steps include the control path between the high-level runtime and the Catalyzer runtime, as well as the loading of user code after sandbox initialization. Secondly, in high-concurrency environments, resource contention leads to significant performance fluctuations during both the sandbox fork and initialization phases.

Revisiting End-to-End Cold Start Latency in Production.

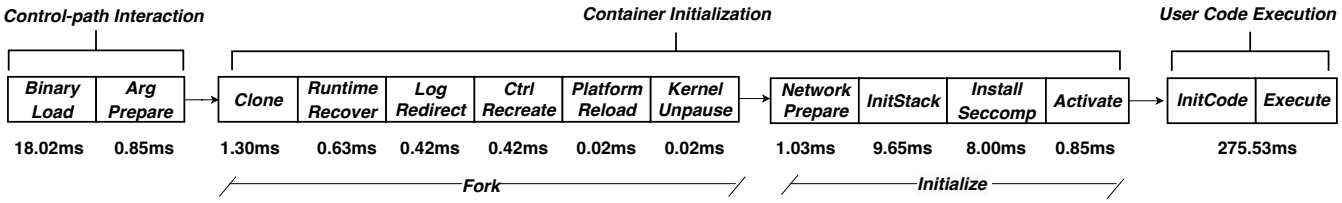

Figure 6: **End-to-end latency of cold start.** The numbers represent the latency of each phase of a Node.js-based function (*nunjucks*—rendering the template to HTML), detailed experimental setup can be found in §6. The entire end-to-end start-up process consists of three main stages: (1) ***Control-path Interaction.*** ① *BinaryLoad*: The runtime shim [22] loads the Catalyzer engine binary and starts the client process. ② *ArgPrepare*: The client process prepares fork-related parameters and invokes the seed sandbox. (2) ***Container Initialization.*** ① *Clone*: The seed sandbox invokes the *clone()* syscall to fork a new sandbox. ② *RuntimeRecover*: The forked sandbox initializes the Go runtime. ③ *LogRedirect*: The stdout and stderr of the sandbox are redirected. ④ *CtrlRecreate*: The sandbox recreates the control server. ⑤ *PlatformReload*: The sandbox transitions from VMX root mode to VMX non-root mode. ⑥ *KernelUnpause*: The guest OS is unpaused to resume execution. ⑦ *NetworkPrepare*: The client process prepares the network interface and creates a raw socket that binds to this network interface, then sends the raw socket to the sandbox. ⑧ *InitStack*: The guest OS initializes the network stack. ⑨ *InstallSeccomp*: The sandbox parses and installs a seccomp filter. ⑩ *Activate*: The sandbox is attached to the host cgroups and mounts the rootfs. (3) ***User Code Execution.*** ① *InitCode*: The sandbox loads the appropriate language runtime, compiles the user code, and also loads the function's dependency framework and libraries. ② *Execute*: The sandbox executes user code and provides a response.

End-to-end latency is a critical metric from the customer's perspective, yet it is often overlooked in existing works [61]. We define *end-to-end (E2E) latency* as the complete process encompassing the following steps: when a node receives a scaling request from the scheduler/auto-scaler, it initiates a cold start for a function instance, loads the corresponding code, retrieves the request from the node gateway, executes the function, and ultimately sends the response back to the end-user. Figure 6 illustrates the latency associated with each phase in a typical production function cold start using Catalyzer. The *end-to-end latency* consists of three main stages: *(1) The control-path interaction stage* involves command execution (e.g., sandbox fork) between high-level runtime (e.g., containerd) and low-level runtime (e.g., Catalyzer). *(2) The container initialization stage* sets up an isolated container from scratch. This stage involves two steps: first, cloning a new VM-process based on a template sandbox using the *sfork* mechanism [28], and second, installing container-related components such as namespace, virtual ethernet interface (veth), and seccomp rules for the VM-process. *(3) The user code execution stage* has undergone significant variation and typically includes initiating the language runtime (e.g., Python or PHP), initializing the code framework (e.g., Django [3] or Spring [72]), loading the function code and common libraries into memory for JIT compilation, and finally executing the user code.

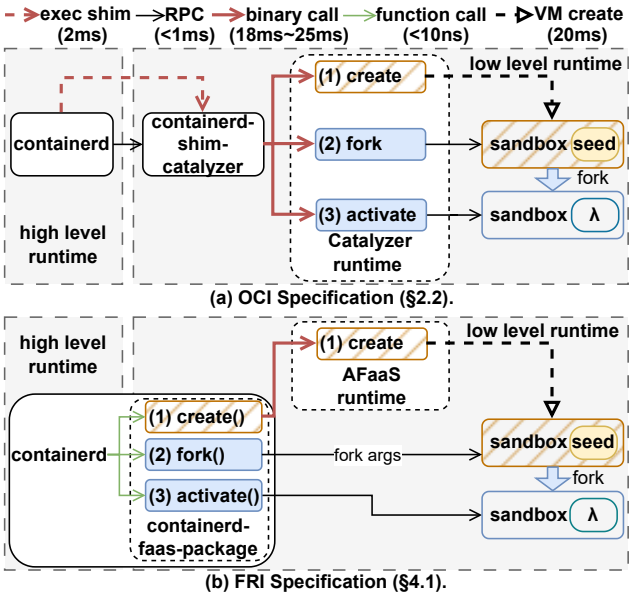

Figure 7: **Interactions between the high-level container runtime and the low-level container runtime.** Operations in the hatched boxes are only performed once during the creation of seeds.

2.2 Gaps from an Industry Perspective

Through real-world deployments, we identify three critical gaps overlooked by existing research on serverless cold starts that significantly impact user request latency.

Gap-1: Control-path latency. In containerized environments, interactions between high-level and low-level runtimes involve a long control path, introducing significant latency. When a creation request is received, the high-level runtime does not directly manage the instance. Instead, it spawns a runtime shim process to act as an adapter (containerd-shim-catalyzer), delegating the actual operations to this shim. Communication between the high-level runtime and the shim occurs via RPC requests. The shim uses the binary call convention [22], i.e., loading a runtime binary first (e.g., Catalyzer runtime) and then calling a function in the binary to manage the container. The loaded runtime binary, provided by the

lower-level runtime, is responsible for starting and stopping the container. This *shim+engine* architecture simplifies the integration of various runtimes, particularly those adhering to the OCI specification [30].

Though Catalyzer has optimized the creation of the sandbox for user code using the sandbox seed, avoiding creating from scratch, the extended invocation chain is still too long. As illustrated in Figure 7(a), the control path from the high-level runtime (containerd [23]) to the Catalyzer runtime primarily consists of three steps: (1) containerd communicates with the Catalyzer shim via RPCs. (2) Catalyzer shim loads and executes the Catalyzer runtime engine (one binary call for each serverless function invocation), and establishes communication with it via RPCs. (3) Catalyzer runtime engine creates the Catalyzer container instance, or triggers operations such as *fork()* and *activate()* through RPC calls. Though in a fork-based scenario, the seed containers are only prepared once during initialization, and subsequent operations are based on forking from the seed, ⓐ the costly binary loading process for *each serverless function invocation* still consumes 18.02*ms* (as shown in Figure 6). Also, ⓑ the use of the shim and Catalyzer runtime has extended the control path for high-level runtime (containerd) to create a sandbox for user code.

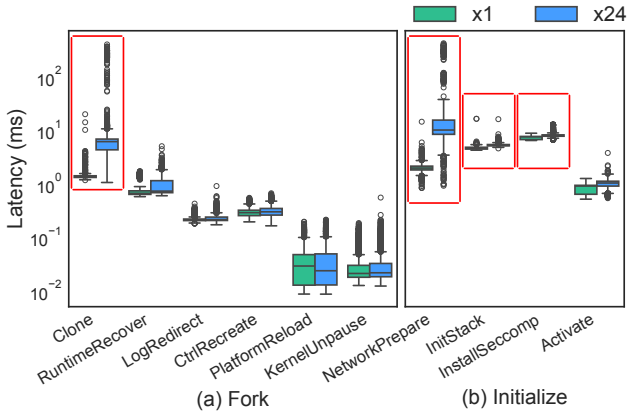

Figure 8: **Comparison of performance fluctuations caused by concurrent scenarios in key phases of container cold start.** The ones in the red boxes have longer delays and are the focus of our optimization.

Gap-2: Resource contention latency. Figure 3(a) shows significant latency fluctuations during each stage of container cold start under high concurrency. We perform a breakdown analysis of the latency fluctuations in different phases of container cold start at various concurrency levels, as shown in Figure 8. Compared to serial execution ($\times$1), cold start latency and fluctuations increase substantially during concurrent execution ($\times$24). We identify four key latency-intensive phases:

First, the latency of ***clone()*** operation during the sandbox fork stage degrades significantly under high-concurrency, increasing from 1.45*ms* to nearly 418*ms* in the worst case. The primary overhead comes from the *clone()* system call which requests new network and IPC namespaces. This process results in contention for host OS kernel locks. Through further profiling, we also discover that the performance degradation shown in Figure 3(b) is also related to the creation of IPC namespaces. IPC namespace creation is tied to POSIX message queues, as each IPC namespace requires a separate mount point for message queues. These mount points depend on VFS operations, including the lookup or allocation of superblocks. Although the Linux kernel employs a superblock caching mechanism, the cache hit rate is relatively low because each IPC namespace usually requires a unique superblock. Under high concurrency scenarios, contention over global locks (such as *sb_lock*) and mount locks (like *mount_lock*) increases synchronization overhead, further exacerbating performance degradation.

Second, the **network preparation** phase exhibits substantial latency degradation (from 2*ms* to 21.14*ms*). During this phase, Catalyzer engine parses the *config.json* file provided by containerd, switches into the specified network namespace via *setns()*, profiles the network interface's IP address, route, and device index, and creates a raw socket binding to this network interface. After setting up the raw socket, Catalyzer engine exits the network namespace using *setns()*. These operations involve intensive interactions with Linux kernel resources and impose a high CPU load, leading to contention and performance fluctuations in concurrent scenarios.

Third, in the **network stack initialization** phase, the sandbox instance uses the raw socket *fd* passed from the Catalyzer engine through RPC to initialize the container's network stack, which involves creating protocol stack ring buffers and initializing complex data structures. This process incurs substantial memory access and frequent VM exits to the host OS, leading to the latency fluctuations from 4.82*ms* to 6.94*ms*.

Last, **the seccomp installation** phase experiences several-fold latency spikes under high concurrency. Seccomp filters (seccomp-bpf) are used to restrict the system call privileges of the sandbox process to enhance container platform security. This phase involves parsing seccomp configurations, compiling seccomp rules, and installing the compiled seccomp rules into the kernel, leading to contention for host kernel locks and resulting in the latency fluctuations from 7.58*ms* to 13.01*ms*.

Gap-3: User code initialization latency. User code initialization involves loading the language runtime (e.g., Node.js, Python, Java), compiling the code, and loading dependent libraries. These phases are time-consuming, often exceeding the function's execution time and significantly impacting cold start latency. For example, in a Node.js-based function, 275.53*ms* of the user code execution phase includes 238.73*ms* spent on loading and initializing dependencies.

2.3 Cold Start Optimizations

By revisiting prior cold-start optimization approaches in the context of the industry challenges discussed in §2.2, we derive key insights that guide the design of AFaaS, as summarized in

Table 1: **Review of prior work and our design in AFaaS.**

Code Path	Prior Work	Design in AFaaS
Control Path	*Liu et al.* [61] surveys orchestration bottlenecks. *Dirigent* [26] proposes inter-node orchestration strategies. **Analysis:** Both overlook intra-node orchestration.	**FRI**: An efficient intra-node control path that replaces OCI (§4.1).
Clone	*Catalyzer* [28], *Molecule* [27], and *MITOSIS* [96] leverage fork/clone mechanisms to accelerate container startup. **Analysis:** Performance degradation arises from host resource contention, such as network and IPC namespaces, under high concurrency or sustained execution.	An enhanced cloning mechanism with pooling and sharing enables faster cold starts under high concurrency and sustained execution while preserving security (§4.2).
Network	*PCPM* [65] uses pause containers to retain and reuse the network stack, including IP configuration, virtual Ethernet (veth), and namespaces. **Analysis:** Sharing veth is an effective practice but with limitations: (1) it only supports traditional containers, as supporting secure containers incurs high memory overhead, and (2) it introduces security risks by reusing the TCP/IP stack from previous containers.	Lightweight veth sharing is achieved through pre-created, independent veth pairs; each fork initializes a clean TCP/IP stack to eliminate security risks (§4.2.1).
Cgroup	*RunD* [58] and *TrENV* [38] reuse cgroups with reconfiguration. **Analysis:** Cgroup reuse is an effective practice and is adopted in AFaaS.	Utilize a cgroup pool to assign and recycle a cgroup for each instance (§4.2.1).
Seccomp	*Catalyzer* [28] and *Firecracker* [5] install a strict seccomp filter to enhance security. **Analysis:** Parsing seccomp configurations, compiling seccomp rules, and installing the compiled rules each time can lead to a slowdown under high concurrency.	Seccomp rules are pre-compiled during seed preparation (§4.2.2).
User Code Initialization	**(1) *fork*:** *SAND* [6] and *Catalyzer* [28] share initialized code (e.g., language runtimes and loaded libraries) via *fork*. **Analysis:** *SAND* does not support multi-process runtimes (e.g., Java, Node.js). Catalyzer's seed can include user code. However, supporting user code fork in Catalyzer is inefficient since each seed consumes a large amount of memory. **(2) *C/R* (Checkpoint/Restore):** *AWS SnapStart* [12], SEUSS [19], and *Sabre* [56] leverage *C/R* techniques to reduce cold start latency. **Analysis:** *SnapStart* achieves only sub-second performance [12]. Unikernels [19] and hardware acceleration [56] face significant hurdles for adoption in production. **(3) Caching:** *RainbowCake* [99] adopts layer-wise pre-warming and keep-alive strategy. **Analysis:** A practical approach, but unfriendly to infrequent functions due to user template downgrades, leaving the cold start issue unresolved. Reusing the same language container also poses data leakage risks. **(4)** *TrENV* [38] and *MITOSIS* [96] share initialized code across nodes via RDMA/CXL. **Analysis:** A reasonable approach, but it requires specialized hardware that is not available in AFaaS. Deploying such hardware would also increase deployment costs.	Tree-structured seeds reduce overall resource usage, while multi-level forking offers best-effort performance with acceptable latency (§4.3). All instances are cloned from a clean-state seed and destroyed after execution for security enhancement (§5).

Table 1. While AFaaS incorporates several proven techniques, such as cgroup reuse [38, 58], our analysis also reveals three fundamental limitations in existing solutions.

Limitation-1: Insufficient Full-Stack Optimization for End-to-End Latency. While prior work focuses on optimizing specific cold-start stages (e.g., container initialization), it often overlooks systemic bottlenecks like control path overhead. Although inter-node orchestration issues have been explored [26, 61], intra-node control path inefficiencies remain largely unaddressed.

Limitation-2: Inconsistent Performance under Stress. Real-world deployments require strict adherence to SLOs [62]. Although recent efforts (e.g., recycled network stacks [65]) partially mitigate kernel-induced degradation, they still overlook critical bottlenecks, such as resource contention during fork/clone [27, 28, 96] and the latency of seccomp rule compilation [5, 28] under high load, leading to unstable tail latency.

Limitation-3: Intensified Complexity in Code Reuse. To achieve low-latency starts, FaaS platforms often cache specific function states for reuse (e.g., checkpoint/restore or fork) [11–13, 28, 99]. However, supporting the caching of user-level code presents challenges, including high memory requirements [11, 28], the need for specialized hardware [38, 56, 96], and vulnerable deployment strategies [99].

3 AFaaS Overview

System Architecture. Figure 9 shows the AFaaS architecture. First, there is a *node gateway* to receive requests from global control plane components (e.g., schedulers), forward the requests to the node's components like high-level runtime or function instances, and respond to external requests. Second, similar to other serverless platforms, the AFaaS platform deploys two levels of runtimes: a *high-level runtime* (containerd), and a *low-level runtime* (AFaaS). The high-level runtime will directly handle requests from the node gateway, while the low-level runtime focuses on managing secure containers. We implement our secure containers based on Catalyzer [28]. Notably, to resolve Gap-1, the high-level runtime and low-level runtime communicate efficiently through a new interface called FRI (Function Runtime Interface). Moreover, AFaaS employs strategies of *resource pooling and sharing*.

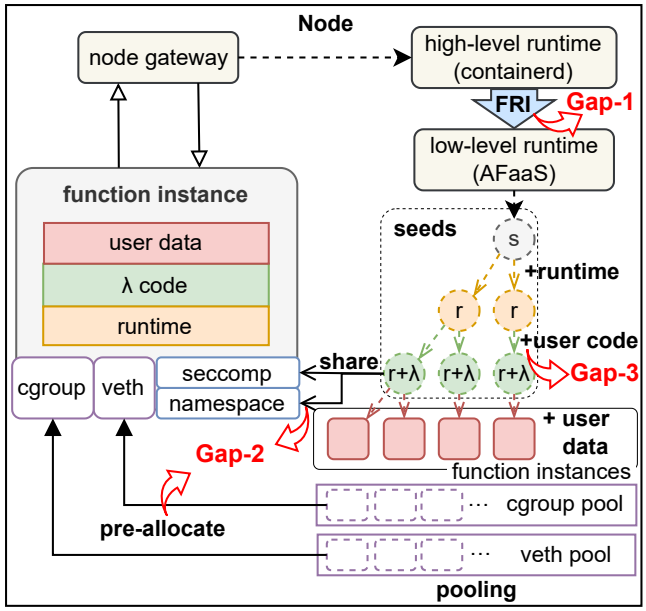

Figure 9: **AFaaS Design.**

Resources related to container allocation are managed to mitigate resource contention latency (Gap-2). Lastly, each node will maintain a tree-structured *seeds* (the template instance of functions) with different levels to resolve Gap-3, balancing performance and memory overhead. Next, we present three key insights that address the gaps identified earlier.

Insight-1: Many of the cross-runtime interactions are shim-calls that can be safely optimized. For Gap 1, we analyze the interaction requirements between high-level runtime and low-level runtime and propose FRI, a general bespoke control interface for serverless functions to shorten the control path (§4.1). A key observation is that cross-runtime interactions can be classified into two types: *shim-calls* (forwarding requests to another component) and *service-calls* (handling requests). For example, in the case of the *fork()* interface, the low-level runtime simply forwards the invocations from high-level runtime to the sandbox but does not perform any specific tasks, which is one of the shim-calls [22]. In contrast, the low-level runtime will perform complex work for *create()* to create a sandbox, which is classified as a service-call in our system. Based on this observation, we choose to replace the shim-calls, which are implemented by binary calls (18.02ms) now, with function calls by adopting a plugin-based method. The control path latency can be reduced accordingly.

Insight-2: Contended resources are more suitable to be reused or shared, rather than being created from scratch. For Gap 2, we observe that contended resources are usually low-level system resources; although their creation is not easily contention-free, they can be effectively reused and shared among instances. We adopt a resource pooling strategy for resources like cgroups and veth pairs to minimize allocation latency and mitigate resource contention. For resources that can be prepared in advance, such as seccomp filters and namespaces, we integrate them into the seed. When forking a new instance, these states can be inherited and reused directly [28, 96].

Insight-3: Fork can achieve both latency-efficient and resource-efficient with multi-level templates (or seeds). For Gap 3, we extend the seed to include user code, i.e., incorporating frequently used and time-intensive functions as templates. To manage the resource overhead of numerous seeds, we implement a hierarchical tree structure, using CoW to efficiently create child seeds from parent seeds and reduce memory usage (§4.3).

4 Detailed Design

In the following sections, we present detailed optimizations addressing each identified gap.

4.1 Shortening Control Path (Gap-1)

Current cloud-native standards, such as OCI [30], are tailored for long-running workloads. The numerous modules and lengthy control path defined by this standard make it ill-suited for serverless scenarios with high-concurrency startups and short container lifecycles. Catalyzer [28] enhances container startup by leveraging fork-based technology in the runtime engine. However, it still introduces a delay of 18*ms*–25*ms* due to executing the Catalyzer runtime engine binary, which sends an RPC to trigger the fork operation in the sandbox seed. This delay diminishes the impact of Catalyzer's sub-millisecond startup speed.

Function Runtime Interface (FRI). AFaaS introduces a lightweight serverless interface, *FRI*, to reduce the control-path latency between the high-level and low-level runtimes. The key innovation of FRI is the use of a *plugin-based interaction* model, replacing binary calls with direct function calls for frequently invoked interfaces in the serverless platform. Specifically, the low-level runtime implements the FRI interface, and the integrated plugin inside the high-level runtime interacts with it via RPC calls. As shown in Figure 7(b), we implement a *containerd-faas-package* plugin for containerd, which includes three main methods: *create()*, *fork()*, and *activate()*. The *create()* method instantiates a sandbox by loading the low-level runtime binary. Only the root seed (*level-0 seed*, §4.3) requires creation via *create()*, and this step is performed only once. After the root seed is created, the AFaaS runtime is ***never*** needed again, and the seed hierarchy is built accordingly. Subsequently, *fork()* and *activate()* are used to fork and activate new sandbox instances to run user code, which do not need to load the runtime binary as AFaaS will invoke these interfaces directly from the high-level runtime via RPCs. Thus, control latency is reduced due to ⓐ the avoidance of loading the AFaaS runtime binary each time a new serverless function is invoked, and ⓑ the shortened path where the high-level runtime directly invokes a corresponding seed to create a new

sandbox for user code. Furthermore, this design enables resource pooling for veth (§4.3), as AFaaS can reuse network resources by sharing the network namespace (netns) and reclaiming the network interface after the sandbox exits. The high-level runtime retains the netns and interface information and passes them via fork arguments.

Decision: *FRI demonstrates that strategic interface specialization for FaaS — sacrificing little modularity versus OCI — unlocks significant efficiency gains in cold starts, a transformative trade-off for serverless systems.*

4.2 Resource Pooling and Sharing (Gap-2)

To reduce resource contention latency, we design two *fork-friendly optimizations* without breaking the isolation guarantee of secure container (security analysis provided in §7): (1) *Resource Pooling*: Resources that can be pre-allocated are allocated or recycled in advance and stored in pools, reducing concurrent conflicts. (2) *Resource Sharing*: Resources that can be inherited and shared from the seed are integrated into the seeds, avoiding unnecessary reallocations.

4.2.1 Resource Pooling

Virtual Ethernet. AFaaS assigns a network device to each container for isolation. To minimize overhead, we pre-allocate a sufficient number of network devices, which are dynamically assigned during container creation and recycled once the container exits. This approach eliminates the significant overhead of network device creation.

Cgroup. Cgroups are used to limit container resource usage. In traditional cloud-native environments, new cgroups are created for each container and removed after the container is destroyed. This management mechanism can be time-consuming under high concurrency. AFaaS introduces a cgroup pool that recycles cgroups when the sandbox instance is deleted. When creating a new instance, an available cgroup will be selected from the pool and assigned to the instance.

4.2.2 Resource Sharing

Namespaces. Linux namespaces isolate containers on the host OS. In Catalyzer, each fork creates and configures new network and IPC namespaces, causing significant resource contention under high concurrency and sustained execution. AFaaS allows seeds and function instances to share the same network and IPC namespaces. Cross-VM instance sharing is secure, as user code runs within the guest OS of secure containers, ensuring isolation and preventing interference.

Seccomp. Seccomp is a Linux kernel feature that restricts the system calls a process can make. Secure containers enforce strict seccomp rules to prevent attacks, but installing seccomp involves parsing configurations, compiling rules, and installing them into the kernel, leading to contention and performance fluctuations. In practice, seccomp rules are generally fixed, as seen in gVisor [40] and Firecracker [5], which use predefined rules. In AFaaS, seccomp configuration parsing and compilation are completed during the seed preparation phase, so that when a new instance is forked, only a simple installation step is required.

Network Stack. The network protocol stack requires substantial memory for ring buffers and the initialization of complex data structures. Since each instance requires its own configuration, sharing the network stack is challenging. However, we observe that most operations are similar across instances. To avoid redundancy after forking, we divide the network module into shareable and non-shareable parts. The shareable components include key TCP/IP stack elements like clock, random seed, protocol handlers, TCP/UDP control blocks, and ARP tables. Non-shareable components, such as IP/MAC addresses and backend devices, must be assigned separately. Memory allocation and structure initialization are performed during the seed preparation phase. After forking, the raw socket is passed to the instance, which is then probed, bound to the veth interface, and the network stack is initialized.

Decision: *Contention bottlenecks are eliminated by decoupling key resources: pooling/sharing high-contention elements while retaining the sandbox fork's low-latency initialization, achieving faster cold starts in high-density deployments without sacrificing security.*

4.3 Seeding User Code (Gap-3)

To reduce application initialization overhead, Catalyzer uses language runtime templates with pre-initialized runtimes (e.g., Python, Node.js, JVM). As discussed in §2, initializing the runtime alone is insufficient for production workloads. User code initialization latency is influenced by factors such as dependent library loading, JIT compilation, and framework initialization (e.g., parsing large XML configuration files in Spring). In AFaaS, frequently invoked functions are optimized with dedicated seeds containing user code to reduce cold start latency. However, maintaining numerous container seeds can increase memory overhead. To balance performance and resource usage, AFaaS employs tree-structured seeds and multi-level fork mechanism.

Tree-structured Seeds. As illustrated in Figure 10, function seeds in AFaaS are organized hierarchically in a tree structure; the child seeds reuse the memory of their parents. During seed preparation, the high-level runtime performs a hierarchical search to select an appropriate seed for forking. The newly forked instance completes incremental tasks (e.g., language runtime initialization, dependency imports, JIT compilation) and then enters a paused state, becoming a new seed. Incremental updates are managed using a CoW mechanism.

Multi-Level Fork. When a new user request requires a func-

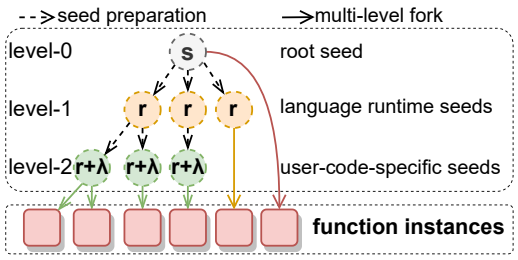

Figure 10: **Seed organization of AFaaS.** There are three types of seeds. The level-0 seed (root seed) contains data from the guest OS and is unique to each computing node. The level-1 seeds (language seeds) are forked from the level-0 seed and initialize the language runtime. The level-2 seeds (user-code-specific seeds) initialize the framework, import libraries, and compile user code.

tion instance, the high-level runtime searches the seed tree for a suitable seed. If a seed with the user code exists, it forks a container from that seed. Otherwise, it searches higher-level nodes to locate seeds with the language runtime, which typically fulfill the request.

Benefits. Our design offers two distinct advantages compared to previous approaches [11, 12] for caching user code: (1) *State Reusing*: The tree structure of seeds enables the sharing of physical memory pages across levels and nodes, leading to a reduction in global resource consumption; (2) *Best-effort fork*: In contrast to previous methods limited to forking from user-code seeds or starting from scratch, our multi-level fork approach based on the seed tree allows for best-effort provisioning. Even if a function lacks user-code-specific seeds, it can still be served with language runtime seeds or root seeds, ensuring acceptable performance.

Decision: *Tree-structured seeds with multi-level forking enable adaptive cold starts — initializing instances from the nearest viable ancestor to reduce resource overhead while maintaining low latency via granular state reuse.*

5 Implementation

We implement AFaaS based on Catalyzer [28] with the following enhancements for production.

Container Early Destroy. Container shutdown is also a critical concern, as the procedure can take over 10 seconds due to factors such as language runtime shutdowns (e.g., JVM), file system flushing, and kernel exit. AFaaS addresses this with container early destroy. Since serverless functions execute user code through a unified handler, the function is considered complete once the handler returns. At this point, AFaaS pauses the guest OS, disconnects TCP connections, and shuts down the container to reclaim resources. Due to the inherently ephemeral and stateless nature of functions in serverless computing, ensuring state correctness is relatively straightforward. For example, database access is typically performed via remote calls to centralized storage. By simply and properly terminating all TCP connections, the integrity of data consistency can be effectively safeguarded. Most production functions adhere to this pattern, enabling early destroy without affecting execution correctness.

EPT Prefill. EPT Prefill is used to reduce overhead from Extended Page Table (EPT) violations. The EPT translates Guest Physical Addresses (GPA) to Host Physical Addresses (HPA). When a seed forks a new instance, the instance transitions from root to non-root mode before executing user code. Although the seed and instance share physical memory pages, the EPT page table is uninitialized, leading to EPT violations when the guest OS accesses memory. Each violation triggers a VM-exit for page table reconstruction, causing significant overhead due to the short execution time of serverless functions. To address this, AFaaS employs EPT Prefill. During the fork, the seed copies its EPT page table to the new instance and marks the last level of the page table directory as read-only. This prevents EPT violations for memory reads.

6 Evaluation

Our evaluation aims to answer the following questions:

- *Q1:* How much improvement does AFaaS offer in reducing end-to-end latency and enhancing performance stability under heavy workloads? (§6.2)
- *Q2:* How does each technique in AFaaS optimize the end-to-end latency and performance stability? (§6.2 & §6.3)
- *Q3:* How does performance scale with varying levels of concurrency? (§6.4)
- *Q4:* How much memory can be saved by organizing FaaS instances in a tree structure? (§6.5)
- *Q5:* How is the performance of the production system after deploying AFaaS? (§6.6)

6.1 Methodology

Experimental Setup. We conduct all our experiments on an x86-64 machine with 24 cores Intel(R) Xeon(R) Platinum 8163 CPU @ 2.50GHz server and 512GB of RAM. The server runs Linux 5.10. The *wrk benchmarking tool* [91] is used to test end-to-end latency with varying concurrent requests. The evaluation takes the following systems as baselines.

1. ***CataOnly*** is the Catalyzer system augmented with our enhancements and optimizations described in §5. This configuration establishes the baseline serverless platform that exclusively leverages Catalyzer's capabilities while deliberately excluding other platform-level optimizations.
2. ***CataOPT1*** [1] represents an upgraded version of Catalyzer, to deal with resource contention latency (**CataOPT1 =**

[1] In practice, we implemented the optimization for Gap-2 first to reduce the container initialization latency, similar to that in related works.

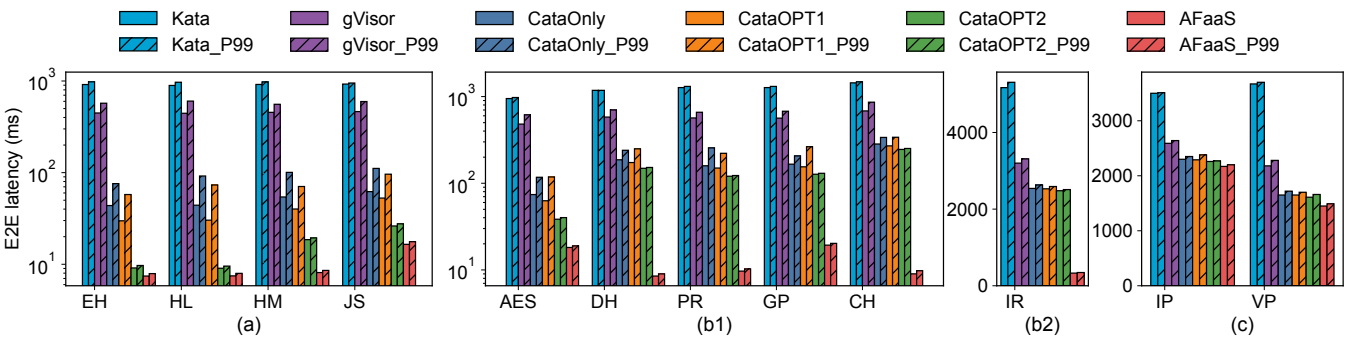

Figure 11: **End-to-end latency (sequential).** The hatched bar represents P99 latency, and the un-hatched bar indicates average latency. To enhance clarity, a logarithmic scale is employed for (a) and (b1), whereas a linear scale is utilized for (b2) and (c).

CataOnly + Gap2-OPT).

3. ***CataOPT2*** utilizes the FRI mechanism to optimize control path (**CataOPT2 = CataOPT1 + Gap1-OPT**).
4. ***AFaaS*** is our final production platform that further optimizes the user code initialization (**AFaaS = CataOPT2 + Gap3-OPT**).
5. ***Kata*** (v3.15.0) initializes by cloning from a pre-created VM (Kata-template [46]).
6. ***gVisor*** (release-20250414.0) starts from scratch [40].

We select Catalyzer as our baseline for its state-of-the-art sub-millisecond startup performance for secure containers. We also include gVisor and Kata as baselines because they are production-proven and open-source, and support the same hardware configurations.

Functions Evaluated. We select functions from representative serverless benchmarks, such as Function-Bench [49] and SeBS [25], which encompass a diverse range of scenarios. These include `EH` (Echo: response without any operation), `HL` (Hello: print "Hello, World"), `HM` (High Memory: malloc 1GB memory), `JS` (JSON Serde: deserialize and serialize JSON), `AES` (PyAES: encrypt messages), `DH` (Dynamic HTML: generate dynamic web pages), `PR` (PageRank: PageRank algorithm), `CH` (Chameleon: render HTML tables), `IP` (Image Processing: apply image processing algorithms to an image), `VP` (Video Processing: convert a video into grayscale), and `IR` (Image Recognition: image recognition using ResNet).

6.2 End-to-End Latency

End-to-End Latency. We first assess the average end-to-end execution time of typical functions in a sequential mode, as shown in Figure 11. Each function was tested for a duration of 1 minute. Based on the user code initialization and execution durations, we classify these typical functions into three distinct groups.

Figure 11(a) illustrates the functions with both short user code initialization and execution time. For these functions, the latency of control-path and container initialization accounts for a significant proportion. AFaaS achieves a speedup of 3.76×–6.68× for average latency and 6.31×–11.74× for P99 latency, compared with CataOnly. These improvements are largely attributed to the reduction in the control-path time facilitated by the FRI mechanism, coupled with optimizations during the container initialization phase. The differences between CataOPT2 and AFaaS are not significant.

Figure 11(b1/b2) illustrates functions that have longer initialization time for user code but with shorter execution time. This pattern is observed in functions that necessitate the one-time loading of large datasets or complex initialization operations. The performance enhancement of the AFaaS is remarkable. It pre-initializes user code in seeds, facilitating subsequent requests to execute promptly through forking. Compared to CataOnly, CataOPT2 reduces average latency by 1.02×–1.92× and P99 latency by 1.04×–2.92×. AFaaS reduces average latency by 4.09×–31.48× and P99 latency by 6.19×–34.51×.

Figure 11(c) illustrates functions with longer execution time. The performance optimizations of AFaaS in control-path, container initialization, and user code initialization are less noticeable compared to the function execution time. The performance improvements are about 1.05×–1.14× on average latency and 1.07×–1.15× on P99 latency.

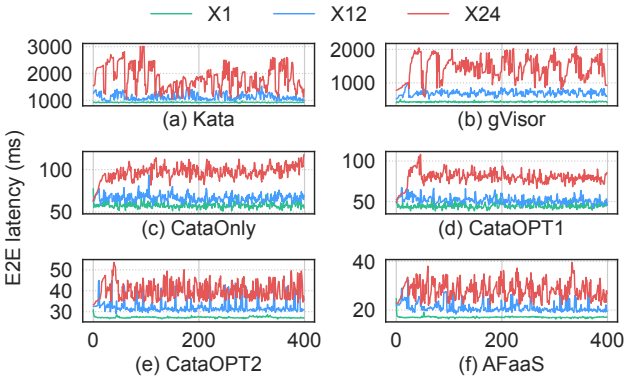

Figure 12: **E2E latency under different levels of concurrency.** 400 continuous samples for each system.

Concurrency and Sustained Traffic Performance. We evaluate the performance stability of AFaaS under different con-

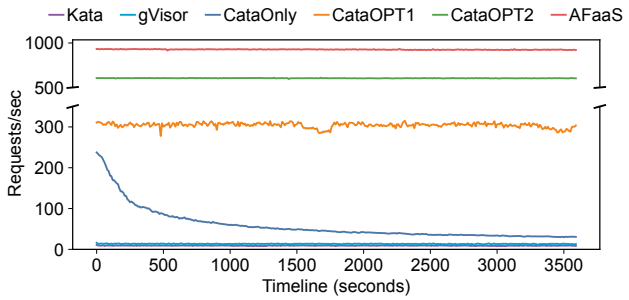

Figure 13: **Throughput variation over time at high sustained concurrency (×24).**

currency levels and sustained traffic using the `JS` function. Figure 12 contrasts the E2E latency and fluctuations under diverse levels of concurrency using `JS`. At concurrency levels ranging from 1 to 24, AFaaS demonstrates superior E2E latency and stability. The E2E latency of AFaaS falls within the range of [16.34 ms, 39.56 ms], compared to CataOnly's latency range of [51.32 ms, 117.92 ms]. Furthermore, the cold start time for AFaaS ranges from 6.97ms to 14.55ms, while for CataOnly, it spans from 38.39ms to 74.05ms. Kata and gVisor exhibit orders-of-magnitude worse E2E performance under high concurrency.

Figure 13 shows a notable decline in CataOnly's performance over time. The degradation is attributed to superblock cache misses and kernel lock contention (analyzed in §2.2), leading to a transition from the fast path to the slow path for newly created IPC namespaces, while other versions maintain relatively stable performance.

6.3 Optimization Breakdown

This section examines how CataOPT1 improves latency compared to CataOnly. The JS test function is used.

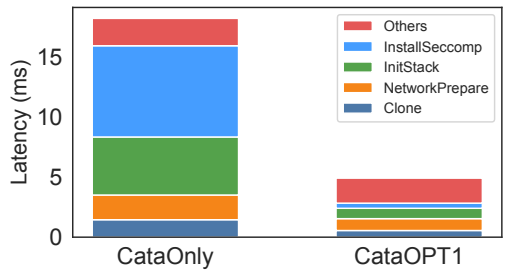

Figure 14: **Latency of CataOPT1 and CataOnly.** The "Others" category includes the remaining phases in the container initialization stage shown in Figure 6.

End-to-End Latency Optimizations. Figure 14 illustrates the optimization across various stages in sequential mode, highlighting key improvements from the *Clone*, *NetworkPrepare*, *InitStack*, and *InstallSeccomp* phases. In the *Clone* phase, Catalyzer invokes *clone()* with `CLONE_NEWNET` and `CLONE_NEWIPC`, placing the new instance into an independent network namespace (netns) and IPC namespace. CataOPT1 reduces namespace creation latency by sharing the namespace with the seed. During the *NetworkPrepare* phase, AFaaS minimizes the latency involved in parsing the specified netns path in *config.json* and executing *setns()*. In the *InitStack* phase, AFaaS decreases the initialization time of the network protocol stack. Finally, in the *InstallSeccomp* phase, AFaaS reduces the latency required to compile and load the seccomp rules.

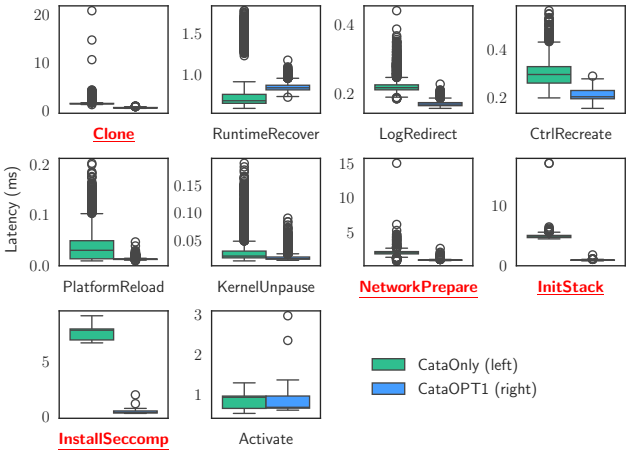

Figure 15: **Latency fluctuation of different phases during container initialization (10 phases in Figure 6).** Evaluated under sustained high concurrency (×24). The underlined phases are optimized.

Resource Contention Optimizations. We measure the fluctuation of various phases in the container initialization phase of CataOnly and CataOPT1 under high sustained concurrency (×24), as shown in Figure 15. Sharing the namespace reduces fluctuation during the *Clone* phase. The veth pool and FRI can decrease the fluctuation in parsing *config.json* during the *NetworkPrepare* phases. Pre-initialization of the protocol stack can mitigate the fluctuation in the *InitStack* phase, and the use of seccomp pre-compile technology can reduce the fluctuation associated with seccomp rule compiling and loading. After mitigating the main resource contentions, fluctuations in other phases are also reduced.

6.4 Scalability

We evaluate the throughput and end-to-end latency of different systems as the degree of concurrency gradually increased with the `JS` function. The results in Figure 16 show that the throughput of AFaaS scales significantly with increasing concurrency, demonstrating the best scalability. AFaaS also maintains the lowest end-to-end latency across all concurrency levels, with the least gradual increase. For comparison, CataOnly shows relatively high end-to-end latency and quickly hits a performance bottleneck, with a slight decline as the number of

concurrent requests increases. Both Kata and gVisor exhibit poor performance in terms of throughput and latency.

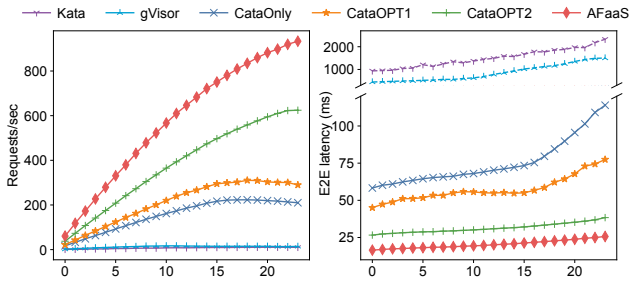

Figure 16: **Throughput (left) and E2E latency (right) with varying levels of concurrency.**

6.5 Memory Consumption of Multi-Level Fork

As shown in Figure 17(a), for seeds with the same user code, AFaaS reduces memory usage by 28.11%–84.91% compared to CataOnly. This is because the seeds share the *guest OS* and *language runtime*. For functions with long initialization time and a high execution volume, this approach is both cost-effective and efficient. When the user code size is large (e.g., `VP`, `IR` in Figure 17(b)), the shared components have a minimal impact, and the benefit is less noticeable.

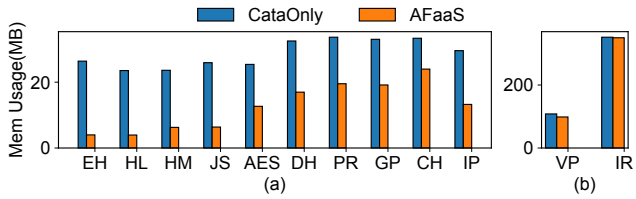

Figure 17: **Memory costs of level-2 seeds.**

6.6 Real-World Workload in Production

End-to-End Latency. AFaaS is widely deployed in Ant Group. To demonstrate the effectiveness of AFaaS, we compare the performance of AFaaS with CataOnly in production environment. We select eight representative Node.js functions for comparison (Table 2). For AFaaS, we perform a statistical analysis of the average end-to-end latency on the server for one day. For CataOnly, we test on the same hardware machine and follow the same pattern (mocked peer call responses).

As shown in Figure 18, the overall speedup ranges from 1.80× to 8.14×. Among them, the *encoder* achieves a lower speedup of 1.80× because its user code incurs higher execution latency. The *cc* function achieves a higher speedup of 8.14× due to reduced module load time. AFaaS maintains a stable startup latency from 5.45ms to 9.41ms.

Deployment Cost. Table 3 summarizes the memory sizes of seeds at different levels in production. Most functions achieve millisecond-level startup with a memory cost ranging from $6.9MB - 135.03MB$. This approach offers a better cost-effective alternative compared to hot start solutions that cache instances (for 1 minute).

Func	Description
mongo	Import an SDK and query the backend DB service.
bff	A service coordinates requests to multiple interfaces. [9].
cc	Schema-based code generator.
png	An image tool merges existing images to create new ones.
nunjucks	Render the template to HTML using Nunjucks [67].
mock	Generate random user data for unit testing.
encoder	Generate the base64 data for a QR code image.
compile	Input a JS file, and build the JS file into V8 code cache.

Table 2: **Representative functions in production.**

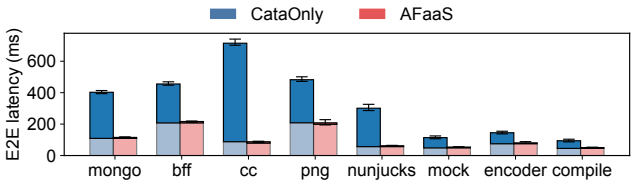

Figure 18: **End-to-end latency of the representative functions in production.** Each bar has two parts: the upper dark part shows the total time for control-path, container initialization, and user code initialization, while the lower light part indicates user code execution time.

Seeds	Memory	Seeds	Memory
level 0	14.31 MB		
level 1 (Node.js)	54.01 MB	*level 1* (Python)	29.05 MB
level 2 (mongo)	54.40 MB	*level 2 (bff)*	63.84 MB
level 2 (cc)	135.03 MB	*level 2 (png)*	90.20 MB
level 2 (nunjucks)	63.70 MB	*level 2 (mock)*	51.40 MB
level 2 (encoder)	9.46 MB	*level 2 (compile)*	6.90 MB

Table 3: **Memory cost of different level seeds in production**.

7 Discussion

Security Analysis. AFaaS follows the threat model of existing secure containers (e.g., Catalyzer [28], FireCracker [5], RunD [58], Kata Containers [31], gVisor [40]), where apps within the container could be compromised or malicious [37, 97, 98] and the sandbox and underlying host kernel are considered potential attack targets. Secure containers reduce the attack surface caused by traditional containers sharing the host kernel. Compared to gVisor, which both Catalyzer and AFaaS are based on, we make design choices to enhance performance. Below, we first examine the security implications of resource pooling and sharing strategies, followed by analyzing other security limitations in the current implementation.

(1) Security of Resource Pooling: (a) veth pool: AFaaS ensures that long-lived connections are gracefully terminated before reclaiming the device to prevent new users of the device from receiving unexpected data packets. (b) cgroup pool:

There is only one container inside the cgroup, and each cgroup is properly released after the exit of the function. Similar mechanisms have been used in previous work [38, 58].

(2) Security of Resource Sharing: (a) network namespaces: Network resources in AFaaS, such as devices, IP addresses and routing tables, are controlled within the guest OS. Therefore, sharing the host's network namespace between seed and sandbox does not pose any security issues. (b) IPC namespaces: The IPC namespace on the host is used mainly to isolate communication through shared memory. It is secure because there are no use cases for inter-sandbox (VM-process) IPC communication through shared memory in AFaaS.

AFaaS enables memory pages to be shared across different levels of seeds and instances, which may result in potential leakage of seeding data. However, instances can only access their own seed data, not that of others. This aligns with prior seed-based works (e.g., Catalyzer [28], Molecule [27], MITOSIS [96]) and does not introduce new side-channel attack risks. To enhance security, we audit function behavior, including IP addresses, ports, and protocols for ingress and egress.

Overall Impact. AFaaS achieves near hot-start performance with minimal additional resource consumption. Compared to strict cold starts, optimization techniques such as pooling, sharing, and seeding incur predictable overhead — a controlled trade-off inherent in production-grade serverless platforms. Beyond the memory footprint of the seed, AFaaS preallocates specific kernel objects, such as veths and cgroups, to alleviate contention bottlenecks. This allocation is limited and lightweight. Specifically, we pre-allocate 1,000 veths and 600 cgroups, resulting in negligible impact on the host OS. Moreover, the scheduler guarantees that function instances remain within the resource capacity of the node.

Generality. The design of AFaaS is broadly applicable to other platforms. First, AFaaS transforms the standard, general-purpose OCI into the specialized and efficient FRI that prioritizes performance over flexibility. Though this tight coupling with FaaS requirements necessitates runtime-specific adaptations, FRI's containerd-plugins architecture proves especially advantageous in performance-critical scenarios. Second, veth, cgroup, namespace, and seccomp are essential components of containers. Current container solutions also experience performance degradation under high stress. Our proposed solutions in this work are practical and deployable. Third, Google Cloud, AWS, and Alibaba Cloud could also benefit from our tree-structured seeds and multi-level fork design by integrating with VM fork [54].

8 Lessons Learned and Experiences

Workload Diversity. Serverless workloads exhibit behavioral divergence across cloud environments. In private clouds, Meta's XFaaS [75] emphasizes resource efficiency for latency-tolerant, non-interactive triggers (e.g., queues, events, and timers) through batched execution. In contrast, public clouds highlight diverse cold-start challenges: 80% of functions in Alibaba's FaasNet and 50% in Microsoft Azure run for over one second [78, 92], while AWS reports that 1% of invocations face cold starts lasting 100ms to 1s [8]. AFaaS operates under distinct constraints: short-lived functions and frequent cold starts demand millisecond-level initialization, a gap this work aims to address.

Fork's Renaissance in Serverless Systems. While prevailing approaches like caching [11, 99] and C/R [12, 19, 20, 56] achieve sub-second cold starts, they face fundamental limitations: caching relies on pre-warmed containers but struggles with unpredictable invocation patterns, while C/R incurs state restore overheads that cap latency reductions. Our production experience demonstrates that *fork*, when augmented with systematic optimizations, redefines viability for latency-critical workloads. Unlike probabilistic caching or I/O-bound C/R, *fork* enables **deterministic millisecond-level cold starts** through direct memory inheritance while preserving security via CoW semantics. This paper details how we overcome *fork*'s limitations (e.g., resource contention) through system optimizations, achieving production-scale deployment with many daily *forks* at millisecond-level (and even sub-millisecond) latency.

AFaaS Deployment Experience. While fork-based approaches offer advantages, there are still some issues that went wrong or were unexpected. We present insights that could be beneficial to know in advance for deployments.

(1) Special handling of uniqueness states is necessary to prevent unexpected behavior. While reusing a running seed's state can reduce startup latency, unique states such as random numbers or cryptographic tokens must be reinitialized carefully instead of being reused directly. For example, gVisor [40] uses a buffered I/O mechanism to batch *getrandom()* syscalls from the host kernel, reducing the frequency of host syscalls. However, this approach unintentionally duplicates random sequences in forked instances due to inherited states. To prevent security risks, AFaaS must ensure proper isolation and re-initialization of these states after fork operations. Similar issues exist in other systems, e.g., Firecracker explicitly warns against entropy reuse in restored microVM snapshots [29] due to the same risk.

(2) Bottlenecks under ultra-high concurrency and co-located deployment. Although AFaaS has optimized the main resource contention, some competition situations can still be observed in extremely high concurrency and co-located deployment scenarios [43]. First, the seed itself may become a bottleneck because only one instance can be cloned from it at a time (serially) as concurrency increases. AFaaS further enhances concurrency by deploying multiple instances of the same seed type. Second, when functions are repeatedly created and destroyed at a high frequency over an extended period, seccomp installation failures may arise due to bpf_jit_limit leaks [16]. Third, in co-located deployment

environments, other workloads (e.g., long-running microservices, large-scale data processing) on the node may acquire and hold the global lock of a cgroup. While AFaaS utilizes a cgroup pool to mitigate resource conflicts, the assignment or recycling of a cgroup to an instance still requires lightweight locks. This can potentially lead to performance jitter under high-concurrency scenarios.

(3) Don't be a noisy neighbor during preparation. AFaaS needs to prepare seed trees and resource pools, such as veth pairs and cgroups, in advance for function requests. Although the allocation is lightweight, the preparation process must avoid disrupting other workloads. First, not all kernel resources require pooling; it is crucial to identify the minimal necessary set. For example, resources like cpuset and cpuacct within cgroups do not need to be pooled. Second, creating resource pools (e.g., cgroup pools or veth pools) for AFaaS during system initialization can affect node workloads. For instance, the *netlink* operation when initializing the veth pool may lead to contention over the *cb_mutex*, resulting in spikes in both pod and node loads. To mitigate this, initialization should be performed serially. Lastly, if there are too many user-specific seeds, the system's memory pressure will increase, and AFaaS will swap some data to disk.

9 Related Work

Optimizations for Cold Start. Besides Catalyzer [28], other techniques also adopt *fork*-based methods [27, 68, 90, 96] to optimize cold start, but often overlook end-to-end life cycle gaps in production environments. These gaps are relevant to various cold start technologies, including lightweight virtualization [5, 31, 40, 58, 64], unikernels [50, 53, 71, 85], new container types [24, 52, 86], container C/R [13, 19, 28, 38, 51, 55, 56, 70, 79–81, 89, 94, 95], caching [17, 33, 63, 73, 74, 93, 99], provisioning [15, 60, 66, 92], and sharing [38, 48, 59, 76, 100, 101]. Notably, SOCK [68], SEUSS [19], and RainbowCake [99] share similarities with our tree-based hierarchical design and also incorporate user code into the seed. For example, RainbowCake [99] introduces a layer-wise container pre-warming and keep-alive strategy. However, unlike these systems, we prepare seeds exclusively during seed preparation (§4.3) and do not support dynamic seed scaling. Our approach is simpler and more practical, having been validated for effectiveness in industrial deployments.

Hot Function Optimizations. There are works that optimize hot functions for throughput and concurrency. Nightcore [42] focuses on efficient processing of internal function calls generated during the execution of a serverless function. MXFaaS [84] shares CPU, I/O, and memory between concurrent invocations of the same function. 95% of the requests on our platform are related to high-frequency functions with hot starts, which can be improved with these works. This paper addresses the remaining 5% infrequent requests (covering over 50% of functions) related to cold start issues.

Control Plane and Orchestration. Most FaaS orchestration efforts, beyond mainstream solutions like Kubernetes [14, 18], focus on improving scheduling policies [21, 32, 42, 57, 82, 87, 88] and load balancing [4, 34]. Studies like Dirigent [26] and [61] highlight control plane bottlenecks in current FaaS cluster management. Dirigent [26] introduces a container orchestration system designed specifically for FaaS, aiming to reduce communication overhead and maximize throughput. These approaches are orthogonal to AFaaS and can complement each other effectively.

Industry Perspective. Recently, platforms such as Azure Functions [78], Alibaba Cloud Functions [58, 92], AWS Lambda [17, 83], Meta [75], and Huawei Cloud [20, 44, 45] have reported their serverless practices, workload characteristics, and optimization strategies [77]. However, prior studies have not thoroughly analyzed cold start issues within complex production environments or addressed unresolved real-world gaps from an end-to-end perspective, which are the key contributions of this paper.

10 Conclusion

This paper addresses the cold start challenge in serverless computing, focusing on industrial-scale deployment. Through an in-depth analysis of existing solutions, we identify three key bottlenecks: (1) inefficient control-path interactions, (2) resource contention under concurrency, and (3) user code initialization overhead. To mitigate these issues, we propose AFaaS. AFaaS replaces the heavyweight OCI with an efficient FRI in the control path, pools and shares resources to alleviate contention, and uses tree-structured seeds with multi-level forking for fast forks and efficient memory use. Our evaluations show that AFaaS reduces the cold start latency by 1.8× to 8.14× compared to state-of-the-art solutions, achieves <15 milliseconds at 24x concurrency, and decreases memory usage by up to 84.9%. Deployed in Ant Group's production environment for over 18 months, AFaaS demonstrates robustness and cost-effectiveness.

Abstract

In virtual machine (VM) allocation systems, caching repetitive and similar VM allocation requests and associated resolution rules is crucial for reducing computational costs and meeting strict latency requirements. While modern allocation systems distribute requests among multiple allocator agents and use caching to improve performance, current schedulers often neglect the cache state and latency considerations when assigning each new request to an agent. Due to the high variance in costs of cache hits and misses and the associated processing overheads of updating the caches, simple load-balancing and cache-aware mechanisms result in high latencies. We introduce *Kamino,* a high-performance, latency-driven *and* cache-aware request scheduling system aimed at minimizing end-to-end latencies. Kamino employs a novel scheduling algorithm grounded in theory which uses partial indicators from the cache state to assign each new request to the agent with the lowest estimated latency. Evaluation of Kamino using a high-fidelity simulator on large-scale production workloads shows a 42% reduction in average request latencies. Our deployment of *Kamino* in the control plane of a large public cloud confirms these improvements, with a 33% decrease in cache miss rates and 17% reduction in memory usage.

1 Introduction

Large cloud providers invest billions of dollars in infrastructure to accommodate the growing demand for different forms of virtual machines (VMs) [16]. The VM allocation systems, which assign VM requests to the physical hardware, are therefore considered critical in the cloud stack. These systems are designed to satisfy two main goals: (i) complete the VM assignment within a stringent latency upper bound (in the order of tens of milliseconds); (ii) achieve "high quality" allocations, which accounts for a variety of provider and customer preferences; one example here is placing the VMs in a way that servers are highly utilized, which leads to high infrastructure Return of Investment (ROI) [16]. Unfortunately, these two design goals are inherently at odds as high-quality allocations require considering numerous objectives and constraints that must be evaluated over huge inventories (e.g., hundreds of thousands of servers). This typically makes the process computationally intensive [13, 31, 36], and a potential bottleneck at high-load scenarios [6, 16].

Cloud providers have dedicated substantial efforts to sustaining low VM allocation latencies without giving up on adequate quality. One standard approach is to utilize multiple allocation agents (or instances) over the same hardware inventory (e.g., an availability zone). A common design choice is to include multiple such allocator agents (henceforth referred to as AA) in a single node (a physical server) and further scale out by using multiple nodes [16, 36, 41]. Intra-node scaling of AAs exploits multicore parallelism and reduces the communication, consistency, and resource usage overheads that arise from scaling AAs across multiple nodes. This paper focuses on the mechanism for deciding which AA should be assigned to handle each incoming request.

In addition to having multiple AAs, a complementary approach to reduce latency and increase throughput when resolving allocation requests is to employ in-memory caching. State-of-the-art VM allocators, such as those employed in Azure, use a domain-specific caching layer [16, 41, 43]. However, unlike traditional caches that store only data objects, VM allocators store a combination of rules with fully or partially computed inventory state and a preferred set of servers for each allocation request type. Additionally, each cache entry size can vary from 10 to 100 MB, which enforces limits on the number of in-memory cache slots. A cache hit involves a combination of cache lookups and minor computations. In contrast, a cache miss might increase the latency to hundreds of milliseconds due to computational and data access costs, which vary significantly based on the complexity of allocation request types. Finally, some VM allocators use private AA caches to avoid concurrency control and synchronization overheads [16].

A key limitation of the state-of-the-art VM allocator de-

*Part of this work was done during an internship at Microsoft Research, Redmond

signs is the *lack of synergy between scheduling a request to an AA and the underlying caching mechanism.* More precisely, state-of-the-art VM allocators resort to standard load balancing techniques [16, 43], where requests are scheduled to an AA even if the request type does not reside in the AA's cache. The schedulers use simple strategies such as round-robin, work-stealing, uniform random assignment, or more complex hashing-based approaches to balance requests across the AA. Unfortunately, these strategies might lead to cache misses and computational overheads at production scale, with thousands of request types over a large inventory of up to hundreds of thousands servers, resulting in excess allocation latencies.

A different approach is to take inspiration from other domains, such as processor caches [26], content delivery networks (CDNs) [48], and storage caching [4], to design cache-aware request scheduling to the AAs. A plausible cache-aware scheduling policy would send requests of the same type to the same set of AAs. However, such simple cache-aware scheduling results in the following critical challenges: (1) Popular requests in certain workloads could create hot spots by scheduling requests to the same AA, increasing queuing delays and raising both average and tail latency. (2) A distinct challenge specific to VM allocators is that caches are generally hierarchical, with a smaller top-level cache that stores the information about the request type and a lower-level cache whose content may be consumed by different request types. Consequently, it is hard to a-priori estimate the resulting outcome of assigning a request to an AA; for example, partial hits are common, latencies are highly variable as a function of the request type, cache state, and system load, and different parts of that cache require more processing time to get up-to-date.

In view of the above challenges, we design and implement *Kamino* – a hybrid latency- and cache-aware VM allocation request scheduling framework for minimizing end-to-end request latency. At a high level, each AA is augmented with a request queue, and Kamino assigns each request to one of the queues based on latency considerations. The underlying algorithmic problem turns out to be a generalization of the classical problem of optimal online job scheduling for latency minimization [5], which is known to be notoriously hard in theory [5, 7]. Intuitively, our problem is even harder than the classical one because now the requests' processing times are not fixed and depend on which information is in the cache, which in turn depends on the scheduler's previous decisions. Nonetheless, the theoretical conceptualization allows us to design our scheduling algorithm based on first principles. We design a novel hybrid algorithm called *LatCache*, a latency-driven request scheduling algorithm that estimates latency even with access to only a set of partial indicators such as the type of requests in each queue and their cache hit predictions.

At its core, the key insight of the *LatCache* algorithm is to estimate the request latency within the target AAs' queues based on estimated processing time of the requests in each queue, and assign a new request to the queue where the end-to-end latency (queuing time + processing time) would be minimal. The processing time estimates are derived by an efficient analysis of the current cache state and how the queued requests effect the cache state as they are processed. This enables Kamino to dynamically adapt to any arrival pattern, while exploiting the AA caches (§2.2.1). While cache-aware load-balancing has been applied in previous works (see §7), a key novelty in our approach is considering the cache state, and in particular cache hit rates, as only one of the components contributing to end-to-end request latency, which is our actual metric of interest. Thus, we need to combine the state of different components (e.g., cache and queue) to efficiently estimate the request latency on the fly, also taking into account our hierarchical cache structure.

We implement and validate the effectiveness of Kamino and *LatCache*, first through high-fidelity simulations and then on Azure's production control plane. Kamino's architecture preserves a clear separation between the internal logic of VM assignments to physical machines and *LatCache* to isolate frequent modifications of the former. To sustain high throughput, we pipeline individual stages of Kamino, such as the request classification and queue assignment.

We compare Kamino against state-of-the-art techniques, including Protean, Azure's VM allocation system, and consistent hashing, which is widely used for workload balancing in other distributed systems [47]. Our simulation using multi-region production allocation traces indicate that Kamino obtains an average 42% reduction in latency over the latency agnostic scheduler. As a by product, *LatCache* accommodates up to 2x more throughput, which is especially significant in bursty load periods.

We deployed Kamino with a simple version of the *LatCache* algorithm in all production zones (with up to hundreds of thousands of machines each), reducing allocation latency by 11.9% at the 90th percentile and reducing cache misses by 33%. Additionally, the memory footprint per AA is reduced by up to 17%, enabling more AAs and other services per control-plane machine.

In more detail, the practical significance of these improvements is the following: the tail latency reduction ensures that resource provisioning remains reliable, especially for latency-sensitive workloads like data analytics platforms, online gaming, and virtual desktops. High tail latency in VM allocation can delay autoscaling, causing unpredictable instance availability and degrading application performance. The improved cache miss rate reduces the number of machines required for AA, which decreases contention and communication overheads, and in turn conflicts and retries in the allocation system. This results in more efficient request handling and overall system stability. The AAs run in ringfenced control plane nodes instead of the general cloud fleet for better predictability and security, and share resources with hundreds of other control-plane microservices. Thus, having resource efficiency solutions, specifically memory efficiency, is critical.

The combined improvements in latency, throughput and resource consumption are enabling Azure to consistently serve hundreds of thousands VM requests in a zone, while freeing up compute for a growing number of other control-plane services.

Beyond VM allocators, we believe that our approach can extend to systems with variable request latencies, including Log-Structured Merge Trees (LSMs), distributed databases, content delivery networks (CDNs), and microservices architectures. Indeed, we conducted preliminary experiments employing latency and cache-centric mechanisms in an LSM-based key-value store. By accounting for the differing request latencies and locality awareness across multiple levels (as in Kamino), our results show a reduction in the overall request latencies (§A.1).

In summary, we make the following contributions:

- We provide a detailed analysis of the challenges in handling VM allocation requests at scale, zooming-in on issues related to latency and resource consumption.
- We propose novel latency- and cache-aware (*LatCache*) request scheduling algorithms that are theoretically sound and are based on careful estimation of latencies based on cache and queue state.
- We realize the algorithms by designing and implementing the Kamino framework. We first develop a high-fidelity request scheduling simulator and subsequently deploy the scheduling framework in production zones.
- We evaluate the benefits and implications of Kamino through an exhaustive simulation study of various plausible algorithmic approaches, followed by measurements from our large-scale production zones.

2 Background and Motivation

We provide a background on VM allocation followed by challenges on reducing VM allocation request latency, resource inefficiencies, and scaling the number of AAs.

2.1 Background on VM allocation systems

Designing low-latency VM (or container) allocators is critical for reducing the instantiation time of application services. It is crucial to do so while also satisfying the large variety of VM/container deployment requirements. State-of-the-art VM allocators like Protean and resource managers, such as Omega [36], Kubernetes [27], Twine [41], and VMWare DRS [15], achieve this through the use of filter *predicates* or *policies* that encapsulate allocation constraints to narrow down the available inventory into a set of candidate machines for a given request. Subsequently, these systems implement designated *preferences* and *priorities* to sort these candidate machines, ultimately establishing a preferred pool from which a machine can be selected.

Computationally-intensive rule-based allocations. VM allocators, like Protean, utilize *rule-based allocations*, where each *rule* defines the logic for filtering and ranking available inventory based on specified allocation constraints or preferences. These constraints and preferences can either be user-defined, such as VM type, or internally defined to enhance allocation strategies. Rules can be added to accommodate additional constraints or preferences as platform offerings grow and allocation strategies evolve.

Time	Request	Cached objects	Hits	Misses
1	$req(a_1,b_1)$	None		$cons(a_1,b_1)$ $R_1(a_1,b_1)$ $R_2(a_1)$

3	$req(a_1,b_1)$	$cons(a_1,b_1)$ $cons(a_1,b_2)$ $R_1(a_1,b_1)$ $R_2(a_1)$ $R_1(a_1,b_2)$	$cons(a_1,b_1)$	

Table 1: Illustration of the hierarchical cache for a system with 2 rules, R_1, R_2, where the latter depends on only one the a-attribute of the request. Each request has 2 attributes, a and b. $cons(\cdot)$ denotes the consolidated node list for a given request. When a request comes, both its consolidated list and rule evaluation for R_1 and R_2 are brought into the cache, if not already present.

Evaluating and fulfilling an allocation request and its constraints is computationally intensive, involving the following steps: First, relevant rules are selected and sorted by priority, with constraints taking precedence. Then, each rule is applied to the inventory, yielding machine sets that satisfy specific constraints. The intersection of these sets is calculated and ordered using preference rules, resulting in a final candidate set that is ranked by both quality and preference, from which one of the top-ranked machine(s) is selected.

The benefits of hierarchical caching. To speed up allocation and reduce computation costs, state-of-the-art cluster managers use caching techniques [16, 36, 41, 43]. The cache design is centered around the observation that requests submitted close in time exhibit locality regarding constraints. State-of-the-art VM allocators like Protean use cache *slots* (logical cache entries) for minimizing re-computation. Specifically, Protean uses *hierarchical caching,* with two levels of caching: a top-level cache (fast path), which is used for resolving identical allocation requests, and a lower-level cache (slow path), used for requests that are non-identical but have a subset of identical traits or constraints (e.g., requests for the same VM size, but with different priority); see Table 1 for an illustration, and §4.2.3 for details. A fast path cache hit can have a significantly lower rule computation cost than a slow path hit. Ultimately, *the fast path reduces the hit latency of identical requests, whereas the slow path reduces miss latency for non-identical requests.* Finally, each cache slot could have a variable memory size, typically ranging from 10 to 100s of megabytes, depending on the complexity of the rules. This limits the number of slots reserved for an AA.

Cluster-level and node-level scaling of AAs. To operate at a large scale and serve thousands of allocation requests per second, scaling the number of allocators is critical. Scaling increases throughput and, importantly, can reduce request la-

tency by increasing cache hits and reducing time spent waiting for requests to be served. Protean employs two levels of scaling: (1) deploying multiple allocation agents (*AAs*) on nodes distributed across multiple clusters; (2) using multiple AAs within a single node to exploit multi-core parallelism. In the case of multi-node AAs, a frontend load-balancer dispatches requests to a specific node with one or more AAs. Within a node, multiple AAs form a pool, and agents in the pool pull and serve requests from the head of a global queue when they become free.

The distributed AAs operate concurrently and optimistically without frequent synchronization. However, concurrency may lead to conflicts in placement decisions. Hence, after evaluating requests, AA commits assignments as transactions to a global inventory store, establishing the inventory state. Conflicts are detected in the inventory store, prompting failed requests to be returned to AAs for rapid reevaluation. Successful allocations are committed, and changes are transmitted to an inventory pub/sub service, updating all AAs.

Despite these steps, *distributing the AAs across multiple nodes increases communication costs, conflict resolution costs, and under-utilization of per-node system resources.* Therefore, increasing the number of AAs within a single system is critical to exploit resources such as multi-core CPUs and reduce the communication and synchronization cost incurred by distributed AAs. The number of AAs in a node is dependent on the core count and memory available for caching besides using them for other management services.

Challenges of shared caches in scaling AAs. When scaling AAs, managing caches becomes a critical challenge. Sharing caches across multiple AAs can increase capacity and reduce redundancy but introduces significant drawbacks. First, shared caches incur heavy locking and synchronization overheads, limiting multi-core CPU efficiency and negating scalability benefits. These challenges are amplified in hierarchical caching, where distinct operations for fast and slow levels with substantially different cache hit and miss costs increase contention. Third, shared caches require periodic synchronization with a shared database, adding latency and communication costs. Compared to private caches, these issues make shared caches less efficient and more prone to stalling under high throughput, ultimately hindering scalability and performance. To our knowledge, state-of-the-art systems do not share caches across AAs. For example, Protean divides cache memory into slots and partitions it across AAs for maximum concurrency. However, reducing the number of per-AA cache slots to increase AA counts can lead to higher cache misses and poor request scaling (see §2.2).

Request assignment and scheduling algorithms. Request scheduling strategies play a crucial role in allocating incoming requests to AAs to achieve objectives such as latency reduction, throughput maximization, or resource utilization efficiency. While large-scale cloud providers often lack documentation on VM allocation request scheduling methods, systems like Protean utilize cache-oblivious scheduling policies like Round-Robin. Although effective in distributing requests with simplicity and generality, this approach's lack of cache awareness may lead to suboptimal performance. Similar strategies are employed in widely deployed systems like Kubernetes for container POD allocator scheduling [27, 29].

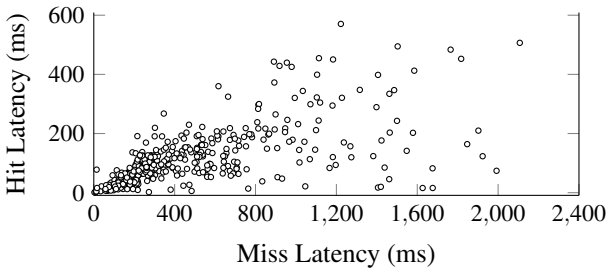

Figure 1: Scatter plot of avg. hit/miss latencies of 400 popular request types.

Cache-aware scheduling policies can leverage information about the AAs' caches and request types to assign each request type to a specific AA, maximizing cache hits and reducing request latencies. Prior works [9, 25, 47] on various other domains, including processor caches, CDNs, web caches, and distributed data caches, optimize performance by relying on cache affinity and utilizing dynamic mechanisms to handle potential load imbalances and adapting to workload changes. However, for VM allocation such strategies might lead to significantly higher latencies (see §6.2). Instead, our design primarily takes a latency-centric approach incorporating cache awareness, utilizing latency estimation to induce lower latencies. Intuitively, our approach can be viewed as 'load-balancing' in terms of the total 'work' done by each allocation agent (rather than traditional load-balancing, e.g., based on queue sizes or request types).

2.2 Evidence from production

To understand the challenges and limitations in state-of-the-art VM allocators, we characterize the latency performance of Protean, followed by assessing resource inefficiencies. We use traces from over 50 allocator nodes for our analysis, each containing a day's worth of requests.

2.2.1 Need for latency-driven scheduling

Our comprehensive study of latency characteristics in large-scale production traces emphasizes the necessity for a *latency-driven scheduling* framework.

Observation 1: Cache hit and miss latencies vary substantially across heterogeneous request types: In contrast to traditional data caching systems, the latencies for hit-and-miss events vary significantly based on the complexity of VM allocation queries among different request types. Figure 1 illustrates the distribution of hit/miss latencies observed by a single allocator node (hit and miss here refer to the top level of the cache). Some request types incur higher cache-hit latency than miss latency for others, contradicting typical assumptions

Node	Avg. Memory Usage	Avg. Peak CPU Usage
Node 1	∼92%	∼50%
Node 2	∼92%	∼61%
Node 3	∼90%	∼74%
Node 4	∼90%	∼39%

Table 2: Approximate resource usage within 4 nodes running allocation agents in a large availability zone.

that a cache hit is always faster than a miss. This variability arises from two primary reasons. Firstly, as discussed earlier, caches are hierarchical, and a request's constraints and preference rules may necessitate partial recomputation upon a cache hit or full recomputation in the case of a miss. Our analysis reveals up to a 5x variation in hit-and-miss latency across request types. Secondly, bursts in allocation requests stall and amplify the time it takes to resolve a request due to inventory updates, regardless of a cache hit or miss, further adding to variable request latency.

2.2.2 Need for cache-aware, latency-driven scheduling

Cache-awareness is critical for exploiting locality by placing similar requests on the same AAs. Consider a scenario with two request types (type 1 and type 2) and two AAs, each with a single cache slot for a specific request type, and a cache policy that adds to the cache the last request type processed by the AA. While cache-oblivious scheduling algorithms like Round-Robin could result in 0% cache hit rate (e.g., on the sequence with request types $1,2,2,1,1,2,2,\ldots$), the cache-aware scheduling that pins a request type to a specific AA could achieve a 100% cache hit rate, minimal queue lengths, and low total latency.

Indeed, Figure 6 in §6.2 shows that simple strategies are not effective enough: Round-Robin and random assignments have respectively $\approx 30\%$ and $\approx 60\%$ higher tail latency than Protean, which is essentially a pure work-stealing strategy.

Observation 2: Latency-driven cache-aware scheduling is critical for handling dynamic workloads: Unfortunately, just a cache-aware strategy like request-pinning or consistent-hashing is not sufficient. As discussed in §2.2.1, under higher load, with only a cache-aware approach, bursts of certain requests could significantly affect the request-type distributions across AAs. In contrast, an effective *latency-driven* scheduler would *dynamically* adapt to changes in latency and, if needed, spread out requests to other AAs even if it impacts locality.

2.2.3 Allocator scalability challenges

Increasing the number of AAs can reduce request wait times and latencies by using multicore CPU and available memory while ensuring sufficient throughput. However, scaling AAs across nodes or even within a node can lead to resource inefficiencies or increased latencies.

Observation 3: Resource imbalance between memory and CPU use limits the number of AAs: Increasing the number of AAs to reduce latency and improve throughput poses a challenge of resource utilization imbalance. The majority of

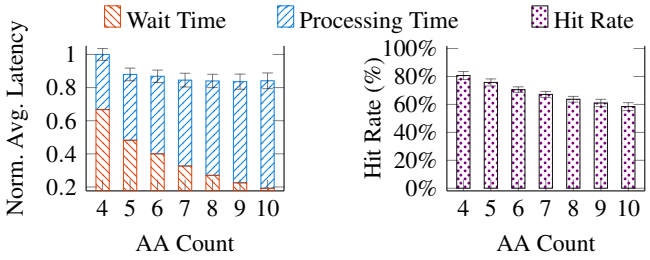

Figure 2: Performance as the number of AAs increases.

nodes exhibit high memory usage while under-utilizing CPU resources, as shown in Table 2. This imbalance arises from two main factors: first, hierarchical request evaluation caches require significant memory, with top-level slots encompassing the entire feasible inventory for a specific request type and lower-level slots containing feasible sets for each constraint. Second, as discussed above, to maximize parallelism and avoid synchronization bottlenecks, each AA maintains its private cache instead of using a shared cache. Due to these factors, our analysis system uses a maximum of four AAs per node to avoid exceeding the available memory limit, even for the largest zones. While scaling AAs across additional nodes is a potential solution, it would exacerbate CPU waste and communication and synchronization overheads.

Observation 4: Naively increasing the number of AAs by dividing cache slots affects latency: An alternative approach to increasing the number of AAs within a node is to divide the total available memory for caching across them further. However, reducing individual cache sizes can lead to more misses and, consequently, higher latency. To illustrate this, we simulate Protean and compare its performance with different AA counts using a day's worth of requests. We start with the baseline configuration of 4 AAs, increasing the AA count and keeping the cache size constant by reducing the size of each AA's private cache. We measure hit rate and latency and present the results in Figure 2. Increasing the AA count to 6-8 reduces request wait times in the queue, improving average latencies compared to the baseline (4 AAs). However, further increases in AA counts lead to smaller cache sizes, resulting in degraded hit rates and increased processing times due to a lack of cache-aware scheduling, where AAs indiscriminately pull requests off the node queue, failing to exploit locality across the AAs' caches.

The aforementioned *four observations drive the design of Kamino's latency-driven, cache-aware algorithm and supporting system implementation.*

3 Kamino overview

We next provide a high-level overview of our VM allocation system, focusing on the allocation path. In §5, we describe the details of the actual architecture.

System overview. Kamino is designed to minimize VM request latencies through concurrency and latency- and cache-aware scheduling; see Fig. 3. Each allocation node employs

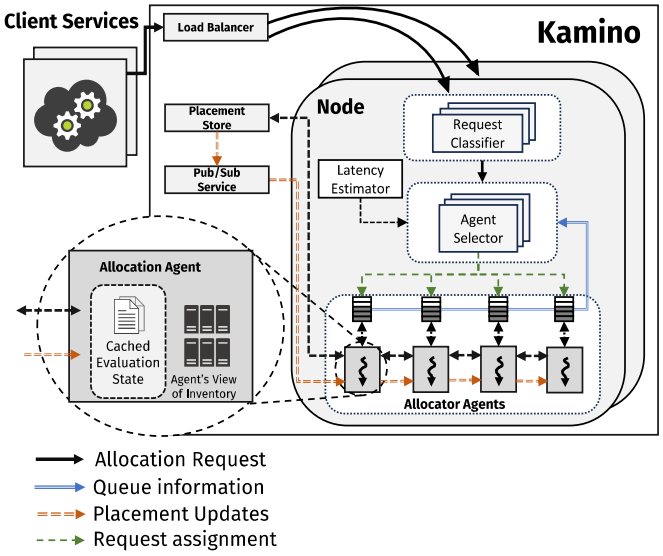

Figure 3: System Architecture with Kamino

multiple concurrent AAs tasked with evaluating rules and assigning VM requests to machines. AAs utilize hierarchical private caches for the evaluations and maintain queues for pending requests. Additionally, AAs have access to real-time data about the machines in the inventory, including available resources like CPU cores and memory.

Request allocation path. When a request enters the system, a gateway/load-balancer routes it to an allocator node. Within the node, the request's estimated latency is computed based on historical latencies as well as the current queue and cache states of each AA. The request is assigned to the AA that is estimated to complete processing the request the earliest. The selected agent runs the rules on the traits of the request, using its hierarchical cache where possible. This results in a list of machines that can receive the VM request, sorted by preference (according to the rules). The VM request is sent to one of the top-ranked machines of this list. The placement decision is committed to a central placement store, and the update is propagated across AAs.

4 *LatCache* Agent Assignment Algorithm

We now zoom in on a central part of our work: directing the incoming VM requests to the AAs in a way that reduces average and tail request latency by best utilizing their memory (i.e., cache) and computing resources. Since each allocator node is treated independently, we focus on a single node and on selecting which of its AAs agents should handle a given VM request, i.e., the design of the *agent assigner algorithm*.

4.1 Agent Assignment Task

We introduce the following task that captures the main elements of the situation at hand and is used as a guide in the design of our assignment algorithm.

An instance of the task consists of multiple AAs, and a sequence of heterogeneous incoming requests to be processed by the AAs. The AAs are identical and run in parallel. Each AA can only process one request at a time, and no preemptions are allowed. Requests cannot be dropped, and each AA has a queue with enough space to hold its pending requests; queued requests are processed in FIFO order.

Each AA has a private cache of bounded size that influences the processing time of a request. At a high level, the current state of the cache affects the processing time in a non-trivial way: it partially reduces the processing time, the extent of which depends on how much of the request is cached (i.e., which of its rule evaluations are cached, see §2.1), and the same portion of the cache (i.e., rules) may help different requests. In addition, even with the same cache state, the processing time of a request may change over time. This is because evaluating a cached rule depends on the changes to the inventory since the last update, which depends on the load of the system. Here, we abstract some of these details and refer the reader to §4.2.3, where we provide lower-level details of our hierarchical cache and how exactly its state affects processing time. Each AA also runs an independent caching policy that decides what data is evicted when the cache is full. Typically, after a request is processed by an AA, it is brought into the AA's cache, but this is not a required assumption.

When a new request arrives, it needs to be immediately assigned to one of the AAs. The goal is to assign the incoming requests to AAs so as to minimize the average latency, i.e., completion time (which includes waiting time) minus release time, of the requests.

Figure 4 provides an illustration of the agent assignment task. In this example, there are 2 AAs, each having a simplified single-slot cache, and two request types (green and orange). The left figure shows the state of the AAs' caches, queues, and current execution of AA 2 at time t_1, when a new request arrives, it needs to be assigned to one of the AAs; in this case, it is assigned to AA 1. The middle figure shows the state at time t_2, when AA 2 finishes its first request and will start processing the one in its queue; in this example, the cache of AA 2 was updated upon completion of the first request. The right figure shows the state at a later time t_3. Notice that the processing time of the second request of AA 2 is smaller, since its type was present in the cache when it started being processed (time t_2). Also, notice that the cache of AA 1 was updated due to the completion of the green request.

4.2 Latency-driven Cache-aware Assignment

4.2.1 Basic algorithm

We now describe *LatCache*, our proposed algorithm for this agent assignment task. Being latency-driven, the main component for making its decision is a careful estimation of what would be the latency incurred by the incoming request if it were assigned to a given AA.

To perform this estimation, we first break the latency into 3 separate components: *processing time*, *queue time*, and the *remaining processing time*. *Processing time* is the estimated

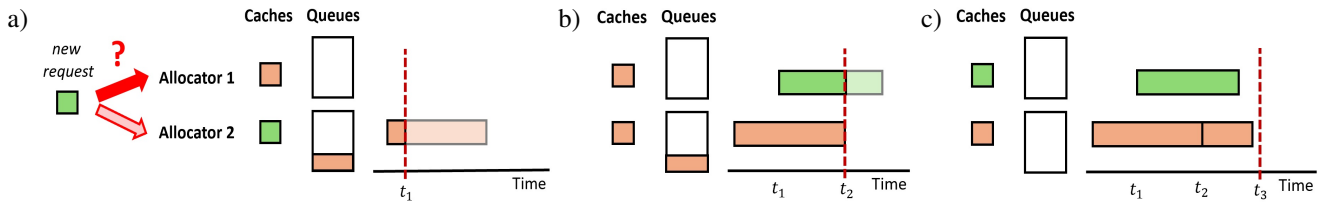

Figure 4: Illustration of the agent assignment task.

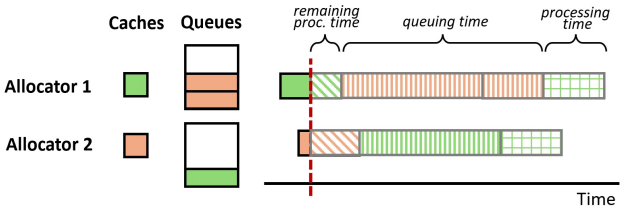

Figure 5: Illustration of *LatCache*'s latency estimation. A new green request (marked by a green square pattern) is considered to be placed on one of the two AAs, each with a single cache slot. Non-solid colors represent estimations.

time it would take to process the incoming request on a given AA, once it starts processing. *Queue time* is the estimated time for processing all the requests in the queue of the AA. *Remaining processing time* is the time left for the AA to finish the request currently being processed. The estimated latency of the request on an AA is obtained by adding the estimates for these three components.

Notice that all these 3 component depend non-trivially on the cache dynamics of the AA under consideration. For example, the *processing time* of the request does not depend on whether it is *currently* found (either fully or partially) in the cache of the AA, but whether the request would be there *by the time it would start processing*. This, in turn, depends on the current cache of the AA, the requests in its queue, and the caching policy it uses. Also note that a similar effect happens with the *queue time* of an AA, which depends on the processing times of the requests in the queue, which in turn depend on the extent that each request's information is present in the cache when processed. Thus, a crucial step in the algorithm is to obtain an adequate cache-aware estimate of each of the 3 latency components. We defer the description of how we estimate these components to §4.2.2.

Once the estimation of the latency of the request on each of the AAs is performed, *LatCache* simply assigns the request to the AA with the lowest estimated latency; see Algorithm 1 for the pseudo-code.

Algorithm 1 *LatCache* (*req* : request)

1: Compute cache-aware estimates $queueTime(a)$, $processingTime(a)$, and $remainingProcTime(a)$ for each allocation agent a
2: Assign *req* to the allocation agent a^* where it has minimum estimated latency $queueTime(a^*) + processingTime(a^*) + remainingProcTime(a^*)$

The design of *LatCache* addresses the challenges highlighted in the previous section. First, being latency-driven, it performs an adaptive load-balancing of requests to AAs, regardless of the identity of incoming requests (contrasting with the request-pinning strategy discussed in §2.2.2). Indeed, we establish that our algorithm maintains the queue waiting times of the AAs almost perfectly balanced; intuitively, if the queue of an AA grows too long, this is factored into the latency estimation of the algorithm which then chooses another AA for future requests.

Theorem 1 (*LatCache*'s load-balancing)**.** *Consider the algorithm LatCache with perfect latency estimation. Then, at all times, it guarantees that for every pair of AAs, their queue waiting times are within maxProcTime of each other, where maxProcTime is the largest request processing time.*

Moreover, no scheduler can guarantee that for every pair of AAs a, a' the difference in their queue waiting times is strictly less than maxProcTime at all times.

We note that the assumption of perfect latency estimation can be relaxed, and was made to simplify the bounds. In addition, with adequate cache-aware latency estimates *LatCache* also promotes co-location of similar requests, which should lead to higher cache hit rates and thus lower processing times: By construction, *LatCache* only prefers an AA that does not have (or has less of) the request in its cache over an AA that has the request in the cache if the latter has worse latency, e.g., due to significantly longer queuing time.

4.2.2 Cache-aware latency estimation

This desired behavior of *LatCache* is contingent on the algorithm computing adequate estimates for the three latency components, which we now address. Following up on previous discussion, the two key challenges here are: (1) It is not obvious whether the current request and the queued requests *will be* (fully or partially) found on an AA's cache, given that the state of the cache can change by the time each request is processed; (2) Estimation errors on the hit and miss latencies might accumulate (e.g., in the estimated queuing times) and lead to highly-suboptimal decisions. With this in mind, the latency components are estimated as follows:

Processing time. This is the main component to be estimated and is used to compute the other components. To estimate the $processingTime(a)$ of the incoming request on AA a, we employ *optimism* and assume that when this request is processed on a (if assigned to it), the cache will still contain all of its current content (i.e., none of it is evicted) *and* will

also completely contain all the requests that are currently in the queue of a (we call this the "augmented cache state"). The estimated $processingTime(a)$ is then a function of this "augmented cache state" and the traits of the current request (exact details of how this is computed in our situation are presented in §4.2.3, Algorithm 2).

We note that this optimistic cache state prediction is quite accurate as long as the number of distinct type of requests in the AAs' queues is small compared to how many types a cache can accommodate (which is what we see in practice for VM allocations). In particular, we tested an alternative estimation procedure that simulates future cache states and did not find significant improvement in estimation quality.

Queuing time. Next, the $queueTime(a)$ of an AA is obtained by estimating the processing time for each request in its queue, using the strategy outlined above. This is done without the need to traverse the queues: when a request is added to the queue of the AA a, the estimated *processingTime* of the request is added to the current $queueTime(a)$, and when a request is dequeued its estimated *processingTime* is subtracted. Note that by subtracting the *estimated* processing time on dequeue, as opposed to the real processing time, limits the accumulation of errors: once a request is dequeued, the effect that any estimation error on its processing time had on the queuing time is erased.

Remaining processing time. Finally, the estimation of the $remainingProcTime(a)$ of an AA is based on *start* and *proc_time* information that is updated by the AA as follows: whenever it starts processing a request, it sets *start* to be the current time, and *proc_time* to be the estimated processing time based on the current state of the cache (not the "augmented cache state"). With this information, $remainingProcTime(a)$ at time t is estimated as $max(0, start + proc_time - t)$ if the AA a is currently busy, else it is estimated as 0. Figure 5 illustrates these estimations.

4.2.3 Hierarchical cache structure and processing time computation

We next discuss rule-based allocations and the cache structure, essential for computing estimated processing times in Kamino.

Rule-based allocations. Our system utilizes *rule-based allocations*, as discussed in §2.1. A rule evaluated over a request returns a filtered (sorted) list of the current inventory based on specified constraints or preferences (e.g., the list of machines with enough free memory to accommodate the request). Each rule only depends on a subset of the traits of the request; requests with the same value on these traits produce the same evaluation, and thus are considered equivalent with respect to this rule. To fulfill a request, all rules are evaluated and lists consolidated, and the request is placed on one of the top-ranked machine(s) from the final list. These steps are performed by the AA handling the request.

Cache structure. The cache present in the AAs is used to speed up these steps. We employ a 2-level hierarchical cache: The top level (fast path) stores the consolidated list of machines for (equivalent) requests, and the lower level (slow path) stores the result of rule evaluations for equivalent requests (with respect to the rule). The latter allows for "partial cache hits" that benefit more requests since more requests are equivalent relative to a single rule than relative to the consolidated evaluation. See Table 1 for an illustration.

Since rule evaluations and their consolidated result depend on the current state of the inventory, they need to be updated even when present in cache; that is, both cache *hits* and *misses* add to the latency of processing the request. An un-cached rule evaluation (rule-miss) is computed from scratch, while cached rule evaluations (rule-hit) are updated with only the changes in the inventory change since its last update; this incremental update is significantly faster than computing it from scratch. If the consolidated evaluation for a given request is present in the top-level cache (hit), then all of the rules it depends on are updated, and the updates are inserted to/removed from the consolidated result. We note that while a consolidated result is present in the top-level cache, all rules that it depends on are pinned to the lower-level cache, i.e., all are rule-hits.

Processing time computation. Given this cache structure, Algorithm 2 describes our estimation of the processing time of a request *req* on a given AA. This procedure receives as input the "augmented cache state" *augCache* of the AA, as defined in §4.2.2, estimate *hit* for a cache top-level hit processing time, and vectors *rule-hits* and *rule-misses* with estimates for the rule-hit and rule-miss times of each rule. These input estimates can be computed, for example, using historical data, see §5. If the request is a top-level hit in the *augCache*, its estimated latency is only *hit*. In case of a top-level miss, we consider the "partial hit" based on the rules present in the lower level of *augCache*.

Algorithm 2 ProcessingTime (*req*, *augCache*, *hit*, *rule-hits* and *rule-misses*)

1: **If** the *req* is a top-level hit in *augCache*, then set *procTime* to be equal *hit*
2: **Else** #*top-level miss*
3: For each rule r, add to *procTime* either its hit time *rule-hits*$[r]$ or miss time *rule-misses*$[r]$ depending whether *augCache* contains the evaluation of R for request (equivalent to) *req*
4: **Return** *procTime*

5 System Implementation

We describe the details of the Kamino request scheduling framework implemented within the Protean system and highlight some practical challenges of the implementation.

Overall system organization. A logical instance of the Protean system is responsible for handling all requests in a zone or a region. The system consists of a pool of stateless AAs backed by a persisted placement store for VM placement

decisions. Each AA uses a dedicated thread and private in-memory state and caches to place VM requests to appropriate servers in the inventory. It uses a specified number of cache slots to limit its memory usage. Multiple AAs are grouped within a process in an allocator node, and multiple nodes can be employed to satisfy peak system demand.

The AAs follow an optimistic concurrency model: an agent makes placement decisions based on its (potentially stale) view of the inventory and persists each placement result to the placement store. The placement store rejects results that are invalid because of the staleness of the AA's view so that the requests can be retried. VM deletes are also persisted in the placement store. The AAs learn about updates to the placement store and other relevant inventory updates, such as those related to server health and power consumption, through a publish-subscribe platform. As an optimization, placement decisions made by the AAs within an allocator node are shared among each other through fast in-memory transfer. Figure 3 shows the overall system architecture.

Kamino request scheduling framework. The front-end gateway/load-balancer service accepts the requests and routes them to an allocator node, but Kamino is responsible for mapping the requests to AAs within a node. Kamino aims to minimize overall request latency and improve the resource efficiency of the AAs while incurring negligible computation and memory overheads. To that end, Kamino is implemented as part of the process the AA itself runs on, thus avoiding any inter-process communication overheads. In addition, we designed our scheduling logic in a computationally efficient manner, resulting in minimal overhead in the order of microseconds per request, which is orders of magnitude lower than request latencies (tens to hundreds ms); thus, the scheduler has negligible overhead on the total latency. Additionally, slower time-scale computations required for making scheduling decisions are done outside the request-handling critical path and so do not introduce any relevant computational overhead. Kamino consists of the *Request classifier*, *Agent selector*, and *Latency estimator* modules. The *Request classifier* and *Agent selector* processes each request in the critical path, whereas the *Latency estimator* runs outside the critical path. We describe these modules below.

Request classifier. A request arriving at the node remains queued until an instance of the request classifier becomes available to handle it. The request classifier computes the equivalence class key of the request depending on the rules relevant to the request and the request traits they depend on (see §2.1). The key uniquely identifies a class of requests that are equivalent to each other as far as the allocation logic is concerned. In other words, each key denotes a *request type* and determines if an AA has a cached consolidated result for the type. It decorates the request metadata with the computed key and queues the request for further processing. The framework allows for multiple instances of the request classifier (and agent selector) modules in order to concurrently process the requests, but in practice just one or two of these are enough because the processing latency of these modules is negligible compared to that of the AA.

Agent selector. Each AA has its own private queue to hold pending requests. The agent selector assigns each request to an AA's queue. Once a request is assigned to a queue, the assignment is never changed. This module implements the core request scheduling algorithm *LatCache*. As described in §4.2, this algorithm requires a few inputs: (1) It needs estimates of top-level cache hit times and hit and miss times for the rules. This is obtained from the *Latency estimator* module. (2) It needs to check whether an incoming request type is cached in an AA or is already queued in its private queue. The agent selector probes the AA's caches with the request type's key to check if it is cached. As part of the queue metadata for each agent, it maintains a map of <Request type key, Count> for the requests in the queue. This map is used to check if a request type is already present in the queue and is updated when requests are enqueued or dequeued. (3) It needs to check if an agent is busy. The agent selector holds a reference to the last dequeued work item for each agent and probes the work item to check if the agent is busy.

Latency estimator. This module is responsible for estimating the hit and miss times. In its simplest form, it can provide estimated hit or miss times from preset service configurations. However, a more practical implementation takes the form of a background task on each allocator node that tracks hit and miss times and periodically produces an updated estimate of their averages. The latest estimates are not only sent to the *Agent selector* but are also persisted in order to have a good initial estimate on process restart. Although we only use a rough estimate of central tendency for hit and miss times, *LatCache* is able to make good assignments and yield a significant improvement in the relevant metrics (see §6.4).

Cache management policy. The AAs employ a hybrid cache eviction policy – objects are evicted from the cache if it is full, using a standard LRU replacement policy, or if they reach a certain age. Age-based eviction allows us to reduce the agent memory footprint during periods of low load.

6 Evaluation

We conduct extensive experiments to evaluate Kamino using both a high-fidelity simulator and the production system. The simulator experiments utilize *real traces* from production across various geographical regions. Our experiments aim to address the following questions:

- Does Kamino and its latency-driven *LatCache* algorithm reduce VM allocation request latency over standard, well-known algorithmic baselines?
- How effective is *LatCache* in reducing cache misses and the overall cache memory consumption?
- How does *LatCache* perform across different loads, cache sizes, and number of AAs?

- Do the benefits of the *LatCache* algorithm translate to production-scale systems?

6.1 Workloads and Methodology

Our simulations utilize six real traces collected from high-traffic allocator nodes across various zones. These traces encompass a diverse range of unique request types, with counts varying between 500 and 1.7k. Additionally, certain zones exhibit notably higher request rates and burstiness than others. Each trace spans a 24-hour horizon and includes all VM requests, providing information such as request id, arrival time, and request traits. The trace also contains information about the actual processing time of each request, which are used to simulate hit and miss times. We have also deployed Kamino with *LatCache* in all production zones and measure performance in a subset of representative zones.

6.2 Effectiveness of *LatCache* on Latency

We first use our simulator to understand the impact of *LatCache* on reducing average and tail VM allocation request latency. We compare it against the load-balancing algorithm used by the state-of-the-art VM allocator Protean. We also compare it against classical cache-oblivious load-balancing algorithms (random assignment and round-robin). Finally, we compare it against a cache-aware solution consisting of using consistent-hashing assignment augmented with work-stealing to reduce hotspots [47]. Thus, we compare *LatCache* against:

(1) **Protean with a shared queue**. This consists of a single FIFO per allocator node that receives all requests, and AAs pull requests from this queue when idle. This is the algorithm previously used in Protean.

(2) **Random assignment (*Random*)**. Assigns the incoming requests uniformly at random to one of the AAs.

(3) ***Round-Robin***. Assign the incoming requests to the AAs in a Round-Robin fashion.

(4) ***Hash+WS***. This uses **consistent hashing + work stealing**, employed in other systems, to determine data location and task execution [47]. The assignment to an AA is computed by hashing the request traits, ensuring that requests with the same cache objects are assigned to the same AA [21, 32], which promotes data locality and reduces cache replication. Additionally, when an AA is idle, it steals a pending request from the AA with the largest queue, if any, which helps reduce hot spots caused by skewed request distributions.

Unfortunately, the scheduling algorithms of other large-scale VM allocators [36, 41] have not been openly documented, preventing us from recreating and evaluating them.

We also evaluate two versions of *LatCache*: In addition to *LatCache-rule*, the algorithm as described in §4, we consider the variant *LatCache-request* that uses a simpler estimation of the processing time of a request based only on its presence at the top-level of the cache of the given AA, i.e., on a top-level miss, instead of looking up the presence of individual rule on the lower-level cache as in Algorithm 2, it assumes that none of them is present in the lower-level cache. Its main advantage is that it requires fewer and simpler (i.e., to a single level) cache lookups. For this analysis, we fix the number of AAs on each node to 4 to match our current production system. We also reserve the total cache memory based on production configuration (up to 58% of the node's total memory); in §6.6, we vary these parameters in our simulated environment.

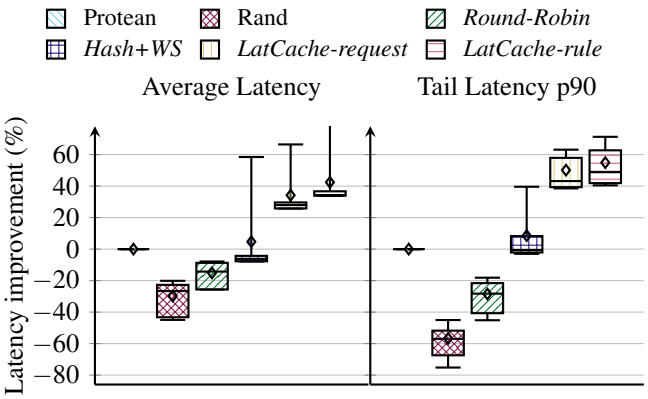

Figure 6: Latency improvements for each algorithm

Fig. 6 illustrates the percentage improvement in average and 90th percentile tail allocation latency of the different algorithms compared to the baseline Protean. Standard load-balancing algorithms *Random* and *Round-Robin* exhibit approximately 20% worse performance on average compared to the baseline. The cache-aware *Hash+WS* algorithm, which promotes request co-location plus simple load-balancing, achieves only 4.4% average latency improvement with high variance and 9.1% improvement in tail latency. In contrast, our *LatCache-request* and *LatCache-rule* algorithms achieve significant improvements in both average and tail latency compared to all other algorithms, with over 50% tail latency improvement over the baseline Protean. Notably, lighter-weight *LatCache-request* is competitive with *LatCache-rule*, despite ignoring lower-level cache content during processing time estimation.

While request allocation latency is our main metric, the superiority of our algorithms also holds in terms of throughput, albeit in a less striking manner. Nonetheless, in periods of bursts of requests, we consistently see a 2x throughput improvement compared to Protean. Fig. 7 plots the throughput profiles of the algorithms in a window with a burst of requests (for clarity's sake, *Random*, *Round-Robin*, and *LatCache-request* were omitted).

6.3 Explaining why *LatCache* works well

Table 3 (second column) shows the top-level cache hit rates for various algorithms. *LatCache-rule* and *LatCache-request* achieve the highest hit rates ($\approx 94\%$), significantly higher than the cache-friendly *Hash+WS* ($\approx 87\%$) and the cache-oblivious Protean, *Random*, and *Round-Robin* ($\approx 81\%$). This validates *LatCache*'s superior ability to promote data locality,

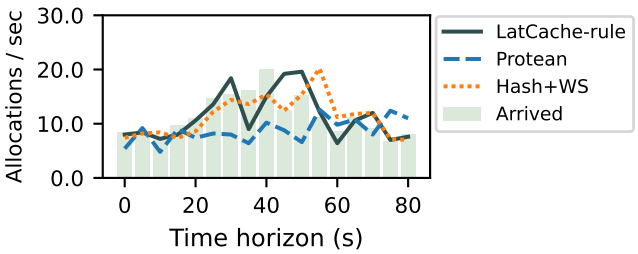

Figure 7: Throughput Comparison. Results are shown for two consecutive bursts of requests.

Algorithms	Hit ratio (%)	Norm. cache memory
Protean	80.7 ± 2.9	1.00 ± 0.00
Random	81.1 ± 3.0	0.98 ± 0.00
Round-Robin	80.6 ± 3.0	1.00 ± 0.00
Hash+WS	87.4 ± 3.1	0.94 ± 0.05
LatCache-request	93.1 ± 3.2	0.85 ± 0.09
LatCache-rule	95.0 ± 2.3	0.77 ± 0.06

Table 3: Cache hit ratio and normalized memory use.

as a consequence of careful latency predictions that use both current and projected cache states.

Next, Fig. 8 shows the breakdown of the average request latency of the algorithms into the time waiting in the queue of an AA and request processing time. *LatCache* algorithms have the smallest processing times, due to their high cache hit rates. However, the major part of *LatCache*'s latency improvement comes from a significant reduction in waiting time. Two main reasons contribute to lower wait times: 1) higher hit rates have a compounding effect on the multiple requests in a queue, leading to faster turnaround; 2) the latency-driven design with careful latency prediction accomplishes an effective request load-balancing across the AAs, as supported by Theorem 1. This *highlights the benefits of combining latency-driven scheduling with cache-awareness*.

6.4 Estimation accuracy and its impact

As mentioned earlier, the two main sources of inaccuracy that might affect the total latency estimation quality are: (1) (top-level) hit and miss event prediction; (2) estimation of the individual hit and miss times of the requests. We now quantify the accuracy of these estimations and their impact on the quality of the assignments of *LatCache-rule*.

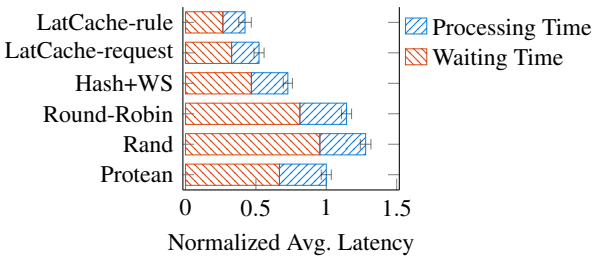

Figure 8: Latency breakdown.

First, our optimistic prediction for hit/miss events using the augmented cache state is highly accurate (99.1% across both cache levels). Given that hit times are significantly lower than miss times (average miss/hit time ratio: 5–10) and that hit/miss predictions directly affect queue latencies estimates, this level of accuracy is crucial for effective assignments.

Regarding the estimation of hit and miss times, we have an average prediction error of 29%. While the error is not small, using these estimates in conjunction with the accurate hit/miss event predictions leads to good allocation decisions: *LatCache-rule* selects the best allocator for 91.9% of the requests (best allocator = lowest actual total latency for the incoming request). Even when the best allocator is not selected, the scheduling decision is nearly optimal – the total latency percentage-gap between the selected allocator to the best allocator is only 2.3% on average. To put these numbers into perspective, a naive version of *LatCache-rule* that ignores the rule-level cache, future hit prediction, and allocators' remaining processing time chooses the best allocator only 65.4% of the time and the resulting total latency can be even 2x more than that of the best allocator.

We note that it is certainly possible to use more sophisticated machinery for estimating hit and miss times, such as applying machine learning techniques [12]. We observe, however, that the added value is not substantial. To quantify the possible gains, we ran *LatCache-rule* fed with perfect predictions of hit and miss times, and observed an additional improvement of 1.1% in tail allocation latency (vs. $\approx 50\%$ improvement that both versions of our algorithm have compared to the baseline). We conclude that the absolute hit and miss time predictions matter less than predicting the actual hit/miss event as well as capturing key elements of the allocation process, particularly the hierarchical-cache dynamics (see §4.2.2-4.2.3). The net outcome is that Kamino's scheduler has a simple yet effective and robust latency estimation that makes near-optimal allocation decisions.

6.5 Reduction in Memory Footprint

Table 3 presents the average cache memory size used by the algorithms, normalized to the baseline Protean. All cache-oblivious algorithms (Protean, *Random*, and *Round-Robin*) exhibit very similar memory occupation. In contrast, the cache-friendly *Hash+WS* demonstrates reduced usage (94% of Protean's memory usage), while our cache-aware *LatCache-request* and *LatCache-rule* show significantly lower usage (85% and 77% of Protean's, respectively). This reduction is attributed to the *LatCache* algorithms, which enhance cache hit rates and facilitate better reuse of cached rule objects by co-locating similar requests on the AAs. Notably, *LatCache-rule* achieves the smallest memory usage by promoting such co-location at the rule level, leveraging information about the objects present on the lower cache level. Overall, *LatCache*'s memory overhead is negligible: cache states are probed at runtime, and hit/miss latencies are already

tracked for monitoring. Reduced memory use effectively allows to increase the number of AAs on the same node by decreasing the required cache-per-AA to store the necessary items, a particularly important consideration in our production system (see §2.2.3).

6.6 Sensitivity to System Parameters

Next, we analyze the performance of the algorithms across different system parameters. For brevity, we drop *Round-Robin* and *Random* from the analysis due to their highly suboptimal performance observed earlier.

Sensitivity to the number of AAs: We vary the number of AAs (R) on a node while keeping the total memory cache (M) fixed, thereby changing the per-AA cache memory (M/R). As shown in Fig. 9a, Protean and *Hash+WS* algorithms scale poorly with increasing AA count. The benefits of parallelism from additional AAs are negated by cache fragmentation, as smaller private caches reduce effectiveness. In contrast, *LatCache-request* and *LatCache-rule* algorithms sustain their performance, with reduced per-agent cache having a smaller impact, consistent with their lower memory usage.

Sensitivity to allocation request load: We evaluate the performance of the algorithms under high load. We reduce the requests' interarrival time by multiplying each request's arrival time by a parameter $\varepsilon \leq 1$. The lower this ε parameter, the higher the frequency of requests. For analysis, we pick ε values that increase request frequency by 25%, 50%, 75%, and 100%. Fig. 9b shows tail latency improvement over Protean baseline. As shown, the benefits of cache-aware algorithms over Protean increase as the load increases, with *LatCache* algorithms exhibiting scalability and consistent gains over *Hash+WS* across all loads.

Sensitivity to cache size: We evaluate the performance of the algorithms under varying system memory for caching across AAs. Fig. 9c shows tail latency gains over Protean for each cache size, where 100% represents the size used in previous experiments. First, even with smaller cache sizes, cache-friendly algorithms like *Hash+WS*, *LatCache-request*, and *LatCache-rule* outperform the cache-oblivious Protean. Furthermore, *LatCache* algorithms consistently exceed both Protean and *Hash+WS*, even under limited cache memory. Second, for larger reserved cache sizes, *LatCache-request* and *LatCache-rule* still outperform Protean and *Hash+WS*, albeit with more modest gains. The gains diminish as larger caches accommodate more objects, reducing the importance of data locality.

6.7 Performance on Production Zones

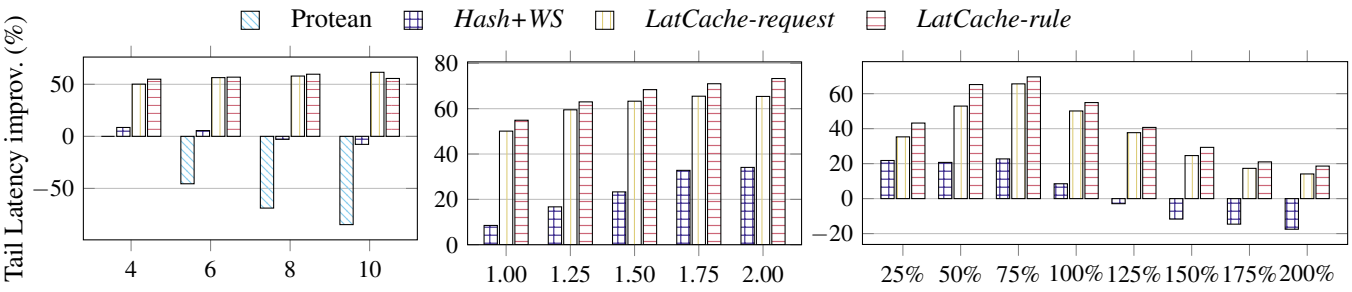
We evaluate Kamino's performance impact with *LatCache* in production on a subset of zones. We deploy the *LatCache-request* algorithm due to its simpler integration with the current cache API and plan to roll out *LatCache-rule* later. We collect performance metrics across 5 production zones, comprising tens of thousands of nodes, over 15 days before and after deployment with *LatCache-request* (Kamino-*LatCache*).

Latency	Protean	Kamino-*LatCache*	Improve.
Avg. (ms)	185.6 ± 20.4	146.3 ± 17.4	21.1%
90p (ms)	378.8 ± 90.8	333.5 ± 64.7	11.9%

Table 4: Allocation latencies before (Protean) and after deploying Kamino.

Impact on latency. We compare allocation latencies before (Protean) and after deploying Kamino-*LatCache*. Table 4 shows average and 90th percentile latencies with standard deviations. We observe a 21.1% reduction in average latency and an 11.9% reduction at the 90th percentile, aligning with simulation results. However, modest gains arise from factors not modeled in the simulator, such as conflicts and retries when multiple AAs place VMs on the same physical machine, causing infeasible placements. Fig. 10 shows disaggregated latency performances of Protean and Kamino, highlighting consistent gains across all zones.

Impact on cache hit rate. To display the impact of Kamino-*LatCache* on cache hit ratios, we aggregate the measurements of the five zones and plot in Fig. 11 the hit rate over 2 months; the dotted line (in early Feb.) marks where Kamino-*LatCache* replaces Protean. Overall, cache hits increase from 80% to 86.6% on average across the five zones; thus, the total cache misses reduced by 33%. Two main factors contribute to the differences in cache hit gains between the simulation and production systems: (a) varying memory cache sizes across the fleet and (b) dynamic workload changes over 15 days on production compared to 24-hour simulation traces.



We also observed that a significant reduction in cache misses reduces the number of AA nodes, lowers contention and communication overhead, and minimizes allocation retries, yielding more efficient request handling and improved system stability.

Reduction in CPU and memory resource usage. We evaluate Kamino-*LatCache*'s impact on resource efficiency in allocator nodes, focusing on aggregate working memory and CPU usage across AAs per node. On average, Kamino-*LatCache* reduces memory usage by 17% and CPU usage by 18.6%, consistent with simulation results (Table 3). By promoting data locality through co-locating similar requests on AAs, Kamino-*LatCache* reduces cache content replication, saving memory. This reduction also lowers CPU usage, as less computation is needed for cache updates. Measurements confirm this, showing a 10–20% drop in cache updates per minute.

7 Related Work

In addition to our earlier overview of allocator systems, we survey related work in resource management.

Request scheduling and cache-awareness. Prior research has focused on efficient request scheduling and load-balancing to minimize latency, especially for sub-second latencies. They include using OS techniques like per-CPU caches, optimizing CPU allocation for application threads,

(a) Number of AAs (b) Trace scale up factor (c) Cache Sizes

Figure 9: Sensitivity to System Parameters: Tail Latency p90 improvement (%)

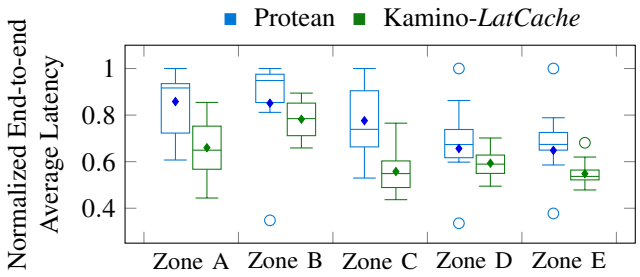


Figure 10: Production: Average latencies before and after deployment, normalized by the largest latency in the zone.

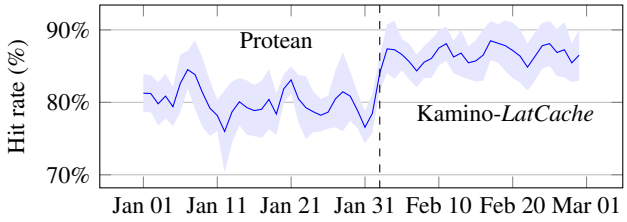

Figure 11: Production: Hit rates before and after deployment day. Dashed line indicates deployment day.

reducing queue wait times and scheduling costs [20, 33, 34]. Web services research explores static and adaptive scheduling strategies to address latency and throughput challenges [23, 28, 39]. However, techniques like preemptive work suspension and network queue polling are unsuitable for VM request scheduling. Cache-aware scheduling has been explored, with Google's search system using hypergraph partitioning for load-balancing [4], and [37] proposing similar methods for Facebook's web traffic and storage sharding. Other studies improve latencies through dynamic cache partitioning of shared caches or adapting cache policies, often using hit rates as latency proxies [10, 48]. To our knowledge, Kamino is the first publicly reported VM allocation framework integrating cache awareness and latency considerations for scheduling.

Cluster and resource scheduling. A huge body of work addresses sharing distributed resources across computations. Frameworks like Omega [36], Twine [41], and others [13, 14, 17, 18, 31, 44, 46] optimize resource utilization for jobs or tasks. Similar approaches target container scheduling (e.g., Kubernetes [27, 29]) and VM deployment (e.g., Protean [16]). Others focus on resource allocation with service-level objectives (SLOs) [19] and dynamic allocation policies leveraging predictions and continual optimization [6, 11, 12, 22, 24, 30, 35, 38, 40, 50]. However, no prior work integrates caching with resource efficiency for VM or container allocation.

Algorithms for scheduling and paging. There is a rich body of theoretical work on page replacement algorithms for single-cache systems [3, 8, 26] and scheduling algorithms for latency minimization, though most focus on systems without caches (e.g., job scheduling models) [5, 7]. The intersection of these areas remains underexplored. [45] addresses scheduling in multi-cache systems but focuses on minimizing cache misses.

8 Conclusion

We design and implement *Kamino* – a latency-driven and cache-aware VM request scheduling framework. Our algorithm, *LatCache*, relies on clever estimates of latency based on the cache state. An extensive simulation study with real traces, followed by measurements from large-scale production zones show increased resource efficiency and sizeable reductions in end-to-end latency. One interesting direction for future work is examining incorporating fast and persistent storage devices such as SSDs to serve as a secondary cache to alleviate memory bottlenecks [4, 42, 49].

Acknowledgments

A Appendix

A.1 Applying *LatCache* Principles Beyond VM Allocators

To evaluate the generalizability and feasibility of applying *LatCache* 's principles—combining locality awareness with latency-aware queuing—to systems with hierarchical data tiers, we built a proof-of-concept prototype that applies *LatCache* scheduling to log-structured merge (LSM) trees.

To test latency- and cache-aware scheduling beyond virtual machine allocation, we adapt LatCache's principles to optimize lookups in Log-Structured Merge (LSM) Trees [1, 2]. Our prototype shows reduced lookup latency and lower computational overhead. Below, we briefly review LSM trees, followed by our approach for latency and cache-sensitive scheduling.

LSM background. LSM trees underpin many key–value stores, including LevelDB and RocksDB [1, 2]. An LSM tree is organized into multiple levels that grow in size from top (level 0) to bottom. New writes buffer in memory and flush as sorted table files at level 0. As levels fill, files merge and compact downward. This design yields high write throughput but can slow reads: each lookup may scan levels sequentially until the key is found or all levels are exhausted. To mitigate read amplification, each SSTable maintains a Bloom filter—a compact, probabilistic structure that can definitively rule out a key or indicate it might be present. By checking the Bloom filter before probing an SSTable, lookups skip files unlikely to contain the key, reducing unnecessary I/O and cache pollution. However, Bloom filters can produce false positives and still require sequential filter checks across levels, so lookups may probe multiple levels and incur latency and cache churn.

Latency and cache-sensitive request scheduling. Our design uses Bloom-filter–based locality hints in LSM trees to direct lookups to the levels most likely to contain the target key and incorporates per-level latency estimates to decide when parallel searches are warranted. This approach reduces redundant computation and cache pollution while still exploiting parallelism.

In our LevelDB-based LSM prototype, this approach achieves a 22% reduction in average lookup latency compared to searching serially across LSM tiers. Although this prototype uses a single worker thread for each level, increasing CPU assignments and refining latency models should yield further gains. These preliminary results confirm that combining locality awareness with latency-aware queuing strikes an effective balance between throughput and resource efficiency in hierarchical storage. Our future work will characterize the trade-offs under mixed read–write and tail-latency–sensitive workloads and generalize *LatCache* 's benefits across diverse architectures.

Abstract

Distributed training is the de facto standard to scale up the training of deep learning models with multiple GPUs. Its performance bottleneck lies in communications for gradient synchronization. Although high tensor sparsity is widely observed, the optimal communication scheme to fully leverage sparsity is still missing. This paper aims to bridge this gap. We first analyze the characteristics of sparse tensors in popular models to understand the fundamentals of sparsity. We then systematically explore the design space of communication schemes for sparse tensors and find the optimal ones. These findings give a new understanding and inspire us to develop a holistic gradient synchronization system for sparse tensors called ZEN. We demonstrate that ZEN can achieve up to 5.09× speedup in communication time and up to 2.48× speedup in training throughput compared to the state-of-the-art methods.

1 Introduction

In recent years, deep learning (DL) models have achieved remarkable empirical performance in real-world applications, such as language processing [6, 22, 32, 40, 64, 67] and recommendation systems [26, 42]. With the ever-growing size of models and training datasets, distributed training has become the norm for model training with multiple GPUs [35, 47, 49, 59, 71]. The synchronization of gradient tensors from different GPUs is commonly required in distributed training. In data parallelism [29, 35, 59], the training dataset is partitioned across multiple GPUs, so the corresponding gradient tensors must be synchronized to maintain model consistency. In tensor parallelism [62], individual layers of a DL model are sharded over multiple GPUs, which synchronize the gradient tensors during backward propagation for the gradient computation of subsequent layers. Furthermore, it is common practice to train large models [17, 49, 58] with a mix of data parallelism and other parallelism strategies, such as pipeline parallelism [28, 47], tensor parallelism [62], and ZeRO [55, 81]. These training workloads must also synchronize the gradient tensors across GPUs.

The major efficiency bottleneck of distributed training lies in the communication for gradient synchronization [23, 72, 73, 80]. Recent hardware developments have greatly improved the computation efficiency of model training. These advancements increase the frequency of gradient synchronization in distributed training and shift more burdens to network systems. However, network upgrades have not kept up with the improvements in computation [43, 50, 51, 80], exacerbating the tension between computation and communication.

Several communication schemes have been developed to alleviate communication bottlenecks in distributed training by fully utilizing the network bandwidth. For example, Ring-Allreduce [53] is provably bandwidth-optimal in homogeneous GPU clusters and it is widely used in collective communication libraries such as MPI [18], NCCL [4], and MSCCL [5]. BytePS [29] is a communication-optimal architecture for heterogeneous GPU/CPU clusters. However, both Ring-Allreduce and BytePS assume that tensors to be synchronized are dense, ignoring their sparsity.

Recent work has shown that DL models exhibit a high degree of tensor sparsity during gradient synchronization. The sparsity comes from either natural gradient computation [16, 37, 42] or gradient compression sparsification algorithms [7, 38, 73]. On the one hand, because model training can focus on updating a subset of parameters instead of all of them [24, 78], some of the gradient tensors in DL models are naturally sparse and most of the gradients in these tensors are zero. For instance, the embedding table in the widely deployed Deep Learning Recommendation Models [70] can reach more than 93% sparsity; Graph adjacency matrix in Graph Neural Networks [69] usually retains the sparsity more than 99%; Word embeddings of those popular natural language processing models, such as NMT [40] and LSTM [44], would achieve more than 97% sparsity. On the other hand, to address the communication bottleneck, a plethora of sparsification algorithms [7, 38, 39, 60, 61, 63, 73] are proposed

*These authors contributed equally.

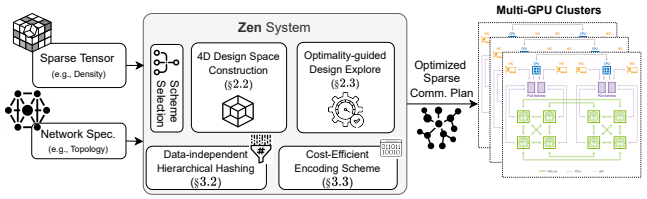

Figure 1: ZEN System Overview.

to reduce synchronization traffic by selecting a subset of the original stochastic gradients. They can save up to 99% of the gradient exchange while maintaining model accuracy [12, 39].

Leveraging the notable sparsity can significantly reduce traffic volume for gradient synchronization and shorten the communication time in distributed training. We can represent non-zero gradients with a sparse format and denote the tensor with a sparse format as a *sparse tensor*. Previous works, such as AGsparse [35], SparCML [56], and OmniReduce [23], have acknowledged this potential. They use various sparse formats and synchronization schemes. However, these approaches do not fully consider the fundamental characteristics of sparsity in DL models and lack understanding of the optimal scheme, resulting in suboptimal communication performance for gradient synchronization. To this end, this paper addresses the research problem: *What is the optimal communication scheme for gradient synchronization of sparse tensors in distributed training?*

To address this question, it is essential to revisit the fundamentals of the tensor sparsity in DL models. We first unveil the characteristics of sparse tensors in popular models [22, 26, 30, 40, 65, 79] across GPUs, iterations, and diverse training workloads. We then explore locations and distributions of non-zero gradients in tensors and the changes observed in sparse tensors before and after aggregation under varying configurations.

In light of these characteristics of sparse tensors, we systematically explore the design space of synchronization schemes for sparse tensors. Four elemental dimensions are proposed, including communication, aggregation, partition, and balance, to construct diverse synchronization schemes, revealing that existing schemes [23, 35, 56] can be described within this framework. This leads to a proof of the existence of communication-optimal schemes to synchronize sparse tensors in distributed training.

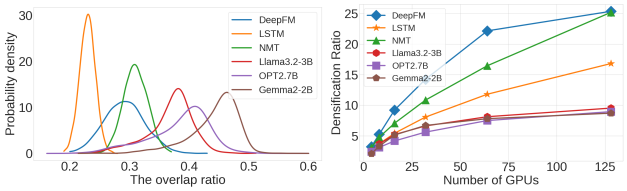
Based on these findings, we develop a sparse gradient synchronization system, called ZEN (Figure 1), which achieves a near-optimal communication time. Specifically, ZEN takes the tensor sparsity and network specification as input and pinpoints the optimized sparse communication plan as output. Our key design insight lies in framing the challenge of achieving optimal schemes as a mathematical problem. We propose a data-independent solution to address this challenge, eliminating costly data-dependency overhead. This solution achieves high efficiency by introducing a novel hierarchical hashing algorithm that attains superior performance on GPUs while ensuring provably near-optimal results without any information loss. ZEN also incorporates an efficient encoding scheme to minimize index representation overhead, irrespective of the random distribution of non-zero gradients after applying the hierarchical hashing algorithm. We evaluate ZEN across various DL training workloads, where tensor sparsity arises from natural computation or gradient compression. ZEN achieves up to 5.09× speedup in communication time and up to 2.48× speedup in training throughput over existing methods for sparse tensor synchronization.

Table 1: Three DL models with natural tensor sparsity.

Model	MLP Size	Embedding Size	Embedding Density
LSTM [44]	20M	406M	1.13%
DeepFM [26]	68M	214M	2.80%
NMT [40]	31M	112M	2.47%

Table 2: Configurations of three LLMs. AH: attention heads.

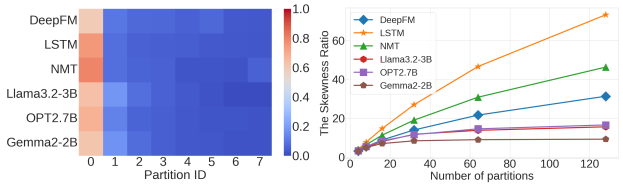
Model	Hidden size	Intermediate	#Layers	#AH
Llama3.2-3B [22]	3,072	8,192	28	24
OPT2.7B [79]	2,560	10,240	32	32
Gemma2-2B [65]	2,304	9,216	26	8



The key contributions of this paper are as follows.

- We analyze the characteristics of sparse tensors in popular DL models to reveal and understand the fundamentals of gradient sparsity in distributed training.
- We systematically explore the design space of sparse communication schemes and pinpoint the optimal ones.
- We develop ZEN, a gradient synchronization system for sparse tensors that achieves near-optimal communication time using a data-independent hierarchical hashing algorithm and an efficient encoding scheme.
- Evaluation reveals that ZEN achieves evident throughput improvement compared to the state-of-the-art methods across diverse training workloads.

2 Analysis of Sparse Tensor Synchronization



2.1 Characteristics of Sparse Tensors

This section analyzes the characteristics of sparse tensors from both natural gradient computation and sparsification algorithms. For natural tensor sparsity, we will study the gradient tensors from the embedding layers of the three DL models listed in Table 1. For the tensor sparsity from gradient compression, we will study three large language models (LLMs) listed in Table 2 and apply DGC [39], one of the most popular sparsification algorithms, to select the top 5% gradients from their gradient tensors [8, 27]. Detailed workloads for the models can be found in §5.1.

Figure 5: An Illustration of two aggregation patterns with Hierarchy. The gradients on each GPU are from the same parameter and 4.7 is the final aggregated result.

Definition 1 (Dense tensor)**.** *We define the original gradient tensor in a DL layer as a dense tensor.*

We define *density* of a gradient tensor as the percentage of its non-zero gradient values. We can represent a gradient tensor in a sparse format when many parameters have zero gradients. A typical sparse format is coordinate lists (COO) that store a list of non-zero gradients and a list of the corresponding indices [23, 77].

Definition 2 (Sparse tensor)**.** *We define a gradient tensor in a sparse format as a sparse tensor.*

We denote the size of a dense tensor G by M, its density is d_G, and the training involves n nodes. For simplicity, we assume that each node has only one GPU in this section.

C1: The overlap of sparse tensors varies. Similar to dense tensors, sparse tensors are aggregated during synchronization. When aggregating dense tensors, the indices of gradients from different GPUs are identical. However, due to different batches as input for training on different GPUs, the indices of non-zero gradients in a sparse tensor are unknown *a priori*. They can have overlaps, but how much they overlap depends on many factors, such as the DL model, the training dataset, and the batches. We define the overlap ratio [68] to quantify this overlap between two sparse tensors.

Definition 3 (The overlap ratio)**.** *Given two sparse tensors and their sets of indices for non-zero gradients are I_1 and I_2, respectively, their overlap ratio is defined as $\frac{|I_1 \cap I_2|}{\min\{|I_1|,|I_2|\}}$, where $|\cdot|$ is the cardinality of a set.*

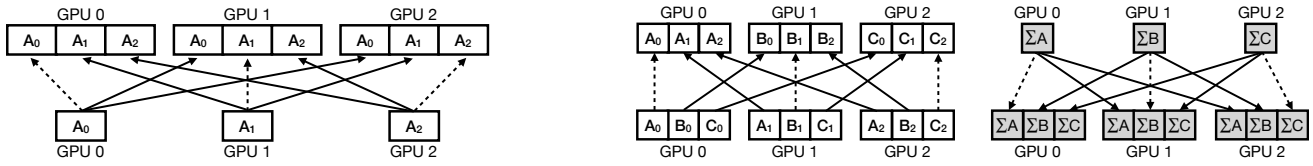

Figure 2a shows the probability density function (PDF) of the overlap ratios for the six DL models studied in the paper. The overlap ratio in a model is approximately normally distributed, and it is in a wide range. In addition, different models have different distributions of overlap ratios.

C2: The tensor size after aggregation varies. When aggregating dense tensors, the tensor sizes before and after aggregation remain the same. However, when aggregating sparse tensors, the unknown overlaps of sparse tensors lead to varying tensor sizes after aggregation. Because the aggregation involves sparse tensors from multiple GPUs, we denote d_G^n as the density after the aggregation of tensors from n GPUs. We observe that sparse tensors get denser after aggregation. We define the densification ratio to quantify this characteristic.

Definition 4 (The densification ratio)**.** *Given a dense tensor G, its densification ratio is defined as $\gamma_G^n = \frac{d_G^n}{d_G}$.*

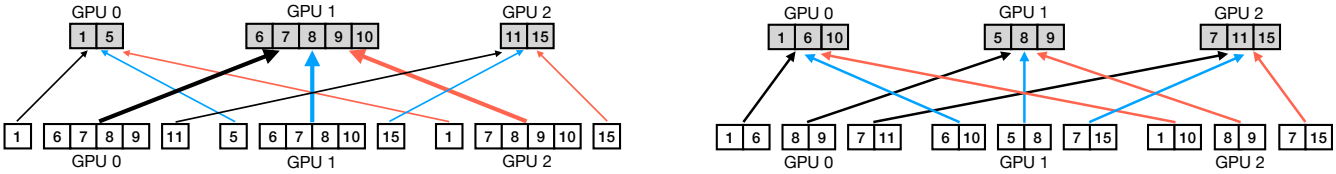

Figure 2b presents the average densification ratio γ_G^n to the number of GPUs for the DL models studied in this paper. The densification ratio increases with the number of GPUs, demonstrating that tensors have a higher density after aggregation. We can also see that the densification ratio is smaller than the number of GPUs, i.e., $\gamma_G^n < n$. It suggests that the indices of non-zero gradients in sparse tensors from different GPUs are partially overlapped.

C3: The distribution of non-zero gradients is skewed. When evenly splitting a dense tensor into multiple partitions, we observe that most of the non-zero gradients are in one of them. For example, with eight partitions, more than 60% of the non-zero gradients are in the first partition in the six DL

(a) Centralization (b) Parallelism

Figure 6: An illustration of the two partition patterns with Point-to-point. In (a), each tensor is communicated as a whole and each GPU receives all the tensors. In (b), each tensor is split into three partitions; the same partition from different GPUs is sent to the same place, and the aggregated results are then sent back to all GPUs.

(a) Imbalanced communication (b) Balanced communication

Figure 7: An illustration of balance patterns with Point-to-point and Parallelism. Each GPU has six non-zero gradients and the numbers are their indices. In (a), four gradients from each GPU are sent to GPU 1. In (b), each GPU sends two gradients to other GPUs, and communications are well-balanced. However, it is non-trivial to achieve such balanced communications.

models. Figure 3a shows the percentage heatmap of the non-zero gradients in each partition. We define the skewness ratio to quantify the skewed distribution of non-zero gradients.

Definition 5 (The skewness ratio)**.** *Given a dense tensor G and we evenly divide G into disjoint n partitions, denoted as $\{G_1, \cdots, G_n\}$, the skew ratio of G with n partitions is defined as* $\frac{\max_{i\in[n]}\{d_{G_i}\}}{d_G}$.

Figure 3b presents the skewness ratios of gradient tensors in the DL models studied in this paper. They are significant in all six models. For example, when we evenly split the gradient tensor from the embedding table in LSTM into 128 partitions, the skewness ratio is over 70. It indicates that more than half of the non-zero gradients are in the same partition.

2.2 Elemental Dimensions for Synchronization

Synchronization for dense tensors has been extensively studied [29, 34, 59, 66]. This section will explore the design space to construct synchronization schemes for sparse tensors. Given a tensor, the outcome of its synchronization is that gradients with the same indices are aggregated and all GPUs have identical aggregated results. We will discuss four dimensions that construct a synchronization scheme for sparse tensors.

Communication dimension. There are typically three communication patterns for synchronization: 1) `Ring`, 2) `Hierarchy`, and 3) `Point-to-point`. They are illustrated in Figure 4 with an example in which there are four GPUs and GPU P_3 aggregates the data from all GPUs. In Ring, all GPUs form a ring structure. P_0 first sends its data to P_1, which then passes the data along with its own data to P_2 and so on until P_3 receives all the data. In Hierarchy, all GPUs form a hierarchical structure and P_3 is the root. There are two stages in Figure 4b. In the first stage, P_0 sends its data to P_1 and P_2 sends its data to P_3. In the second stage, P_1 sends the data from both its own and P_0 to P_3. In Point-to-point communication, the other three GPUs directly send data to P_3.

Aggregation dimension. A communication pattern can have multiple communication stages and there are two options for aggregation: 1) `Incremental aggregation`, i..e, aggregate tensors at each stage; and 2) `One-shot aggregation`, i.e., only aggregate tensors from all GPUs after the last stage. These two options lead to different amounts of traffic volume in different communication stages because of C1 and C2 discussed in Section 2.1. In the example illustrated in Figure 4, Ring has three stages and Hierarchy has two stages. Figure 5 displays an example with Hierarchy as the communication pattern. When P_1 receives a tensor from P_0, it has two tensors. P_1 can either aggregate the two tensors and send the aggregated result to P_3, as shown in Figure 5a; or it can just send the concatenated tensor to P_3, as shown in Figure 5b.

Partition dimension. There are two partition patterns to ensure that all GPUs have the same aggregated results after synchronization: 1) `Centralization`, in which each tensor is communicated and aggregated as a whole; and 2) `Parallelism`, in which each tensor is decomposed into multiple partitions and each partition is communicated and aggregated separately. Figure 6 compares the two partition patterns with Point-to-point as the communication pattern. With Centralization, as shown in Figure 6a, each GPU sends its tensor as a whole to other GPUs. With Parallelism, as shown in Figure 6b, each GPU first decomposes its tensor into three

partitions and it requires two steps for synchronization. The first step aggregates the same partition from different GPUs in different places and the second step ensures that all GPUs have the aggregated results of all partitions.

Balance dimension. With Parallelism, the number of non-zero gradients in each partition can vary. Therefore, there are two patterns in terms of the traffic volume received at each GPU: 1) `Balanced communication`, in which the GPUs receive the same amount of data; and 2) `Imbalanced communication`, in which the traffic volumes received at different GPUs are greatly different. Figure 7 compares the two balance patterns among three GPUs with Point-to-point. There are 15 gradients in the tensor and six of them are non-zero. As shown in Figure 7a, four non-zero gradients are in the middle partition and they are sent to GPU 1. The traffic volume received at GPU 1 is 4× that received at GPU 0 and GPU 2. In Figure 7b, each GPU sends two non-zero gradients to other GPUs and the volume among them is well balanced. Naively partitioning a tensor can cause imbalanced communications due to C3 discussed in §2.1.

The four dimensions describe the design space of synchronization schemes for sparse tensors. Table 3 classifies existing schemes [23, 35, 56] based on their dimensions.

2.3 Optimal Synchronization Schemes

Next, we analyze optimal synchronization schemes for sparse tensors based on the four design dimensions. For convenience, we introduce two special schemes: ***Balanced Parallelism*** and ***Hierarchical Centralization***.

Definition 6 (Balanced Parallelism)**.** *It refers to the synchronization scheme characterized by [Point-to-point, Incremental aggregation, Parallelism, and Balanced communication].*

Definition 7 (Hierarchical Centralization)**.** *It refers to the synchronization scheme characterized by [Hierarchy, Incremental aggregation, and Centralization].*

Theorem 1 (Optimal schemes)**.** *To minimize communication time for sparse tensors, the optimal synchronization scheme is either Balanced Parallelism or Hierarchical Centralization.*

Proof. Theorem 1 is proven using Lemma 1 and Lemma 2. Here, we present the main intuitions and the detailed proof is in Appendix B.1.

Lemma 1. *When the partition pattern is fixed to Parallelism, the optimal scheme is Balanced Parallelism.*

There are three intuitions for Lemma 1: 1) Balanced communication outperforms imbalanced communication; 2) Point-to-point communication outperforms both Ring and Hierarchy by minimizing the traffic volume of unique gradients in the Parallelism partition pattern. and 3) Incremental aggregation outperforms One-shot aggregation as it reduces the traffic volume by aggregating the overlaps of sparse tensors.

Lemma 2. *When the partition pattern is fixed to Centralization, the optimal scheme is Hierarchical Centralization.*

There are two intuitions for Lemma 2: 1) when the partition pattern is fixed to Centralization, the search space is reduced to six candidates because the Balance dimension is not applicable. 2) Among these candidates, Hierarchical Centralization minimizes the traffic volume for overlapped gradients. We use an extreme case to demonstrate the second intuition. Suppose a non-zero gradient with index *idx* appears in all sparse tensors. In Point-to-point or One-shot aggregation, each GPU has to receive this gradient $n-1$ times. In Ring, the gradient from each GPU is aggregated at every stage and forwarded to the next GPU, causing each GPU to receive the gradient $n-1$ times. However, with Hierarchy and Incremental aggregation, each GPU only receives the gradient $\log n$ times.

Lemma 1 and Lemma 2 imply Theorem 1. □

Communication time analysis. We will analyze the theoretical communication time of the two schemes mentioned in Theorem 1. The symbols used in the analysis are listed in Table 4. We assume that each node is equipped with a single GPU, and that each pair of nodes has direct bidirectional connections [56]. The theoretical communication time is defined as the transfer time of messages, L/b, where L is the message size and b is the network bandwidth. For this analysis, we adopt the COO sparse format. For simplicity, we assume that the tensor on each GPU has identical d_G and the average densification ratio for all GPUs is γ_G^n. Additionally, the number of GPUs, n, is a power of 2.

• **Balanced Parallelism.** Communication in this scheme involves two steps. The traffic volume each GPU receives is $\frac{2(n-1)}{n} d_G M$ in the first step and $\frac{2(n-1)}{n}\gamma_G^n d_G M$ in the second step. The total traffic volume that each GPU receives is $\frac{2(n-1)}{n}(\gamma_G^n+1)d_G M$. resulting in a communication time of:

$$T_{bp} = \frac{n-1}{n}(\gamma_G^n+1)2Md_G/b. \quad (1)$$

• **Hierarchical Centralization.** Communication in this scheme is performed in $log n$ stages. In the i_{th} stage, the traffic volume that each GPU receives is $2\gamma_G^{2^{i-1}} d_G M$. The total traffic volume that each GPU receives is $2\sum_{i=1}^{\log n}\gamma_G^{2^{i-1}} d_G M$. The corresponding communication time is:

$$T_{sm} = \sum_{i=1}^{\log n}\gamma_G^{2^{i-1}} 2Md_G/b. \quad (2)$$

Balanced Parallelism as the practical optimal scheme. According to Theorem 1, the optimal scheme is determined by comparing Equations (1) and (2). Based on the characteristics of sparse tensors in DL models, we observe that Balanced Parallelism is often better than the other scheme because $\sum_{i=1}^{\log n}\gamma_G^{2^{i-1}} > \frac{n-1}{n}(\gamma_G^n+1)$ in practical distributed training. To illustrate, we consider two extreme cases. The first case is

Table 3: Comparison of different synchronization schemes for sparse tensors based on their dimensions.

Schemes	Communication	Aggregation	Partition	Balance	Note
AGsparse [35]	Ring, Hierarchy, Point-to-point	One-shot	Centralization	N/A	Cannot fully use overlaps
SparCML [56]	Hierarchy	Incremental	Centralization	N/A	to reduce traffic.

d_G	The density of G
γ_G^k	The densification ratio of G with k GPUs

that any two tensors are *fully overlapped*, i.e., $\gamma_G^n = d_G$. The left-hand term becomes $\log n$, while the right-hand term is $2(n-1)/n < 2$, which is much smaller. For typically large n, such as $n \geq 16$, the right-hand term is several times smaller. The second case is that any two tensors have *no overlaps*, i.e., $\gamma_G^k = kd_G$. The left-hand term becomes $n-1$, while the right-hand term is $(n-1)(1+1/n)$, which is slightly larger than $n-1$. However, practical overlap ratios are much higher than 0.05, as shown in Figure 2a. More specifically, when $n = 16$, $\sum_{i=1}^{\log n} \gamma_G^{2^{i-1}} > \frac{n-1}{n}(\gamma_G^n + 1)$ even if the overlap ratio of any two tensors is as low as 0.05.

2.4 A Case Study on NMT model

In this section, we will empirically validate Theorem 1. As listed in Table 3, several synchronization schemes for sparse tensors are proposed [23, 35, 56]. We will compare their performance from an algorithmic perspective, i.e., only consider their theoretical communication time and ignore other overheads, such as the computation time for aggregations and the sparse tensor encoding and decoding overheads.

• **AGsparse [35].** It adopts [One-shot aggregation, Centralization], and separately collects non-zero gradients and the corresponding indices. It cannot fully exploit the overlaps among the sparse tensors to reduce traffic volume. Note that there are different implementations for AGsparse with different communication patterns [66].

• **SparCML [56].** It adopts Hierarchical Centralization. It cannot fully leverage the overlaps among the sparse tensors to reduce traffic volume. The performance of AGsparse and SparCML both depends on the overlaps. The fewer overlaps, the closer their performance is to optimal. However, as shown in Figure 2, sparse tensors across GPUs in DL models have significant overlaps.

• **OmniReduce [23].** It adopts [Point-to-point, One-shot aggregation, and Parallelism]. OmniReduce consists of workers and aggregators. It splits a gradient tensor into blocks of gradients and only sends non-zero blocks, i.e., blocks with at least one non-zero gradient, to aggregators for aggregations. OmniReduce does not need to transmit indices for non-zero gradients. It requires multiple aggregators for better scalability. However, its performance suffers from imbalanced communications because it evenly partitions tensors.

The sparse data formats are as proposed by each scheme, i.e., AGsparse and SparCML use COO; OmniReduce uses tensor block format. We assume the sparse data format of Balanced Parallelism to be COO for a fair comparison.

The case where Balanced Parallelism is optimal. Figure 8 compares the performance of these synchronization schemes to synchronize sparse tensors in NMT with a batch size of 64. The comparison with other DL models has similar trends. Their communication times are normalized to *AllReduce*, which is the synchronization scheme for dense tensors. The communication time of AGsparse increases linearly with the number of GPUs. It performs worse than AllReduce with more than 40 GPUs because it does not leverage the overlaps among the sparse tensors to reduce traffic volume. OmniReduce outperforms AllReduce with a small number of GPUs. However, its performance improvement becomes marginal with more than 64 GPUs. Due to the skewed distribution of non-zero gradients, most of the non-zero gradients are in one partition, leading to imbalanced communications. In addition, the tensors become denser after aggregation. When splitting this partition into tensor blocks (e.g., each block has 256 gradients [23]), most of them are non-zero blocks. Therefore, almost all gradients in this partition are sent to one aggregator, and it becomes the communication bottleneck. SparCML is worse than AllReduce with a large number of GPUs due to the duplicated indices and their gradients received at each GPU. In contrast, Balanced Parallelism greatly outperforms existing synchronization schemes and AllReduce. For example, existing schemes cannot reduce communication time compared to AllReduce with 128 GPUs, but the communication time of Balanced Parallelism is still 36% lower than AllReduce.

The case where SparCML is optimal. This case is rare in practical distributed training. We have to reduce the batch size of NMT to a very small value for demonstration. For example, when the batch size is 1 and the number of GPUs is 8, the density of the gradient tensors of the embedding layer is less than 0.1%, and the sparse tensors hardly have overlaps, i.e., $\gamma_G^k \approx k$. In this scenario, SparCML outperforms AGsparse

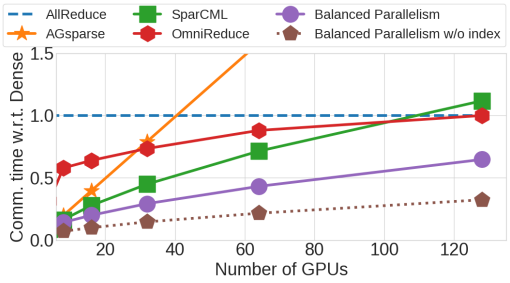

Figure 8: Comparison of different schemes for synchronizing sparse tensors in NMT [40] with a batch size of 64.

and Balanced Parallelism by 4% and 9%, respectively. As the GPU number increases, SparCML still outperforms Balanced Parallelism, but the performance gap becomes more marginal.

The index communication overhead is non-negligible. When the sparse data format is COO, each non-zero gradient in a sparse tensor comes with an index, significantly inflating the traffic volume for gradient synchronization and communication time. To demonstrate its costly overhead, Figure 8 displays an ideal scheme named Balanced Parallelism without index, in which only non-zero gradients are synchronized with Balance Parallelism without any index information. Compared to the ideal scheme, Balanced Parallelism doubles the communication time.

3 ZEN System

We crystalize the above observations and insights into a holistic gradient synchronization system, ZEN (Figure 1), which leverages the sparsity in DL models to minimize the synchronization time in distributed training. ZEN comprises both schemes described in Theorem 1 to minimize communication time under different scenarios. At the runtime, ZEN collects the lightweight sparsity profiling results of the first few iterations and intelligently determines the optimal scheme by comparing Equations (1) and (2).

We will focus on Balanced Parallelism in this section because to date no existing solution realizes it, while SparCML [56] has been proposed. We first formulate the problem for Balanced Parallelism (§3.1) and then develop a hierarchical hashing algorithm to solve it (§3.2). We then design a new sparse data format to minimize the communication overhead incurred by gradient indices (§3.3) in sparse tensors.

3.1 Balanced Parallelism Formulation

For convenience, we borrow the concepts of workers and servers from the Parameter Servers (PS) architecture [34] to Balanced Parallelism. Because there are two steps in Balanced Parallelism for gradient synchronization, we also call them Push and Pull, respectively.

Suppose that there are n workers and n servers in Balanced Parallelism. $I_i \subset \mathbb{N}_+$ is the indices of non-zero gradients generated by worker i. We define the problem of achieving balanced parallelism as follows.

Problem 1. *Let I denote the union of $\{I_1, I_2, \cdots, I_n\}$. We would like to have a mapping $f : I \to [n]$ such that:*

1. *For every $i \in [n]$ and $j \in [n]$, the cardinality of set $\{idx \in I_i | f(idx) = j\}$ is equal to $|I_i|/n$.*
2. *For every $j \in [n]$, the cardinality of set $\{idx \in I | f(idx) = j\}$ is equal to $|I|/n$.*

Here we elaborate more on the two requirements for the mapping f accordingly as follows.

1. **Load balance in Push.** For every worker, mapping f needs to decompose its non-zero gradients evenly into n partitions. Therefore, workers can transmit the same amount of non-zero gradients to each server.
2. **Load balance in Pull.** Each of the servers should have the same number of non-zero gradients after aggregation. It also implies that the same index from different workers should be sent to the same server.

Definition 8 (The imbalance ratio)**.** *Given a mapping f that decomposes I_i into n partitions, denoted as $\{I_i^1, \cdots, I_i^n\}$. The imbalance ratio of Push with f is $\max_{i,j\in[n]}\{n|I_i^j|/|I_i|\}$.*

Let I denote the union of $\{I_1, I_2, \cdots, I_n\}$ and the sets of indices on the n servers after aggregation are $\{\mathbb{I}_1, \mathbb{I}_2, \cdots, \mathbb{I}_n\}$. The imbalance ratio of Pull with f is $\max_{i\in[n]}\{n|\mathbb{I}_i|/|I|\}$.

Based on Definition 8, the imbalance ratio of Push and Pull in Balanced Parallelism is 1. Our goal is to minimize the imbalance ratio for any distributions of non-zero gradients.

Data-dependent solutions cause costly overheads. Due to different sets of indices on different workers, data-dependent solutions need to analyze their overall distribution and calculate one mapping for all workers, inevitably incurring non-negligible computation overheads. In our testbed, the measured computation cost is orders of magnitude greater than the iteration time. Hence, we cannot afford to apply a data-dependent algorithm and obtain a mapping f for every iteration. A possible approach is to compute f periodically and maintain it for the next iterations. However, this approach still leads to high imbalance ratios due to the varying index distributions across iterations. One strawman following this approach is to sort the index set I, evenly partition it into n parts, and use the boundary indices as thresholds to partition the index sets in the next iterations. When computing the thresholds every 1000 iterations for the NMT model [40] with $n = 16$ and applying these thresholds to the following iterations, the imbalance ratio of Push fluctuates between 1.4 and 5.1, causing imbalanced communications between servers. Moreover, the imbalanced communications introduced by data-dependent solutions make it difficult to estimate the iteration time. Many resource scheduling mechanisms for GPU

clusters assume predictable and stable iteration times to allocate resources to training jobs [41, 48, 54]. It is cumbersome to schedule GPU resources with fluctuating communication time.

3.2 Data-independent Hierarchical Hashing

Due to the limitations of data-dependent solutions, we must develop a data-independent solution to achieve load balance in both Push and Pull with negligible computation overheads.

A naive solution to solve Problem 1 is to apply a universal hash function across multiple threads on a GPU, i.e., each thread independently operates hash functions on a disjoint input and writes them into a hash memory. Unfortunately, this approach is lossy. When two indices are hashed to the same location in a hash memory, only one index can be written into the hash memory while the other is overwritten, leading to significant information loss. For example, when the hash memory size equals the size of a dense tensor with 10% density, 17.5% gradients are lost due to hash collision. Increasing the hash memory size can reduce the information loss, but it introduces non-negligible computational overhead because the algorithm must extract the non-zero values from the hash memory after the hash operations. To illustrate, consider the embedding layer (1.6GB) in LSTM [44]. When the hash memory size is four times the tensor size, the information loss rate decreases to 4.8%. However, the extraction overhead increases to 41.8ms using the built-in `nonzero()` API in PyTorch 2.2 on an NVIDIA V100 GPU. This overhead is unacceptable, as it is roughly 40% of the single-GPU iteration time (114 ms in our testbed). In addition, increasing the hash memory size significantly increases GPU memory usage, potentially causing out-of-memory issues and crashing the training process.

We develop a novel hierarchical algorithm to solve Problem 1. We leverage multiple threads on GPUs to efficiently perform hash functions. We achieve no information loss and minimal GPU memory usage by using four techniques.

Technique #1: communication-oriented hash memory management. The hash memory is divided into multiple partitions and the data written into each partition is for the corresponding server. Each partition is further divided into parallel memory and serial memory to prevent data loss. When a thread within a GPU executes a hash function, it initially examines for hash collisions by checking if the hashed location is occupied. In the absence of a collision, the data are written to the parallel memory, enabling concurrent writing operations across all threads. In case of a collision, the colliding indices are sequentially written to the serial memory using an atomic operation, allowing only one thread to write data at a time. Although the indices written in the memory are in random order, there is no need to sort them because their orders do not affect the aggregated results.

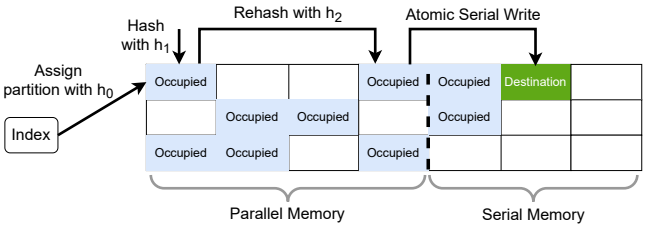

Figure 9: Demonstration of the hierarchical hashing algorithm. We perform parallel hashing on the indices. For each index, we use hash function h_0 to assign its partition. We next use hash function h_1 to assign it to the first location. However, because this location is occupied, we rehash it with function h_2 to the fourth location. As it is also occupied, we serially write the index into the serial memory with an atomic operation.

Unfortunately, we observe that the expense of serial writing becomes significant when the hash collision rate is elevated.

Technique #2: multiple hash functions for each thread in GPU. Multiple hash functions are used to reduce the cost of serial writing. When a hash collision occurs, a GPU thread can rehash the index with a new hash function to another location in the parallel memory. There is a chance that this new location is available and the number of sequential write operations to the serial memory can be reduced. Although hash collision still exists even with multiple hash functions, we observe that the collision rate is less than 1% with four hash functions and the cost of serial writing into the serial memory becomes acceptable.

However, rehashing with multiple hash functions can cause incomplete aggregations. Because different GPUs have different sets of indices for non-zero gradients, their sequences of indices being hashed are also different. Therefore, the location of a particular index can be different between GPUs. For example, two indices idx_1 and idx_2, where $idx_1 < idx_2$, are hashed to the same location with the first hash function. GPU 1 has idx_2; GPU 2 has both idx_1 and idx_2. In GPU 1, the location of idx_2 is determined by the first hash function, but in GPU 2, the location of idx_2 is determined by the second hash function because the location hashed by the first one has been occupied by idx_1. Subsequently, partitioning the memory will lead to the same index assigned to different partitions on different GPUs, resulting in incomplete aggregations.

Technique #3: consistent hierarchical hashing across workers. We propose a two-level hierarchical hashing algorithm to guarantee complete aggregations. The first-level hashing determines the partition to which an index belongs and guarantees that an index will belong to the same partition across all GPUs. The second-level hashing determines its locations in this partition. To ensure that the same index from different workers can be sent to the same server, ZEN allocates the same first-level hashing function to all workers but allows

them to have independent second-level hashing functions.

Technique #4: lock-free read-after-write mechanism. There is a concern that two values from two threads can be hashed to the same available location simultaneously, and this hash collision cannot be detected by conventional mechanisms, leading to information loss. ZEN uses a read-after-write mechanism to check this collision, eliminating this type of information loss. After memory writing, a thread reads the value stored in the location and this operation has no dependency on the values from other threads. If the value equals what it writes, this thread will move on to the next input. However, if the value is not what it writes, it implies that there is a hash collision and its value is overwritten. Then the thread will take a rehash or serial writing.

Hierarchical hashing algorithm. The pseudocode with the four techniques is shown in Algorithm 1. An example of this algorithm is also illustrated in Figure 9. Given a dense tensor G and the indices of its non-zero gradients I, it allocates a memory x with shape $n \times (r_1 + r_2)$, where n is the number of partitions, r_1 is the memory size for parallel hashing operations, and r_2 is the serial memory size. It performs a hashing operation for every $idx \in I$ in parallel (Lines 4-17). A universal hash function $h_0 : \mathbb{N}_+ \to [n]$ is used to locate idx to partition $p = h_0(idx)$ (Line 5). The algorithm also needs k universal hash functions $H = \{h_1, \cdots, h_k\}$ with $h_i : \mathbb{N}_+ \to [r_1]$. After determining the partition p, the algorithm attempts to find an available destination $x[p][h_1(idx)]$ with h_1. If this location is available, idx is written into it. Otherwise, the algorithm rehashes idx with h_2 to find a new location. It rehashes an index for at most k rounds and uses h_i as the hash function for round i until it finds an available destination (Lines 6-16). The algorithm writes idx to the serial memory of partition p after k rehash attempts fail (Lines 8-11). Serial writing is an atomic operation (Lines 9-10) to ensure no information loss. Once all indices are written into the memory, it extracts sparse tensors from the memory (Lines 19-23).

Next, we will analyze the properties of Algorithm 1 and its imbalance ratio.

• **No impact on model accuracy per iteration.** ZEN is an efficient communication scheme for sparse tensor synchronization and it has no impact on the iteration-wise convergence rates of models. For distributed training with natural tensor sparsity, the aggregated result of sparse tensors with ZEN is identical to that of the corresponding dense tensors with AllReduce. When using sparsification algorithms, some accuracy loss may occur due to the compression itself, depending on the sparsity level. However, ZEN does not introduce additional accuracy loss beyond what is inherent to the sparsification algorithm. Specifically, ZEN's Push ensures no further information degradation through its four techniques, and both its gradient aggregation and Pull operations are lossless. The aggregated tensor after sparse synchronization with ZEN is identical to that produced by other schemes such as AGsparse [35] and OmniReduce [23]. Consequently, ZEN preserves the same model accuracy per iteration while achieving shorter wall-clock iteration time. More detailed accuracy evaluations and discussion are shown in Figure 18.

Algorithm 1: Hierarchical Hashing Algorithm

Input: G is a dense tensor and $I \subset \mathbb{N}_+$ is the indices of its non-zero gradients. n is the number of partitions. Each partition has a memory size $r_1 + r_2$, where r_1 and r_2 are the memory sizes for parallel and serial operations, respectively. $h_0 : \mathbb{N}_+ \to [n]$ is a universal hash function. $H = \{h_1, \cdots, h_k\}$ is a set of universal hash functions where $h_i : \mathbb{N}_+ \to [r]$.

Output: The partitioned sparse tensors.

```
1  Function hierarchical_hash(I, G, h_0, H):
2      Allocate memory x ← 0^{n×(r_1+r_2)}
3      Allocate atomic counters c ← 1^n
4      foreach idx ∈ I in parallel do
5          p ← h_0(idx)
6          for i ← 1 to k+1 do
7              q ← h_i(idx)
8              if i = k+1 then
9                  q ← atomicAdd(c[p], 1)
10                 x[p][q] ← idx
11             end
12             if x[p][q] == 0 then
13                 x[p][q] ← idx
14                 break
15             end
16         end
17     end
18     output = []
19     for i ← 0 to n−1 do
20         indices = nonzero(x[i])
21         values = G[indices]
22         output.append((indices, values))
23     end
24     return output
```

• **Negligible memory and extraction overhead.** Thanks to multiple hashing functions and serial memory, Algorithm 1 can achieve no information loss with a small memory size, which is typically less than 150MB (<1% GPU memory capacity) in our implementation for all the evaluated models. The incurred overhead to extract the indices from the memory after hashing (Line 20 in Algorithm 1) becomes negligible.

• **No dependency on workloads.** Note that we impose no assumptions on the data distributions and only use the property of universal hashing algorithms. Hence, Algorithm 1 can obtain a general theoretical guarantee for different distributions of non-zero gradients in DL training workloads.

• **Guaranteed imbalance ratio.** Because the hash function h_0 determines the partition of each index, the imbalance ratio of Algorithm 1 is guaranteed by the following theorem.

Theorem 2 (Load Balance of Algorithm 1)**.** *Given a dense*

tensor G with $|G|$ parameters. Algorithm 1 provides a mapping $f : I \to [n]$ such that

1. *With probability at least $1-1/n$, its imbalance ratio of Push is at most $1+\Theta(\sqrt{\frac{n\log n}{|G|d_G}})$.*
2. *With probability at least $1-1/n$, the imbalance ratio of Pull is at most $1+\Theta(\sqrt{\frac{n\log n}{|G|d_G^n}})$.*

The proof can be found in Appendix B.2. Because $n\log n$ is orders of magnitude smaller than $|G|$, Algorithm 1 performs a good approximation to the exact solution of Problem 1 for both Push and Pull. Suppose $n=128$, $|G|=10^7$, and $d_G^n=0.5$, $\sqrt{\frac{n\log n}{|G|d_G^n}} < 0.02$. Its practical imbalance ratio is always less than 1.1 for the six models studied.

3.3 Cost-Efficient Encoding Scheme

3.3.1 Existing Sparse Formats are Inefficient

There are several sparse formats to represent sparse tensors for their synchronization. Unfortunately, none of them can minimize the overhead incurred by the indices for non-zero gradients. We assume that the data type of gradients is FP32.

• **COO.** It is efficient with low tensor density [39, 74]. However, it doubles traffic volume and becomes inefficient for a high density. As shown in Figure 2b, the tensors become denser after aggregation. For example, the average tensor density of BERT increases from 1.06% to 40.8% after the aggregation of the sparse tensors from 128 GPUs. Theoretically, transmitting sparse tensors in Pull can reduce the traffic volume by 2.5× compared to transmitting dense tensors, but the reduction shrinks to only 1.2× due to the indices for non-zero gradients.

• **Tensor block.** It is used in OmniReduce [23]. A dense tensor is split into blocks of gradients, and only non-zero blocks are transmitted. However, it is inefficient when the tensor density is high. When splitting a tensor with high density into tensor blocks (e.g., each block has 256 gradients), most of them have at least one non-zero gradient and become non-zero tensor blocks. The synchronization scheme has to communicate a large amount of zero gradients. We evaluated the percentage of gradients communicated with the tensor block format compared to the tensor density. DGC with top 5% gradients is applied to OPT-2.7B. When the block size is 256, more than 30% gradients are communicated, much higher than the tensor density of 5%.

• **Bitmap.** It only needs one bit to indicate whether a gradient is zero or not. Unfortunately, a conventional bitmap still incurs non-negligible traffic volume to identify non-zero gradients. When the dense tensor G is evenly partitioned, the indices of non-zero gradients in each server are in a subrange of $[1,|G|]$, where $|G|$ is the number of gradients in G. For example, when $|G|=15$ and there are three servers, the index range in Server i is $[5i+1, 5(i+1)]$. The extra bitmap size required to represent the indices of non-zero gradients in each server is $|G|/n/32$ when the data type of gradients is FP32. The total bitmap size received by each worker is $|G|/32$. When the tensor size of G is 856MB, which equals the embedding table size in DeepFM, the total bitmap size is 27 MB. Although Algorithm 1 enables load balance, the non-zero gradients in each server are randomly distributed throughout the range. If we still use a bitmap to represent the indices, the extra bitmap size in each server is $|G|/32$ and the total bitmap size received at each worker becomes $n|G|/32$, which linearly increases with the number of servers. When there are 16 servers, the total bitmap size is 428MB.

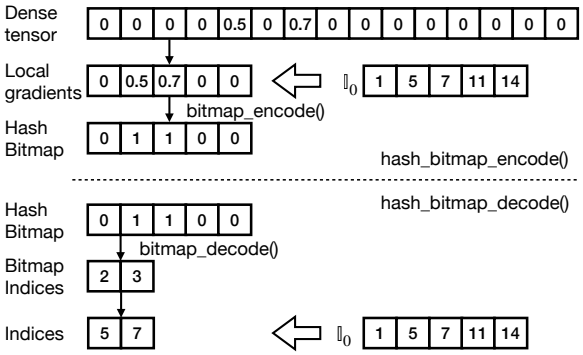

Figure 10: An illustration of the hash bitmap.

Algorithm 2: The hash bitmap

Input: G is a dense tensor. $\mathbb{I}_i = \{idx \in [1,|G|] \mid h_0(idx) = i\}$, where h_0 is defined in Algorithm 1.

```
Function hash_bitmap_encode(G, I_i):
    local_gradients = G[I_i]
    hash_bitmap = bitmap_encode(local_gradients)
    return hash_bitmap
Function hash_bitmap_decode(I_i, hash_bitmap):
    bitmap_indices = bitmap_decode(hash_bitmap)
    indices = I_i[bitmap_indices]
    return indices
```

3.3.2 Hash Bitmap

We develop a novel *hash bitmap* for ZEN to minimize the overhead to represent indices for non-zero gradients in Pull. Given a dense tensor G and h_0 in Algorithm 1, the set of indices $\mathbb{I}_i = \{idx \in [1,|G|] \mid h_0(idx) = i\}$ in each worker that should be pushed to Server i is determined, although it is not in a continuous range. Since $\mathbb{I}_i$ and $\mathbb{I}_j$ are disjoint when $i \neq j$, it provides an opportunity to construct the bitmap based on $\mathbb{I}_i$, rather than the entire range.

Figure 10 illustrates how the hash bitmap works for $\mathbb{I}_0$ with $|G|=15$ and three servers. The indices for the two non-zero gradients are $\{5,7\}$. `hash_bitmap_encode()` is used to encode the indices. Given a dense tensor G, it first extracts local gradients according to the indices in $\mathbb{I}_0$. It then

encodes the local gradients into a bitmap. Because the second and third gradients are non-zero, the second bit and the third bit in the hash bitmap are 1 and the other bits are 0. `hash_bitmap_decode()` is used to decode the hash bitmap to a set of indices. It first decodes a hash bitmap to the bitmap indices, which are the indices of 1. For example, because the second and third bits in the hash bitmap are 1, the bitmap indices are $\{2,3\}$. It then uses the bitmap indices as the indices to extract the corresponding values in $\mathbb{I}_0$ as the global indices for non-zero gradients. In this example, the values are $\{5,7\}$, which are exactly the indices for the two non-zero gradients. The pseudocode is shown in Algorithm 2.

The function `hash_bitmap_encode()` is invoked on each server, which then broadcasts the hash bitmap to all workers. After each worker receives the hash bitmaps from all the servers, it invokes `hash_bitmap_decode()` to decode the hash bitmaps to the indices with the corresponding $\mathbb{I}_i$. Note that $\mathbb{I}_i$ is computed and sorted offline and it remains unchanged for the same h_0 on both servers and workers.

The hash bitmap guarantees that the total hash bitmap size received at each worker is constantly $|G|/32$ in ZEN's Pull. Suppose that there are n servers. The set of indices that should be pushed to Server i is $\mathbb{I}_i = \{idx \in [1,|G|] \mid h_0(idx) = i\}$. With `hash_bitmap_encode()`, the size of the hash bitmap encoded in Server i is $|\mathbb{I}_i|/32$. Because each worker needs to receive the hash bitmap from all servers, the total size is $\sum_{i=0}^{n-1} |\mathbb{I}_i|/32 = |G|/32$. Zen still uses COO to represent sparse tensors in Push due to the low tensor density.

4 Implementation

We implement ZEN [1] with about 900 lines of Python code, 250 lines of CUDA code, and 500 lines of code for hacking ColossalAI [36]. For DL model training, we use ColossalAI to implement data parallelism and hybrid parallelism (data parallelism + tensor parallelism, with tensor parallelism degree set to 8, typically within a single node). We also extend ColossalAI to support the Gemma2 [65] model from Google with custom policies for efficient tensor parallelism.

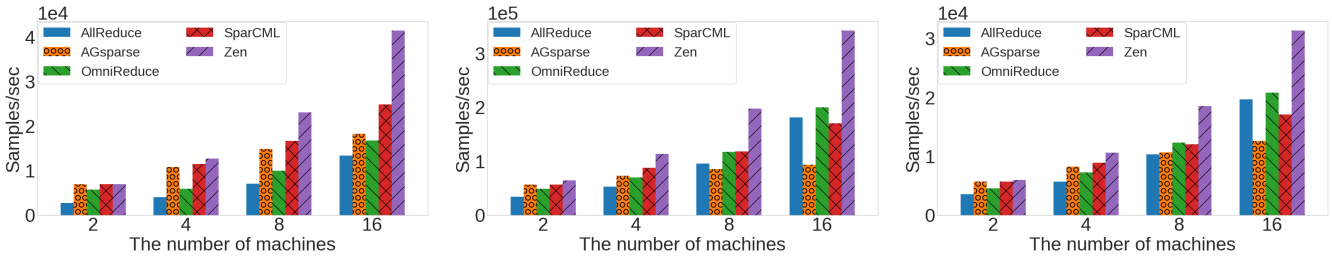
For natural tensor sparsity, we only apply sparse tensor synchronization schemes to gradients from the embedding layers for their communications across machines. For the sparsification algorithm, we use DGC [39] and adapt it to tensor parallelism: sampling data locally on each device, gathering these samples across all devices, computing a global top-k threshold based on aggregated data, and applying this threshold locally to determine top-k values on each device. We register a `custom_comm_hook` in PyTorch's DDP [35] to enable DGC and our synchronization scheme. Gradient computations overlap with gradient synchronization during backward propagation. Gradient tensors are fused into communication buckets in DDP before applying DGC to tensors [73]. We determined a 128MB bucket size that works best for the evaluated models.

We implement the hierarchical hash algorithm in CUDA C and use it as an extension for PyTorch. The used hash function is MurmurHash [9]. We set different seeds for MurmurHash to generate different hash functions. At the beginning of training, ZEN generates a set of random seeds and broadcasts them to all GPUs to ensure hash consistency among workers. ZEN communicates dense tensors within machines with ReduceScatter/AllGather [25, 66] because NVLink is typically equipped in GPU machines. In our evaluations, Balanced Parallelism is the optimal scheme for the studied models.

5 Evaluation

5.1 Experimental Setup

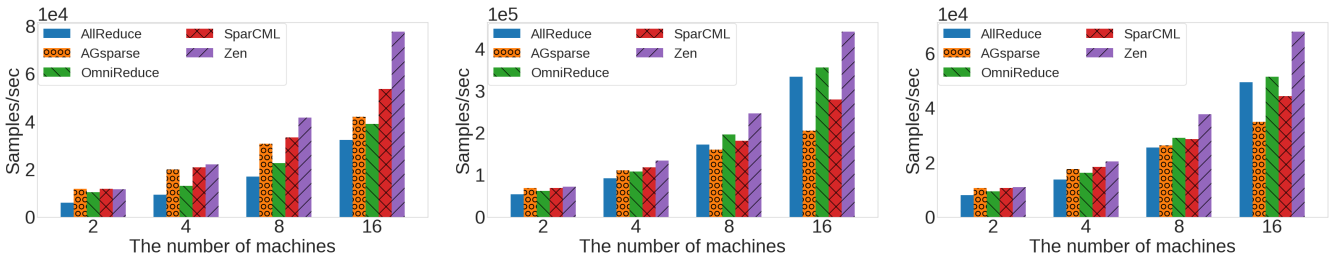
Testbeds. We use 16 p3.16xlarge instances from AWS EC2 for our evaluations. Each machine has 8 NVIDIA V100 GPUs (16GB GPU memory) and NVLink is equipped to support intra-instance GPU-to-GPU communications. These instances are connected by a 25 Gbps network. We also evaluate end-to-end training throughput with 16 p3dn.24xlarge from AWS EC2. Each machine has 8 V100 GPUs (32GB GPU memory) and NVLink. These instances are connected by a 100 Gbps RDMA network with AWS's Elastic Fabric Adapter (EFA). Each machine runs Ubuntu 20.04 and the software environment includes CUDA-11.0, PyTorch-2.2, NCCL-2.7.8, CuPy-11.0, and ColossalAI-v0.4.6. Each p3dn.24xlarge instance also includes aws-ofi-nccl-v1.9.2 and libfabric-v1.11.1 to support EFA.



Workloads. For natural tensor sparsity evaluation, we use three models, LSTM [44], DeepFM [26], and NMT [40], as listed in Table 1. The datasets are One Billion Word [1], Criteo [2], and IWSLT 2014 De-En [3], respectively. The batch sizes are 128, 1024, and 64, respectively. These models can fit in the memory of each GPU. The per-GPU batch size is kept constant as the number of GPUs increases. For the tensor sparsity from sparsification algorithms, we use three LLMs, Llama3.2-3B, OPT-2.7B, and Gemma2-2B, as listed in Table 2. We use RedPajama [75] as the training corpus. Because these models cannot fit into a single GPU, we use tensor parallelism (TP) with degree 8. The batch size within an TP group is 1 and the sequence length is 1024 tokens.

Baselines. We compare ZEN with AGsparse [35], SparCML (SSAR_Recursive_double) [56], and OmniReduce [23]. We use `AllReduce` [59] for the synchronization of dense tensors. We apply DGC [39] to the three LLMs and select the top 5% gradients from their gradient tensors.

5.2 DL Training Evaluation



In this section, we present the training efficiency of ZEN on the six models and compare it with the baselines. We set $k = 3$,

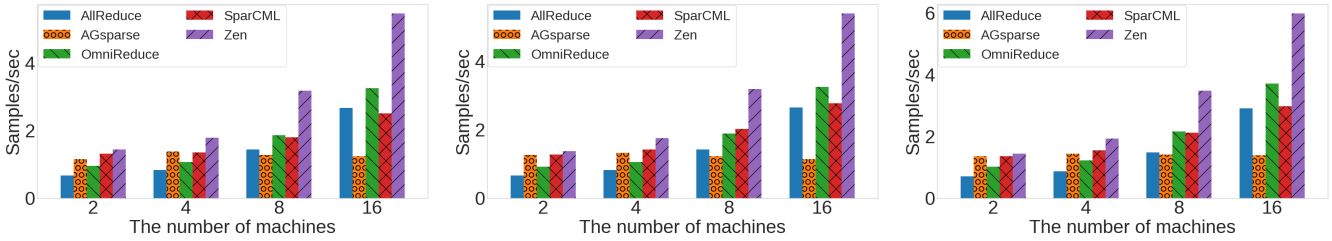
Figure 12: Training throughput of models with natural tensor sparsity in a 100 Gbps RDMA network.

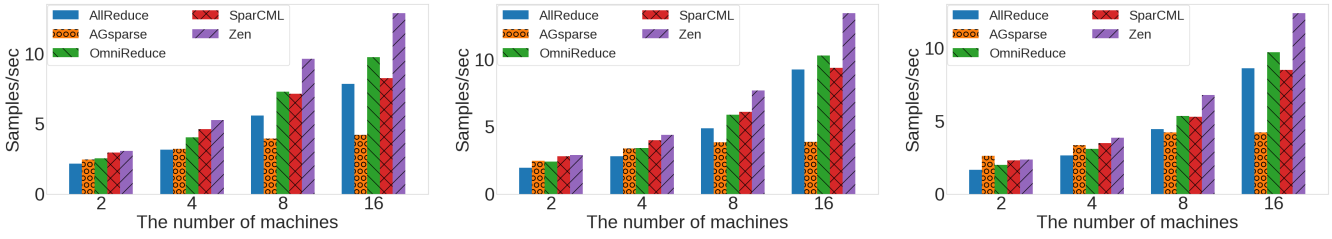
$r_1 = 2|G|d_G$, and $r_2 = r_1/10$ for Algorithm 1.



Training throughput for models with natural sparsity. Figure 11 shows the training throughput of models with natural tensor sparsity in a 25G network. ZEN outperforms all baselines by processing more samples in a second. When training LSTM with 16 machines, ZEN achieves up to a 1.67× speedup over SparCML (the best baseline), a 2.48× speedup over OmniReduce and a 3.1× speedup over AllReduce. In both DeepFM and NMT, the best baseline is OmniReduce. ZEN achieves 1.44× speedup and 1.51× speedup over OmniReduce for DeepFM and NMT, respectively. As the number of machines increases, the benefits of ZEN over SparCML and OmniReduce are enlarged, indicating ZEN's great scalability. When increasing the network bandwidth from 25 Gbps to 100 Gbps, ZEN still has noticeable end-to-end speedups, as shown in Figure 12. Specifically, in LSTM, ZEN achieves up to 1.44× speedup over SparCML, which is the best baseline. In DeepFM and NMT, ZEN achieves up to 1.33× and 1.38× speedups over AllReduce and up to 1.25× and 1.32× speedups over the best baseline OmniReduce.

Training throughput for models with gradient compression. ZEN has great speedups over the baselines for gradient compression scenarios, as shown in Figure 13. For Llama3.2-3B, it achieves up to a 1.68× speedup over OmniReduce, a 2.19× speedup over SparCML, and a 2.02× speedup over AllReduce. In OPT-2.7B and Gemma2-2B, ZEN achieves up to 2.10× and 2.04× speedups over AllReduce, and 1.66× and 1.61× speedups over OmniReduce. We also evaluate the training throughput improvement in a 100 Gbps RDMA network, as shown in Figure 14. ZEN outperforms AllReduce by 64%, 45%, and 44% in Llama3.2-3B, OPT-2.7B, and Gemma2-2B, respectively. OmniReduce is the best baseline for the three models, while ZEN still achieves up to 1.32× in Llama3.2-3B, 1.31× in OPT-2.7B, and 1.27× in Gemma2-2B over OmniReduce. These results demonstrate ZEN fully leverages sparsity in DNN models to optimize training efficiency.

Communication improvement. The performance of ZEN is driven by the reduction in communication time. Figure 15 shows the speedups of different synchronization schemes over AllReduce with 16 machines in a 25 Gbps network. The speedup of OmniReduce is up to 1.58×. We observe that the performance of AGsparse, Sparse PS, and SparCML can be even worse than AllReduce in some cases. They use COO as the sparse format. With high density, the sparse tensor size with COO is larger than the dense tensor size. The communication time of AGsparse increases linearly with the number of machines. With SparCML, the overlaps among the sparse tensors can be received multiple times on each GPU. In contrast, ZEN achieves 6.77× speedup for LSTM and 3.51× speedup for Gemma2-2B. Its speedups over SparCML and OmniReduce are up to 2.82× and 5.16×, respectively. ZEN also achieves 2.10× speedup for DeepFM and 3.44× speedup for OPT-2.7B over Allreduce.



5.3 Understanding ZEN

A study on parameters for Algorithm 1. We simulate a tensor with 214M parameters (same as the embedding gradients in DeepFM) and vary its density to perform a study on both r_1 and k in Algorithm 1. We first study the parameter r_1. We

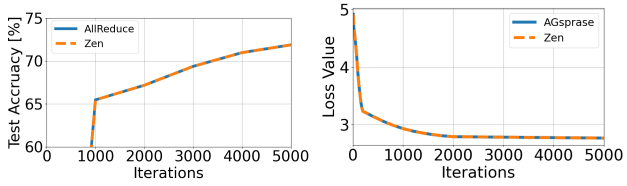
(a) (b)

Figure 16: The computation overhead of Algorithm 1. (a) Different memory sizes and (b) Different numbers of rehash.

set $r_2 = r_1/10$ and $k = 3$. As shown in Figure 16a, when we increase r_1 from $|G|d_G$ to $2|G|d_G$, there is a notable reduction in operation cost because the larger memory size increases the probability of successful parallel writing and reduces the workload of serial writing. But when we further increase r_1 from $2|G|d_G$ to $4|G|d_G$, it leads to a longer computation time. There are two reasons behind this effect. Firstly, the workload of serial writing is already low with $2|G|d_G$ memory. Further increasing r_1 only marginally reduces the computation overhead. Secondly, a larger memory size can increase the computation overhead to extract the indices (see Algorithm 1) and thus degrade the overall performance. Figure 16b shows the computation costs versus k when we use $2|G|d_G$ memory. Increasing k from 1 to 3 can reduce the operation cost as it alleviates serial writing workload, but $k = 3$ and $k = 4$ have very similar operation costs.



Negligible compute overhead. ZEN's performance gains mainly come from communication savings by only synchronizing non-zero values in gradient tensors and load-balancing the traffic volume across GPUs at the cost of additional hashing computation, which is much smaller than the communication savings. We use the tensor with 214M parameters in DeepFM for example. The hashing computation overhead is around 6 ms in our testbed as the practical tensor density is 5.2% after intra-machine aggregation. When the network bandwidth is 25 Gbps, the communication saving over AllReduce is around 270 ms, which suggests that ZEN's compute overhead is negligible. Even with a 100 Gbps RDMA network, the hashing compute time only accounts for 9% of communication savings.

Hash Bitmap. We show the effectiveness of hash bitmap in representing the indices of non-zero gradients. Figure 17a shows the tensor size with different sparse formats. The sizes are normalized to the dense tensor and there are 16 servers. The tensor density is the total density of all servers after aggregation. The gap between the hash bitmap and the COO increases with the tensor density. It also significantly outperforms the bitmap. In addition, the hash bitmap can still reduce traffic volume with a density of 95% compared to the dense

Figure 18: ZEN has no impact on model accuracy per iteration.

tensor, but the bitmap and the COO cannot save the volume when the density is greater than 50%. The performance of tensor blocks varies with the distribution of non-zero gradients. Some sparse tensors in the studied DL models can even transmit higher traffic volume than COO because a non-zero block has more zero gradients than non-zero gradients.

Performance breakdown. We break down the performance of ZEN by Algorithm 1 and the hash bitmap. Figure 17b illustrates the training throughput speedup breakdown over AllReduce with 16 machines. It can be seen that the primary performance benefits of ZEN come from Algorithm 1, with the hash bitmap format providing noticeable additional benefits. For example, when the data format is COO after applying Algorithm 1, the speedup is 2.74× and 1.53× for LSTM and Llama3.2-3B, respectively. Replacing COO with the hash bitmap can further improve the speedups by 13% and 34%.

Model accuracy validation. We first validate that ZEN has no impact on model accuracy per iteration compared to training with AllReduce for natural sparse tensors. Figure 18a shows the model accuracy of DeepFM with 16 machines in a 25 Gbps network. The test accuracy per iteration with ZEN matches exactly that with AllReduce. This is because ZEN balances the synchronization traffic across workers to reduce the iteration time without information loss for gradient synchronization. We then evaluate ZEN's impact on model quality for training with sparsification algorithms. Figure 18b shows the training loss values of OPT-2.7B with DGC selecting top 5% gradients. AGsparse [35] is used as the baseline for sparse tensor synchronization, and we can see that ZEN and AGsparse have identical iteration-wise loss curves, demonstrating that ZEN retains the model convergence rates and model accuracy per iteration as other communication schemes.

6 Related Work

Related work on schemes to support sparse tensor synchronization has already been discussed in Section 2.4.

Acceleration of dense tensor synchronization. ATP [33] and SwitchML [57] exploit programmable switches for the synchronization of dense tensors. BytePS [29] uses the spare CPU and bandwidth resources in GPU clouds to optimize communications. These approaches disregard the values of the gradients and communicate all gradients. In contrast, Zen leverages sparsity in DNN models and only transmits non-zero gradients to reduce the synchronization time.

Acceleration of sparse tensor synchronization. Parallax [31] utilizes parameter servers for sparse tensor synchronization and it cannot achieve balanced communications in synchronization. ZEN can achieve balanced communications using a novel hierarchical hashing algorithm. Flare [21] and Libra [52] use programmable switches to accelerate sparse tensor communications, but they rely on specific hardware. Ok-Topk [38] proposes a novel sparse allreduce algorithm; however, its inherently data-dependent balancing strategy results in significant overhead. ZEN analyzes the characteristics of sparse tensors and explores the design space for communication schemes to determine the optimal one, but prior approaches did not consider these factors.

Hash algorithms for load balance. Previous works attempt to achieve load balance using hashing [11,13,14,19,76]. They typically assign two partitions to a given index using two hash functions and then select the partition with more available memory [20,45,46]. However, these methods require serial writing of indices to memory and cannot leverage multiple threads in GPUs. In contrast, ZEN enables parallelizable computing on GPUs. While DRAGONN [74] introduces a hash-based algorithm for parallel writing of non-zero gradients to memory, it does not address the imbalanced communications in distributed training and cannot handle hash collisions, resulting in information loss. In contrast, ZEN achieves balanced communications and avoids information loss.

7 Conclusion

We make two primary contributions in this work. First, we systematically explore the design space to identify optimal synchronization schemes for sparse tensors in distributed training. Second, we propose ZEN, a practical design to pursue optimal synchronization schemes with a novel hashing algorithm using parallel computing on GPUs without information loss. ZEN greatly improves the efficiency of sparse DNN model training without any impact on model accuracy.

Appendix

A Algorithm for a Strawman Solution

In this section, we present Algorithm 3, which is the algorithm for the data-independent solution with a straightforward hashing algorithm. This algorithm supplements the discussions in Section 3.2.

Algorithm 3: A strawman solution with hashing

Input: G is a dense tensor and $I \subset \mathbb{N}_+$ is a set of indices of its non-zero gradients. $n \in \mathbb{N}_+$ is the number of partitions. $r \in \mathbb{N}_+$ is the memory size for each partition. $h : \mathbb{N}_+ \to [nr]$ is an universal hash function.
Output: The partitioned sparse tensors.

```
Function Main(I, G, h(·)):
    Allocate memory x ← 0^{n×r}
    foreach idx ∈ I in parallel do
        p ← ⌊h(idx)/r⌋
        q ← h(idx) mod r
        x[p][q] ← idx
    end
    output = []
    for i ← 0 to n − 1 do
        indices = nonzero(x[i])
        values = G[indices]
        output.append((indices, values))
    end
    return output;
```

A naive solution to address Problem 1 is to apply a universal hash function across multiple threads on a GPU, i.e., each thread independently operates hash functions on a disjoint input and writes them into a hash memory. Given a dense tensor G, the set of indices of its non-zero gradients is I. The algorithm first allocates a memory x with shape $n \times r$, where n represents the number of partitions and r is the memory size for each partition. For every $idx \in I$, it uses a given universal hash function [15] $h : \mathbb{N}_+ \to [nr]$ to generate the hash value $h(idx)$, where nr is the range of hash function h. Next, it writes idx to the $(h(idx) \mod r)$th location in partition $\lfloor h(idx)/r \rfloor$. The hashing operation is performed in parallel to minimize the computation overhead [74]. After that, it extracts the non-zero indices from the memory of each partition and uses them to look up the corresponding gradients from G. Finally, it returns a sparse tensor for each partition and pushes them to the corresponding servers.

B Theoretical Analysis

B.1 Proof of Theorem 1

Theorem 1 (Optimal schemes)**.** *To minimize communication time for sparse tensors, the optimal synchronization scheme is either Balanced Parallelism or Hierarchical Centralization.*

We prove Theorem 1 with two lemmas.

Lemma 1. *When the partition pattern is fixed to Parallelism, the optimal scheme is Balanced Parallelism.*

Proof. There are three communication patterns: Ring, Hierarchy, and Point-to-point. We first consider synchronization schemes with [Point-to-point communication and Parallelism], namely, the PS architecture. Given n servers and a gradient tensor G with the density of d_G. We first analyze the communication time of Push and Pull operations separately. We then discuss the communication time of different PS schemes.

Push. Because the skewness ratio is s_G^n, the largest density in the n partitions is $s_G^n d_G$. The size of the sparse tensor extracted from this partition is $2s_G^n d_G M/n$. As a result, the communication time of Push in sparse PS is $2(n-1)s_G^n d_G M/n/B$.

Pull. After aggregation, the largest density in the n partitions becomes $s_G^n d_G^n$. In existing implementations of the PS architecture, the communication time of Pull is $2(n-1)s_G^n d_G^n M/n/B$ because each server needs to broadcast its aggregated results to all the workers with Point-to-point communications [29, 34]. In theory, there are other ways to implement Pull in the PS architecture. For example, each server can perform a `broadcast` collective operation. The performance of `broadcast` with different algorithms is analyzed in [10] and its communication time for Pull can be expressed as $2bd_G^n M/B$, where b is the number of rounds in an algorithm. For example, $b = \lceil \log n \rceil$ when it uses Binomial Tree Algorithm and $b = \frac{2(n-1)}{n}$ when it uses Scatter-AllGather Algorithm [10, 25].

Sparse PS. Combining the communication time of Push and Pull with Point-to-point communications, it overall communication time is $2(n-1)(d_G + d_G^n)s_G^n M/n/B$.

Sparse PS with broadcast. When considering `broadcast` for Pull, the overall communication time becomes $2(n-1)s_G^n d_G M/n/B + 2bd_G^n M/B$. We denote this case as Sparse PS with broadcast.

Balanced Parallelism. In Balanced Parallelism, the skewness ratio s_G^n is always 1. We replace the s_G^n in the communication time of sparse PS as 1 and have the communication time for Balanced Parallelism: $2(n-1)(d_G + d_G^n)M/n/B$.

Balanced Parallelism is optimal among schemes with Parallelism. It is clear that Balanced Parallelism is much better than sparse PS when the skewness ratio is large. The performance ratio of Spase PS with broadcast to Balanced Parallelism is $\frac{s_G^n}{1+\gamma_G^n} + \frac{n}{n-1}\frac{b\gamma_G^n}{1+\gamma_G^n} > \frac{s_G^n + b\gamma_G^n}{1+\gamma_G^n}$. Because both s_G^n and b are greater than 1, the ratio is also greater than 1. Hence, Balanced Parallelism always outperforms Sparse PS and Sparse PS with broadcast in terms of communication time.

We then prove that Balanced Parallelism outperforms other schemes. Because One-shot aggregation cannot leverage the overlaps among sparse tensors, the performance of synchronization schemes with One-shot aggregation is worse than those with Incremental aggregation. Therefore, we only consider Incremental aggregation for schemes with Ring commu-

nication or Hierarchy communication. We consider the best case for them, i.e., the skewness ratio is 1 after tensor partition with Parallelism. In addition, we only need to compare the first step because they have the same communication time in the second step. The communication time of the first step in Balanced Parallelism is $2(n-1)d_GM/n/B$.

Schemes with Ring and Incremental Aggregation. They have $n-1$ communication stages. The tensor density in the i_{th} stage is d_G^i. Note that $d_G^1 = d_G$. Therefore, the communication time is $2\sum_{i=1}^{n-1} d_G^i M/n/B$. Because tensors can get denser after aggregation, we have $d_G^i \leq d_G^j$ when $i < j$ and $\sum_{i=1}^{n-1} d_G^i \geq (n-1)d_G$. As a result, the communication time of schemes with Ring and Incremental aggregation is no less than that of Balanced Parallelism.

Schemes with Hierarchy and Incremental aggregation. They have $\log n$ communication stages. Because each partition has a hierarchical structure, the traffic volume in the i_{th} stage is $\frac{d_G^{2^{i-1}}}{2^{i-1}}Mn$ and the total traffic volume in all $\log n$ stages is $V = \sum_{i=1}^{\log n} \frac{d_G^{2^{i-1}}}{2^{i-1}}Mn$. Because $d_G^{2^{i-1}} \geq d_G$, $V \geq \sum_{i=1}^{\log n} \frac{d_G}{2^{i-1}}Mn = 2(n-1)d_GM$. Therefore, the traffic volume received at each GPU is no less than $2(n-1)d_GM/n$ and they are not better than Balanced Parallelism. □

Lemma 2. *When the partition pattern is fixed to Centralization, the optimal scheme is Hierarchical Centralization.*

Proof. When any two sparse tensors have no overlaps, the minimum traffic volume each GPU has to receive is all the tensors from other GPUs. Any synchronization scheme with Centralization achieves the optimal communication time.

When sparse tensors overlap, let n denote the number of GPUs and $I_0, I_1, \ldots, I_{n-1}$ the set of indices for non-zero gradients in each GPU, respectively. C is the overlap of all the sparse tensors, i.e., $C = \bigcap I_i$. If a synchronization scheme adopts Point-to-point communication or One-shot aggregation, each GPU has to receive C for $n-1$ times. Then we consider Incremental aggregation and the communication pattern is Ring or Hierarchy. With Ring, the tensor from each GPU is aggregated at each stage and then forwarded to the next GPU. Consequently, this tensor is received by every GPU. Because C is the common overlap, each GPU also has to receive C for $n-1$ times. When the communication pattern is Hierarchy, each GPU receives data from all the other GPUs with its own hierarchical structure that has $\log n + 1$ levels, as shown in Figure 4b. Because the root GPU is in each level, it has to receive C for $\log n$ times. It suggests that the traffic volume in the scheme with [Hierarchy, Incremental aggregation, and Centralization] is less than that in other schemes with Centralization. Let C' denote the overlap of a subset of the sparse tensors, we can draw a similar conclusion that a subset of GPUs has to receive C' multiple times. In other words, each GPU still has to receive the overlaps multiple times. □

Lemma 1 and Lemma 2 imply Theorem 1.

B.2 Proof of Theorem 2

Theorem 2 (Load Balance of Algorithm 1)**.** *Given a dense tensor G with $|G|$ parameters. Algorithm 1 provides a mapping $f : I \to [n]$ such that*

1. *With probability at least $1 - 1/n$, its imbalance ratio of Push is at most $1 + \Theta(\sqrt{\frac{n \log n}{|G|d_G}})$.*
2. *With probability at least $1 - 1/n$, the imbalance ratio of Pull is at most $1 + \Theta(\sqrt{\frac{n \log n}{|G|d_G^n}})$.*

Proof. The imbalance ratio of Algorithm 1 is only determined by $h_0 : \mathbb{N}_+ \to [n]$, while the set of hash functions H focuses on exact memory write.

The number of indices in I_i is $|G|d_G$, where d_G is the density of G. Since h_0 is data independent, part 1 in Problem 1 can be formulated as: given $|G|d_G$ balls, we would like to toss them into n bins with the universal hash function h_0. Taking the results from [11], the maximum load of the bins is at most $\frac{|G|d_G}{n} + \Theta(\sqrt{|G|d_G \log n/n})$ with probability at least $1 - 1/n$. Recall the definition of the imbalance ratio of Push in Definition 8:

$$Push_{h_0}^n = \max_{i,j \in [n]} \frac{n|I_i^j|}{|I_i|}.$$

Because $\max\{|I_i^j|\} \leq \frac{|G|d_G}{n} + \Theta(\sqrt{|G|d_G \log n/n})$, we have

$$\begin{aligned} Push_{h_0}^n &\leq \frac{|G|d_G + \Theta(\sqrt{|G|d_G n \log n})}{|G|d_G} \\ &= 1 + \Theta(\sqrt{\frac{n \log n}{|G|d_G}}), \end{aligned}$$

with probability at least $1 - o(1)$. Thus, we finish the proof of the first part.

Since h_0 is data independent, part 2 in Problem 1 can be formulated as: given $|I| = |G|d_G^n$ balls, we would like to toss them into n bins with the universal hash function h_0. The maximum load on the bins is at most $\frac{|G|d_G^n}{n} + \Theta(\sqrt{|G|d_G^n \log n/n})$ with probability at least $1 - 1/n$. Recall the definition of the imbalance ratio of Pull in Definition 8:

$$Pull_{h_0}^n = \max_{i \in [n]} \frac{n|I_i'|}{|I|}.$$

Because $\max\{|I_i'|\} \leq \frac{|G|d_G^n}{n} + \Theta(\sqrt{|G|d_G^n \log n/n})$, we have

$$\begin{aligned} Pull_{h_0}^n &\leq \frac{|G|d_G^n + \Theta(\sqrt{|G|d_G^n n \log n})}{|G|d_G^n} \\ &= 1 + \Theta(\sqrt{\frac{n \log n}{|G|d_G^n}}), \end{aligned}$$

with probability at least $1 - 1/n$. Thus, we finish the proof of the second part.

Abstract

This paper presents the Extension Interface Model (EIM) and bpftime, which together enable safer and more efficient extension of userspace applications than the current state-of-the-art. EIM is a new model that treats each required feature of an extension as a resource, including concrete hardware resources (e.g., memory) and abstract ones (e.g., the ability to invoke a function from the extended application). An extension manager, i.e., the person who manages a deployment, uses EIM to specify only the resources an extension needs to perform its task. bpftime is a new extension framework that enforces an EIM specification. Compared to prior systems, bpftime is efficient because it uses extended Berkeley Packet Filter (eBPF)-style verification, hardware-supported isolation features (e.g., Intel MPK), and dynamic binary rewriting. Moreover, bpftime is easy to adopt into existing workflows since it is compatible with the current eBPF ecosystem. We demonstrate the usefulness of EIM and bpftime across 6 use cases that improve security, monitor and enhance performance, and explore configuration trade-offs.

1 Introduction

Developers extend their software to customize it for the needs of a particular deployment. For example, extensions can improve application performance [2, 40], add custom features [48, 50], enhance security [46, 62], and enable application observability for performance monitoring [61, 77] and debugging [39, 45]. Software extensions do not require modifying the original application, which enables customization while ensuring that the deployment can easily integrate maintenance updates from upstream repositories. Many software applications support extensibility, including web browsers [21, 43], HTTP servers [17, 25], text editors [24, 64], and databases [49, 59].

To extend software, a developer defines new logic for the program as a set of extensions, and associates each extension with a specific location in the host application, called an *extension entry*. When a user invokes the application, the system loads the host application and the user's configured extensions. Each time an application thread reaches an extension entry, the thread jumps to the associated extension. It executes the extension in the extension runtime context; once the extension completes, the thread returns to the host at the point immediately after the extension entry.

This paper presents a new approach for specifying the interface between an extension and a host, called the *Extension Interface Model* (EIM), and a new extension runtime system, called bpftime, that together provide safer and more efficient software extensions. EIM and bpftime are motivated by the challenges current extension frameworks face in balancing key extensibility features.

First, current extensibility frameworks struggle to navigate the tradeoff between extension interconnectedness and safety. On the one hand, enabling extensions that perform meaningful work requires *interconnectedness*, i.e., the ability to observe or modify the host application's state and to execute functions defined by the host. On the other hand, application deployments require that their extensions are safe, i.e., that an extension failure cannot harm the health of the host application and the underlying system. Achieving safety requires restricting an extension's behavior to limit both the system resources it consumes (e.g., the memory it uses, the files it opens) and the host interactions it performs (e.g., the host state it reads). Interconnectedness and safety are in tension because interconnectedness often necessitates allowing an extension to modify the host in potentially unsafe ways. We introduce the term *extension manager* to describe the person who is responsible for configuring the extensions on a given deployment and thus must navigate the tradeoff between interconnectedness and safety.

To maximize system safety, an extension manager should follow the principle of least privilege, granting extensions only the minimal set of features their use cases require. For example, a deployment that supports observability extensions for debugging and monitoring may have different interconnectedness/safety needs than one that supports extensions for customizing application behavior. Unfortunately, current

extension frameworks poorly support specifying and enforcing such deployment-specific interconnectedness/safety tradeoffs. Many frameworks (e.g., safe language runtimes [23, 38], NaCl [75]) cannot express an interconnectedness/safety tradeoff. Instead, they rely on applications to enforce their own safety, which is ad hoc and error-prone (see §2). Other frameworks (e.g., lwC [37], RLBox [44], Shreds [11]) do not support fine-grained limits on extensions. They either cannot restrict certain unsafe extension behaviors or cannot do so on a per-extension-entry basis. Finally, some frameworks (e.g., Orbit [31], Wedge [7]) do support fine-grained interconnectedness/safety tradeoffs, but they are not designed for extensibility and require modifying host application source code to impose different tradeoffs.

Our first contribution, EIM, supports fine-grained interconnectedness/safety tradeoffs. EIM's key idea is to represent the extension features needed for interconnectedness or restricted for safety through a single abstraction called a *resource*. For example, a resource can represent an extension's ability to call a host function or read a host variable. EIM represents the ability to use resources with capabilities [55, 60, 71]. An EIM specification is produced by two parties: the original application developer and the extension manager. First, developers define capabilities that represent the resources the host application can provide to extensions, essentially enumerating the extension interconnectedness that the host application supports. Then, during deployment, the extension manager creates extension classes that specify the set of capabilities allowed at a particular extension entry, essentially choosing the interconnectedness/safety tradeoff for each extension entry. In sum, EIM specializes interfaces for fine-grained protection, such as those for access control of OS objects (e.g., SELinux [54]) or browser manifest files [22], to support the fine-grained tradeoffs necessary for software extensions.

EIM specifications are runtime-agnostic, and we could enhance an existing extension framework to enforce them. However, current extension frameworks poorly navigate the tradeoff between three properties: extension safety, as specified in an interconnectedness/safety tradeoff; extension isolation, which prevents a host application from harming an extension and is necessary for security monitoring extensions; and extension efficiency, which requires that extensions execute at near-native speed. Current frameworks are inefficient because they employ heavyweight techniques for isolation and safety. For example, many frameworks (e.g., Orbit [31], lwC [37], Wedge [7]) provide new operating system-level isolation abstractions and require context-switch-like overhead to switch between a host and an extension. Other frameworks (e.g., Wasm [23], NaCl [75]) enforce safety and isolation using software fault isolation (SFI), which is much slower than native execution [29].

Our second contribution is bpftime, a new extension runtime that efficiently supports EIM and extension isolation using two design principles. First, the system uses lightweight approaches to provide extension safety and isolation. It enforces the safety in an EIM specification without any runtime overhead using extended Berkeley Packet Filter (eBPF)-style verification, and it enforces isolation with minimal overhead using ERIM-style intraprocess hardware-supported isolation [66, 72]. Second, bpftime introduces concealed extension entries, which improve efficiency by eliminating runtime overhead from extension entries that are not in use by a running process. Concealed extension entries use binary rewriting [10, 14, 18, 70] to inject an extension entry into a host only when a user loads an associated extension. While prior work uses techniques similar to bpftime's verification, isolation, and rewriting techniques, bpftime is the first system combine them to satisfy EIM's requirements.

Additionally, bpftime is fully compatible with eBPF, streamlining the system's path to adoption. With eBPF compatibility, not only can current users of eBPF extensions (e.g., uprobes) seamlessly adopt bpftime[1], but bpftime extensions can also share state and interact closely with eBPF kernel extensions, thereby supporting extensibility use cases that require extending both the kernel and applications.

We maintain bpftime as an open source project [2]; bpftime has 1,000 stars on GitHub, more than 20 contributors, and several PRs per month. Our users currently rely on bpftime and EIM for many use cases, including observability, fault injection, hot patching, and other application customizations. Inspired by these users, we present 6 use cases that highlight the benefits of bpftime and EIM. These use cases explore design tradeoffs, improve security, monitor performance, and enhance system efficiency. In particular, we use bpftime to monitor a microservice application, create new durability configurations in Redis, cache metadata operations in FUSE, implement an SSL-supporting distributed tracing tool, monitor system calls for performance analysis, and enhance webserver security.

We evaluate bpftime's performance on the aforementioned 6 use cases. We find that bpftime improves the throughput of profiling microservices by a factor of 1.5 compared to eBPF. bpftime enables a Redis durability configuration that loses orders of magnitude less data in a crash while decreasing throughput by only about 10%. bpftime enables FUSE caching that accelerates operations by orders of magnitude. The system adds only 2% overhead when extending Nginx, which is up to 5× lower than state-of-the-art alternatives such as WebAssembly, Lua, ERIM [66], and RLBox [44]. bpftime reduces the overhead of SSL traffic monitoring by a factor of 3.79 compared to native eBPF. Moreover, bpftime offers configurations that prevent monitoring overhead from affecting unmonitored processes, a feature eBPF cannot provide. We also use microbenchmarks to illustrate the key features that enable bpftime's performance advantages and demonstrate bpftime's compatibility with eBPF.

[1] Note: eBPF uprobes do not support all bpftime features.

[2] available at https://github.com/eunomia-bpf/bpftime.

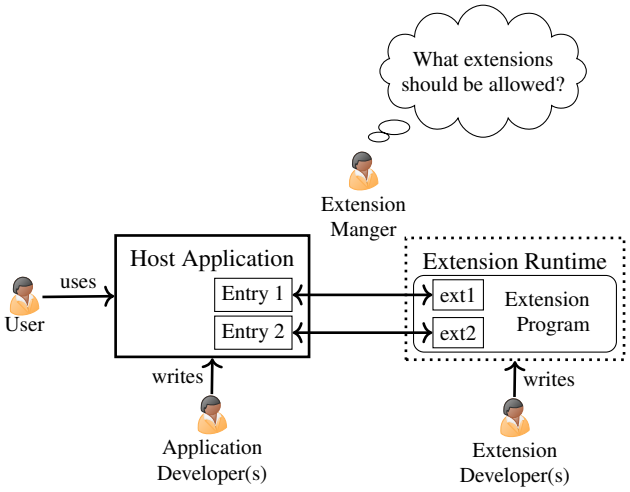

Figure 1: A process extended with two extensions, ext1 and ext2, with associated extension entries, entry1 and entry2, respectively. The application developer(s) and extension developer(s) write the host application and extension program, respectively. The User uses the host application. The Extension Manager decides which extensions to allow and use in the deployment.

In sum, our contributions are:

- EIM, which allows users to specify fine-grained interconnectedness/safety tradeoffs.
- bpftime, an efficient extension runtime system that enforces EIM specifications and isolation through two separate verification techniques and concealed extension entries.
- An evaluation of EIM and bpftime demonstrating their usefulness and efficiency in 6 use cases.

In the rest of the paper, we motivate EIM and bpftime (§2), describe EIM (§3), explain the design and implementation of bpftime (§4), discuss 6 use-cases (§5), evaluate bpftime(§6), describe related work (§7), and conclude (§8).

2 Motivation

System extensions augment an application without modifying its source code to customize behavior, enhance security, add custom features, and observe behavior. By supporting application modifications without requiring source code changes, extensions allow a customized deployment to integrate maintenance updates from upstream repositories easily and can provide assurances of security and safety. The rest of this section discusses the principal roles of system extensions (2.1), provides an example web-server use-case (2.2), articulates the key properties of extension frameworks (2.3), discusses limitations of the current state-of-the-art (2.4), and articulates the threat model (2.5).

2.1 Roles

The system extension usage model considers four key principals. The *application developers* are a group of trusted developers who write the original application, while the *extension developers* are a group of trusted developers who create the extensions. System extensions assume that both the application developer(s) and extension developer(s) are trusted but fallible, so applications and extensions might be exploitable but are not intentionally malicious. Next, the system extension model includes an *extension manager*, a trusted individual that installs and manages the extensions; the model relies on the manager to be both trusted and infallible. Finally, *users* are untrusted individuals who interact with the extended application; users can be malicious and may try to craft inputs that would trigger vulnerabilities in otherwise benign code.

Figure 1 provides a representation of an extended application and shows the role of each principal. The application developers write the host application. The extension developer creates the extension program, which can read and write application state and execute application-defined functions. The extension manager is responsible for deciding which extensions to use at each extension entry. Finally, users produce input that interacts with the host application and, indirectly, the extension program.

2.2 Web-Server Example

Consider an instance of Nginx deployed as a reverse proxy. The application developers write the server, while the extension developers provide a suite of possible extensions to deploy on the system for monitoring, firewalls, and load balancing. The extension manager determines the extensions for the deployment and the privileges to provide each extension. First, the manager uses an extension program that monitors traffic to detect reliability issues [27]. Second, the manager deploys an extension program that implements a firewall that returns a 404 response for URLs that are indicative of SQL injection and cross-site scripting attack. Finally, the manager deploys an extension program to perform load balancing across the possible servers downstream from the proxy by periodically contacting downstream servers to measure system load [26].

2.3 Key Extension Framework Features

Extension use-cases require three key features:

Fine-grained Safety/Interconnectedness tradeoffs. Extensions must be *interconnected*, i.e., able to interact with the host application. Host interactions include reading/writing host state and executing host-defined functions. The Nginx example extension programs highlights both of these features: extensions in the observability use-case require read access to host state, while the firewall, load balancing, and statistics

Bug	Software	Summary
Bilibili [73]	Nginx	Livelock (infinite loop) in an extension caused production outage.
CVE-2021-44790 [47]	Apache	Buffer overflow in httpd's lua module causes application to crash.
CVE-2024-31449 [42]	Redis	Stack overflow in Lua script leads to arbitrary remote code execution.

Table 1: Example issues caused by extension safety violations.

extensions call Nginx functions to parse user requests and return responses.

At the same time, an extension manager wishes to ensure that extensions are *safe*, i.e., do not harm the health of the deployment. Safety does not aim to thwart malicious extensions, but rather to ensure that a bug in the extension cannot harm the reliability or security of the host. Extension bugs have lead to catastrophic consequences in production, including livelock, system crashes, and remote code execution; Table 1 provides examples.

There is no single definition of safety appropriate for all extension use-cases, since safety and interconnectedness are in tension. Instead, the manager should be able to follow the principle of least privilege and allow each extension to perform only the actions necessary for the interconnectedness required for its task. For example, the Nginx observability extensions only need to read from specific host states, but would be unsafe if allowed to write to them. In contrast, the Nginx firewall extension needs to read/write to a different set of host states, but would be unsafe if it were allowed to read the observability states.

Safety rules that can be applied to each individual extension are *fine-grained safety/interconnectedness tradeoffs*. We note two desirable properties. First, the same extension entry may need to support different safety/interconnectedness tradeoffs since it may be useful for separate extension use-cases. Second, while the universe of possible interconnectedness features depends on the host application and thus requires a knowledgeable application developer to modify the host source code, the manager should be able to modify the safety/interconnectedness tradeoffs for their extensions without changing the original application.

Isolation. Extensions must be *isolated*, i.e., not be harmed by the host application. Isolation does not thwart a malicious host application, but rather ensures that attackers cannot circumvent extension-based security by exploiting bugs in the host application. Isolation requires ensuring that host applications cannot modify extension states. The Nginx firewall extension is an example that relies upon isolation.

Efficiency. Extensions should be *efficient*, i.e., execute at near-native speed, since they may be deployed on the hot path of production systems. For example, the Nginx load balancer extension is invoked on the hot path for all user requests.

2.4 The Limitations of State-of-the-Art

We describe the limitations of existing extension frameworks.

Native Execution. A number of extensibility approaches execute the application and extension in the same execution context, essentially treating the extension as a component of the original program. Such approaches include those that use dynamic loading (e.g., `LD_PRELOAD`) and dynamic binary instrumentation [8, 39, 45]). These systems provide efficiency but neither isolation nor support fine-grained safety/interconnectedness tradeoffs.

SFI-based tools. Many extension frameworks use SFI [69] to provide isolation, including XFI [16], NaCL [75], RLBox [44], and language-based sandboxes such as WebAssembly [23] and Lua [38]. Some of these tools (e.g., Lua, WebAssembly, and NaCL) do not provide an interface for safety/interconnectedness tradeoffs. Instead, they rely on the host application to check for safety violations, an approach that has proven buggy (see Table 1). Other tools (e.g., RLBox, XFI) lack fine-granularity or the ability to limit certain extension behaviors. Additionally, SFI-based tools are typically inefficient since they validate extension behavior at runtime [29].

Subprocess Isolation. Subprocess isolation systems, such as Wedge [7], Shreds [11], lwC [37], and Orbit [31], separate extensions from the host application through operating system isolation abstractions. Such systems ensure isolation. However, some lack fine-grained interconnectedness/safety tradeoffs (Lwc and Shreds), while others (Orbit and Wedge) could provide such tradeoffs, but only after code changes to the host application, because they are not designed for extensibility. Finally, such systems struggle to be efficient for frequently-executed extension use-cases, since they require context-switch-like overheads when switching between the host application and its extensions.

eBPF uprobes. While it is usually used for kernel extensions, the extended Berkeley Packet Filter (eBPF) framework provides userspace extensions through the uprobe interface. eBPF uprobes are isolated from the host application, but do not support fine-grained interconnectedness/safety tradeoffs. Moreover, eBPF uprobes are not efficient. eBPF uprobes place a software breakpoint on every extension entry, causing the system to trap into the kernel to execute each extension.

Aspect-oriented programming.. Aspect-oriented programming allows extensions, but existing aspect-oriented languages do not support safety/interconnectedness tradeoffs. For example, if an AspectJ extension were exploited [34], the attacker would have unrestricted ability to observe and modify the original host application.

2.5 Threat Model

The system extension threat model is as follows. First, it assumes that the extension manager accurately and completely identifies the correct safety/interconnectedness tradeoff for each extension entry. This means that a buggy extension cannot corrupt, crash, or hang an application through the interface that the extension manager allows. Second, the model assumes that the control-flow of the application cannot be modified or corrupted even if an application is compromised—essentially equivalent to control flow integrity [1]—since an attacker could otherwise circumvent extension execution. Given these limitations, the threat model considers two key threats. First, it considers buggy extensions that accidentally crash or hang the application through errant pointers, infinite loops, or stack corruption that are outside of their allowed safety/interconnectedness tradeoff. Second, it considers compromised applications that modify or corrupt the state used by extensions to alter the extension's behavior.

3 Extension Interface Model (EIM)

The Extension Interface Model (EIM) is a new model for specifying fine-grained interconnectedness/safety tradeoffs. Using the model, an extension manager can follow the principle of least privilege and specify a tradeoff that would enable extensions to perform their tasks (i.e., sufficiently interconnected) with minimal potential harm to the system (i.e., are sufficiently safe). The model is sufficient to prevent past extension bugs from harming production; e.g., an extension manager can use EIM to prevent each of the bugs in Table 1. An extension framework (e.g., bpftime) can later ensure that the extensions loaded into an application follow their EIM specification, thereby ensuring their safety.

EIM's key idea is to represent the extension features that might be necessary for interconnectedness or restricted for safety as a *resource*. Such resources include both classical systems resources, such as compute cycles, and host application interactions, such as the ability to call a host function or read/write to a host variable. EIM models the ability to use a resource as a capability [55, 60, 71]. An EIM specification encodes fine-grained interconnectedness/safety tradeoffs by specifying the set of capabilities that a loaded extension is allowed to use when configured for a given extension entry.

An EIM specification consists of two separate components. First, the EIM specification includes a development-time configuration, prepared by an application developer, that specifies the set of possible safety and interconnectedness features (§3.1). Second, an EIM specification includes a deployment-time configuration, prepared by an extension manager, that specifies precise interconnectedness/safety tradeoffs (§3.2).

3.1 Development-time EIM Specification

```
1 State_Capability(
2 name = "readPid",
3 operation = read(ngx_pid))
4
5 Function_Capability(
6  name = "nginxTime",
7  prototype = (void) -> time_t,
8  constraints = {rtn > 0})
9
10 Extension_Entry(
11  name="processBegin"
12  extension_entry = "ngx_http_process_request",
13  prototype = (Request *r) -> int))
14 Extension_Entry(
15  name="updateResponseContent"
16  extension_entry = "ngx_http_content_phase",
17  prototype = (Request *r) -> int*)
```

Figure 2: An EIM development-time specification for a simplified version of the Nginx observability use-case.

The development-time EIM specification encodes the possible interconnectedness features and extension entries of the host application. Since these features are tightly coupled with the host application, the development-time EIM is created by an application developer while developing the host application. A development-time EIM specification defines three sets of entries: state capabilities, function capabilities, and extension entries. Figure 2 provides an example of a development-time EIM specification for the Nginx observability use-case.

State Capability. A state capability expresses the ability to read or write to a global state located in the host. A state capability includes a name and an operation of the form `read(var)` or `write(var)`, which specify the capability to dereference and read or write to a variable, `var`, respectively. Figure 2 includes a state capability, `readPid`, that enables reading the global variable in Nginx that stores the process id of the current worker process (Lines 1– 3).

Function Capabilities. A function capability expresses the ability to execute a host-provided function. An application developer defines a new function capability by providing the capability a name, the function prototype of the function, and a set of constraints that provide pre- and post-conditions for the function. Figure 2 includes a function capability in Lines 5–8. The capability specifies the ability to call Nginx's function for getting a timestamp. The function constraints provide the post-condition that its return value is positive.

Constraints. Constraints ensure that extensions safely use host-provided functions and can encode two things. First, constraints can encode binary relationships between arguments and return values, high-level semantic facts, and boolean operators over other constraints. Second, constraints can encode high-level fats about the function that an extension framework could support. Currently, EIM supports allocation facts indicating that a function's return was allocated, IO facts in-

```
1 Extension_Class(
2  name = "observeProcessBegin",
3  extension_entry = "processBegin",
4  allowed = {instructions<inf, nginxTime,
       readPid, read(r)})
5 Extension_Class(
6  name = "updateResponse",
7  extension_entry = "updateResponseContent"
8  allowed = {instructions<inf, read(r),
       write(r)})
```

Figure 3: A deployment-time EIM specification for the simplified Nginx observability use-case.

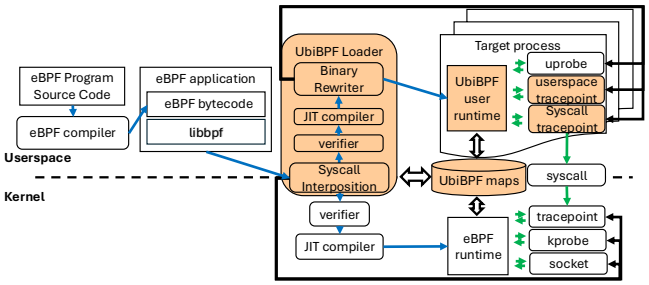

Figure 4: bpftime Design. White components are from eBPF; orange components are new to bpftime. Blue arrows show execution flow when compiling and loading an eBPF application. Green arrows show execution flow when an eBPF extension executes. White arrows with black outline indicate components that interact with eBPF maps

dicating that the function requires the capability to perform IO, annotation facts that indicate a relationship between arguments equivalent to those that linux provides through current eBPF annotations [35], and read/write facts indicating that the caller must hold read/write capabilities for a specified field within a function argument.

Extension Entry. An extension entry specifies the points in the host application that an extension can override. EIM supports extension entries that specify a function—i.e., extending an EIM extension entry replaces the definition of the associated function. An extension entry includes a name, the name of the original function from the host application, and the prototype of the function. Conveniently, many applications already include extensibility support through function interposition that an application developer can reuse for the EIM specification. However, developers may need to define and call new functions in the host application to support emerging extension use-cases. Figure 2 includes two extension entries, `processBegin`, for extending Nginx immediately after it is finished parsing a request, and `updateResponseConent`, for modifying the response that Nginx returns to a client.

3.2 Deployment-time EIM Specification

Deployment-time EIM specifications identify the interconnectedness/safety tradeoffs for a deployment. In particular, the specification identifies the capabilities that an extension requires for its task. Extension Managers write the deployment-time EIM specifications, since identifying the right tradeoff requires reasoning about a deployment's extension use-cases and available resources.

A deployment-time EIM specification includes a set of *Extension Classes*, each representing an interconnectedness/safety tradeoff at an extension entry. An extension class includes a name, the name of an extension entry from the development-time EIM specification, and a set of capabilities allowed by the class. An extension class' allowed capabilities can include capabilities outlined in the development-time EIM specification, state capabilities over the arguments in the extension entry's prototype, and resource capabilities, which specify an ability to consume a hardware resource. EIM provides two such resources, `instructions` and `memory`.

Figure 3 is a deployment-time EIM for the simplified Nginx observability use-case. The specification includes constraints that prevent extension bugs; e.g., it prevents the extension livelock that caused a production outage to an Nginx deployment [73]. The specification includes two extension classes, one for each of the extension entries defined in Figure 2. The allowed capabilities (Lines 4 and 8) include state capabilities (e.g., `read(r)`), resource capabilities (e.g., `instructions < inf`), and function capabilities (e.g., `nginxTime`).

4 bpftime Design

EIM specifications are platform independent, so we could expand existing extension frameworks to enforce them. However, existing frameworks provide safety and isolation through inefficient heavyweight operating-system supported isolation [7, 11, 31, 37] or software-fault isolation [23, 38, 44, 75]. Expanding such systems to enforce EIM's capability model would further degrade their efficiency and yield an unusual system.

So, we designed and implemented bpftime, a new extension framework for extending compiled applications (e.g., those written with C,C++,Go, etc.). bpftime efficiently enforces EIM specifications and supports extension isolation by employing two design constraints. First, the system uses separate lightweight approaches for EIM enforcement and for isolation, similar to how KFlex [15] uses two separate verification techniques for kernel extensions. Namely, bpftime enforces EIM safety/interconnectedness tradeoffs without imposing any runtime overhead by employing eBPF-style verification and provides efficient extension isolation using ERIM-style [66] intra-process hardware-supported isolation. Second, bpftime introduces concealed extension entries, which use binary rewriting [10, 14, 18, 70] to inject extensions into the

host application so that extension entries are zero-cost when not in use by an extension.

bpftime is compatible with eBPF: it provides nearly identical development model, execution models, and even reuses some architecture from eBPF. Thus, existing eBPF uprobe use-cases can seamlessly employ bpftime, and users can easy deploy bpftime extensions alongside kernel eBPF extensions. Alas, ensuring eBPF compatibility is challenging. Linux's eBPF ecosystem consists of tightly coupled components—compilers, runtime libraries, and the kernel—that are nearly impossible to disentangle. Instead of decoupling them, prior user-level eBPF systems [28, 53] re-implementing the entire eBPF technology stack and ultimately failed to provide reasonable performance and compatibility. Instead, bpftime identifies a narrow waist in the current eBPF ecosystem and interposes at this point. In particular, the system interposes on eBPF-related system calls and on the shared map mechanism for sharing data across extensions.

We implemented bpftime in 13,000 lines of code; Figure 4 provides the high-level design. bpftime's trusted computing base includes the kernel eBPF verifier, the binary rewriter, the operating system, and hardware-supported intra-process memory protections. Our current implementation only supports isolation on Intel x86, but different hardware vendors have similar technology that bpftime could employ to add support (e.g., ARM memory domains).

The rest of this section describes bpftime's usage model (§4.1), the bpftime loader (§4.2), and the bpftime runtime (§4.3).

4.1 bpftime Usage

bpftime follows a usage model similar to eBPF. Application developers first create development-time specifications for their application. Extension developers then write programs using eBPF. Extension managers later create deployment-time EIM, and load the extension into the host application with eBPF system calls. The bpftime loader intercepts these calls, validates extensions against their class-defined capabilities, initializes bpftime maps, sets up the bpftime runtimes, and attaches extensions to their extension entries. During execution, the runtime enforces extension isolation.

We elaborate on bpftime's support for EIM and bpftime extension programs.

4.1.1 bpftime support for EIM

To reduce the challenge of maintaining consistency between an application and its EIM specification, bpftime supports development-time EIM specifications through the use of annotations. Namely, application developers annotate their code using a set of annotations that are based upon eBPF's kfunc annotations [35] to specify state capabilities, function capabilities, and extension entries. During compilation, bpftime uses static analysis to extracts the development-time EIM specification from the annotations as well as symbol and type information from the application's debug symbols. The system encodes the resulting specification at the binary level that could, in principle, support any compiled language; the tool currently supports C/C++.

In addition to the application-specific development-time EIM specification, bpftime adds generic extension entries and function capabilities. The system adds `uprobe` and `uretprobe` execution entries for every host-defined function; the host logically executes these entries at the beginning and return of their affiliated function, respectively. Similarly, bpftime adds `sysenter` and `sysexit` execution entries for system calls. The prototype for the `uprobe` and `sysenter` entries include the arguments for the associated function or systemcall, respectively, while the prototype for `uretprobe` and `sysenter` includes the return value for the associated function or systemcall return, respectively. Additionally, bpftime defines a number of runtime-defined helper functions for common tasks and encodes them as function capabilities in the development-time EIM specification. For example, it adds a function capability to modify the return value for `uretprobe` and `sysexit` probes and separate capabilities to interact with bpftime-provided shared memory for process-local memory, inter-process memory, or process-kernel memory.

bpftime supports concealed extension entries when it generates the development-time EIM specification. The system removes the calls to all defined extension entries from the compiled program, both the developer-specified and automatically generated ones, thereby ensuring that any entries that are not used by an extension do not impose a runtime cost.

bpftime supports deployment-time EIM specifications through a YAML configuration language. In addition to extension classes that an extension manager defines, bpftime supports two built-in extension class types that auto-generate useful extension entries. First, bpftime supports observability, which adds an observability extension class for all auto-generated entries (i.e., `uprobe`s, `uretprobe`s, `sysenter`s, and `sysexit`s). Each observability extension class allows capabilities to read the entry's arguments, use a bounded number of instructions, and use a subset of the bpftime-provided function capabilities. Second, bpftime supports customizability, which adds customizability for all auto-generated entries. Each customizability extension class allows capabilities to read/write the entry's arguments using a bounded number of instructions and to use many of the bpftime-provided functions.

4.1.2 bpftime support for extension programs

bpftime supports extension programs that are similar to those supported by traditional eBPF. A developer writes an event-based program consisting of two parts: (1) a set of bpftime extensions and (2) a userspace control application that loads

and communicates with the extensions. Each user-defined extension specifies an associated extension class from EIM. Meanwhile, the eBPF application uses standard APIs (e.g., libbpf) to share data and interact with extensions through bpftime maps.

4.2 bpftime Loader

The bpftime loader prepares the extensions for execution by loading them into the host application and initializing the bpftime maps required for the eBPF application. To cope with the complexity of ensuring compatibility with eBPF, the loader is a thin interposition layer between eBPF applications and the kernel. The loader exposes the eBPF-related system calls interface from the eBPF ecosystem to userspace, but implements them using standard POSIX abstractions (files, unix sockets, etc.). Thus, bpftime supports control applications that use standard eBPF runtimes (e.g. bcc and libbpf) and are compiled using a standard eBPF compiler without requiring kernel modifications. The loader consists of two key components, the verifier, which implements bpftime's eBPF-style verification of extension safety, and the binary rewriter, which supports extensions that use concealed extension entries.

The Verifier. The verifier ensures that extensions are allowed by their associated extension class in the EIM specification. It receives each extension as an eBPF bytecode program. The verifier first performs a few basic verification checks: it ensures that an extension's function signature matches its extension class and that the extension only calls functions allowed by the extension class' function capabilities.

Next, the verifier converts the EIM specification into constraints that it adds to the eBPF bytecode program and uses the eBPF verifier to verify the extension. First, bpftime parses DWARF debugging information from the host application to produce BTF information to add types to the eBPF bytecode. The verifier supports function capabilities by replacing each call to a function capability in the extension with a mock new eBPF kfunc that it generates; using mock kfuncs allows bpftime to reuse the eBPF verifier's support for external functions. Additionally, the verifier converts all function capability constraints into assertion statements that it inserts into the eBPF bytecode before the generated kfunc. Next, the verifier uses the extension class' capability to add additional constraints. It supports state capabilities by modifying the function prototype (e.g., adding `const` for read only arguments) and encodes resource capabilities using verifier-supported clauses [3]. Finally, the verifier uses the verifier to ensures that the extension upholds the EIM specification, is memory and type safe, and will not execute a hardware exception.

Once verified, extensions pass through a userspace JIT compiler, which compiles them into native code. The JIT compiler passes the compiled extensions to the rewriter.

[3]The Linux kernel provides minimal support for custom resource constraints, so our implementation falls back to using PREVAIL [19] for these.

The Rewriter. The rewriter uses `ptrace` to pause the host application and load the bpftime user runtime (§4.3) into it, which allows the system to support use-cases that extend live applications; the system could use existing live-update solutions, such as MCR [20] and KUP [33], to improve performance. The rewriter instruments the program's instructions using Frida [18] and libcapstone [36] to ensure that extensions are invoked when the host reaches their associated extension entry. For extension entries that relate to a single instruction (e.g., `uprobes`, `uretprobes`), the rewriter uses a standard instruction trampoline: it replaces the instructions that were originally at the hook point with a `call` into a preamble for the point's associated eBPF function and places the overwritten instructions at the end of its preamble. Supporting extension entries that relate to system calls is more complex since an application can execute a system call instructions (e.g., `sysenter`) at any point throughout their application. Thus, the runtime iterates through all of the instructions in the application and places a trampoline on all system call instructions. Since `sysenter` is smaller than a trampoline, the system uses zpoline [74], which uses the zero page to accommodate two-byte call instructions. The current implementation only supports a single extension per entry point; users requiring multiple extensions can use a dispatcher pattern to individually call each extension, similar to the design used by libxdp.

4.3 bpftime Runtime

The bpftime runtime executes extensions in the same process as the original application to ensure efficiency. The runtime implements bpftime's intra-process isolation approach to provide extension isolation, which is less expensive than the isolation techniques of existing extension frameworks (e.g., software-fault isolation). Finally, the runtime implements bpftime maps, which are compatible with eBPF maps.

Intraprocess Isolation. The bpftime runtime uses ERIM-style intraprocess isolation to ensure extension isolation [66]. The runtime ensures that the application cannot modify extension logic by setting the memory pages that contain extensions and extension trampolines to be non-writable. The runtime ensures the integrity of extension memory using intra-process memory protections. During loading, the bpftime loader allocates a memory protection key for the extension's memory. The loader adds instructions that use the allocated key (i.e., `WRPKRU`) immediately before all userspace extensions, and adds instructions to reset the key immediately before returning to the original application. To protect the key itself, bpftime loads the key's value directly into the extension and sets the extension's memory permissions to be non-readable. The system is currently susceptible to the syscall-based attacks on ERIM [13], but could adopt Jenny's syscall filtering defenses [56] to resolve the issue.

bpftime Maps. Conventional eBPF provides maps to store

state across extension invocations. Unfortunately, eBPF maps support access to userspace programs through expensive system calls. So, bpftime provides a new map implementation to support system call free access across extension invocations, including bpftime extensions, eBPF kernel extensions, and bpftime control applications. Additionally, bpftime maintains compatibility with the existing eBPF ecosystem by interposing on eBPF map system calls and adding logic that uses bpftime maps instead of traditional eBPF ones. bpftime maps support three sharing modes: local process (nonshared), shared across multiple processes, and shared across processes and the kernel. bpftime maps provide a wide-range of data structures, including hash maps, arrays, LPM tries, ring buffers, perf event arrays, per-CPU variants. Additionally, bpftime maps are highly efficient: they offer per-cpu variants to remove contention and use lock-free synchronization when necessary.

5 Use Cases

We maintain bpftime as an open source project and have cultivated a small use-base. EIM and bpftime have many use-cases, including observability, hot patching, and security enforcement. Inspired in part by the experiences of our users, we craft 6 use-cases of EIM and bpftime that explore design tradeoffs, improve security, monitor performance, and improve performance.

Nginx Plugin. An extension manager manages an Nginx deployment that frequently receives suspicious traffic and wishes to deploy an extension to ensure that the system remains secure. While Nginx currently supports extensions through Lua and WebAssembly, the extensions framework offer poor safety/interconnectedness trade-off and impose high overhead since the extensions copy data to-and-for Nginx instead of operating over the same objects. Since Nginx is already designed for extensibility, creating the development time EIM specification only requires an application developer add annotations to current Nginx extension functions. The extension manager specifies the deployment time EIM by adding a single extension class to an extension entry that corresponds to processing request. The extension class supports reading from an argument representing the current request and writing to the return value. The manager then deploys an extension that implements a firewall to return a 404 response when a request's URL is indicative of SQL injection and cross-site scripting attacks.

sslsniff. Distributed tracing tools struggle to provide useful results when used on encrypted traffic. `sslsniff`, a tool from the bcc [52] project, allows an extension manager to intercepts all SSL/TLS data within userspace to enable better distributed tracing for encrypted data. `sslsniff` uses eBPF `uprobe`s on SSL/TLS encryption and decryption functions in OpenSSL. It suffers from high overhead due to eBPF `uprobe` inefficiencies. bpftime's automated `uprobe`s and observability extension classes enable `sslsniff` to work on bpftime without requiring changes.

Syscount. Syscount [3], another bcc tool, allows aggregating system call activity for a process on a running system by using system-wide extensions on `sysenter`s and `sysexit`s. To limit monitoring to a single process, the tool must observe the system calls of every process on the system and perform manual filtering in the extension. As a result, Syscount imposes overhead on every process, even those that are not monitored. An extension manager can run Syscount on bpftime without any modifications by using bpftime's automated `sysenter` extension entries and its automated observability extension classes. Since bpftime adds Syscount extensions into only the monitored process, the Syscount overhead is localized to the monitored processes.

DeepFlow. DeepFlow is an open-source observability platform for observing a microservice's behavior across the kernel and userspace with eBPF. Unfortunately, Deepflow can lead to as much as a 50% drop in application throughput due to the overheads of eBPF `uprobe`s. We ported DeepFlow to bpftime, modifying 10 out of the 5,000 lines of eBPF code, so that the tool could benefit from bpftime's efficiency. DeepFlow extensions use bpftime's automated uprobe and system call extension entries. DeepFlow uses the system's automated observability extension classes with one caveat: it adds support for using process-kernel shared maps.

FUSE Caching. The Filesystem in Userspace (FUSE) framework offers reliability and security advantages compared to in-kernel alternatives, but imposes considerable runtime overhead because it requires numerous additional context switches for every I/O systemcall [67]. ExtFuse [6] eliminates much of the overhead from using FUSE by enabling a FUSE filesystem to push its logic into the kernel. However, ExtFuse is invasive: it requires a custom kernel module that is difficult to maintain. In this use-case, an extension developer uses bpftime to implement and support the same benefits of ExtFuse without requiring a custom and difficult to maintain kernel model. They configure bpftime's automated customizability extension classes on the system's automated `syscall` tracepoints and add function capabilities for bpftime helpers that interact with file paths, such as `realpath`, and for using process-kernel shared maps. Then, they configure the deployment to use two extensions, written by an extension developer, that accelerate applications that use FUSE. The first is a metadata cache that accelerates repeated lookups to the same file system entries by extending `open`, `close`, `getdents`, and `stat`. It exploit's bpftime's compatibility with eBPF to maintain cache consistency using a kprobe extension on `unlink` in the kernel [4]. The second extension implements a blacklist to accelerate permission checking for functions that access filesystem entries (e.g., `open`).

Redis Durability Tuning. Redis, a key-value store, offers durability through a write-ahead log (called an Append-Only

[4]The second extension must operate in the kernel since non-extended processes may `unlink` a cached file.

```c
int writeback_fin_cnt;

SEC("user_define_ops/fsync_ext")
int BPF_UPROBE(start_fsync, int __fd) {
 if (writeback_fin_cnt == 0) {
   io_uring_wait_and_seen();
 } // else fsync is complete so no wait
 successful_writeback_count = 0;
 io_uring_prep_fsync(__fd);
 io_uring_submit();
 return 0;
}

SEC("kretprobe/file_write_and_wait_range")
int BPF_KPROBE(file_write_and_wait_range,
            struct file *file, loff_t start,
            loff_t end) {
 ... // Check if fsync was from redis/AOF
 __sync_fetch_and_add(&writeback_fin_cnt, 1);
 return 0;
}
```

Figure 5: The Redis Delayed fsync extension.

File (AOF)). By default, Redis offers three durability configurations that tradeoff durability and performance overhead: no AOF, which does not provide durability; everysec, which ensures that writes are durable every second; and alwayson, which ensures that every write is immediately durable. The durability gap between alwayson and everysec is substantial: a crash under everysec can lead to the loss of tens of thousands of updates. Unfortunately, alwayson also reduces throughput by a factor of six compared to everysec.

Redis can use bpftime to provide customizable durability through extensions. Since Redis AOF is not currently designed for extensibility, the application developer needs to add new functions to the source code to support extensibility. The developer defines three new functions and call them at the top of Redis's functions for `write`, `fsync`, and `fdatasync`. Then, they use bpftime annotations to identify the new functions as extension entries. Altogether, this change required about 20 lines of code.

With the updated Redis, the extension manager can explore a custom durability policy for their deployment. They first configure an extension that converts synchronous I/O operations into batched ones by using Linux's `io_uring`. The extension batches *b* I/O operations (calls to `write` and `fsync`) before waiting on them to complete, which ensures that the system loses at most *b* updates in an untimely crash. To use the extension, the extension manager creates two extension classes for `write` and `fsync` that have bounded computation and function capabilities to execute `io_uring` and bpftime map helpers for process-local memory.

However, the performance of highly durable configurations (i.e., small values of *b*) remains poor. So, the extension manager tries another extension. The new extension, *delayed-fsync* (Figure 5), extends the behavior of `fdatasync` so that it waits for the *previous* call to `fdatasync`. This design ensures that the system loses at most 2 updates. The extension also implements a fast-path optimization that extends the kernel to expose a shared variable to userspace that tracks the number of completed `fdatasync` operations on each of a process' open files. The `fdatasync` extension reads from the shared variable and only execute system calls in the event that the previous `fdatasync` has not completed. To use delayed-fsync, the extension manager creates an extension class for `fdatasyc` that has bounded computation and function capabilities to execute `io_uring` and bpftime map helpers for process-kernel shared memory.

6 Evaluation

We implement the 6 case studies on bpftime and answer the following questions:

1. How does bpftime's performance overhead compare to state-of-the-art extension tools, including eBPF, Lua, WebAssembly, ERIM [66], and RLBox [44]?
2. Why does bpftime impose lower runtime overhead than existing tools,?
3. How compatible is bpftime with existing extension use-cases and kernel eBPF runtime?

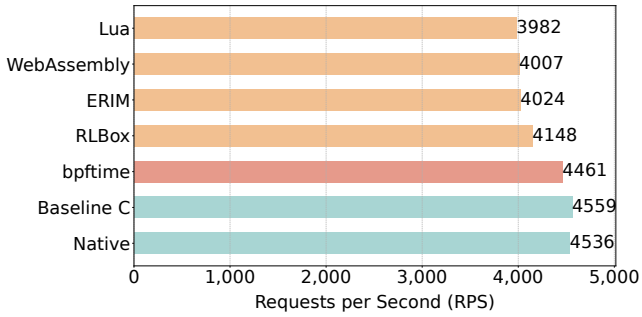
Experimental Setup. We evaluate bpftime running on two servers. Server A is a dual-socket Intel Xeon Gold 5418Y Processor (24 cores, 2.00 GHz, 45 MB LLC) with 256 GB DDR5 memory. Server B is a dual-socket Intel Xeon E5-2697-v2 processor (48 cores, 2.7 Ghz, 30 MB LLC) with 256 GB DDR3 memory. Unless otherwise mentioned, each metric is the average of 10 trials. We report averages using geometric mean when that is appropriate (e.g., when calculating an average speedup). We compare bpftime to two baselines: the native execution on each system (native) and the performance running the extension on the linux eBPF ecosystem.

6.1 bpftime Performance

This section evaluates bpftime's performance across the 6 case studies. In summary, we find that bpftime offers a significant improvement compared to the current state-of-the-art extension frameworks such as eBPF, Lua, WebAssembly, RLBox [44], and ERIM [66].

6.1.1 Nginx Plugin

We evaluated bpftime performance improvements for extending Nginx against the current plugins approaches, including Nginx's builtin support for Lua and WebAssembly, and prior state-of-the-art systems including ERIM [66] and RLBox [44]. We deployed security and tracing modules for each framework in Nginx on System A and benchmark the system using `wrk` (8 threads, 64 connections, 30s tests, averaged over 20 runs). Figure 6 shows throughput results: bpftime introduces 2% overhead compared to native Nginx. In contrast, Lua and WebAssembly incur 11% and 12%, so bpftime achieves 5.5×



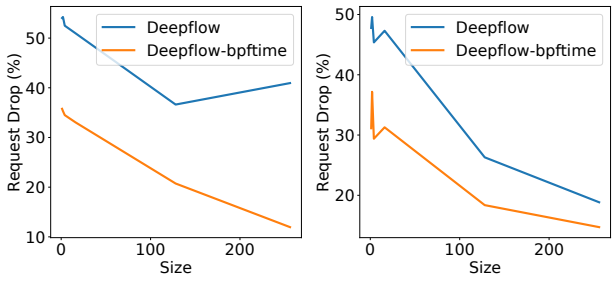


Figure 6: Comparison of extension approaches for Nginx module

(a) HTTP (b) HTTPS

Figure 7: Deepflow throughput overhead

and 6× lower overhead, respectively. ERIM and RLbox impose 11% and 9%, so bpftime achieves 5.5× and 4.5× lower overhead, respectively. In summary, this experiment illuminates a tradeoff between the current extension approaches and bpftime: bpftime and EIM will require more development time to write the specification and pass the verifier when compared to prior work, but significantly improve efficiency and safety.

6.1.2 Deepflow

We deploy Deepflow on System B and use it to monitor a microservice that returns a random string for each request, implemented on a Golang server, and configured to use either HTTP and HTTPS. We route traffic to the service using `wrk`, configured to use 10 threads with 500 concurrent connections for a 10-second test duration. We execute the tests with three configurations: native microservice execution without Deepflow, Deepflow using eBPF, and Deepflow-bpftime using bpftime.

We measure the server's throughput as the response size increases from 1KB to 256KB (Figure 7). Without DeepFlow, the microservice achieves 250,000 requests/s for small responses and 47,000 requests/s for large responses. With DeepFlow using eBPF, throughput drops by up to 54%. bpftime improves DeepFlow throughput by at least a factor of

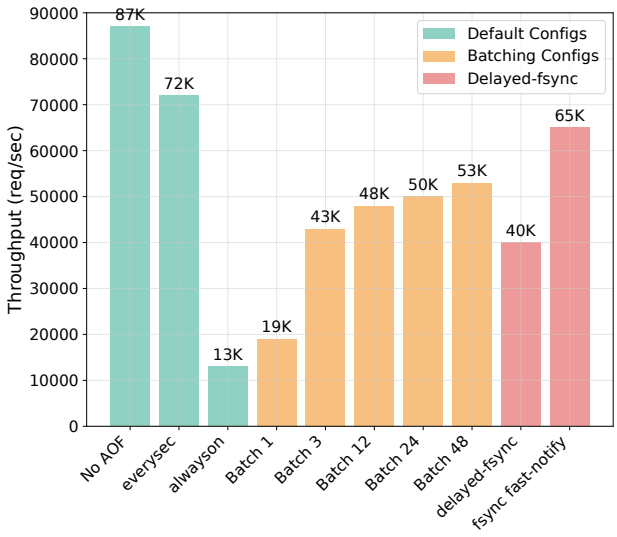

Figure 8: Redis throughput with bpftime Batch-I/O and Delayed-fsync extensions

1.5. DeepFlow's remaining overhead comes from the system's large set of probes that it uses throughout both the kernel and in userspace.

6.1.3 Durability Tuning

We evaluate the Durability Tuning use-case on System A and use redis-bench [65] to send 1M set requests with 5 parallel clients and 3 byte payloads. We execute Redis with the built-in configurations (always on, everysec, and No AOF), varied batch sizes (1, 3, 12, 24, and 48), delayed-fsync, and delayed-fsync with the fast-notify optimization. We configure Redis with always on when configured to use a batching and delayed-fsync. Figure 8 shows the throughput of each of the configurations.

The batched-I/O exposes interesting durability/performance tradeoffs. Using a batch size of 48 improves Redis always on throughput by a factor of 4.17, and incurs a modest durability cost of losing 24 updates in the event of a crash (roughly half of the function in a batch are `writes`). For comparison, the everysec configuration can lose 72,000 updates in the event of an untimely crash. Thus, a batch size of 48 reduces data loss relative to everysec by three orders of magnitude. Additionally, we observe that the batched-I/O implementation improves Redis performance even for small batches: e.g., a batch size of 1 improves Redis always on throughput by a factor of 1.51.

Delayed-fsync presents a powerful configuration. On its own, delayed-fsync achieves a throughput of 40k requests/second, which is 4.15 times larger than the Redis always on's throughput. Adding the fast notify user-kernel interaction further accelerates Redis to 65k request/second, more than 5

Test	Native (s)	bpftime (s)
Passthrough, fstat	3.65	.176
LoggedFS, fstat	7.40	.184
LoggedFS, openat	17.0	0.074
Passthrough, find	5.1	1.6

Table 2: FUSE operation latency.

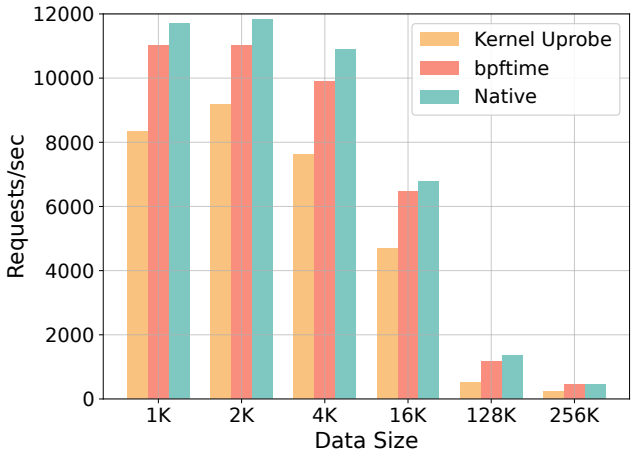

Figure 9: SSlsniff test with nginx

times larger than Redis alwayson. In sum: delayed-fsync with fast notify is only 10% slower than Redis everysec, but it reduces the number of updates that could be lost in a crash by 5 orders of magnitude.

6.1.4 FUSE

We evaluate the performance improvement from using bpftime to implement caching in FUSE when running on System A. We deploy two FUSE file systems: Passthrough, which passes filesystem operations to the underlying file system directly, and LoggedFS [41], which logs all file system operations to a file before passing them to the underlying file system. We measure the end-to-end latency of three workloads: one that issues 100000 `fstatat` calls to a file in the FUSE directory, one that issues 100000 `openat` calls to a file in the FUSE directory, and one that uses the linux utility `find` to travel through the linux 6.7 source code directory. Table 2 shows the results on FUSE and with bpftime caching. We observe that the caching extension implemented with bpftime accelerates the latency of the workloads by a factor of up to 2.4 orders of magnitude.

6.1.5 Sslsniff

We evaluate `sslsniff` on System B while monitoring Nginx. Using the `wrk` benchmark, configured with 4 threads, 512 concurrent connections, and a 10-second test duration. The evaluation includes three configurations: native, `sslsniff` with eBPF, and `sslsniff` with bpftime. We measure nginx throughput when varying response size from 1 KB to 256 KB; figure 9 shows the results. eBPF `sslsniff` significantly impacts Nginx's performance, reducing throughput by up to 28.06% compared to native execution. In contrast, bpftime `sslsniff` has a much smaller effect, with a worst-case throughput reduction of only 7.41

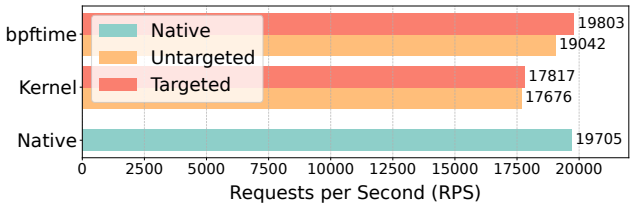

Figure 10: syscount test with nginx

Bench Type	eBPF(ns)	bpftime (ns)
Uprobe	2561.57	190.02
Uretprobe	3019.45	187.10
Syscall Tracepoint	151	232
User memory read	23.3	1.5
User memory write	23.9	1.4
hash_map_update	50.8	23.8
hash_map_delete	19.5	10.1
hash_map_lookup	9.8	22.0

Table 3: Microbenchmark comparison of bpftime and eBPF

6.1.6 Syscount

We evaluate syscount on System B using the same Nginx server config as in the sslsniff evaluation. Figure 10 compares the measured throughput across five configurations. eBPF Syscount reduce throughput on monitored and unmonitored processes by 10.3% and 9.6%, respectively. In contrast, bpftime syscount reduces throughput on the monitored process by 3.36% and does not affect the unmonitored process.

6.2 Microbenchmark Performance

We use microbenchmarks to analyze bpftime's performance.

bpftime vs. eBPF. Table 3 compares bpftime performance to eBPF on microbenchmark operations. First, we create microbenchmarks that measure the overhead of each type of extension entry (`uprobe`, `uretprobe`, or `syscall tracepoint`) on System A. bpftime is more than an order of magnitude faster than eBPF for `uprobe` and `uretprobe`, but about 1.5x slower for `syscall tracepoint`. Then, we measure the latency of using helper functions to access userspace memory and eBPF maps and to update and delete hash entries on System A. We observe that bpftime operations are up to an order of magnitude faster than comparable eBPF operations, since bpftime's extension compiler can inline calls and does not require the address space of kernel eBPF

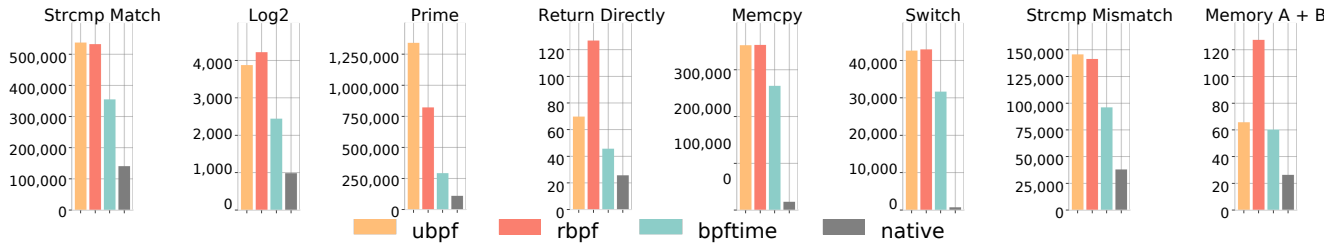

Figure 11: Performance comparison of bpftime, ubpf, rbpf, and native on microbenchmarks.

bpftime execution engine efficiency:. We evaluate the efficiency of bpftime's runtime compared to ubpf [28] and rbpf [28] on 8 micro-benchmarks, including integer heavy computation ('log2', 'prime'), memory heavy workloads ('memory a+b', 'memcpy'), cstring benchmarks ('strcmp match', 'strcmp mismatch'), and control-flow benchmarks ('return directly', 'switch'). Figure 11 shows the latency of each microbenchmark and indicates that bpftime is significantly faster than existing userspace eBPF runtimes. Namely, bpftime accelerates average benchmark latency by a factor of 1.53 and 1.72 compared to ubpf and rbpf, respectively.

bpftime Load latency. We evaluate the latency of loading an extension with bpftime on system A. We write an extension that monitors `malloc` in `libc`, load it into a running process, and observe a 48ms load latency. For comparison, we load the same extension using LD_PRELOAD, and observe a 30ms load latency.

bpftime Cost Breakdown. We isolate the performance improvements of bpftime's two key optimizations: MPK isolation and concealed extension entries. We create a microbenchmark that repeatedly executes a null extension function. The microbenchmark calls the extension function with three settings: first, through its trampoline; second, without the trampoline but with the bpftime execution engine; and third, without the trampoline or execution engine. We observe that the average latency of calling the extension function with the trampoline is 190ns, without the trampoline but with the extension entry is 106ns, and without both is 1.35ns. This means that concealed extension entries save 1.35ns for every unused extension entry that the application executes dynamically; since extension managers often use bpftime's automated extension entries (see §5), these small per entry savings yield large end-to-end performance improvement. The tradeoff is that concealed extension entries require a trampoline that adds an additional 84ns for every executed extension. We reran the experiments with MPK isolation on and off, and did not observe a measurable difference in average extension execution.

6.3 bpftime Compatibility

We evaluate the compatibility of bpftime with existing eBPF extensions. We test 17 BCC [52] and bpftrace [68] tools on bpftime without code changes. Also, bpftime fails only one test in the the bpf-conformance test suite [32], whereas ubpf and rbpf fail 22 and 23, respectively.

7 Related Work

EIM and bpftime improve the safety and efficiency of software extensions in userspace. EIM allows extension manager to specify fine-grained interconnectedness/safety tradeoffs, while bpftime enforces the tradeoffs efficiently. We outline the related work on userspace extensions, kernel extensions, Intra-process Isolation, and Userspace eBPF.

Userspace Software Extensions. Userspace software extensions fall into three categories. Some systems execute extensions in the same execution context as the host application and thus provide efficiency but not safety or isolation, such as dynamic binary instrumentation tools [8, 39, 45] and `LD_PRELOAD`-based tools. Other systems use SFI [69] to provide isolation, but either do not support safety/interconnectedness tradeoffs [23, 38, 75] or lack the ability to specify such tradeoffs at a fine granularity [16, 44]. Moreover, such systems are typically inefficient due to the overhead of SFI's runtime checks. Finally, some systems [7, 11, 31, 37] use subprocess abstractions for isolation. These systems were not designed for extensions and would be inefficient for extension use-cases since they require context-switch-like overheads to switch between contexts. Moreover, some [11, 37] lack support for specifying fine-grained interconnectedness/safety tradeoffs. Others [7, 31] could support fine-grained interconnectedness/safety tradeoffs, but their usage models do not support extensions: a user of these tools would have to modify their application to extend it.

Kernel Extensions. Many systems support kernel extensions [5, 9, 15, 58, 63]; none of these systems support EIM's rich set of fine-grained interconnectedness/safety trradeoffs. Moreover, most [5, 9, 58, 63] use SFI to enforce safety and isolation, which imposes runtime overhead. eBPF has emerged as the de facto extension framework in linux and is increasingly

used in academia [15, 76] and industry [4, 12]. eBPF provides an interface for specifying per hook interconnectedness/safety tradeoffs, but (1) does not support EIM's fine granularity since eBPF bundles large sets of features into sets called program types, (2) does not support all of EIM's features (e.g., eBPF lacks constraints on host-provided functions), and (3) has poor userspace extension support. bpftime's concealed extension entries approach is inspired by recent efforts to support kernel eBPF extensions without traps [30].

Intra-process Isolation. bpftime's use of intra-process memory protection is adopted from the approaches taken by Donky [57], ERIM [66] and libmpk [51]. bpftime's key difference between these systems is its target domain—bpftime applies these ideas to extend an existing application without requiring source-code changes, whereas prior work uses intra-process memory protection to provide lightweight protection domains that a rewritten application can use.

Userspace eBPF. ubpf [28] and rbpf [53] implement virtual machines for userspace eBPF. These systems have high runtime overhead and incomplete eBPF support.

8 Conclusion

In this work, we presented EIM and bpftime, which together provide software extensions that are safer and more efficient. EIM is a new model that allows an administrator to specify fine-grained interconnectedness/safety tradeoffs, effectively reducing the potential for a buggy extension to harm the extended application or underlying system. bpftime is a new extension runtime that enforces EIM specifications. bpftime is more efficient than existing extension frameworks because it uses eBPF-style verification, hardware supported intra-process isolation features, and binary rewriting techniques. Plus, bpftime is easy to adopt since it is compatible with the current eBPF ecosystem. We released bpftime as an open-source project and have cultivated a small user-base. We evaluated EIM and bpftime using 6 use cases to show that they are useful and efficient.

Tintin: A Unified Hardware Performance Profiling Infrastructure to Uncover and Manage Uncertainty

Ao Li Marion Sudvarg Zihan Li Sanjoy Baruah Chris Gill Ning Zhang
Washington University in St. Louis

Abstract

Hardware performance counters (HPCs) enable the measurement of microarchitectural events, which are crucial for tracking and predicting program behavior. High-fidelity measurement and precise attribution are essential for accurate profiling. However, existing profiling tools have fundamental challenges in both aspects. In measurement, numerous events compete for limited hardware monitoring resources; while for attribution, applications have diverse requirements, but systems provide limited support. Existing tools mitigate the former limitation through event multiplexing, but this approach introduces non-trivial errors. The latter limitation, however, remains largely unaddressed.

This paper introduces *Tintin*, an HPC profiling infrastructure with a modular three-component design that addresses both challenges. Tintin introduces mechanisms to mitigate multiplexing errors by characterizing uncertainty at runtime, scheduling events to minimize it, and reporting uncertainty to applications. It also proposes the Event Profiling Context (*ePX*) as a new OS primitive to unify diverse profiling requirements. Tintin is evaluated using benchmarks as well as real-world resource orchestration, performance debugging, and intrusion detection systems, to demonstrate its ability to improve hardware profiling with low runtime overhead.

1 Introduction

Performance profiling involves *measuring* runtime cost metrics and *attributing* these measurements to a portion of one or more programs' execution. Modern processors provide hardware performance counters (HPCs) that can profile microarchitectural events (e.g., cache loads and misses). The hardware events collected from HPCs, referred to as HPC data, are valuable across a wide range of application domains, including debugging [5,23,49,50], workload optimization [8,15,35], power analysis [58,60,76], diagnostics [8], online resource provisioning [25,27,37,54,72], and intrusion detection [19,20]. However, existing profiling infrastructures

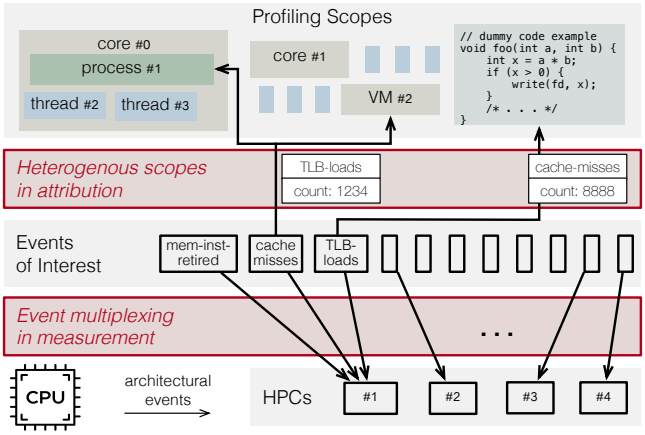

Figure 1: An event profiling infrastructure must accurately measure and attribute microarchitectural events to a heterogeneous set of profiling scopes, while managing a limited number of HPCs.

for hardware events have fundamental limitations in both measurement and attribution.

Problems. When measuring HPC data, each individual HPC can be programmed to record only a single type of event at a time, but the number of events of interest (typically tens to hundreds) often exceeds the available HPCs (usually 2–6), as shown in Figure 1. Therefore, many existing solutions [44,46] adopt *event multiplexing*, scheduling events in a time-shared manner (where each event typically receives an equal portion of time). Observed counts are interpolated to estimate the total; however, this multiplexing inevitably introduces errors, as events may remain unmonitored for extended intervals. Most approaches to avoiding multiplexing involve running the target application multiple times, each time monitoring a different subset of events, and then merging the results into a single trace [31,41,48]. However, these offline techniques are impractical for emerging applications that use HPC data as real-time input for online decision-making [25,35,54,72], such as dynamic resource orchestration.

Furthermore, hardware event attribution remains challeng-

ing. Unlike software events [6] (e.g., memory usage and page faults) that are directly tied to profiled program execution, hardware events are counted independently by standalone HPCs. Attribution requires system support to align these events with program execution. However, there is a fundamental mismatch between the abstractions provided by existing tools [10, 33, 53, 55, 73] and application requirements. Existing tools only allow profiling events for specific tasks (i.e., threads/processes) or cores. For task-level profiling, HPCs start counting when the target task is scheduled in, then stop when it is switched out. While this design is straightforward to implement – in Linux, events are bound to the task_struct and logic is added to the CPU rescheduling routine – it means the profiling scope[1] is bound to schedulable entities (e.g., task/core switches). However, there is a significant need to define more flexible profiling scopes in practice. For example, developers may want to profile events for specific code regions [1, 4, 35, 62, 64] as shown in Figure 1. Current abstractions are insufficient for these heterogeneous profiling requirements, leading to event misattribution. This heterogeneity might also cause conflicts between overlapping scopes that result in some events remaining unmeasured.

Our Solution – Tintin. This paper proposes Tintin, a new hardware event profiling infrastructure that harnesses two key ideas to address the aforementioned challenges. First, Tintin characterizes multiplexing errors as uncertainty at runtime. Leveraging this, Tintin implements an event scheduling algorithm to minimize the overall uncertainty. The algorithm is grounded in real-time scheduling theory and is proven to be optimal. Since uncertainty cannot be fully eliminated, Tintin also reports it to the application via user-space interfaces; to the best of our knowledge, this is the first profiling tool to do so. We present case studies that demonstrate how these reported values may improve application-level decision making. Second, to address the inflexibility of attribution, Tintin proposes to elevate profiling scopes via a first-class object, the Event Profiling Context (*ePX*). Heterogeneous *ePX*s are uniformly managed across the entire system, allowing for flexible scope definition while resolving conflicts between overlapping scopes by jointly scheduling their events.

The system design of Tintin consists of three modular kernel components, each introducing techniques to improve accuracy and reduce overhead in realizing the basic design. *Tintin-Monitor* simultaneously characterizes uncertainty while measuring event counts. As ground truth is not available at runtime, it estimates uncertainty using variance as a proxy. To reduce overhead, it adopts incremental variance updates. *Tintin-Scheduler* represents event multiplexing as an elastic real-time scheduling problem [12, 13] to minimize total expected uncertainty. It presents a novel extension of elastic scheduling to multiple HPCs, assigning shares of HPC time and constructing a schedule in quasilinear time. *Tintin-Manager* serves as another level of indirection to uniformly handle and manage the heterogeneous attribution requirements originating from user space. It extends Linux's familiar perf_event API to specify explicit profiling scopes with flexible granularity and report uncertainty back to user space.

Summary of Results. Tintin is evaluated on three real-world applications: Pond [37] for cloud resource provisioning, DMon [35] for performance debugging, and the Diamorphine rootkit [43] for intrusion detection. In these case studies, we demonstrate that Tintin can be easily integrated into existing applications in place of other profiling tools with minimal adaptation. By tracking, minimizing, and reporting uncertainty, Tintin allows Pond to predict latency sensitivity with 64% greater accuracy, and the AUC for Diamorphine rootkit classification increases by 22.8%. Additionally, Tintin's operability to adjust targeted profiling scope allows DMon to identify performance issues in a push-button fashion. Furthermore, we conduct a comprehensive evaluation to assess accuracy improvements, runtime overhead, and scalability on SPEC 2017 [11] and PARSEC [9] benchmarks. Results indicate that Tintin incurs low overhead (2.4%) while interpolating multiplexed event counts 3.09× more accurately than the state of the art.

Contributions. This paper proposes Tintin, a kernel infrastructure for hardware event profiling. It includes:

- An uncertainty-driven hardware performance measurement mechanism that quantifies, reports, and schedules to minimize estimated errors.
- A new OS primitive, the Event Profiling Context, to enable flexible and accurate attribution while resolving compatibility issues between conflicting profiling scopes.
- The design, implementation, and evaluation of Tintin[2], a kernel hardware event profiling infrastructure with a three-component modular structure.

2 Background

Performance Monitoring Counters. Modern processors make hardware event profiling available to system software via a per-core Performance Monitoring Unit (PMU), which provides a set of programmable HPCs that can be configured individually to measure a specific type of microarchitectural event, e.g., cache or bus accesses, cache writebacks or refills, branch misprediction, etc. When enabled, an HPC increments whenever its programmed event occurs. The number of measurable events is substantial, typically exceeding several

[1] Here, we adopt definitions from Saltzer and Schroeder's subject-object model [56, 57]. Hardware events are the *objects* of profiling, while the corresponding sources of those events are the *subjects*. A "scope" therefore defines a subject to profile. This could be execution on CPU core(s), across a virtual machine, a single thread, or originating from a specific code segment.

[2] Source code is available at: https://github.com/WUSTL-CSPL/tintin-kernel and https://github.com/WUSTL-CSPL/tintin-user.

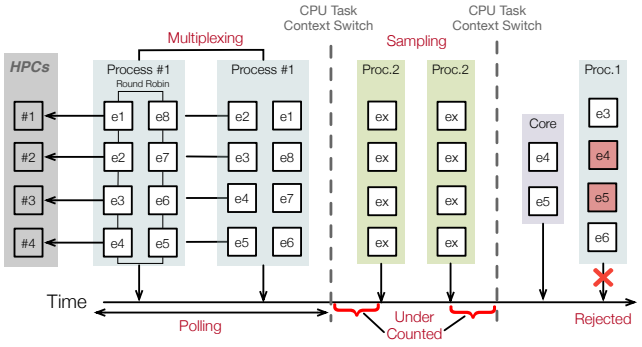

Figure 2: The Linux perf_event subsystem multiplexes events on limited HPCs. It is not aware of scope overlap; joint scheduling and common attribution remain unsupported. If a per-core event is pinned to an HPC, per-task events may be rejected, leading to measurement starvation. perf_event supports both instrumented polling and time- or event-triggered sampling. When sampling, events may be undercounted when the sampling intervals do not align with task context switches.

dozen on ARM processors (e.g., 58 on the Cortex-A53 [38] and 151 on the Cortex-A78 [39]) and over one thousand on Intel processors (e.g., 1,623 on HaswellX [75]).

2.1 Linux perf_event Subsystem

The Linux perf_event subsystem [65] is Linux's kernel-level abstraction layer for interacting with HPCs. It serves as the de facto infrastructure widely utilized by many tools such as PAPI [10], Intel EMON [33], VTune [55], pmu-tools [73], and the Linux Perf utility [70]. It provides access to both hardware-level HPC data and software-level data (e.g., memory footprint and tracepoints). This section discusses its hardware aspects, which are the exclusive focus of Tintin.

Polling vs. Sampling. Events on HPCs can be monitored through either *polling* [44,62] or *sampling* [21,74]. In polling, HPCs are configured and enabled at explicit points during program execution (via instrumented syscalls) and then read at later points. With sampling, HPCs are read periodically, either in time-triggered fashion at periodic intervals (e.g., by explicit timer handlers or in the system timer interrupt routine) or in event-triggered fashion every time a pre-defined threshold is reached (e.g., using Intel's Precise Event-Based Sampling (PEBS) hardware or ARM's PMU interrupt). It is worth noting that sampling does not necessarily incur less overhead than polling. They in fact represent a trade-off between intrusiveness and precision. Polling typically requires instrumentation but offers higher accuracy by placing calipers at the boundaries of profiling scopes. In contrast, sampling does not require instrumentation but suffers from misattribution, as it does not align events precisely with the target scope, such as task context switches as shown in Figure 2.

Event Scheduling. When an HPC is configured to count a particular event, we say that the event is *scheduled* on the counter. If the number of events to be monitored exceeds the number of available HPCs, they must time-share the counters, being multiplexed in a round-robin fashion. Figure 2 presents an illustrative example in which the available HPCs on the CPU are limited to 4, while Process #1 requires monitoring for 8 events. In this scenario, the events {e1, e2, e3, e4} are allocated to the initial time slice, followed by the scheduling of events {e2, e3, e4, e5} in the subsequent time slice.

Profiling Scope. The perf_event subsystem enables specification of hardware event monitoring for either individual tasks (processes/threads) or CPU cores. A key advantage of this design is its simplicity as the kernel only needs to track specified events and their counts within existing data structures for the profiled subject, e.g., the task_struct. It additionally requires minimal additional logic in the task scheduler to switch between the events associated with different tasks or cores.

Upon CPU task scheduling, perf_event first schedules events bound to the current core before adding those associated with the active process. Since events are bound to per-core and per-task data structures, they are managed independently, even if they share common events of interest. The right side of Figure 2 illustrates this scenario: a user assigns two events, {e4, e5}, to the current core; these are placed on HPCs #2 and #3. Consequently, events {e4, e5} monitored for Process #1 are not scheduled, even though they represent the same event types, resulting in unnecessary starvation.

2.2 Sources of Uncertainty in HPC Profiling

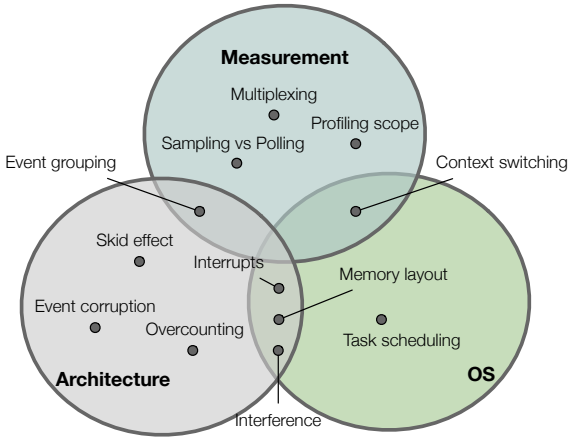

Figure 3: Uncertainty sources.

Sources of HPC measurement uncertainty can originate from a combination of three factors: architectural uncertainty, the operating system, and measurement method limitations, as illustrated in Figure 3.

Architectural Uncertainty. This type of uncertainty is caused by flaws in the microarchitecture. Several known sources of such uncertainty have been studied in prior work.

- Skid effect [28, 74]: To support event-triggered sampling, many PMUs can be configured to deliver an interrupt when an HPC overflows. On some processors, additional instructions execute during the time delay between interrupt initiation and signal delivery to the CPU; associated events may be incorrectly counted or attributed.
- Event corruption [21]: On some Intel processors with Hyper-Threading, certain event counts will be corrupted if monitored by matching counters on the same physical core.
- Overcounting [67, 68]: Certain events will cause an unrelated counter to increment on several older x86 processors from both Intel and AMD.

OS Uncertainty. Profiling might not yield identical results across different runs of the same program, primarily because the runtime environment can vary between measurements. For example, factors such as OS activity, program scheduling in multitasking environments, memory layout and pressure, and multi-processor interactions may differ from run to run.

Measurement Method Uncertainty. Many tools have been developed to facilitate the collection of HPC data through various measurement methods. However, these methods often introduce uncertainty. For example, as discussed in the previous section, the Linux perf_event subsystem provides profiling support through several mechanisms, each contributing to potential measurement error. These include the data collection technique (e.g., polling or sampling), the profiling scope (e.g., thread, process, core, or multiple cores), and the use of multiplexing. As polling and sampling each represent a different trade-off between accuracy and intrusiveness, removing their uncertainty is out of Tintin's scope. In fact, Tintin works seamlessly with either technique.

3 Challenges and Pitfalls

Limited HPCs Compared to Events of Interest. Modern CPUs support dozens to hundreds of types of events that can be monitored. However, the number of available HPCs is very limited; most processors provide only 2–6 HPCs per physical core [70, 75], and this number is effectively halved per logical core when Simultaneous Multithreading (SMT) is enabled. Additionally, Linux reserves one HPC by default for the watchdog timer, further reducing the counters available. This creates a fundamental tension between the number of events of interest and the available HPCs.

Can We Profile Fewer Events? Existing work has sought to select relevant events carefully for a given application. However, the number of events of interest remains large. For example, in [45], the 120 events available on an ARMv7-A CPU were narrowed to just 34 of importance for predictive DVFS. CounterMiner [41], an offline analysis tool for predictive modeling with event counts, achieves the most accurate IPC predictions for HiBench [32] workloads using ~150 events. Furthermore, some applications profile derived metrics, such as

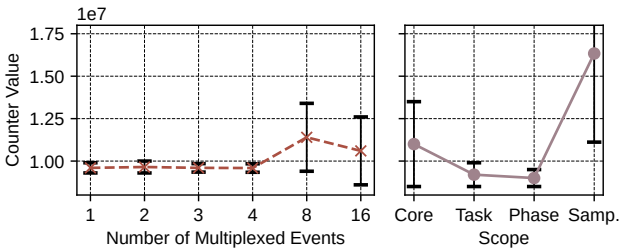

Figure 4: Preliminary examination of multiplexing and scope-based errors. (Left) When the number of events exceeds the number of HPCs, variation in reported event counts increases. (Right) A precise definition of profiling scopes is also essential for accurate results.

Memory_Bound [35]. These combine as many as 16 individual events [18]. Pond [37], which we evaluate as a case study in §8.1.1, provides a memory pooling model for cloud infrastructure. Its model takes 7 derived metrics as inputs, spanning 20 events on Intel Skylake.

Event Multiplexing Introduces Errors. The current approach to managing this limitation is through event *multiplexing*. In the Linux perf_event subsystem, events are scheduled for monitoring in a time-shared fashion on the available HPCs [2, 21, 47, 75]. HPC measurements for each event can then be interpolated to estimate the total count. However, this method unavoidably introduces errors, as the reported values are based on interpolation, and variance in event arrival further contributes to inaccuracies in the results.

Examination of Multiplexing Error. To illustrate this effect, we use the Linux Perf utility to profile the 541.leela_r Go engine in the SPEC CPU®2017 benchmark suite [11] on an Intel Xeon Gold 6130 Skylake CPU. The target PMU has 4 generic counters, so we profiled 1–4 (non-multiplexing), 8, and 16 selected events. The multiplexing frequency in the experiments is set to the default value (4 ms) in Linux perf_event, which aligns with the CPU task scheduling frequency. The mean and standard deviation of reported LLC-load-misses over 10 runs are plotted in Figure 4. Without multiplexing, reported event counts remain stable; they do not vary significantly with the number of events profiled. However, when the number of events exceeds the available counters, the reported metrics vary significantly, as multiplexing fails to capture the true characteristics of the workload [59, 75].

Heterogeneous Profiling Scopes. HPCs are simply counters and are decoupled from the profiling scope. Therefore, profiling infrastructure must align recorded events with program execution on the CPU. Developing such mechanisms is challenging due to the heterogeneity of profiling requirements.

Incomplete Handling of Diverse Scopes. Applications require event attribution to diverse scopes, such as execution instances [25, 37, 54] (e.g., a process, a core, a VM) or code segments [1, 35, 62, 64] (e.g., functions, basic blocks). Existing abstractions only explicitly bind events to per-process or

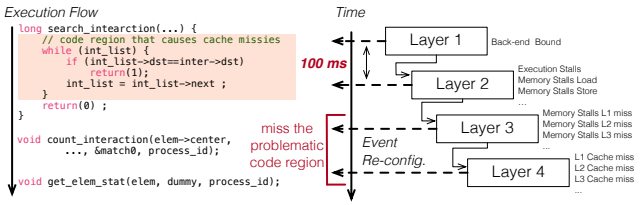

Figure 5: In DMon [35], inflexible profiling scopes cause event misattribution and thus misidentification of data locality issues.

per-core scopes. While the sampling-based method can record program counters (i.e., code addresses) and map events back to source code using debugging tables, this approach cannot filter events for a specific scope and suffers from sampling bias, favoring frequently executed code [16].

Ignorance about Overlapping Scopes. Different scopes may overlap both temporally (e.g., when a process and the core it runs on both have active profiling scopes) and in their profiled event types. If these scopes are unaware of each other, the direct result is that, due to the limited availability of HPCs, events assigned earlier are scheduled, while subsequent assignments are rejected, leading to unfair HPC sharing.

Inflexibility Leads to Misattribution. Without flexible abstractions for defining profiling scopes, users risk mismatches among them; this may lead to misattribution of unrelated event counts. For example, the survey study in [19] examines various applications that aim to characterize program workloads. These often profile the entire task, starting immediately after the process is created, which incidentally captures events from process initialization that are unrelated to the actual profiling scope of interest. To profile events across multiple tasks, dCat [72] pins target tasks to specific cores and then profiles these cores. This approach inevitably includes event counts from context switches on these cores and may also capture events from other tasks running on the same cores.

Misattribution Example. We use Dmon [35] as an illustrative example of the necessity of flexible profiling scopes. DMon [35] is a performance diagnostic tool that detects software data locality issues using memory- and cache-based event profiling. It employs Intel's Top-Down methodology [73] to categorize events into a four-layer hierarchy, monitoring events at subsequent layers based on profiling results from the current layer. As shown in Figure 5, DMon starts by profiling the derived Back-end Bound metric (revealing how often micro-ops are not delivered due to back-end resource shortages) for 100ms. If the program is identified to be back-end bound, DMon then profiles the metrics in the next layer (e.g., execution and memory stall load).

Problematic code segments with data locality issues are often loops that repeatedly perform data operations, e.g., recursive pointer chasing [35]. To identify these operations, DMon must attribute events to the corresponding regions of code. However, DMon modifies events on the fly as it moves through the top-down hierarchy, during which time the target program's execution may move away from the problematic code segments; events from subsequent layers of the hierarchy might therefore be attributed to other segments, with problematic ones remaining undetected. [35] suggests mitigating this by switching to the next layer more swiftly. However, this requires manual tuning of the time window, which varies across different workloads and platforms.

Examination of Mismatched Scope Errors. We extend our preliminary study to quantify the effects of misattribution due to mismatched profiling scopes. We again profile the 541.leela_r benchmark, pinning the workload to a single core and using Linux Perf to count all occurrences of LLC-load-misses in four different profiling scopes: (i) on that core, (ii) by the process, (iii) between explicit polling points instrumented at the beginning and end of program execution, and (iv) using time-triggered sampling. Results are measured across 10 runs and plotted in Figure 4. The instrumented scope produces the most stable results, acting as calipers to filter just those events related to the program.

4 Tintin Design Overview

Tintin is a hardware event monitoring infrastructure that aims to solve these limitations, harnessing the following insights.

4.1 Key Insights

I1. Multiplexing errors can be characterized at runtime and reported to applications.

While multiplexing errors cannot be entirely eliminated, the profiling infrastructure can quantify the expected magnitude of these errors based on observed variance in event rates. These can be reported back to user-space applications alongside the measured counts. These errors serve as indicators of confidence in the measurements and can inform the application's decision-making accordingly.

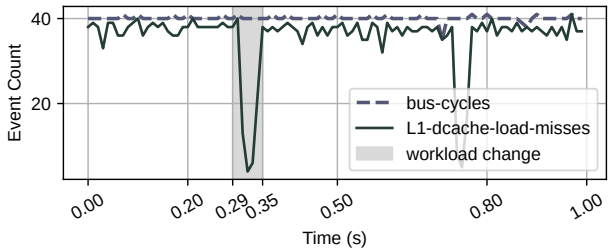

Figure 6: Event count changes over time.

I2. Events exhibit dynamic and distinct errors at runtime, presenting opportunities for scheduling.

By allocating more HPC time to events with larger variance, the overall error can be mitigated. Figure 6 plots counts of the

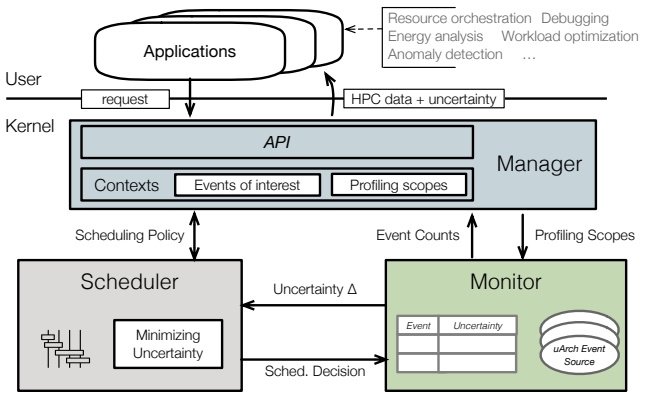

Figure 7: Tintin design overview.

bus-cycles and L1-dcache-load-misses events when profiling the 541.leela_r benchmark for 1 second. This illustrates that variance may depend on the specific execution phase. In this period, L1-dcache-load-misses fluctuates significantly, while bus-cycles remains stable. Allocating more HPC time to the former could reduce measurement errors.

It is worth noting that Tintin does *not* require offline analysis to characterize execution phases of the target workload. Instead, it detects sharp changes online, which is made possible because these typically persist for at least tens of milliseconds [59], as shown by the gray area in Figure 6. Sharp changes at the millisecond level tend to be imperceptible to system performance [25, 45, 54, 72]. Nonetheless, Tintin supports programmable intervals of 1ms or less with negligible overhead, allowing it to capture even these transient effects.

I3. A level of indirection can provide a uniform mechanism to handle the heterogeneity of profiling requirements.

> *"We can solve any problem by introducing an extra level of indirection."* – often attributed to Butler Lampson, who attributes it to David Wheeler.

The two issues related to profiling scope – inflexibility in definition and conflicts due to overlap – both point to the same solution: a new layer to standardize and manage heterogeneous profiling requirements. With such a layer in the kernel, the system can provide a rich programming API to define diverse profiling scopes without adding management complexity. The heterogeneous requirements are translated into a uniform abstraction within the indirection layer. This allows for collaborative management of all profiling requirements across the system, resolving scope conflicts.

4.2 Tintin Structure

Figure 7 depicts the structure of Tintin, which consists of three internal modular components.

Tintin-Monitor (§5) measures HPC data and characterizes errors simultaneously at runtime. It tracks event counts and unmonitored time, and based on this data, employs a lightweight calculation method to estimate errors caused by multiplexing. These error estimates are maintained alongside the HPC data and reported to user-space applications upon request.

Tintin-Scheduler (§6) uses the errors reported by Tintin-Monitor to schedule events on HPCs, assigning each event a unique share of time with the objective of minimizing overall error. This problem is shown to be semantically equivalent to elastic scheduling in real-time scheduling theory [12, 13]. We present a quasilinear algorithm to solve this optimally for events on multiple HPCs, maintaining low overheads.

Tintin-Manager (§7) provides another level of indirection in the kernel. It proposes a new first-class OS abstraction object – the *ePX*– translating heterogeneous profiling requirements from user space into a uniform representation. It then manages these *ePX*s collectively for all applications, avoiding inefficiency caused by conflicting profiling scopes. Additionally, most of Tintin-Manager's APIs have counterparts in existing profiling tools, ensuring minimal effort to migrate existing applications to use Tintin.

5 Tintin-Monitor

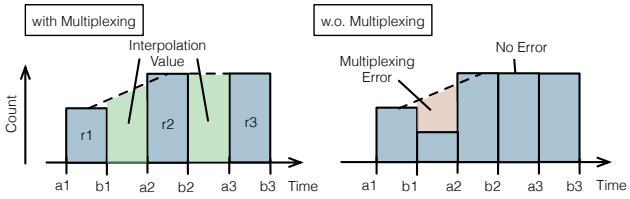

Figure 8: Tintin leverages variance as a proxy to model the uncertainty in the context of multiplexing.

Tintin-Monitor interpolates multiplexed event counts and aims to characterize the resulting estimate errors. These errors are then used for event scheduling and are reported to user space to inform the measurement confidence.

Modeling Runtime Uncertainty. A challenge in calculating runtime errors in estimated event counts is the lack of ground truth measurements during runtime. To address this, Tintin-Monitor leverages measurement variance as a proxy for error. The underlying idea is that existing interpolation mechanisms [47] implicitly assume linear changes in event rates [22] between subsequent counts. Figure 8 shows an example of interpolation, where the rectangles represent the time slices during which events are measured. If the rate of change in interstitial time slices remains strictly linear, there would be no errors in the reported counts. Prior work [22] therefore links interpolation uncertainty to non-linearity in the unmeasured quantities.

Interpolation. Formally, an event $e_i \sim (x_i, \sigma_i)$ has an estimated count x_i and expected uncertainty σ_i due to interpola-

tion over multiplexed observations. As shown in Figure 8, the event e_i is measured with count x_i^j over some continuous time interval $I_i^j = [a_i^j, b_i^j]$ of duration δ_i^j. Then its average rate r_i^j over this interval is x_i^j/δ_i^j. To interpolate over unmonitored intervals, Tintin-Monitor uses a custom implementation of the trapezoid area method (TAM), which was shown to be the most accurate methodology for online interpolation of event counts [47]. Tintin-Monitor assumes a linear rate of change in the event rate, constructing a trapezoid so that its top passes through the midpoint $((b_i^{j+1} + a_i^{j+1})/2, r_i^{j+1})$ of the second measured interval.

Uncertainty. For an event e_i with interpolated count x_i, Tintin-Monitor defines uncertainty as the expected error σ_i in the count. The instantaneous rate of event arrival is a random variable $\mathbf{r}_i$, with a mean rate r_i^j obtained during each measurement interval I_i^j. Since instantaneous rates cannot be measured at every instant, Tintin-Monitor instead characterizes expected variance $V(\mathbf{r}_i)$ by taking the variance of the sample means, weighted by duration. In many stochastic processes, variance scales linearly with time [26]; since we are measuring variance in *rate*, it therefore follows that the expected variance $V(x_i, t)$ in event *count* x_i over the time t that the event is not monitored can be expressed as $V(x_i, t) = V(\mathbf{r}_i) \cdot t^2$. Using variance as a proxy for uncertainty, the expected error σ_i in the estimated event count is $\sqrt{V(x_i, t)}$.

Efficient Incremental Update of Uncertainty. Tintin-Monitor needs to update variance at each monitoring interval. The standard computation of variance requires revisiting all past data points, which is time- and space-consuming. Tintin-Monitor instead implements a weighted version of Welford's method [69] for incremental variance updates. At the end of monitoring intervals I_i^j $(j>1)$, variance is updated as $V_i \leftarrow V_{i-1} \cdot (r_i - \mu_i) \cdot (r - \mu_{i-1})$, where μ is the time-weighted mean over collected counts.

Uncertainty Usage Models. To the best of our knowledge, Tintin is the first hardware event profiling system to report measurement uncertainty to user space. By serving as an indicator of measurement confidence, uncertainty can be explicitly incorporated into application decision-making. While the use case depends on the specific application, our investigation shows that profiling-informed decision making generally follows two broad patterns: rule-based processes [8, 15, 25, 27, 35, 72], which rely on procedural logic derived from human domain expertise; and model-based decision making [20, 37, 54] based on data-driven learning.

For rule-based approaches, conditional logic may be predicated on observed HPC data, e.g., an event count must exceed a certain threshold for an action to be taken. In this context, uncertainty can be incorporated to ensure actions are taken only when the observed data reflect with sufficient confidence that the target condition has been met (i.e., uncertainty is sufficiently low), thereby increasing the reliability of the decision. For example, Caladan [25], a global task scheduler for multicore and multiprocessor systems, attributes memory bandwidth usage to scheduled tasks based on LLC misses and revokes a core from the task with the highest count. However, uncertainty in the profiling data can lead to false identification of high bandwidth usage. By incorporating an uncertainty threshold as an additional condition, the system can avoid mistakenly penalizing tasks.

Model-based approaches can incorporate reported uncertainty values directly into the model as additional input dimensions, allowing the system to account for the confidence of each measurement during prediction. For instance, in our case studies (§8.1), we included error estimates as input features to the predictive models used by Pond to improve the accuracy and robustness of resource orchestration.

Implementation. Tintin-Monitor is activated using the Linux kernel's hrtimer. It leverages the existing hardware interfaces in perf_event for reading and configuring PMUs across architectures, intercepting functions to read raw HPC data to perform TAM-based interpolation and incorporate uncertainty characterization. Variance is initialized by a warm-up period where events are scheduled in a round robin fashion, then updated with each HPC read using Welford's method. To avoid involving floating-point operations in the involved division steps, we apply a scaling factor, where necessary, to the numerator then perform integer division to achieve a fixed-precision result. To prevent overflow, we use 64-bit integers and hand-tune the order of operations to avoid large values.

6 Tintin-Scheduler

Tintin-Scheduler draws from a branch of real-time systems theory that addresses scheduling tasks on limited resources. More specifically, elastic scheduling theory [12, 13] adapts the allocation of processor resources to tasks on overloaded systems to optimize some objective (e.g., result quality). Tintin-Scheduler's goal is similar: it aims to adjust allocations of time for events on limited monitoring resources (HPCs) to minimize overall uncertainty. In this section, we formulate the event scheduling problem and translate it into a form that is semantically equivalent to elastic scheduling.

Scheduling Model. Formally, for a profiling scope, we define $\mathbf{E} = \{e_i\}$, the set of events to be monitored, where $|\mathbf{E}| = n$. Similarly, $\mathbf{C} = \{c_j\}$ denotes the set of HPCs available to monitor them, where $|\mathbf{C}| = m$. The problem is to determine a schedule $\mathcal{S}(t) : \mathbf{C} \rightarrow \{\mathbf{E}, \phi\}$ that defines, at each time t, the event assigned to each counter. We define an event's *utilization* U_i as the fraction of time it occupies a counter. A function $\mathcal{L}_i(U_i)$ characterizes the loss associated with multiplexing event e_i. $\mathcal{L}_i(1)$ is assumed to be 0 (if the event is always counted, there is no multiplexing error), and the function is assumed to be monotonically non-increasing.

Scheduling Policy. From §5, the expected error σ_i in the

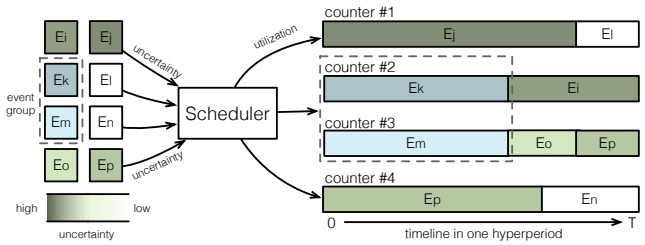

Figure 9: Tintin-Scheduler workflow.

estimated count of event e_i is $\sqrt{V(\mathbf{r}_i)} \cdot t$, where t is the amount of unmonitored time. Future unmonitored time for event e_i is thus proportional to $1 - U_i$, where U_i is its utilization; thus, we express the expected error, normalized to the count, as $\sigma_i = \left(\sqrt{V(\mathbf{r}_k)}/x\right) \cdot (1 - U_i)$. To minimize the sum of squared errors, the loss function $\mathcal{L}_i(U_i)$ is formulated as $\sigma_i^2 = \left(V(\mathbf{r}_i)/x_i^2\right) \cdot (1 - U_i)^2$. The scheduling problem is therefore stated as the following constrained optimization problem:

$$\min_{U_i} \quad \sum_{i=1}^{n} \frac{w_i V(\mathbf{r}_i)}{x_i^2} \cdot (1 - U_i)^2 \tag{1a}$$

$$\text{s.t.} \quad \sum_{i=1}^{n} U_i \le m \quad \text{and} \quad \forall_i, \; U^{\min} \le U_i \le 1 \tag{1b}$$

where w_i is a weight assigned to event e_i, denoting its relative importance. By default, w_i is set to 1, but users can adjust it manually to specify the importance of events.

Online Solver. The above optimization problem is the same quadratic program as that presented in [14] to represent real-time elastic scheduling [12, 13]. The existing solver is tailored for single-core scenarios, whereas the problem under consideration involves multiple HPCs, which is conceptually equivalent to a multi-core scenario. Tintin-Scheduler adapts the solver by concatenating multiple HPC resources into a single virtual resource and scheduling events sequentially. This prevents any event from being scheduled concurrently on multiple counters, which would yield identical counts and not reflect the effective utilization assignment.

Formally, the "hyperperiod" of the schedule, denoted as H, represents the time after which the schedule repeats. For simplicity, it is normalized to $H = 1$. Events and counters are considered in order: event e_1 is assigned the interval $[0, U_1]$ on counter c_1. Events are placed sequentially on a counter until the total utilization on that counter would exceed 1, whereupon a portion of the event's utilization is assigned to the end of the hyperperiod interval on the current counter, and the remaining utilization is placed at the beginning of the interval on the next open counter. Since $U_i \le 1$, these intervals do not overlap in time. The schedule construction is illustrated in Figure 9, with the detailed procedure and an optimality sketch provided in Appendix A.

Event Groups. The Linux perf_event subsystem supports user-specified event groups, ensuring that even as events are multiplexed, those in the same group are always scheduled simultaneously. This is useful for identifying correlations among related events. Tintin-Scheduler extends this functionality, treating the group as a single schedulable entity. The total time allocated among all events in a group by the elastic scheduling policy is split evenly between them so all events are allocated to the same time slices across different counters.

Efficiency and Robustness Optimization. The solver retains the same runtime complexity as the original in [12], which is quadratic – $O(n^2)$ – in the number of events n. This is not negligible given the high scheduling frequency. Briefly, the solver iterates through all events to calculate their utilization. If any event produces a negative utilization, it must be set to zero, indicating that the event will not be scheduled. This requires backtracking and re-iterating through all the events. Consequently, the worst-case complexity is $O(n \times (n-1))$. With the insight that only low-uncertainty events produce negative utilization, the solver can prioritize high-uncertainty events, avoiding re-iterations. Leveraging this invariant, the solver first sorts all events by their uncertainty and then calculates utilization in a single pass. The overall complexity is quasilinear, only dominated by the sorting step, $O(n \log n) + O(n) = O(n \log n)$.

Furthermore, the calculated utilization could be extremely low in some cases. Besides the performance impact caused by closely triggered timer interrupts, such low utilization results in unstable estimations, as measured errors may be amplified when scaled to the full range. As such, Tintin-Scheduler imposes a lower bound $U^{\min}$ on the scheduling quantum (minimum schedulable utilization time slice), which is set to one-tenth of the hyperperiod in our implementation.

Event Starvation. A potential issue is that events with low uncertainty might not be scheduled, resulting in a persistently low uncertainty value. However, the uncertainty metric addresses this by increasing an event's uncertainty as the interval since its last scheduling grows, thereby ensuring that all events are eventually allocated on the HPC.

Implementation. Tintin-Scheduler is activated when Tintin-Monitor detects the end of a hyperperiod H, which is set by default to the CPU task scheduling interval. In addition to elastic scheduling, Tintin-Scheduler can be configured for simple round-robin multiplexing. A simpler priority-driven scheduling policy, *Uncertainty-First*, does not compute utilization, but instead prioritizes the events with the highest uncertainty at each hyperperiod. We note that support for PMU architectures that restrict some events from being assigned to certain HPCs is still limited, as existing algorithms to solve the restricted assignment problem with elastic scheduling are too complex for an efficient in-kernel implementation.

7 Tintin-Manager

Internally, Tintin-Manager is composed of two parts: a component for managing profiling scopes and HPC data, and an interface for handling user requests.

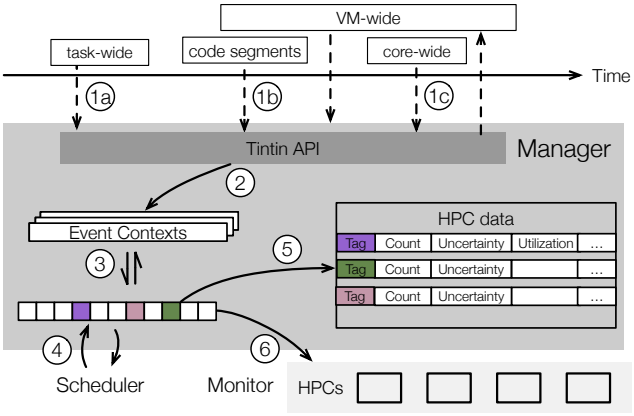

Figure 10: Tintin-Manager workflow. (1a) An *ePX* is created for a task, (1b) associated to code segments, or bound to a broader scope such as (1c) core-wide or VM-wide profiling. (2) Upon switching *ePX*s, Tintin-Manager updates outgoing event statistics and (3) fetches events for any incoming *ePX*s. It then (4) invokes Tintin-Scheduler to assign event priorities and time shares. It also (5) updates the HPC data if any events need to be scheduled out. Finally, (6) it places new events on the HPCs.

Event Profiling Context. To abstract heterogeneous profiling requirements, Tintin elevates profiling scope via a new first-class kernel object, the Event Profiling Context (*ePX*) abstraction. The *ePX* encapsulates the monitoring of all events associated with a given profiling scope, $ePX \sim \{e_i,..,e_j\}$. An *ePX* can be defined from the perspective of execution instances (e.g., a thread, a process, or all threads on a single core) and from the perspective of code segments (e.g., a function). Multiple contexts, ePX_m and ePX_n, may share common events e_k, but the HPC data (including counts and uncertainty) are maintained separately, with $e_k^m \rightarrow ePX_m$ and $e_k^n \rightarrow ePX_n$.

Contexts have been successfully used as first-class objects in prior work [40, 42, 51, 61], primarily for flexible privilege separation [17, 40, 51, 61] and time management [42]. Here, the *ePX* concept enriches hardware event profiling as follows.

Unified Management of *ePX*s. Figure 10 depicts the workflow and unified management approach of Tintin-Manager.

Flexible Definition of Profiling Scopes. Tintin-Manager translates the heterogeneous profiling requests from program segments and execution instances into a unified *ePX* format. Additionally, it supports *ePX* binding, enabling explicit scoping to arbitrary profiling scopes, such as multiple code segments or threads. The bound *ePX*s form a new *ePX*. This allows *ePX*s to be managed uniformly and collectively.

Correct Attribution of Event Counts. Tintin-Manager places calipers at an *ePX*'s entry and exit points to filter unrelated event counts, activating counting upon entry and deactivating it upon exit. To remain aware of *ePX* switches, Tintin-Manager listens for two types of signals. For *ePX*s associated with code regions, it utilizes instrumentation to insert specific syscalls at relevant code locations, triggering *ePX* switches.[3] For *ePX*s associated with execution instances, Tintin-Manager listens for CPU scheduling events to detect *ePX* switches.

Scope Conflict Resolution. To support overlapping profiling scopes, Tintin-Manager supports the simultaneous activation of multiple *ePX*s. Specifically, when more than one *ePX* is active, it groups all events and schedules them collectively, avoiding contention from overlapping events. An *ePX* may be assigned a weight, e.g., to avoid unfairness in resource allocation when it profiles numerous types of events. Tintin-Scheduler applies these weights as multipliers to the individual event weights within the *ePX*. Counts, variance, and uncertainty for each event are still maintained separately within each individual *ePX*. When an HPC is read, Tintin-Monitor attributes the count to all active *ePX*s monitoring that event, but their interpolated counts and uncertainty are updated individually. Upon *ePX* exit, Tintin-Manager removes the relevant events and reschedules.

On-the-fly Event Reconfiguration. Since *ePX*s are elevated to first-class objects, they can be shared and used by other components to reconfigure the events of interest dynamically within a profiling scope. This capability is crucial for applications that require adaptive profiling [35].

Programming API and Generality. In general, existing applications using perf_events may use Tintin instead without modification.

The perf_event Usage Model. Section §2.1 describes the Linux perf_event subsystem. In general, applications use it either via explicit instrumentation of syscalls, or by launching processes with the Perf command-line utility. In keeping with the Linux philosophy that "everything is a file," the driving syscall is *perf_event_open*, which takes several arguments indicating the profiling settings, and returns a file descriptor from which, among other data, HPC counts can be read.

Using Tintin Instead. A Linux kernel patched with Tintin switches between Tintin and the classical perf_event via an interface in procfs. When Tintin is selected, Tintin-Monitor and Tintin-Scheduler become active, but both the syscall API and Perf remain the same, allowing compatibility with existing applications. To access extended functionality, e.g., *ePX* creation and reported uncertainty values, Tintin-Manager provides the extended API outlined in Table 1. An *ePX* can be created for a given scope with a call to *tintin_create_context*. The API allows any *ePX* to be disabled on demand using *tintin_disable_context* and allows on-the-fly event modifica-

[3] A less intrusive alternative [62] is to leverage CPU debugging registers to insert interrupts at specific binary addresses without modifying the target executable; extending this functionality is left for future work.

tion with *tintin_add/remove_event*. Since an *ePX* identifier can be referenced globally, it can also be used to associate different *ePX*s using *tintin_associate_contexts* across different threads or processes, merging their events.

Table 1: Tintin-Manager API Functions

System calls	Descriptions
tintin_create_context(s)	Create an *ePX* at the specified scope *s*
tintin_enable_context(c)	Begin monitoring of the given *ePX c*
tintin_disable_context(c)	End monitoring of the given *ePX c*
tintin_add_event(e, c)	Begin monitoring event *e* in given *ePX c*
tintin_remove_event(e, c)	Stop monitoring event *e* in given *ePX c*
tintin_set_event_weight(e, w)	Set or modify event *e* scheduling weight *w*
tintin_associate_contexts(c_1, c_2)	Aggregate the counts of two *ePX*s
tintin_read_with_uncertainty(e)	Read both event count and uncertainty

Implementation. All APIs are implemented as system calls, wrapped in C. To reduce the effort required for instrumentation, we implemented a set of LLVM [36] compiler passes that automatically instrument the system calls during compilation. By utilizing different levels of passes (e.g., function-level, basic block-level), users can achieve various levels of granularity by adding a compilation flag. The current Tintin implementation defines profiling scopes in source code, but binary instrumentation [62] could extend this to binaries.

8 Evaluation

This section seeks to answer the following questions:

- How can Tintin be used in real-world applications? (§8.1)
- How effective is Tintin in improving event measurement accuracy? (§8.2)
- What is Tintin's overhead? (§8.3)
- How scalable is Tintin? (§8.4)

Experimental Setup. All experiments were conducted on a server with two Intel Xeon Gold 6130 (Skylake) CPUs and 32GB of RAM. Each CPU has 16 physical cores running at 2.10GHz with Hyper-Threading disabled. By default, the hyperperiod (scheduling cycle) in Tintin-Scheduler is set to 4 ms (250 Hz), aligning with the default scheduling interval of the Linux perf_event subsystem [65] on the tested machine. The scheduling quantum is set to $^1/_{10}$ the hyperperiod (0.4 ms). As part of our scalability analysis in §8.4, we explore the effects of these parameters with different values.

Ground Truth. Due to the non-determinism of modern CPUs, obtaining ground truth data outside of simulation is nearly impossible. Similarly to CounterMiner [41] and BayesPerf [2], we measure ground truth by pinning an event to an HPC, then reading its value on completion of a benchmark.

8.1 Case Studies

We use three case studies to demonstrate the effectiveness and usability of Tintin.

8.1.1 Dynamic Resource Provisioning with Pond

Target Application. Pond [37] is a resource orchestration subsystem developed by the Microsoft Azure team. In cloud environments, memory pooling may improve DRAM utilization and reduce cost, but using pooled instead of local memory might substantially increase the latency of some virtual machine workloads. To allocate the limited local memory appropriately, Pond predicts whether a VM workload's latency will be sensitive to the use of pooled memory.

Evaluation Methodology. Pond is a proprietary, closed-source system, so its authors do not provide the data or models used in [37]. Instead, we use Pond's open-source emulation layer [66] to reproduce its latency insensitive model [37, Figure 12] according to the paper's description. The predictive model is a random forest regressor implemented using Scikit-learn [52]. The model's inputs consist of 20 hardware events, sampled at 100 ms intervals via Intel's EMON tool [33]. To generate the training data, Pond runs the workload entirely on a local NUMA node, then again with memory from a remote node, reporting the execution time increase. We follow the experimental setup in [37], generating data using 12 workloads from SPEC CPU®2017 [11] and 30 from the GAP Benchmark Suite [3]. We randomly select 30 workloads for training and 12 for testing.

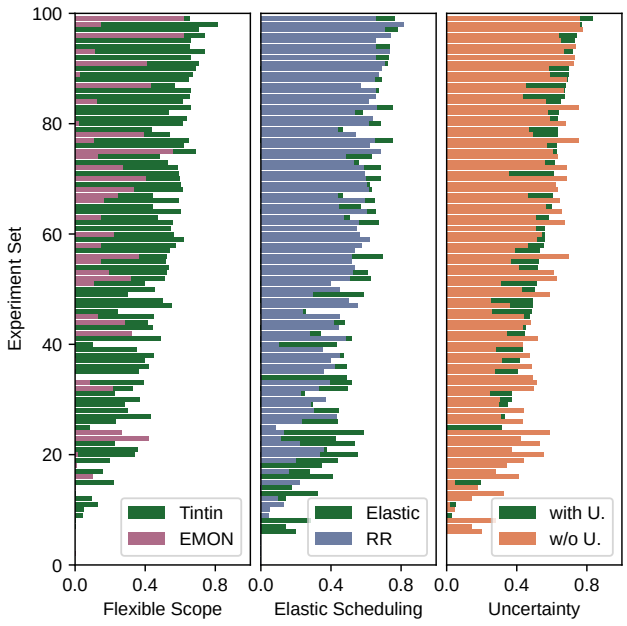

Figure 11: Results on Pond [37]. Each bar represents the score of the latency sensitivity prediction.

Results. A comparison of model prediction accuracy is shown in Figure 11; values closer to 1 indicate better performance.

Profiling Scopes. As Intel EMON only supports CPU-level event profiling, Pond's emulation layer pins VM threads to specified cores, then attributes all event counts from those cores to the VM. We modify Pond to instead use Tintin to associate an *ePX* with all VM threads. In the plot on the left, Tintin outperforms the baseline, measured by EMON [33], in 95 out of 100 experiments. On average, Pond's accuracy with Tintin is 0.51 higher than the baseline. This improvement is primarily due to Tintin's ability to attribute events directly via correctly defined profiling scopes.

Elastic Scheduling. To demonstrate the advantages of Tintin-Scheduler's elastic scheduling approach in reducing total uncertainty, we compare it to a round-robin scheduling strategy across another 100 experiment sets. The results are shown in the middle plot of Figure 11. Elastic scheduling outperformed the round-robin strategy in 64 out of 100 experiments, improving model prediction scores by an average of 0.15.

With Uncertainty. To demonstrate how user-space applications might use the uncertainty reported by Tintin, we modify our implementation of Pond's latency prediction model to include the uncertainty values reported by Tintin-Monitor as inputs. Results are illustrated in the right plot in Figure 11. With this additional information, scores are higher in 55 out of 100 cases compared to the model without uncertainty, and the average score increases by more than 0.02. The minor improvement is attributed to the fact that, in these tests, Tintin's targeted scope and scheduling policy succeed in minimizing uncertainty, so the small error values given to the model provide only incremental improvements.

Resolving Scope Conflicts. To evaluate Tintin's ability to resolve profiling scope conflicts, we modify the workloads managed by Pond to also require their own event monitoring, leading to potential conflicts with Pond's profiling scope. We instrument each workload to profile 16 events and then measure both the counting accuracy of the target workload and the prediction accuracy of Pond's latency model. The counting accuracy is measured by pinning a specific event (e.g., cache misses) to a dedicated hardware counter, which serves as the ground truth for comparison.

By default, Pond profiles events at the CPU core scope, and the Linux perf_event subsystem prioritizes these events over any other event bound to tasks. As a result, if other workloads attempt to profile events on the same core, their events may never be scheduled, leading to starvation. Tintin avoids this issue by collectively scheduling all events. Under this collective scheduling approach, measurement accuracy does not degrade significantly compared to separate runs that just profile each scope in isolation. From the workloads' perspective, the counting error increases slightly from 3.11% to 3.56%. From Pond's perspective, the prediction accuracy remains comparable, with an average score decrease of only 0.01 across 100 test cases. Moreover, the overhead of Tintin remains below 2.4% in both conflicting and non-conflicting scenarios, demonstrating that resolving conflicting scopes does not introduce significant overhead.

Cores	Metrics		% Slots

Figure 12: Results on DMon.

8.1.2 Data Locality Problem Detection with DMon

A description of the target application, DMon [35], and its limitations has already been introduced in §3.

Evaluation Methodology. We use DMon's artifact [24] as a baseline for comparison and target the workload from its repository, which contains one data locality issue. Rather than using DMon's built-in time window, Tintin binds *ePX*s at the individual loop level via syscalls automatically instrumented at the beginning and end of each function in a compiler pass. This enables profiling different layers in Intel's Top-Down event hierarchy [73] every time a function is entered, eliminating the need to switch layers during function or loop execution. Since some functions may be invoked only once in a given run, a user may execute the target workload multiple times to ensure each layer is adequately profiled. By providing more targeted profiling scopes via its *ePX*s, Tintin ensures that events are correctly filtered for each function so as to correctly attribute the locality issue. In our case study, results are evaluated based on the accuracy with which they identify the code region experiencing Back-end Bound behavior.

Results. Visualization of DMon's output is shown in Figure 12. Among 10 experiment runs, DMon often results in an ambiguous mixture of Front-end and Back-end Bound instances, failing to identify data locality issues when using Linux perf_event. In Figure 12(a), the results indicate that most of the time is spent on the frontend. However, the program is actually Back-end Bound. Since DMon aggregates the counts over the program's execution, the events originating from Back-end Bound code segments are overshadowed by other normal code. In contrast, Tintin offers more precise profiling via loop-level scope. Notably, in Figure 12(b), the target function is identified as spending 96.8% of its time on the backend, directly indicating a data locality issue. Among

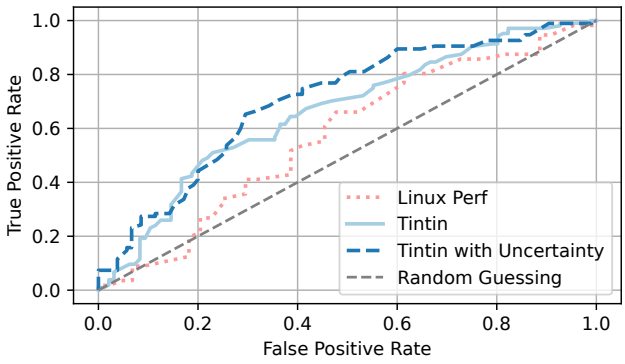

Figure 13: Accuracy of the random forest classifier in detecting the Linux rootkit.

10 repeated experiment runs, DMon failed in 9 out of 10 runs with perf_event. However, with Tintin, DMon reliably detects Back-end Bound issues; the reported backend time for the target consistently exceeds 91.1%.

8.1.3 Intrusion Detection System

HPC data has also been used for security purposes in the last two decades. Previous works [20, 34] leverage the measured HPC values to classify an unknown program as either benign or malicious. This case study investigates whether Tintin enhances the efficacy of intrusion detection.

Evaluation Methodology. We adopt the experimental setup from the seminal work of Demme et al. on detecting Linux rootkits with hardware event data [20]. As our malware, we use the open-source Linux rootkit Diamorphine [43], which is implemented as a loadable kernel module. To activate the rootkit's functionality, we execute common Linux commands, including ps, ls, whoami, printenv, and pwd, while monitoring their behavior. The rootkit is configured to hide processes, escalate user privileges to root, and conceal files. Since Demme et al. do not specify the hardware events used in their experiments, we select the 10 commonly used events predefined under PERF_TYPE_HARDWARE as described in [44].

We conducted three sets of experiments. The first set evaluates perf_event at the granularity of the target victim tasks. The second set evaluates Tintin's elastic scheduling. In this setup, we replaced the event scheduling logic with Tintin's scheduler but kept the rest unchanged. The third set extends the previous configuration by collecting uncertainty information at each measurement point. For each set, we collect 800 samples for training and 200 samples for testing; these are evenly split between execution scenarios with and without the rootkit. For the detection model, we adopt a random forest classifier, which is also used in [20, 77].

Results. We observed that using HPC data to detect malware within a single, fixed target task (e.g., ls) yields excellent classification results. However, this approach requires constructing a separate HPC-based malware signature for each individual task, which is impractical and limits generalizability. In our more realistic experimental setting, where the five target tasks vary, the detection performance is less compelling. Figure 13 presents the ROC curves for Linux perf_event, Tintin without uncertainty information, and Tintin with uncertainty information. The AUC (Area Under the Curve) for perf_event is 0.57. Tintin improves the AUC to 0.66 through its event multiplexing-aware scheduling. When uncertainty information is incorporated, the AUC further increases slightly to 0.70. Although the improvement is modest, these results indicate that Tintin provides benefits in this scenario.

Further Discussion. There are inherent limitations of relying solely on HPC data for intrusion detection because malicious software behavior may not always manifest in the specific microarchitectural events captured by HPCs [77]. Although our experiments showcase that Tintin raises the bar for attackers, sophisticated attacks can still evade detection.

8.2 Effectiveness of Tintin

For a more comprehensive evaluation, we use the SPEC CPU®2017 [11] and PARSEC 3.0 [9] benchmark suites to assess the accuracy of the event counts collected online by Tintin, comparing it to Linux perf_event and CounterMiner [41]. While CounterMiner is primarily intended for offline predictive modeling and analysis of events, it does attempt to reduce event count errors by smoothing outliers. For a reasonable runtime comparison, we implement its data cleaning phase in Linux perf_event. Another related infrastructure, BayesPerf, is not included in the comparison because it requires algebraic relations between events, which are absent from most event primitives in practice.

To evaluate the effectiveness of elastic scheduling, we compare it to Tintin-Scheduler's "Uncertainty-First" policy. In this configuration, events with higher uncertainties are prioritized, and the scheduled event occupies the HPC until the next hyperperiod. We select the 24 default predefined events in Linux perf_event to profile simultaneously [44]. To obtain ground truth, we pin one event to an HPC in each run. We repeat the experiments for the first 5 pre-defined events in PERF_TYPE_HARDWARE in [44]. The average errors are reported in Figure 14.

Event counts obtained with Linux perf_event were, on average, 9.01% off from the ground truth, with a maximum error of 53.27%. CounterMiner performed similarly with an average error of 8.80% and a maximum of 56.21%. In comparison, Tintin's errors remained well under 5% in most cases. Furthermore, while "Uncertainty-First" also reduces errors, it does not perform as well as elastic scheduling, achieving an average error of 6.51%, compared to 2.91%. This is due to two factors: first, its scheduling is heuristic rather than optimal; second, it cannot allocate finer-grained timeslices for

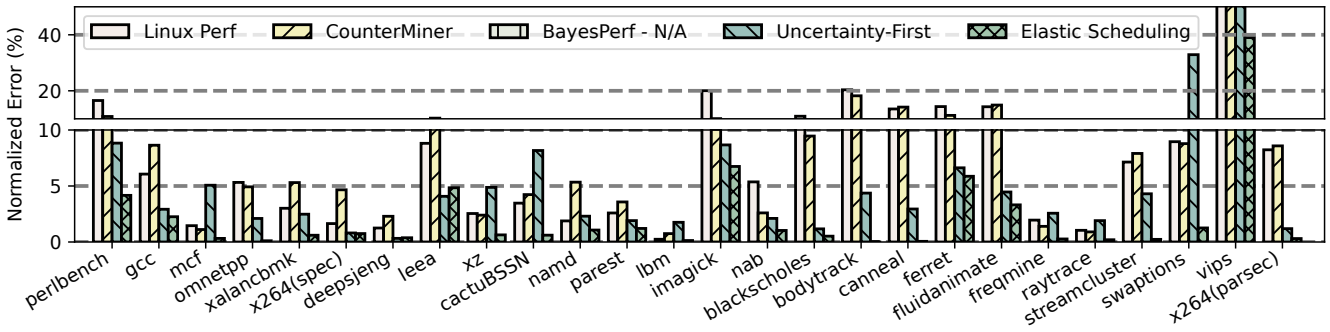

Figure 14: Measurement errors.

events, causing each event to occupy the HPC for an entire hyperperiod, which may lead to event starvation.

8.3 Runtime Overhead of Tintin

We also evaluate the runtime overhead of Tintin in comparison to Linux perf_event and BayesPerf [2]. We exclude CounterMiner [41] from these experiments, as it is a purely offline analysis tool. We instrument a CPU implementation of BayesPerf by modifying the Linux perf_event timer callback to run BayesPerf's Expectation Propagation algorithm [2, Alg. 1]. Figure 15 presents execution time means and standard deviations across 10 runs of each considered benchmark (normalized to the execution time without profiling). Without the dedicated hardware accelerator in [2], BayesPerf incurs excessive overhead, with up to 31.3% slowdown in the profiled benchmarks. This limits portability, as it cannot achieve acceptable runtime performance on standard hardware.

On the other hand, Tintin exhibits an average overhead of only 2.4%, only slightly higher than perf_event's 1.9%. This difference was found to be statistically insignificant. In the worst-case scenarios, we observed Tintin's overhead to reach up to 7.6% while perf_event's could be up to 12.7%. In some scenarios, Tintin achieves even better execution time performance than Linux perf_event due to its elastic scheduling method, which can trigger fewer interrupts.

8.4 Scalability Analysis

There are three factors impacting the accuracy and overhead of Tintin: scheduling hyperperiod, scheduling quantum, and number of monitored events. In this section, we examine how Tintin's performance scales with these factors. While the number of scopes might also impact scalability, these effects are reflected by the number of events.

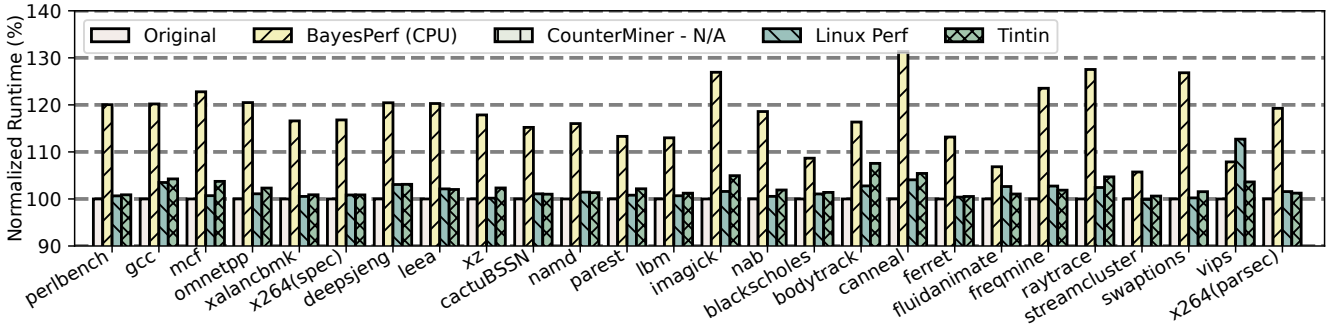
Hyperperiod. We target the 505.mcf workload from the SPEC 2017 benchmark, varying the hyperperiod from 15 ms to 1 ms. The resulting changes in accuracy and overhead are recorded in Figure 16. We observe in Figure 16(a) that the accuracy improves with finer-grained hyperperiods, achieving an error rate of only 0.2% at 1 ms. In contrast, the error rate increases to 1.01% at a 15 ms hyperperiod. Meanwhile, perf_event exhibits significantly higher error rates across all hyperperiod settings, reaching up to 7.8% at 15 ms. Nonetheless, Figure 16(b) shows that while overhead increases with smaller intervals, it remains below 5%.

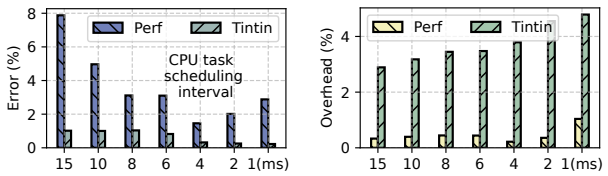
Scheduling Quantum. Since Linux perf_event schedules events at the hyperperiod, it does not support tuning the scheduling quantum. Consequently, we exclude experiments involving it. The accuracy and overhead results are presented in Figure 17(a). Accuracy stabilizes at 0.5 ms, with an error rate of 0.6%. Reducing the scheduling quantum further does not significantly enhance accuracy but noticeably increases overhead. For instance, at a quantum of 0.05 ms, the overhead surpasses 7.5%.

Number of Events. We evaluate the scalability of elastic scheduling in handling varying numbers of events, as shown in Figure 17(b). The error remains below 5.4% with 512 event types, but when the number reaches 1024, Tintin can render the kernel unresponsive. This issue occurs when TintinScheduler is triggered during a CPU context switch. To generate a new schedule, it sorts all events by uncertainty, which takes too long with 1024 events. As a result, it may not finish before the next jiffy, causing the CPU scheduler to miss the deadline and be deemed unresponsive. In practice, the number of profiled events is usually less than 256, so Tintin remains usable. In contrast, the errors in perf_event increase more significantly with the number of events, exceeding 20% when monitoring 256 events.

9 Related Work

Measurement Error. Most existing work that avoids multiplexing does so by running a target application multiple times, each time monitoring a different subset of events. Results are aligned into a single trace [31, 41, 48] using techniques such as dynamic time warping [7] or uniform scaling [47]. However, these offline techniques are unsuitable for online monitoring, which is required in many applications such as resource orchestration [37, 54] and performance interference





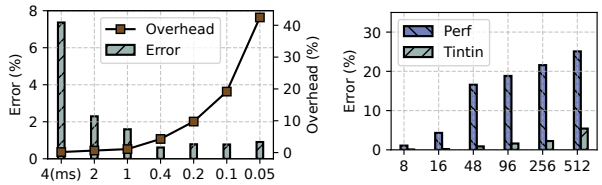


Figure 15: Runtime overhead.

mitigation [25, 54, 72]. Additionally, merging runs may fail to identify some performance anomalies, as performance can vary widely across runs, with anomalies only appearing in some.

BayesPerf [2] schedules events online, constructing event groups to guarantee statistical dependencies between events in adjacent groups, thus inferring the counts of unscheduled events. However, it has three main drawbacks. First, it depends on algebraic relationships among events, which are unavailable for most event primitives on platforms like Intel [18], IBM [30], and ARM. Second, it incurs prohibitive overhead, necessitating customized hardware for acceleration. Third, its scheduling algorithm is designed offline, preventing adaptation for dynamic workloads. With elastic scheduling, Tintin overcomes these limitations and achieves accuracy improvements comparable to those reported in prior work [2].

Attribution Error. Existing work on attribution falls into two main categories. The first focuses on precise event filtering for target profiling scopes, achieved either through efficient instrumentation during compilation [1, 62] or by using techniques for post-mortem analysis [64]. The second addresses conflicts within overlapping profiling scopes. For example, Metis [71] virtualizes HPCs using time division, allowing multiple users in different virtual machines to monitor various CPU events simultaneously. Tintin unifies these functionalities across various use cases through the *ePX* and system support.

Another line of research focuses on architectural misattribution caused by skid effects, which is discussed in §2.2. Addressing this issue often requires hardware redesign [28, 29]. Software-based methods, such as padding with dummy instructions, are also an alternative [74] but incur significant overhead. These are out of scope for this paper.

10 Conclusion

This paper introduces Tintin, a hardware event profiling infrastructure designed to address event multiplexing errors and the inflexibility of profiling scope definitions. Designed with a three-component structure, each component of Tintin individually mitigates these tensions to some degree, while also collaboratively working together for enhanced overall performance. The evaluation results showcase that Tintin provides flexibility in profiling and improves profiling accuracy with minimal overhead.

Acknowledgment

We thank our shepherd, Pedro Fonseca, and the anonymous reviewers for their valuable feedback. We also thank Tobias Pristupin and Lien Zhu for their contributions to the implementation. Algorithm 1: Elastic_Scheduling

Input: Lists $\{U_i^{\min}\}, \{U_i^{\max}\}, \{E_i\}$ sorted in non-decreasing order of $\frac{U_i^{\max}-U_i^{\min}}{E_i}$ and a desired utilization U_D

Output: The list of assigned U_i values

$U_{\text{SUM}} \leftarrow 0$; $E_{\text{SUM}} \leftarrow 0$; $\Delta \leftarrow 0$
forall $\tau_i \in \Gamma$ **do**
  $U_{\text{SUM}} = U_{\text{SUM}} + U_i^{\max}$
  $E_{\text{SUM}} = E_{\text{SUM}} + E_i$
end
forall $\tau_i \in \Gamma$ **do**
  if $\left(U_i^{\max} - \frac{U_{\text{SUM}}-(U_D-\Delta)}{E_{\text{SUM}}} \times E_i \le U_i^{\min}\right)$ **then**
    $U_i \leftarrow U_i^{\min}$
    $\Delta \leftarrow \Delta + U_i^{\min}$
    if $(\Delta > U_D)$ **then return** INFEASIBLE
    $U_{\text{SUM}} \leftarrow U_{\text{SUM}} - U_i^{\max}$
    $E_{\text{SUM}} = E_{\text{SUM}} - E_i$
  else
    $U_i \leftarrow U_i^{\max} - \frac{U_{\text{SUM}}-(U_D-\Delta)}{E_{\text{SUM}}} \times E_i$
  end
end
return FEASIBLE

A Solving the Scheduling Problem

The scheduling problem in Section 6 assigns a utilization to each event of interest to minimize total expected normalized error, with additional weights assignable by the user. This is expressed as the following constrained optimization problem:

$$\min_{U_i} \quad \sum_{i=1}^{n} \frac{w_i V(\mathbf{r}_i)}{x_i^2} \cdot (1-U_i)^2 \tag{2a}$$

$$\text{s.t.} \quad \sum_{i=1}^{n} U_i \le m \tag{2b}$$

$$\forall_i \quad U^{\min} \le U_i \le 1 \tag{2c}$$

where U_i is the utilization assigned to event e_i, w_i is a user-defined weight, $V(\mathbf{r}_i)$ is the observed variance, and x_i is the estimated count. m denotes the number of available HPCs. This reduces in polynomial time to the formulation in [14] of elastic scheduling as a constrained optimization problem,

$$\min_{U_i} \quad \sum_{i=1}^{n} \frac{1}{E_i}(U_i^{\max}-U_i)^2 \tag{3a}$$

$$\text{s.t.} \quad \sum_{i=1}^{n} U_i \le U_D \tag{3b}$$

$$\forall_i, \ U_i^{\min} \le U_i \le U_i^{\max}, \tag{3c}$$

by setting $U_i^{\max} = 1$, $E_i = \frac{x_i^2}{w_i V(\mathbf{r}_i)}$, and $U_D = m$.

A.1 Optimal Solution Algorithm

From [63, Algorithm 1], this can be solved in quasilinear time by the procedure listed in Algorithm 1.

A.2 Constructing a Schedule

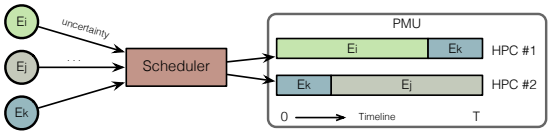

Figure 18: Constructing a schedule of 3 events on 2 HPCs from assigned utilizations.

Although the adopted elastic scheduling problem targets uniprocessor scheduling, we now show that our problem admits a valid schedule for events on *multiple* HPCs. We denote by H the hyperperiod of the schedule, after which it repeats itself; for simplicity of explication we normalize to $H = 1$. Events and counters are considered in order: event e_1 is assigned the interval $[0, U_1]$ on counter c_1. Events are placed sequentially on a counter until total counter utilization would exceed 1, whereupon an event's utilization is split between the end of the hyperperiod interval on the current counter and the beginning of the interval on the next open counter. This continues until all events have been scheduled. This method guarantees that no event is scheduled concurrently on two counters at the same time: if an event is assigned to two counters, the assignments are respectively at the end and beginning of the hyperperiod. Since $U_i \le 1$, these intervals do not overlap, as illustrated in Figure 18.

Building Bridges: Safe Interactions with Foreign Languages through Omniglot

Leon Schuermann[†], Jack Toubes[†], Tyler Potyondy[‡], Pat Pannuto[‡], Mae Milano[†], Amit Levy[†]

†*Princeton University,* ‡*University of California, San Diego*

Abstract

Memory- and type-safe languages promise to eliminate entire classes of systems vulnerabilities by construction. In practice, though, even clean-slate systems often need to incorporate libraries written in other languages with fewer safety guarantees. Because these interactions threaten the soundness of safe languages, they can reintroduce the exact vulnerabilities that safe languages prevent in the first place.

This paper presents Omniglot: the first framework to efficiently uphold safety and soundness of Rust in the presence of unmodified and untrusted foreign libraries. Omniglot facilitates interactions with foreign code by integrating with a memory isolation primitive and validation infrastructure, and avoids expensive operations such as copying or serialization.

We implement Omniglot for two systems: we use it to integrate kernel components in a highly-constrained embedded operating system kernel, as well as to interface with conventional Linux userspace libraries. Omniglot performs comparably to approaches that deliver weaker guarantees and significantly better than those with similar safety guarantees.

1 Introduction

Systems built using type-safe and memory-safe programming languages are safer, more reliable, and more secure than their unsafe counterparts. Languages like Swift, Go, and Rust promise to eliminate entire classes of bugs by construction. While the advantages of memory and type safety have been understood for decades [5, 15], recent advances in making safe languages more practical, along with encouragement from government agencies [48], have fostered their adoption in real, practical systems by both researchers [6, 21, 30, 31] and practitioners [7, 9, 47].

At the same time, real-world systems often require incorporating components written in several languages. As legacy and new systems evolve to use newer, safer languages [7, 9], both old and new languages must co-exist, potentially for years. Components such as filesystems, networking stacks, and device drivers have been fine-tuned over decades by scores of engineers. Pragmatic development does not immediately discard such thoroughly tested code but incrementally replaces it with safe languages when new features or complex fixes would otherwise be required.

Unfortunately, integrating foreign libraries into type-safe programs can re-introduce the exact vulnerabilities safe languages eliminate. When foreign code is invoked, it runs in the same address space and with the same privileges as the host language. A bug in a foreign library, such as the infamous OpenSSL Heartbleed vulnerability [39], can arbitrarily violate the safety of the host language by, for example, accessing memory that the host language assumed was private.

Recent contributions propose isolating foreign code in separate protection domains [4, 16, 29, 35]. Unfortunately, memory isolation *alone* is insufficient to maintain safety. Differences in semantics across languages mean that even interactions with internally correct foreign libraries—ones that operate only on sandboxed memory—may violate safety in subtle ways. For example, two languages may differ in their restrictions on pointer aliasing and corresponding types may have subtly different memory layouts or permissible values. Manually enforcing these invariants and translating types between different languages is error prone and endangers security and reliability [25]. Instead, we need a safe Foreign Function Interface (FFI) that maintains memory safety as well as all other language invariants.

We present Omniglot, the first framework to efficiently maintain all of Rust's safety-critical language invariants in the presence of foreign code. Rather than expose foreign functions directly to the host program, Omniglot invokes foreign functions through a memory sandbox and wraps returned values and shared memory in special types that ensure host code only uses foreign objects once they are validated to adhere to the host language's requirements. By designing a safe FFI using these types, in contrast to prior work, Omniglot maintains both memory and type safety of the host program. Importantly, Omniglot does so while avoiding expensive operations such as copying or (de)serialization across the FFI, which retains the efficiency of raw, unchecked FFI transitions.

Our implementation of Omniglot for the Rust programming language works with arbitrary foreign libraries and with any memory isolation mechanism that meets certain common criteria (Section 4.2). We implement Omniglot for use in a Rust operating system kernel using RISC-V's Physical Memory Protection (PMP) and in Linux userspace applications using x86 Memory Protection Keys (MPK).

Finally, we modify the widely used FFI binding generator for Rust, `rust-bindgen`, to generate foreign library bindings for Omniglot. Our evaluation shows that this allows developers to effectively use Omniglot in both kernels and userspace programs for a variety of practical libraries, such as cryptography, compression, image decoding, filesystem and TCP/IP networking. Omniglot has negligible overhead compared to memory isolation alone, practical overhead compared to an unchecked FFI, and performs significantly better than related work that copies and (de)serializes shared data.

2 Background & Motivation

Many of the safety advances in modern systems programming languages are rooted in their strict enforcement of memory and type safety. This enforcement allows these languages to leave out runtime-checks otherwise required in unsafe languages. For example, whereas a C string (`const char *`) may contain arbitrary 8 bit values, Rust strings (`str`) are guaranteed at compile-time to include only UTF-8 codepoints [40]. However, safe languages' reliance on such properties makes their enforcement critical. A single, subtle violation of memory safety, type safety, or other important invariants can lead to arbitrary undefined behavior and have significant implications for security and reliability.

Unfortunately, current tools used to facilitate interactions between languages do not capture many of these invariants. This deficiency means that all interactions with foreign code must be presumed *unsafe*. Instead, these tools place the proof burden of safety onto the developer who has to verify not only that foreign code is correct, but also that any interactions with this code maintain both the host and guest (foreign) language's invariants.

In this section, we show how current cross-language bindings insufficiently capture language invariants and illustrate how this can violate Rust's safety properties.

2.1 Cross-Language Interactions

Code written in different programming languages can interact through a Foreign Function Interface (FFI). This interface allows one language to invoke foreign language functions by emulating the Application Binary Interface (ABI) and calling conventions of the foreign language. As it is infeasible to support the calling conventions of every other language, many programming languages feature support for the C ABI as a universal, intermediate interface to facilitate interactions between high-level languages. As we will see throughout this section, the C ABI encodes virtually no assumptions about a language's properties such as its memory model, which values are valid for a given type, and synchronization behavior. While this flexibility makes the C ABI useful to connect languages that differ in these properties, it also places a heavy burden on developers to maintain correctness across FFIs.

crypt.h:

```
bool aes_encrypt(
  const uint8_t *key, uint8_t *src,
  uint8_t **const dst, size_t len, bool in_place);
```

crypt.rs:

```
extern "C" {
  // Implicitly marked as `unsafe`:
  pub fn aes_encrypt(
    key: *const u8, src: *mut u8,
    dst: *mut *const u8, len: usize,
    in_place: bool) -> bool;
}
```

Listing 1: Simplified Rust bindings for a C header file `crypt.h` as generated by `rust-bindgen`. The Rust binding is wrapped in an **`extern`** `"C"` block and uses raw pointers instead of Rust references.

Rust developers can use the `rust-bindgen`[1] tool to automatically generate a set of Rust bindings from a C header file. Listing 1 shows a C function signature and its corresponding Rust binding function as generated by `rust-bindgen`. The **`extern`** `"C"` tells the Rust compiler to invoke symbols using the C ABI. External function definitions are automatically tagged as **`unsafe`**—this attribute indicates that the Rust compiler cannot reason about the safety of this function and instead shifts the burden of proof to the developer. Consequently, developers must surround the call-sites of such functions with an **`unsafe`** block promising to the compiler that they verified the safety implications of the function call. For instance, Listing 2 shows an attempt at writing a safe wrapper around the foreign function of Listing 1.

Throughout this section we use the function `aes_encrypt` in Listing 1 as a running example. This function takes an encryption key and a `src` buffer with unencrypted data. Depending on the value of `in_place`, it can either encrypt data in-place, overwriting the contents of `src`, or by allocating a new buffer. For both modes, `dst` will be set to a pointer to the encrypted buffer.

2.2 Memory Safety

Guest (foreign) code has unrestricted access to the host code's memory, even when not explicitly provided to a foreign function. This is a problem. In Listing 2, if `Vec src`'s internal length attribute were stored one memory word before the

[1] https://github.com/rust-lang/rust-bindgen

```rust
pub enum Message<'a> {
  Encrypted(bool, &'a [u8]),
  Unencrypted(CString),
}

pub fn enc(src: &mut Vec<u8>) -> Message<'_> {
  let mut dst: *const u8 = ptr::null();
  unsafe {
    // Calling aes_encrypt from Listing 1
    let res = aes_encrypt(KEY, src.as_mut_ptr(),
      &mut dst, src.len(), IN_PLACE);
    Message::Encrypted(res,
      slice::from_raw_parts(dst, src.len()))
  }
}
```

Listing 2: A Rust wrapper around the C library function `aes_encrypt` from Listing 1, which returns a **`bool`** value to indicate whether the encrypt-operation succeeded. The Rust program exposes a function `enc` that takes a byte-array and uses the C library function to encrypt its contents. It returns the `Encrypted` variant of the **`enum Message`** type, a tagged union. This variant includes a buffer constructed from the pointer written to `dst` and the encryption-operation's result. Can you spot the safety violations?

buffer's contents, then a simple off-by-one error in the C function could overwrite this value (at address `src - 1`). This can then cause Rust code to believe that this array is larger than its actual underlying allocation.

In Rust, `Vec` is an instance of a safe abstraction. It provides an API through which the programmer is unable to violate Rust's safety invariants. When changing the internal length parameter, the C function prevents this API from living up to its promise, as the `Vec` may overflow its allocation.

Rust prevents such unsoundness by only providing functions with references to valid `Vec` instances. Unlike the raw pointers required by the unchecked C ABI, references do not allow a developer to perform arbitrary reads and writes to their memory. Instead, references are well-typed, and all accesses to their memory must be made through the type's API.

To maintain memory safety and thus *soundness*—crucial to security and integrity—interactions with foreign code must uphold an equivalent set of restrictions. In practice, for the example in Listings 1 and 2 this means that the `aes_encrypt` function, being passed a pointer to the `src` vector, must only read and modify the user-accessible part of the `Vec` data structure. The caller must, in turn, ensure that the vector outlives this function call.

2.3 Aliasing and Mutability

Apart from basic memory safety, programming languages often have additional, high-level invariants they require for correctness and optimizations. A prominent example of this

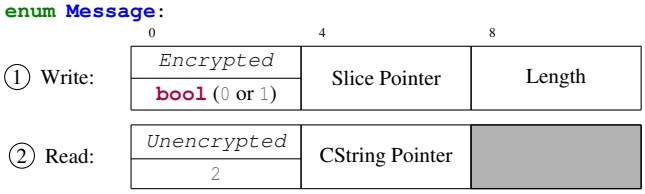

Figure 1: Memory layout of the **`enum Message`** type. Rust encodes the **`bool`** value of the `Message::Encrypted` variant into the same memory location as the enumeration's active variant (called *niche filling*). When ① writing an `Encrypted` value with a slice and an invalid **`bool`** value (*e.g.*, 2), the value may be ② misinterpreted as a different variant, such as `Unencrypted` and a `CString`.

are Rust's rules around aliasing and mutability. McCormack et al. explain these rules in great detail [25]; for brevity we illustrate them through the example of Listing 1.

Such an idiomatic C function interface can easily cause issues when paired with Rust's restriction on *aliasing XOR mutability*. This rule governs that at any time a value may either have multiple immutable *shared* references, or a single mutable *unique* reference, and never both. The `enc` wrapper of Listing 2 violates this rule: it invokes `aes_encrypt` with a `src` pointer obtained from a mutable reference to the data contained in the `src` vector (line 10). To pass on the encrypted data as part of the `Message` enum, it creates an immutable reference to this buffer (a *slice*) from the `*dst` pointer (line 13). However, when `aes_encrypt` is set to perform an *in-place* operation, `*dst` will be pointed to the exact same memory as `src`. Thus, creating an immutable reference from `*dst` is unsound while the original mutable reference for `src` still exists. Therefore, developers must reason about the provenance of pointers as they flow through both host and guest (foreign) code—a task that is difficult in practice, infeasible without source code, and where getting it wrong is commonplace [25] and leads to critical security vulnerabilities [1].

2.4 Type Safety and Valid Values

Finally, safe languages rely on type safety to maintain safety-invariants at runtime. In Rust, examples of this are the UTF-8 validity requirement for strings mentioned previously or the `Vec` abstraction shown in Section 2.2. In addition to these high-level invariants, Rust places restrictions onto the valid values of primitives and algebraic data types. For example, the **`bool`** primitive is a type occupying one byte of memory, whose only valid values are `0` or `1`. Treating memory containing any other value as a **`bool`** is thus unsound.

The implications of this are not solely of theoretical interest, though, as is apparent by surprising runtime behavior of Listing 2 when this invariant is violated: it may crash with

a segmentation fault![2] This is because Rust performs an optimization known as *niche filling*. Since Rust trusts that the `bool` type will only ever contain `0` or `1`, it encodes the value of this type directly into the discriminant of the `enum Message` type, and represents the `Unencrypted` variant with a discriminant[3] of value `2`. Figure 1 illustrates the memory layout of this type. However, if we were to violate the aforementioned validity restriction of `bool` we can construct a `Message::Encrypted` instance that, when read back, will be misinterpreted as an `Unencrypted` variant instead. This is not farfetched. For example, in many C implementations, a `bool` is `typedef`ed as an `int`, and hence may contain values outside of `0` or `1`. Because Rust assumes the returned `bool` is valid (`0` or `1`), it simply copies its memory into the `enum Message`'s discriminant and performs no further validations. As such, the memory occupied by the slice (`&'a [u8]`) member in Figure 1 will erroneously be interpreted as an element of type `CString`, leading to undefined behavior and a soundness violation in theory, and a use-after-free or out-of-bounds access in practice.

3 The Omniglot Approach

Interactions with foreign languages through Rust's existing *unsafe* FFI can trivially reintroduce the exact security and reliability vulnerabilities that safe Rust eliminates. Through this FFI, foreign code has unrestricted access to host memory. Moreover, even with coarse grained memory access restrictions, a foreign library could still introduce vulnerabilities due to subtle differences in language semantics.

Omniglot provides a *safe* interface for Rust programs to interact with foreign libraries. This is a high bar. Safety in Rust relies on *soundness*, i.e., interactions with a foreign library must not introduce any undefined behavior [44]. This includes[4] an absence of data races, dangling or misaligned accesses, aliasing violations, producing invalid values, etc.

Unfortunately, reasoning about whether a foreign library violates any of Rust's soundness conditions is hard. One conventionally achieves this by modeling the entire program and ensuring that the host code, foreign code, and their composition is sound. While the Rust compiler validates soundness of safe Rust code, it cannot do so for interactions with foreign code. Despite this difficulty, maintaining soundness is vital[5] to leverage the safety guarantees of type-safe languages.

[2] In practice, compiler optimizations happen to often avoid faults in simple cases like `bool` and other `enum` types with a 1 bit discriminant. For brevity, we elide an example that faults with a recent Rust compiler toolchain.

[3] The actual value chosen by the Rust compiler is not specified; at the time of writing it happens to use `2` for 32 bit platforms.

[4] Rust defines undefined behavior through its *Rust Reference* [41], *Unsafe Code Guidelines Reference* [44], and *Rustonomicon* [42]. In the absence of a formal model of Rust's semantics there is no exhaustive list of defined or undefined behavior; as such we design Omniglot against the currently known invariants.

[5] The Rust Unsafe Code Guidelines Reference states more bluntly that in the presence of undefined behavior, "the program produced by the compiler is essentially garbage." [44]

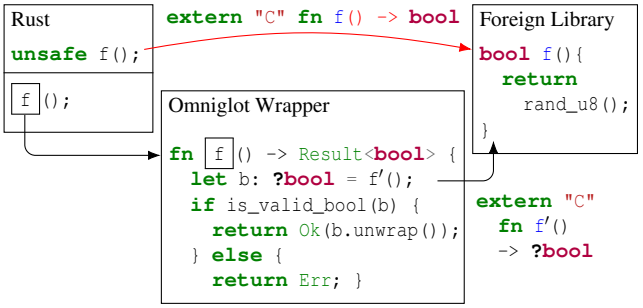

Figure 2: Omniglot interposes on interactions between Rust and foreign code. In this example, Omniglot models a foreign function through a *weaker* function binding `fn f'()`, and restores the original function's return type through a runtime check in the wrapper `fn f()`.

Omniglot does not model the entire program, and instead takes a different approach. We argue that it is sufficient to reason about an execution of the foreign library, as opposed to proving the soundness of the composition of host and foreign code for all such executions. Figure 2 demonstrates this approach: `f()` is a foreign function that would violate Rust's soundness through a naïve FFI binding. When a Rust program calls this function, the compiler *assumes* certain invariants hold across the foreign function's execution (we enumerate this set of invariants below). In this example, `f()` violates one such invariant by returning a potentially invalid value for the Rust `bool` type (*e.g.*, the number `2`).

Nonetheless, Omniglot can provide a safe encapsulation of this foreign function, `f`. Recall that Rust's invariants for a given value depend on its ascribed type. The problem with the example of Figure 2 arises from the fact that `f()` is said to return a value of the Rust type `bool`. Omniglot instead produces a foreign function binding `f′`. This binding returns a different type, `?bool`, which is not subject to those same restrictions. As such, calling `f′` does not endanger soundness.

While the foreign function binding `f′` is sound, it is not very useful. Because `?bool` is not subject to the same invariants as Rust's regular `bool` type, we also give up on the guarantees that follow from these invariants. Omniglot re-establishes these invariants through a set of runtime checks. In the above example, Omniglot tests whether the returned value is indeed a valid `bool` and, if so, casts it to this more useful type. This allows Omniglot to safely expose an encapsulated function `f` with the same interface as its unsound counterpart, `f`.

This example shows how we reason about type safety invariants to develop Omniglot's safe foreign function interface. In addition to type safety, there are also memory safety, aliasing and mutability, and concurrency-related invariants. Over

the remainder of section, we describe these remaining invariants, and show how we can uphold them in a similar way.

Memory Safety. We adopt Dhurjati et al.'s definition of memory safety: a software entity is memory-safe if it only references memory allocated by or for that entity [10]. As this is ultimately a language-specific property, strictly enforcing it across an FFI is difficult. For instance, moving an object—a common operation in Rust—has no equivalent counterpart in a language like C with no defined ownership model.

However, Omniglot only needs to retain the *host* language's memory safety invariants, a more tractable problem. By dividing each language's allocations into a distinct set of memory regions, where each side is restricted from accessing the other's allocations, we ensure that any memory safety issues within foreign code cannot impact the surrounding Rust program. Memory isolation techniques, including memory protection, virtual memory, or software fault isolation, are well suited to this purpose.

Unfortunately, such strict isolation also prevents memory sharing with foreign libraries. To enable sharing, Omniglot allows Rust to dereference pointers into foreign memory if and only if the object they reference is wholly contained inside the foreign library's valid memory regions.

Aliasing and Mutability. Rust uses strict aliasing rules to statically reason about which references can be used to safely mutate or read memory. While *unique*, mutable references can never be aliased, *shared* (aliased) references must never be modified (a rule known as *aliasing XOR mutability*).

This is problematic in the presence of foreign code: for instance, a foreign function may return references to the same memory multiple times. Since we cannot track pointer provenance through foreign memory or code, we must conservatively assume that all references derived from such pointers are mutably aliased with each other. The only way to safely support mutable aliasing in Rust is through mutual exclusion. Section 4.4 show how Omniglot introduces a zero-cost and deadlock-free mutual exclusion mechanism for references into foreign memory.

Type Safety. Saraswat defines a language as type-safe if "the only operations that can be performed on data in the language are those sanctioned by the type of the data." [36] Violating this property can break safe abstractions (Section 2.2), and introduce arbitrary undefined behavior.

Even if a foreign library is itself written using a type-safe language, its types are likely not identical in either semantics or representation to their counterparts in Rust. Indeed, translating objects between the type systems of two languages is an active area of research [32, 33, 34]. Omniglot must therefore assume that objects passed to or obtained from a foreign function do not preserve Rust's notion of type safety.

As illustrated by the example in Figure 2, Omniglot considers objects returned from a foreign library or in foreign memory *tainted* and ascribes them a special "any"-type. Omniglot can downcast such objects to a more useful type only after *validating* them. Specifically, an object is considered valid if its underlying size, alignment, bit-pattern, and other high-level invariants match those of an object of the same type created in safe Rust. For example, a well-aligned 32 bit object is a valid `char`, so long as it contains a valid, non-surrogate Unicode code point [43].

Certain Rust types carry higher-level invariants that cannot be validated solely by observing their size, alignment, and underlying bit-pattern. Examples of this are Rust references, which impose additional restrictions on their provenance and lifetimes, or typestates [2, 37]. Omniglot can never safely validate these types once written into foreign memory. Developers can instead pass symbolic representations of these objects to foreign code, referring back to a copy in memory owned by Rust.

Concurrency. Many of Rust's invariants pertain to the underlying memory state of its objects. However, when this state changes after being validated, such as through concurrent modifications by foreign code, these invariants may no longer hold, introducing unsoundness.

Thus, Omniglot requires that foreign code not modify certain values without explicit coordination with Rust. This can be accomplished through synchronization and memory isolation primitives, or by ensuring that foreign code does not execute concurrently with Rust.

4 Design

In this section we present the design of Omniglot, a framework to provide a *safe* interface to interact with foreign code. Omniglot's workflow is similar to that of Rust's conventional unsafe FFI with `rust-bindgen`, as described in Section 2.1: for a set of C header files, Omniglot generates a set of safe FFI bindings that developers can use to manipulate foreign data types and call into foreign functions.

To safely interact with an untrusted foreign library, Omniglot combines a set of inter-operating mechanisms. It features a pluggable runtime component (described in Section 4.2) responsible for loading libraries into a sandbox and isolating their memory. Omniglot further features a set of reference and validation types (Section 4.3) that capture and progressively validate the aliasing and type safety invariants described in Section 3.

However, simply applying the approach described in the previous section is not sufficient: interactions between the Omniglot runtime and its types can violate invariants that Omniglot's reference and validation types rely on. Thus, in Section 4.4 we introduce a mechanism called *scopes* that captures and enforces an additional set of *temporal invariants* to uphold the required invariants. Scopes are zero-cost, are enforced at compile-time, and statically reject code that would violate these invariants.

4.1 Threat Model

Omniglot maintains Rust's soundness across interactions with arbitrary, untrusted, and adverserial foreign code.

To achieve this goal, we assume that there is an available hardware, OS-provided, or software-based memory isolation primitive that provides strong memory protection—i.e. it can prevent a foreign library from accessing all but explicitly permitted memory regions.

Furthermore, we assume that there are OS or hardware primitives that allow restricting when foreign code can run. In particular, these primitives must be able to limit the ability of a foreign library to execute concurrently with host code, such as by preventing it from spawning and running threads that continue to run in the background, or executing in response to asynchronous signals.

We also assume that the Omniglot library, runtime implementation, Omniglot's bindings generation tool, as well as the Rust type-checker and compiler are correct. Omniglot provides a set of interfaces and types that safe Rust cannot use incorrectly. Thus, safe Rust code of the host application does not need to be trusted. However, any code that uses Rust's **`unsafe`** feature to circumvent restrictions imposed by Omniglot through the type system is considered trusted.

Omniglot can maintain Rust's soundness across interactions with adverserial libraries when using a *strong Omniglot runtime*—a runtime *enforcing* the above assumptions using strong primitives for memory isolation and restricting concurrency. We present an implementation of a strong runtime in Section 5.1. However, when these assumptions are violated, Omniglot's threat model changes. For example, a *weak runtime* may not be able to entirely prevent a foreign library from circumventing memory protection (e.g., through system calls), or restrict its access to concurrency primitives. In this case, Omniglot cannot safely run fully untrusted and adverserial foreign libraries. Instead, developers must trust that Omniglot's requirements concerning memory isolation and concurrency are upheld by the foreign library. Section 5.2 describes such a weak Omniglot runtime and further discusses its threat model implications.

Omniglot does not guarantee application-level correctness properties. For example, while it guarantees that a **`bool`** returned from a foreign function is either **`true`** or **`false`**, it does not guarantee that the foreign library computed this value correctly. Furthermore, Omniglot does not protect foreign code from operations issued by host code: for example, the host program may write to arbitary locations in foreign code's memory, including in ways that can cause foreign code to misbehave. However, assuming a strong Omniglot runtime, such misbehavior cannot compromise the host program's soundness.

Finally, Omniglot does not address timing and other side-channel attacks that might allow foreign code to infer the contents of host program memory it cannot access directly.

4.2 Sandboxing Foreign Libraries

Omniglot divides memory into regions owned exclusively by Rust, and regions delegated to foreign library instances. It uses a memory isolation primitive to uphold the host's memory safety when executing foreign libraries by restricting them to only be able to access their own, sandboxed memory regions.

As these memory isolation primitives vary between different architectures and platforms, Omniglot features a set of platform-specific runtimes. A runtime offers an interface to integrate with the core Omniglot framework. For instance, a runtime allows Omniglot and developers to to interact with a system's memory isolation primitive. It also imposes other restrictions on foreign code like limiting its access to concurrency primitives, to prevent untrusted foreign code from invalidating Rust's invariants after they have been validated by Omniglot. Omniglot's runtimes expose the following (simplified) API which host code uses to interact with foreign code:

`OGRt::new(library)` Constructs a new runtime instance and loads `library` into the sandbox.

`rt.stack_alloc(size, closure)` Allocates `size` bytes on the foreign library's stack, and invokes a closure during which this allocation is valid. It restores the previous foreign stack pointer when the closure returns.

`rt.setup_callback(callback, closure)` Prepares a callback that foreign code can trigger, and invokes a closure during which this callback is valid. This function creates an address for which, whenever foreign code jumps to it, the Omniglot runtime will execute `callback`.

`rt.invoke` Invokes a foreign function within the memory isolation sandbox. After invoke returns, the runtime guarantees that no foreign threads are running. This symbol is not called directly, and instead used by a trampolining mechanism described in Section 5.3.

The Omniglot FFI bindings for a foreign library are portable across multiple runtime implementations. These bindings resemble Rust's unsafe FFI interface, but call out to the Omniglot runtime instead of directly invoking foreign code. Nonetheless, Omniglot requires developers using a foreign library (or those writing Rust wrappers) to transform their code, for instance by using the above methods for allocating memory or callbacks that will be used by foreign code. When a foreign library attempts to access an allocation outside of its sandbox, or invokes a host callback not prepared though `setup_callback`, it triggers a fault in the memory isolation mechanism, which the Omniglot runtime catches and exposes as an `Err` value returned to Rust by `invoke`.

4.3 Communication between Rust and Foreign Code

Omniglot divides memory into mutually-exclusive regions for the host program and foreign code: it uses a memory iso-

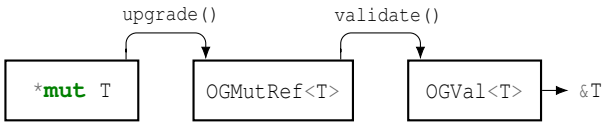

Figure 3: Omniglot captures arbitrary addresses in foreign memory as raw pointers (`*mut T`). The *upgrade* and *validate* methods transform a potentially invalid reference into writeable (`OGMutRef<T>`) and readable (`OGVal<T>`) wrappers.

lation mechanism to prevent foreign code from changing host memory. Furthermore, safe Rust is incapable of constructing arbitary references into foreign memory. While this strict division trivially upholds memory safety, it also prevents efficient transfer of data between guest (foreign) and host code.

Omniglot cannot allow foreign libraries to access memory belonging to the host program (Rust), as unrestricted, arbitrary access of foreign code to Rust's memory can break its invariants (see Section 3). Instead, Omniglot provides a mechanism that allows host code to allocate and access values in foreign memory. This is sufficient to allow host code to communicate with foreign libraries, while at the same time making it feasible to maintain Rust's soundness.

Using the runtime interface, host code can allocate objects in memory accessible to a foreign library (e.g. using `rt.stack_alloc`). Depending on the runtime, these allocations can happen on the foreign library's stack, a separate stack dedicated for such host-language allocations, or using heap memory dedicated to foreign code. These operations alone have no impact on the safety of the host program—their effects are limited to the foreign library's memory regions.

However, for Rust to safely dereference or modify memory belonging to a foreign library, we must ensure that it is contained within a *valid foreign allocation*, and that it represents a *valid instance* of its ascribed type. In this section we introduce a set of types following the typestate paradigm [2, 37] that capture validation operations and offer a *safe* API to access data shared with foreign code.

Figure 3 illustrates these *reference* and *validation* types. The first type, a raw pointer, forms the base of Omniglot's type infrastructure. It can capture arbitrary addresses in foreign memory. This pointer does not have to maintain any invariants; it may be dangling, misaligned, or alias host memory. Thus, safe Rust is not able to dereference it.

The second type, `OGMutRef<T>`, expresses pointers that refer to an active, well-aligned foreign memory allocation of sufficient size for a type `T`. It can be obtained through *upgrading* a raw pointer and checking the aforementioned invariants at runtime, by checking against the runtime-tracked set of memory regions dedicated to the foreign library. An `OGMutRef<T>` represents a useful intermediate type: when considering our model of memory safety in the presence of foreign code from Section 3, because this type must point into a *valid* allocation of foreign memory, writing to it does not violate memory safety.

However, Rust's limitations around mutable aliasing complicate this: in general, an aliased Rust reference must not be modified. As shown in Section 3, given that an `OGMutRef<T>` can be constructed from an arbitrary raw pointer supplied by foreign code, we cannot track its provenance and must instead assume that it is (partially) aliased by other references. To avoid violating Rust's aliasing constraints while still allowing `OGMutRef<T>` references to be modified, Omniglot opts out of Rust's strict aliasing model for this reference type, by representing it as the composition of two of Rust's standard library types: `&UnsafeCell<MaybeUninit<T>>`. Whereas `MaybeUninit` prevents the Rust compiler from making assumptions about the validity of values stored behind this reference, `UnsafeCell` allows values to be mutably aliased. However, an `UnsafeCell` annotation can only be used as long as every other reference to this value also carries this same annotation. As a result, Omniglot must ensure that no regular Rust references (ones not wrapped in such an `UnsafeCell`) point into foreign memory. This holds by construction, as foreign allocations are disjoint from any of Rust's allocations.

A final type, `OGVal<T>` captures pointers that refer to memory which contains an actual, dereferenceable instance of type `T`. This memory may be safely read and interpreted as its ascribed type without any risk to the soundness of the host program. Host code can attempt to *validate* an `OGMutRef<T>` into an `OGVal<T>` by inspecting its underlying bit-pattern, as described in Section 3. Omniglot performs this validation using a Rust trait, and provides implementations for many of Rust's primitive types. For any types that cannot be validated solely by inspecting their size, alignment, and bit-pattern, this trait is not implemented.

Omniglot's restrictions on concurrency also follow from the above types and reflect a fundamental constraint: so long as any validated Rust references to foreign memory exist, they must retain the invariants described in Section 3. However, if foreign code were to execute concurrently with host code, it could break these invariants at any time, such as by arbitrarily modifying any memory it can access. If the host program would access a foreign library *instance's* memory concurrently with *that instance's* execution, then the above validations could be subject to a time-of-check to time-of-use (TOCTOU) bug: after performing an *upgrade* or *validate* operation in Rust, foreign code may change its available memory allocations or write invalid values to previously validated memory locations. This would then invalidate the invariants gained in the *upgrade* and *validate* typestate transitions. Therefore, Omniglot requires that host code does not hold references into a foreign library *instance's* memory concurrently with *that instance's* execution. Omniglot's architecture can support running multiple Rust threads, as well as running multiple instances of foreign libraries concurrently.

`OGRt::new()` yields a unique allocation and access scope per library: `OGRt::new(library) -> (Rt, AllocScope, AccessScope)`

Allocation scopes prevent dangling references:
`ptr::upgrade(&AllocScope<'l>) -> OGMutRef<'l>`
`OGRt::stack_alloc(&'a mut AllocScope<'l>, Fn(&'b mut AllocScope<'m>))`

Access scopes prevent invalidating references through writes:
`OGMutRef::write(val: T, &mut AccessScope)`
`OGMutRef::validate(&'a AccessScope) -> OGVal<'a>`

`invoke` may write to memory and modify allocations in callbacks: `OGRt::invoke(&mut AllocScope, &mut AccessScope)`

Table 1: Interactions between Omniglot's runtime, reference and validation type APIs, and its *allocation-* and *access-scopes*: by binding `OGMutRef` references to their originating allocation scope, we eliminate dangling references. Validated `OGVal` references are further bound to an access scope, which expires upon foreign function execution or when foreign memory is modified.

4.4 Temporal Constraints

Omniglot's reference and validation types allow a developer to safely read and write foreign memory, as long as their underlying invariants hold (Section 3). However, even without concurrency, seemingly unrelated operations can affect these invariants: for example, writing to an `OGMutRef` may modify foreign memory previously validated into an `OGVal`. Revoking foreign allocations may cause reference or validation types to be dangling. And invoking a foreign function can both modify memory, and trigger a callback which may do any of the above.

In other words, the invariants of Omniglot's reference and validation types must be *temporally constrained*. These constraints may be quite subtle, as we can see in the following example: a foreign library yields two pointers, referencing overlapping memory that the caller interprets as an integer and a boolean respectively. The caller upgrades these pointers to `OGMutRef`s and validates one into an `OGVal<bool>`. Then, if both pointers alias each other, writing a non-boolean value to the integer reference would invalidate the invariants checked when creating the `OGVal<bool>`. As such, the boolean reference must not exist beyond the write to its aliasing integer reference. Similarly, any of these references may become invalid when Omniglot revokes foreign memory.

We could enforce these temporal constraints through mutual exclusion by using a read-write lock. Assume that we have a single lock for reading and writing a given library's memory. Then, calling `OGMutRef::validate` to produce an `OGVal<T>` could acquire a read-lock internally. This lock would be released when the resulting `OGVal<T>` goes out of scope. Additionally, both operations that can modify foreign memory, `OGMutRef::write` and `OGRt::invoke`, will acquire a corresponding write lock. Under this model, it will be impossible to retain an `OGVal<T>` across any modification of this memory—doing so will result in a deadlock.

Similarly, a read-write lock for each foreign allocation can protect upgraded references (both `OGMutRef` and `OGVal`) from memory allocation and revocation operations invalidating them. In this model, operations which may revoke memory (`ptr::stack_alloc` and `OGRt::invoke`) take a write-lock on the relevant memory allocations. Conversely, `upgrading` a pointer to create an `OGMutRef` requires a read-lock, released only when it goes out of scope. This would ensure that, if there are any outstanding references to an allocation, an attempt to revoke the allocation would result in a deadlock.

Unfortunately, *dynamic* locks do not reject incorrect code at compile time and thus place an undue burden on developers to ensure their code is deadlock-free. Such dynamic locks are also unnecessary. Given Omniglot's restrictions on concurrency—namely that Rust code does not hold references into a foreign library instance's memory concurrently with that instance's execution—we can statically enforce mutual exclusion by reasoning about data-flow patterns in programs. We design a zero-cost, compile-time enforced, static, and single-threaded locking mechanism based on lexical scopes. Omniglot uses these scopes in tandem with Rust's restriction on *aliasing XOR mutability* to implement a form of read-write mutual exclusion, and enforces it through Rust's borrow checker.

Table 1 describes Omniglot's API using scope-based exclusion. Creating a new, unique, instance of a foreign library using `OGRt::new` yields an `AllocScope` and an `AccessScope`—two branded types [19, 50] that are uniquely bound to a particular call to the constructor. *Unique* (`&mut`) borrows of these values correspond to obtaining a write-lock, and a *shared* (`&`) borrow corresponds to obtaining a read-lock. Rust prevents concurrent *unique* and *shared* borrows of the same scope. Omniglot's reference types carry a lifetime derived from the lifetime of these borrows, ensuring that they cannot outlive the `AccessScope`s and `AllocScope`s in which they have been created.

Omniglot uses these scopes to enforce its temporal constraints on `OGMutRef` and `OGVal` types. When an `OGMutRef` is validated, it captures a *shared* borrow of an `AccessScope` for an anonymous lifetime `'a`. It produces an `OGVal<'a>` that captures this lifetime. As long as this new value exists, Omniglot statically prevents calling any functions that could invalidate its invariants, such as `OGMutRef::write`, by requiring these functions to take a *unique* reference to the `AccessScope`.

We use a similar approach to maintain the constraints for `OGMutRef`. Upgrading a pointer captures a *shared* reference to an `AllocScope`, while any operations that may revoke memory, and thus endanger the invariants of this type, take a *unique* `AllocScope` reference.

In practice, Omniglot can be slightly more permissive about letting `OGMutRef`s outlive certain revocations of memory. By combining an allocation with its corresponding revocation

into a single function—`stack_alloc`—Omniglot allows references that were created before this allocation to also outlive its revocation. In other words, while Omniglot must prevent any reference created in a call to `stack_alloc` from escaping its inner closure, those created in outer scopes can remain live. Omniglot does so by separating the lifetime that an `AllocScope` is active for (`'a`), from the lifetime of its underlying memory allocation (`'l`), as shown in Table 1.

Finally, invoking a foreign function can both modify memory, and trigger a callback that can revoke allocations, and thus captures *unique* references to both allocation and access scopes.

4.5 Omniglot API Walkthrough

Listing 3 illustrates how all of Omniglot's mechanisms interact to provide a safe interface to an arbitrary, untrusted foreign library. On line 3, this example loads a fictional compression library (`libcompress.so`) into an Omniglot runtime. Constructing a runtime and loading a library yields four return values: a runtime object `rt` exposing the API shown in Section 4.2, a library shim `lib` featuring wrapper methods for all foreign library functions, and allocation and access scope marker values as described in Section 4.4.

In this example, we use the foreign library to compress an array of 4 bytes. On line 7 we use the runtime's `stack_alloc` function to place a new allocation of type `[u8; 4]` on the foreign library's stack. Because allocating memory can change the set of allocations accessible to foreign code, it interacts with Omniglot's allocation scopes: `stack_alloc_t` (to allocate space for a generic type `T`) obtains a *unique* reference to the outer allocation scope marker `oalloc` on line 8 and holds onto it through line 31. This *unique* borrow prevents new *upgrade* operations (potentially on the new, stacked and ephemeral allocation) from using this outer allocation scope. In turn, `stack_alloc_t` provides a new *inner* allocation scope `ialloc` which is valid for the duration of this new allocation. Any *upgrade* operations will thus use this new allocation scope instead; we say the *active* allocation scope changes (switching from a solid to a dashed line in Listing 3).

We write uncompressed data to this newly allocated buffer on line 10. As illustrated in Section 4.4, writing any foreign memory may invalidate other references. Thus, this operation obtains a *unique* reference to the access scope marker: it closes the previous scope, and immediately re-opens a fresh access scope (dotted line in Listing 3). Finally, we invoke the foreign library's `compress` function on line 15, which executes it in the Omniglot runtime's sandbox. Invoking a foreign function may both change foreign memory *and* change the set of foreign allocations (in a callback), and thus requires a *unique* reference to both allocation and access scopes.

Listing 3 demonstrates scope-based enforcement of Omniglot's temporal constraints: for instance, line 12 validates the allocated buffer into an `OGVal<[u8; 4]>` reference.

```
1       // Load a library into a runtime, creating
2       // allocation and access scope markers:
3       let (rt, lib, mut oalloc, mut access) =
4         Rt::new("libcompress.so");
5
6       // Allocate a [u8; 4] on the foreign stack
7       rt.stack_alloc_t::<[u8; 4]>(
8         &mut oalloc, |array, ialloc| {
9           // array: OGMutRef<'_, [u8; 4]>
10          array.write([0, 1, 2, 3], &mut access);
11
12          let validated = array.validate(&access);
13          println!("{:?}", validated);
14
15          let compressed_len = lib.compress(
16            buf: array.as_ptr(),
17            length: 4,
18            &mut ialloc, &mut access).validate();
19
20          // Would not compile, as `validated` is
21          // bound to the previous access scope:
22          println!("{:?}", validated);
23
24          let upgraded = array.as_ptr()
25            .upgrade_slice(compressed_len, &ialloc);
26          let revalidated = upgraded.validate(&access);
27          println!("{:?}", revalidated);
28
29          // `array` and `upgraded` cannot escape
30          // closure, capture the `ialloc` scope.
31        }
32      )
33    Active Access Scope
34  Active Allocation Scope
```

Listing 3: A basic Omniglot wrapper around a compression library, with its allocation and access scopes visualized. We create an Omniglot runtime, allocate memory, invoke a foreign function, and validate its returned result. Dashed and dotted lines represent the active and open allocation and access scopes, respectively. Each mutable borrow of a scope marker closes the current and re-opens a new scope, causing all references bound to the previous scope to be inaccessible.

However, this reference is bound to the access scope closed on line 15. Thus, any attempts to access it (as on line 22) will result in a compile-time error. Instead, correct bindings create a new `OGMutRef<[u8]>` reference over the compressed data length (line 25), and then re-validate it against the currently open access scope (line 26).

5 Implementation

We implement Omniglot and its two runtimes in a set of Rust crates of approx. 7000 LoC. We further extend `rust-bindgen` by 860 LoC to automatically generate Omniglot-compatible bindings from C header files. Our implementation is available on GitHub: https://github.com/

omniglot-rs/omniglot.

In this Section, we first present our two prototype Omniglot runtime implementations for the Tock operating system (using RISC-V PMP) and Linux userspace (using x86 Memory Protection Keys) respectively. As these runtimes use different isolation primitives and run in different environments, we classify them into *strong* and *weak* runtimes as per our threat model (Section 4.1), and discuss which—if any—assumptions the Omniglot runtimes make on the behavior of foreign libraries.

Finally, in Section 5.3 we present Omniglot's `invoke` trampoline. While Omniglot is implemented in the type-system of an unmodified Rust compiler, Rust normally does not allow libraries to interpose on calls to foreign functions. Omniglot's `invoke` trampoline makes Omniglot practical by allowing it to switch to a foreign protection domain on calls to foreign functions. In contrast to existing approaches like `libffi`[6], we do so with minimal overhead, by using the Rust compiler's knowledge of the foreign function's ABI to statically generate code for loading function arguments into registers and on the stack.

5.1 Omniglot for the Tock Operating System

OG_{PMP} is an implementation of Omniglot for the Tock embedded operating system kernel [21], utilizing the RISC-V Physical Memory Protection (PMP) unit as its memory isolation primitive. The Tock kernel is itself written in Rust and used for security critical applications, such as in the firmware of the OpenTitan silicon root-of-trust or Microsoft's Pluton security controller embedded in modern x86 CPUs [49]. Because Tock heavily relies on Rust's safety for enforcing isolation between mutually distrustful applications and must, for instance, integrate existing and certified cryptography libraries, it is an ideal target for Omniglot.

The RISC-V PMP is a secure memory isolation primitive and thus enables OG_{PMP} to provide strong soundness guarantees. In particular, OG_{PMP} loads foreign libraries into protection domains similar to Tock processes, running at a lower privilege level, and without any memory of the Tock kernel accessible to them. It executes library functions by loading their arguments into registers and onto a dedicated stack in foreign memory, and context-switching to a lower-privilege mode. Libraries can transition back into the Tock kernel (which corresponds to Omniglot's host program) by one of three mechanisms: returning from the function invoked by the kernel, invoking a registered callback, or producing a fault—in which case Omniglot returns an error to host code. Notably, there is no standard system call interface accessible to foreign code, and OG_{PMP} does not expose any concurrency primitives.

Because OG_{PMP} fully isolates memory belonging to a foreign library, does not provide any means to circumvent this isolation, and does not expose any concurrency primitives to the foreign library, it is considered a *strong* Omniglot runtime. It can run arbitrary, untrusted and adverserial foreign libraries, while maintaining the soundness of the Tock kernel.

[6] https://sourceware.org/libffi/

5.2 Omniglot for Linux Userspace

On the other end of the spectrum, OG_{MPK} brings Omniglot to Linux userspace applications on desktop- and server-class systems. OG_{MPK} utilizes x86 Memory Protection Keys (MPK), a recent isolation mechanism built around the idea of assigning virtual memory pages one of 16 *protection keys*. A core-local and userspace-writeable register controls which protection keys are accessible at any given time. Notably, MPK does not require a system call to switch protection domains, making domain transitions fast.

OG_{MPK} uses *link-map lists* to load conventional shared libraries into an isolated namespace. It then uses MPK to assign all pages associated with a foreign library—and its transitive dependencies—a protection key. When running functions of the foreign library, OG_{MPK} disables access to all memory pages not assigned this protection key—making the memory of host code and other foreign libraries inaccessible.

While MPK is a popular tool for intra-process memory isolation [4, 16, 20, 23, 38, 46], in particular due to its low overheads, it presents some challenges for security: for instance, Connor et al. show that MPK-based isolation can be circumvented through system calls, memory mappings, signal delivery, and race conditions [8]. As Omniglot's focus is on maintaining Rust's soundness assuming a strong memory isolation primitive, we do not address the inherent security properties of MPK in this work. Therefore, OG_{MPK} is a *weak* Omniglot runtime.

Our implementation of OG_{MPK} does override some symbols such as `alloc` and `free` to use a custom, memory-isolation aware allocator. However, actively malicious libraries can circumvent OG_{MPK}'s memory isolation by using system calls like `mmap`. Developers will need to validate that foreign libraries do not perform such operations, or employ `seccomp-bpf`-based mitigations as presented in ERIM [46]. Similarly, OG_{MPK} does not prevent foreign libraries from accessing concurrency primitives. Developers must ensure that libraries do not register signal handlers and run background threads concurrently with host code execution, such as by manually inspecting the foreign libraries, disallowing them from using certain system calls, or inspecting the state of the program at runtime.

Despite these weaker guarantees, OG_{MPK} is still useful to isolate libraries that are not assumed to be actively malicious. Its reference and validation types can prevent many cases of improper mutable aliasing and can ensure that values used by Rust conform to its strict validity requirements.

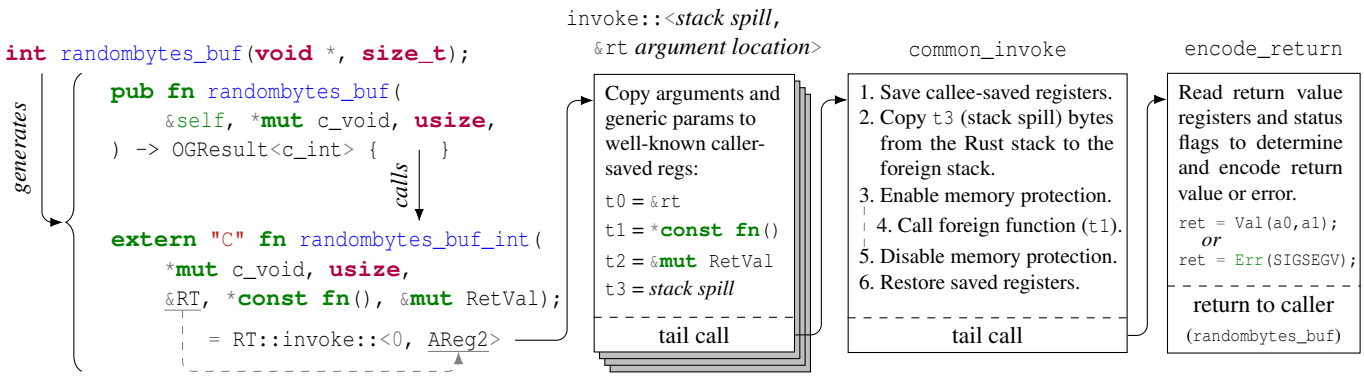

Figure 4: Omniglot wraps foreign functions by creating an internal, unsafe FFI binding and aliasing it to the Omniglot runtime's generic invoke symbol. The runtime preserves the Rust compiler's argument registers and stack.

5.3 The `invoke` Trampoline

An Omniglot runtime is responsible for ensuring that any foreign code runs within its sandbox and, in turn, all callbacks execute in Rust's context, with access to both Rust and foreign memory. Implemented naïvely, however, this could prevent a foreign function from accessing its parameters or writing its return value, as they might be spilled on the host's stack. Omniglot solves this issue by copying this memory to and from the foreign stack. This poses a challenge: how can the Omniglot runtime know which memory to copy? Importantly, this depends not only on the platform's calling convention, but also on each individual function's signature.

To solve this problem, we introduce a generic `invoke` trampoline mechanism, illustrated in Figure 4. Rather than manually placing function arguments into their appropriate registers and stack offsets, Omniglot relies on the Rust compiler's knowledge of the C calling convention (as opposed to using a dynamic approach like `libffi`). In particular, our modified `rust-bindgen` generates a new **`extern "C"`** Rust function for each C function binding, which expects the same arguments as the original C function. When calling this generated symbol, the compiler will therefore correctly lay out arguments according to the C calling convention. This process is captured on the left column of Figure 4, for an example C function `randombytes_buf`.

We must now switch protection domains before executing the function. This switch is implemented by a single, generic `invoke` function, implemented once per runtime. The invoke function executes some argument-specific setup code, some common protection setup code, and then dispatches to the target C FFI function. We must ensure that `invoke` is called whenever a C FFI function is invoked. To do this, we alias the C-ABI function symbol for the FFI call directly to the generic `invoke` symbol. This has the effect of translating calls to our generated FFI binding (**`fn`** `randombytes_buf_int` in Figure 4) to calls to `invoke`, allowing the protection domain setup to proceed. This technique effectively allows us to insert custom protection instructions directly into a function prologue, *without modifying* the foreign library or Rust compiler, and without requiring Omniglot users to write any boilerplate code. It does however introduce its own challenge: within the body of the `invoke` function, we do not automatically know which function should be invoked!

To solve this, we pass a combination of runtime and generic arguments to the invoke function (which causes the compiler to monomorphize it into concrete instantiations bound to its generic parameters). Taken together, these arguments allow the monomorphized `invoke` routine to find the function to be invoked, locate the arguments for that function, find the current foreign stack pointer, and finally store the function's returned value. These arguments can be seen in the example in Figure 4. The first two arguments to `randombytes_buf_int` are the arguments for the target C function. Of the remaining invoke-specific arguments, the `&rt` parameter is used to lookup library-specific information (like the location of the foreign stack pointer), the **`*const fn`**`()` function pointer stores the location of the original foreign function (**`int`** `randombytes_buf()`), and the `RetVal` parameter is a container for the eventual return value. The generic argument `AReg2` tells invoke where to find these extra arguments[7].

6 Evaluation

This section evaluates Omniglot using multiple libraries across different application domains and two memory isolation primitives. With our evaluation we show the following:

Omniglot is general. It is able to safely encapsulate libraries with different interface paradigms, across a wide range of application domains. Omniglot further supports a wide range of systems, from high performance desktop and

[7] Its accompanying integer is used to indicate arguments' offset into the stack, whenever arguments need to stack-spill.

Library	Runtime	#invoke	#callback	#upgrade	#validate	unsafe	isolation only		Omniglot	
`CryptoLib`	PMP	14	0	10	2	9105 µs	9145 µs	(+0.44%)	9145 µs	(+0%)
`LittleFS`	PMP	7	0	0	7	3115.3 µs	3742.8 µs	(+20.1%)	3764 µs	(+0.5%)
`LwIP`	PMP	3	1	2	5	51.74 µs	78.71 µs	(+52.1%)	81.4 µs	(+3.4%)
`Brotli`	MPK	2	0	0	4	3.12 ms	3.14 ms	(+0.6%)	3.14 ms	(+0%)
`libsodium`	MPK	1	0	0	2	51.61 µs	53.41 µs	(+3.4%)	53.41 µs	(+0%)
`libpng`	MPK	5	15	16	3	352.98 µs	397.93 µs	(+12.7%)	401.25 µs	(+0.8%)

Table 2: Omniglot overheads for a diverse set of libraries, across two runtimes. We show the number of Omniglot operations per benchmark iteration, and compare its overheads to an unsafe baseline, and memory isolation without Omniglot's runtime checks.

server systems to highly resource-constrained microcontrollers, as well as userspace and kernel environments.

Omniglot is fast. Omniglot's ability to perform zero-copy accesses into foreign memory allows it to efficiently convey data between host and foreign code. As we will show in Section 6.2, this allows Omniglot to outperform related work that delivers similar safety guarantees.

We lift the enforcement of Omniglot's mutual exclusion requirement into Rust's type-system, turning it into a zero-cost abstraction. In this evaluation, we further show that the Rust compiler is able to optimize out validation in many cases and, where it cannot, those overheads are small.

Because Omniglot's overheads are primarily governed by its underlying memory isolation mechanism, it delivers competitive performance to existing systems that do not maintain other safety-critical invariants such as aliasing or type safety.

We consider two case studies: Section 6.1 shows how Omniglot can be used to efficiently integrate existing, unsafe foreign libraries into an operating system kernel. Section 6.2 evaluates Omniglot's support for loading and interacting with widely-used userspace libraries. Table 2 summarizes the results of our measurements across both case studies. Finally, Section 6.3 provides a breakdown of Omniglot's overheads through a series of microbenchmarks.

Experiment Setup. We evaluate two different Omniglot runtimes on different systems. User-space Linux evaluations run on a CloudLab Wisconsin `c220g5` node with two Intel Xeon Silver 4114 CPUs at 2.2 GHz, and frequency scaling and hyperthreading disabled, using rustc 1.84.0-nightly and Linux 5.15.0. The benchmark process is pinned to a single CPU core. Kernel evaluations run using a port of the Tock operating system[8], on a ChipWhisperer CW310 FPGA with the OpenTitan EarlGrey silicon root-of-trust design[9] and a RISC-V `rv32imc` CPU at 24 MHz.

6.1 Case Study: Tock Kernel

Tock is an operating system commonly used in security-critical resource-constrained systems. Its kernel is written in Rust and its design goes to significant lengths to minimize the use of unsafe Rust. Nonetheless, practical deployments of Tock often rely on foreign libraries to implement critical operations. We evaluate OG_{PMP} on three such libraries, across a range of application domains and interface paradigms.

We evaluate the OpenTitan CryptoLib library by encapsulating its HMAC-SHA256 algorithm. The results in Table 2 show the execution time, as well as the number of Omniglot operations performed in a single HMAC operation over 4 kB of data, carried out in batches of 512 B. Because this benchmark requires Omniglot to copy data into the CryptoLib's memory, enabling PMP-based memory isolation increases execution time by 0.44%. Omniglot's runtime checks (during *upgrade* and *validate*) introduce no measureable overhead in this case. In this benchmark, Omniglot tracks only a single allocation in the foreign library, its *HMAC context*, making upgrade operations fast. Furthermore, Omniglot requires developers to *validate* the returned *HMAC* tag. However, because this tag is a simple byte-array, and a `u8` integer is an unconditionally valid type, the Rust compiler is able to optimize such validation away entirely.

Additionally, Omniglot supports libraries that maintain state between calls. We evaluate OG_{PMP} on LittleFS, a filesystem library. We repeatedly format the filesystem, mount it, create and open a file, write 1 kB UTF-8 code points to it, read the data back, and then close the file. In this benchmark, we compare the contents of the file with the original string. To do this, Omniglot forces us to validate that the returned buffer is a valid Rust string (*i.e.*, valid UTF-8). This operation is linear in the amount of data to validate, and explains OG_{PMP}'s overhead of 0.5% compared to memory isolation.

Finally, we demonstrate Omniglot's ability to handle callbacks. We do so by evaluating OG_{PMP} with the LwIP embedded network stack. Our benchmark sends an ICMP echo request by allocating a new buffer, copying the packet, and injecting it into the network stack. In response, LwIP invokes a

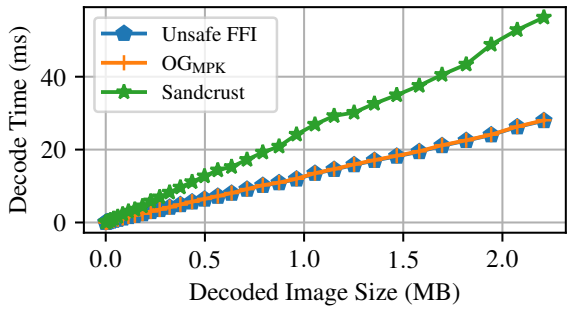

Figure 5: Execution time of decoding a PNG image, as function of the decoded image size. We compare OG_{MPK} against an unsafe FFI baseline and Sandcrust. Omniglot's ability to perform zero-copy accesses to foreign memory allows it to outperform Sandcrust, which requires serialization and copying.

(a)	Setup		Invoke	
	PMP	MPK	PMP	MPK
Unsafe	0.17 µs	1.49 ms	0.17 µs	13.74 ns
Omniglot	73.88 µs	4.08 ms	6.57 µs	98.90 ns
Sandcrust		1.79 ms		10.87 µs
Tock Upcall			56.20 µs	

(b)	Upgrade		Callback	
allocs / CBs	PMP	MPK	PMP	MPK
1	0.6 µs	32.30 ns	8.66 µs	230.1 ns
8	1.7 µs	164.1 ns	9.82 µs	364.3 ns
64	9.4 µs	1.10 µs	18.22 µs	1.32 µs

(c) Validate	64 B `u8`	8 kB `u8`	64 B `str`	8 kB `str`
PMP	0.22 µs	0.23 µs	2.74 µs	161.5 µs
MPK	1.67 ns	1.70 ns	359.6 ns	70.94 µs

Table 3: Omniglot's overheads broken down by operation.

callback previously registered with OG_{PMP}, passing a pointer to the ICMP echo response packet. OG_{PMP} needs to upgrade this pointer to a reference to read it, adding an overhead of 3.4% over memory isolation. Using this reference, it is able to directly access and read this response in foreign memory without copies. Nonetheless, the small packet size of ICMP echo requests result in a pronounced memory isolation switching overhead for invocations and callbacks of 52.1%.

6.2 Case Study: Linux Userspace

Our OG_{MPK} implementation makes Omniglot usable for isolating conventional userspace libraries. To demonstrate this, we evaluate OG_{MPK} on three libraries performing data compression, cryptographic algorithms, and image encoding. We also compare the performance and overheads of Omniglot to Sandcrust [18], an IPC and serialization-based approach to isolate untrusted code within a Rust program.

Brotli, a data compression library, and Sodium, a cryptography library, feature similar interface paradigms. Specifically, they perform "one-shot" computations on some input buffer, producing a corresponding output buffer. For Brotli, we benchmark compressing and decompressing 1 kB of UTF-8 encoded English text. Following decompression, we check that the decompressed text equals our input. Similar to LittleFS, Omniglot forces us to perform Rust's string validation for this operation. The overhead of this validation is masked by the long compression routine. For Sodium, we hash 32 kB of random inputs. As the output is a simple byte-array, validation is optimized out by the compiler.

Lastly, we use an encapsulated `libpng` to decode reference images with varying dimensions. Figure 5 shows the runtime of these operations compared to both an unsafe FFI and Sandcrust for a range of output sizes, whereas Table 2 shows the runtime for a 23 kB image (Omniglot's relative overheads decrease in the image size). `libpng` uses a callback to progressively read image data from the host program's memory. It also expects callers into the library to use `setjmp` for handling errors internal to the library. Omniglot does not support this directly, as it expects every function to return normally. We thus create a wrapper in C around these functions, converting a `longjmp` into an error return value.

Figure 5 shows that OG_{MPK}'s performance is close to that of the native, unsafe FFI bindings, while Sandcrust incurs additional overheads increasing with the decoded image size. This is because Sandcrust uses IPC and serialization to shuttle data between host and foreign memory. While this gives Sandcrust strong soundness properties, similar to those of Omniglot, it imposes significant overheads.

6.3 Microbenchmarks

We quantify Omniglot's runtime overheads through a comprehensive set of microbenchmarks. Subtable 3 (a) illustrates the time required to instantiate an Omniglot runtime (*Setup*, measured as time it takes to start the process and run a single foreign function until it returns), and to invoke a single foreign function which returns immediately (*Invoke*). The table shows OG_{PMP}'s *hot invoke* path, where the RISC-V PMP is already configured. When this is not the case, for instance by switching to a different library or process, OG_{PMP} instead incurs an overhead of 10.49 µs (adding 3.92 µs for PMP re-configuration to the 6.57 µs for the *hot invoke* path). We compare Omniglot's overheads across its two runtimes with Rust's unsafe FFI as a baseline. We further compare OG_{MPK} to Sandcrust's IPC-based approach [18], and OG_{PMP} to conventional Tock process isolation.

Omniglot must keep track of the set of allocations and callbacks registered at runtime. Subtable 3 (b) shows that Omniglot's overheads for *upgrade* operations and callbacks are linear in the number of such elements tracked. OG_{PMP} has

higher base-overhead for callbacks compared to OG_{MPK}, as they are implemented similar to a context switch.

Finally, Subtable 3 (c) shows that Omniglot's *validate* is linear in the amount of data validated. However, when types are unconitionally valid, such as fixed-width integer types, the Rust compiler is able to optimize out validation entirely. We can see this in the difference between validating 64 B and 8 kB for `u8` integers.

7 Related Work

Omniglot builds upon a significant body of work in the programming languages, systems, and security communities. The security implications of foreign function interfaces have only recently been recognized as their own class of vulnerabilities. For instance, Mergendahl et al. establishes the concept of *Cross-Language Attacks*, an entirely new set of attack vectors [26]. One way to reduce these vulnerabilities is through static analysis techniques, such as proposed by Li et al. [22].

Omniglot employs intra-process isolation mechanisms similar to a range of contributions [3, 4, 14, 16, 17, 18, 23, 29, 35, 38, 46, 52]. However, each of these require expensive operations such as copying and serialization to maintain soundness, or do not consider it at all. Omniglot is the first system that maintains soundness across interactions with foreign code while supporting zero-copy accesses into foreign memory.

We design a type infrastructure to model and mediate safe interactions with foreign code. This closely relates to work on *Linking Types*, which seek to extend the type system of a host language to encode the behaviors and semantics native to guest (foreign) code [13, 32, 33, 34, 45]. Existing work on linking types is focused primarly on the core semantic questions or type system development, attempting to express foreign semantic guarantees within a host's type system. However, these contributions assume that foreign code is internally correct. Omniglot can safely interact with libraries without reasoning about whether they are correct.

Finally, verification based approaches like eBPF [24, 28], promise safe interactions with untrusted code, with only few or no runtime checks. While these tools are growing increasingly capable and are used in complex settings such as storage functions [51] and network functions [27], they cannot encapsulate arbitrary, untrusted and unmodified libraries. Recent work proposes augmenting the static nature of such verification-based approaches with runtime checks to regain more expressiveness [12].

8 Discussion & Future Work

Deeper integration with foreign languages. Omniglot can isolate untrusted foreign libraries without making any assumptions about their behavior. While this is generally desirable, by exploring deeper integrations with foreign languages we might be able to reduce Omniglot's overheads even further. Additionally, while Omniglot as presented does not prevent a host program from violating soundness in foreign libraries, relying on specific properties of the language in which foreign code was written may allow Omniglot to enforce safety and soundness in foreign code as well.

Other host languages. In this paper, we focus on implementing Omniglot specifically for Rust, a popular choice for safe systems programming today. However, other safe languages have a similar need for sound interactions with foreign code. Future work should explore how Omniglot's concepts can be mapped to other safe languages.

Better host language bindings. Finally, Omniglot is not API-compatible with Rust's existing, unsafe C FFI. While our experience shows that most libraries can be integrated with the Omniglot bindings in a highly mechanical way, Omniglot does not support automatically transforming existing, unsafe usages of foreign libraries to Omniglot's safe APIs. We do argue that Omniglot's API does not place undue burdens on developers though—in fact, even for correct bindings with Rust's unchecked FFI, developers would still need to perform the validations that Omniglot enforces.

9 Conclusion

Software written in type-safe and memory-safe programming languages has to interact with components written in foreign, unsafe languages. A single violation of the language's safety invariants can infringe upon the application's overall safety.

This paper presents Omniglot, a system that preserves soundness of host code in the presence of untrusted foreign code. We demonstrate Omniglot's generality and low overheads by evaluating it on two systems and a diverse set of libraries. We show that Omniglot can safely encapsulate foreign libraries with minimal overheads.

A Artifact Appendix

Abstract

Omniglot is a framework to safely interact with libraries written in foreign languages from within Rust. This artifact contains our research prototype implementation of the Omniglot framework for Linux userspace (x86 MPK) and the Tock embedded operating system kernel (RISC-V PMP). We also include scripts to install any required dependencies for building and running Omniglot, and scripts to generate the evaluation results as presented in the paper. More details are available in the artifact's `README.md` file.

Scope

This artifact demonstrates Omniglot's ability to work across multiple platforms, such as in Linux userspace or resource-constrained embedded systems, and its support for a range of libraries. It allows readers to evaluate the performance and overheads of Omniglot, and validate the claims made in the paper. Specifically, it can reproduce the results of the following experiments:

- Omniglot's overheads for a set of libraries (for both OG_{MPK} and OG_{PMP}, Table 2).
- Omniglot's ability to perform zero-copy accesses into foreign memory (Figure 5).
- Omniglot's overheads broken down by operation (for both OG_{MPK} and OG_{PMP}, Table 3).

Contents

The artifact contains the implementation of Omniglot, its two runtime implementations, and other dependencies. The Omniglot framework is implemented as a set of Rust crates, split across multiple repositories available on GitHub in the `omniglot-rs` organization (`https://github.com/omniglot-rs`):

`omniglot`: Contains shared infrastructure and implementations of the reference and validation types (see Section 4).

`omniglot-mpk`: Contains the implementation of the OG_{MPK} runtime for Linux userspace, as well as bindings and benchmarks for the libraries evaluated using this runtime (see Section 6).

`omniglot-tock`: Contains the implementation of the Omniglot runtime for the Tock operating system kernel on RISC-V platforms (OG_{PMP}). It also contains bindings and benchmarks for the libraries which we evaluate using this runtime (see Section 6).

`rust-bindgen`: This repository holds our fork of the `rust-bindgen` utility for generating Omniglot FFI bindings from a C header file.

Hosting

The Omniglot framework is maintained under the `omniglot-rs` GitHub organization: `https://github.com/omniglot-rs`.

We provide instructions for reproducing the artifact evaluation through a Zenodo record under the following identifier: doi:10.5281/zenodo.15602886. This record also contains scripts and archived versions of the Omniglot components and dependencies required for reproducing the evaluation results of the paper.

Requirements

Each Omniglot runtime is designed to be evaluated on a specific platform:

OG_{MPK}: The OG_{MPK} evaluations must be run on a system with x86 MPK support. We design our evaluation scripts to run on a CloudLab [11] `cc220g5` node. The included instructions demonstrate how to set up a CloudLab experiment for evaluating OG_{MPK}.

We caution against executing the evaluation scripts on a developer's personal machine, as it installs system-wide dependencies and attempts to make persistent changes to the machine's bootloader configuration.

OG_{PMP}: The OG_{PMP} evaluations expect to be run on a ChipWhisperer CW310 FPGA running the OpenTitan EarlGrey SoC design, built from the OpenTitan repository at revision `bbbd9b0`.

Installation and Experiment Workflow

The artifact's `README.md` file contain detailed instructions on how to prepare the OG_{MPK} and OG_{PMP} evaluation platforms and reproducing the evaluation results.

KRR: Efficient and Scalable Kernel Record Replay

Abstract

Modern kernels are large, complex, and plagued with bugs. Unfortunately, their large size and complexity make kernel failures very challenging for developers to diagnose since failures encountered in deployment are often notoriously difficult to reproduce. Although record-replay techniques provide the powerful ability to accurately record a failed execution and deterministically replay it, enabling advanced manual and automated analysis techniques, they are inefficient and do not scale with modern I/O-intensive, concurrent workloads.

This paper introduces KRR, a kernel record-replay framework that provides a highly efficient execution recording mechanism by narrowing the scope of the record and replay boundary to the kernel. Unlike previous record-replay whole-stack approaches, KRR adopts a split-recorder design that employs the guest and the host to jointly record the kernel execution. Our evaluation demonstrates that KRR scales efficiently up to 8 cores, across a range of different workloads, including kernel compilation, RocksDB, and Nginx. When recording 8-core VMs that run RocksDB and kernel compilation, KRR incurs only a $1.52\times \sim 2.79\times$ slowdown compared to native execution, while traditional whole-VM RR suffers from $8.97\times \sim 29.94\times$ slowdown. We validate that KRR is practical and has a broad recording scope by reproducing 17 bugs across different Linux versions, including 6 non-deterministic bugs and 5 high-risk CVEs; KRR was able to record and reproduce all but one non-deterministic bug.

1 Introduction

Modern kernels are particularly challenging to build correctly because they are huge and exceptionally complex. As a result of growing size and complexity, they are plagued with bugs. The Linux kernel, for example, has more than 30 million lines of source code and Syzkaller alone, a popular automated testing tool, found 3736 bugs in a 3-year span [55]. While many kernel bugs are routinely found through code reviewing and testing, many others end up finding their way to stable releases, leading to production failures in real-world deployments with drastic consequences for users [45–48, 51, 52, 65].

Record-replay (RR) techniques [40, 42, 49, 53, 56, 60, 64, 68] are particularly effective at helping developers diagnose non-deterministic and complex failures like those often found in kernels. At a high level, RR techniques rely on instrumenting a program (or VM) to record all input events that impact its execution into a trace such that, during a replay run, the same input can be fed to the program (or VM), reproducing the execution with 100% accuracy. This allows repeatable executions of the failure and the use of sophisticated offline analysis on the replayed execution, such as reverse debugging [43] and automated and expensive techniques [40]. Because of its accuracy, RR techniques are particularly useful for the most complex bugs. However, despite its appeal and decades of research on record-replay techniques, even the most well-developed record-replay frameworks, like Mozilla RR [56], tend to have very high overheads, particularly under multi-threaded or multi-core environments where the overhead factor exceeds the thread/core count [49, 56, 60].

This work presents KRR, an efficient and scalable record-replay framework that is specially designed to assist kernel developers in diagnosing kernel failures [32, 46, 47]. KRR aims to support modern data center workloads and multi-core VMs with significantly lower overheads than existing approaches. Like other approaches, KRR replays executions at the VM level; however, unlike existing approaches, KRR only records and replays the kernel execution. This approach departs from existing approaches in that the record and replay boundary is a slice of the software stack—the kernel—introducing significant technical challenges and an opportunity for major scalability and performance improvements.

The design of KRR relies on two key observations about modern data center workloads and the state of the art of RR techniques. First, modern workloads are increasingly concurrent; hence, supporting multi-core executions is critical even for emerging data center paradigms like serverless computing. Unfortunately, existing RR tools for x86 VMs have overhead factors that exceed the number of cores for gen-

eral workloads [42, 60]. For instance, recording a 2-core VM adds a 2.3-3.5× overhead [60]. Second, data center workloads are increasingly distributed and I/O intensive, a trend that has motivated the thriving field of kernel-bypassing techniques [33, 58, 59, 72]. Unfortunately, the higher the VM I/O, the more event data needs to be recorded by existing whole-VM RR approaches, increasing recording overheads. Hence, a practical RR tool should support well workloads that are concurrent and I/O intensive, but these workloads are exactly the less well supported by current RR techniques.

This work turns this problem on its head by precisely targeting and exploiting these workloads' properties – concurrency and I/O intensity. Since data centers increasingly use kernel-bypassing techniques to avoid kernel overheads, the bulk of the VM input is no longer kernel input. Hence, recording only the kernel input under these settings can reduce the input that needs to be recorded to replay the kernel when compared with a whole-VM replay. Second, under typical workloads, and even more so under kernel-bypassing workloads, cores are most often not executing kernel code; they are typically executing application code. Therefore, restricting the schedule recording to the kernel execution can significantly reduce the scalability impact on end-to-end user workloads. While combining multi-core VMs and kernel bypass is expected in demanding scenarios, our findings show that the KRR approach offers significant performance improvement even when only one property is present, underscoring its particularly broad utility.

Traditional whole-VM RR requires hypervisor modifications to trap all hardware-level inputs. In contrast, KRR narrows the record-replay boundary to the kernel, recording software inputs such as system calls and user data (e.g., via copy_from_user) alongside hardware inputs. Although this kernel-focused approach appears simple, it introduces fundamental challenges that require a novel split-recorder architecture. KRR divides recording responsibilities between the hypervisor recorder and the in-guest recorder. The in-guest recorder captures software inputs to the kernel and hardware inputs that bypass the hypervisor, while the hypervisor recorder handles remaining hardware events. This design addresses four key challenges: First, KRR must record more event classes than VM-RR, managing two recording interfaces rather than one. Second, it must coordinate cross-layer event recording to establish a total order without costly VM exits. Third, the kernel must serialize itself and record serialization order without hypervisor involvement to avoid VM exits. Fourth, since replay execution is a subset of recorded execution, injecting non-deterministic events requires a new mechanism beyond traditional instruction counts. All these challenges require a careful design of both the record and replay mechanisms.

We implemented KRR on KVM/QEMU and Linux, along with a comprehensive validation mechanism to check correctness through testing. We evaluate KRR against traditional whole-VM RR using real-world applications, including RocksDB and kernel compilation workloads. Our results show that KRR has high recording efficiency and scalability. For example, when recording 8-core VMs that run RocksDB and kernel compilation, KRR incurs only a slowdown of 1.52× ∼ 2.79×—significantly outperforming traditional whole-VM RR, which introduces slowdowns of 8.97× ∼ 29.94×. Furthermore, under kernel-bypass configurations, KRR achieves even lower overhead by allowing guest user-space applications to communicate directly with the hardware, incurring no recording cost on these data paths. Thus, in a 4-core VM running the Redis benchmark, KRR incurs at most 1.05× runtime overhead on throughput, whereas in a 2-core VM running RocksDB, the slowdown ranges from 1.17× to 1.26×. Single-core workloads with kernel-bypass similarly benefit from KRR 's efficient recording design.

To evaluate the effectiveness of recording real-world bugs, we applied KRR to reproduce 17 bugs across different Linux versions, including 6 non-deterministic bugs and 5 high-risk CVEs. KRR was able to record and reproduce all but one non-deterministic bug, showing that KRR is effective at recording and replaying complex and serious real-world kernel bugs, including many non-deterministic bugs.

2 Sliced Record Replay

Record-replay techniques record executions and replay them at a later time, allowing developers to conduct postmortem analysis of faulty executions. Record-replay approaches have been applied at the level of applications and virtual machines. In practice, this approach records all nondeterministic inputs into a trace log and feeds them into another execution, reproducing the control and data path of the original execution, while giving an opportunity for developers to retroactively apply powerful analyses and debugging techniques. These analyses are instrumental to help developers diagnose the most complex failures, such as failures where the root cause is distant from the failure point [37, 40, 73].

Key observations. This work makes two key observations. First, although the kernel is often the most complex system running on a machine, it is not the one that is most often running on a given core. Second, when data-intensive applications use kernel-bypassing, input provided to the kernel can be significantly smaller than the input provided to the machine. Combined, these observations make us question the common approach to recording kernel executions, which relies on recording the non-deterministic inputs of the whole VM. Instead of recording the entire VM execution, we postulate that recording only the kernel execution, i.e., a slice of the stack, may allow us to achieve much better recording performance. However, as explained next, this represents a significant change to record-replay techniques, which currently assume a single interface for the record and replay boundary

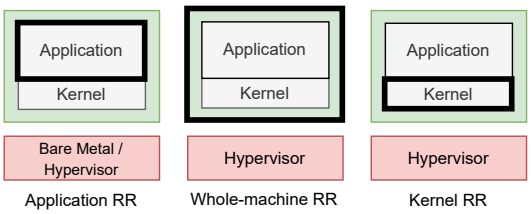

Figure 1: Traditional RR approaches and Kernel RR approach. Record-replay boundary is highlighted in bold.

(e.g., the system call or machine interface), posing unique challenges to the tool design.

2.1 Goals and Assumptions

We aim to build a record-replay framework that (a) records kernel executions, (b) ensures matching, functionally-accurate kernel replays, and (c) achieves high *recording* efficiency. Our goal is to drastically reduce the recording overhead of traditional record-replay frameworks, especially in multi-core environments, to enable recording all executions of large-scale workloads.

Non-goals. Replaying efficiency beyond ensuring sufficient speed for practical debugging is not a goal of this work. Every replayed execution has to be recorded, but often only some recorded executions – those that happen to trigger failures – are replayed. Replaying application executions is not our focus since we aim to help kernel developers find and diagnose kernel bugs. We assume that the kernel is designed to work correctly regardless of the input provided by applications, hence determining why applications provide certain input that leads to kernel failures is out of the scope of this work.

Assumptions. Since we aim to help kernel developers fix kernel bugs, we assume that they can modify the kernel. Furthermore, we assume that the kernel executions run on a virtualized environment, which is typical in the cloud and datacenters, but that developers or data center providers can modify the hypervisor, which is a standard assumption for VM-based techniques. Our design is architecture-agnostic, although our implementation and discussion targets x86 due to its wide adoption in data centers.

2.2 Efficient and Scalable Kernel RR

Accurately replaying executions requires recording all non-deterministic inputs of a given execution. In practice, this means that all the explicit inputs (i.e., inputs provided by users) and implicit inputs (e.g., program schedules) need to be recorded such that they can later be fed into the program, ensuring the same execution behavior during replay.

To record and replay kernel executions, the state-of-the-art approach records the whole system execution (Whole-machine RR in Figure 1). In practice, this is done with a modified hypervisor that records all the VM (implicit and explicit) inputs. By running the target kernel inside a VM, the record and replay boundary becomes the entire VM. In contrast to the prior approach, KRR restricts the *recording and replaying boundary* to the guest kernel from the entire VM (Kernel RR in Figure 1), therefore avoiding the unnecessary cost of recording the guest applications.

At first glance, it may appear that by recording a smaller layer of the software stack (i.e., the kernel layer), the recording overheads become smaller. But the size of the layer does not directly determine the costs. In fact, reducing the RR boundary to the kernel could increase costs because a sliced recording that only targets the kernel would require recording (a) the hardware input provided to the kernel (e.g., data read from the disk or network and interrupt timings) and (b) the input provided by applications to the kernel (e.g., system calls invoked by the applications). Whereas recording the VM execution would only require recording the former source of (explicit) inputs. Despite this additional cost to the sliced RR approach, there are two factors that make KRR not just viable but significantly more efficient and scalable than whole-machine RR.

Adoption of kernel-bypass workloads. Because datacenter workloads increasingly use kernel bypassing for higher performance, the input provided to the kernel can actually be smaller than the input to the machine. Hence, under kernel-bypassing workloads, restricting RR to the kernel boundary can reduce the number of recorded events, thereby increasing recording efficiency.

High cost of schedule recording. The typical Achilles heel of RR techniques is parallelism. The few RR systems that support multi-core machines (or multi-thread applications) on commodity hardware primarily do so by serializing the execution of multiple cores (or threads) [56], which cancels the parallelism benefits, or recording memory access orderings, which has comparable or higher costs [42, 60]. Thus, the state-of-the-art RR techniques for x86 have overheads that exceed the number of cores for general workloads (e.g., 2.3-3.5× overhead for a 2-core VM [60]), canceling the performance benefits of using multi-core machines. Sliced RR that selectively targets the kernel can drastically mitigate this cost, at the end-to-end level, by only serializing the execution of the kernel while allowing full application parallelism. Since in many workloads, the vast majority of the CPU time is spent in user mode, sliced RR can scale kernel recording to several cores on commodity hardware with low CPU overhead. It is worth noting that despite the use of serialization to handle parallelism, as discussed later (§3.3), fine-grained serialization is effective even at recording failures that trigger non-deterministic, including important classes of concurrency

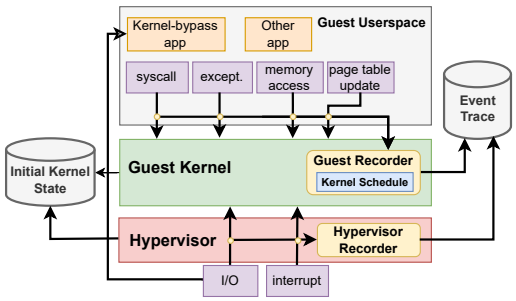

Figure 2: KRR Split Recorder Architecture.

bugs.

3 KRR Design

KRR's unique recording boundary imposes two major design challenges. First, while existing record-replay systems focus on either the user-space (application RR) or hardware interface (whole-machine RR), KRR must simultaneously record both interfaces, as illustrated in Figure 1. This dual-interface recording requirement creates significant architectural challenges. Traditional approaches can record from a higher-privilege level—using the kernel to record the application, or the hypervisor to record the VM. However, neither interface provides a good vantage point to effectively record both interfaces given the limited visibility from each interface. The second challenge lies in the recording efficiency. Because the kernel frequently interacts with user space and hardware and often with fine granularity, intercepting communications over these two interfaces can be expensive, particularly when recording from the hypervisor. Naively recording even just some event types could cause frequent VM exits or require expensive introspection mechanisms that we cannot afford.

To address these challenges, KRR employs a split-recorder design (Figure 2) that uses an in-guest recorder and an in-hypervisor recorder to collaboratively record the kernel execution. This design enables KRR to record both interfaces effectively and with low overhead. Together, the two recorders record all non-deterministic events that impact the kernel execution and output a recorded trace of events in total order, allowing KRR to accurately reproduce the slice of the kernel execution during replay by injecting the recorded events one by one. Specifically, KRR records three types of events: (1) all inputs provided to the kernel (§3.1 and §3.2), (2) the kernel schedule and other non-determinism (§3.3), and (3) the initial state of the kernel (§3.4).

3.1 Kernel Input from User-space

KRR implements an in-guest recorder that monitors all input, both directly and indirectly, provided to the kernel by applications. The guest recorder runs in the guest kernel and intercepts the kernel's accesses to software input. Fortunately, the kernel interface is generally very well defined for maintainability and security reasons, making it practical to determine the source code locations where the kernel receives input. The in-guest recorder handles several sources of software input.

System Calls. Applications invoke a system call by requesting the index of the desired call and passing the respective arguments. Thus, correctly replaying the system call requires recording the requested call index and the arguments. To do so, the guest recorder monitors the common entry point of system call handlers. When a system call request is received, the guest recorder accesses the CPU registers to get the call index and parameters.

User-Memory Accesses. The kernel can read user-space memory to fetch application structures, buffers, and for other reasons, which therefore constitutes another type of input event for the guest recorder to monitor. For instance, to fulfill a `write()` system call, the kernel needs to read the user-space memory to fetch the contents to write. In abstract, monitoring user-memory accesses is challenging because the kernel can make the read accesses at arbitrary points during its execution. An interesting observation that makes our solution particularly feasible is that modern kernels treat user-memory reads as security-sensitive operations due to their potential as attack vectors. As a result, such reads are performed through a small set of internal APIs that have been thoroughly reviewed and hardened with security features such as the x86 SMAP extension. This design property allows KRR to reliably record user-memory reads by instrumenting well-defined API functions such as `copy_from_user` and `get_user` [30]. When the kernel reads data from user-space through the instrumented functions, KRR inspects the corresponding destination kernel-space memory to record the copied content. Importantly, KRR does not access the user-space memory directly for recording, thereby avoiding consistency issues such as double reads (e.g., TOCTOU [29]).

Additionally, the kernel's execution could be affected by inputs from memory that is shared between the kernel and user-space. A typical example is `io_uring` [15], which uses shared circular queues for asynchronous I/O operations. With `io_uring`, the kernel directly accesses the submission queue in the shared memory region, which the user-space can access and modify at the same time. KRR records this type of kernel input by instrumenting kernel reads to both the submission queue and its entries in the guest recorder, ensuring that user inputs via this shared memory are captured deterministically. This approach is also applied to other mechanisms, such as inter-process communication (`process_vm_readv`), and can be extended to other shared-memory inputs that affect kernel behavior.

Page Table Updates. In addition to the explicit inputs described above, user-space execution can implicitly influence

kernel behavior through changes to the page table state. Specifically, when applications access memory, these accesses may update the `accessed` and `dirty` bits in the corresponding page table entries. These updates, in turn, can affect the kernel memory management, as the kernel relies on those bits to make decisions such as page replacement. To record the page table entry update, KRR instruments kernel accesses to the entries and records their exact values. This approach is generic and can record other forms of implicit inputs if needed. In practice, our comprehensive validation and evaluation (§4.1, §5) suggest that page table state changes are the only typical implicit input provided by processes, and recording these changes is sufficient to ensure accurate replay.

3.2 Kernel Input from Hardware

Hardware inputs (interrupts, I/O read, and device DMA) are primarily recorded by the hypervisor recorder, while non-deterministic instructions and exceptions are recorded by the guest to avoid introducing VM exits.

Interrupts and Exceptions. The hypervisor recorder intercepts every interrupt to record the interrupt type (i.e., vector number), timing (§3.2.1), instruction pointer (RIP), and all general-purpose registers that may be accessed during interrupt handling. For example, RCX register is accessed to identify the position within repeating string instructions [42, 60], and RIP is accessed to handle restartable sequences [18].

Because KRR only records the kernel slice of the execution, exception handling, such as those caused by division by zero from user-space, are no longer deterministic events in every situation. In particular, exceptions triggered by applications need to be recorded and injected during replay by KRR. For each exception, KRR records the exception number, all general-purpose registers, and any additional machine state required by each specific exception handler. For instance, when recording page faults on x86_64, the guest recorder additionally records the faulting memory address and error code stored in the stack memory.

I/O Operations. KRR records the data read by the kernel from hardware devices through port I/O (i.e., `IN` and `OUT` instructions), memory-mapped I/O (MMIO), and DMA accesses. Since they are handled by the host hypervisor, KRR uses the hypervisor recorder to monitor these events. When an I/O read request is intercepted, the hypervisor records it only if initiated by the kernel. By excluding I/O requests from guest user-space applications, KRR significantly improves recording efficiency for kernel-bypass workloads (§5.2).

Other Non-deterministic Instructions. Because some instructions produce non-deterministic results, KRR needs to record their results to ensure correct replay. On x86, this includes instructions such as `RDTSC`, `RDTSCP`, `RDSEED`, and `RDRAND`. While a common approach is to trap and record them from the host hypervisor [60, 64], KRR instead records them with the guest recorder to avoid expensive VM exits. This shows another advantage of choosing the kernel as the record boundary – it would be impractical to ensure that these instructions are consistently recorded for every application in a VM-RR approach by modifying all applications, since there is no intra-VM trap mechanism for these instructions in x86. However, it is practical to manually modify a single system (the kernel, in our case) to intercept them.

3.2.1 Asynchronous Event Timing

Unlike other hardware inputs, interrupts and DMA accesses are asynchronous events. Thus, their timing has to be recorded precisely so that KRR can replay them at the exact same point observed during recording. To achieve this, KRR leverages x86 kernel-mode-only hardware counters to track the number of executed kernel instructions during recording. When the interrupt or DMA event happens, KRR records the counter value as its timing signature, enabling accurate replay by injecting the event at the same instruction count.

To prevent conflicts with the guest kernel over hardware performance counter usage, KRR takes advantage of the multiple counters available on modern processors (e.g., Intel processors typically provide four programmable counters per core [13]). KRR reserves one counter for its exclusive use, leaving the remaining counters accessible to the guest kernel. This is achieved by intercepting the `CPUID` instruction's output to mask the reserved counter, thereby making it invisible to the guest.

3.3 Kernel Schedule

A common approach to ensure accurate record and replay on concurrent software is to serialize the multi-thread execution—allowing only one thread to run at a time—thereby resolving data races and other schedule-non-determinism during recording. However, while this approach guarantees correct replay, it can impose substantial performance overhead by preventing parallelism. To address this limitation, KRR takes advantage of its reduced recording boundary. Since KRR records the kernel execution exclusively, it only has to serialize the concurrent kernel execution, while still allowing user-space threads to run in parallel.

In addition, unlike other approaches that serialize at the hypervisor-level [44], KRR serializes the execution from the guest kernel, avoiding expensive VM exits on every kernel-user space transition. KRR uses a special-purpose spinlock from the guest kernel, ensuring that only one vCPU core can execute in kernel mode. Although this approach may seem simple, not using the hypervisor to control the schedule requires a careful design, as discussed next.

Replay-Coherent (RC) Spinlock. While the serialization spinlock is integrated into the guest kernel, its execution

should not be replicated during replay since it is, conceptually, a component of the recorder and it would slow replay. Even more importantly, a normal spinlock is itself non-deterministic, meaning that the spin count (instructions executed by the spinlock) and its outcome depend on the schedule. If left unhandled, the outcome of a normal spinlock would not match across record and replay. Furthermore, even if the outcome of the spin lock is recorded, the spin count difference across runs would make the instruction count inconsistent across runs, preventing KRR from using the instruction count to decide when to inject interrupts and other asynchronous events that are timing-dependent (§3.2). After exploring several approaches to address this problem, including relying on expensive VM exits, we concluded that a simple modification to the spinlock is sufficient to solve this problem. KRR introduces a new spinlock design, the RC spinlock, that counts the number of cycles (instructions executed) before it is acquired as well as the acquisition ordering, which KRR records as events. This allows KRR to enforce the same ordering and adjust the instruction count to match the recorded values during reply, thereby reproducing the exact multi-threaded kernel execution

Deadlock Prevention. KRR manages kernel execution serialization through its RC spinlock. The vCPU acquires this lock when (a) entering kernel mode (through system calls, interrupts, or exceptions) or (b) waking from an idle state, and releases it when (a) returning to user-space or (b) entering the idle state.

However, this basic locking scheme can lead to deadlocks. For example, when a thread holding the RC spinlock waits for an internal kernel lock that is owned by another thread, which in turn is waiting for the RC spinlock. To prevent such deadlocks, KRR adds another acquisition/release point: the kernel releases the RC spinlock before acquiring certain internal locks (including the CSD lock [17] and spinlock) and reacquires it afterward.

When multiple vCPUs wait for the same internal lock, KRR applies a similar strategy as used for the RC spinlock - recording the acquisition ordering to ensure correct replay. Since the waiting time at internal locks is non-deterministic, KRR uses hypercalls to synchronize instruction counts between record and replay runs. While hypercalls incur VM exits, these synchronization points are not common during normal kernel execution, resulting in a low performance impact.

Bug Recording Scope. Like other practical record-replay tools, KRR affects executions through subtle changes to the timing of events due to instrumentation overheads or the serialization mechanism, making some failures potentially harder or easier to trigger. Despite the use of serialization, KRR can record concurrency bugs, as our experience shows. This is possible because KRR allows concurrency, although at a coarser grain than native executions, through interrupts and context switches. To empirically assess KRR's ability to reproduce real-world bugs, we evaluated it on a diverse set of Linux kernel bugs (details in §5.3). The results show that KRR successfully reproduces 16 out of 17 randomly-sampled bugs, encompassing 5 out of 6 non-deterministic bugs and all five tested kernel CVEs. This validates its effectiveness for a broad spectrum of real-world kernel problems, including several concurrency-related bugs. §6 discusses further the scope of the recorded executions.

3.4 Initial Kernel State

KRR allows users to start recording the guest kernel execution at arbitrary points during the VM lifetime. This selective recording capability is particularly useful in performance-critical cases where only specific execution periods are recorded due to lower overhead tolerance (e.g., during intensive workloads).

Once recording starts, KRR takes a memory snapshot of the VM. Unlike traditional VM-RR, KRR requires only a kernel memory snapshot for replay, presenting a significant optimization potential. Snapshotting only kernel memory, instead of the entire VM's memory, can substantially improve snapshot efficiency and reduce storage costs, particularly for VMs with large amounts of user memory. This snapshot is then used in the replay to ensure that the event trace is applied to a kernel execution that starts from the same initial state (§3.5). Currently, KRR uses synchronous snapshotting where the guest's execution is paused during snapshot creation to ensure state consistency. However, future work could adopt techniques, such as asynchronous snapshotting [1] and efficient fork, like on-demand fork [74] and others [69], to further reduce the performance impact of snapshotting operations.

3.5 Replayer

During replay, KRR reconstructs kernel execution through a carefully orchestrated process. KRR first loads the VM snapshot and follows the recorded event trace to recover the original execution environment. The system employs several techniques to ensure identical execution: vCPU thread scheduling based on logged execution order, memory state recovery using VM breakpoints to intercept memory accesses to user-space memory, hardware input replication during I/O operations, and precise timing control through instruction counting to inject asynchronous events at the exact points they occurred during recording.

Replay Debugging. Since performance is less critical during replay, we implemented our KRR prototype replayer using the QEMU emulator, which has the advantage of simplifying introspection and providing a convenient kernel debugging environment through GDB integration. Our implementation allows developers to use powerful debugging features including breakpoints, watchpoints, and automation scripts [16] to analyze the kernel behavior during replay. Moreover, other

binary analysis techniques [37, 40, 61] can be integrated into KRR, allowing developers to track memory accesses, monitor register changes, and analyze execution paths at instruction-level granularity.

Reverse Debugging. Reverse debugging [11] enables developers to navigate backward through a program's execution history to examine how a particular state was reached. This capability is invaluable for diagnosing complex bugs whose root causes are difficult to pinpoint with forward-stepping debuggers alone.

To implement reverse debugging, KRR augments its standard kernel replay by also periodically taking VM snapshots, each tagged with the instruction count. To start reverse debugging, e.g., a backwards instruction step, KRR performs a two-stage process. First, it identifies and loads the last VM snapshot that was captured before the target backward point. Second, it replays the execution forward from the snapshot, using the recorded event trace, until the exact desired execution point is reached. This approach is conceptually similar to QEMU's native reverse debugging [20].

However, robust reverse debugging for multi-core VMs presents challenges not addressed by existing approaches [21, 40]. In multi-core systems, each vCPU progresses independently, making a single instruction counter insufficient to uniquely define the system state for consistent reverse execution. To overcome this, KRR introduces a *multi-core execution coordinate*: a vector of per-vCPU instruction counts captured during replay. Both snapshots and past breakpoints are tagged with these coordinates during replay. During a rollback to the last breakpoint, KRR loads the closest prior snapshot and replays forward until the target coordinate is reached, restoring both VM state and replay progress to ensure consistency.

4 Implementation

We implement KRR based on Linux-KVM (5.17.5) and QEMU (7.0.0). We develop the guest recorder on Linux 6.1.0 and then port it to different kernel versions, ranging from 5.10 to 6.1 (§5.3). The modifications to KVM, QEMU, and the guest Linux are around 1.2k, 4.5k, and 1.2k lines of C code, respectively.

Guest Recorder. KRR implements a kernel recording library with 16 APIs that record system calls, exceptions, user-memory access, page table accesses, non-deterministic instructions, and RC spinlock operations. The library, implemented in about 1.2K LoC C code, is used to instrument 37 kernel source files for recording these events. The recording library also facilitates compatibility and portability across kernel versions. When using KRR to reproduce known kernel bugs (§5.3), we are able to support 13 unique kernel versions ranging from 5.10 to 6.1. Supporting a new kernel version typically requires less than 30 minutes to apply our patch files and resolve code conflicts.

Hypervisor Recorder. We implement the hypervisor recorder in KVM/QEMU to capture hardware-related events. The implementation consists of modifications to KVM (0.8K LoC) and QEMU (1.2K LoC), providing 5 instrumentation interfaces for recording. In total, we modify 7 files across the KVM/QEMU codebase. We instrument KVM's interrupt injection function to record interrupt information and extend PIO & MMIO emulation functions to record I/O read results.

Hypervisor recorder records data from both the emulated disk and network interfaces, with each requiring different handling strategies due to their distinct access patterns. For disk I/O, KRR records data written to device DMA memory regions and pairs each DMA buffer chunk with its triggering disk I/O instruction (e.g., IDE DMA read command). This pairing, along with the timing information, enables precise injection of recorded DMA data during replay when the kernel executes the corresponding I/O instruction. Network I/O presents a unique challenge due to Linux's NAPI mechanism [19]. NAPI allows concurrent access to the network ring buffer by both the kernel and the device, creating potential data races. KRR addresses this by trapping the vCPU in kernel mode before the device writes to the network ring buffer, similar to VMware FT's network I/O synchronization approach [63]. During this trap, KRR records both the data written to the ring buffer and the current instruction count, enabling accurate replay of network inputs. For kernel-bypass devices, KRR provides a QEMU parameter that allows users to specify which device inputs should be ignored during recording.

Atomic and Ordered Event Recording. Because KRR uses both the guest kernel and hypervisor recorder to record input events, it is critical that the event trace is updated atomically and sorted in the correct order (i.e., by occurrence time). To guarantee atomicity, KRR grants exclusive access to the event trace only to the RC spinlock owner vCPU. When one recorder is updating the event trace, KRR disables the interrupt for the guest and pauses the corresponding vCPU core on which the event happens until the event is recorded into the trace. By doing so, KRR ensures that only one recorder can update the event trace at a time.

While KRR serializes kernel execution, interrupts may still occur concurrently on multiple vCPUs that are in user mode, making it challenging to order these interrupt events correctly. KRR's recorded ordering of RC spinlock acquisitions (§3.3) ensures these interrupts are properly ordered according to the serialized execution.

4.1 Validation

We run the test suite from Linux Test Project (LTP) to test the correctness of our prototype. In the recorded execution, at every *N-th* instruction, we log the instruction pointer (RIP), the instruction counter (i.e., number of executed kernel instructions) and all `x86_64` registers, including control, general-

purpose, and segment registers. During the replay, we assert that the replayed execution shows consistent states at every *N-th* instruction. We use the value 1K for *N* by default and increase it to 32K if too frequent logging causes test timeouts during recording. Overall, KRR can successfully replay the kernel execution of 8,156 LTP tests, demonstrating its high recording accuracy.

5 Evaluation

This section evaluates KRR along the following questions:

RQ1: Can KRR efficiently record multi-core workloads? (§5.1)

RQ2: What is the recording performance of KRR on kernel-bypass workloads? (§5.2)

RQ3: Can KRR record/replay complex kernel bugs? (§5.3)

RQ4: What is the storage cost of KRR? (§5.4)

RQ5: What is the replay performance of KRR? (§5.5)

Experimental setup. We evaluate the record/replay performance of KRR on the CloudLab platform [3] using instances of machine c6420, which is equipped with two 16-core Intel Xeon Gold 6142 CPUs (hyper-threading and cstate disabled), 384 GB RAM, and a dual-port Intel X710 10GbE NIC for performance. In addition, we evaluate the effectiveness of KRR in reproducing kernel bugs on a separate machine with a 2-core Intel i7-7660U CPU and 16GB RAM. We run the modified Linux kernel 5.17.5 on the host, and 6.1.0 on the guest in the default recording performance evaluation. For the bug reproduction in §5.3, we run 13 unique guest Linux kernel versions ranging from 5.10 to 6.1.

VM-RR. Our evaluation compares the recording performance between KRR and the whole-machine RR approach(Figure 1). A direct comparison with prior whole-machine RR implementations is unfeasible for several reasons. First, some implementations are proprietary or have been deprecated [42, 64]; thus, they are inaccessible to us. Second, despite our considerable adaptation efforts, the old codebase of some systems caused compatibility issues on modern hardware [60]. Third, the other alternatives lack multi-core VM support or critical hardware-assisted virtualization capabilities, such as KVM, which are central to our work [21, 40]. Thus, to enable a fair and relevant comparison, we implemented VM-RR, a whole-machine RR prototype using the same version of QEMU and KVM as KRR, which is the fastest implementation we have access to (§4).

VM-RR differs from KRR in three aspects. First, it uses the traditional, wider recording boundary: VM-RR captures all hardware inputs to the VM, including non-deterministic events (e.g., interrupts), the results of non-deterministic instructions, and data from device I/O reads. KRR, in contrast, must also record inputs from the guest user-space to the kernel (§3.1) but does not record VM input that bypasses the kernel. Second is the handling of non-deterministic instructions (e.g., `RDTSC`): VM-RR relies on hypervisor traps to capture their output, whereas KRR uses its in-guest recorder to log these values, avoiding expensive VM exits (§3.2). Third, VM-RR enforces determinism through full-system serialization, allowing only one vCPU to execute at any time. vCPUs are scheduled via FIFO, each running for up to a 50K instruction time slice. While this serialization incurs overhead, like it does in KRR, it is a standard technique in prior deterministic systems [44, 46, 56]. Importantly, our evaluation results (§5.1.2) demonstrate that VM-RR's performance overhead is comparable to that of existing deterministic record-replay systems on multi-core workloads, affirming its validity as a representative baseline.

Methodology. To understand the recording overhead of KRR and VM-RR, we measure the system performance both with and without recording enabled, using the native execution (no recording) as the baseline. We conduct multiple trials of each experiment and report the average result. To ensure consistent measurements across trials, we clear the host page cache, pin every vCPU thread to a dedicated physical core, and boot the VM from scratch between trials. Our evaluation graphs present both the absolute measurement values and the relative slowdown caused by recording.

5.1 Recording multi-core workloads

This section evaluates the recording overhead of KRR on modern applications, with a focus on scalability.

5.1.1 RocksDB

First, we compare KRR and VM-RR on a modern key-value store, RocksDB [41], using its built-in benchmark suite [2]. We run multi-threaded workloads, aligning the number of threads with the available vCPU cores, to understand the recording overhead for concurrent RocksDB operations.

Throughput. Figure 3 illustrates the substantial performance disparities between VM-RR and KRR when recording multi-core RocksDB workloads. While all workloads demonstrate strong multi-core scaling under native execution, their throughput under VM-RR decreases greatly as the number of cores increases. Notably, with VM-RR, RocksDB performs worse on multi-core VMs than on single-core VMs across all workloads. In contrast, KRR introduces considerably lower overhead. On single-core VMs, KRR is expected to be slower than VM-RR because it needs to record userspace inputs while VM-RR does not (§3.1). However, contrary to this expectation, VM-RR is observed to be slower than KRR on certain workloads, despite avoiding userspace input recording. Our analysis shows that this is because VM-RR incurs significant overhead when handling `RDTSC` instructions, as

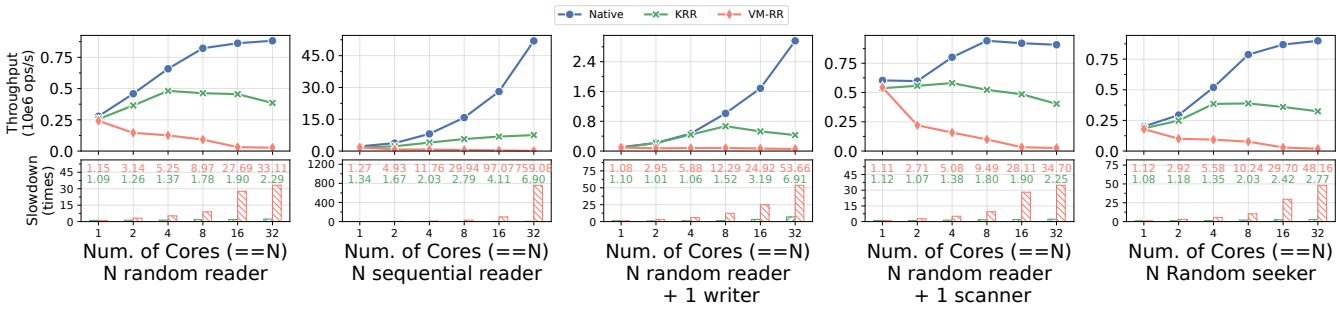

Figure 3: RocksDB benchmark throughput. Slowdown is the ratio between the native and recording throughput.

each instance necessitates a costly VM exit. The performance impact becomes substantial with higher instruction frequencies. For example, the *random reader* and *random seeker* benchmarks incur over 18k and 14k `RDTSC` instructions per second, respectively, while other benchmarks incur less than 7k. On 2-core VMs, KRR incurs a slowdown ranging from 1.01× to 1.67×, and on 4-core VMs, the slowdown ranges from 1.06× to 2.03×. These slowdowns are markedly lower than those observed with VM-RR, which range from 2.71× to 4.93× on 2 cores and 5.08× to 11.76× on 4 cores. Due to this moderate overhead, KRR enables most workloads to achieve increased throughput as the number of cores increases from 1 to 4. However, beyond 8 cores, RocksDB's throughput, under KRR, begins to decline. Our investigation reveals that the increasing lock contention on large VMs is the primary performance bottleneck.

Latency. The latency measurements mirror the throughput patterns described above. From 2-core to 8-core VMs, the operation latency under VM-RR, is slower than the native by 2.73× ∼ 29.99×, while for KRR, the latency is only increased by 1.01× ∼ 2.80×.

5.1.2 Kernel Compilation

We next evaluate KRR and VM-RR using a code compilation workload on VMs with 1, 2, 4, 8, 16, and 32 vCPU cores and 8GB of memory. Within the VM, we compile the Linux kernel 6.5.1 using the command `make -j $(#cores + 1)`. The number of worker threads is set to one more than the number of cores to better saturate the CPU [42, 60].

Figure 4 presents the compilation time with and without recording and the slowdown caused by KRR and VM-RR. On a single-core VM, both KRR and VM-RR introduce moderate slowdowns of 1.15× and 1.11×, respectively. The slightly higher slowdown observed with KRR is because KRR needs to additionally record guest user-space inputs to the kernel, whereas VM-RR records only hardware inputs. However, the scaling behaviors of KRR and VM-RR diverge significantly when recording multi-core VMs, where concurrency-induced non-determinism must be recorded. With KRR, kernel compilation scales effectively up to 8 cores, resulting in only 22%

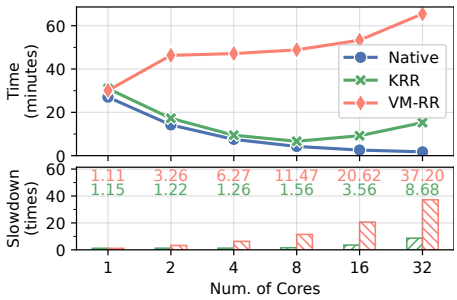

Figure 4: Linux Kernel build time. Slowdown is the ratio between the recorded build time and the native build time.

and 56% slower than the native on 2-core and 8-core VMs. In contrast, with VM-RR, kernel compilation does not scale with more CPU cores. The performance under VM-RR is 226% and 1047% slower than the native on 2-core and 8-core VMs. Similar to the RocksDB workload, kernel compilation, under VM-RR, performs worse on multi-core VMs than on single-core VMs. This finding aligns with prior work on whole-machine RR [42, 60], which reported that kernel build performance on 2-core VMs is slower than on single-core VMs.

For VMs with 16 and 32 cores, KRR's kernel build no longer benefits from more CPU resources. The performance downgrade, similar to the results observed with RocksDB, stems from the increased lock contention between vCPUs as the VM size grows.

5.2 Recording Kernel-bypassing Workloads

The difference in recording boundaries allows KRR to achieve significantly lower overhead when recording kernel-bypass workloads. The following section quantifies the recording efficiency of KRR on three modern kernel-bypass applications: RocksDB (§5.2.1), Redis (§5.2.2), and Nginx (§5.2.3).

5.2.1 RocksDB with SPDK

We run RocksDB with SPDK to directly access the disk from the user-space. In this experiment, we run several single-threaded RocksDB workloads in a 2-core VM with 8GB of memory and an emulated NVMe device. Following the SPDK best practices [27], we pin the RocksDB worker thread to one vCPU core and the SPDK polling thread to another, which continuously monitors the NVMe device state and handles I/O requests from the worker. The NVMe device is emulated on a standard SATA disk with our modified QEMU (§4) that implements NVMe data recording, which is necessary for VM-RR and KRR—under the non-kernel-bypass mode—but is not supported by existing NVMe devices.

Throughput. Figure 5 compares the throughput of different RocksDB workloads with and without SPDK. The results show that several workloads benefit from bypassing the kernel for I/O handling. For instance, in the *1 sequential writer* workload, RocksDB-SPDK achieves 3.27× higher throughput compared to RocksDB without SPDK. However, when VM-RR is used for recording, RocksDB-SPDK experiences significant performance degradation. Specifically, the throughput decreases by 29.37× in the *1 random appender* workload and 64.51× in *1 sequential deletion*. These slowdowns are substantially greater than those observed with standard RocksDB using kernel I/O, which exhibits slowdowns ranging from 1.67× to 2.30×. The severe performance degradation results from the whole-system serialization approach in whole-machine RR: when VM-RR blocks the CPU core running the SPDK polling thread but allows the core running the worker thread to execute, the worker thread stalls on pending I/O requests despite having CPU time. In contrast, the RocksDB worker can progress normally when using kernel I/O.

Conversely, KRR achieves reasonable recording overhead with RocksDB-SPDK by allowing user-mode polling threads to run alongside workers. For write workloads, KRR's overhead on RocksDB-SPDK is 10% $\sim$ 22.7% lower than on traditional RocksDB, primarily because SPDK drastically reduces both system calls (by 77% $\sim$ 94%) and userspace-to-kernel data copies (by 94% $\sim$ 99%). The *Sequential reader* benchmark also shows substantially lower slowdown under SPDK, as KRR does not need to record the substantial DMA data transfers that dominate this workload's intensive disk I/O operations.

Latency. When using kernel I/O, KRR consistently outperforms VM-RR with a much lower impact on operation latency. KRR's slowdown is within 1.14× $\sim$ 1.54× across all workloads, while VM-RR's slowdown is between 1.67× $\sim$ 2.33× For RocksDB with SPDK, VM-RR slows down its latency by 29.36× $\sim$ 64.51× compared to native execution. In contrast, KRR marginally affects the latency of RocksDB-SPDK, with slowdowns ranging from 1.17× to 1.27×.

5.2.2 Redis with DPDK

Next, we evaluate KRR on Redis with kernel-bypass. The evaluation utilizes two inter-connected c6420 machines on CloudLab: one for hosting the Redis server inside the VM, and another for running the Redis benchmark [24]. The VM is configured with 4 vCPU cores, 8GB memory, and has direct access (i.e., passthrough) to the dual-port Intel X710 10GbE NIC. Within the VM, we deploy the Redis implementation from the f-stack kernel-bypass framework [10], which leverages DPDK [9] for direct network card access. The client machine runs the Redis GET and SET benchmarks separately with 5 million requests and different numbers of concurrent client threads $\in \{1,2,4,8,16,32,64\}$. Due to the lack of data recording support in the physical NIC under this setup, VM-RR is unable to accurately record all hardware inputs to the VM. Thus, it is excluded from this evaluation.

Figure 6 shows that KRR can efficiently and scalably record the guest kernel under the Redis-DPDK workload, Across all numbers of concurrent clients, KRR only reduces the GET throughput by 0.26% and the SET throughput by 1.14% on average. Additionally, the P99 latency measurement exhibits slowdowns ranging from -5.19% to 11.27%. The minimal recording overhead is because the guest kernel receives significantly fewer inputs under Redis-DPDK. By delegating the heavyweight data path to the user-space, the guest kernel is primarily responsible for handling the I/O control path, thereby reducing the number of events that need to be recorded.

5.2.3 Nginx with DPDK

Using a similar setup to the Redis-DPDK experiment, we evaluate KRR's recording performance on Nginx with DPDK kernel-bypass (version 1.25.2, implemented in f-stack). On the server side, we use VMs with different numbers of vCPUs $\in 1,2,4,8,16,32$ and run Nginx with the matching number of worker processes. On the client side, we run the benchmark tool wrk [31] to request files of size $\in 1KB, 4KB, 16KB, 64KB$ over 1024 connections (32 connections per client thread) for a duration of 10 seconds.

Figure 7 shows that the recording overhead of KRR varies significantly with the requested file size. For small files (1KB and 4KB), KRR incurs a relatively high slowdown exceeding 46%, and this overhead becomes increasingly severe as the number of cores increases. However, for larger files (16KB and 64KB), the overhead of KRR becomes almost negligible, reducing to merely 2% for 16KB files and 5% for 64KB files across all VM sizes. Our analysis reveals that this discrepancy is due to the unique performance bottlenecks in serving files of different sizes. For small files, the bulk of the request processing time is spent in the kernel reading the file. Since KRR instruments these kernel operations, the recording overhead causes a significant slowdown in the end-to-end throughput. In contrast, when serving larger files, the primary performance bottleneck shifts to the network transfer. Under

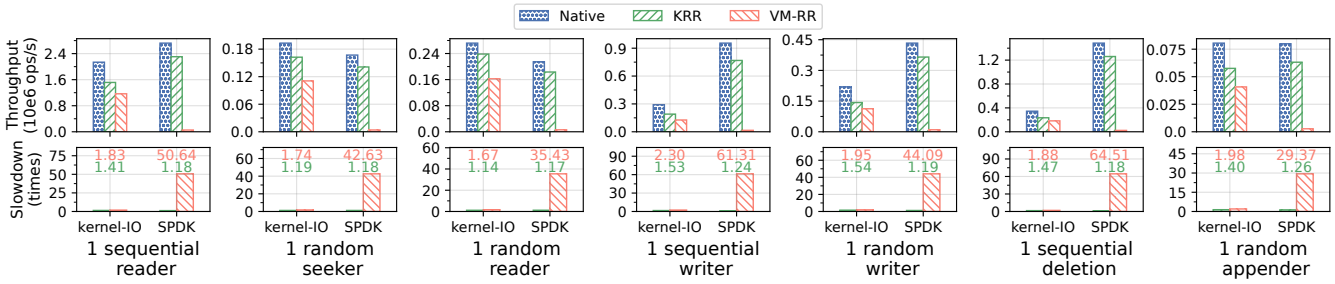

Figure 5: Throughput of RocksDB w/ and w/o SPDK on single-threaded workloads. Slowdown is the ratio between the native and recording throughput.

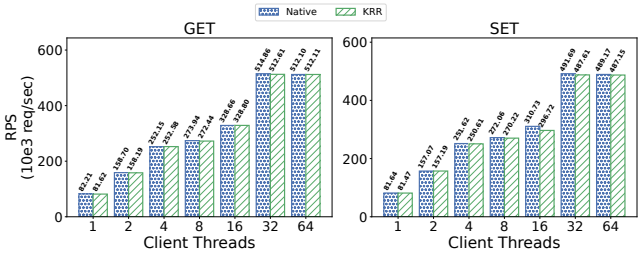

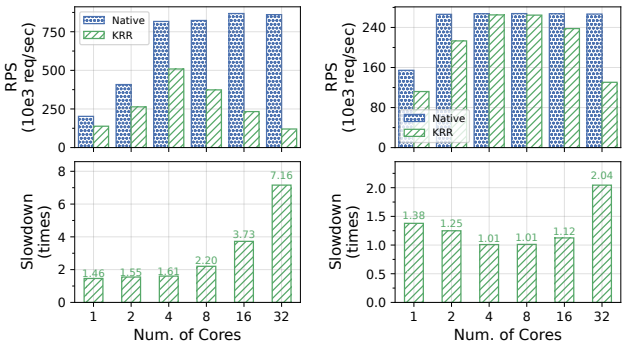

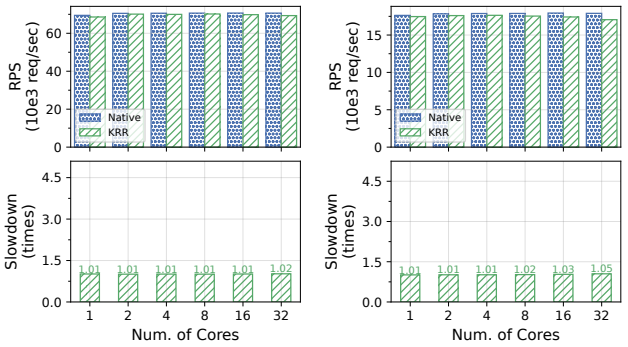

Figure 6: Redis Kernel-bypass Throughput

(c) File Size == 16KB (d) File Size == 64KB

Figure 7: Throughput of Nginx kernel-bypass benchmarks with different file sizes.

the kernel-bypass setup, KRR does not need to record these transfer operations, resulting in minimal performance impact.

5.3 Reproduce kernel bugs using KRR

This section evaluates the effectiveness of KRR in recording and replaying Linux kernel bugs. To construct a representative evaluation dataset, we systematically collect bugs from two well-established bug-reporting sources. First, we gather bugs found by Syzbot [28], a Linux kernel continuous testing project that publicly reports kernel bugs along with reproducers (if any). Specifically, we identify 92 bugs that are found by Syzbot in Linux kernel 6.1.X and have associated reproducer programs. Next, we collect 81 bugs whose titles contain any of the keywords: *WARNING*, *BUG*, *deadlock*, and *KASAN* to focus on severe kernel errors. From these bugs, we randomly select 12 bugs. Next, to evaluate KRR on high-impact kernel vulnerabilities, we additionally collect 5 recent Linux kernel CVEs [4–8] that have high severity scores and were evaluated by prior research work [75] and rated at least as "Important Impact" by Red Hat Product Security [23]. The resulting dataset consists of 17 Linux kernel bugs.

Table 1 presents the bug reproduction results for 12 bugs found by Syzbot, along with the average iteration required to execute the reproducer before triggering the bug. First, 6 bugs (50%) are considered deterministic bugs because they can be reproduced consistently within the first iteration of the reproducer under native execution. KRR successfully reproduces all 6 deterministic bugs within a single iteration as well.

Second, the remaining 6 bugs are non-deterministic, requiring varying numbers of iterations to reproduce in native execution. Among these bugs, KRR is able to reproduce 5 of 6. Furthermore, our analysis of the median number of iterations required to first trigger the bug does not show a significant difference between the two approaches. In fact, in 3 out of the 6 non-deterministic cases, KRR reproduced the bugs with fewer iterations than the native execution.

For example, KRR performs better than native on bug #5. This bug is caused by a race condition, in which two threads

concurrently execute the function `gsm_cleanup_mux`, and accesses to the shared variable `dlci` need to occur in a specific order to trigger the use-after-free. KRR can reproduce this bug because the function acquires a mutex using `mutex_lock` halfway through its execution, giving a chance for other tasks to be scheduled even in a serialized execution given our algorithm (§3.3).

Bug #8, a potential deadlock in `rcu_report_exp_cpu_mult()`, can only be reproduced in a multi-core VM with native execution. This bug involves a lock ordering violation: when multiple cores contend for the same spinlock, one core acquires it with interrupts disabled (making it `hardirq-safe`). During this execution, the system triggers a BPF trace that attempts to acquire a `hardirq-unsafe` lock. This sequence—acquiring a `hardirq-safe` lock followed by a `hardirq-unsafe` lock—violates lockdep's locking rules and can lead to deadlock. The bug requires parallel execution: multiple cores must concurrently attempt to acquire the same lock with the interrupt disabled. This scenario cannot occur on single-core systems, where only one execution context can run at a time. Thus, KRR cannot reproduce this bug because its serialization approach prevents concurrent lock contention between cores.

Security-sensitive bugs. Table 2 shows the bug reproduction results for 5 Linux kernel CVEs. These vulnerabilities encompass a diverse range of bug types, including three privilege escalation vulnerabilities, a heap overflow vulnerability, and a control flow hijacking vulnerability. KRR can successfully record and replay all 5 CVEs, demonstrating its effectiveness in reproducing complex kernel exploitations.

ID	Description	Kernel	Det.	Repro.	Iterations Median	
					Native	KRR
#1	Paging error in vsyscall	6.1.77	N	Y	39.0	52.5
#2	null-ptr-deref in hugetlb	6.1.61	N	Y	22.0	21.0
#3	use-after-free in af_unix	6.1.62	N	Y	45.5	52.0
#4	null-ptr-deref in fs/sysv	6.1.34	Y	Y	1.0	1.0
#5	use-after-free in tty	6.1.35	N	Y	28.0	1.5
#6	Deadlock in ext3	6.1.31	Y	Y	1.0	1.0
#7	Deadlock in vfs_write	6.1.34	Y	Y	1.0	1.0
#8	Deadlock in bpf	6.1.84	N	N	115.0	N/A
#9	Deadlock in vhci	6.1.66	Y	Y	1.0	1.0
#10	Deadlock in af_unix	6.1.84	N	Y	209.0	187.0

#12	Warning in BPF	6.1.86	Y	Y	1.0	1.0

Table 1: Reproduction results of bugs found by Syzbot. Some bugs are deterministic ("Det.") and all bugs except for one are reproducible by KRR ("Repro."). The table shows the median number of test iterations required to hit the bug across 10 runs.

CVE	Type	Kernel	Repro.
CVE-2024-1086	Privilege Escalation	6.1.0	Y
CVE-2022-0847	Privilege Escalation	5.10.222	Y
CVE-2022-0185	Heap Overflow	5.10.222	Y
CVE-2021-4154	Control Flow Hijacking	5.10.222	Y
CVE-2022-2639	Privilege Escalation	5.17.4	Y

Table 2: Summary of evaluated CVEs.

5.4 Storage Cost

KRR's storage cost is lower than VM-RR when recording kernel-bypass workloads because KRR does not need to record the data between the guest user-space and the hardware while VM-RR does. Across all evaluated workloads (§5.2.1), VM-RR on average records at a rate of 9.4 MB of data per second while KRR records 4.8 MB per second—the storage cost of KRR is 48.9% lower. The storage cost deduction also aligns with the low recording overhead of KRR on kernel-bypass workloads (§5.2).

When recording workloads that do not use kernel-bypass techniques, KRR imposes higher storage cost compared to VM-RR because it records additionally the software inputs. Specifically, for the RocksDB workloads (§5.1.1), VM-RR records an average of 8.26 MB of data per second, whereas KRR records 53.39 MB per second (546.57% more). In total, KRR and VM-RR on average record 999.22 MB and 464.48 MB of data, respectively. However, the recording data of KRR is highly compressible. After applying gzip compression, the recorded data of KRR is reduced to 144.52 MB (a 6.91x reduction), suggesting the potential for using hardware compression features [14] to compress the data in real-time—an optimization we leave for future work. These numbers are well within the bandwidth of data center storage, which reaches a few GB/s, so it can be easily sustained. Furthermore, the length of the trace can be reduced by taking frequent snapshots even on very long-running workloads.

5.5 Replay Performance

While KRR skips the userspace execution during the replay, which contributes significantly to reducing replay overhead, its replay execution is still generally slower than native execution by $20\times \sim 150\times$. This slowdown is expected given that our prototype's replayer uses the QEMU emulator (§3.5) in the single-step mode (one instruction per translation block). Based on our tests on the benchmarks in §5.1.1, with whole system execution, full emulation (TCG) alone introduces a $7.5\times \sim 20.6\times$ slowdown compared to native KVM. With single-step enabled, the slowdown reaches $120\times \sim 400\times$. KRR also disables QEMU TCG's optimization of lazy EFLAGS evaluation to simplify the logic that ensures consistency between the record and replay runs. Together, these factors contribute to the bulk of the replay over-

head in our prototype, but are not fundamental to the KRR's sliced record replay approach (§2).

Despite this performance trade-off, emulation-based replay is commonly used in existing record-replay systems [21, 40] for its rich debugging capabilities and portability. The periodic snapshots taken during recording also mitigate performance concerns by allowing replay to start from intermediate points rather than always replaying from the beginning. Future work could explore optimizations like enabling batch translation blocks [22] while maintaining replay accuracy to improve performance further under full emulation.

6 Discussion

Scalability. While the evaluation (§5.1.2, §5.1.1) shows that the scalability of KRR decreases with higher numbers of vCPU cores (e.g., beyond 8 cores), it demonstrates that KRR enables modern workloads to scale effectively on VMs with 1-8 vCPU cores—a sweet spot for most real-world deployments. This range aligns with industry standards, as exemplified by Azure's session host sizing guidelines, which designate 8 vCPUs as sufficient for heavy workloads [25].

Nevertheless, future work could enhance parallelism in KRR, moving beyond the current serialization of kernel execution. A promising direction is to integrate techniques from chunk-based serialization algorithms, such as Samsara's algorithm [54, 60]. Adopting such an approach in KRR could enable true parallel kernel execution and potentially broaden the class of bugs that KRR can reproduce.

Pass-through Device. KRR currently does not support pass-through devices or SR-IOV [26] that operate outside of kernel-bypass mode. This limitation is because KRR relies on hypervisor emulation to record device DMA buffers and timing. A potential solution involves leveraging KRR's in-guest recorder component. Since this recorder already operates within the guest kernel with privileged access to kernel data structures, it could be extended to intercept and log interactions with these pass-through devices. Following an approach similar to prior work [70], the in-guest recorder could monitor device driver operations, capturing DMA buffer contents and I/O timing information directly at the driver interface level rather than requiring hypervisor intervention.

Recording Scope. Without specialized hardware, no technique can record all non-deterministic failures – subtle timing changes can make such failures more likely or less likely to occur. KRR employs serialization to ensure deterministic execution of the kernel, which is crucial for accurate replay but can potentially mask certain concurrency bugs that depend on parallel thread interactions. Despite serializing the kernel execution, KRR's mechanism effectively models a single-core system where concurrency still occurs through context switching and interrupts. This is because KRR's serialization mechanisms allow for a change in which threads can grab the RC spinlock and run during preemption or interrupts, mirroring how the kernel's built-in schedule would change the running thread in response to such events. Consequently, KRR is still effective at reproducing a broad class of concurrency bugs that only manifest under specific thread interleavings. In essence, if a concurrency bug can be triggered on a single-core system through context switching, KRR can record and replay it.

On the other hand, by design and like other RR systems, KRR cannot reproduce concurrency bugs that strictly require true parallelism—i.e., the simultaneous execution of kernel code on multiple physical cores. This category includes bugs related to weak memory models or specific scenarios involving the parallel execution of uninterruptible kernel code on one core and normal kernel code on another. Furthermore, serialization may also make bugs that surface only within extremely narrow race windows, highly sensitive to precise parallel timing, more challenging to capture [50]. Despite the limitations in reproducing certain concurrency bugs, alternative approaches can be used to detect them. For instance, some concurrency bug detection techniques [52], such as the lockset data race detector [62], have a high degree of schedule independence, enabling the detection of bugs even in executions that do not manifest failures.

Privacy. Since KRR records user-space data to ensure correct kernel replay, this could raise potential privacy concerns. Like traditional settings, which assume hypervisors and kernels are trusted, we assume that KRR is trusted and privacy is not a design concern. This approach aligns with traditional VM RR approaches [60, 64], which also collect all VM data. However, our design has the advantage that it limits exposure by only recording data that directly interacts with the kernel (through system calls and memory accesses). Future work could explore selective data filtering [34] or trace encryption for use cases where privacy guarantees are important.

7 Related Work

Reproducing the execution in which a failure occurs is essential for developers to diagnose bugs in system software. Two main approaches have emerged to address this challenge: record and replay techniques that capture and reproduce the exact execution, and partial reconstruction methods that recreate critical aspects of the execution without full recording.

Application RR. Application record-replay techniques record non-deterministic inputs to the application and its internal non-determinism such as concurrency. Among them, Mozilla RR [56] provides deterministic record-replay for multi-threaded applications. Similar to KRR, RR records the concurrency non-determinism by serializing concurrent threads and recording the schedule. Castor [53] focuses on improving the recording performance on multi-threaded but data-race-free applications. Specifically, Castor allows user-space threads to run

in parallel but records the ordering of the thread synchronizations. During the replay, Castor reproduces the execution by replicating the synchronization ordering. However, this approach is impractical for recording the kernel due to the prevalence of data races in operating systems [67].

Whole-machine RR. Whole-machine record-replay techniques record and replay the entire VM execution by capturing all non-deterministic events across the VM boundary. Retrace [64] introduces the first whole-machine RR tool based on the hypervisor, which is adopted later by VMWare in its first Fault Tolerance implementation [63]. More recently, PANDA [40] develops a whole-machine RR platform with powerful extensions for binary analysis. However, they all focus on single-core systems. Multi-core record and replay has evolved through several key systems. SMP-Revirt [42] introduced CREW (concurrent-read, exclusive-write) protocols for recording memory access ordering. ReEmu [35] enhanced CREW's scalability based on full system emulation. Samsara [60] improved efficiency by leveraging hardware assistance and employing chunk-based memory access recording.

Failure Reconstruction. Prior work [36, 38, 39, 57, 66, 71, 76] explores failure diagnosis without record-replay. REPT [38] leverages Intel PT [12] to record both program control flow and timing information, along with the final memory dump. It then tries to reconstruct the execution history through binary analysis of these recorded traces. However, it faces two important limitations: it is not fully accurate and cannot reconstruct all data values that are necessary for debugging, struggling, in particular, to reconstruct long executions. Kernel REPT [45] extends this to kernel failures with more extensive analysis functionality. In contrast, KRR provides a more efficient and scalable solution for kernel-level record-replay, enabling reliable reproduction of failures.

8 Conclusion

This paper presents KRR, an efficient and scalable kernel record-replay system. Unlike the traditional whole-VM RR approach, KRR incurs low overhead on the VM performance because it reduces the RR boundary from the entire VM to the guest kernel only, completely avoiding the expensive yet unnecessary cost that whole-VM RR has to pay for recording the guest user space. The evaluation shows that KRR achieves high recording performance on several real-world workloads, and scales well to multi-core VMs. On modern workloads that exploit kernel-bypass, KRR even shows close-to-native recording performance. We believe KRR fills the gap between application RR and whole-VM RR, and we hope KRR can help developers efficiently and effectively diagnose failures in the kernel.

Acknowledgments

We would like to thank the anonymous reviewers and our shepherd for their feedback, which greatly improved the paper. We also thank the Purdue Reliable and Secure System Lab members for their helpful comments on this work and earlier drafts. We are also grateful to Cloudlab for providing experimental machines. This work was funded in part by National Science Foundation (NSF) under grants CNS-2140305 and CNS-2145888 and gifts from Google and Intel.

Abstract

This paper presents Deterministic Client (DeCl), a software-based sandboxing system for enforcing deterministic behavior on untrusted machine code, either x86-64 or Arm64. DeCl adapts techniques from Software Fault Isolation (SFI) traditionally used to guarantee memory isolation to instead enforce the stronger property of determinism. By using a simple and efficient machine code verifier that can guarantee that a program behaves deterministically, DeCl does not rely on a trusted compiler/interpreter for correctness. This allows the use of LLVM without compromising the size of the trusted code base. We also describe how to implement two efficient metering mechanisms that enforce deterministic preemption of sandboxed programs, and how DeCl can be implemented in combination with traditional software-based isolation, by making the sandboxed code position-oblivious. DeCl is able to combine and improve upon the benefits of both interpreters and JIT compilers at once, with low CPU overhead, fast startup time, and strong security via a small trusted code base. We evaluate DeCl's effectiveness on general-purpose CPU benchmarks, as well as in an application-specific context by integrating with the Groundhog smart contract engine, and using DeCl for zero-knowledge-proof verification.

1 Introduction

Program determinism is essential for executing smart contracts correctly. Smart contracts are programs that are uploaded by completely untrusted parties, and yet must be guaranteed to perform the same set of operations every time they are run by an honest node. Since smart contract programs increasingly form the backbone of digital currency systems, it is important for them to be performant. Existing approaches to smart contract sandboxing are language-based: they define an intermediate language (IL) with deterministic semantics, such as WebAssembly or EVM bytecode, and then execute the language via a trusted interpreter or just-in-time (JIT) compiler. Unlike with sandboxes that enforce memory isolation, this language-based approach is the only existing method for enforcing determinism in an adversarial setting. Approaches for enforcing determinism must necessarily be software-based, as commodity hardware does not provide sufficient mechanisms for hardware-based enforcement.[1]

Enforcement	Memory isolation	Determinism

Hardware	Pagetables, Segmentation	–

Table 1: Approaches that enforce memory isolation and determinism via hardware-based or software-based methods.

This paper introduces Deterministic Client (DeCl), a new software-based approach to enforcing determinism. By adapting binary analysis techniques from Software Fault Isolation (SFI) [36, 50, 54, 57], we design a machine code analyzer that can determine if a program is part of a deterministic subset of either x86-64 or Arm64. If so, the program is guaranteed to be deterministic, and can be directly run as native code, without any intermediate translation step. This design significantly reduces runtime CPU overhead and startup latency, and removes the need for a trusted translator. Highly optimizing ahead-of-time compilers such as LLVM can be used without needing to trust them. In order to generate programs that can pass verification, we develop a program rewriter that operates on assembly files, allowing us to rewrite the output of LLVM/GCC and therefore support many existing languages and compiler optimizations.

Binary analysis techniques from SFI are well-known for enforcing memory isolation, but this is the first work to apply

[1] Both x86-64 and Arm64 have cases of instructions that cause unpredictable behavior that is not trapped by hardware. Existing hardware cannot prevent these instructions from executing.

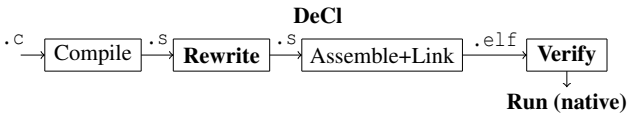

Figure 1: The DeCl compilation flow. Determinism properties are enforced directly on the machine code output of a compiler. In order to produce binaries that pass verification, a rewriter is used during compilation. Non-bold steps use existing compiler infrastructure.

them to determinism. Table 1 summarizes existing sandboxing approaches for both memory isolation and determinism, and Figure 1 shows the overall architecture of DeCl, which is typical of SFI systems. We describe three main components:

1. Deterministic instruction enforcement: programs that attempt to use non-deterministic instructions must be rejected. We describe cases of non-determinism in x86-64 and Arm64, along with how to guarantee their absence.

2. Deterministic metering: programs cannot be permitted to run indefinitely. However, a traditional timer interrupt on its own may cause the program to terminate after different side effects each time the program runs. We describe two mechanisms for deterministic preemption.

3. Integration with software-based memory isolation: DeCl can be used in conjunction with any memory isolation mechanism (hardware-based or software-based). We describe additional changes that are necessary in order to use DeCl with LFI [57], a software-based sandbox where all sandboxes share an address space. This makes it possible to use DeCl sandboxes within a Linux process and enables fast sandbox startup times.

We evaluate DeCl's performance in terms of CPU overhead and startup time. We measure both general benchmarks (SPEC 2017) and benchmarks specific to smart contracts. With both metering and software-based isolation, DeCl only imposes a modest $\sim 20\%$ overhead with metering, measured on a subset of SPEC 2017 for both x86-64 and Arm64.

We integrate DeCl into Groundhog [45], a scalable smart contract engine currently using a WebAssembly interpreter. Using native code for smart contracts allows them to run CPU-intensive computations faster, by roughly $2\times$ (compared to JIT compilation) or $30\times$ (compared to interpretation). Since some important smart contracts are short-lived, we have optimized the system to have a sandbox startup latency of less than $15\mu s$ (load and execute), and we ensure that loading sandboxes does not interfere with Groundhog's scalability.

The rest of the paper describes the design of DeCl for both x86-64 and Arm64. We find that properties of x86-64 such as undefined flags, variable-length instructions, a small register file, flags-based conditional branches, and stack-based `call`/`ret` are most responsible for higher complexity compared to Arm64.

2 Background

2.1 Threat Model

DeCl enforces determinism against adversarially-constructed programs. An untrusted party provides a program (expressed as x86-64 or Arm64 machine code), and the DeCl verifier accepts it only if it can be guaranteed to be deterministic. The verifier is allowed to reject programs if it cannot confirm determinism, but nonetheless, we would like to be able to accept as wide a variety of programs as possible, while imposing minimal performance overhead. The determinism guarantee only applies within a particular architecture, but covers all valid microarchitectures. For example, a program validated for DeCl-Arm64 will behave deterministically on all Armv8.0-compliant processors, including virtual processors such as QEMU. In certain cases, we require a processor to have certain architectural extensions, such as the x86-64 BMI2 extension for the `SHRX` instruction. Existence of extensions like these can be probed using `cpuid` (or equivalent). Requiring extensions reduces the number of processors that can be used to run the program (older processors become excluded), but allows for newer instructions to be used.[2] We rely on the hardware being correct for the ISA-subset accepted by the verifier.[3]

We also support requiring that the programs that run inside DeCl are *metered*, and therefore cannot use more than a limited amount of CPU time. This requirement, when combined with the determinism requirement, requires special design, since the preemption must happen in a deterministic way. The runtime system is initialized with a limit on the number of instructions that can be executed before preemption occurs.

We assume the following properties about the runtime system, which are typical for adversarially-deterministic systems such as smart contract engines:

1. The runtime provides a deterministic "runtime call API" that a sandboxed program uses to have external effects.

2. The runtime disables shared-memory multiprocessing.

3. The runtime deterministically initializes the sandbox by zeroing the initial memory. Section 7.2.1 discusses the performance impact on startup time.

Enforcing determinism requires that the sandboxed program must not be able to access memory outside its sandbox (memory isolation). DeCl can work with either hardware or software-based memory isolation, and we describe additional

[2] Older processors could be supported via dynamic recompilation, but we do not implement or evaluate this approach.

[3] Recently discovered hardware issues we are aware of [1, 3, 5] involve programs that are already disallowed by the verifier by default.

changes needed for the software-based case in Section 5. We also terminate programs after a memory fault. This is relevant due to *torn stores*: stores that straddle a mapped and unmapped page boundary. On Arm64, it is implementation-defined whether the memory in the mapped region is altered or not. While there are multiple mechanisms to solve this issue, such as simulating the stores, or performing a load before every store [20], we simply terminate the program.

Side channels Side-channel attacks exploit non-determinism in the runtime API or instruction behavior to recover information about parts of the system that should not be available to the application. These exploits most commonly use timers to recover information about data in the cache. Since DeCl removes all non-determinism in the runtime API and available instruction set, timers or other side-channel vectors (e.g., parallelism or atomics [59]) are impossible to use.

2.2 Secure Machine Code Analysis

The verifier must be able to guarantee that the program cannot execute any instructions that have not been analyzed. Binary analysis systems that enforce memory isolation, such as NaCl [50] and LFI [57], contend with the same issue. Hence, we can use the same techniques they use, which we summarize below.

On Arm64, thanks to fixed-width instructions, it suffices to enforce that memory is never executable and writable at the same time (commonly called W^X). As a program cannot write to executable regions and it cannot jump to the middle of an instruction (which causes a trap), all instructions can be verified before making memory executable.

On x86-64, in addition to W^X memory, we must prevent untrusted code from jumping to the middle of an instruction and executing a completely different instruction sequence from the one disassembled. The solution we use is *aligned bundles*, first introduced by the PittSFIeld [36] system, and now supported by both the LLVM and GCC assemblers. Instructions are organized into 32-byte bundles, as illustrated in Figure 2. The verifier rejects any program that includes instructions that span bundle boundaries, so a compiler targeting DeCl adds `nop` padding to move these into the next bundle. Additionally, the verifier ensures that all jumps target bundle boundaries—static branches are directly inspected, and indirect branches (including returns, which are rewritten into indirect branches) are required to include a preceding mask instruction that aligns the target to a bundle boundary by zeroing the bottom 5 bits of the target.

In both cases, programs must separate code and data, lest the data correspond to unsafe instructions that would be rejected by the verifier. Fortunately, modern x86-64 and Arm64 compiler toolchains already can generate separate code and read-only data segments by default. The `-z separate-code` linker flag can be used to instruct the linker to create distinct code and data segments in the final binary.

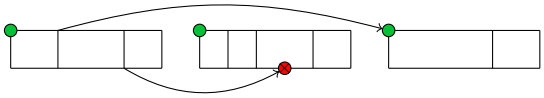

Figure 2: Illustration of aligned bundles. Each bundle consists of multiple instructions, padded such that no instruction spans a bundle boundary. Jump targets must be bundle-aligned (indicated by green dots). The verifier rejects jumps that may target the middle of a bundle or instruction.

With these methods for guaranteeing secure machine code analysis in hand, we can design machine code analyzers that only accept programs with known instructions whose semantics are fully understood by the analyzer. Programs containing any unknown instructions are rejected. Traditionally, this technique has been used to make verifiers that only accept programs with instructions known to be memory-safe, but we show that this can also be applied to accept only programs with instructions known to be deterministic.

3 Deterministic Machine Code

The DeCl verifier must only accept programs that execute deterministically. Therefore, these programs must contain only instructions known to be deterministic. Additionally, some x86-64 instructions execute with unpredictable semantics only for certain inputs. To accept these (useful) instructions, the verifier must ensure that these problematic inputs are not present when those instructions execute. Enforcement on Arm64 is simpler because the ISA has fewer cases of unpredictable behavior. We describe our implementation for Arm64 and x86-64 separately.

Floating point We restrict our analysis to the integer subsets of x86-64 and Arm64, including SIMD but not including floating point. In particular, instructions like `rsqrtss` (Reciprocal of Square Root) are required to provide at most some amount of error but within those bounds can use any precision, which can cause non-determinism. We believe a deterministic subset of floating point operations could be safely included in DeCl (including things like FP addition, but excluding `rsqrtss`), but leave this out of scope in this paper.

3.1 Arm64

In Arm64, the following cases of non-determinism exist at the instruction level:

- Instructions encoded with malformed SBZ/SBO (should-be-zero/should-be-one) fields are UNPREDICTABLE.

- Some instructions have explicitly non-deterministic semantics, such as instruction pairs for atomic loads and stores. For example, the instruction `stxr` returns different values depending on the status of the exclusive monitor, which can depend on factors such as timer interrupts generated for the host kernel. As another example, memory instructions that both increment and write back to the same register are UNPREDICTABLE: `ldr x0, [x0], #16`. Early versions of LLVM could erroneously produce this instruction [17].
- Unallocated instructions.

Our verifier rejects programs that contain such instructions, as well as instructions that are UNDEFINED,[4] with one exception: we allow the `udf #0` instruction as an explicit way to generate an undefined instruction exception.

The DeCl Arm64 subset only supports instructions from the Armv8.0 base ISA, with roughly 180 base instructions and an additional 430 SIMD instructions. These instruction counts are derived from the decoder we use, so different counts could be expected if using a decoder that classifies distinct instructions differently.

Arm64 also allows hardware-enforced stack pointer alignment. When enabled by the OS, stores to the stack pointer when it is not aligned to a 16-byte boundary cause a fault. While we could simply require that this check always be enabled (as is done by Linux), our verifier also requires that modifications to `sp` preserve its alignment. Arm64 also supports multiple base page sizes (4KiB, 16KiB, or 64KiB), and for determinism DeCl must pick one. A machine with a smaller page size can efficiently emulate one with a larger page size, so picking the largest page size is best. Our implementation uses 16KiB pages because there isn't any commodity hardware configured with 64KiB pages.

3.2 x86-64

The situation on x86-64 is more complex, as the instruction encoding space is far larger. We start by limiting the instructions accepted by the verifier to a known, fully-enumerable, subset of x86-64. We recorded all instructions that can be encoded by the Fadec encoder [18] and represent this set with a binary decision diagram (BDD), which can be stored in less than 200KiB. Instructions accepted by the verifier must first be decoded by the BDD, guaranteeing that the verifier operates only on instructions with known semantics. Once approved by the BDD, the instructions are further restricted to the DeCl subset, which includes roughly 100 instructions from the base x86-64 ISA, along with 125 SIMD instructions from the SSE2 extension. For branch-based metering, we also require the `SHRX` instruction from the BMI2 extension.

[4] Even though according to the Arm manual, UNDEFINED instructions deterministically generate an "undefined instruction" exception.

Instruction	Undefined if	Ex. guarded sequence
`SHLD`, `SHRD`	`COUNT > OPSIZE`	`andb $0x1f, %cl` `shrdl %cl, %ebx, %eax`

`BSR`, `BSF`	`SRC = 0`	`test %eax, %eax`
		`jz .SKIP`
		`bsr %eax, %ebx`
		`.SKIP:`

Table 2: x86-64 instructions that may produce undefined results for certain inputs, and guards that can be applied beforehand to rule out this possibility. The guard sequence for shifts may additionally require saving and restoring `%rcx` (because `%cl` is modified), which can be done using the rewriter-reserved `%r11` register.

Moreover, some instructions may generate *undefined* (i.e., non-deterministic) values. For example, the `SHLD` instruction produces an undefined value if the shift operand is larger than the bit-width of the shifted value. Many instructions also put flags into undefined states. For example, the `BT` (bit-test) instruction modifies the CF flag, leaves the ZF flag unchanged, and makes the OF, SF, AF, and PF flags undefined. Observing the state of an undefined flag can cause non-deterministic behavior. While individual CPU implementations are typically deterministic in this respect, the behavior is not consistent across CPU microarchitectures. A program that abuses an undefined flag will behave differently when run on Intel vs. AMD processors, and in some cases even when run on P-cores vs. E-cores within the same processor, since P- and E-cores do not necessarily share the same microarchitecture.

3.2.1 Preventing undefined results

The instructions in Table 2 may produce undefined results [26, 27]. Our program rewriter adds one or more guard instructions to force the input to be valid, and the verifier checks for the presence of these guards before marking memory executable. For example, for a shift of 16-bit data, we apply a mask to the shift amount to force it to be less than or equal to 16.

As of October 2024, the Intel SDM has been updated to say that if the content source of a `BSR`/`BSF` is zero, the result is unmodified, rather than undefined. However, the pseudocode of the operation continues to say the result is undefined, and other parts of the manual (documentation for `TZCNT`/`LZCNT`) still refer to the result as undefined in the case of a zero input. We continue to consider the output as undefined for `BSR`/`BSF` instructions with an input of zero.

3.2.2 Preventing use of undefined flags

Blocking all instructions that may read or write undefined flags would unreasonably restrict the set of verifiable programs. Instead, our verifier reasons about the data-flow of the

Algorithm 1 Flags Analysis

```
1:  function ANALYZE(B, Report)
2:      U ← IN[B]                          ▷ Set of undefined flags
3:      for all instruction I in basic block B do
4:          if Report and I reads a flag f and f ∈ U then
5:              Raise error
6:          end if
7:          for all flags f defined by I do
8:              U[f] ← 0
9:          end for
10:         for all flags f undefined by I do
11:             U[f] ← 1
12:         end for
13:     end for
14:     OUT[B] ← U
15: end function
16: function ANALYZECFG(CFG)
17:     for all basic block B in CFG do
18:         IN[B] ← 1*
19:     end for
20:     for all basic block B in CFG do
21:         ANALYZE(B, false)
22:     end for
23:     for all basic block B in CFG do
24:         IN[B] ← OUT[B_p1] | ... | OUT[B_pn]
25:     end for
26:     for all basic block B in CFG do
27:         ANALYZE(B, true)
28:     end for
29: end function
```

flags, so that it can verify whether any instruction that reads a flag does not observe an undefined value.

Although indirect branch targets are not statically known, the verifier enforces the target bundle-alignment requirement via a masking `and` instruction directly before an indirect jump. This instruction leaves every observable flag in a defined state[5], so we need only reason about data-flow of flags on the part of the control-flow graph of the program that is defined by static branches.

We define a function called ANALYZE (Algorithm 1) that runs on each basic block and uses a set IN, representing the set of flags that are undefined at entry to the basic block, to compute OUT, the set of flags that are undefined after executing the basic block. ANALYZE steps through each instruction in the basic block, updating its set of undefined flags initialized from IN, and signals an error on instructions that appear to read an undefined flag. Once complete, it updates the OUT set for the corresponding basic block. In each *iteration*, ANALYZE is run on every basic block. In a full analysis, iterations are run until the program passes verification, or until a fixpoint. In practice, we have have found that all conforming programs we have compiled with LLVM or GCC pass verification within 2 iterations. Thus it is reasonable to stop analysis and reject the program after 2 iterations if the verifier can not yet prove that no undefined flags are read. ANALYZE uses an internal table adapted from the Intel manual [28] that specifies for each x86-64 instruction whether it reads, modifies, or undefines a flag.

This analysis may reject programs that do not read undefined flags, but it will never accept a program that reads undefined flags. A program can always be written such that it passes verification in only one iteration by always setting flags in the same basic block where they are read. The cross-basic block analysis is only necessary to support code generation behavior in existing compilers (as we want to avoid modifying LLVM/GCC).

3.2.3 Spurious prefixes

CPU implementations consistently accept instructions with unnecessary prefixes, which are ignored (but have caused security bugs [5]). Our verifier only accepts programs that do not use spurious prefixes—this is a side effect of the fact that the verifier only accepts instructions that can be produced from an x86-64 encoder. We make an exception for `nop` instructions, which are often encoded with additional prefixes for padding and have canonical representations.

3.3 CPU Fuzzing

In order to gain confidence in the system beyond just the information in architectural reference manuals and formal ISA semantics, we have a fuzzer that distributes programs to machines of various microarchitectures. The fuzzer is not a necessary component of the DeCl system, but is used as a testing mechanism to find errors in the hand-written verifier. Ultimately, the verifier is the trusted component that must determine if a program is guaranteed to be deterministic or not.

The fuzzer randomly samples instructions from the ISA (for Arm64 this is the set of 4-byte integers; for x86-64 this is the set represented by the BDD used to restrict instructions to a known encodable subset). These instructions are used to create small basic blocks until they pass verification and then concatenated into verified programs consisting of megabytes-to-gigabytes of code. These code blocks are then executed in an execution environment that records the final state of the registers and memory. The verifier can be configured to allow memory accesses that are masked to target a certain memory region (the fuzzer will map pages in the region as they are accessed). Our fuzzer currently does not generate any branch instructions, but this is not a fundamental limitation—it is simpler to disallow branches during fuzzing, and since there are very few branch instructions (on the order of 10), we can

[5] AF is undefined by `and`, but AF cannot be observed by any instruction in DeCl's x86-64 subset.

manually analyze their behavior.

We have run our fuzzer on several (5+) microarchitectures for both Arm64 and x86-64. In our testing, the fuzzer quickly finds cases of non-determinism caused by undefined flags or undefined results if we allow such cases to pass verification.

4 Deterministic Metering

By default, there are no constraints on the amount of CPU time that a DeCl program may consume. To prevent a program from taking over the CPU, we use a notion of "metering," (commonly called "gas"). The program continues running until there is no more gas in the meter, at which point it is preempted. A typical operating system would implement this by using timer interrupts. However, that design is not deterministic, since the interrupt may fire non-deterministically before or after a runtime call with side-effects. In the case of atomic transactions, aborting after a timeout could cause replicas to disagree about whether a transaction succeeded or ran out of gas.

A deterministic alternative is to keep an instruction count. By terminating after N instructions have executed, programs can be deterministically preempted. Unfortunately, the performance monitoring unit (PMU) in modern processors does not provide deterministic instructions counts. As a result, we must manually track the number of executed instructions (the amount of "gas" used) via additional instructions that must be included in a sandboxed program. At a high level, these extra instructions debit a gas counter register (`x23` or `%r12`) according to the number of instructions executed in a basic block and use this counter to cause deterministic termination, either via a trap/branch into the DeCl runtime or via preemption from a timer. We will refer to these two mechanisms as *branch-based* and *timer-based* metering respectively. While timer-based metering makes use of a non-deterministic timer, its use in combination with the gas counter allows for deterministic preemption (details in Section 4.3).

Furthermore, since we are enforcing metering directly on machine code programs, the metering schemes must be efficiently checkable by our static verifier. The verifier must be certain that there is no way to execute a branch instruction without also executing the immediately preceding metering instructions. This could happen if a previous branch or jump skipped over the metering instructions and directly targeted a branch. We use *aligned bundles* to prevent this scenario.[6]

4.1 Aligned Bundles

With metering enabled, we require aligned bundles (discussed earlier in Section 2.2) on both Arm64 and x86-64. To implement bundling on Arm64, we reserve the `x24` register for holding bundle-aligned addresses. The verifier will only accept indirect branches that target `x24`, and will only accept instructions that modify `x24` by zeroing the bottom $\log(N)$ bits from the source register, where N is the bundle size (e.g., `bic x24, xN, 0xf`). All branches must target the beginning of a bundle, making it impossible to execute instructions at the end of a bundle without executing those at the start.

On Arm64, we use 16-byte (4-instruction) bundles for branch-based metering, and 8-byte (2-instruction) bundles for timer-based metering. On x86-64, we use the 32-byte bundles that are already required for machine code verification.

4.2 Branch-based Metering

Branch-based metering keeps an instruction meter in a reserved register (`x23` or `%r12`). The verifier enforces that every basic block ends with instructions that decrease the meter by the number of instructions in the block, and checks that the meter has not reached zero.

In general, detecting basic blocks in machine code is not possible because indirect branches may jump anywhere in the program. However, we do not need precise basic block analysis in order to provide metering, so long as any imprecision is conservative and deterministic. Consider a program without indirect branches; in this case all basic blocks are known statically, and we can charge the correct amount of gas at the end of each basic block. Now, if the program includes indirect branches, those branches may arrive somewhere within an existing basic block. The program will then be charged as if the entire basic block executed, even if it was only partially executed due to an indirect branch arriving in the middle. This may deterministically overcharge the program, but that is safe and only means the program terminates sooner. A program can remove this imprecision by splitting its basic block at indirect branch targets. Splitting a basic block is always legal.

A metering epilogue, shown in Fig. 3, must be inserted at the end of every basic block. This epilogue decreases the instruction meter and then checks if the top bit of the count is 1. If so, the meter has underflowed and a trap instruction is executed. Due to the encoding of the subtract instruction, it is impossible to both underflow and have a zero at bit 63 of `x23`/`%r12` (the immediate cannot be large enough).

Preserving flags On Arm64 and x86-64, many branch instructions jump based on the status of the flags. A gas check inserted before a branch cannot, therefore, modify the flags. Arm64 provides the `tbz` instruction, which performs a conditional branch based on a bit test rather than a flag. On x86-64, the only conditional branch that does not read flags is `jrcxz`, which performs a jump if `%rcx` is zero. We use `jrcxz` to build a metering sequence that preserves flags (Fig. 3a). We must also use an `lea` instruction in order to subtract from the gas register without modifying any flags, and a flags-preserving shift (`shrx`, provided by the BMI2 extension). One possible

[6] It is also possible to use hardware-enforced control-flow (BTI on Arm64 and IBT on x86-64), but these mechanisms are not yet widely deployed.

optimization would be to detect the preceding instruction that sets the flags and, if possible, pull that instruction into the metering sequence directly before the branch—avoiding the need to preserve flags. We do not perform this optimization.

4.2.1 Removing gas checks

The expensive part of the basic block epilogue is the underflow check. We can optimize away this check if the basic block does not end with a backwards branch. Consider a program of size N where a basic block that ends with a forwards branch exhausts all remaining gas, and no check is performed. Within at most N instructions, the program must either execute a backwards branch, causing a gas check, or terminate because no instructions remain. Thus, if the basic block exhausts all gas, the program will terminate after at most N further instructions. This means we can cap the value of N at a small amount, such as 10M instructions, and elide all gas checks for forward branches.

4.3 Timer-based Metering

Timer-based metering uses a timer interrupt in combination with the gas counter to enable deterministic preemption. This scheme relies on the insight that a program running in a DeCl sandbox can only have externally visible effects when it makes a runtime call. As long as the program does not make any externally visible changes after it runs out of gas, it does not need to be immediately preempted. Thus, timer-based metering works as follows:

- A timer interrupt is configured to fire frequently.
- When the program makes a runtime call, it is terminated if its gas is negative.
- When a timer interrupt occurs, the program is terminated if its gas is negative.

Since the runtime always checks the gas before applying the effects of a runtime call, it is impossible for a program to have any effect after it runs out of gas, even though it may continue running for a non-deterministic amount of time. To an external observer, the program behaves deterministically. This scheme assumes that a runtime call is the only way to cause an externally visible effect—this would not work if the memory state of the program were also externally visible.

Since gas checks are only performed after interrupts or runtime calls, basic block epilogues only need to update the gas counter, and can always omit the expensive gas check. This makes it possible to use a bundle size of 8 on Arm64. Fig. 4 shows metering sequences for Arm64 and x86-64.

Timer-based metering relies on the ability to configure a timer interrupt, for example via signals on Linux. This scheme also allows a program to use up to t seconds of CPU time after running out of gas, where t is the size of a time slice. While timer-based metering allows all gas checks to be elided, it can cause overhead if the time slice is too short. As a result, branch-based metering may be better for systems that give programs only a tiny amount of gas.

5 Integration with Lightweight Sandboxing

DeCl can be used with hardware-based or software-based memory isolation. For a smart contract engine, fast startup time and context switches are crucial. For this reason, we have integrated DeCl with LFI, a software-based sandboxing system where all sandboxes run in the same address space. LFI supports both x86-64 and Arm64 using techniques described in prior work [40,50,57]. Section 5.1 provides an overview of these techniques, and Section 5.2 discusses the modifications to LFI required to make it deterministic.

5.1 Background: LFI

Lightweight Fault Isolation (LFI) is a sandboxing system that uses software-based fault isolation (SFI). Programs running in LFI are restricted to accessing a 4GiB region of contiguous virtual memory, and may not execute system call instructions or other instructions deemed "unsafe." These restrictions are enforced via a static verifier that analyzes the machine code of untrusted programs. In order to accurately disassemble programs, LFI uses the techniques described in Section 2.2.

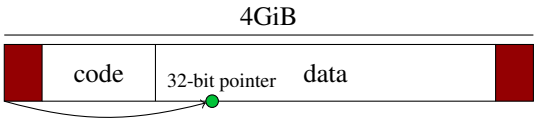

Figure 5: Layout of an LFI sandbox. Red regions indicate unmapped pages.

The basic LFI scheme allocates each sandbox at an address aligned to 4GiB, illustrated in Figure 5. Unmapped guard pages are required between adjacent sandboxes, with sizes determined by architectural details and the chosen sandboxing scheme (typically chosen to be 80KiB for Arm64 and 40GiB for x86-64). Several Arm64/x86-64 registers are reserved for special use and must contain:

- `x21` / `%r14`, `%gs`: the base address of the sandbox.
- `sp` / `%rsp`: an address within the sandbox.
- `x18` (Arm64-only): an address within the sandbox.
- `x30` (Arm64-only): an address within the sandbox.

Note that Arm64 has 32 64-bit integer registers (`x0`-`x30` and `sp`), which can also be accessed via names that only access the bottom 32 bits (`w0`-`w30` and `wsp`). When `wN` is written, the top 32 bits of `xN` are set to zero. Similarly, x86-64 has 16 64-bit registers (`%rax`-`%r15`), which can be accessed via 32-bit subsets (`%eax`-`%r15d`).

All loads and stores are rewritten into safe versions that perform the memory access as a 32-bit offset from the base of the sandbox. This way, the memory access cannot reach memory outside of a 4GiB region, starting from the base address. The following instructions are example of safe memory accesses on Arm64 and x86-64:

```
ldr x0, [x21, w1, uxtw] // Arm64
mov %gs:(%eax), %rdi    // x86-64
```

The first instruction above takes the 32-bit value `w1` (namely the low 32 bits of `x1`), treats it as an unsigned 32-bit value before extending it to 64 bits (specified by the `uxtw` modifier), adds the extended value to register `x21`, loads the value at that computed address, and stores the result in `x0`. Since `x21` contains the 4GiB-aligned base address of the sandbox region, the address that is loaded is guaranteed to be within the sandbox, regardless of the value of `x1`. A similar operation takes place for the x86-64 instruction through the use of `%gs`, an optimization introduced by Segue [40].

We omit many further details of the sandboxing scheme for brevity. Please see prior work on these kinds of sandboxing systems for details [36, 40, 50, 54, 57, 58].

5.2 Position-Oblivious Code

The particular 4GiB slot allocated to an LFI program is determined by the runtime and is non-deterministic, as we want to support running multiple sandboxes at the same time. Since LFI programs are able to read their base address, their stack pointer, or any absolute address used to perform memory accesses, an LFI program can determine where in the address space it is executing, and behave differently depending on this value. While this is not a problem for enforcing memory isolation, it becomes a problem for determinism.

To solve this problem, we introduce *position-oblivious code* (POC): programs that cannot determine their load address. A position-oblivious program may be loaded at any address, and its result is guaranteed to have no dependence on that load address. A program can be verified to be position-oblivious by a static verifier before it is loaded.

Position-oblivious code builds on the LFI technique by statically verifying that absolute addresses are never directly observed. The verifier ensures that reserved registers, which may contain absolute addresses, are only ever accessed via their bottom 32 bits (i.e., `w30` instead of `x30`). Thus, the program may only directly observe offsets from the base address. If the absolute sandbox base address can never be observed, the program is oblivious to where it was loaded.

For example, the following sequence is used to store the return address (`x30`) into the address offset stored in `x0`. This is usually performed as `str x30, [x0]`, but with LFI and position-oblivious code it becomes:

```
mov w22, w30
str x22, [x21, w0, uxtw]
```

This first reads the bottom 32 bits of `w30` into `w22` and then stores that value into memory, instead of the 64-bit `x30`.

Similarly, moves from the stack pointer, such as `mov x0, sp`, are rewritten to read only the 32-bit subset of `sp`:

```
mov w0, wsp
```

Absolute addresses that contain the correct top 32 bits identifying the sandbox location are only stored in reserved registers that are verified to never be directly observed. Before accessing a memory location, the top 32 bits are always set to the correct value and only the bottom 32 bits of a reserved register may be read. On x86-64, the verifier checks that the `%r11` register, which is used for computing safe bundle-aligned indirect branch targets, may only be read as `%r11d` (the bottom 32 bits of `%r11`).

The verifier also ensures that any instructions that produce an address dependent on the program counter (the `adr` and `adrp` instructions, or `%rip-relative addressing`) immediately zero the top 32 bits of the address:

```
adr x0, foo
mov w0, w0
```

These extra constraints mainly affect only three situations: storing the return address on the stack, loading the address of a global, and loading the value of the stack pointer to perform arbitrary computation. These cases are less frequent than regular loads/stores, so the additional overhead is minor.

When implementing a runtime with POC support, care must be taken so that the runtime does not reveal a sandbox's true addresses. For example, pointers returned from runtime calls must have their top 32 bits zeroed. Since POC programs behave the same no matter where they are loaded, they are compatible with a POSIX `fork` API, even though they all exist within the same hardware address space.

x86-64 calls On x86-64, the `call` instruction pushes the return address (an absolute address) onto the stack. As a result, the verifier must reject `call` instructions. The rewriter replaces `call` instructions with a `leal`+`push`+`jmp` sequence that never exposes an absolute address to memory/registers. Unlike a real `call`, this call sequence sets the return address to an instruction further away than the immediate next instruction, and as a result does not need to be placed at the end of a bundle. In some cases this can actually improve performance, as the nops at the end of a bundle after a position-oblivious call sequence are skipped, whereas they would have been executed (and placed before the call) if using a `call` instruction. Returns already must be instrumented to enforce bundling, and will add the base address to the return address before indirect branching. Additionally, instructions like `stos` and `movs` instructions that access memory through `%rdi`/`%rsi` without using addressing modes must zero the top 32 bits of `%rdi`/`%rsi` after executing.

x86-64 flags Finally, information about the sandbox base must not leak via the flags. The `or %r14, %r11` instruction that guards branch targets after the bundle mask sets the ZF, SF, and PF flags. PF is always unaffected by the sandbox base since it only tracks the parity of the bottom byte of the result. SF is unaffected as long as sandboxes are only allocated from one half of the address space (e.g., user addresses), and ZF is unaffected as long as the zero sandbox is never allocated. It is possible to avoid these issues if one wants to allocate sandboxes in both the top (kernel) and bottom (user) halves of the address space by using a slightly larger `lea (%r14, %r11), %r11` instruction instead, which does not affect flags.

5.3 Other Modifications to LFI

Dedicated runtime call register LFI reserves the first page of the sandbox to store metadata about the process, including the entrypoint for runtime calls. This allows the system to reuse `x21` as the address of this metadata page instead of reserving another register for this purpose. However, the contents of this page are not deterministic, so the sandbox cannot be allowed to read it. Thus, DeCl cannot use this page for metadata (DeCl simply leaves it unmapped) or take advantage of the associated optimization, and instead stores the runtime call table outside of the sandbox, while reserving a separate register (`x25`/`%r13`) to contain the address of the runtime call table page. The verifier enforces that this register is only ever accessed for performing runtime calls.

System	Reserved registers	Bundle size
DeCl-HW-x64	`%r11`*	32B
DeCl-LFI-x64	`%gs`, `%r14`, `%r11`, +`%r13`	32B
DeCl-timer-x64	+`%r12`	32B
DeCl-branch-x64	+`%r12`	32B
DeCl-HW-A64	none	none
DeCl-LFI-A64	`x21`, `x18`, `x30`, `x22`*, +`x25`	none
DeCl-timer-A64	+`x24` +`x23`	8B
DeCl-branch-A64	+`x24` +`x23`	16B

Table 3: Register and bundle requirements for all configurations of DeCl, targeting x86-64 (x64) and Arm64 (A64). A + indicates an additional register not reserved by LFI's base configuration. A * indicates a register reserved as a temporary for the rewriter, but its use is ignored by the verifier.

Redundant guard hoisting Guard hoisting is an optimization used by default in the original implementation of LFI, which reserves two registers. To avoid reserving these two additional registers, we use a more limited form of this optimization that simply eliminates redundant guards of the same address without any intervening modifications to `x18`.

Gas register When metering is enabled, DeCl also reserves a register to store gas (`x23`/`%r12`). On Arm64, the `x24` register is also reserved to store bundle-aligned addresses.

6 Implementation

DeCl supports multiple configurations, useful in different scenarios, and summarized in Table 3:

1. DeCl-HW: enforces that programs are deterministic, but relies on hardware protection for memory isolation, and does not provide any metering. This is the configuration that imposes the least overhead, but requires process isolation or a custom kernel to provide memory isolation.
2. DeCl-LFI: provides determinism on top of LFI's memory isolation. This configuration is easy to integrate with Linux applications, since sandbox isolation is handled within a single Linux process. Additionally, sandboxes are extremely lightweight, allowing for faster startup and context switch times compared to DeCl-HW.
3. DeCl-metered: Additional branch or timer-based metering can be enabled in combination with either DeCl-LFI or DeCl-HW. This is necessary for smart contract engines that require preemption. For smart contracts, we choose metered DeCl-LFI for fast startup times.

The implementation of DeCl consists of three components: a compiler, a static verifier, and a runtime implementation. This section describes the first two components. The runtime implementation depends on the application using DeCl. Section 7.2 describes the integration with Groundhog.

6.1 Compiler

Programs are compiled for DeCl using a standard LLVM/GCC toolchain, followed by an assembly rewriter. The rewriter consumes assembly text produced by the compiler and inserts additional instructions. The metering extension inserts sequences before branch instructions. To create aligned bundles, we use the `.bundle` directives supported by Clang and GCC, including `.bundle_align_mode` to set the bundle size, and `.bundle_lock`/`.bundle_unlock` to force sequences of instructions into the same bundle.

6.2 Static Verifier

The DeCl verifier determines if an input is a valid DeCl program. It is a standalone program with limited complexity that runs in linear time. First, it decodes all instructions in the input program and rejects programs that contain any unknown instructions. The decoder is constructed from a fully enumerable set of instructions that only includes well-formed and deterministic instructions. For example, x86-64 instructions with invalid prefixes are never added to the enumerable set, and are thus considered unknown. Instructions from unsupported extensions (e.g., x87 FPU) are also not included.

Next, the verifier ensures that each instruction is safe, depending on the configuration in use. For example, for DeCl-HW-x64, it imposes the following restrictions: (1) No instruction spans a bundle boundary, (2) all direct branches target a bundle-aligned address, (3) indirect calls or jumps are only used as part of a *macro-instruction* consisting of a bundle-masking `AND` immediately followed by the indirect branch.

Finally, on x86-64, the verifier applies the undefined flags analysis described in Section 3.2.2.

When using an LFI-based configuration, the verifier additionally checks for memory isolation properties: loads, stores, and indirect branches are only performed with safe addressing modes/macro-instructions, and reserved registers are only modified in specific ways (to preserve sandbox invariants).

6.2.1 Enforcing Metering

In order to validate metering, the verifier must first determine the program's basic blocks. It does so using the linear-time leader construction algorithm, marking an instruction as a leader if it is the first instruction, any instruction following a branch, or any instruction that is the target of a direct branch.

Next, the verifier iterates through the leaders and enforces that each basic block ends with the appropriate metering sequence. If the basic block ends with a branch, the metering sequence and the branch must be in the same bundle. For example, for DeCl-branch-A64, the metering sequence is:

```
    sub x23, x23, #n  (d1nnn2f7)
    tbz x23, #63, end (b6f80057)
    brk #0            (d4200000)
end:
```

The value `n` is calculated from the location of the current instruction and the previous leader, and is verified against the immediate in the (program-provided) subtraction instruction.

The verifier also tracks the locations of these instructions, and in a final pass ensures that no modifications to `x23` or `tbz x23` instructions occur outside these areas, and that branches do not target instructions within gas update sequences by making sure that branches correctly target aligned bundles.

Some "basic blocks" may be unreachable—for example, the padding between the end of one function and the beginning of another. The assembly rewriter does not know about padding and does not insert gas update sequences there. However, the verifier still expects such padding to be metered. To solve this problem, we allow basic blocks to be merged: if the verifier sees a basic block that ends without a gas update sequence and that has no terminating branch (it just falls through), the verifier accepts the code so long as the next basic block's gas update sequence charges for both blocks. Hence, the first basic block of a function charges for padding between it and the previous function, incurring a small amount of gas overcharging. However, this also means compilers targeting DeCl can opt to merge basic blocks, trading off the possibility of some overcharging for reduced metering overhead.

7 Evaluation

Our evaluation of DeCl seeks to answer the following questions: first, what is the performance overhead of enforcing determinism, metering, and position-oblivious code, and how does this compare with existing state-of-the-art approaches? To answer this, we evaluate DeCl on the SPEC CPU2017 benchmark suite with a variety of configurations.

Next, in the context of smart contracts (the primary industry use-case for adversarial determinism), what tradeoffs does DeCl provide, what metrics are important, and how does DeCl perform on those metrics compared to existing approaches? We evaluate DeCl with Groundhog, a scalable smart contract engine, and evaluate on a payment transaction benchmark (where we find startup overheads to be very important) as well as on contracts that perform zero-knowledge proof verification (where CPU overheads dominate).

7.1 General Performance

To evaluate general CPU overheads imposed by DeCl, we use the SPEC CPU2017 benchmark suite. Benchmarks are

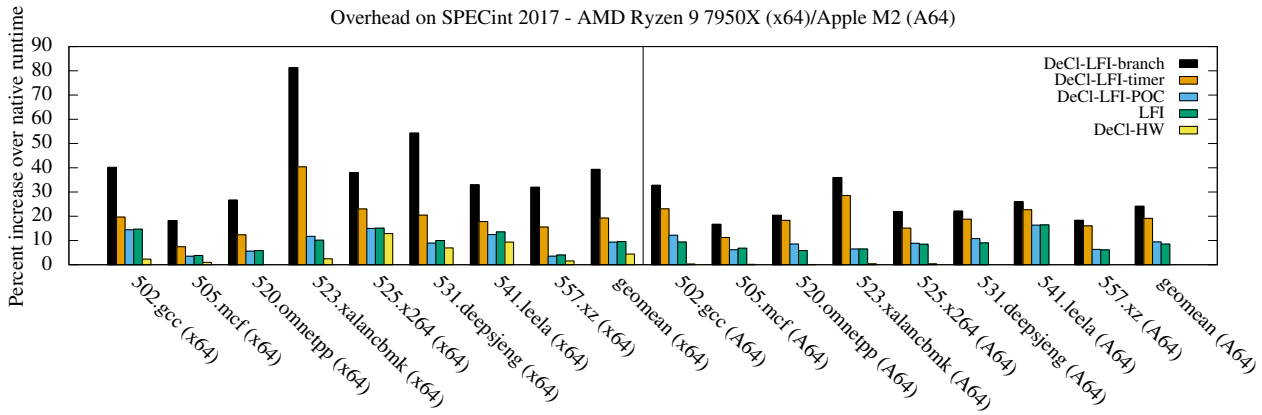

Figure 6: Overheads of all DeCl configurations on integer SPEC benchmarks.

limited to ones that compile with LFI: they must be written in C or C++ and compile with a Musl/LLVM toolchain. We also use the SPECrate benchmarks rather than SPECspeed due to the 4GiB memory restriction imposed by LFI (SPECspeed requires 16GiB RAM per benchmark). We also exclude the SPEC floating point benchmarks, since we consider floating point out of scope.[7] This restricts the suite to 8 benchmarks. All benchmarks are compiled with LLVM 19.1.4, with link-time optimization enabled.

While the programs in SPEC are compiled to be deterministic, in order to run the benchmarks, the runtime must provide non-deterministic functions, such as system calls that return the time. Our runtime for SPEC provides these non-deterministic functions for evaluation purposes. We only run SPEC programs with DeCl to quantify the runtime overheads caused by rewriting. A system that actually uses DeCl for full determinism would implement a custom runtime with a deterministic API and programs would be compiled in a freestanding environment. We evaluate such a system in §7.2.

We evaluate on a Mac Mini M2 running Debian Asahi Linux (not virtualized) for Arm64, and on an AMD Ryzen 9 7950X running Ubuntu for x86-64. Both machines are configured so that benchmarks run at the fixed base clock rate and are shielded from activity outside the benchmarking core, giving highly consistent results.

Fig. 6 shows the overheads of all configurations of DeCl: DeCl-HW, DeCl-LFI-POC, and DeCl-LFI-metered. We also provide LFI overhead as a point of reference.

Table 4 provides a summary of the geomean overheads. The DeCl-LFI-POC performs similarly to unmodified LFI ($\sim$ 9% versus $\sim$ 8% overhead), since the main change is the addition of position-oblivious code, which in general only affects code that saves return addresses or loads globals. Timer-based metering is the most efficient form of metering, with 19% overhead, since it is able to omit all gas checks, but branch-based metering is not far behind at 20-40% overhead. Branch-based metering is more expensive on x86-64, since expensive flags-preserving metering sequences are often needed. We believe there is potential for more optimization here with a more advanced rewriter/compiler. DeCl-HW only incurs overhead on x86-64 ($\sim$ 3%), entirely due to the use of aligned bundles and the need to rewrite return instructions into indirect branches. On Arm64, DeCl-HW incurs no overhead since it does not use any rewrites (Arm programs do not require bundles in order to be analyzed by a verifier).

[7] We believe a large subset of floating point operations are deterministic and could be supported. Evaluation on the full SPEC suite with floating point yielded lower geomean overheads since FP benchmarks utilize less control-flow and have lower pressure on integer registers.

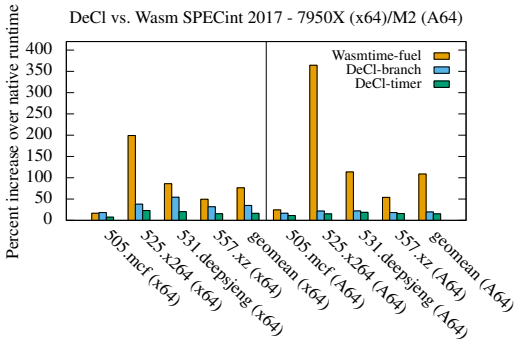

Figure 7: Comparison between metered DeCl and Wasmtime-fuel on integer SPEC benchmarks.

Next we compare DeCl with Wasmtime version 24.0.0 [9], an optimizing WebAssembly JIT compiler designed for running untrusted code, with support for deterministic metering, called fuel. We also enable WebAssembly's 128-bit SIMD extension for Wasmtime. The results are shown in Figure 7. DeCl significantly outperforms Wasmtime in both metered and unmetered configurations, incurring over 2$\times$ less overhead than Wasmtime for equivalent configurations. Table 4 summarizes the geomean experimental results.

System	Fig. 6 x64	Fig. 6 A64	Fig. 7 x64	Fig. 7 A64
Wasmtime-fuel	-	-	76.5%	109%
Wasmtime	-	-	56.3%	82.2%
DeCl-LFI-branch	39.3%	24.1%	35.0%	19.7%
DeCl-LFI-timer	19.2%	19.1%	16.5%	15.3%
DeCl-LFI-POC	9.30%	9.40%	7.64%	8.01%
LFI	9.54%	8.52%	8.11%	7.59%
DeCl-HW	4.40%	-0.14%	5.47%	-0.16%

Table 4: Summary of geomean overheads from Figure 6 (full set of supported benchmarks) and Figure 7 (only benchmarks supported by WebAssembly). Configurations with metering are shown in bold. Some configurations are only shown in this table and not in the referenced figures due to space constraints.

7.2 Application to Smart Contracts

We integrate DeCl within the smart contract engine Groundhog [45], replacing the WebAssembly interpreter (wasm3 [32]) it previously used. This integration required only minimal changes to Groundhog, as both DeCl and the WebAssembly interpreter have approximately the same input-output behavior. Smart contracts are compiled with picolibc [43] and interact with the blockchain's environment (for example, accessing persistent storage, or requesting metadata such as the current block number) via a set of specific functions; DeCl replaces imported WebAssembly functions with runtime calls.

7.2.1 Optimizing Startup and Teardown

A key challenge with the integration is that Groundhog is designed to scale over many CPU cores via concurrent execution of smart contracts. Maintaining this concurrent execution is possible with DeCl because it supports many separate sandboxes in the same process. However, maintaining the scalability requires care when setting up sandboxes, so as to avoid contention on kernel resources. Additionally, smart contracts can be very short programs (running for less than 100μs), so it is imperative that sandbox startup be fast.

In the existing LFI runtime, sandboxes are loaded and mapped into the address space using `mmap`/`mprotect` This approach is not suitable for Groundhog, since it has high startup overheads (multiple system calls), and is not scalable because the use of `mprotect` causes TLB shootdowns.

We solve this problem by preallocating sandboxes with code and data regions. Programs are given 128KiB of read-execute code, and 128KiB of read-write data. These regions are marked with the appropriate protections only the first time a sandbox is used, and subsequently can be reused for future sandboxes without the need for any system calls (only a `memset` to zero the memory).

We use page aliasing (via in-memory files) to map the code region twice: once within the sandbox as read-execute, and separately within the runtime as read-write. This allows the runtime to write to a sandbox's code region without needing to change any memory protections (necessary for loading sandboxes). On Arm64 (but not x86-64), the runtime must then flush the instruction cache on the executable region. With these optimizations, the time to load, execute, and exit from an empty program is 15μs on the M2 processor, and 2μs on the AMD 7950X. Zeroing pages is faster on the M2, but the cache flush dominates the overall time on the M2.

Splitting a contract's code and data into two separate 128KiB regions requires a slight modification to the default linkerscript used by GNU LD. We have chosen sizes for these regions that are as small as possible, while still being usable, because these regions must be cleared after the sandbox terminates. The throughput of the `memset` operation to perform this clear can become a bottleneck if the regions become too large (such as 1MiB). For workloads with a wide variety of contract sizes, the system could pre-allocate sandboxes with varied code/data region sizes.

Code caching As a further optimization, it is possible to cache a sandbox's code and reuse it if the same contract is launched again (skipping the `memset` operation for the code region). This is effective for commonly used contracts like popular ERC20-like tokens, but at the moment our system does not implement this optimization.

7.2.2 Native Cryptography Primitives

One major benefit of DeCl over WebAssembly sandboxes for practical smart contracts is that DeCl enables users to efficiently implement their own cryptography. Even basic operations, like verifying a signature, are sufficiently expensive that today's blockchains must provide hard-coded runtime calls for common operations. This allows the cryptography to run at the speed of native code, bypassing sandbox overhead, but limits the operations available to smart contracts.

Ethereum [55] for example, implemented the BN254 curve [12, 41] within its smart contract environment [15, 46]. Improvements to the cryptanalysis [31] have given this curve less than 128-bit security, and users may wish to use a stronger cryptographic primitive, such as BLS12-381 [11, 13, 49]. Yet applications building on Ethereum have no option to change their cryptographic tools, precisely because deploying a new special-cased operation in an active blockchain requires a difficult, coordinated upgrade. By contrast, DeCl allows contracts to implement their own cryptographic functions internally, and run fast enough that little performance is lost.

Fig. 8 plots the throughput of Groundhog using various sandbox environments: DeCl (branch and timer), Wasm3, and Wasmtime using fuel and the pooling allocator. Each transaction sends a payment between two accounts (of 1,000,000) chosen uniformly at random. Throughput is measured on

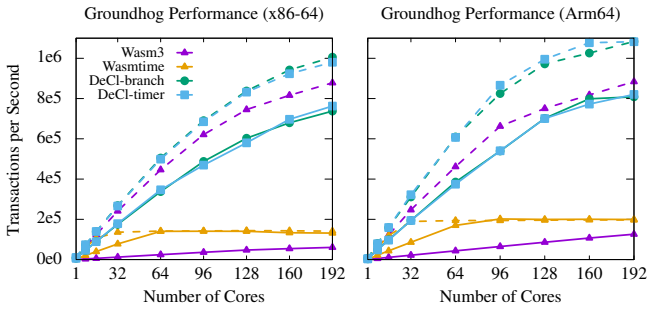

Figure 8: Groundhog throughput on varying numbers of threads, showing that DeCl does not impede scalability. The solid line shows performance when the smart contract provides the implementation of Ed25519, and the dashed line shows performance when Ed25519 is provided by the runtime as unsandboxed native code.

batches of size 100,000. These experiments are run on one c7a.metal (x64) or c8g.metal (Arm64) instance in an Amazon Web Services datacenter. Each system has a 192-core processor (Graviton 4 or AMD EPYC) without hyperthreading.

Each of these transactions verifies one Ed25519 signature and microbenchmarks show that approximately 80 to 90% of each transaction's runtime is spent on that computation. As a result, startup time is critical for this benchmark, since each contract is very short-lived. Wasm3 scales well with access to a native Ed25519 in the runtime thanks to low startup time, but significantly degrades once it must perform cryptography in the sandbox. Wasmtime performs better at low parallelism in both cases but hits a scaling limit due to startup overhead. DeCl can combine low startup time with low CPU overhead, allowing competitive performance even when all of the cryptographic operations run within the sandbox. A smart contract developer can implement alternative cryptographic primitives internally and still attain good performance.

We also evaluate DeCl on zero-knowledge proof verification workloads, which are often some of the most CPU-intense programs run on-chain in smart contracts. We benchmark verification time for Groth16 and Plonk proofs generated using the SP1 zkVM [8] and verified using SP1's `no_std` Rust verifier. Table 5 shows overheads associated with DeCl, Wasmtime (JIT compiler with SIMD enabled), and Wasm3 (interpreter). With DeCl, runtimes for contracts that perform on-chain zero-knowledge proof verification would be reduced by at least a factor of 2, and up to a factor of 30 for blockchains that use an interpreter for contract execution.

8 Limitations

Portability By enforcing determinism at the machine code level, we lose some degree of portability. While the programs can be run on architectures other than their native architecture

System	Groth16	Plonk
Native (x64)	.313s	.588s
DeCl-timer	.344s (1.10×)	.650s (1.11×)
DeCl-branch	.407s (1.30×)	.763s (1.30×)
Wasmtime-fuel	.745s (2.38×)	1.38s (2.34×)
Wasm3	10.5s (33.7×)	20.4s (34.7×)
Native (A64)	.189s	.338s
DeCl-timer	.202s (1.07×)	.365s (1.08×)
DeCl-branch	.210s (1.11×)	.379s (1.12×)
Wasmtime-fuel	.587s (3.11×)	1.08s (3.07×)
Wasm3	5.38s (28.5×)	10.1s (30.0×)

Table 5: Groth16 and Plonk zero-knowledge proof verification time on the 7950X (x64) and M2 (A64) machines. Times are shown along with the slowdown factor relative to native code.

via binary translation, this can come with a significant performance loss, and sacrifices security benefits by introducing a binary translator after verification. Depending on the binary translator, the overhead of translation can be estimated to be around 25%-65% on average for high-performance binary translators [19, 22]. Additionally, a binary translator designed for sandboxing (e.g., using Cranelift as a backend) may have further overheads.

Compiler Toolchain Since the x86-64 and Arm64 instruction sets bundle SIMD and floating point together in the same extension, compilers likewise cannot separate the two. DeCl's verifier allows SIMD instructions while prohibiting floating, which presents challenges with existing compiler toolchains. In particular, it is not possible to enable soft-float support while also keeping SIMD enabled—the compiler only supports enabling/disabling FP/SIMD as a single unit. Currently, we just enable FP/SIMD and catch floating point instructions in the verifier, either rejecting the program, or replacing them with nops. A better solution would be to modify the compiler to allow soft-float and hardware integer SIMD to coexist.

Fragility and Hardware Bugs As part of our threat model, we assume that the hardware within the subset of instructions we allow is trustworthy. While this is likely to hold in practice, it is not necessarily the case. Hardware bugs can occur due to overclocking or slow degradation of the silicon, or can occur due to an error in the hardware design. The former results in glitches that happen sporadically, while the latter is typically restricted to a particular microarchitecture, but deterministically causes a glitch until the hardware vendor releases a fix. Smart contracts already run within byzantine-fault-tolerant systems, and these hardware faults are infrequent and independent enough that as a result they are unlikely to cause issues in practice. Hardware bugs are likely easier to exploit in DeCl than in a JIT-based system, though in many cases they may still be exploitable in both, and are likely much more

difficult/impossible to exploit in an interpreter-based system. Once instruction sequences that trigger hardware bugs are discovered, the verifier can be patched to detect them. If there are existing programs with these sequences, those programs must either be disabled or run in an emulator. Note that since our scheme allows the program to read its own code, the emulator must provide the illusion that the old unpatched code is running, while actually running a different sequence that does not trigger the hardware bug. A different SFI scheme could be chosen to avoid this issue—one which would strictly separate code and data into distinct 4GiB regions.

Fast & Secure Sandboxing Any replicated state machine that runs untrusted programs requires a sandbox that both runs deterministically and can preempt a contract after an execution limit. Bitcoin [39] achieves deterministic termination with a scripting language without loops [6], while other blockchains run more complex virtual machines like WebAssembly [24], eBPF [37], or the Ethereum Virtual Machine [55]. Our approach is a variant of Software Fault Isolation [36, 50, 54, 57, 58], which instruments native code and verifies that the code cannot escape the sandbox. We build on top of the existing Lightweight Fault Isolation project [57]. A recent proposal for Ethereum suggests using RISC-V machine code as the language of smart contracts [14], which could make use of our technique to allow smart contracts to execute natively on appropriate hardware rather than in an emulator.

These sandbox designs face three key challenges in practical systems, beyond the requirements of deterministic, metered execution. First, they must run as fast as possible; any overhead reduces overall system throughput, leading to higher fees for end-users. Executing smart contracts is a key bottleneck in some blockchains today [25]. Techniques like optimistic concurrency control [23], speculative execution [16], or selective transaction (re)ordering [34, 44, 48, 52, 56] can provide throughput improvements, but these approaches are complementary to faster sandboxing.

Second, any sandbox must execute code securely; any possibility of reading or writing data outside of the sandbox can introduce non-determinism, which can cause two replicas of a state machine to disagree on system state. Translating the bytecode of an IL into efficient machine code is a complex task. Security relies on the correctness of key tools, like the eBPF verifier or a WebAssembly compiler, which are large software systems that have previously contained serious bugs [2, 4, 29]. Approaches include software bytecode interpreters, to minimize complexity (at the cost of runtime overhead), simplifying a JIT compiler [7], formal verification of the compiler [53].

Program Metering Mellor-Crummey et al. implement a native-code instruction counter in software for profiling, using a reserved counter and instrumenting only the backwards branches of a program [38]. Unlike this approach, our metering technique must be verifiable so that the verifier can guarantee that programs are properly metered.

Wasmtime considered a proposal for slacked metering [51], which is similar to our timer-based metering, but it was never fully implemented.

Determinism One example application of determinism is efficiently distributing computation across many machines, as performed by `gg` [21]. Another example is the Exokernel file system, XN [30], which allowed applications to supply their own code for parsing file system data structures as untrusted deterministic functions or UDFs. DeCl provides a more efficient alternative to UDFs.

Record and replay systems [33, 35, 42, 47] can run unmodified, often parallel, programs in a deterministic way. These work by running a program and capturing the results of any non-deterministic operations. Then the program can be deterministically replayed. However, this setting is non-adversarial and does not provide bounded termination or isolation. In a similar vein, Determinator [10] offers a deterministic OS API that can handle parallel programs and is compatible with conventional OS abstractions.

10 Conclusion

We presented Deterministic Client (DeCl), a software sandboxing system that can enforce that sandboxes are deterministic and metered, while running them at near-native speeds. We explain how to guarantee deterministic execution of native code even in an adversarial setting, for the x86-64 and Arm64 architectures. The verification process we describe uses linear-time algorithms and, after some rewrites to the assembly generated by the compiler, can accept programs produced by LLVM. These properties make it possible for DeCl to run smart contracts that are written as machine code programs, enabling bare-metal smart contracts. We demonstrate the feasibility of this approach by integrating DeCl into Groundhog, a scalable smart contract engine.

Disentangling the Dual Role of NIC Receive Rings

Boris Pismenny*

Dan Tsafrir
Technion – Israel Institute of Technology

Abstract

CPUs parallelize packet processing across cores via per-core receive (Rx) rings, which are typically sized to absorb bursts with ≥1Ki entries by default. The combined I/O working set (packet buffers pointed to by all Rx rings) easily exceeds the LLC capacity, thus degrading performance due to high memory bandwidth pressure. Recent work has reduced the I/O working set size by sharing Rx rings among cores with the "shRing" system. But this approach suffers from a bottleneck under imbalanced loads, which are common.

We contend that the bottleneck stems from an unnecessary entanglement of two orthogonal producer-consumer structures: (1) memory allocation, where the core produces empty buffers that the NIC consumes to store packets; and (2) packet delivery, where the NIC produces incoming packets that the core consumes. We propose rxBisect, a new CPU-NIC interface that decouples these structures. RxBisect replaces each Rx ring with two separate rings corresponding to the two structures, allowing memory allocation to be performed independently of packet reception. RxBisect can thus pass empty buffers efficiently between cores upon imbalance, thereby eliminating the aforementioned bottleneck. We implement rxBisect with software emulation and find that it improves throughput by up to 20% and 37% relative to the state-of-the-art (shRing) and state-of-the-practice (per-core Rx rings).

1 Introduction

With Ethernet speeds growing to hundreds of gigabits per second (Gbps), the performance of network-intensive applications depends on the effectiveness of technologies such as direct data I/O (DDIO) [15]. DDIO enables the network interface card (NIC) to perform direct memory accesses (DMAs) that read from and write to the last-level cache (LLC) instead of main memory. Software can thus access packets more quickly and conserve main memory bandwidth [1,13,18,23,51,54,64,65,74,79], enabling applications to achieve higher throughput and lower latency.

The effectiveness of DDIO depends on the size of the I/O working set, which consists of the memory regions DMAed by the NIC for packet exchange [66]. If the I/O working set exceeds the LLC capacity, newly arriving packets written by the NIC can evict from the LLC other packets that have not yet been processed [22, 79]. As a result, CPU accesses to packet data slow down because they are served from main memory, which can then become a bottleneck resource [46, 54], degrading both throughput and latency.

The I/O working set is determined by the CPU-NIC packet exchange interface (§2), which consists of two types of producer-consumer queues: one for transmission (Tx) and another for reception (Rx). These queues are circular arrays, known as "rings," whose entries are architected descriptor structures that point to packet buffers. To support high data rates, NICs distribute incoming traffic across multiple per-core Rx rings, enabling systems to sustain ≥ 100 Gbps rates using multicore parallelism [25,27,53,54,59,67,78].

Each Rx ring is initially filled by software with empty 1500 B buffers, matching the network's maximum transmission unit (MTU). As packets arrive, the NIC consumes empty buffers in cyclic order by populating them with incoming packets. Software then consumes the full buffers in the same cyclic order, removing each for processing and immediately replacing it with an empty buffer.

This producer-consumer NIC-CPU interaction implies that every empty buffer in an Rx ring must be used before any can be re-used. Consequently, the I/O working set size is at least $N \times R \times 1500\,\text{B}$, where N is the number of rings and R is the size of each ring. The default ring size for ≥100 Gbps NICs is $R = 1{,}024$ entries [11,16,47,55,73,73,80], required to absorb packet bursts caused by increasing network speeds [2,40,56]. Since CPUs typically provide less than $R \times 1500\,\text{B} \approx 1.5\,\text{MiB}$ of LLC capacity per core, multicore network processing can easily exceed the overall LLC capacity.

Keeping the I/O working set in the LLC thus requires reducing the number or size of Rx rings. Reducing size means rings might be unable to absorb packet bursts, which degrades the throughput a single core can sustain without incurring packet loss [66,83]. We therefore rule this alternative out.

The other alternative is more practical: reducing the number of Rx rings by sharing a single ring among two or more cores, as we proposed in the shRing system [66]. The problem is that shRing requires software synchronization, which adds overhead to packet processing. Moreover, shRing can be effective only when packet processing is roughly computationally balanced across the sharing cores. But if some cores are consistently overloaded while others are not, queueing theory dictates that packet loss is inevitable: overloaded cores impede packet delivery to underloaded cores by monopolizing the shared Rx entries. Accordingly, shRing disables itself upon detecting such situations, falling back on default-size private rings, which can exceed the LLC capacity.

*Work done mostly while at Technion.

structure	*producer*	*consumer*	*elements*
memory allocation	CPU core	NIC	empty buffers
packet reception	NIC	CPU core	full buffers

Table 1: *The canonical Rx interface between the NIC and the CPU entangles two producer-consumer structures in one ring.*

In §3, we explain and demonstrate the I/O working set problem and show that real-world imbalance capable of nullifying the potential benefits of shRing is widespread—although it has been referred to as "pathological" [66].

Our new insight is that the root cause of the problem—the inability to shrink or share Rx rings without the aforementioned undesirable side effects—is the canonical Rx interface, which unnecessarily entangles two orthogonal producer-consumer structures: one for allocating empty buffers, with the CPU core acting as producer and the NIC as consumer; and another for delivering full buffers (housing newly arriving packets), where the roles are reversed as summarized in Table 1. Due to this entanglement, we cannot simply reduce the number of buffers allocated per core without also impairing the core's ability to absorb bursts. Nor can we share allocated buffers among cores without simultaneously forcing them to share (and compete over) packet reception capacity.

To solve this problem, we propose rxBisect, which redesigns the Rx NIC interface to disentangle packet allocation from reception (§4). RxBisect splits the traditional circular Rx array into separate allocation (Ax) and bisected reception (Bx) rings, which are independent and may have different sizes. RxBisect supports cross-core receive buffer sharing: the NIC may consume a buffer from any Ax ring to store an incoming packet, regardless of the destination Bx ring, as long as both rings belong to the same software entity and reside on the same NUMA node. To replenish allocated buffers, the NIC posts a notification to a core's Bx ring whenever it consumes a buffer from that core's Ax ring. Commonly, the Ax and Bx rings of a newly arriving packet belong to the same core, so this notification is included in the new packet's Bx descriptor. When processing this notification, the core places a fresh empty buffer into its Ax ring.

With rxBisect, each core can employ a 1 Ki Bx ring, which may be empty or full if, respectively, none or most of the incoming traffic is directed at that core. Allocation rings can then be smaller, reducing the overall I/O working set and achieving the desired effect. Fewer Ax buffers are needed because rxBisect implements cross-core buffer sharing, quickly moving Ax buffers between cores and using them to populate Bx rings as needed, even when a buffer's source Ax and destination Bx are associated with different cores. Notably, rxBisect frees software from synchronization overheads associated with cross-core buffer sharing (which shRing suffers from), offloading them to the NIC.

We prototype rxBisect using emulation on top of a software NIC framework we developed, which also emulates other NIC models: the private per-core ring baseline and shRing. These allow us to compare the performance of emulated and non-emulated versions and assess the emulation fidelity (§5). We show that emulated performance is similar to real performance or worse, reducing throughput by up to 12% and increasing latency by up to 94%. We therefore gain confidence in experimental results that compare emulated rxBisect performance to non-emulated baseline and shRing performance and find rxBisect to be preferable.

Our evaluation setup employs two 100 Gbps NICs. We show that rxBisect improves throughput by up to 37% and reduces packet latency by up to 11x compared to the default-sized per-core Rx baseline. (The significant latency gains occur when rxBisect sustains line-rate whereas the baseline is unable to.) Under load imbalance, rxBisect improves throughput by up to 20% relative to an idealized shRing (§6).

2 The NIC-CPU Interface Today

Software interacts with NICs via per-core logically cyclic arrays called receive (Rx) and transmit (Tx) rings. We focus on Rx rings as they dictate the I/O working set (see §3). The NIC spreads incoming traffic among cores using receive side scaling (RSS [59]). With RSS, when a packet arrives from the network, the NIC selects its destination Rx ring according to a hash computed over packet header fields.

Rx rings combine two producer-consumer functionalities: (1) software producing empty buffers for the NIC to consume by storing incoming packets (memory allocation) and (2) the NIC producing incoming packets for software to consume (packet reception).

Software configures the Rx ring size and allocates it in main memory, prepopulating ring entries, called *descriptors*, with pointers to MTU-sized buffers. When a packet arrives, the NIC writes it to the buffer pointed to by the *head* ("next empty") descriptor index and advances the head unless it reaches the *tail* ("next full") descriptor index. Software processes packets in order, swapping the buffer pointed to by the tail (with the received packet) for a new empty buffer and incrementing the tail unless it reaches the head.

Software informs the NIC about new free buffers (ring tail advances) by means of an MMIO write to a NIC register, known as "ringing a doorbell." In contrast, software does not poll the ring head to detect new packets, as such polling would result in cache line bounces between the NIC and the CPU (if the head were stored in memory) or expensive MMIO reads (if it were stored in a NIC register). Instead, the NIC informs software of produced packets by means of a cache-friendly memory-based protocol, described next.

Completion Rings Modern NICs notify software of delivered packets via per-core in-memory completion ring (CR) structures [24, 35, 57]. (Intel NICs have used CRs since 2022 [30].) CRs, like descriptor rings, are circular buffers. Each CR is associated with one or more descriptor rings. CR

entries indicate which Rx ring descriptors are ready for software processing by specifying their ring and index.

To optimize cache coherence traffic, the NIC exclusively writes CR entries while software only reads them, coordinating access via a sense reverse mechanism [60]. Both the NIC and software maintain a "generation" bit that flips on every pass through the ring. Each CR entry has a "done" bit that the NIC fills with its "generation" bit when a new packet arrives. Software polls the head CR entry, comparing its "done" bit with its internal "generation" bit to detect new packets.

Figure 1 depicts packet reception with CRs. Initially (Figure 1a), three packets arrive for a core whose Rx ring and CR are empty. Packet delivery (Figure 1b) consists of (1) the NIC using RSS to find the Rx ring and CR matching the packet; (2) writing the packet to an Rx descriptor, and (3) writing a CR entry, indicating the index of the Rx descriptor that holds the packet. These entries have "done" set to 1, because the CR's generation is 1. Packet processing (Figure 1c) occurs when the core, polling the head CR entry, notices its "done" flag has changed. It starts traversing "done" CR entries, processing packets pointed to by the Rx descriptors indicated by them, replenishing these buffers, and advancing both rings' tails. Once the core reaches a CR entry with "done" set to 0, it stops and resumes polling the CR.

We remark that a separate CR is used instead of piggybacking this protocol on Rx descriptors to avoid having both the NIC and software writing to the same cache line concurrently (by updating different descriptors in the same cache line), which creates cache contention and hazards [72].

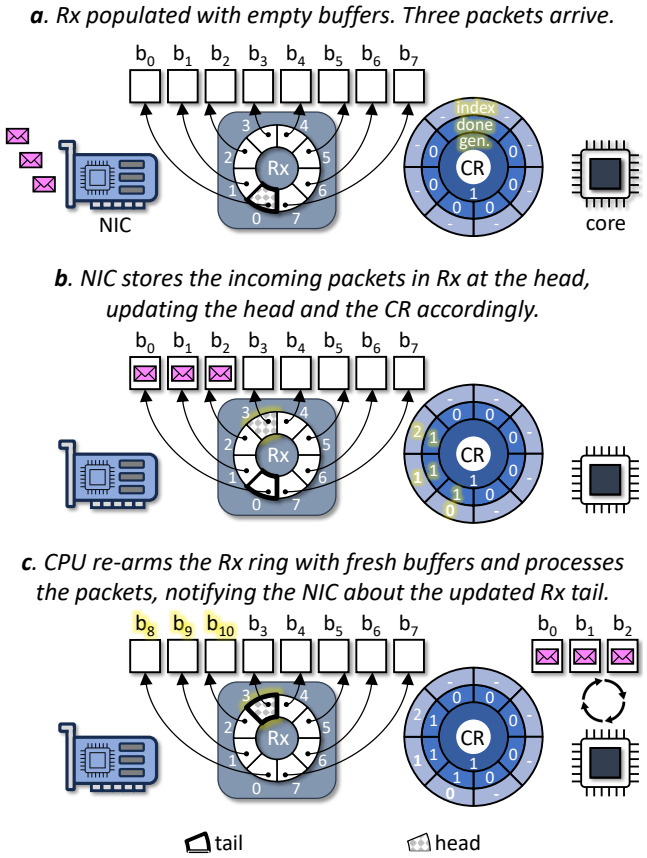

Figure 1: *PrivRing packet reception using a single private receive ring and associated completion ring. Highlighted regions indicates changes relative to the previous stage. For simplicity, we depict only the Rx ring's head and tail positions, assuming identical head/tail positions in the CR (which is not necessarily the case).*

3 Motivation

We focus on kernel-bypass applications that interact directly with the NIC using, e.g., the data plane development kit (DPDK) [38]. These applications process packets in a run-to-completion manner and employ polling to receive packets [3, 39, 43]. The I/O working set problem has been shown to affect socket-based applications as well [66, §6]

3.1 The I/O Working Set Problem

Network-intensive applications depend on DDIO [15] and similar technologies to keep up with network rates of hundreds of Gbps and to enable low-latency packet processing. DDIO allows I/O devices to perform DMAs directly to/from the CPU's LLC, bypassing main memory when possible. With DDIO, DMA reads are satisfied by the LLC if the requested bytes are present. DMA writes place data into the LLC, either overwriting existing cached contents of the receive buffer or allocating new cache lines for it. By default, DDIO may allocate new cache lines in up to 10% of the LLC ways (two ways in the setup described in §6).

When DDIO allocates new cache lines, it evicts existing entries, writing them back to main memory. If this evicted data is later needed for further processing or transmission, it must be fetched from memory. At high data rates, the resulting increase in memory traffic—from both evictions and re-accesses—can create memory bandwidth bottlenecks.

DDIO effectiveness depends on the size of the I/O working set, defined as the memory regions DMAed by an I/O device over some time interval [66]. When an I/O-intensive workload has a working set that exceeds LLC capacity, it leads to the "leaky DMA" problem [22, 79]: new packets written by the NIC evict not-yet-processed packets from the LLC. As a result, CPU accesses to packet data are served from main memory, which is slower and may even become a bottleneck [1, 13, 21, 23, 42, 51, 54, 62, 64, 65, 69, 74, 79, 82]. If slower memory accesses cause a core to fall behind the packet arrival rate, its Rx ring fills up, and latency becomes proportional to the ring size, as each new packet must wait for an entire ring's worth of packets to be processed.

Ideally, the I/O working set would depend only on software processing time, i.e., buffers could be reused by the NIC immediately when released by software. However, the NIC

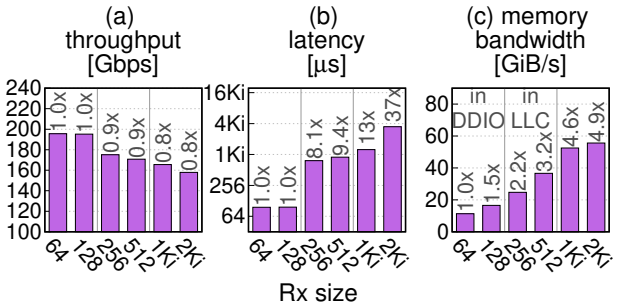

Figure 2: *Large I/O working set causes high memory bandwidth (c), degrading throughput (a) and latency (b). Top labels compare to Rx size of 64. Vertical lines delimit where the I/O working set size fits in DDIO's portion of the LLC, in the LLC, or exceeds the LLC.*

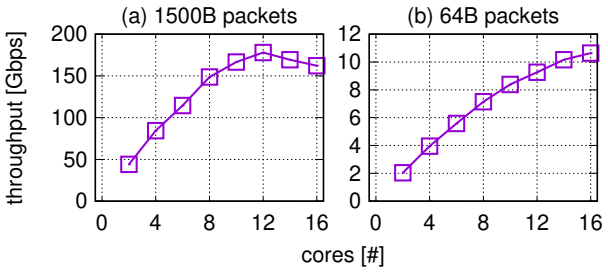

Figure 3: *NF throughput scales with small 64 B packets but not with large 1500 B packets due to the increased I/O working set.*

interface creates a dependency on the number (N) and size (R) of Rx rings. Rx rings are prepopulated with buffers, and as ring descriptors are cyclically accessed, an Rx buffer b can be reused only after the NIC uses all other buffers in the ring, even if software has released b earlier. In contrast, Tx rings contain only in-flight packets, so they are usually empty or partially full. Thus, the I/O working set size is at least the union of all Rx buffers, which is of size $|Rx| = N \times R \times 1500\,\text{B}$.

The growing gap between stagnant CPU speed and ever-increasing NIC bandwidth results in $|Rx|$ growing with hardware advances, thus exceeding LLC capacity [28, 66, 74]. The reason is that this gap necessitates increasing both the size R and number N of the Rx rings, because: (1) packet bursts experienced by individual cores become bigger and should be absorbed to avoid packet loss [20, 37, 81], and (2) packet processing requires additional cycles, disallowing any single core from driving the NIC to its full capacity [27, 65].

We demonstrate the I/O working set problem by evaluating the impact of increasing the Rx ring size on a stateful load balancer (LB) network function (NF). In each experiment, LB uses all cores of a 16-core CPU, which has a 22 MiB LLC and two 100 Gbps NVIDIA ConnectX-5 NICs, for processing 1500 B packets (§6 details the full experimental setup). Figure 2 shows that enlarging the I/O working set worsens throughput by up to 0.8×, latency by up to 37× (due to rings filling, as explained above), and memory bandwidth by up to 4.9×. Line rate throughput is achieved when the I/O working set fits in the two LLC ways used by DDIO (ring size $R \leq 128$). Results degrade in two steps: when the I/O working set exceeds the DDIO ways but fits in the LLC ($128 < R < 1024$) and when it exceeds the LLC ($R \geq 1024$). Other NF applications behave similarly (not shown).

One may wonder why NFs should use all cores, if the result is an excessive I/O working set. The answer is that systems often do not have fixed workloads, and all cores are necessary to maximize throughput in certain workloads. Figure 3 demonstrates this issue by showing LB throughput under maximal rates of either 1500 B or 64 B packets, as the number of LB cores varies. For 1500 B packets, maximal throughput is reached at 12 cores. But for 64 B packets, throughput peaks at 16 cores, as the I/O working remains small. Thus, our goal is to address the I/O working set problem in the most demanding cases—for the benefit of all workloads.

3.2 Limitations of Existing Solutions

We next discuss various approaches for shrinking the I/O working set to fit in the LLC and explain why they are unsatisfactory. In §4.3, after introducing rxBisect, we detail how it avoids the limitations discussed here.

Few Dispatchers This approach, showcased by Shinjuku [42] and Shenango [62], uses a few "dispatcher" cores, each with a large Rx ring, to distribute packets among the remaining worker cores. While such systems can saturate ≈40 GbE links, the dispatcher cores become the bottleneck as link speeds increase to 100 Gbps and beyond [27].

Small Private Rings (PrivRings) A privRing system can employ smaller private per-core rings, such that the I/O working set fits in the LLC. But reducing the Rx ring size below the default (1 Ki) makes rings unable to absorb packet bursts, resulting in packet loss that degrades the performance of loss sensitive protocols such as TCP [66].

ShRing ShRing reduces the I/O working set by sharing default-sized Rx rings among multiple cores [66].[1] ShRing associates several per-core CRs with a single Rx ring, enabling the NIC to spread packets among the sharing cores in a lockless manner. But shRing still necessitates locking and atomic instructions when cores update the shared Rx ring, which adds overhead to packet processing compared to the lockless privRing design (as we show in §6.2).

A major problem with shRing is that it leads to packet loss under load imbalance, where some application cores are consistently overloaded (receiving packets faster than they can process) while others are not. In such conditions, by queueing theory, the overloaded cores monopolize the shared Rx queue and starve their underloaded counterparts for space.

[1] ShRing is based on Mellanox Receive Memory Pools (RMP) [57], which are insufficient to implement rxBisect; see discussion in §7.

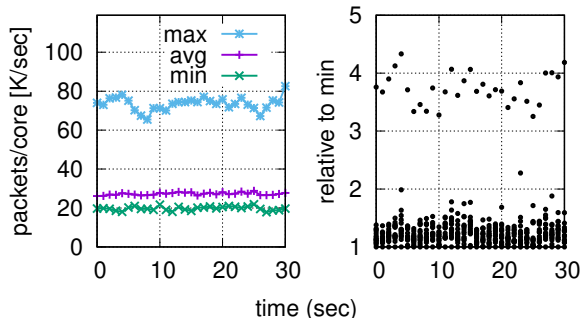

Figure 4: *Imbalanced RSS distribution across 16 cores during a 30-second segment of a real-world packet trace.*

Consequently, shRing is necessarily a dynamic heuristic that should be turned off upon such imbalance.

3.3 Imbalanced Load in the Wild

Imbalance is uncommon in IETF (Internet Engineering Task Force [34]) benchmarks and academic network function (NF) studies. But it does occur in NF workloads [6, 43] and is widespread in other contexts like microsecond-scale remote procedure calls [17, 42, 45, 50, 67, 77].

Figure 4 exemplifies real-world imbalance by analyzing a 30-second sequence from the 2018-03-15 NYC CAIDA dataset [12]. We compute the per-packet Receive Side Scaling (RSS) [59] hash values that the NIC uses to assign packets to 16 cores, and we display the number of packets per second received by each core (left), along with the ratio between the minimum and maximum per-core packet rates (right). The ratio stays between 325–433% throughout. In §6.2, we evaluate dynamic shRing and rxBisect by replaying this trace, and we show that rxBisect throughput is 20% higher as it accommodates imbalance, whereas shRing turns itself off.

4 RxBisect

RxBisect is a new NIC-CPU interface designed to address the I/O working set problem. RxBisect disentangles the traditional Rx ring's empty buffer allocation and packet reception functionalities, allowing them to be managed independently. RxBisect supports two types of rings: *allocation (Ax) rings*, where a core produces empty buffers for the NIC, and *bisected reception (Bx) rings*, where the NIC produces incoming packets, stored in buffers it consumes from allocation rings.

The crux of rxBisect is that each bisected reception ring r can be associated with *several* allocation rings (of different cores), enabling the NIC to deliver packets to r as long as *some* allocation ring is not empty. This association is not exclusive—multiple Bx rings can be associated with overlapping (or identical) sets of Ax rings. In this way, rxBisect turns the union of the set of empty buffers produced by each core into a *globally shared* resource, co-managed by the NIC and software in a lockless manner. This design allows each core to maintain a large bisected reception ring (for absorbing bursts) without having to independently maintain a large set of empty buffers—it only requires a small allocation ring. Thus, rxBisect ensures that the I/O working set size is kept below LLC capacity.

In the following, we detail rxBisect's receive-side processing in the NIC (§4.1) and by software (§4.2). RxBisect does not modify the Tx side and so we do not discuss it. We then pinpoint how rxBisect addresses the limitations of the privRing and shRing designs (§4.3). Next, we discuss NIC hardware implementation issues (§4.4). Finally, we present rxBisect parameter configuration guidelines (§4.5).

4.1 NIC Side

An rxBisect NIC supports two types of receive-side rings: allocation (Ax) and bisected reception (Bx) rings. Each Ax ring entry points to an empty buffer for the NIC to consume in order to store an arriving packet. Each Bx ring entry holds a descriptor through which the NIC notifies software of packet delivery and/or consumption of an empty buffer. Each Bx ring entry holds a pointer to a received packet and the index of the Ax entry and Ax ring that produced the packet's buffer. Bx entries also hold a "done" flag and a corresponding sense-reverse indication flag, whose purpose is the same as in the CRs of the existing NIC interface described in §2.

Figure 5 depicts rxBisect's flow. Initially (Figure 5a), software allocates memory for allocation and bisected reception rings. Allocation rings are filled with entries pointing to MTU-sized buffers to receive packets and bisected reception ring entries are left empty, as the NIC will overwrite them. Crucially, the number of allocated buffers in each Ax ring can be smaller than the size of the Bx rings, which is the key to reducing the I/O working set size (§4.3).

Software then *associates* each Bx ring r with several Ax rings, indicating to the NIC that buffers from these allocation rings can be used to store packets destined to r. Software also *links* each Ax ring a with some Bx ring r, indicating to the NIC that notifications about buffers consumed from a should be delivered through r. For simplicity, assume for now that software (1) allocates per-core Ax and Bx rings, (2) links a core's Ax ring to its Bx ring, and (3) associates every Bx ring in an application with all the Ax rings of that application. (We discuss another software usage model in §4.2.)

When packets arrive (Figure 5b), an rxBisect NIC maps each incoming packet to a Bx ring exactly as a packet is mapped to an Rx ring in today's NICs, e.g., using RSS. For each packet, the NIC chooses an Ax ring with available buffers according to some policy (e.g., the linked Ax ring or a random non-empty Ax ring if it is empty), and consumes a buffer from that Ax ring to store the packet. In the depicted scenario, a burst of five packets arrives for core 0. The first four packets exhaust its Ax ring, and thus the fifth packet is placed in a buffer allocated from core 1's Ax ring. To deliver each packet,

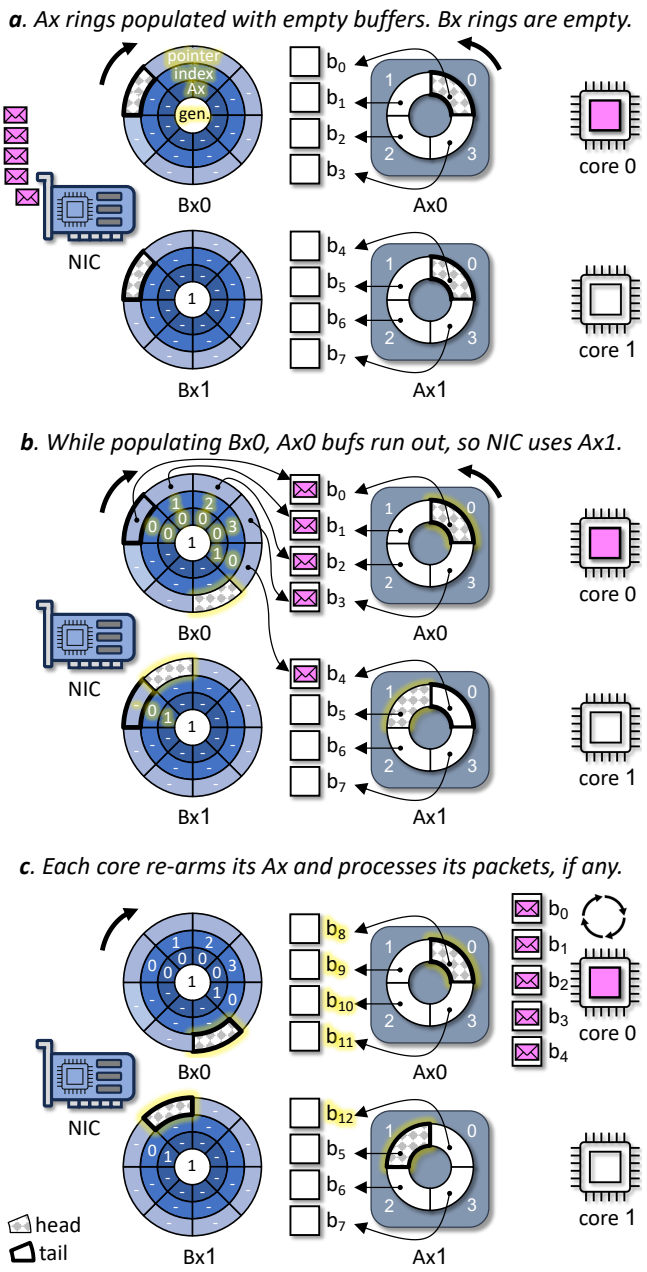

Figure 5: *RxBisect packet reception using two allocation (Ax) rings and two bisected reception (Bx) rings. Ax ring buffers are shared by both Bx rings through NIC hardware. Highlighted text indicates changes relative to the previous stage. The Ax head advances counter-clockwise and the Bx head advances clockwise.*

the NIC first DMA-reads a packet buffer address from the Ax head descriptor entry, and then DMA-writes the packet's data to the packet buffer.

The NIC notifies the receiving core about a delivered packet by DMA-writing the packet buffer's address to the target Bx ring's head descriptor entry. The NIC notifies the allocating core about the consumed buffer by DMA-writing the buffer's Ax ring and entry to the head descriptor of the Bx ring linked to it. In the common case, in which the receiving core is also the allocating core, these notifications are combined into a single descriptor, as shown in Figure 5b for buffers $b_0, \ldots, b_3$. Finally, the NIC updates the Ax and Bx ring head indexes, optionally raising an interrupt for both. Importantly, packet delivery latency that is determined by the number of dependent DMAs, which we call the "critical path," is the same in privRing, shRing, and rxBisect (§4.4).

Finally (Figure 5c), each core processes notifications in its Bx ring (either by polling or following the aforementioned interrupt). It processes delivered packets and/or replenishes buffers consumed from its Ax ring with empty buffers that it allocates, including notifying the NIC (by means of updating the Ax ring's tail) that new buffers are available. After processing a packet, its buffer is freed back to the system allocator. We expand on software-side processing in §4.2.

4.2 Software Side

Our discussion relates to software that directly interacts with the NIC, i.e., kernel-bypass applications or in-kernel drivers. Software has flexibility in how it leverages rxBisect to minimize the I/O working set by configuring Ax rings such that the aggregated size of their buffers does not exceed LLC capacity. For example, software can use small (e.g., 128-entry) per-core Ax rings. Or, software can employ a small number of large Ax rings, which are served by a few dedicated allocation cores while the remaining cores focus on packet reception. The discussion below does not assume a specific configuration. In any case, the buffer-free bisected receive rings should remain large, to absorb bursts. We detail Ax and Bx configuration guidelines in §4.5.

Allocation Mechanism The only constraint rxBisect makes on the software architecture is that it support allocation and freeing of a buffer by different threads/cores. This scenario can occur when a buffer allocated from one core's Ax ring is used to hold a packet destined to a different core, which will then have to free this buffer after processing the packet. Fortunately, many modern multicore allocators support this allocator capability [9]. In particular, both the Linux kernel and DPDK already use such allocators [4, 19]. At a high level, these allocators employ a two-level design consisting of a shared buffer pool with a per-core caching level, which reduces contention on the shared pool. Caches are filled from the shared pool when they run out of buffers and caches drain excess buffers to the shared pool when they grow beyond some threshold of the cache's expected size (e.g., 1.5× in DPDK). The two-level allocator design is important for amortizing the cost of buffer transfer between cores. Due to it, we observe a difference of at most 15 cycles in average allocator call latency between rxBisect and privRing (where buffers never move across cores).

```
1  int RxBisect(Ring *ax, Ring *bx,
2               void **pkts, int len) {
3   uint32_t idx, npkts = 0, nalloc = 0;
4   BXEntry *bxe;
5   while (npkts < len && bxe = consumeBXE(bx)) {
6     if (bxe->buf != NULL)
7       pkts[npkts++] = bxe->buf;
8     if (bxe->idx == ax->idx) {
9       ax->desc[bxe->idx].buf = alloc_buf();
10      nalloc++;
11    }
12  }
13  if (nalloc > 0) {
14    ax->tail += nalloc;
15    *ax->doorbell = ax->tail;
16  }
17  return npkts;
18 }
```

Listing 1: RxBisect disentangled ring receive code.

Receive Flow Listing 1 shows the rxBisect receive function, which dequeues a batch of packets for processing as well as handles notifications about allocated buffers that require replenishing. The function receives an allocation ring (`ax`), a bisected reception ring (`bx`), and an output array of packet pointers (`pkts`) of length `len`. It returns the number of received packets. Multiple cores run this code in parallel with different ring arguments, which are all interlinked by NIC hardware to share Rx buffers.

Lines 5–12 check the Bx ring for new entries. The Bx ring check in `consumeBXE(bx)` uses the sense reverse technique (§2) to identify ready entries without writing to Bx descriptors. When no Bx entry is ready, this function returns `NULL`; otherwise, it returns the first ready entry and updates the Bx ring's tail. (We omit `consumeBXE`'s code.)

Each returned Bx entry indicates both the pointer of a received buffer, if there is one, and an Ax ring and entry index of a buffer consumed by the NIC. If the Bx entry contains a packet buffer, the packet is stored for processing (lines 6–7). If the Bx entry describes a buffer originating from the core's Ax ring, then a new Ax buffer is allocated in its stead (lines 8–10). Lines 13–16 check if allocation requests were handled and advance the Ax ring's tail index if necessary. It is correct to advance the tail because the NIC consumes buffers in ring order and enqueues all the related notifications to this Bx ring in the same order. The code does not limit the number of allocations, to replenish as many buffers as possible. Nevertheless, the number of allocation iterations is bounded by the Ax ring size, because once it becomes empty, only this function can replenish it.

4.3 Comparison to PrivRing and ShRing

By disentangling buffer allocation from reception, rxBisect obtains three advantages: (1) the total number of allocated buffers in Ax rings can be smaller than the total size of the Bx rings, which reduces the I/O working set size; (2) the NIC can use buffers from any Ax ring to populate any Bx ring, so buffer sharing is achieved similarly to shRing; but (3) in contrast to shRing, sharing buffers is achieved without sharing the cores' packet reception capacity or software synchronization.

Figure 6 depicts these differences. The figure compares the minimal I/O working set of two cores running privRing, shRing, and rxBisect. In privRing (Figure 6a), each core can work independently, without synchronization or other dependencies on other cores' behavior. However, the existing NIC ring interface necessitates that an Rx ring able to absorb packet bursts must also hold many empty buffers, resulting in an excessive I/O working set.

ShRing (Figure 6b) solves privRing's I/O working set problem by sharing a default-sized Rx ring, which can absorb packet bursts, between the cores, but it requires synchronization (with locks) to serialize reposting of buffers to the shared ring and advancing the ring's tail. Crucially, shRing always incurs this latency-increasing per-packet overhead, even if the workload does not suffer from the I/O working set problem (e.g., because the packet rate allows a packet's processing to complete before its eviction from the LLC).

In addition, with shRing, traffic destined to an overloaded core can monopolize the shared ring, preventing other cores from receiving packets. E.g., in Figure 6c, because the overloaded core 2 cannot sustain its packet rate, packets destined to it start queueing, eventually filling the ring. Thus, packets to core 1 get dropped, despite it being able to process them.

RxBisect (Figure 6d) combines the advantages of privRing and shRing without inheriting their disadvantages. Disentangling the existing Rx ring functionality into bisected reception and allocation rings with independent sizes allows rxBisect to realize a shared buffer pool, based on small per-core allocation rings—but with cores still working independently, without software synchronization or inter-core dependence. Synchronization is only required when moving freed buffers between cores, but as explained in §4.2, this synchronization is infrequent and its cost is low.

Handling of Imbalanced Load Like shRing, RxBisect reduces the minimal I/O working set by relying on a shared buffer pool, which avoids the over-provisioning of Rx buffers that occurs in privRing. It is therefore natural to ask how rxBisect responds to load imbalance that, in shRing, causes the ring to be monopolized by overloaded cores. As discussed next, thanks to rxBisect's disentanglement of packet reception from buffer allocation, overloaded cores can only "hog" packet buffers, leading to more buffers being allocated, but they cannot interfere with packet reception by other cores.

In rxBisect, per-core Ax rings guarantee the availability of vacant receive buffers for the NIC to consume as long as there is at least one underloaded core with an Ax ring and the buffer allocator can satisfy allocation requests. For allocators preconfigured with a fixed number of buffers, their buffer pool must be large enough to keep satisfying allocation requests even when Bx rings of overloaded cores are full.

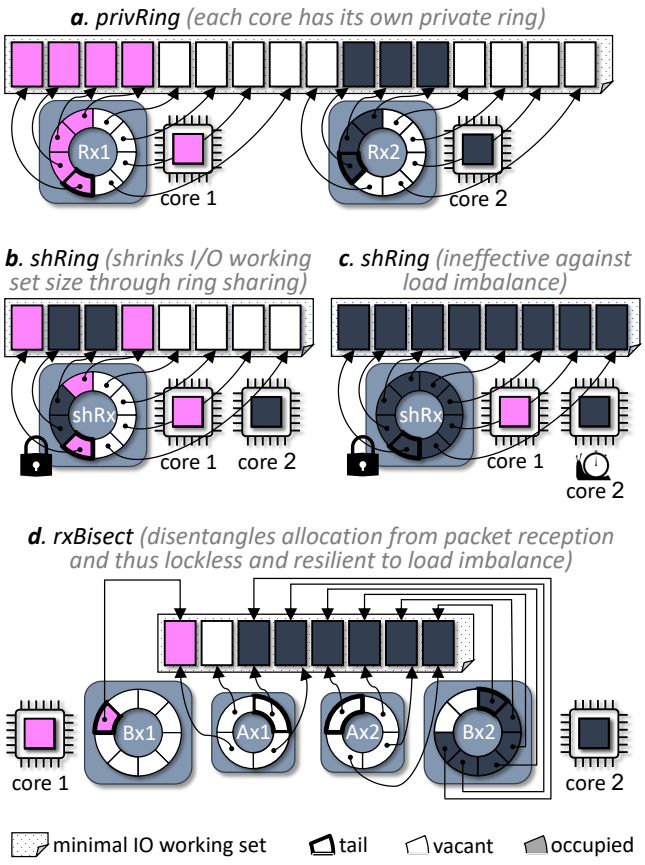

Figure 6: *RxBisect and shRing reduce the I/O working set size compared to privRing. Unlike shRing, rxBisect shares buffers without software locks, and it allows each reception ring to consume buffers from any allocation ring belonging to the same application.*

Let us denote cores 1 and 2 as C_1 and C_2, and consider, for example, the scenario in Figure 6d, where C_2's Ax is exhausted and its Bx is nearly full. Suppose this Bx becomes completely full—which necessarily means it contains buffers from C_1's Ax—and then C_2 stalls. In this case, C_1's Bx contains notifications to repopulate its Ax buffers, and because C_1 is not overloaded, it can process them. Subsequently, C_1's Bx can continue to receive packets using buffers allocated from its own Ax. Meanwhile, the lack of empty Bx entries on C_2 causes the NIC to drop packets of C_2. The important property here is that cores with available cycles *can* receive packets, which is not true of shRing (Figure 6c). Note, however, that the I/O working set might grow due to the additional buffer allocations, beyond the minimal set depicted in the figure.

4.4 Hardware Design Considerations

RxBisect is a new NIC-CPU interface whose complete implementation in ASIC is beyond our scope. Instead, we contrast rxBisect with existing NIC ASICs and show that the necessary changes are compatible with existing NIC mechanisms.

Packet Delivery Mechanically, rxBisect's packet delivery algorithm is analogous to that of existing NICs, which already access two rings (Rx and CR) on packet delivery (§2). Consequently, the critical path of packet delivery in rxBisect is identical to that which current NICs use for privRing and shRing. In all hardware designs, the NIC DMA-reads (and can prefetch) buffer addresses populated by software in ring structures (an Rx ring in current NICs and an Ax ring in rxBisect). RxBisect selects the destination ring in the same way as privRing and shRing when buffers are available, and otherwise it finds a ring with available descriptors based on availability information known from Ax and Bx doorbells. Subsequently, all types of NICs DMA-write packet data followed by DMA-writing a notification in a descriptor of a target ring (a CR in current NICs and a Bx ring in rxBisect). When rxBisect needs to notify different Bx rings about packet delivery and buffer consumption, it performs these DMA-writes in parallel, without increasing the critical path length.

While such parallel writes might increase PCIe bandwidth consumption, this issue can be mitigated by batching notifications. The NIC will delay writing a Bx entry that describes only a buffer consumption until a packet for that Bx ring arrives (or a timeout). Because the waiting Bx entry and the new Bx entry (for packet arrival) are adjacent, they can typically be written with the same PCIe transaction. Similar "completion compression" mechanisms already exist in NVIDIA NICs [32, 33], indicating that this technique is practical.

Hardware vs. Software Synchronization Both rxBisect and shRing implement a shared buffer pool, but shRing places the synchronization burden on software, whereas rxBisect offloads it to hardware as follows. NIC ASICs use pipeline parallelism to meet line-rate speeds. The pipeline stage that assigns packets to ring entries processes them sequentially, one at a time. The rxBisect pipeline stage operates like privRing when both Ax and Bx rings corresponding to an arriving packet have available entries. But it must consume a buffer from another Ax/Bx pair when the destination Ax is empty. This decision can be made efficiently using combinatorial logic circuits, such as priority encoders. We discussed rxBisect applicability to real ASIC NICs with NVIDIA NIC architects, who made the following statement regarding rxBisect's applicability to the ConnectX NIC pipeline [52]:

> *"An rxBisect implementation in ConnectX fits within the existing pipeline stage [that implements shRing] while maintaining current performance for multiple rings with available entries. In the worst case, when a single [Ax] ring provides buffers to several reception rings, performance will be limited by the allocation rate of the single ring."*

4.5 Parameter Configuration Guidelines

We propose the following guidelines to configure Ax and Bx rings. We first discuss the case of a single NIC and subsequently generalize to multiple NICs.

Ax/Bx Association For maximum flexibility, an application should use an all-to-all association of Ax/Bx rings. The reason rxBisect supports configurable Ax-to-Bx associations is to allow different applications (with disjoint Ax/Bx-sets) to work concurrently on disjoint core-sets.

Bx Ring Size ($|Bx|$) The primary consideration in setting $|Bx|$ is that it will be large enough to absorb packet bursts. For 100 Gbps NICs, Figure 3a in the shRing paper [66] shows that $|Bx| = 1024$ is necessary and sufficient. This size is also the default for many systems and NIC vendors.

Ax Ring Size ($|Ax|$) The Ax ring should be sized to achieve two goals: (1) the I/O working set should fit into the LLC's DDIO capacity, i.e., $k \times |Ax| \times 1500\,B \leq |DDIO|$, where k is the total number of Ax rings and $|DDIO|$ is the DDIO capacity; and (2) the Ax rings should have enough buffers to absorb a packet burst without software buffer re-filling, i.e., $k \times |Ax| \geq |Bx|$. In addition, $|Ax|$ cannot be smaller than the vendor-enforced minimum (e.g., 64 in NVIDIA NICs).

In theory, the number of cores may be so large or DDIO capacity so small that $|Ax|$ constraints (1) and (2) cannot both be satisfied, but we did not encounter this issue in practice.

Multiple NICs Cores should be divided among NICs in proportion to traffic demands. For example, if traffic is balanced among the NICs, cores should be equally divided between the NICs. When setting $|Ax|$, the total number of Ax rings over all NICs should be used for k in condition (1) above, but k in condition (2) should remain the number of per-NIC Ax rings.

5 Prototype

Implementing rxBisect requires changes to the NIC ASIC. Therefore, like other related studies [5, 31, 44, 63, 75, 76], we evaluate rxBisect using a software NIC framework, which we developed in DPDK. The framework allows us to run unmodified DPDK applications and emulate all NIC architectures of interest for comparison purposes.

Implementation We implement the emulation using a dedicated core, referred to as the emulator, which acts as the NIC for all worker (application) cores. The emulator uses either multiple physical Rx rings when emulating privRing (one per worker; see emulator in Figure 7a), or a single physical Rx ring shared by multiple workers when emulating shRing and rxBisect (Figures 7b and 7c). Multiple physical Rx rings are required for privRing to ensure strict separation of packet buffers between workers, as placing empty buffers from different workers in the same Rx ring would allow incoming packets for one worker to be stored in buffers allocated by another—violating privRing's isolation property.

The emulator mediates incoming traffic by exposing virtual rings to worker cores (queues on top of the emulator in Figures 7a–7c). It does so by executing an infinite loop that: (1) reads a batch of packet pointers from the physical Rx ring(s); (2) dispatches packets to the appropriate virtual queues (completion rings for privRing and shRing, Bx rings for rxBisect); and (3) replenishes the physical ring(s) with buffers taken from virtual Rx or Ax rings. Dispatching determines the target virtual queues by the least significant bits of RSS hash values, which are computed from each packet's 5-tuple. For privRing, the value is always the same per physical Rx ring, which corresponds to a single virtual ring. In contrast, for shRing and rxBisect, packets from the same physical Rx ring may yield different RSS values.

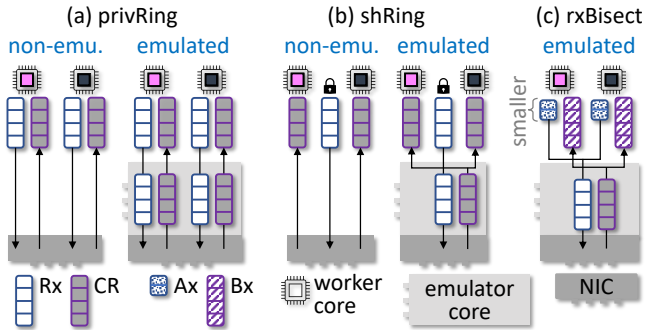

Figure 7: *An emulated NIC uses twice as many Rx entries as the corresponding non-emulated architecture, thereby doubling the I/O working set size. This also applies to rxBisect (as Σ |Ax| = |Rx| in Figure c), so comparing rxBisect to the emulated versions is fairer.*

Usage The I/O working set of each emulated version is twice that of its non-emulated counterpart because: (1) it doubles the number of Rx entries by maintaining a virtual Rx ring in addition to using a physical one; (2) each physical or virtual Rx ring is fully populated by design; and (3) each Rx entry must be used before it can be reused. The 2× ratio also applies to rxBisect, as the combined size of all Ax rings is set equal to that of the physical Rx ring used by the emulator—a ring that would not exist in a hardware implementation.

Thus, methodologically, it is fairer to compare rxBisect to its emulated counterparts, which better isolates performance differences due to changing I/O working sets, constituting an apples-to-apples comparison. Frequently, however, emulated rxBisect performs similarly to or better than non-emulated versions, in which case we prefer to compare it to the latter. These results likely underestimate the benefit of rxBisect.

DDIO DDIO effects (§3.1) are reflected in the emulated setup. To avoid competing with worker cores, the emulator runs on a separate CPU located on a different NUMA node than the workers (Figure 8). DDIO, however, operates only within the node directly connected to the physical NIC (denoted N0). Nevertheless, running the emulation code on another node, remote from the NIC, is not problematic in our framework for two reasons. First, the emulator only manipulates *pointers* to packet buffers and never accesses the packet contents. As a result, packets remain on N0—local to the NIC—ensuring DDIO functions normally from the workers'

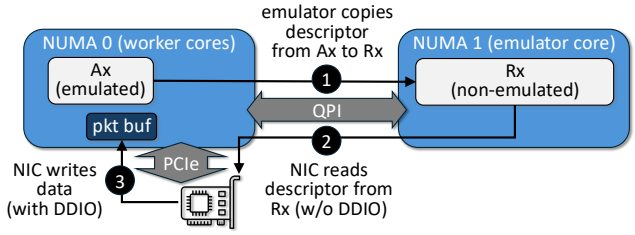

Figure 8: *Emulation captures DDIO effects as packet buffers and worker cores reside on the same NUMA node as the physical NIC.*

		throughput (Gbps)			*latency (µsec)*

Table 2: *Emulation fidelity (non, emu, and dif stand for non-emulated, emulated, and difference, respectively).*

perspective with respect to packet data. Second, our evaluation focuses on larger ($\leq$ 1500 B) packets to stress the memory subsystem. Unlike packets, the virtual queue descriptors that point to them ping-pong between nodes. But the size of each descriptor (one cache line) is small compared to the associated packet, so the effect is limited.

Overheads To faithfully emulate the overhead of hardware NIC packet delivery, we emulate worker doorbell writes via MMIO writes to NIC memory. Additionally, we emulate the extra DMA write to the Bx ring that occurs when a packet's buffer does not originate from the receiving core's Bx ring by issuing 64 B self-target RDMA writes from NIC memory to host memory.

Fidelity To be useful, the emulation should underestimate the performance achievable with a real hardware NIC, while remaining comparable. We assess whether this is the case in Table 2, which compares the performance of the emulated and non-emulated versions of default privRing, small privRing, and shRing (described in §3.2) using the NAT and LB NFs. Full experimental details are provided in §6. We observe that emulated throughput and latency indeed underperform by up to 12% and 94%, respectively. Emulation latency nearly doubles in the NAT/privRing case as workers are overloaded and each packet must wait through two full Rx rings (virtual and physical) before being processed. Throughput, in contrast, is insensitive to such queueing delays.

6 Evaluation

We evaluate rxBisect using network function benchmarks and the MICA key-value store [49], when load is balanced and shRing performs well (§6.1) and when it does not (§6.2).

System Setup We use two Dell PowerEdge R640 servers. One server is the system under test and the other is the load generator. The load generator runs the stateless Cisco T-Rex packet generator [14], modified to improve latency measurement accuracy [68]. Each server has dual 2.1 GHz Xeon Silver 4216 CPUs, each with 16 cores and an 11-way 22 MiB LLC, and 128 GiB (=4 $\times$ 16 GiB) 2933 MHz DDR4 memory. The servers are connected back-to-back via two pairs of 100 Gbps NVIDIA ConnectX-5 Ethernet NICs [58] and are configured following NVIDIA's DPDK best performance guidelines [61].

All experiments use the default system and application settings. We report trimmed means of ten runs, i.e., with the minimum and maximum discarded. Standard deviation is always below 5%. Throughput results reflect the traffic rate sent back to the load generator after processing, i.e., they discount packets dropped by the server.

Applications We use address translation (NAT) and load balancing (LB) NFs, implemented with FastClick [7]. NAT remaps network addresses. LB assigns flows to one of 32 servers. Both rewrite packet IP headers, using a 10 M-entry hash table to maintain state. As a macrobenchmark, we use the MICA key-value store [49]. Applications run on one CPU of the test server (the other CPU is reserved for emulation). Unless noted otherwise, we dedicate 8 cores to each NIC.

Evaluated Architectures We compare five architectures: (1) rxBisect, with 128-entry Ax ring and 1 Ki-entry Bx ring for each core (emulated); (2) privRing, with the default 1 Ki-entry Rx ring per core; (3) small privRing, which decreases the per-core ring size by 8$\times$ (from 1 Ki to 128) to obtain the same I/O working set size as rxBisect and shRing (proven impractical, as it impedes burst absorption, but included as a yardstick); (4) shRing, with two shared default-sized (1 Ki-entry) Rx rings, one per NIC, such that each is shared by 8 cores (implemented using the RxArr variant [66]); and, when relevant, (5) an idealized version of dynamic shRing, which does not run but instead reports the better result between privRing and shRing.

Comparison Methodology As explained in §5, rxBisect should be compared to the emulated variants. We nevertheless compare it to the non-emulated executions, showing the emulated counterparts (with patterned bars or dashed lines) only when non-emulated execution outperforms rxBisect.

6.1 Balanced Load

This section shows that rxBisect, like shRing, performs well when load is balanced or bursty and it outperforms privRing even when rxBisect is emulated and privRing runs natively.

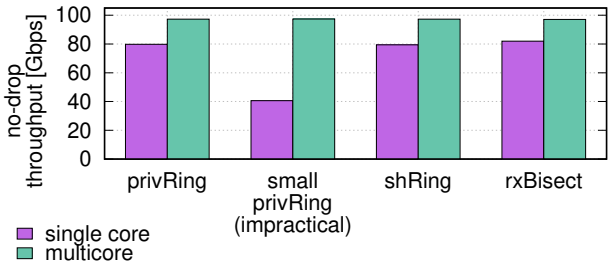

Figure 9: *Buffer sharing allows single-core rxBisect and shRing to achieve the same no-drop throughput as 1 Ki privRing with only 1/8 of its buffers, in contrast to small privRing, which does not share.*

No-Drop Throughput Figure 9 shows the DPDK l3fwd RFC2544 no-drop throughput of one 100 Gbps NIC with 1500 B packets when using an individual core ("single core") and 8 cores combined ("multicore"). RxBisect and shRing's buffer sharing enables them to match privRing's throughput with only 1/8 of its I/O working set, both with multiple cores (each of which handles 1/8 of the traffic) and with a single core, which can absorb bursts by using all available buffers. In contrast, small privRing does not share and thus fails to similarly absorb bursts, which makes it impractical [66].

NAT and LB We run NAT and LB on all 16 cores and load them with 200 Gbps using 1500 B packets. Figure 10 shows (a) throughput, (b) latency, (c) ring occupancy, (d) DDIO hit rate, and (e) memory bandwidth. The latter two are measured using Intel PCM [36]. At this load, architectures with a small I/O working set achieve line rate throughput and comparable average latency (100 µs–119 µs). This is due to their effective use of the 2 LLC ways assigned by default to DDIO (Figure 10e). Since rxBisect is emulated while others run natively, its latency, ring occupancy, memory bandwidth, and DDIO miss rate are higher than the rest (see also §5).

Due to its large I/O working set, privRing throughput collapses by up to 20% compared to rxBisect. As a result of failing to sustain line rate, privRing's Rx rings fill up, causing latency to increase by 11× due to the additional queueing time. PrivRing can achieve line rate in LB if DDIO's LLC portion is increased to 8 LLC ways, but fails to achieve line rate for NAT even if all the LLC is assigned to DDIO. (Of course, exposing more LLC ways to DDIO is a double-edged sword, as I/O and application memory accesses compete [83].)

Key-Value Store We use the MICA key-value store [49] to evaluate the effect of rxBisect beyond NFs. We run MICA on 8 cores (using a single NIC) with 128 B keys and 1024 B values. MICA maps incoming requests to processing cores by hashing the target key. We use workloads with 95% `PUT` requests at the highest possible rate.

Figure 11 shows throughput obtained when the key distribution is (a) uniform or (b) skewed (Zipf with parameter 0.99).

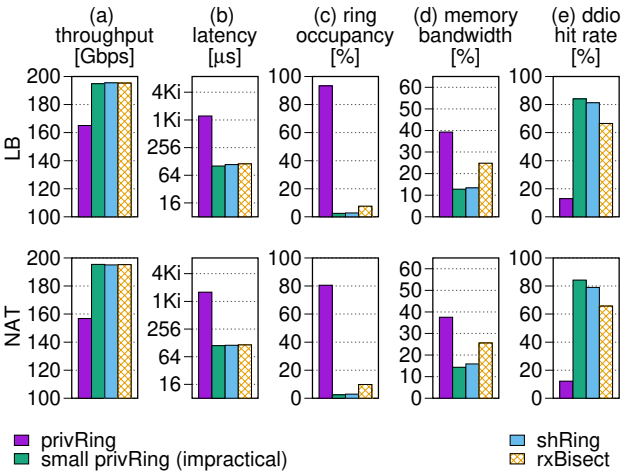

Figure 10: *LB and NAT performance.*

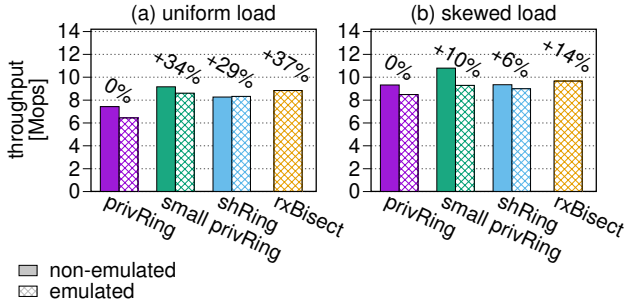

Figure 11: *MICA key-value store throughput with uniform and skewed key distributions. Top labels compare to emulated privRing.*

The throughput of rxBisect is higher than privRing, small privRing, and shRing (all emulated) by up to 37%, 3% and 7%, respectively. The throughput of rxBisect is also higher than non-emulated privRing and shRing by up to 18% and 6%, respectively. RxBisect underperforms (by up to 12%) only the yardstick non-emulated small privRing, which is not a practical architecture.

6.1.1 Impact of Ring Sizes

This section shows the impact of varying Ax and Bx ring sizes. It demonstrates that buffer sharing enables improved burst absorption with small Ax rings, and that the I/O working set is not sensitive to the size of Bx rings.

Varying Ax ring size We evaluate the impact of Ax ring size on no-drop throughput using the RFC2544 [10] benchmark in DPDK l3fwd. The test uses 1500 B packets from a single flow directed at an application running on four cores, while varying the size of rxBisect Ax rings and non-emulated privRing Rx rings. The size of rxBisect Bx rings is fixed at 1 KiB. Figure 12 shows the results.

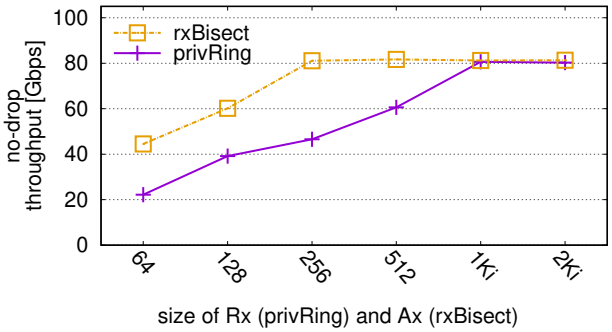

Figure 12: *DPDK l3fwd no-drop throughput, utilizing 4 cores and a single 100 Gbps NIC while varying the size of Ax rings (rxBisect) and Rx rings (privRing). RxBisect Bx rings are set to 1 Ki entries for all runs, similarly to Rx rings. RxBisect buffer sharing improves burst absorption, leading to higher no-drop throughput.*

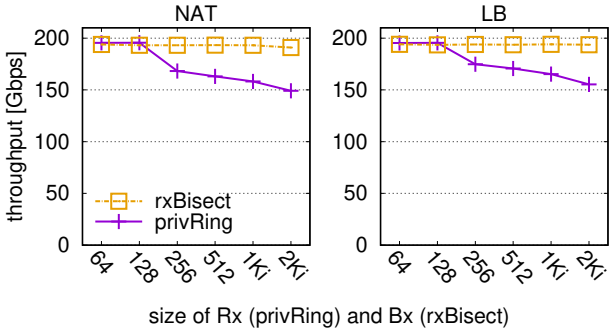

Figure 13: *Throughput at 200 Gbps load while varying the size of Bx rings (rxBisect) and Rx rings (privRing). The size of rxBisect Ax rings is 128 entries for all runs. The rxBisect I/O working set size is constant and small, regardless of Bx size, avoiding the performance degradation experienced by privRing with ≥256 Rx entries.*

RxBisect leverages buffer sharing across the four Ax rings, allowing a single core's Bx ring to absorb bursts up to four times larger than a single Ax ring and up to the size of the Bx ring. Consequently, rxBisect achieves the maximum single-flow no-drop throughput of ≈80 Gbps with just 256 Ax ring entries, whereas privRing requires four times more—1 Ki entries—to reach the same performance.

Varying Bx ring size We evaluate the sensitivity of the I/O working set to Bx ring size using the following experiment. NAT and LB run on all 16 cores under a 200 Gbps load with 1500 B packets. Figure 13 shows throughput as we vary the size of rxBisect Bx rings and non-emulated privRing Rx rings, with rxBisect Ax rings fixed at 128 entries.

As expected, increasing privRing Rx ring size grows the I/O working set, reducing throughput—first as it exceeds the DDIO-allocated portion of the LLC (at 256 entries), and more significantly when it exceeds the total LLC capacity (at 1 Ki entries). In contrast, increasing rxBisect Bx ring size does not increase the working set, sustaining line-rate throughput.

6.2 Unbalanced Load: ShRing Limitations

Next, we show that rxBisect remains effective even when shRing is not. ShRing is ineffective upon imbalance that leads to overload, which may occur because incoming traffic is spread unevenly across cores, or because per-packet processing times are highly-skewed. Additionally, shRing is ineffective when its smaller I/O working set does not compensate for its synchronization overheads.

The dynamic shRing variant addresses these limitations by switching between shRing and privRing at run time using a heuristic that assesses which is currently more beneficial [66]. We therefore compare to this variant as well.

Conceivably, dynamic core frequency scaling can mitigate imbalance by helping overloaded cores at the expense of less busy cores. But when using DPDK, dynamic core scaling is irrelevant due to core busy polling. We confirm this by running with and without scaling and observing similar results.

Processing Variability We evaluate a synthetic NF workload running on all 16 cores and processing 1500 B packets. Packet processing consists of accessing two random addresses in a 40 MiB buffer, performing a routing table lookup (similarly to the l3fwd NF), and sending the packet out. We designate one core per each NIC as the "target core." We modify the load generator to send only 1 Gbps of traffic to the target core while the rest is spread between the other cores. We also tweak the target core's packet processing routine to access memory a configurable number of times per packet (other cores' processing remains unchanged).

Figure 14 presents the resulting throughput. RxBisect and small privRing attain line rate throughput. However, shRing's throughput degrades by up to 60% as the target core's processing slows down, clogging the shared ring with its traffic and blocking other cores from receiving packets (which thus get dropped). Dynamic shRing only offers the best of shRing and privRing, and thus it declines from shRing's line rate speed to privRing's throughput (never above 178 Gbps, due to its I/O working set) when the target core's processing exceeds 100 memory accesses per packet. Consequently, rxBisect outperforms dynamic shRing by up to 12%.

Traffic Variability We use the same synthetic NF as above. Only now, all cores run the same packet processing logic, but we modify the load generator configuration to vary the percentage of packets directed at the target core. We use 64 B packets for traffic directed at the target core and 1500 B packets for traffic directed at all other cores, to minimize the target core's impact on overall throughput.

Figure 15 shows the resulting throughput. RxBisect and small privRing attain line rate throughput. RxBisect experiences a 6% throughput degradation when the target core's

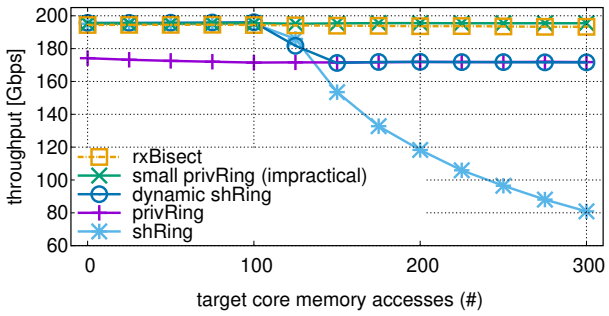

Figure 14: *Processing variability caused by increased memory accesses has no effect on rxBisect throughput despite ring sharing, whereas shRing's sharing degrades throughput when faced with such increased variability.*

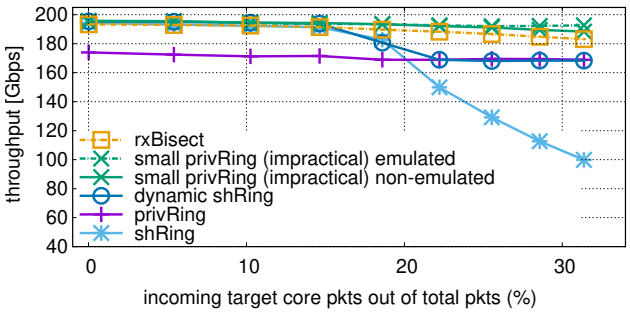

Figure 15: *Traffic variability caused by increased packet arrival rate on a single core has no effect on rxBisect throughput despite ring sharing. In contrast, shRing's approach to ring sharing degrades throughput in this case.*

$\frac{tgt}{total}$ *packets*	*tgt* $\frac{alloc}{total}$	*tgt* $\frac{free}{total}$	*non-tgt* $\frac{alloc}{total}$	*non-tgt* $\frac{free}{total}$
1% (minimum)	0.140%	0.000%	0.002%	0.003%
31% (maximum)	0.001%	0.010%	0.039%	0.000%

Table 3: *RxBisect inter-core memory allocator cycles out of all cycles on target (tgt) and non-target (non-tgt) cores during minimum (1%) and maximum traffic imbalance (31%) to target core.*

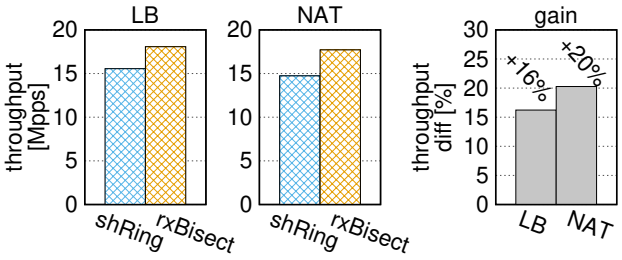

Figure 16: *RxBisect outperforms dynamic shRing when processing the imbalanced CAIDA trace (see §3.3) with PageRank co-location.*

packet rate exceeds 20%, as a result of the emulator core becoming a bottleneck. To demonstrate this, we also show small privRing emulation, whose performance degrades at a rate similar to rxBisect when the target core's packet rate exceeds 25%. ShRing throughput declines by up to 49% as the target core's incoming packet rate increases, again due to its traffic clogging the shared ring. PrivRing throughput never exceeds 175 Gbps, and so dynamic shRing is outperformed by rxBisect.

Inter-Core Memory Allocator RxBisect depends on inter-core memory allocators (e.g., DPDK's `pktmbuf_pool`), which use per-core caches to reduce synchronization. However, rxBisect packet buffer sharing can transfer buffers between cores, potentially stressing the memory allocator (allocating on one core and releasing on another core can deplete the per-core cache on the former).

We analyze the global allocator cycles from the traffic variability experiment. Table 3 presents results for rxBisect at the extremes of imbalance. For other architectures, allocator cycles are always under 0.001% of total cycles (not shown). Overall, the allocator uses less than 0.2% of total cycles in all cases. At minimal target core load, it processes fewer packets, spending 0.14% of cycles in the allocator providing buffers to other cores. At maximal load, non-target cores spend 0.039% cycles allocating buffers to be used by the target core, which spends 0.01% cycles' returning buffers to the global allocator.

Real Packet Trace Figure 16 shows NAT and LB throughput when processing the CAIDA trace analyzed in §3.3, co-located with PageRank [8] to increase memory bandwidth pressure. Dynamic shRing selects the better option between privRing and shRing, but both perform suboptimally: the added memory bandwidth pressure degrades privRing, while the imbalanced load (highlighted in Figure 4) degrades shRing. Thus, rxBisect outperforms dynamic shRing throughput for LB and NAT by 16% and 20%, respectively.

Figure 17 shows results from a similar set of experiments, this time with a varying number of co-located STREAM triad [41] instances, which are memory bandwidth intensive. RxBisect throughput exceeds dynamic shRing by up to 16% (emulated) and up to 8% and 13% (non-emulated) for NAT and LB, respectively. We show both emulated and non-emulated results because, unlike other workloads we studied, CAIDA trace processing slows down under emulation. As a result, non-emulated privRing—and therefore non-emulated dynamic shRing—can outperform (emulated) rxBisect by up to 7% in the absence of memory contention.

With no memory bandwidth contention, dynamic shRing defaults to privRing, which performs well with the imbalanced trace. But as contention increases, shRing begins to outperform privRing, prompting the dynamic variant to switch to shRing. In both cases, when making an apples-to-apples comparison of emulated NICs only (by "usage" in §5), rxBisect performs better, as it uses less memory bandwidth and is resilient to imbalanced load.

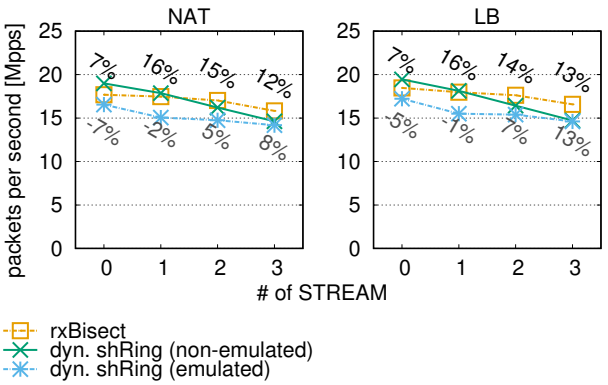

Figure 17: *When comparing emulated setups (apples-to-apples), rxBisect outperforms dynamic shRing regardless of the number of co-located STREAM instances. Top and bottom labels compare rxBisect to emulated and non-emulated dynamic shRing, respectively.*

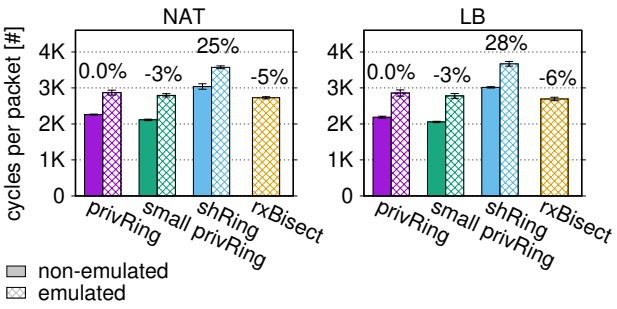

Figure 18: *Under low load, shRing yields no benefit and demonstrates its synchronization overhead. In contrast, rxBisect's overhead is minimal. Top labels compare against emulated privRing.*

Low Traffic Rate Figure 18 shows the per-packet processing time (in CPU cycles) for NAT and LB when arriving traffic consists of 1 Gbps of 1500 B packets, which are spread evenly among all cores. Non-emulated shRing's synchronization overhead results in it spending up to 34% and 46% more cycles per packet than non-emulated privRing and small privRing, respectively. In contrast, rxBisect (which runs under emulation) requires $\approx$ 10% fewer cycles to process a packet than non-emulated shRing. We can safely conclude that with rxBisect hardware, rxBisect will leverage Rx buffer sharing for a small I/O working set with faster packet processing than in shRing. Based on rxBisect's design, which is similar to privRing, and emulation results, we hypothesize that native rxBisect packet processing efficiency will be comparable to privRing's.

7 Related Work

Leaky DMA NICs write directly to two LLC ways with DDIO. Poor I/O working set management causes incoming packets to unnecessarily evict LLC data including other packets being processed; this is also called the "leaky DMA" problem [79]. Several works, complementary to ours, tackled the leaky DMA problem by partitioning the LLC between I/O and applications to avoid interference [83] and by placing only packets headers in the LLC [29, 65, 71].

Host-NIC Interfaces Recently, Ensō [70] proposed a streaming interface for NIC that reduces PCIe overheads which enables line-rate processing of small packets. Ensō is, however, orthogonal to rxBisect because it still suffers from the I/O working set problem which rxBisect solves. The two are complementary: Ensō helps with small I/O working sets and rxBisect helps with large I/O working sets.

Sharing Receive Buffers ShRing [66] and RDMA shared receive queues (SRQ) [35], like rxBisect, share Rx buffers between cores. But both shRing and SRQ perform poorly with load imbalance. Mellanox receive memory pools (RMP) is a hardware abstraction that can be used to share buffers between several Rx rings that reside on the same core [48] or to implement shRing, but RMP still employs a traditional, entangled Rx ring through which both allocation and reception are done. As a result, RMP cannot share buffers between several cores without locking to advance the shared ring's tail pointer. Junction [26] shares receive buffers via RMP and handles load imbalance by using work stealing and a dedicated core that monitors workers and refills ring buffers. RxBisect, in contrast, allows all cores to be workers, improving total packet processing capacity.

Load Imbalance Load imbalance is a fundamental problem in parallel processing. In end-host networking, packets are typically spread among cores using receive side scaling (RSS), which assigns packets to cores based on a hash value computed from packet header fields [59]. Custom RSS functions can rebalance the load between cores [6], but this approach is inherently static and cannot address dynamic load imbalance. Several recent works tackle the dynamic imbalance problem by offloading transport or application layers to the NIC, such that it can rebalance incoming messages among cores according to their load [17, 50, 77]. RxBisect is complementary to these approaches as it helps reduce the I/O working set size by sharing packet buffers without synchronization.

8 Conclusion

Today's NIC interface needlessly overcrowds the LLC with I/O buffers to absorb worst-case packet bursts, degrading the performance of high-throughput applications. RxBisect absorbs bursts with much fewer buffers by untangling the dual role of Rx rings.

XSched: Preemptive Scheduling for Diverse XPUs

Weihang Shen, Mingcong Han, Jialong Liu, Rong Chen*, Haibo Chen
Institute of Parallel and Distributed Systems, Shanghai Jiao Tong University

Abstract

XPUs, such as GPUs, NPUs, ASICs, and FPGAs, lack flexible scheduling capabilities, failing to meet rich application requirements (e.g., priority and fairness) in multitasking environments. This paper presents XSched, a scheduling framework that enables preemptive scheduling on diverse XPUs with flexible policies. XSched provides unified interfaces for scheduling XPU tasks through a preemptible command queue abstraction (XQueue). The key challenge in implementing the abstraction is adapting to XPUs with diverse and evolving hardware capabilities and software stacks. XSched proposes a multi-level hardware model that enables mature, advanced XPUs to achieve optimal scheduling performance while maintaining compatibility with emerging, wimpy XPUs. To demonstrate the generalizability of XSched, we adapted it to ten XPUs of different types, brands, and generations across seven software platforms and implemented two hardware-agnostic scheduling policies. We further evaluated XSched through three case studies of multitasking workloads on XPUs. XSched effectively achieves various scheduling objectives using its efficient and flexible preemption mechanisms.

1 Introduction

"Providing education for all without discrimination;
Teaching students in accordance with their aptitudes."

— Confucius, *The Analects*

XPUs—referring to various accelerators, such as GPUs, NPUs, ASICs, and FPGAs—are extensively deployed in emerging systems, from cloud to edge, to offload intensive computations from host CPUs [52, 56, 64, 138]. These systems often involve multiple concurrent XPU tasks [26, 53, 102, 110, 121, 130]. Sharing XPUs among these tasks is a common practice to improve hardware efficiency and an inevitable choice for resource-constrained platforms. For example, cloud providers share a single GPU among multiple tenants to reduce costs [35, 131, 136], while edge platforms run multiple AI models on a single NPU [53, 68, 97, 105].

Rich application scenarios pose diverse requirements for XPU task scheduling. For instance, real-time systems (e.g., autonomous vehicles) need immediate responses for critical XPU tasks [2, 51, 134], while cloud providers prioritize fairness among tenants and maximum hardware utilization [126]. Although XPUs accelerate individual tasks effectively, they often struggle to meet application requirements under multitasking workloads due to inadequate scheduling support. The hardware scheduler baked into XPUs adopts either non-preemptive first-come, first-served (FCFS) scheduling (e.g., Intel NPUs [45], NVIDIA and AMD GPUs [75, 99]) or simple round-robin (RR) scheduling (e.g., multi-process GPU tasks [3]). This may lead to unfairness and priority inversions [60, 61, 100, 103, 113], which manifest as service-level objective (SLO) violations in data centers or missed deadlines in latency-critical autonomous systems. For example, in a video conferencing application (see §8), the tail latency of a real-time fake-background task increases by over 20× when running alongside a speech-to-text task on an Intel NPU [45].

Previous studies have proposed several software-based preemptive scheduling systems [16, 19, 39, 129] to bypass inadequate hardware schedulers, enabling the host CPU control over XPU task scheduling.[1] However, current solutions show a serious lack of **generalizability** when deployed across diverse XPUs of different types, brands, and generations, commonly found in modern cloud and edge computing platforms [26, 45, 53, 85, 126]. *Portability*: Existing preemptive scheduling systems [12, 19, 39, 129] are designed specifically for certain GPUs, making it challenging to port them to other accelerators like NPUs, ASICs, and FPGAs, or even to GPUs from different manufacturers and architectures [39]. To our knowledge, no software-based preemptive scheduling solutions exist for NPUs and ASICs. *Uniformity*: The lack of a unified abstraction for scheduling tasks on XPUs hinders the development of hardware-agnostic policies tailored to different application requirements. This also creates barriers to scheduling tasks on heterogeneous hardware with multiple XPUs, which is becoming increasingly popular in AI PCs [45] and autonomous devices [85]. *Evolvability*: The tight coupling between software and hardware implementations prevents them from evolving independently. This makes it difficult for existing scheduling systems to quickly integrate newly released or undocumented hardware features while flexibly excluding obsolete or disabled ones.

The root cause of the challenges in implementing general preemptive XPU scheduling is twofold. First, XPUs have significant and evolving differences in hardware capabilities. For example, while most systems rely on the general-purpose programmability of GPUs for preemptive scheduling through

*Corresponding author (rongchen@sjtu.edu.cn) and project leader

[1] This paper also considers preemption from the perspective of tasks, which typically comprises hundreds or thousands of XPU commands, e.g., kernels.

code transformation [12, 19, 39, 129], mainstream NPUs [82] and ASICs [89, 90] are non-programmable. Additionally, prior work [123] uses a specific `ioctl` to control timeslices of NVIDIA Tegra embedded GPUs [86], which is not available in desktop or server GPUs. Second, the software stacks of XPUs (e.g., user/kernel-mode drivers and firmware) are notoriously complex and highly customized. This often leads scheduling systems—both their mechanisms and policies—to become tightly coupled with specific details of the XPU. For example, TimeGraph [60] only works on Direct Rendering Infrastructure (DRI) drivers, and REEF [39] is integrated with the runtime and driver of AMD GPUs.

Key idea. We propose establishing a *unified abstraction* with a *multi-level hardware model* for preemptive XPU scheduling, which effectively conceals the differences and complexities in hardware capabilities and software stacks, ensuring generalizability. The abstraction provides unified interfaces for task scheduling across diverse XPUs, enabling hardware-agnostic policies and cooperation between XPUs. The model defines support levels aligning with fundamental requirements of preemptive scheduling, allowing developers to seamlessly implement one or more levels based on the hardware capabilities of each XPU and agilely evolve as capabilities change.

Our approach. We introduce XQueue, a *preemptible command queue* abstraction designed for XPU task scheduling. XQueue is analogous to CPU thread abstraction, as illustrated in Fig. 1. Each XQueue hosts an XPU task, which consists of a sequence of *commands*—such as GPU kernels, memory-copy operations, tensor operators, and other XPU-specific operations. An XPU functions as a worker, consuming commands from multiple XQueues. Task preemption is accomplished by switching between these XQueues. XQueue offers simple yet powerful interfaces for preemptive scheduling, making it easy to implement various hardware-agnostic policies, like fixed priority [74] and bandwidth partition [1].

We propose a *multi-level hardware model* to implement the XQueue abstraction on diverse XPUs. The model decouples preemption mechanisms from XPU-specific details and categorizes them into three levels. Level 1 (Lv1) allows XPUs to preempt (pending) commands that have been submitted but not launched. Level 2 (Lv2) extends Lv1 by enabling XPUs to preempt (in-flight) commands that have been launched but not executed. Level 3 (Lv3) builds upon Lv2 by allowing XPUs to preempt (running) commands that are being executed.

Based on our unified abstraction and multi-level hardware model, we implement XSched, a preemptive XPU scheduling framework. XSched is designed to be both efficient in scheduling XPU tasks and transparent to applications. For efficiency, XSched launches XPU commands *asynchronously* but *progressively* to pipeline command launch and execution for low task latency, while keeping most of the commands under host control for scheduling. For transparency, XSched provides a *shim* layer that intercepts commands from applications using

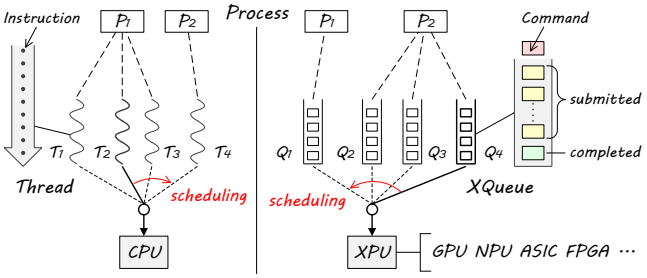

Fig. 1: *A unified abstraction for preemptive XPU scheduling.*

APIs of the original platform and forwards them to XSched. Moreover, we devise two new techniques for Lv2 preemptive scheduling on NVIDIA GPUs [128] and Intel NPUs [45], as well as one for Lv3 on NVIDIA GPUs released after the Pascal architecture [79].

To showcase the generalizability of XSched, we adapted it to different types, brands, and generations of XPUs across seven software platforms: NVIDIA (Kepler, Volta, and Ampere) [128], AMD [127], and Intel [45] GPUs; Ascend [43], Intel [45], and NVIDIA [82] NPUs; NVIDIA (PVA [90] and OFA [89]) ASICs; and Xilinx [4] FPGAs. Thanks to the multi-level hardware model, XSched makes it possible (even easy) to enable preemptive scheduling on emerging, wimpy XPUs, while fully leveraging the capabilities of mature, advanced XPUs. XSched is the first software-based system to support preemptive scheduling on these NPUs and ASICs. The Lv1 implementations require just 214–841 lines of C++ code and can be shared across XPUs supported by the same software platform. Additionally, we implemented Lv2 and Lv3 preemption on five and three categories of XPUs, respectively, using our new techniques with specific hardware capabilities.

We implemented two hardware-agnostic scheduling policies based on our unified abstraction and evaluated them on ten distinct XPUs against their native hardware schedulers. For the fixed priority policy [74], XSched reduces the tail latency (99^{th} percentile, P_{99}) of high-priority tasks by up to 2.10×. For the bandwidth partition policy [1], XSched partitions the XPU according to the throughput assigned for each task, with an acceptable overhead (1.5% on average). XSched also enables cooperative scheduling among XPUs, reducing the P_{99} latency of foreground NPU tasks by up to 2.63×, when running background tasks on both NPU and GPU.

We further evaluated XSched through three case studies. In a multi-tenant cloud scenario hosting two containers on a single GPU, XSched harvests 2.74× more GPU resources than TGS [130] while maintaining production container performance. In a video-conferencing application that runs two tasks on a single Intel NPU, XSched reduces the P_{99} frame latency by 9.26×. For multi-model inference serving, XSched reduces the P_{99} inference latency in Triton [94], a production-level system, by 30.0%, and achieves performance comparable to Paella [75], a state-of-the-art hardware-specific solution. Integrating XSched requires only a dozen lines of code.

2 Background and Motivation

2.1 Characterizing XPU Tasks

The XPU functions as a peripheral device that is managed by the host CPU. Despite the diversity of XPU architectures, runtimes, and programming models, XPU tasks share a common execution pattern. Typically, an XPU task consists of a sequence of *commands*, including GPU kernels, memory-copy operations, tensor operators on NPUs and TPUs, color space conversions on image-processing ASICs, and other XPU-specific operations. These commands execute sequentially based on data dependencies [22, 39, 75]. Additionally, auxiliary commands, such as CUDA and OpenCL events, are available to monitor command execution on XPUs. For each XPU task, the host CPU launches all its commands and then uses synchronization APIs to wait for their completion, since commands run asynchronously with it. Take a DNN inference task on a GPU as an example: the host CPU first initiates a memory-copy command to load the input into GPU memory. Then, it launches hundreds or thousands of GPU kernel commands to perform the inference layer by layer, followed by a memory-copy command to retrieve the results. These assumptions about XPUs and their tasks apply to most modern accelerators, including GPUs, NPUs, ASICs, and FPGAs.

2.2 Necessity of Preemptive Task Scheduling

XPUs are widely deployed across emerging systems—from cloud to edge—to offload intensive computations from host CPUs. Sharing XPU among multiple tasks enhances hardware utilization in cloud platforms and is essential for resource-constrained edge and mobile devices. For example, cloud providers commonly use a single GPU to serve multiple tenants or serverless function instances [26, 102, 130]. In autonomous vehicles, various algorithms, including perception, planning, and decision-making, are deployed on one TPU or ASIC [110]. On smartphones, both foreground and background AI tasks, like real-time voice input and photo indexing, run simultaneously on one NPU [53].

The demand for multi-task scheduling varies across different application scenarios. For instance, industrial automation applications like robotics and autonomous driving require low and deterministic latency [39, 41, 68]. Datacenters must ensure the service-level objective (SLO) [9, 36, 130, 139] and fairness among tenants [17]. Meanwhile, mobile devices like smartphones and AI PCs prioritize power efficiency [11, 31, 112] and user responsiveness [53]. Task preemption is a crucial mechanism to meet these diverse scheduling requirements [19, 22, 39, 57, 73, 101, 139], as it can significantly enhance system responsiveness and fairness while providing flexibility in scheduling.

2.3 Solution 1: XPU Hardware Scheduling

Lack of preemption support. Since XPUs typically function as peripherals, the host CPU launches commands sequentially to XPUs through a first-in, first-out (FIFO) ring buffer [39, 60]. This leads to tasks being naturally scheduled on a first-come, first-served (FCFS) basis. The non-preemptive policy is deeply embedded in the hardware, firmware, and drivers of various XPUs, including NVIDIA and AMD GPUs [39, 75, 109, 129], TPUs [22, 77, 106], Ascend and Intel NPUs [43, 45], and Jetson embedded ASICs [85]. Consequently, urgent tasks can be blocked by less critical ones, leading to priority inversions [28, 60, 129] and unpredictable task latencies. For example, we observed on different XPUs that sharing an XPU with just a background task can increase the tail latency of the foreground task by up to 2.19× (see §7.2). These issues are unacceptable in real-time scenarios like autonomous driving [2, 51, 134] and network packet processing [33, 59]. The non-preemptive policy also causes unfairness among multiple tenants in cloud environments [35, 136]. While some modern GPUs incorporate a simple time-sliced round-robin (RR) policy to serve tasks from different processes, latency-sensitive tasks still suffer from unpredictable performance degradation as the number of concurrent tasks increases [123].

Hard to support flexible policy. Hardware scheduling is restricted by its elementary, fixed policies. Due to real-time constraints and limited on-chip resources [133], native hardware schedulers cannot accommodate sophisticated policies. They also lack adequate runtime feedback and task information (e.g., priority and deadline), which are essential for implementing workload-aware scheduling strategies like those in SHEPHERD [139] and Paella [75]. Furthermore, since the policy is baked into the hardware or firmware, it cannot adapt agilely to changing workloads and scheduling requirements.

2.4 Solution 2: Host-managed XPU Scheduling

Scheduling XPU tasks on the host CPU is a preferred solution as it offers enhanced flexibility and customizability. Users can select from various scheduling policies tailored to application requirements, akin to traditional CPU thread scheduling.

Design for specific XPUs. Prior work proposed several host-managed scheduling approaches to bypass the inefficient XPU hardware scheduler and take over scheduling on the host CPU. However, these solutions lack generalizability due to their reliance on specific hardware capabilities. For example, EffiSha [19] and FLEP [129] enable preemption through GPU kernel transformation, which requires general-purpose programmability. A recent work [123] uses a specific `ioctl` interface to control timeslices of NVIDIA Tegra embedded GPUs. REEF [39] and a prior work [66] depend on a microcontroller function on AMD or ARM GPUs to reset compute units. Moreover, these solutions are tightly coupled with XPU-specific software stacks, further limiting their generalizability. For example, REEF [39] is integrated with the AMD GPU driver and compiler. TimeGraph [60] only works with drivers built on the Direct Rendering Infrastructure (DRI).

XPU-specific solutions bring issues with portability, uni-

formity, and evolvability, especially for users and developers of heterogeneous cloud and edge platforms that host different types, brands, and generations of XPUs. First, these solutions are difficult to port between different XPU types or across vendors and architectures. Second, they lack a unified abstraction for task scheduling across different XPUs, which impedes the development of hardware-agnostic policies and cooperative scheduling on heterogeneous platforms like Intel Core Ultra [45] and NVIDIA Jetson Orin [85]. Third, these solutions struggle to evolve with hardware changes, whether incorporating new features (e.g., interrupts on NVIDIA GPUs since Pascal architecture [75]) or handling deprecated ones.

Lack of unified abstraction and hardware model. The major challenge towards general solutions is the lack of unified abstraction and appropriate hardware models for diverse XPUs. A class of traditional hardware, like CPUs and disks, can be uniformly managed by the OS, regardless of their different architectures or manufacturers, as they share similar hardware capabilities that a general hardware model can adequately describe. For example, CPUs offer interrupts and privilege modes, while disks implement block device interfaces. Based on these models, the OS provides unified abstractions, like threads and files, to assist users in managing and utilizing the same class of devices.

For XPU scheduling, the hardware model conceals the complexity and heterogeneity of XPUs. Supporting new hardware requires only implementing the hardware model interfaces. Meanwhile, a unified abstraction for XPU tasks enables hardware-agnostic and cooperative scheduling policies by decoupling policies from task preemption mechanisms and providing a uniform view across different XPUs. The abstraction and hardware model keep the OS design clean and flexible to evolve. However, XPUs currently lack such unified abstraction and hardware model due to their significant and evolving differences in hardware capabilities.

3 The XQueue Abstraction

Opportunity. Despite the significant and evolving differences in their hardware capabilities and software stacks, XPU drivers in different software platforms generally provide queue-like programming model and interfaces, which we collectively refer to as *hardware queue* (hwQueue). Examples of these include GPU streams in CUDA [93] and HIP [5], ZE command queues in LevelZero [47], MTL command queues in Metal [6], ACL runtime streams in Ascend [43], CL command queues in OpenCL [62], and VPI streams for vision processing ASICs [91].

3.1 Preemptible Command Queue

We propose XQueue, a *preemptible command queue* abstraction for preemptive scheduling on diverse XPUs. XQueue is a queue of XPU commands that are executed sequentially in the order of submission. When an application process runs a task (e.g., DNN inference) on the XPU, it instantiates the task into a sequence of commands (e.g., GPU kernels, memory-copy operations, and tensor operators) and **submits** them to the XQueue in order. These commands execute asynchronously and sequentially on the XPU. The process can **wait** for the commands in an XQueue to complete. Note that a process can have multiple XQueues and submit different tasks to them.

Table 1: *Interfaces of the* XQueue *abstraction.*

XQueue **Interface**	**Description**
`submit(xq, cmd)`	Submit a command (*cmd*) to XQueue (*xq*)
`wait(xq, cmd)`	Wait for a given *cmd* in *xq* to complete
`suspend(xq)`	Suspend *xq* to pause task execution
`resume(xq)`	Resume *xq* to continue task execution

This abstraction is familiar to developers, since many XPUs have already adopted it. There is no semantic gap between XQueue and hwQueue in task execution, allowing XQueue to be seamlessly integrated with existing applications. XQueue differs from hwQueue in how it schedules submitted commands of a task. hwQueue is non-preemptible [19, 75, 129], meaning that once commands are submitted to the hwQueue, there is no practical way to pause them. In contrast, commands submitted to the XQueue can be preempted by the host CPU. Specifically, the host can **suspend** an XQueue to pause the running XPU task, yielding the XPU to other tasks. It can also **resume** the XQueue to continue task execution. This scheduling process is transparent to applications, which still perceive normal execution behavior of the XPU.

The XQueue abstraction is analogous to CPU thread abstraction, as illustrated in Fig. 1. An XPU task is a sequence of commands executed by an XQueue, while a CPU task is a sequence of instructions executed by a CPU thread. Both XPU tasks and CPU tasks are scheduled by suspending and resuming their corresponding XQueues and threads.[2] Moreover, multiple XQueues can run concurrently to achieve higher hardware utilization and overall throughput if the XPU supports spatial multiplexing mechanisms like GPU streams, which is akin to CPU hyper-threading. In summary, the XQueue abstraction preserves the programming semantics of the hwQueue, while providing familiar thread-like preemptive scheduling capabilities, which facilitates application compatibility and simplifies unified XPU task scheduling.

Interfaces. Table 1 lists the interfaces of XQueue. The XQueue provides a preemptible command queue abstraction for XPU task execution and preemptive scheduling. It offers `submit` and `wait` interfaces that enable applications to submit commands for asynchronous execution and wait for their completion on XPUs. Additionally, the XQueue provides `suspend` and `resume` interfaces, allowing the scheduler to control whether its commands can be executed on the XPU. These interfaces hide the implementation de-

[2]The hwQueue functions similarly to a kernel thread in CPU scheduling, where the actual task scheduling occurs (Fig. 1 omits this detail for brevity).

```
# fixed priority policy
void schedule(xq_status)
1   xqs = get_ready_xqueues(xq_status)
2   highest = find_highest_priority(xqs)
    # schedule ready XQueues with highest priority
3   for xq in xqs
4     if get_priority(xq) == highest then
5       resume(xq)  # resume highest-priority XQueue
6     else
7       suspend(xq)  # suspend others

# bandwidth partition policy
void schedule(xq_status)
8   current = get_running_xqueue(xq_status)
    # schedule next XQueue if timeslice expires
9   if timeslice_is_expired(current) then
10    next = get_next_ready_xqueue(xq_status)
11    suspend(current)  # suspend current XQueue
12    resume(next)  # resume next XQueue
13    timeslice = get_ratio(next) × QUANTUM
      # call schedule() when timeout
14    add_timer(timeslice)
```

Fig. 2: *Pseudocode of fixed-priority and bandwidth-partition scheduling policy implementations based on* XQueue *interfaces.*

tails of preemption mechanisms on diverse XPUs, enabling hardware-agnostic scheduling policies.

3.2 Scheduling Policy

XQueue interfaces are flexible for implementing various preemptive scheduling policies, such as fixed priority (FP) [74], shortest remaining time first (SRTF) [114], earliest deadline first (EDF) [74], and bandwidth partition (BP) [1]. Fig. 2 demonstrates the implementation of fixed priority and bandwidth partition scheduling using XQueue. In the fixed priority policy, each XQueue is assigned a priority that reflects the urgency of its task. The scheduling policy is triggered when XQueue status (`xq_status`) changes, such as when a new command arrives (making the XQueue *ready*), or when all commands complete (making the XQueue *idle*). The policy then finds and resumes ready XQueues with the highest priority while suspending others. This allows urgent tasks to preempt less critical ones. In the bandwidth partition policy, each XQueue is assigned a timeslice proportional to its allocated bandwidth. When a timeslice expires, the current XQueue is suspended, and the next one is resumed in a round-robin order. A timer is set to trigger rescheduling when the timeslice runs out. This policy ensures that tasks share the XPU utilization according to their specified ratios.

4 Multi-level Hardware Model

XQueue provides a unified abstraction for preemptive XPU scheduling. The hardware model plays a crucial role in implementing XQueue on different XPUs by decoupling the preemption mechanism from XPU-specific details. However, embracing both portability and high preemption performance presents a significant challenge. For instance, if the model

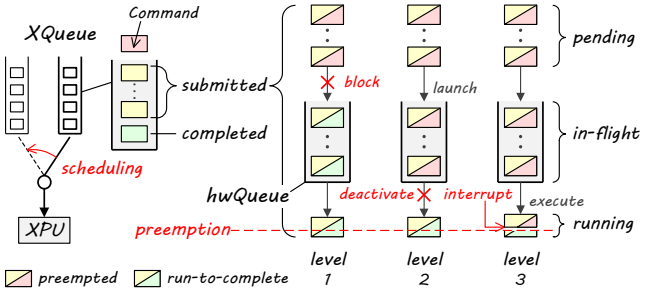

Fig. 3: *Comparison of three preemption levels for XPU scheduling.*

defines a preemption capability specific to certain XPUs to achieve optimal performance, it may not be portable to other XPUs that cannot support this capability.

Inspired by transaction isolation levels [13], we introduce a *multi-level hardware model* for preemptive scheduling on diverse XPUs. We characterize three levels of task preemption from the perspective of command states, as illustrated in Fig. 3. Each preemption level targets commands in one of three states: **pending** (ready to be launched[3]), **in-flight** (launched but not executed), or **running** (currently being executed). For each level, we identify the necessary hardware capabilities and interfaces to implement task preemption. Higher levels require more advanced capabilities for finer-grained preemption, while lower levels need only basic capabilities, making them applicable to a broader range of XPUs.

4.1 Level 1: Pending Command Preemption

Level 1 (Lv1) preemption targets commands in the pending state before launch. Once a command is launched, it is enqueued to the hardware queue (hwQueue), becoming in-flight and escaping host control. Therefore, the host can preempt pending commands by simply blocking their launch. Lv1 only requires capabilities to **launch** and **synchronize** commands, which all XPUs provide. The preemption latency is the total execution time of all launched commands, as shown in Fig. 3.

4.2 Level 2: In-flight Command Preemption

Unlike Lv1, which passively waits for in-flight commands to complete, Level 2 (Lv2) preemption can actively prevent in-flight commands from executing. This greatly reduces the preemption latency to just the execution time of the currently running command, as shown in Fig. 3. The key capability is to **deactivate** and **reactivate** the hwQueue. Once deactivated, no new commands from this hwQueue will execute until reactivation, enabling Lv2 preemption. This deactivation can be implemented by stalling-based or flushing-based approaches.

Stalling-based deactivation. The hwQueue can be deactivated by stalling command dequeuing, which prevents new commands from being fetched for execution. This approach requires advanced XPUs with integrated microcon-

[3]Launch refers to enqueuing a command to a hwQueue, after which launched commands escape host control—unlike the `submit` interface of XQueue.

Table 2: *Interfaces of the multi-level XPU hardware model.*

Level	Interface	Description
Lv1	`launch(hwq, cmd)`	Enqueue a given command (`cmd`) to a hwQueue (`hwq`) for executing it sequentially and asynchronously
	`sync(hwq, cmd)`	Wait for a given `cmd` in a `hwq` to complete
Lv2	`deactivate(hwq)`	Deactivate a given `hwq` to prevent all its commands from being selected for execution
	`reactivate(hwq)`	Reactivate a given `hwq` to allow all its commands to be selected for execution
Lv3	`interrupt(hwq)`	Interrupt the running command of a given `hwq`
	`restore(hwq)`	Restore the interrupted command of a given `hwq`

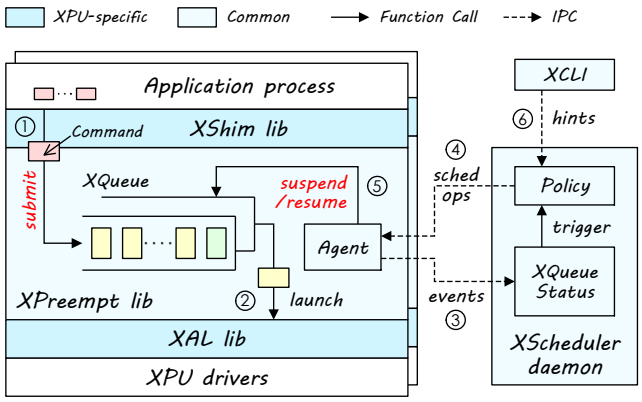

Fig. 4: *Architecture and workflow of* XSched.

trollers [30, 44, 46, 55, 72] that can selectively dequeue commands based on their attributes. The host can either instruct the microcontroller directly or modify command attributes to control dequeuing, achieving deactivation and reactivation.

Flushing-based deactivation. Another approach is to flush all in-flight commands in the hwQueue and relaunch them upon reactivation. Prior work [19, 39, 129] proposes that commands could be retrofitted to flush themselves, which solely requires the commands to be programmable. This approach works on all programmable XPUs, e.g., GPUs and many NPUs [43].

4.3 Level 3: Running Command Preemption

Lv2 preemption still requires waiting for the running command to complete, which leads to unpredictable preemption latency and may not meet strict real-time requirements for applications like automation [2, 51, 134] and networking [33, 59]. In contrast, Level 3 (Lv3) preemption targets the running command, aiming to achieve ultra-low and stable preemption latency, as illustrated in Fig. 3. This requires hardware capabilities that can **interrupt** and **restore** the running command. Once interrupted by the host, the running command is instantly paused and preempted for the execution of another command. The interrupted command is later restored to continue its execution. These capabilities are already present in modern GPUs [39, 44, 79].

4.4 Hardware Model Interfaces

The hardware model hides XPU hardware and driver differences through multi-level interfaces, as listed in Table 2. The three levels form a hierarchical design. The higher level introduces advanced preemption functionality and relies on the implementation of all lower levels to function properly. Lv1 interfaces consist of native hwQueue operations: `launch` for asynchronous command execution and `sync` for command synchronization. Lv2 interfaces include `deactivate` and `reactivate` to control the execution of in-flight commands in the hwQueue. Lv3 further introduces `interrupt` to instantly pause the running command and `restore` to resume the interrupted command.

5 The XSched Framework

5.1 Overview

We present XSched, a preemptive scheduling framework that implements XQueue based on the multi-level hardware model and supports diverse XPUs. As illustrated in Fig. 4, XSched consists of four key components: XPU shim (XShim), XPU task preemption (XPreempt), XPU adapter layer (XAL), and scheduler. XShim, XPreempt, and XAL are three dynamically linked libraries that are preloaded into the application process, while the scheduler runs as a shared system service daemon.

XShim. Typically, applications call driver APIs to launch XPU commands, with task scheduling handled entirely by the underlying hardware. The XShim library changes this workflow by intercepting XPU driver API calls and redirecting commands to the XQueue (① in Fig. 4). The approach provides transparency, allowing applications to run on XSched without modifications. The XShim library can be reused across XPUs that share the same driver. Note that the XShim library is optional when porting XSched to a new XPU, since applications can directly call XQueue interfaces instead.

XPreempt. The XPreempt library implements the interfaces of XQueue abstraction listed in Table 1, including `submit` and `wait` to support task execution, and `suspend` and `resume` to schedule XQueues. Commands submitted to the XQueue are buffered and launched to the XPU at a proper time (② in Fig. 4) to achieve task preemption. The XPreempt library contains an agent that watches the state of XQueue (e.g., ready or idle) and generates scheduling events to notify the scheduler (③ in Fig. 4) via inter-process communication (IPC). The agent is also responsible for applying the scheduling operations (e.g., suspend or resume an XQueue) received from the scheduler (⑤ in Fig. 4).

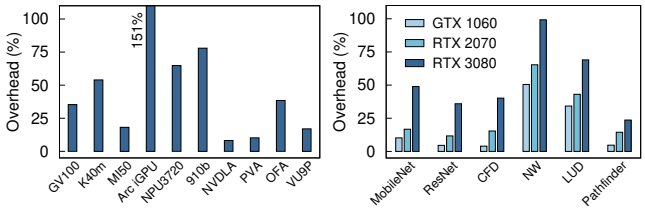

Fig. 5: *The performance overhead of synchronous execution (a) on various XPUs (GPUs/NPUs: ResNet-152 [40], OFA: Stereo Disparity [88], PVA: Gaussian Filter [88], VU9P: Vector Addition [132], and (b) using various deep learning (DL) [40, 42] and scientific computing [18] workloads on three NVIDIA GPUs.*

XAL. The XAL library implements the multi-level hardware model interfaces (listed in Table 2) by calling XPU driver APIs. Note that only Lv1 interfaces are mandatory for supporting a new XPU, while Lv2 and Lv3 interfaces are optional for better performance. Like XShim, the Lv1 implementation can be reused across XPUs sharing the same driver.

XScheduler. The scheduler runs as a daemon process, coordinating all XQueues from different processes. It monitors global XQueue status through agent-reported events (③ in Fig. 4), and invokes the scheduling policy to make decisions when status changes occur. The daemon performs these decisions by sending scheduling operations to agents (④ in Fig. 4). The policy in XScheduler is modular and customizable to suit various workloads. Users can change the policy and give scheduling hints (e.g., priority or bandwidth) through XCLI, a command-line tool (⑥ in Fig. 4).

5.2 XPreempt Design

The XPreempt library implements the preemptible XQueue abstraction using interfaces of our multi-level hardware model provided by the XAL, as shown in Fig. 6. Since the model conceals hardware details, it is challenging for XPreempt to enforce task preemption efficiently, particularly when using only Lv1 interfaces. This is because once commands are launched, they move beyond host control, and the scheduler can only passively wait for their completion.

Strawman: synchronous command execution. A straightforward solution [19, 61, 103, 111, 129] is to synchronize the XPU and block the host CPU after launching each command, preventing excess commands from being enqueued to the hwQueue. Consequently, the task is effectively preempted by simply blocking the host thread, and the preemption completes right after the currently running command finishes. However, this approach is highly inefficient for modern XPUs since it ignores their asynchronous nature. Synchronization is costly due to the communication latency between the CPU and the peripheral XPU, as well as driver overhead. More importantly, modern XPUs utilize asynchronous execution to pipeline command launching and execution, hiding the launching latency. Forcing synchronization creates frequent pipeline stalls (bubbles) that severely reduce command

```
# XQueue APIs
void submit(xq, cmd)
1   push_pending_cmd(xq, cmd)

void wait(xq, cmd)
2   if find_pending_cmd(xq, cmd) then
3     ...  # wait to launch cmd
4   sync(xq.hwq, cmd)  # sync for completion

void suspend(xq)
5   xq.mode = SUSPENDED  # suspend XQueue
6   if LEVEL >= 2 then deactivate(xq.hwq)
7   if LEVEL == 3 then interrupt(xq.hwq)

void resume(xq)
8   xq.mode = RUNNING  # resume XQueue
9   if LEVEL >= 2 then reactivate(xq.hwq)
10  if LEVEL == 3 then restore(xq.hwq)

# progressive command launching
void worker_thread(xq)
11  while TRUE
12    if get_inflight_cnt(xq) >= THRESHOLD then
        # wait until half of launched cmds complete
13      mid = get_inflight_middle(xq)
14      sync(xq.hwq, mid)  # sync for completion
15      pop_completed_cmds(xq)
16    cmd = pop_pending_cmd(xq)
17    while xq.mode == SUSPENDED
18      pause()  # pause cmd launching
19    launch(xq.hwq, cmd)  # launch cmd to hwqueue
20    push_inflight_cmd(cmd)
```

Fig. 6: *Pseudocode of* XQueue *APIs and progressive command launching implementation in* XPreempt.

throughput. As shown in Fig. 5 (a), synchronous command execution imposes substantial performance overhead on different XPUs, ranging from 8.2% to 151.3%. Furthermore, this overhead grows larger with more advanced XPUs, as pipeline stalls consume a greater proportion of time when XPU command execution speed increases. Fig. 5 (b) shows that the performance overhead increases by 3.04× on average when upgrading from GTX 1060 to RTX 3080.

Our solution: progressive command launching. Inspired by our prior work [39], XPreempt introduces a progressive command launching mechanism to balance preemption latency and runtime overhead, as shown in Fig. 6. This approach maintains a small number of in-flight commands, preventing pipeline stalls while enabling fine-grained preemption. When suspending the XQueue, the scheduler waits only for these few in-flight commands to complete, rather than all submitted commands (usually hundreds of commands).

Each XQueue contains a worker thread, a pending command buffer, an in-flight command log, and a corresponding hwQueue. When a command is submitted to the XQueue, it is first pushed into the pending command buffer (Line 1). The worker thread then *progressively* launches it to the hwQueue and records these in-flight commands in the log. Specifically, the worker checks the count of in-flight commands against a user-defined threshold (Line 12). If the count exceeds this

threshold, the worker invokes `sync` to wait for half of in-flight commands to complete (Lines 13–15). This threshold can be adjusted based on workloads to trade off preemption latency and runtime overhead. When the XQueue is suspended, the worker pauses to block new command launches (Lines 17–18). Once the XQueue is resumed, the worker continues to launch pending commands (Lines 19–20).

Lv2 and Lv3 preemption. For XPUs supporting Lv2 interfaces, XPreempt additionally deactivates the hwQueue after the worker is paused to accelerate task preemption when suspending the XQueue. Also, the hwQueue is reactivated when resuming. For XPUs supporting Lv3 interfaces, XPreempt further interrupts the currently running command in the hwQueue to preempt the task instantly when suspending the XQueue, and restores the command when resuming. The design of XPreempt is compatible with all three levels and can fully leverage the hardware capabilities thanks to the multi-level hardware model implemented in the XAL.

5.3 XScheduler Design

As depicted in Fig. 4, the XScheduler daemon is an event-driven service that coordinates all XQueues from different processes in the system, in cooperation with the XPreempt agents. Each agent monitors the change events of XQueue states, e.g., become *ready* when new commands are submitted and *idle* when all commands are completed. These events are sent to the XScheduler daemon to maintain global XQueue status (each XQueue: ready or idle, XPU device ID, process ID, etc.) and trigger the policy upon status changes. The policy decides which XQueues to suspend or resume based on current status. The decisions are sent back to the agents and applied by calling `suspend` and `resume` interfaces of these XQueues. Messages between XScheduler and the agents are passed via shared-memory IPC, enabling XSched to schedule XQueues across both processes and containers. For cross-VM scheduling, message passing can alternatively be implemented over network. This distributed XQueue design separates the control and data planes, minimizing command submission overhead and isolating errors within the application process.

The policy in XSched is designed to be flexible and customizable. XSched provides a `send_hint` API for applications and a command-line tool (XCLI) for users to provide hints to the policy, which set policy-specific parameters (e.g., priority, bandwidth, and deadline) of an XQueue. This is similar to how `setpriority` syscall and `nice` command set the priority in Linux. In addition to several built-in policies (e.g., fixed priority, bandwidth partition), users are free to customize policies optimized for their application scenarios. The policy should implement two basic interfaces: `schedule` and `recv_hint`, which are called when XQueue status changes and a new hint is given, respectively. As mentioned in Fig. 2, `schedule` uses `suspend` and `resume` to schedule XQueues, and `add_timer` to trigger itself after an interval.

6 Implementation on XPUs

We propose several new techniques to implement three preemption levels (XAL) on different XPUs, spanning various software platforms (CUDA, HIP, LevelZero, ACL, OpenCL, etc.), accelerator types (GPU, NPU, ASIC, and FPGA), and manufacturers (NVIDIA, AMD, Intel, Ascend, etc.).

6.1 Level 1 (Lv1) Preemption

Implementing Lv1 preemption is straightforward on XPUs since their drivers natively support hwQueue to launch and synchronize commands. Examples include `CUstream` in CUDA [93] (for NVIDIA GPUs), `hipStream` in HIP [5] (for AMD GPUs), `ze_command_queue` in LevelZero [47] (for Intel GPUs and NPUs), `aclrtStream` in ACL [43] (for Ascend NPUs), `VPIStream` in VPI [91] (for vision processing ASICs), and `cl_command_queue` in OpenCL [62] (for Xilinx FPGAs). The `launch` interface is implemented by calling the appropriate driver API corresponding to the command type, e.g., `cuLaunchKernel` for launching kernels on a `CUstream` and `cuMemcpyAsync` for memory copy commands. These drivers also support events, e.g., `CUevent` in CUDA and `cl_event` in OpenCL, which are fine-grained synchronization points that can be recorded on the hwQueue. The `sync` interface is implemented by synchronizing with an extra event recorded after a given command. If the driver does not support events, it can alternatively be implemented by synchronizing with the hwQueue. Since Lv1 implementation relies only on basic driver APIs, it can be shared across XPUs that use the same software platform. For example, the OpenCL implementation supports GPUs, FPGAs and even CPUs from various manufacturers.

6.2 Level 2 (Lv2) Preemption

XSched implemented hwQueue deactivation and reactivation using a hardware-assisted stalling approach on Intel NPUs and a software-based flushing approach on NVIDIA GPUs.

Stalling-based preemption. On-chip microcontrollers have been widely integrated into XPUs to selectively dispatch commands to execution units. Examples include Falcon microcontrollers in NVIDIA GPUs [10, 30, 55, 108], Command Processors in AMD GPUs [39], Graphics microcontrollers (GuCs) in Intel GPUs [44], LeonRT cores in Intel NPUs [46], and Taishan cores in Ascend NPUs [72]. These XPUs can preempt in-flight commands by instructing their microcontrollers to stall command dequeuing for deactivation. Recently, Intel released a new NPU firmware that supports these capabilities [48]. We modified the driver [116] to expose them to the host and implemented the Lv2 interfaces on Intel NPUs [45].

Flushing-based preemption. For XPUs without microcontroller support or exposed interfaces, we implement a software approach for flushing-based deactivation on programmable XPUs, demonstrating this on NVIDIA GPUs. XSched leverages command programmability, instead of hardware micro-

```
# GPU code injected at the beginning of kernel binary
void guardian(flag_ptr, hwq_id, cmd_id)
1     if *flag_ptr == DEACTIVATED then
2       push_aborted_cmd(hwq_id, cmd_id)
3       exit_thread()  # abort kernel execution

# host CPU code in XAL to implement Level 2 interfaces
void deactivate(hwq)
4     int *flag_ptr = get_deactivation_flag(hwq)
5     *flag_ptr = DEACTIVATED  # set per-hwqueue flag
void reactivate(hwq)
6     int *flag_ptr = get_deactivation_flag(hwq)
7     *flag_ptr = NORMAL # clear per-hwqueue flag
      # relaunch aborted cmds
8     while cmd = pop_aborted_cmd(hwq)
9       launch(hwq, cmd)
```

Fig. 7: *Pseudocode of flushing-based preemption implementation.*

controllers, to flush all in-flight commands in the hwQueue. As shown in Fig. 7, XSched prepends a *guardian* code snippet to each GPU kernel (i.e., command) that checks a per-hwQueue deactivation flag in GPU global memory. When this flag is set, the guardian code records the command ID and exits this command immediately. To deactivate the hwQueue, the host sets the flag, prompting all in-flight kernels to abort themselves. When reactivating, the host clears the flag and relaunches the aborted kernels.

XSched injects the guardian code snippet into each GPU kernel at runtime using dynamic binary instrumentation (DBI) technique [118]. This guardian code is compiled to binary using the NVIDIA compiler (NVCC) [83] and loaded into GPU instruction memory at process startup. As shown in Fig. 8, XSched rewrites the first instruction of each kernel with a `JMP` instruction to a per-kernel helper snippet. This snippet first loads the arguments of the guardian code from GPU constant memory, where kernel arguments are stored, and then calls the guardian code. After that, the snippet executes the original replaced instruction and returns to the next instruction in the kernel. Note that XSched leverages the hidden functions in the CUDA export table to allocate and access GPU instruction and constant memory.

Prior work proposed similar kernel-flushing schemes [19, 39, 129]. However, these approaches require modifications to kernel source code or PTX assembly, making them incompatible with closed-source frameworks (e.g., TensorRT [87]) or just-in-time compiled kernels (e.g., TensorFlow XLA [98]). To our knowledge, XSched introduces the first flushing-based deactivation at the binary level, allowing it to work seamlessly with all CUDA applications, including those built with closed-source CUDA kernel libraries (e.g., cuBLAS [81], cuDNN [84]) and inference frameworks like TensorRT.

6.3 Level 3 (Lv3) Preemption

Advanced modern XPUs, including NVIDIA GPUs released after the Pascal architecture [79], as well as recent AMD, Intel, and ARM GPUs [39, 44, 66], can interrupt running

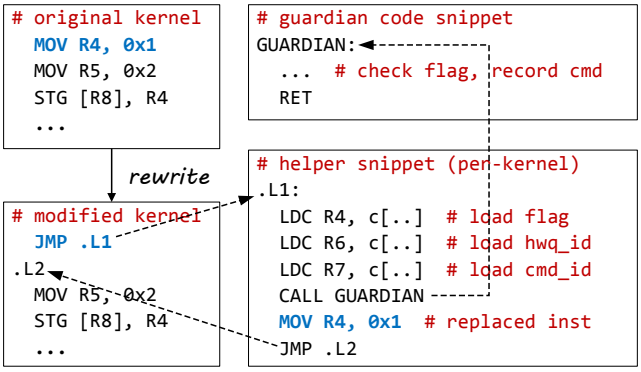

Fig. 8: *Binary instrumentation for flushing-based preemption.*

commands. We implemented Lv3 preemption on NVIDIA GPUs using two distinct approaches as illustrative examples.

TSG-based preemption. The interrupt mechanism on GPUs is designed for scheduling processes, or timeslice groups (TSGs) for NVIDIA GPUs [80, 123]. Each process is assigned a CUDA context corresponding to a TSG. When a TSG's timeslice expires, the GPU interrupts all running kernels in this TSG and switches to the next TSG in a round-robin manner. A previous study [123] found that TSGs of NVIDIA Tegra embedded GPUs could be adjusted through driver `ioctl` for task preemption. We implemented a similar approach on desktop and server GPUs (e.g., GV100), which dynamically adjusts TSG timeslices for Lv3 preemption. Specifically, the `interrupt` interface sets the timeslice to zero for the TSG containing the hwQueue to be preempted, and the `restore` interface resets the timeslice to its original value. Since this interrupt affects the entire TSG, this approach is only capable of inter-process scheduling. Note that the TSG-based approach achieves both Lv2 and Lv3 preemption by preempting both in-flight and running commands.

Queue-based preemption. We devise the first fine-grained interrupts on NVIDIA GPUs to implement Lv3 preemption at the hwQueue granularity. Although GPU interrupts are undocumented [75, 111], by tracing CUDA application syscalls, we discovered a specific `ioctl` that triggers GPU interrupts by writing to a GPU control register—a feature originally intended for kernel debugging. When the GPU is interrupted, it immediately stalls all running kernels and invokes the trap handler to save context and check trap reason. Using the DBI-based guardian technique for flushing-based preemption, XSched extends the trap handler to detect interrupts triggered by XSched. When detected, the target kernel is aborted for preemption, and the rest ones restore the context and continue execution. Unfortunately, NVIDIA GPUs do not expose support for resuming an aborted kernel from its interruption point. Inspired by prior work [39], XSched only preempts idempotent kernels and restarts them from the beginning.[4]

[4]We currently identify idempotent kernels manually, similar to prior work [39, 66, 70, 101]. A recent work [38] enables validation of idempotent kernels at launch time, and we plan to incorporate it to reduce manual efforts.

7 Experimental Evaluation

7.1 Portability

The support for preemptive scheduling on diverse XPUs. To demonstrate the portability of XSched, we adapted it to seven XPU platforms, as listed in Table 3. Thanks to our multi-level hardware model, only Lv1 implementation is necessary for basic preemptive scheduling, requiring just 214–841 lines of C++ code. Moreover, implementing Lv1 for a new XPU is straightforward, as most of the code simply unwraps and launches commands through the hwQueue provided by the drivers, sharing similar logic with just different function names. For example, implementing a memory copy command for the `cuMemcpyAsync` API in CUDA requires only 12 lines of code, and over 70% of the APIs follow a similar pattern. Additionally, the Lv1 implementation can be shared across XPUs that use the same software platform. For example, the implementation for OpenCL works seamlessly with FPGAs and GPUs from various manufacturers, including Xilinx, Intel, and Qualcomm [120]. For Lv2, we implemented stalling-based preemption on Intel NPUs and flushing-based preemption on NVIDIA Kepler, Volta, and Ampere GPUs. For Lv3, we implemented TSG-based preemption on NVIDIA GPUs released after the Pascal architecture and queue-based preemption on NVIDIA Volta and Ampere GPUs.

For performance experiments, we selected ten distinct XPUs: four GPUs (NV GV100 and K40m; AMD MI50; and Intel Arc iGPU [45]), three NPUs (Intel NPU3720 [45]; Ascend 910b [43]; and NV DLA [82]), two ASICs (NV PVA [90] and OFA [89]), and one FPGA (Xilinx VU9P [4]).

7.2 Uniformity

The support for flexible scheduling policy. Thanks to the unified abstraction of XSched, we implemented two hardware-agnostic and portable scheduling policies: fixed priority [74] and bandwidth partition [1], which required only 104 and 200 lines of C++ code, respectively. We evaluated them across ten distinct XPUs at their highest preemption level (see Table 3).

Workloads. In our experiments, we run two independent processes that submit the same types of tasks to a single XPU, with no shared data between them. We designate one process as foreground and the other as background, which the scheduling policy treats differently. For GPUs and NPUs, both processes submit DL inference tasks of the ResNet-152 model [40]. For ASICs, they execute the Stereo Disparity algorithm [88] on OFA, and the Gaussian Filter algorithm [88] on PVA. For FPGA, they perform vector addition tasks [132]. Note that commands are variably-sized, e.g., ranging from 2 to 113 μs for GV100, and 95 to 661 μs for DLA.

Fixed priority policy. The foreground process issues tasks periodically at a fixed frequency (20% of its peak throughput), and the background process issues tasks continuously at maximum frequency. XSched assigns a high priority to the foreground process and a low priority to the background process.

Table 3: *Description of XPUs and development effort (in lines of C++ code) for porting* XSched. ● *indicates a level that can be supported but has not yet been implemented, while* ○ *indicates a level that cannot be supported based on current hardware capabilities. Note that flushing-based Lv2 implementation on NVIDIA GPUs shares 513 LoCs for DBI, and TSG-based inter-process preemption takes 90 LoCs to implement Lv3 along with Lv2.*

Fig. 9 (top) shows the latency CDF of foreground tasks. The native hardware scheduler of all XPUs treats both processes equally, which doubles the tail latencies (99^{th} percentile, P_{99}) of foreground tasks compared to standalone execution (1.60× to 2.19×). In contrast, XSched preempts background tasks upon foreground task arrival. As a result, the P_{99} latencies of foreground tasks are close to standalone performance (1.02× to 1.30×) and are up to 2.11× lower than those experienced with the native hardware scheduler.

Bandwidth partition policy. Both the foreground and background processes continuously issue tasks at their maximum frequency. XSched allocates 75% of the XPU utilization to the foreground process and 25% to the background process. This simulates a scenario where an XPU is temporarily partitioned between two users with different QoS requirements [35]. Fig. 9 (bottom) shows the throughput of both tasks, normalized by the throughput of standalone execution. For all XPUs, the native hardware scheduler shares the XPU equally between foreground and background tasks. XSched achieves similar overall throughput to standalone execution with only 1.5% overhead on average, while guaranteeing the desired throughput partition ratio between two processes. On MI50, 910b, and VU9P, the native hardware scheduler surpasses both standalone execution and XSched in total throughput, as a single process cannot fully utilize hardware resources.

The uniform policy for heterogeneous XPUs. The XQueue interface facilitates seamless implementation of policies that cooperatively schedule multiple XPUs.

Workloads. The experiments are conducted on an NVIDIA Jetson Orin and an AI PC powered by Intel Core Ultra 9 185H. Initially, we run the same workload (i.e., two pro-

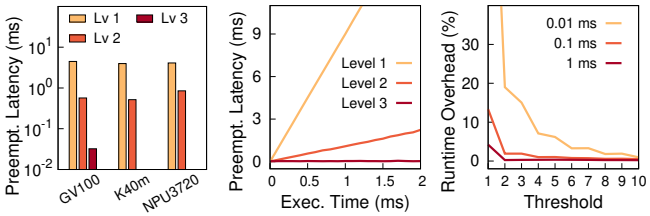

Fig. 11: *(a) The P_{99} preemption latency using different preemption levels, (b) the P_{99} preemption latency of GV100 for commands with different execution times, and (c) the runtime overhead of Lv1 on GV100 with different thresholds and command execution times.*

cesses running inference) as in Fig. 9 (top) for NPUs (i.e., NVIDIA DLA and Intel NPU3720). Subsequently, we run memory bandwidth-consuming tasks in another low-priority background process using the integrated GPU on the SoC.

Heterogeneous priority policy. Fig. 10 shows the CDF of the foreground task latencies. Although GPU and NPU operate independently for the computing resources, they may compete for the memory bandwidth and power supply on the SoC, leading to performance interference. Consequently, when scheduling only NPU tasks (XSched NPU), the latency, while reduced compared to the native hardware scheduler, remains significantly worse than the standalone case (1.67× and 1.55× for P_{99}). To address this, we implement a scheduling policy that uniformly schedules NPU and GPU tasks, allowing a high-priority XQueue to preempt other lower-priority ones, regardless of their associated XPU. With this policy (XSched N+G), the latency of foreground NPU tasks is close to standalone (1.18× and 1.09× for P_{99}), achieving a reduction of up to 2.63× compared to the native hardware scheduler.

7.3 Evolvability

The effect of advanced preemptive scheduling. The multi-level hardware model enables XPUs with advanced scheduling capabilities to further enhance the scheduling performance. As shown in Fig. 9 (top), XSched generally performs better on XPUs that support Lv2 and Lv3 interfaces (i.e., GV100, K40m, and NPU3720) compared to other XPUs that only support Lv1 interfaces. Specifically, the P_{99} latency of the foreground tasks on GV100, K40m and NPU3720 using XSched is only degraded by 1.9%, 3.8% and 5.4% compared to standalone execution. In contrast, the degradation is more significant on other XPUs, ranging from 7.3% to 29.6%.

We further evaluated the preemption latency of GV100, K40m, and NPU3720 with varying level configurations, as depicted in Fig. 11 (a). In this experiment, preempted tasks continually launch commands with an execution time of 0.5 ms (referred to as T hereafter), while the in-flight command threshold is set to 8. The P_{99} preemption latency with Lv1 support for all XPUs is approximately $8T$ due to the necessity to wait for all commands in the hwQueue to complete. This P_{99} latency is reduced to about $1T$ with Lv2, as only one command needs to be waited on. When employing Lv3 for GV100, the P_{99} preemption latency is further reduced to 32 μs, becoming independent of T. Fig. 11 (b) illustrates the P_{99} preemption latency of the GV100 with commands of varying execution durations, reinforcing this observed trend.

The adaptability to the evolution of XPUs. The multi-level hardware model also enables XSched to adapt to the evolving hardware capabilities and software interfaces of XPUs.

Hardware evolution. As many emerging XPUs are still under development, their hardware capabilities for preemption and scheduling may be enhanced in the subsequent generations. For example, the NVIDIA K40m does not support interrupt-based preemption [78, 79] for implementing Lv3 interfaces, while GV100 does. XSched can easily adapt to such

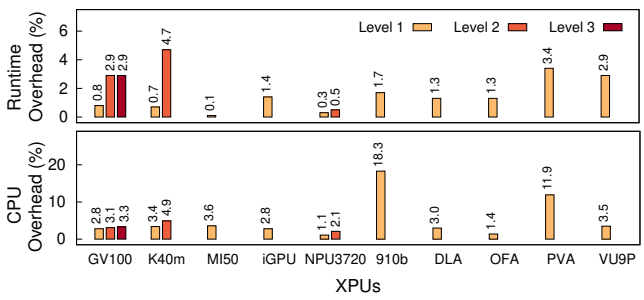

Fig. 12: *(a) The runtime overhead, and (b) the increased single-core CPU utilization of executing an XPU task with* XSched.

new hardware capability by *incrementally* implementing the higher levels of interfaces (e.g., Lv3 for GV100), while maintaining compatibility with the earlier generations of XPUs that only support lower levels of interfaces (e.g., Lv2 for K40m). We believe that for future generations of XPUs, XSched can continue to adapt to their evolved hardware capabilities.

Software evolution. The software interfaces of XPUs are also evolving rapidly. For example, XSched implements Lv2 for NPU3720 based on a new firmware released in July 2024 [48], seven months after the release of the hardware product. Additionally, the Lv3 implementation for GV100 relies on an undocumented and potentially unstable driver interface. If this interface is deprecated, XSched can selectively disable the Lv3 interfaces without altering other parts of the system.

7.4 Scheduling Overhead

Compared to the native hardware scheduler, XSched incurs additional overhead to support preemptive scheduling. We evaluate this overhead using the same tasks as in Fig. 9.

Runtime overhead. Fig. 12 (a) shows the runtime overhead of running an XPU task with XSched. The runtime overhead is less than 3.4% on all XPUs for Lv1, primarily due to the additional synchronizations required by the progressive command launching. For Lv2 on GV100 and K40m, the overhead increases by 2.1% and 4.0%, respectively, compared to Lv1. This is attributed to the execution of instrumented guardian code, whose performance is dominated by the latency of reading the flag. Therefore, XPUs with a high-performance memory (e.g., HBM2 on GV100) may show a less performance degradation compared to those with a low-performance memory (e.g., GDDR5 on K40m). In contrast, the hardware-assisted Lv2 on NPU3720 incurs no additional overhead.

Fig. 11 (c) further shows how in-flight command threshold and command execution time affect the runtime overhead of Lv1. Increasing the threshold can reduce runtime overhead as it reduces pipeline stalls. When the threshold exceeds 10, the overhead becomes negligible (less than 1%). The threshold in experiments is tuned to the minimum value that achieves overhead less than 3%. Moreover, shorter command execution time incurs more overhead due to the increased proportion of pipeline stalls, demonstrating the necessity of progressive launching as XPUs become faster.

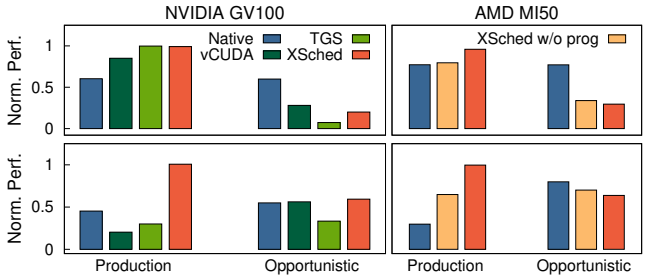

Fig. 13: *The scheduling performance of (Top) two containers running PyTorch training jobs, and (Bottom) financial algorithms as production jobs and scientific computing as opportunistic jobs. The performance is normalized by the standalone execution.*

CPU overhead. XSched employs several worker threads to manage queues and schedule XPUs, increasing CPU usage. As shown in Fig. 12 (b), XSched raises single-core CPU utilization by less than 5% in most cases, except for 910b (18.3%) and PVA (11.9%) because their drivers employ a spinning approach for synchronizing the hwQueue.

8 Case Studies

Next, we demonstrate the practical benefits of XSched through three case studies under different scenarios.

Case 1: GPU harvesting on multi-tenant server. To demonstrate the efficiency of XSched with its multi-level hardware model, we study how it manages two types of jobs on a single GPU: production jobs (Pjob) and opportunistic jobs (Ojob). Pjobs have stringent performance requirements with minimal degradation, while Ojobs should harvest remaining GPU resources on a best-effort basis.

We compare XSched against the native hardware scheduler, and two open-source GPU sharing systems, vCUDA [35, 115] and TGS [130]. Since vCUDA only supports quota-based configurations, we pre-profile the GPU utilization of Pjobs to allocate sufficient quota. TGS is evaluated without modifications, as it natively accommodates such workloads. XSched employs the fixed priority policy, assigning higher priority to Pjobs. The evaluation includes two workloads: (1) two containers running DL training jobs, the workload as in TGS, and (2) a container running financial algorithms (Black-Scholes [95]) as Pjob and a container running scientific computing (CFD [18]) as Ojob. We measure the request latency of financial algorithms and the throughput of other jobs.

Fig. 13 (left) shows the normalized performance of these systems on an NVIDIA GV100 GPU. Due to the lack of priority-based scheduling, vCUDA causes a 15.1% and a 80.0% performance degradation for Pjobs in DL training and financial algorithms, respectively. TGS can be regarded as a Lv1 implementation that carefully manages the number of in-flight commands for Ojobs by estimating the kernel submission rate of Pjobs. However, it presents two limitations. First, it misses the execution opportunities for Ojobs if the estimated kernel submission rate is inaccurate. Consequently,

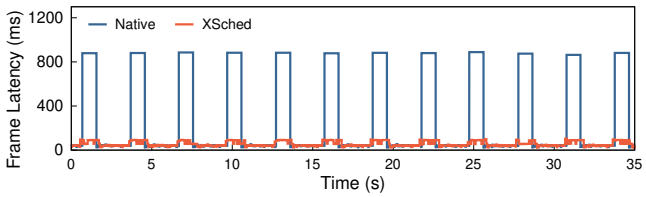

Fig. 14: *The frame latency of LFBW (fake-background) when running along with whisper.cpp (speech-to-text) on an Intel NPU3720.*

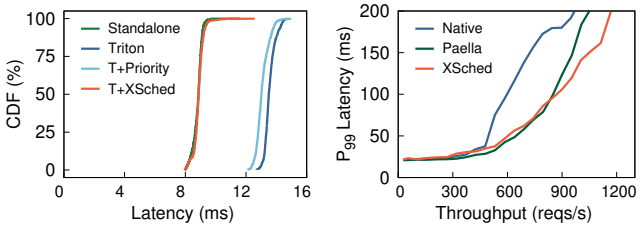

Fig. 15: *(a) The latency CDF of a high-priority Bert-large model inference using Triton and* XSched*, and (b) the throughput-latency curve of inference serving workloads using Paella and* XSched*.*

TGS can only harvest 7.3% of the GPU resources for Ojobs during DL training while XSched can utilize 20.0%, representing a 2.74× improvement. Second, TGS is effective only for Pjobs with specific patterns (e.g., DL training), and fails to accommodate other job types (e.g., financial algorithms). As a result, TGS exhibits a 70.0% performance degradation for Pjobs of financial algorithms. XSched overcomes these limitations by supporting Lv2 preemption, which mitigates the impact of in-flight commands from Ojobs on Pjobs' performance, thereby ensuring the performance of Pjobs (1.0% degradation) while improving the GPU utilization of Ojobs.

We further conducted the experiments on an AMD MI50 GPU, shown in Fig. 13 (right). Although XSched only implements Lv1 interfaces on AMD GPUs, it achieves a 4.1% and 0.4% performance degradation for Pjobs of DL training and financial algorithms, respectively. We also evaluated the performance of XSched without the progressive command launching technique (i.e., using synchronous command execution, denoted as XSched w/o prog), demonstrating its effectiveness for XPUs with only Lv1 implementations.

Case 2: Video conferencing on AI PC. In this case, we demonstrate the flexibility of XSched's policy by scheduling two applications simulating a video conferencing scenario: fake-background (LFBW [29]) and speech-to-text (whisper.cpp [32]). LFBW blurs the background of a video stream at a rate of 25 FPS. Whisper.cpp transcribes an audio stream every 3 seconds. Both applications run an AI model on Intel NPU3720 within an AI PC [45].

Fig. 14 shows the frame latency (i.e., the time between consecutive frames) of LFBW when running alongside whisper.cpp. Without XSched, the frame latency of LFBW is unstable and the P_{99} frame latency spikes up to 880 ms (20.12× higher than standalone), resulting in frequent frame drops and a jittery experience. This instability is due to the native hardware scheduler of the NPU3720 adopting a FCFS policy, causing LFBW to wait for the completion of whisper.cpp (0.8 s). To address this issue, we first attempted to use the fixed priority policy of XSched to prioritize LFBW. However, although the frame rate stabilized at 25 FPS, the latency of whisper.cpp significantly increased and exceeded its period, leading to the loss of transcribed text content. Therefore, we further implemented a laxity-based policy [96], which aims to maximize LFBW's frame rate while ensuring that whisper.cpp can complete within 3 s. Ultimately, the P_{99} frame latency of LFBW is reduced to 95 ms, an improvement of 9.26× compared to the native hardware scheduler, while ensuring that whisper.cpp did not lose any content.

Case 3: Multi-model inference serving. XSched is easy to be integrated into existing systems, thanks to the clean and unified XQueue interface. We demonstrate this by integrating XSched into two GPU-based inference serving systems to achieve low-latency inference through preemptive scheduling. The experiments are conducted on a single GV100.

Triton. We integrated XSched into a production-level inference serving system, Triton [94], with only 10 lines of code changes, to enable scheduling using the fixed priority policy of XSched. Specifically, we modified Triton to submit the scheduling hints to XSched when enqueueing inference requests. Triton allows users to specify the priority of a model. XSched retrofits this setting to assign the priority of the XQueues. To illustrate the effectiveness of integrating XSched, we used two clients to send inference requests for two Bert-large models [25]. The high-priority client sends requests with a frequency of 10 reqs/sec, while the low-priority client sends requests continuously. Fig. 15 (a) shows the latency CDF of the high-priority model. The vanilla Triton, which employs the native hardware scheduler, and Triton with priority settings (T+Priority) exhibit a 1.53× and 1.51× higher P_{99} latency compared to standalone execution. By integrating XSched (T+XSched), the P_{99} latency of the high-priority model is only 1.07× higher than standalone, a reduction of 30.0% compared to vanilla Triton.

Paella. We next compare the performance of XSched with Paella [75], a state-of-the-art inference serving system with GPU-specific scheduling techniques. We integrated XSched into the naive baseline (referred to as CUDA-MS in Paella's paper [75]) from the Paella artifact [76], which employs native hardware scheduling. The integration requires only 15 lines of code changes. We implemented a K-earliest deadline first (K-EDF) policy, which executes the K tasks with the earliest deadlines in parallel. K is set to 16 in this experiment. Fig. 15 (b) shows the throughput-latency curve. The workload used is consistent with that described in Paella's paper, where each client sends requests based on a log-normal distribution with a standard deviation of $\sigma = 2.0$. XSched achieves similar P_{99} latency as Paella at a lower throughput, and even outperforms Paella by 1.3× at a high throughput (1,000 reqs/sec).

9 Discussion and Limitations

Command-based offloading. Most XPUs function as peripheral devices passively managed by the host CPU, which issues commands to offload XPU tasks. Some XPUs, such as DPUs [14] and certain FPGAs [49, 117], can proactively execute tasks without host intervention. For these XPUs, host-managed scheduling solutions [19, 39, 123, 129], including XSched, are not applicable. One potential solution is to integrate XSched into the control unit of these XPUs, such as the ARM cores on DPUs [14].

Single-command tasks. Lv1 and Lv2 preemption mechanisms are designed for tasks that contains multiple commands, such as GPU kernels, memory-copy operations, and tensor operators. For tasks containing only a single command, such as CUDA graph or model inference on certain NPUs, developers need to either implement Lv3 or divide the task into multiple fine-grained commands through techniques like model slicing [37, 105] to enable fast task preemption.

Sufficient XPU memory. XSched currently focuses solely on computation scheduling and assumes sufficient XPU physical memory to hold all task data. On-demand paging mechanisms like CUDA Unified Memory [92], DeepUM [58], and SUV [7] can handle memory oversubscription. XSched could work together with these systems to support memory swapping with task scheduling, and we leave it to future work.

Untrusted tenants. XSched relies on applications to submit commands via XQueue APIs or use XShim to intercept those commands. However, a malicious tenant could bypass XSched or submit excessive commands to monopolize the XPU. Fortunately, XPU virtualization based on API remoting [27, 107, 122] can prevent tenants from direct XPU access. By integrating XSched into the hypervisor's API remoting server, all commands to the XPU can be properly managed.

10 Related Work

XPU hardware scheduling. Prior work proposed hardware-based scheduling techniques for various XPUs, including GPUs [73, 101, 124, 125, 135], TPUs [8, 137], NPUs [22, 24, 63, 67, 133], and FPGAs [57, 65, 69, 104]. Some are aimed to enhance the scheduling mechanisms of XPUs, e.g., fast kernel preemption [22, 73, 101] or efficient spatial sharing [124, 133]. XSched is orthogonal to these techniques, and the multi-level hardware model allows XSched to integrate these hardware enhancements. Some other work enhances the scheduling policy of the hardware scheduler, e.g., deadline-aware policy [135] or QoS-based policy [125]. These techniques require hardware modifications, while XSched can implement flexible software-defined policies.

Host-managed XPU scheduling. Prior work proposed various host-managed XPU scheduling techniques. Some aim to improve hardware utilization through GPU spatial multitasking [20, 21, 23, 50, 71, 119], while others focus on GPU task preemption [15, 19, 39, 54, 66, 129, 140]. For example, PTask [103], TimeGraph [60], Gdev [61], vCUDA [35, 115], and TGS [130] schedule pending GPU commands (Lv1) by restricting the command launching rate. EffiSha [19] and FLEP [129] preempt unexecuted GPU kernel parts (Lv2) by transforming the kernel source code to voluntarily abort inactive GPU thread blocks. REEF [39] supports running kernel preemption (Lv3) by modifying the AMD GPU driver to reset the whole task, yet is incompatible with closed-source systems and non-GPU hardware. Unlike prior work that focused on specific hardware platforms, XSched is the first general scheduling framework to support commodity GPUs, NPUs, ASICs, and FPGAs. Moreover, XSched can seamlessly incorporate new task preemption techniques (see §6) as implementations for their appropriate preemption levels.

Unified programming models and interface. Previous efforts like OpenCL [62], SYCL [34], and LevelZero [47] (oneAPI) also aimed to provide unified programming models and interfaces across different XPUs. However, hardware differences have led to numerous vendor-specific extensions, fragmenting their ecosystems. These platforms face a fundamental limitation—by defining only basic interfaces to maintain compatibility with common hardware capabilities of different XPUs, they restrict themselves to minimal functionality. In contrast, XSched introduces a multi-level hardware model to harness different capabilities of diverse XPUs while providing a unified abstraction.

11 Conclusion

Modern hardware accelerators (XPUs) are experiencing unprecedented growth, with numerous types, brands, and generations deployed across cloud and edge computing platforms. Their diverse hardware capabilities and complex software stacks expose unique challenges in designing and implementing preemptive scheduling with excellent generalizability. To tackle this, XSched proposes a unified XQueue abstraction with three-level hardware models, enabling mature, advanced XPUs to achieve optimal performance while maintaining compatibility with emerging, wimpy XPUs. We have adapted XSched to various XPU platforms and deployed it on a dozen XPUs to support preemptive scheduling with flexible policies. Our experimental evaluation and case studies demonstrate the efficacy and efficiency of XSched and its novel techniques. XSched, with its diverse XPU implementations, is open-source and publicly available at https://github.com/XpuOS/xsched.

A Artifact Appendix

This artifact provides the source code of XSched, a detailed readme, and scripts to reproduce the main experimental results from the OSDI 2025 paper—"XSched: Preemptive Scheduling for Diverse XPUs" by W. Shen, M. Han, J. Liu, R. Chen, and H. Chen. XSched is a scheduling framework that enables preemptive scheduling on diverse XPUs through a general XQueue abstraction and multi-level hardware model. We provide instructions to build the software package and run experiments. Our artifact obtained the "Artifacts Available," "Artifacts Functional," and "Results Reproduced" badges from the Artifact Evaluation process of OSDI 2025. The DOI of our artifact is https://doi.org/10.5281/zenodo.15308935.

Artifact repository. The project source code and comprehensive instructions for building and running the main experiments on different XPUs are available in this GitHub repository: https://github.com/XpuOS/xsched-artifacts.git

OS Rendering Service Made Parallel With Out-of-Order Execution and In-Order Commit

Abstract

Rendering service is an indispensable OS service on smart-device OSes like Android, iOS and OpenHarmony. However, the recent shift towards highly scalable display scenarios, such as foldable and multiple screens, has notably amplified the rendering workload, leading to low frame rates that degrade user experience. Yet, rendering services predominantly follow a sequential model, which is notoriously hard to parallelize due to the complex *state dependency*, *drawing order dependency*, and *interface dependency*.

This paper observes that a significant portion of the rendering procedure is potentially parallelizable through proper state pre-untangling and drawing order post-preserving. To this end, this paper introduces *Spars*, a scalable parallelized OS rendering service inspired by the out-of-order execution with in-order commit in computer architecture. *Spars* revolutionizes the rendering procedure by initially generating self-contained rendering tasks through *in-order preparation*, executing such tasks in an *out-of-order manner* to maximize multi-core parallelism, and subsequently committing the tasks *in-order* to enforce drawing order dependencies. Evaluation results on state-of-the-art single-screen, dual-fold, and tri-fold smartphones (Mate 70, X5, XT) as well as one-chip-multiple-screen configurations show an average frame rate improvement of 1.76×–1.91×. Moreover, *Spars* is able to decrease the device power consumption by 3.0% or increase the budget of graphics primitives by 2.31× for more appealing visual effects with the same stable frame rate.

1 Introduction

Rendering service is a crucial system service on smart-device OSes like iOS [19], Android [6], and OpenHarmony [22], enabling the display of exquisite graphical user interfaces (GUIs). On average, people worldwide spend 6 hours and 40 minutes per day on screens [56], not accounting for emerging graphical devices such as intelligent cockpits, head-up displays, smart homes, and wearable devices. Rendering service represents one of the most demanding workloads in smart OSes — our evaluations show that rendering-related tasks typically occupy 65%–95% of total CPU and GPU running time in commercial smartphones.

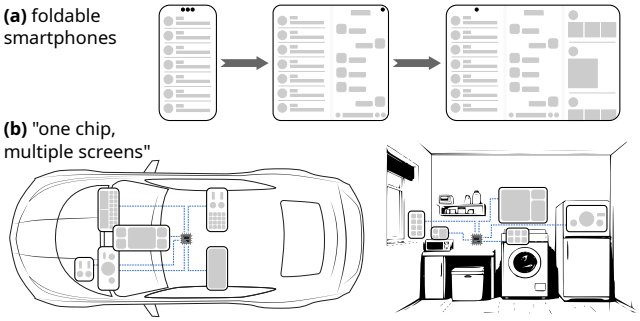

Figure 1: Demands for rendering scalability in foldable smartphones and one-chip-multiple-screen display setups.

The workflow of state-of-the-art rendering services follows a *sequential* model, encompassing management of a render tree, translation of draw commands into GPU objects, and GPU rasterization into pixels. First, the rendering service maintains a render tree, where each render node stores draw commands and parameters of graphics primitives, such as the height and width of a rectangle. Meanwhile, each node contains relative information with respect to its parent, such as the relative position, and its child nodes are sorted based on the drawing order from back to front. Subsequently, a 2D drawing engine translates draw commands in the tree into GPU objects like meshes, textures, and pipelines. When sequentially traversing the tree node by node, it tracks a stack of relative information and enforces the correct drawing order. Eventually, the GPU handles triangle rasterization, texture sampling, pixel shading, etc., based on the GPU objects provided through standard GPU APIs like Vulkan [34].

Emerging demand for scalable rendering. While the sequential model continues to be effective for traditional devices, the recent shift towards smart devices featuring foldable screens [11, 13, 16, 17, 25] and multiple screens [7, 46] in smartphones and intelligent cockpits (Figure 1) has placed increasing pressure on the OS rendering services. For example, while the Huawei Mate 70 (single-screen), Mate X5 (dual-fold), and Mate XT (tri-fold) possess similar System-

on-Chip (SoC), the latter two need to render 70% and 117% more pixels in each frame due to the larger screen area. The limitations of state-of-the-art sequential rendering services in coping with such heightened demands compel smartphone manufacturers to make compromises on other display parameters, such as pixel density reduction in Samsung and frame rate decrease in Huawei (§3.1). Intelligent cockpits with one-chip-multiple-screen display configurations face the same dilemma of trade-offs.

Key observation: bottleneck due to core underutilization in rendering services. We have identified a critical issue of underutilization in the hardware capabilities of rendering services. Despite the availability of multiple CPU cores, many remain underutilized or idle, even when they could contribute to handling the increased workloads. In real-world experiments (§3.3), for example, the rendering service's render thread monopolizes 80% utilization of a single core, limiting the frame rate. The remaining cores are only partially engaged in application logic, leaving 9 out of 12 cores idle and underutilized. This underutilization highlights the potential to improve performance by better leveraging the multi-core parallelism of modern SoCs, enabling rendering services to scale more effectively to meet the growing demands.

Based on this key observation, we argue that *the next-generation rendering service should adopt a parallel architecture to address scalable rendering demands*. Nevertheless, designing a scalable and parallel rendering service presents three significant challenges posed by dependencies.

Challenge-1 (C1): State dependency. Rendering tasks exhibit state dependencies that hinder parallelization efforts. Each node only contains the relative information with its parent. This design ensures that modifying a single node triggers updates across its entire subtree, while necessitating a sequential depth-first traversal to convert the relative information into absolute values before executing each draw command.

Challenge-2 (C2): Drawing order dependency. Rendering tasks involve critical drawing order dependencies that must be maintained. When two graphics primitives overlap, the background should always be rendered before the foreground (i.e., *overlapping relations*). While the render tree organizes the children of each node from back to front and preserves the sequence through a depth-first traversal, the pre-defined drawing order impedes parallelization efforts.

Challenge-3 (C3): Interface dependency. Refactoring for parallelization would impact existing interface compatibility. Traditional 2D rendering systems utilize a stateful interface, such as Skia Canvas [27] or Drawing API [9], where new commands may rely on past commands. Also, traditional state-based rendering optimizations like command batching should not be ignored under the new rendering paradigm.

To tackle these challenges, we introduce *Spars*, a scalable and parallel OS rendering service, powered by a novel drawing engine *Spade*2D. Our key insight in overcoming the aforementioned challenges is that *rendering tasks do not need to be executed sequentially to satisfy the three dependencies* — our study reveals that a large portion (76%) of the rendering procedure could be self-contained and potentially parallelizable, as long as *the states are properly untangled for inputs* and *the drawing orders are carefully maintained for outputs*. This approach is closely analogous to out-of-order execution in computer architecture [83], where instructions are dispatched as soon as dependencies are resolved, while their results are committed in-order to ensure program correctness.

Drawing inspiration from the concept, *Spars* employs a three-stage rendering procedure: *in-order preparation*, *out-of-order execution*, and *in-order commit*, to effectively utilize multi-core SoCs without violating dependency constraints. Specifically, *Spars* introduces the concept of *self-contained rendering tasks* derived from the render tree, allowing each task to be executed out-of-order and in parallel, thereby untangling state dependencies (**C1**). We observed that the actual execution of rendering does not impact the preparation of required drawing states. A quick in-order dry run, without rendering, suffices to decouple non-parallelizable states from the parallelizable tasks. Next, to ensure correct drawing order (**C2**), *Spars* explicitly manages overlapping relations of the rendering tasks for a dedicated commit thread. A finished rendering task can be committed to the GPU command only if all the drawing order dependencies are respected. Finally, *Spars* decouples the rendering procedure into two phases: a stateful phase and a stateless phase. The former maintains a consistent interface (**C3**) for custom-rendering applications and state-based optimizations, while the underlying *Spade*2D drawing engine, in contrast, employs a stateless interface for parallelism and scalability.

We have implemented and tested *Spars*[1] with 42 representative smartphone scenarios on Mate 70, Mate X5, Mate XT, and 12 one-chip-multiple-screen configurations. Comparing the results with the state-of-the-art sequential rendering models of OpenHarmony demonstrates an average frame rate increase of 1.76×–1.91×. Through leveraging multi-core parallelization, *Spars* is able to reduce the whole-device power consumption by 3.0% or allow a 2.31× budget for the total number of rendering graphics primitives for more appealing visual effects under the same frame rate. We anticipate that the design of *Spars* will significantly influence the evolution of next-generation OS rendering services.

2 OS Rendering Service Explained

The OS rendering service, as a system service, is responsible for rendering all of the GUI elements specified and synchronized from applications into every pixel (color value) of the frame buffer. This section uses the state-of-the-art iOS [31] and OpenHarmony [3] designs to illustrate the core rendering

[1] https://github.com/SJTU-IPADS/Spars-artifacts

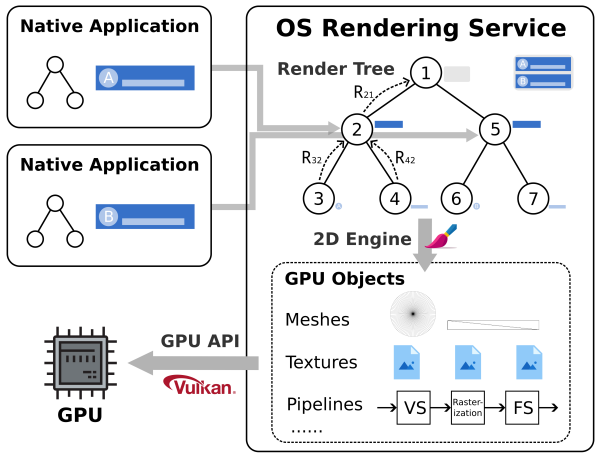

Figure 2: OS core rendering procedure.

procedure, demonstrated in Figure 2.

2.1 Render Tree

The render tree in the OS rendering service unifies and manages all of the drawing information on the screen(s). Different types of the render nodes on the tree record screen parameters, window parameters, and most importantly, parameters of the draw commands. Each draw command encodes a 2D graphics primitive, such as the height and width of a rectangle or the radius of a circle. When an application needs to update its content, it synchronizes a modified subtree or specific animation instructions of the render nodes with the OS rendering service through inter-process communication. Compared to the window-divided rendering approach used by Android [14] or Wayland [58], where each application process renders its own frame buffer locally for later system-wide composition, a unified render tree enables richer inter-window animations and visual effects. With finer-grained occlusion culling and reduced frame buffer memory usage, iOS [31], visionOS [30], OpenHarmony [3], etc., all adopt such strategy.

Implication-1: Current rendering services only maintain relative information in render nodes. Each render node on the tree only contains the *relative information* (R) with respect to its parent, such as the relative transform matrix (encoding translation, scaling, and rotation) and the relative clippings (scissoring the drawing region). This design ensures that modifying R of any node sufficiently and efficiently updates the entire subtree — for example, moving its position.

Implication-2: Drawing order should be strictly enforced for correctness. Each render node has its children sorted based on the *drawing order*, from back to front. Note that node drawing is not always commutative due to possible overlapping. Left subtree must be drawn before the right subtree based on the pre-definition. Therefore, a depth-first traversal of the render tree implicitly keeps the drawing order, as the numerical example (from 1 to 7) shown in Figure 2.

2.2 2D Engine

The 2D drawing engine translates the parameters of the draw commands (i.e., the mathematical expressions of 2D graphics primitives) into GPU objects like meshes, textures, and pipelines, which are later sent to GPU for actual rasterization.

Implication-3: The core rendering logic (translation from commands to GPU objects) is a time-consuming CPU procedure. Modern 2D engines like Skia [29] or Impeller [18] mostly use CPU tessellation to triangulate 2D primitives into meshes for GPU to rasterize, combined with signed distance field (SDF) [52, 70] and stencil then cover (StC) [61] algorithms for anti-aliasing and rendering specific graphics primitives. While SDF and StC help reduce some CPU load, the end-to-end rendering procedure still involves CPU-intensive tessellation, memory buffer filling, and other GPU object preparations, with CPU time accounting for 82% of the total frame rendering time in commercial OS rendering (§3.3). Besides, glyphs (text) are still rasterized by the CPU into an atlas using tools like FreeType [12] for functional completeness, and then mapped by the GPU to specific positions.

Implication-4: Existing 2D engines expose stateful interfaces for rendering, which keep internal states so past commands would affect future commands. When the rendering service depth-first traverses the render tree, it issues state-update commands to the underlying 2D engine using the relative information R. At any node during the traversal, the 2D engine always keeps a stack of relative information along the path — from the tree root to the current node — so that a subsequent draw command can derive the absolute state of the transform matrix and clippings.

Implication-5: Stateful interfaces enable 2D engines to use state-based optimizations internally. One important optimization is *command batching*. Rather than individually doing the translation one command by another, 2D engines first organize them into a chain structure, serving as an intermediate representation (IR) for GPU object generation. Each new command will be appended to the end of the chain, and then try to coalesce with the previous command if they can share the same GPU pipeline, i.e., using the same shaders and pipeline configurations. If not, the iteration can go one command backward as long as the current non-coalescible command does not overlap with the new command, so the drawing order is still correct if batching with previous commands. The backward iteration typically has a constant maximum limit to prevent the linear complexity from degrading into quadratic for building the entire chain.

2.3 GPU API

The GPU API, implemented by the GPU driver, provides standardized interfaces (i.e., abstractions of the GPU objects) that enable 2D engines to leverage the GPU for efficient graphics rasterization. It provides the capabilities of drawing triangles,

sampling textures (images), shading graphics primitives with various visual effects via programmable shaders, etc.

Implication-6: Modern GPU APIs are already stateless and can support parallel tasks. The next-generation GPU APIs such as Vulkan [34], Metal [20], and DirectX12 [8], on which state-of-the-art rendering services and 2D engines are built, are *stateless* within the GPU driver. In contrast with traditional APIs like OpenGL [23] which maintain a single-threaded state machine model within the GPU driver, they delegate the management of GPU objects to the API users. This provides a necessary condition for scalable and parallel rendering in multi-core configurations.

Implication-7: Modern GPU APIs still have constraints that must be considered in system design for compatibility. Modern GPU APIs still have *parallelization constraints*, considering the need for compatibility with existing GPU hardware. For instance, in Vulkan, command buffers should not be arbitrarily small because of the limitations in CPU submission and GPU scheduling. Also, parallel-recorded secondary command buffers cannot target at a different frame buffer (i.e., render pass) than the primary command buffer [59], which is a common case in OS rendering services where some components need to render into a separate layer. Our system is designed with these parallelization constraints in mind.

3 The Need for Scalable Rendering

In recent years, the demand for visually captivating, smooth, and immersive displays has been driving the evolution of next-generation smart devices [66, 87, 93], particularly in the form of foldable smartphones and multi-screen environments. Achieving larger display area, higher pixel density, and higher refresh rate at the same time has become both a user expectation and a technical challenge, pushing traditional fixed-thread sequential rendering models into their limits. This section analyzes the current and future display capabilities of flagship commercial smart devices, identifies their performance bottlenecks, and presents our observations.

3.1 Increased Rendering Loads in the Wild

Scenario-1: Foldable large screen. Foldable smartphones, including dual- [13, 16, 25] and emerging tri-fold devices [17], represent a significant advancement in screen design, and the market size was valued at 27.79 billion USD in 2023 with expected annual growth of 13.5% [11]. These devices offer users the ability and flexibility to view and interact with multiple pages and more content simultaneously, enhancing both immersion and productivity. However, the increased display area — compared to traditional single-screen devices — results in higher demands on frame rendering performance.

Figure 3 compares the screen specifications of contemporaneous flagship models. As foldable devices often use the same chipset as their single-screen counterparts, the larger display area in reality requires trade-offs in other aspects. For example, Samsung opts to reduce pixel density, keeping the total number of pixels similar to that of traditional smartphones with a sacrifice of definition. On the other hand, Huawei reduces the frame rate of foldable smartphones to 90Hz in common use cases, sparing more time for each frame to be rendered, even if today's mainstream screen hardware supports up to 120Hz, with a sacrifice of smoothness.

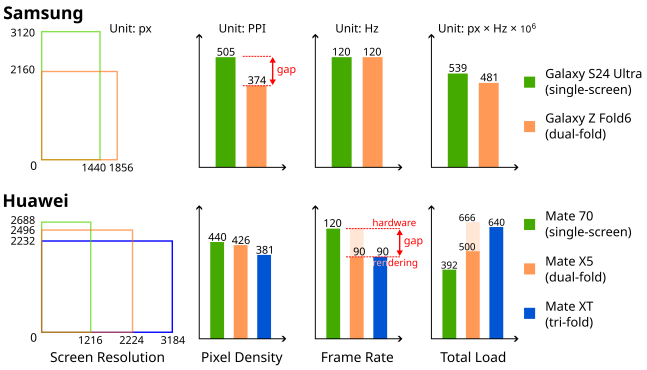

Figure 3: Display specifications of flagship smartphones. Large screen area means trade-offs in other parameters.

Scenario-2: One chip, multiple screens. In 2023, multi-screen solutions were installed in about 3.6 million cars in China, with 43 and 52 brands offering multi- or dual-screen intelligent cockpits, respectively [7]. For example, AITO M9 (2024) [5] features five screens: a center screen (1× 15.6"), a dashboard screen (1× 12.3"), a copilot screen (1× 16"), and two backseat screens (2× 17.3"). In multi-display environments, a single chipset is often responsible for driving multiple screens simultaneously to achieve a consistent and synchronous experience, with graphical elements able to freely and seamlessly stream between different screens [46].

Challenges arise for the OS rendering service when preparing content for multiple displays at once, as the computational demands increase proportionally. As a result, current state-of-the-art multi-screen environments can only operate at 45Hz–60Hz frame rate [92] and trade display quality (e.g., number of graphics primitives) for stable performance. This disparity between hardware display limit and software rendering capability underscores the need for a scalable and parallel OS rendering service.

3.2 State-of-the-Art Efforts

State-of-the-art rendering services in commercial operating systems adopt two classes of parallelization: *inter-frame parallelism* and *multi-window parallelism*, to tackle the CPU performance bottleneck in 2D rendering.

Inter-frame parallelism. iOS [31], Android [14], and OpenHarmony [3] all employ a multi-stage pipeline for inter-frame parallelism, where each frame is sequentially rendered across

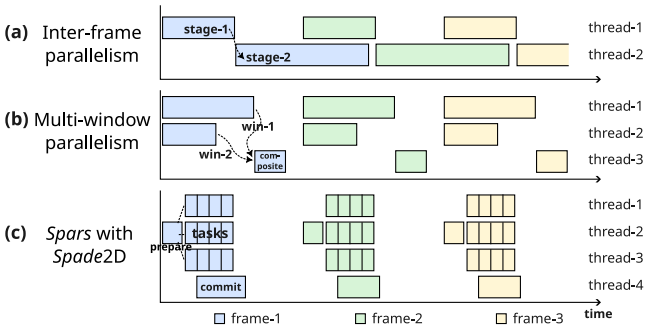

Figure 4: The threading model of different methods. Compared to state-of-the-art efforts (inter-frame and multi-window parallelism), our solution enables finer-grained parallelism.

a fixed set of threads, with consecutive frames in different stages rendered in parallel, as shown in Figure 4(a). Inter-frame parallelism does improve multi-core utilization, but it has three limitations. First, the number of threads that can be used are not scalable, as the number of stages (usually 2 or 3) are tightly coupled with the rendering logic, statically divided in advance. Second, the performance is bottlenecked by the longest stage. Due to the static logic-coupled division, stage imbalance is unavoidable. In OpenHarmony, we observed that the running time of stage-1 is <50% shorter than the heavily-loaded stage-2. Last, inter-frame parallelism may increase rendering latency, as each frame needs to span two to three Vertical Synchronization (VSync) periods [33] to finish.

Multi-window parallelism. In multi-window parallelism, each window is rendered in different threads (or processes), and later all the window frame buffers are composited into a single display frame buffer, as shown in Figure 4(b). Android [14] adopts this approach, and Skia Graphite [85] supports parallelization with render passes (i.e., tile or frame buffers). Although multi-window parallelism is useful for multiple windows, it also has three limitations. First, the workloads are highly imbalanced, as usually a single focused application occupies the entire workloads, with status or navigation bar at the corner seldom updating. Second, many scenarios do not have the windowing abstraction, which is however necessary for parallelism. For example, a chatting app on a large foldable screen can display the contacts, chat history, and posted photos simultaneously on different sections of the same window (Figure 9(d)), while the rendering service does not have any semantics. Last, multi-window parallelism introduces more memory for window frame buffers and additional workloads for window composition.

State-of-the-art system research. Existing system research usually focuses on multi-GPU parallelism for 3D rendering on screen walls [53, 62, 71, 80] and graphics emulators [51, 67, 68, 79], which is different from our smart device configurations and demands (i.e., OS 2D rendering). *D-VSync* [87] exploits single-core CPU capabilities in smartphones to tackle workload fluctuations, handling sporadic frame drops via pre-rendering during animations. Nonetheless, *D-VSync* cannot scale to large multiple screens and multiple CPU cores. Table 1 summarizes the system techniques for rendering performance.

Table 1: Performance comparison of different system techniques. Inter-frame and multi-window parallelism methods have been adopted by commercial smartphone OSes including Android, iOS, and OpenHarmony, but still cannot handle workload fluctuation and constant heavy loads due to the coarse-grained parallelism. *D-VSync* [87] is the state-of-the-art deployed in HarmonyOS NEXT, but cannot handle constant heavy loads due to its lack of parallelism support.

	Applicable Scenarios	Extra Loads	Rendering Latency	Workload Fluctuation	Constant Heavy Loads
Baseline	100%	/	/	Frame Drops	Low Frame Rate
Inter-frame Parallelism	100%	Minor	Serious Influence	Frame Drops	Medium Frame Rate
Multi-win Parallelism	<5%	Some	Some Influence	Frame Drops	Medium Frame Rate
D-VSync	85%	Minor	No Influence	No Frame Drop	Low Frame Rate
Spars with *Spade*2D	100%	Minor	No Influence	Leveraging *D-VSync*	High Frame Rate

State-of-the-art graphics research. Existing graphics research proposes various rendering algorithms that attempt to offload CPU-intensive 2D rendering onto GPUs and accelerators [36]. Legacy systems such as Windows GDI [86] and early versions of Cairo [75] and Skia [29] rely on pure CPU-based scanline rasterization [88]. Nowadays, modern 2D engines on smart devices primarily use tessellation and triangulation with SDF algorithms [52, 70] for GPU rasterization. A series of subsequent studies further explore stencil-buffer-based [61, 63, 64, 82] and vector-texture-based [50, 74, 78] algorithms. However, they increase the total load and power consumption on mobile (tile-based [2]) GPUs due to costly stencil operations and complex shader computation, limiting their universal applicability in OS rendering.

3.3 The Breakdown of Rendering Workloads

We present two quantitative analyses of rendering workloads based on our long-term industry experience with the OS rendering service.

Observation-1: CPU dominates the rendering costs. The end-to-end rendering process is CPU-intensive for 2D scenarios. Figure 5(a) illustrates the distribution of CPU and GPU execution time for each frame in representative scenarios, such as desktop and application pages. On average, sequential CPU processing accounts for 82% of the end-to-end frame rendering time. In contrast to 3D games that require the GPU to render millions of triangles per frame [72], 2D scenes typically involve fewer than 1,000 triangles. The primary workload of the OS rendering service falls on the CPU, responsible for preparing render tree states, tessellating and

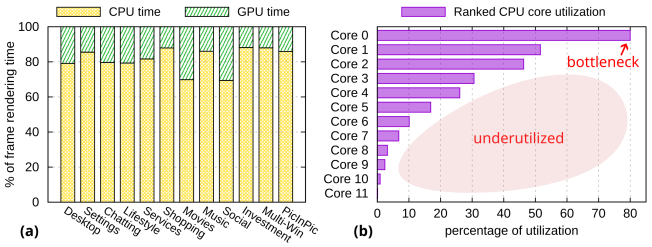

Figure 5: Breakdowns of rendering workloads on Huawei Mate X5, between (a) CPU and GPU, and (b) CPU cores.

triangulating mathematical abstractions of 2D primitives into vertices, and generating GPU objects. As the CPU and GPU run asynchronously, the CPU execution time fully covers the GPU execution time, becoming the bottleneck.

Observation-2: Sequential rendering model limits the hardware utilization. The current state-of-the-art rendering procedure follows a fixed-thread sequential model, restricting the multi-core utilization. Figure 5(b) highlights the imbalanced CPU per-core utilization in the Lifestyle scenario on Mate X5 (Figure 9(c)) with OpenHarmony 5.0, struggling to achieve the frame rate of 90Hz. While the rendering service's render thread monopolizes 80% utilization of a single core with inter-frame parallelism and application logic partially utilizing other cores, most CPU cores (cores 3∼11) remain largely idle, making the single core the performance bottleneck. Modern chipsets typically feature 8 to 12 CPU cores, with this trend set to continue [21]. Given the significance of rendering services in smart-device operating systems, achieving scalability and parallelization across multiple cores is crucial for optimal performance.

4 Scalable Rendering

4.1 Parallelism with Out-of-Order Execution

A multi-core parallel OS rendering service is the key to support scalable rendering. However, it faces three major challenges detailed in §1. First, *state dependency* prevents encapsulating tasks for parallel execution, as each node in the render tree only contains the relative information in terms of its parent. Second, *drawing order dependency* for graphics primitives must be maintained for correctness, while individual tasks scheduled on the worker threads lose the pre-defined order. Last, *interface dependency (compatibility)* should be considered for existing applications and optimizations that rely on stateful rendering, which contrasts with the stateless nature of parallelization.

Revisiting parallelism in computer architecture. In processors, parallelism can be achieved through out-of-order execution and in-order commit [83]. Out-of-order execution refers to a strategy where a processor executes instructions in an order different from their original program sequence. This technique allows the processor to *bypass potential instruction dependencies* and better utilize idle execution units, thereby enhancing overall performance and efficiency. On the other hand, in-order commit ensures that the results of these out-of-order executed instructions are committed to memory or storage in the original sequential order of the program, preserving the correctness and consistency of the final output.

Insights on parallel rendering. We observed that the challenges of parallel rendering exhibit similarities to those encountered in out-of-order processors, for example, the dependencies between draw commands and between instructions. Drawing inspiration from practices in computer architecture, our key insight is to *methodically decouple the rendering procedure into in-order task construction, out-of-order task execution, and in-order dependency enforcement*, enabling (mostly) parallel processing without violating dependency requirements. Specifically, the scalable and parallel rendering procedure comprises three stages: (1) *in-order preparation*, which involves constructing self-contained tasks based on the render tree, allowing out-of-order execution while ensuring the eventual enforcement of overlapping relations; (2) *out-of-order execution*, where tasks are executed using a configurable number of worker threads distributed across multiple cores; (3) *in-order commit*, which collects the execution results from the worker threads and serializes the outputs in a correct drawing order before submitting to the GPU for final rasterization. Compared to the design in computer architecture, a new stage, the in-order preparation, is introduced to satisfy specific requirements in parallel rendering.

The three-stage design increases minor total workloads, because it simply **decouples** the state management, drawing order management, and state-based optimizations — procedures originally existed and embedded in the state-of-the-art sequential rendering — from the core rendering workload, so the latter can be parallelized.

Building on the insight that scalability and parallelism can be achieved through out-of-order execution and in-order commit, this paper presents *Spars*, a novel scalable and parallel OS rendering service, powered by the underlying novel drawing engine *Spade*2D.

4.2 Design Overview

Figure 6 shows the overall rendering architecture of *Spars*. Instead of directly performing a depth-first traversal of the render tree to render each node sequentially, *Spars* divides the rendering procedure into the aforementioned three stages. These stages are supported by three types of threads in *Spars*: the *main thread*, *worker thread*, and *commit thread*.

In-order preparation (main thread). During the preparation stage, the render tree is still traversed once in a depth-first manner by the main thread to prepare self-contained rendering tasks (§5.1). The key difference is that no core rendering logic (i.e., invoking the 2D engine to generate any GPU object) is performed, making the in-order preparation a very fast dry

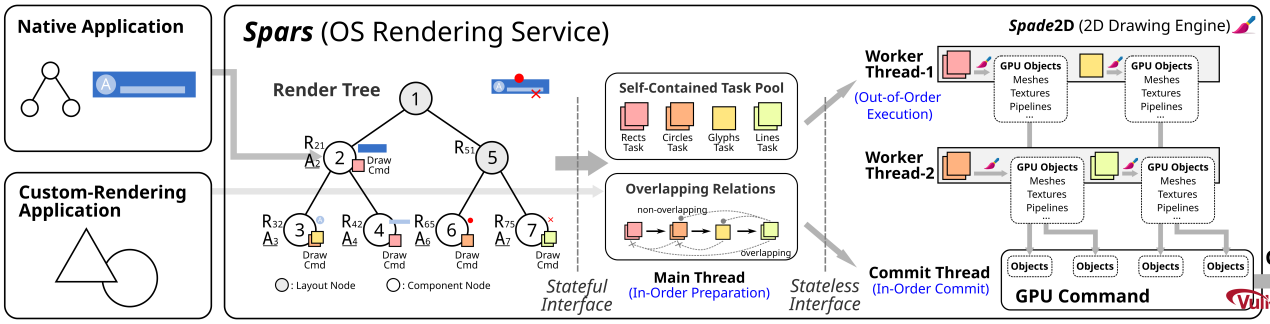

Figure 6: The parallel rendering architecture of *Spars* with *Spade*2D. The main thread prepares self-contained rendering tasks for out-of-order execution in the worker threads and overlapping relations for in-order commit in the commit thread.

run. At the same time, overlapping relations (§5.2) between the rendering tasks are recorded, which the commit thread will later use (in the in-order commit stage) to preserve a correct drawing order. State-based batching optimization (§5.3) can also be conducted here. Finally, the main thread puts all the self-contained rendering tasks into a single-producer multi-consumer (SPMC) task pool, and synchronizes the overlapping relations with the commit thread.

Out-of-order execution (worker thread). Worker threads in *Spars* execute rendering tasks retrieved from the SPMC pool. As every rendering task is self-contained without interdependency in states, they can be scheduled onto any worker thread with any order — enabling out-of-order and parallel execution. For each task, the worker thread invokes the *Spade*2D drawing engine to translate mathematical expressions of 2D graphics primitives into GPU objects like meshes, textures, pipelines, etc. *Spade*2D provides a stateless interface (§5.3), allowing each task to be executed independently on multiple cores without interference from one another (§5.4). Finally, the generated GPU objects are packed and put into a multi-producer single-consumer (MPSC) resource pool for the commit thread to perform in-order commit.

The number of worker threads is configurable at runtime, based on the chipset's multi-core configuration and the current execution environment. At least one worker thread is required. It is recommended to reserve several cores for the commit thread, application threads, and other system threads to avoid unnecessary scheduling overhead. In practice, 3 to 5 worker threads are typically sufficient (§6).

In-order commit (commit thread). The commit thread is responsible for gathering the generated GPU objects from the MPSC pool and committing them into the GPU command, based on the overlapping relations prepared by the main thread. This procedure is straightforward, with the commit thread simply binding the handles of the generated GPU objects into the GPU command by reference. Notably, the commit thread does not need to wait for all worker threads to complete their tasks. Instead, upon receiving a completed task with its associated GPU objects, the commit thread assesses the feasibility of committing it into the GPU command — whether all drawing-order-dependent tasks have already been committed (§5.2). If this condition is not met, the commit thread waits until all the dependent tasks complete and commit, ensuring a correct drawing order.

The waiting does not impact the end-to-end frame rendering time, as the main thread submits rendering tasks to the SPMC task pool in a naïve topological drawing order derived from a depth-first traversal. Although tasks are executed out-of-order with differing execution time, the completion order retrieved from the MPSC pool is mostly retained from the SPMC pool, and the chance of dependency waiting (i.e., waiting for the background primitive to complete first) in the commit thread is minor. Except for the last several rendering tasks, the execution time of the commit thread is fully covered by the worker threads, as illustrated in Figure 4(c). Finally, the GPU command will be submitted to the GPU driver for GPU rasterization, producing a color for each pixel.

5 Detailed Design

This section introduces detailed key techniques behind the design of *Spars* with *Spade*2D.

5.1 Self-Contained Tasks

For rendering to be scalable and parallel, *Spars* divides the entire rendering workloads into individual *self-contained* rendering tasks that can be executed on multiple worker threads in an out-of-order manner. This requires that self-contained tasks encapsulate all the essential drawing states for the *Spade*2D drawing engine to generate the corresponding GPU objects. A complete *drawing state* encompasses a transform matrix encoding the drawing position, scaling, and rotation, clippings encoding the valid drawing region, parameters encoding specific graphics primitives, as well as coloring and styles.

Challenge. However, as discussed earlier, rendering services face the challenges of state dependencies. In the existing render tree, each node does not contain the complete drawing state; instead, it only holds information relative to its parent. The benefit of the relative-state design is its efficiency in updating screen content, as modifying the root node of a subtree is sufficient to alter a group of nodes. In the render tree shown

in Figure 6, R_{ij} denotes the relative information of node i with respect to node j. For example, when an animation or a drag operation needs to move the card represented by the subtree rooted at node ②, it can just modify the transform matrix of R_{21}, which automatically moves node ③ and ④ with unchanged R_{32} and R_{42}, supposed that node ① is a larger container inside which node ② is able to move. The presence of state dependencies mandates that modern rendering services process render nodes (or tasks) sequentially in accordance with depth-first order to access the correct states, thereby impeding parallelization efforts.

Constructing self-contained tasks with a dry run. We observed that the actual execution of rendering tasks does not affect the construction of the complete drawing state required for them. Based on this observation, we introduce a *dry-run* method to generate the absolute information for each node. During the preparation stage, *Spars* traverses the render tree in a depth-first order (without invoking the 2D engine to do any actual rendering), calculates the complete states, and records the absolute information A_i — relative to the screen coordinates or the absolute zero — for node i that includes at least one draw command. By following this approach, *Spars* encapsulates the original draw commands in the render tree into a collection of self-contained rendering tasks devoid of state dependencies, as shown in Figure 6. When the screen updates in a frame, invalid A_i values are recalculated during the depth-first traversal in the main-thread preparation. For example, in a scenario where R_{21} undergoes updates (i.e., invalidation) due to drag operations, *Spars* dynamically adjusts the subtree containing nodes A_2, A_3, and A_4 during the dry-run traversal, before encapsulating tasks for these nodes. Notably, recorded A_6 and A_7 will not be affected, because their paths to the root have no relative information change.

Computation costs. The computation incurs minor additional workload overhead compared to the state-of-the-art rendering services. The conversion from relative to absolute information is originally integrated in the sequential rendering procedure through stateful interfaces provided by 2D engines. *Spars* simply decouples the fast, non-parallelizable preparation logic from the core parallelizable rendering logic. Additionally, unchanged absolute information is reusable across frames, making the preparation efficient and fast.

Resource costs. Storing absolute information incurs minor memory overhead. *Spars* observes the sparsity of draw commands relative to the total number of render nodes. Many internal nodes in the render tree are layouts rather than actual components, containing no draw commands. For example, node ① and ⑤ in Figure 6 only contain the relative information R, which does not require bookkeeping of any absolute information for drawing. In the desktop scenario on Mate XT, approximately 200 out of 800 nodes (25%) have draw commands, and each piece of absolute information, consisting of the transform matrix and clippings, occupies at most 10KB. Additional 2MB of memory usage is permissible.

5.2 Overlapping Relations

Rather than using the implicit drawing order pre-definition in the render tree, *Spars* explicitly manages the overlapping relations for in-order commit, which can enable out-of-order execution while not violating drawing order dependencies.

Challenge. Graphics rendering follows a partial order defined by the render tree, where tasks (i.e., graphics primitives) at the back must be drawn before tasks at the front when they overlap. For example, the dark blue background in Figure 6 must be drawn before the light blue and red components, while the order among node ③, ⑥, and ⑦ does not affect the correctness of drawing. Traditional sequential rendering applies a depth-first traversal when processing each node, as the children of every node are pre-defined to be in back-to-front order (i.e., z-order). However, the out-of-order task execution in *Spars* does not provide such a guarantee.

Overlapping relations. To tackle this challenge, *Spars* entrusts the main-thread preparation to explicitly construct overlapping relations of the self-contained rendering tasks for the commit-thread in-order commit. While it is possible to build a complete directed acyclic graph (DAG) for the partial order, *Spars* finds itself costly and unnecessary to do so — the commit thread just needs to follow one correct topological order, and the commit stage barely becomes a bottleneck as discussed in §4.2. Therefore, during the depth-first traversal in preparation, *Spars* just chains the generated self-contained tasks for a naïve drawing order and manages their axis-aligned bounding boxes (AABBs) [48]. An AABB is defined as the x- and y-axes aligned rectangular bounding box of each task's drawing region. It is one of the most efficient methods in computer graphics for determining whether two graphics primitives overlap — if two primitives overlap, their AABBs must also overlap. The chain with AABBs is later synchronized from the main thread to the commit thread.

In-order commit with overlapping relations. During the commit stage, the commit thread checks whether it is possible to commit the received completed task (i.e., its generated GPU objects) into the GPU command, based on the task chain and AABBs. If the task received is the current head of the chain when all the tasks before it have already been committed, then it is correct to commit the task next. This is the most common case, as the tasks (with possible varying execution time) are dispatched from the main thread to the worker threads using the same chain order. If the task is not the current head, then the commit thread checks the AABBs of all the unfinished tasks before it in the chain. When no AABB overlaps with the current completed task, then it is also correct to commit the task next into the GPU command. For example, in Figure 6, the *Lines Task* can be committed as long as the *Rects Task* has been committed. Otherwise, the commit thread must block to wait for a valid background task to commit first. The AABB checking only performs a preset maximum times (3 to 5 times) for each completed task. The

Figure 7: Stateful and Stateless APIs in *Spars*.

mechanism ensures that one or two heavy tasks do not block the commits of subsequent tasks, so the commit procedure can almost be covered by the execution time of the heavily-loaded worker threads. Although there is no complete construction of a DAG, the commits follow a logical partial order, based on the overlapping relations of the chain and the AABBs.

Costs. The construction of the overlapping relations incurs minor extra workload, as traditional 2D engines use a similar chain structure for command batching (§2.2). In *Spars*, the same chain is reused for both the state-based batching (§5.3) and the overlapping relations. Moreover, pointer maintenance and AABB checks are lightweight operations.

5.3 Stateful and Stateless APIs

Existing rendering services and 2D engines utilize stateful APIs, hindering parallel rendering. Although it is possible to define new APIs capable to support parallel rendering without state dependencies, they are not compatible with custom-rendering apps and are not intuitive to use. Therefore, we decouple APIs into two parts: *stateful* and *stateless* APIs. The stateful APIs (provided by *Spars*) ensure compatibility with existing interfaces and support state-based batching optimizations, while the stateless APIs (provided by *Spade*2D) can enable parallel and out-of-order task execution. The vertical dashed lines in Figure 6 show the division.

Definitions. *Spars* defines *stateful* as a paradigm in which each executed command leaves corresponding states in the system, impacting the completeness and correctness of subsequent commands, as shown in Figure 7. This includes state dependencies, drawing order, and command reordering or coalescing. In contrast, a *stateless* interface implies that each rendering task is independent and self-contained, leaving no residual state that affects the correctness of subsequent draws.

Interface compatibility. The decoupling ensures interface compatibility with traditional 2D drawing engines for custom-rendering applications who might directly invoke them for drawing, such as games, Flutter apps [10], and web apps [90]. Although the underlying *Spade*2D is stateless, the stateful APIs serve as an adapter to untangle the intricacies and encapsulate self-contained tasks for it. Therefore, these third-party apps can enjoy the same traditional stateful interface such as the Drawing API [9] or Skia Canvas [27] for compatibility, ensuring practicality and applicability of our system.

Traditional state-based optimizations like command batching are also supported based on the decoupling. Draw commands that can share the same GPU pipeline prefer to be grouped together instead of processed individually, thus producing a single set of GPU objects and reducing the number of draw calls. This also saves CPU execution time for less GPU object management (§5.4) and fewer rendering tasks. The main-thread preparation does the same re-ordering and coalescing algorithm discussed in §2.2, when depth-first traversing the render tree and leveraging the same chain structure and AABBs for overlapping relations. For example, the two rectangle draw commands (shown in pink) in Figure 6 are batched together to form a single *Rects Task* for *Spade*2D GPU object generation. Since pointer operations and AABB checks suffice, the non-scalable stateful APIs decoupled from the parallelizable core rendering logic is lightweight and fast.

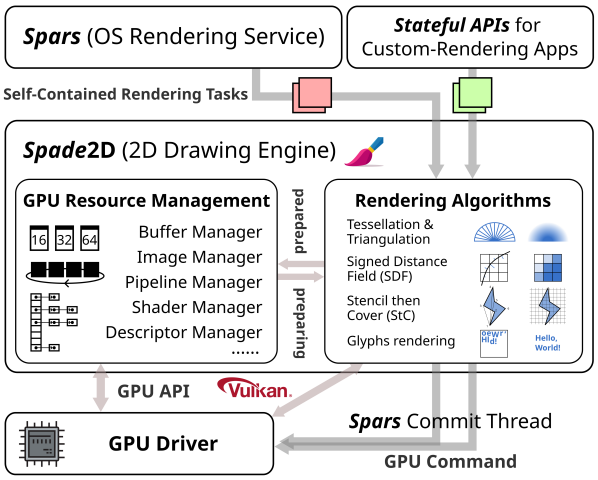

Figure 8: The architecture of *Spade*2D drawing engine.

5.4 *Spade*2D Drawing Engine

*Spade*2D is responsible for the stateless rendering (i.e., task out-of-order execution) in the worker threads. Similar to traditional drawing engines like Skia [29], Impeller [18], Direct2D [60], etc., *Spade*2D converts mathematical expressions of 2D graphics primitives into GPU objects for frame buffer rasterization. However, *Spade*2D differentiates itself in terms of *input and output formats* as well as *GPU resource management*. Figure 8 illustrates the architecture of *Spade*2D.

Input and output formats. Rather than accepting both state-update commands and draw commands, *Spade*2D employs stateless inputs: self-contained rendering tasks that can be executed out-of-order and in parallel across multiple CPU cores. *Spade*2D relies on external mechanisms to maintain state and drawing order dependencies. Furthermore, instead of handling a single primitive (e.g., a rectangle) per draw command, each rendering task in *Spars* may contain a batch of primitives (e.g., a vector of rectangles) that can share the same rendering algorithm and produce a single set of GPU objects. For outputs, *Spade*2D depends on the *Spars* commit thread for the in-order commit before submitting to the GPU,

for correct overlapping relations.

GPU resource management. GPU resources in *Spade*2D are managed by *thread-safe* managers that *prevent resource double creation* caused by parallel rendering. Similar to other 2D engines, *Spade*2D tracks GPU resources needed for various rendering algorithms, including buffers, images, pipelines, shaders, descriptors, etc. These resources are shared among rendering tasks and reused across frames if possible, each of which has a manager using size-class-based pools, hash tables, circular queues tied to the frame buffer rotation, etc.

Thread safety. In *Spade*2D, operations on these data structures need to be thread-safe. However, note that modern stateless GPU APIs, such as Vulkan [34], Metal [20], and DirectX12 [8], allow the parallelization of actual resource usage and creation within each rendering task. Time-consuming operations like vertex and index buffer filling, image decoding and creation, and GPU pipeline creation can all be executed without locks. Also, *Spade*2D uses shared locks [4] for resource reading, ensuring no contention when multiple rendering tasks refer to the same created GPU object (e.g., pipeline or image). Thus, the cost of synchronization is minimized and unnoticeable, as insertions and deletions for GPU resource handles in most data structures can finish in constant time.

Preventing resource double creation. Double creation might happen in parallel rendering when two rendering tasks refer to the same unprepared GPU resource simultaneously on different cores, and both attempt to prepare it, for example, drawing the same new image or using the same new GPU pipeline. To prevent double creation of GPU resources, *Spade*2D maintains *preparing* GPU resources in the resource managers, in addition to the *prepared* (created) and *unprepared* (free) GPU resources. The first task that needs a specific resource will atomically mark it as *preparing* in the corresponding manager before actually creating it. When the second task needs the same *preparing* resource, it will block and yield to another rendering task until being notified by the *prepared* condition variable. This mechanism avoids unnecessary double creation with no impact on performance, as blocking occurs only in rare cases when two similar non-batched tasks have contention, and after all other self-contained tasks can be scheduled to run.

6 Evaluation

6.1 Implementation and Setup

Implementation. We have implemented the scalable and parallel OS rendering service *Spars* with the stateless drawing engine *Spade*2D in C++ with the Vulkan GPU backend [34], the most common modern graphics API in smart devices. We deploy *Spars* as a custom-rendering service that directly utilizes GPU resources and bypasses the vanilla rendering service in Android and OpenHarmony for performance evaluation.

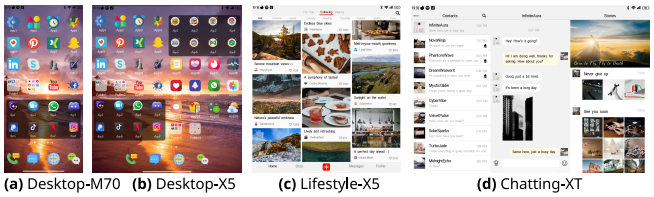

Figure 9: Representative scenarios rendered by *Spars*.

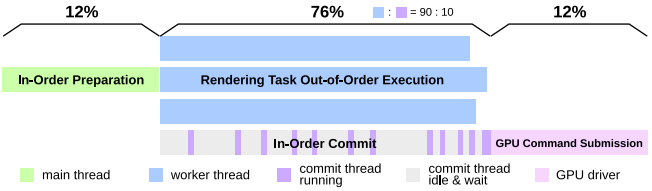

Figure 10: Execution time proportion of a frame in *Spars*.

We run *Spars* with *Spade*2D on state-of-the-art commercial smartphones, Mate 70 (single-screen) [15], Mate X5 (dual-fold) [16], and Mate XT (tri-fold) [17], as well as multi-screen configurations using the Kirin 9010 chipset [54].

Methodology. To analyze *Spars* performance under real scenarios, we export the render trees in OpenHarmony rendering services (in commercial smartphones) and reconstruct them in *Spars*. Figure 9 shows representative scenarios rendered by *Spars* with *Spade*2D. *Spars* is sound enough to render common graphics primitives, such as rectangles, rounded rectangles, circles, lines, images, glyphs (text), etc., with different coloring and styles. As *Spars* still lacks some features compared with vanilla rendering services, to better analyze the benefits and costs of our parallel design, we build *Sequential*, a sequential version of *Spars* with the standard rendering procedure discussed in §2. In addition to *Commercial*, the commercial rendering service in OpenHarmony 5.0, we also report the data of *Sequential* as another baseline for a more fair comparison with *Spars*.

In the following sections, we evaluate the parallelizable proportion (§6.2), frame rate improvement (§6.3), multi-core utilization (§6.4), power consumption reduction (§6.5), scalability (§6.6), and costs (§6.7) of *Spars*.

6.2 Theoretical Speedup Analysis

Spars enhances performance for rendering content that features a large number of rendering tasks, including diverse images, text, graphics primitives, and visual effects. The potential performance gains of *Spars* are determined by the parallelizable proportion of the end-to-end rendering workloads. As described by Amdahl's Law [39], the maximum achievable speedup is limited by the inverse of the fraction of the workload that must be executed sequentially [81].

Figure 10 illustrates the proportion of the execution time for different stages of a frame in *Spars*, averaged across all 42 scenarios (§6.3). The parallelizable out-of-order task exe-

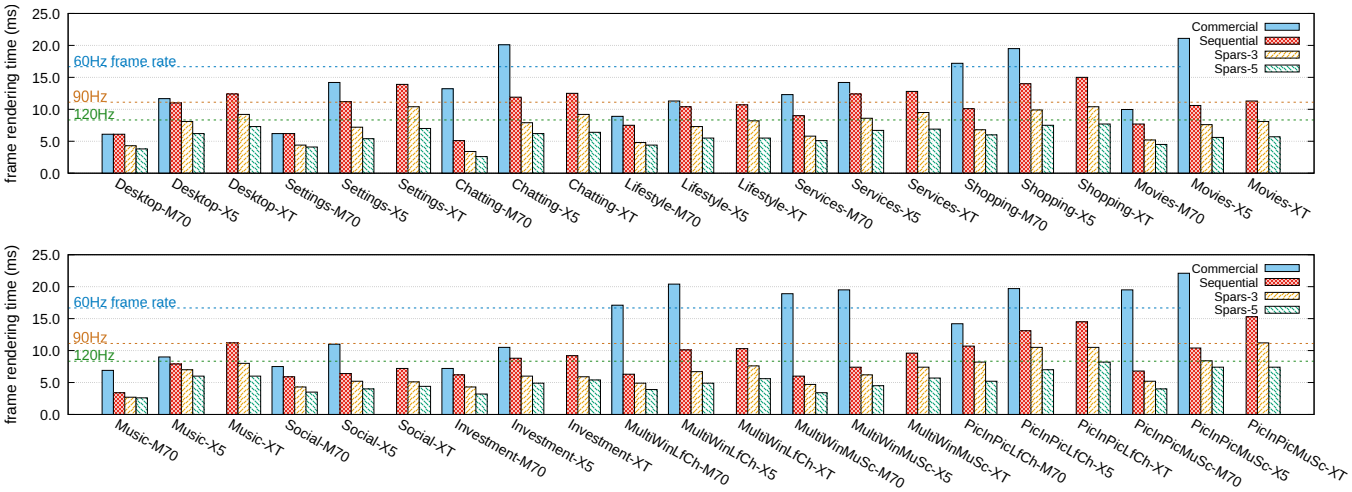

Figure 11: Frame rendering time on Mate 70, X5, XT with *Commercial*, *Sequential*, and *Spars* of 3 or 5 worker threads. All loads are pinned to medium cores with the same clock rate. Relative to *Sequential*, *Spars*-5 improves the frame rate by 1.76×.

cution and the in-order commit altogether account for 76% of the total workload. The commit thread is mostly idle and waits for the rendering tasks to complete. The non-parallelizable in-order preparation and the GPU driver command submission collectively occupy the remaining 24%.

With 3 worker threads, Amdahl's Law yields a theoretical maximum speedup of 2.14×, and with 5 workers, the speedup increases to 2.65×. In practice, however, scheduling and synchronization overhead during task dispatch, result collection, and resource management is unavoidable, influencing the overall performance.

6.3 Frame Rate Improvement

We evaluate the frame rate improvement of *Spars* on the latest Mate 70 (single-screen), Mate X5 (dual-fold), Mate XT (tri-fold), and Kirin 9010 chipset for multi-screen configurations. They all feature a heterogeneous CPU architecture with 4 little cores, 6 medium cores (3 physical cores with simultaneous multithreading [84]), and 2 big cores (1 physical core).

Common smartphone scenarios. We test *Spars* across altogether 42 representative smartphone use cases. Figure 9 shows some examples. These scenarios, drawn from our years of experience with OS rendering service deployment, provide a comprehensive snapshot of everyday smartphone usage — such as desktop operations, chatting, shopping, browsing services or movies — all of which involve rendering a variety of graphics primitives. We export and adapt the page layouts (i.e., render trees) from real-world apps and fill in dummy data for *Spars* to render. Each scenario is tested against two baselines, *Commercial*[2] and *Sequential*, and with *Spars* configured to use 3 and 5 worker threads (denoted *Spars*-3 and *Spars*-5), all pinned to medium cores running at the same clock rate (approximately 0.7GHz) as the baselines.

[2] *Commercial* data for Mate XT is not reported.

Figure 11 demonstrates the frame rate improvement. On average, *Spars*-3 reduces the CPU frame rendering time of *Sequential* by 27.3%, and *Spars*-5 reduces it by 43.2%. Consequently, the average frame rate could be increased by 1.38× and 1.76×, respectively. *Spars*-5, the standard configuration of *Spars* on these devices, achieves stable 120Hz frame rate across all 42 tested scenarios, whereas 27 (64%) sequential rendering baselines struggle to maintain the smooth experience, especially on large foldable screens. In heavily-loaded multi-window and picture-in-picture scenarios, *Spars*-5 is able to increase the frame rate by at most 2.07× with higher parallelizable proportion and better load balancing.

Worker thread configurations. *Spars* allows the number of worker threads to be configured both statically — based on the smart-device's SoC — and dynamically at runtime. On current SoCs with 6 medium cores, we use 5 worker threads as the standard setup, reserving one core for the commit thread. Dynamically adjusting the number of worker threads would require estimating or predicting the total workload, which is challenging due to the inherently dynamic nature of rendering [87] — for instance, whether certain GPU objects are already cached. In practice, we observed no performance regressions when increasing the number of worker threads, as long as the total remains below the number of available cores.

Core and clock rate configurations. A straightforward and traditional way for *Sequential* to boost the frame rate is to use a bigger CPU core or apply a higher clock frequency. However, this results in significantly more power consumption, often leading to unsustainable thermal output within minutes. As chip advancements slow with the decline of Moore's Law [73], *Spars* takes a different strategy by leveraging CPU multi-core parallelism to enhance the frame rate, offering long-term scalability across diverse (and possibly weak) smart-device hardware platforms.

To show the general benefits of *Spars*, we apply different

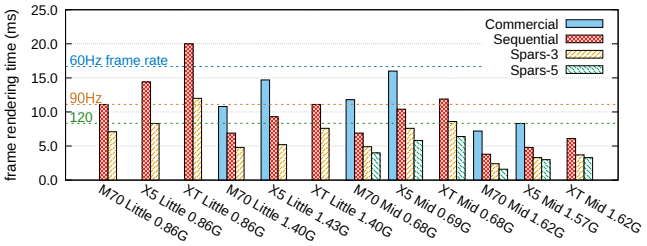

Figure 12: Frame rendering time with different configurations of cores and clock rates.

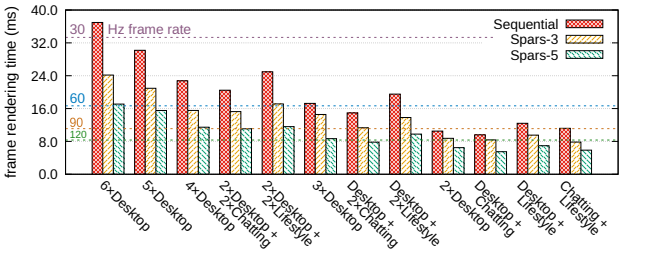

Figure 13: Frame rendering time with multiple screens.

configurations of CPU cores and clock rates on our smartphones. Specifically, we test *Commercial*[3], *Sequential*, and *Spars* on little cores and medium cores with both low and high clock rates. For a fair comparison with *Sequential*, we only report the frame rate improvement of *Spars* on homogeneous core configurations.

Figure 12 shows the average frame rendering time of all the scenarios under different configurations. For *Spars*-3 on little cores, it is reduced by 39.5% and 36.7% for low and high clock rates, respectively. Consequently, the frame rate is increased by 1.65× and 1.58×. For medium cores, *Spars*-3 brings 1.38× and 1.56× gains. Little cores have slightly more performance improvement, due to the lower synchronization overhead relative to the execution time. For *Spars*-5 on medium cores with low and high clock rates, the frame rate improvement is 1.76× and 1.89×.

One chip, multiple screens. We further run *Spars* to drive two to six 2K-resolution virtual screens on the Kirin 9010 chipset (2024), as shown in Figure 13. On average, *Spars*-3 boosts the frame rate by 1.34×, and *Spars*-5, the standard configuration, delivers 1.91×. Rendering more screens tends to have better performance gains. For six or five desktops, *Spars*-5 provides 2.16× and 1.94× gains, respectively, while for two desktops, it is just 1.62×. Heavier workloads yield a higher parallelizable proportion (more rendering tasks) in the end-to-end rendering procedure.

6.4 Multi-Core Utilization

The scalable and parallel rendering service optimizes the utilization of multi-core hardware in smart devices and ensures a more balanced workload across cores, preventing any single core from becoming the frame rate bottleneck.

[3] For reasonable frame rate, *Commercial* rendering service is never scheduled on little cores with low clock rate.

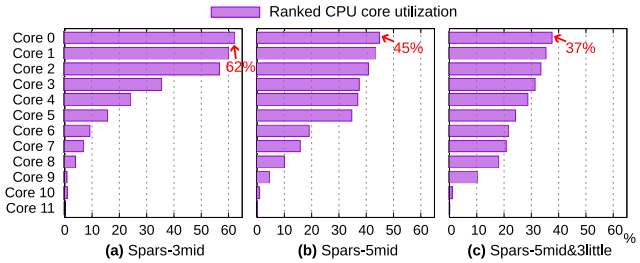

Figure 14: Multi-core CPU utilization of *Spars*.

Figure 14 demonstrates the system CPU utilization when *Spars* renders the Lifestyle scenario on Mate X5. The frame rate is locked at 90Hz, and the clock rate is kept the same for a fair comparison. As opposed to Figure 5(b) where the most loaded core reaches 80% utilization and bottlenecks the frame rate, *Spars*-3 and *Spars*-5 only lead to 62% and 45% utilization for the most loaded core. With a heterogeneous configuration of 5 medium cores and 3 little cores, the heaviest utilization further decreases to 37%, reducing the frame rendering time and potentially boosting the frame rate.

Influence on other workloads. *Spars* has minor influence on other system or application workloads, as it simply redistributes the entire rendering workload across multiple cores without increasing its total — additional logic for task encapsulation, dispatch, and collection is within 2%. As shown in Figure 14, all CPU cores still have a considerable amount of idle time available to process other tasks (although this idle time has been rebalanced). Other workloads are still scheduled and executed by the system scheduler according to their original priority.

6.5 Power Consumption Reduction

With balanced multi-core utilization, the power consumption of *Spars* is reduced in comparison to *Sequential* when running at the same configured frame rate.

The state-of-the-art QoS-guided scheduling and governing [43] puts the (parallelized) rendering workloads at little cores with lower clock rates if it predicts that the current frame can finish rendering within its VSync period (i.e., before its display deadline). Also, commercial DVFS (Dynamic Voltage and Frequency Scaling) can only adjust the frequency of an entire cluster (e.g., all medium cores) based on the QoS predictions. In *Sequential*, rendering on a single core often forces DVFS to raise the cluster voltage and frequency to meet the frame deadlines. In contrast, *Spars* spreads the workload across multiple cores, allowing DVFS to maintain the same stable frame rate at a lower overall voltage and frequency, and thus reducing the power consumption.

We measure the Mate XT whole-device instantaneous power consumption through battery counters [26] for 5 min-

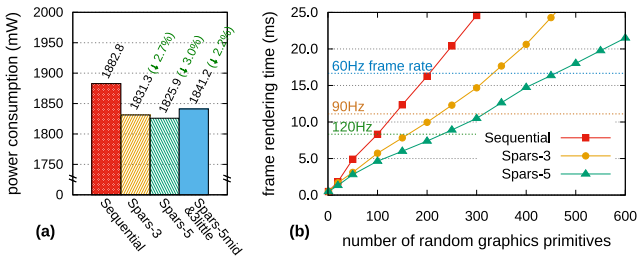

Figure 15: (a) Power consumption of *Sequential* and *Spars* under the same frame rate. (b) Scalability of *Spars*, allowing more graphics primitives under the same time budget.

utes after a one-minute warmup, with all other apps closed. Averages are taken for all the common smartphone scenarios. Figure 15(a) demonstrates the results. *Spars*-3 reduces the device power consumption by 2.7%, and *Spars*-5 reduces it by 3.0% under the same frame rate with *Sequential*.

6.6 Rendering Scalability

Parallelization allows the OS rendering service to render more graphics primitives under the same time budget (i.e., frame rate), achieving scalability of rendering. *Spars* gives application developers and GUI designers a larger design space for richer page content and more appealing visual effects, especially on large foldable screens, important for the commercial success of smart devices.

We measure the CPU frame rendering time with respect to the number of random graphics primitives (including rounded rectangles, circles, decoded images, text, etc.) that *Spars* and *Sequential* render under the same core configuration and clock rate. Note that this is the lower bound for the number of graphics primitives, as randomness forbids most draw command batching opportunities.

As illustrated in Figure 15(b), for 120Hz frame rate (8.33ms time constraint), *Spars*-3 is able to render 1.62× graphics primitives, and *Spars*-5 is able to render 2.31× primitives compared to the *Sequential* baseline, unleashing more possibilities for the GUI design.

6.7 Costs and Discussions

We discuss the costs of a scalable and parallel rendering service in terms of memory consumption and deployment efforts.

Memory consumption. The primary memory cost arises from the thread creation, with each thread consuming approximately 8MB of memory in the operating system. The additional memory required for the absolute information, self-contained tasks, and overlapping relations does not exceed 10MB. Therefore, for *Spars*-5, the extra memory usage does not exceed 50MB, which is permissible for modern smart devices with ≥8GB of memory.

Deployment efforts. *Spars* is a complete refactoring of the OS rendering service and the 2D drawing engine. A traditional rendering service consists of approximately 200,000 lines of code (LoC) in C++ [24], and a traditional drawing engine contains around 400,000 LoC [28]. To implement a functionally complete scalable and parallel rendering service and drawing engine, we anticipate that modifications required for the refactoring will exceed one third of the source code.

7 Related Work

We present other related work optimizing the rendering services in smart devices in addition to §3.2.

Parallel rendering. Arnau et al. [40] propose parallel frame rendering where consecutive frames can render in parallel to trade responsiveness for energy on mobile GPUs. Skia Graphite backend [85] supports parallel command recording based on tiles (i.e., render passes) in web pages. Other 2D engines [18, 35, 37] enable parallelization for specific tasks, such as image decoding. In comparison, *Spars* can achieve finer-grained parallel rendering necessary for trending foldable and multi-screen devices. Besides, the job systems of game engines [32] support parallelization for physics simulation, AI computation, and rendering preparation in AAA games, while *Spars* is specifically tailored and optimized for operating system 2D rendering.

Scheduling for rendering and displaying. *D-VSync* [87] decouples rendering and displaying to utilize saved computation in short frames for long frames during workload fluctuation. However, *D-VSync* cannot handle scalable and parallel rendering for emerging devices. LTPO [1, 42] supports variable screen refresh rates to save power. Presto [91] reduces touch latency by relaxing synchrony. DSA [45] provides apps a unified view for multiple screens. Other systems [44, 47, 69, 76, 77, 94] implement CPU-GPU power management strategy, e.g., dynamic frequency, to save energy. However, they cannot meet the frame-rate performance demands of foldable and multi-screen devices.

Prediction-based optimizations. Another method to handle the increasing rendering loads is to predict frames in advance. Huang et al. [57], Yan et al. [89], and Baeza-Yates et al. [41] predict the next app to be opened for faster launches. Agrawal et al. [38] reduce activity transition time by pre-inflating UI layouts. PES [49] anticipates DOM events of web apps for better scheduling. Outatime [65] predicts navigation inputs to mask network latency in cloud gaming, while Hou et al. [55] predict head and body motion in VR using LSTM. Although these optimizations function in specific cases, the final effects highly depend on the prediction algorithms and outcomes.

8 Conclusion

This paper presents *Spars* with *Spade*2D, a next-generation scalable and parallel OS rendering service and drawing en-

gine designed for smart devices. The primary innovation lies in its ability to untangle state dependency, drawing order dependency, and interface dependency, allowing out-of-order execution with in-order commit of self-contained rendering tasks. Evaluations demonstrate that *Spars* substantially enhances frame rates on emerging foldable smartphones and multi-screen configurations, efficiently leveraging multiple CPU cores while reducing power consumption and scaling the number of graphics primitives. We anticipate that the design of *Spars* will play a pivotal role in shaping the future development of OS rendering services.

EMT: An OS Framework for New Memory Translation Architectures

Siyuan Chai, Jiyuan Zhang*, Jongyul Kim, Alan Wang, Fan Chung, Jovan Stojkovic,

University of Illinois Urbana-Champaign †University of Rhode Island ‡Carnegie Mellon University

Abstract

With terabyte-scale memory capacity and memory-intensive workloads, memory translation has become a major performance bottleneck. Many novel hardware schemes are developed to speed up memory translation, but few are experimented with commodity OSes. A main reason is that memory management in major OSes, like Linux, does not have the extensibility to empower emerging hardware schemes.

We develop EMT, a pragmatic framework atop Linux to empower different hardware schemes of memory translation such as radix tree and hash table. EMT provides an architecture-neutral interface that 1) supports diverse memory translation architectures, 2) enables hardware-specific optimizations, 3) accommodates modern hardware and OS complexity, and 4) has negligible overhead over hardwired implementations. We port Linux's memory management onto EMT and show that EMT enables extensibility without sacrificing performance. We use EMT to implement OS support for ECPT and FPT, two recent experimental translation schemes for fast translation; EMT enables us to understand the OS perspective of these architectures and further optimize their designs.

1 Introduction

> "It so happens that a tree format is the only sane format..." [105] —Linus Torvalds, 2002

Virtual memory translation has become a major performance bottleneck of emerging memory-intensive computing [34, 56, 63, 69, 77, 87, 98]. With unprecedented growth of memory capacity, driven by terabyte-scale memory [31, 52] and memory expanders like CXL [71, 96], TLBs cannot scale in the same way as memory. Moreover, emerging workloads like machine learning, graph processing, and bioinformatics have irregular memory access patterns with weak locality, making TLBs and other MMU caches less efficient. As a result, TLB misses are inevitably increasing, resulting in expensive address translation across the memory system.

However, today's translation architectures were designed at a time of scarce memory, and optimize space-efficiency over performance. The *de facto* schemes organize translations into a multi-level radix tree [11, 17, 19]; upon a TLB miss, the MMU must *sequentially* walk the tree, resulting in multiple memory accesses. The x86-64 architecture uses a four-level tree, with a fifth level added in recent hardware [3, 110]. In virtualized environments, translation overhead is magnified by nested translation [39, 79] which takes a two-dimensional walk over the guest and host page tables, resulting in up to 24 sequential memory accesses on four-level page tables.

To address this pressing problem, many new hardware architectures for MMUs have been developed to realize fast translation for today's terabyte-scale, heterogeneous memory. For example, hashing-based translation schemes are revisited [35, 53, 68, 98–100, 109], as hashing is inherently more scalable than walking a tree [109]; a recent hashing scheme, based on Elastic Cuckoo Page Table (ECPT), is reported to reduce translation overhead significantly by enabling parallel lookups of page table entries [98, 100]. New translation schemes using flattened or linear page tables [65, 87] have also been developed. In addition, recent studies advocate for hybrid translation architectures that use different schemes collectively or selectively [26, 27, 49, 57, 63, 111].

Unfortunately, OS support for hardware innovations falls short; few aforementioned new hardware schemes were experimented with commodity OSes like Linux. Instead, evaluations of experimental architectures mostly use performance models to estimate OS overhead [28, 65, 77, 95, 109, 111], or trace-driven simulation with traces collected by running workloads on unmodified Linux [77, 95, 98, 109]. The assumption is that OS overhead on different translation architectures is constant. However, our paper shows that translation architectures could have significant impacts on OS performance.

In fact, the difficulties of OS support has affected hardware research—disruptive hardware designs are often considered "*undesirable*" and lose to incremental approaches (see [77]). Our discussions with hardware vendors tell us that the lack of commodity OS support and evaluation is a major barrier to assessing and adopting new hardware translation schemes.

The unsatisfactory OS effort is largely due to memory management systems in commodity OSes not having the extensibility for emerging translation architectures. For example, Linux assumes a radix-tree based page table structure and lacks extensibility to support hardware schemes that cannot fit in its tree definition. As a result, supporting a new architecture often requires heavy modifications of memory management code in architecture-independent modules. Essentially, Linux provides no extensible interface for memory translation, un-

*Co-lead of the EMT project

like its other subsystems (e.g., VFS for file systems [51]).

Contributions. We develop a pragmatic OS framework and toolchains atop Linux to embrace new hardware translation architectures for today's memory technologies. We term our framework Extensible Memory Translation (EMT). We target Linux as it is still the *de facto* commodity OS and is mostly assumed by architecture research on memory systems.

EMT provides an architecture-neutral Linux interface that 1) supports diverse memory translation architectures, 2) enables hardware-specific optimizations, 3) accommodates modern hardware and OS complexity, and 4) has negligible overhead over Linux's hardwired implementation. By abstracting translation-related operations, EMT simplifies the effort to support and experiment with new translation architectures on Linux. With EMT, developers only need to implement an MMU driver as a hardware-specific implementation of translation logic, without modifying the architecture-independent memory management code. EMT also makes it easy to profile and analyze OS performance with regard to hardware translation schemes as it abstracts translation-related operations.

We implement EMT on Linux (v5.15), referred to EMT-Linux. We modularize architecture-independent code with EMT API, removing hardwired assumptions. EMT realizes negligible overhead through careful engineering and optimizations (with less than 0.5% overhead on average across key OS operations). Moreover, EMT-Linux realizes all existing features and hardware-specific optimizations in vanilla Linux.

We build on EMT-Linux to add OS support for ECPT [98] and FPT [87], two new translation schemes. Porting these new hardware schemes on Linux without a framework like EMT would require major rewriting of Linux's memory management module. With EMT, supporting them on Linux is modularized with manageable engineering efforts.

Evaluating new hardware schemes on EMT-Linux faces a common challenge of hardware-software codesign—the hardware is not yet available to run the OS. To address this problem, we assemble a toolchain that runs EMT-Linux on QEMU with an emulated MMU where we implement the hardware translation logic. Our toolchain enables us to understand the OS perspective of new translation architectures, such as its OS overhead over x86. The toolchain also supports cycle-accurate hardware simulation.

We share our experience of supporting new translation schemes on EMT-Linux, which enables us to understand OS memory management challenges beyond hardware perspectives. We present our reflection on the ECPT design and address correctness challenges such as managing the kernel page table (kECPT) and the paradox involved in changing the translations of the kECPT itself and of the kernel code that manages kECPT, as well as performance challenges like efficient locking and memory scanning. Arguably, OS framework support is essential to encourage and embrace disruptive hardware innovations, and EMT is an important step forward.

Summary. This paper makes the following contributions:

- A discussion on empowering new, experimental hardware-assisted translation architectures on commodity OSes.
- EMT as an extensible framework for developing and evaluating OS memory management on new translation architectures, and its implementation on Linux.
- An experience of building ECPT and FPT on Linux using EMT and the reflection on hardware/OS designs.
- An open platform for developing, testing, and evaluating OS kernels on new memory translation architectures.
- Our artifacts: https://github.com/xlab-uiuc/emt.

2 Background

2.1 Memory Translation Hardware

Modern computer systems use hardware-assisted memory translation, where the translation schemes are defined by the hardware architecture. Upon a TLB miss, the MMU searches the translation structures (e.g., a page table) to obtain the translation—the virtual-to-physical address mapping.

x86 Translation Scheme. All x86 processors since Intel 80386 have used a radix tree, as depicted in Figure 1. The depth of this tree has increased from two levels in 80386 to four levels in x86-64, with the fifth level upcoming [3, 110] and already supported in Linux [43].

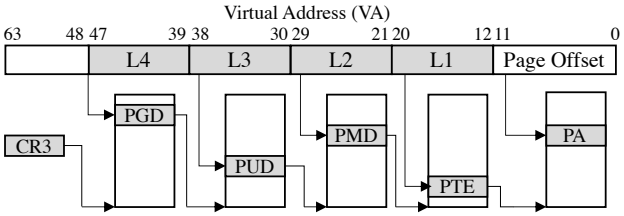

Figure 1: **Radix-tree based page table walk in x86-64 ISA.**

The main advantage of radix-tree based translation is space efficiency—tables at each level are created on demand—if at any level, no page is allocated within an address range, the sub-tree is not allocated. This yields significant memory savings, as the address space of typical applications is sparse.

However, tree-based translation suffers from a major performance drawback—it must *sequentially* walk the tree with multiple memory accesses. Page walk caches [32, 40, 87] and huge pages [69, 81] are used to reduce the length of the walks, but struggle to address emerging workloads with large memory footprints and weak-locality access patterns. The overhead is further magnified in *nested translation* for virtualized environments. The MMU performs a two-dimensional walk over the guest and the host page tables. A nested translation takes up to 24 sequential memory accesses with four-level page tables, and up to 35 with five-level tables. It is reported that nested translation can take more than 50% of the execution time of memory-intensive workloads [27, 48, 77].

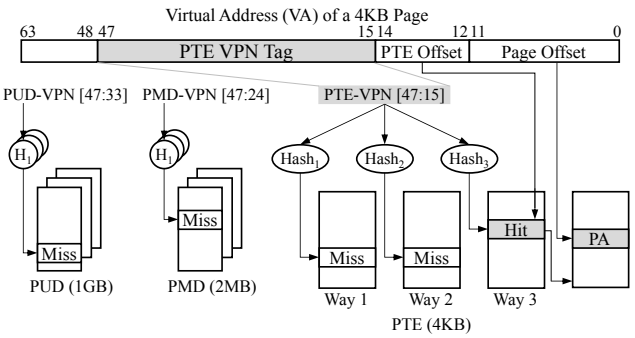

Figure 2: **Parallel page-table lookup in an ECPT-based architecture [98] using three-way cuckoo hashing.**

```
1  void vunmap_pmd_range(pmd, addr, end) {
2    pmd_t *pmd = pmd_offset(pud, addr);
3    do { ...
4      // try remove huge page entry
5      int cleared = pmd_clear_huge(pmd);
6      ...
7      if (pmd_none_or_clear_bad(pmd))
8        continue;
9
10     // try remove underlying PTEs
11     vunmap_pte_range(pmd, addr, next, mask);
12     ...
13   }
14   while (pmd++, addr = next, addr != end);
15 } /* mm/vmalloc.c */
```

Find a 2MB entry (PMD) from the addr. of a 1GB entry (PUD).

Overloaded semantics:
(1) The entry does not point to a 2MB huge page;
(2) The entry is not a directory;
(3) No entries of 4KB pages in the 2MB address range.

The iterator assumes the spatial locality of entries.

Figure 3: **Examples of Linux memory management code that is hardwired to radix-tree based translation.**

Flattened Page Table (FPT). Recently, extensive efforts are being made to optimize memory translation architectures. A common principle is to shorten page table walks of the x86-64 scheme [26, 28, 48, 65, 77, 87, 111]. A recent proposal from Arm, known as Flattened Page Table or FPT [87, 106], flattens the x86 page tables by dynamically merging intermediate tree levels to reduce indirections and prioritize caching of page table entries. Specifically, FPT tries to merge L4 and L3, as well as L2 and L1, in Figure 1, shortening the walk by half.

Hashing-based Translation and ECPT. Hashing is being actively revisited for translation [35, 53, 63, 68, 98–100, 109]. We focus on ECPT (Elastic Cuckoo Page Table) [98], a new hashing-based scheme which effectively speeds up translation with fully parallel lookups of page table entries.

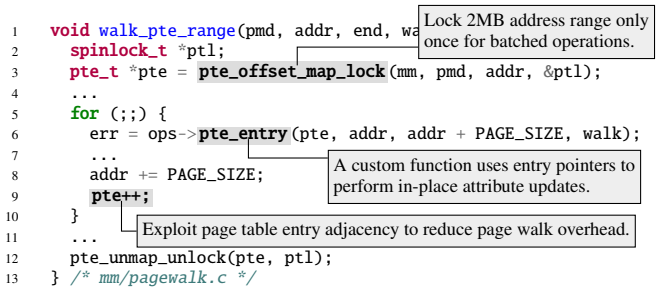
Figure 2 depicts ECPT-based memory translation. Different from conventional hashed page tables [46, 54, 60, 104, 109], ECPT uses process-private hashed page tables that are dynamically resized based on occupancy. ECPT uses Cuckoo Hashing [83] and maintains multiple tables (called *ways*) to proactively resolve hash collisions by moving entries across ways. During a page table walks, the MMU computes hashes of the Virtual Page Number (VPN) to look up the ways in parallel. It eliminates the need for sequential tree walks. ECPT supports multiple page sizes (e.g., 1GB, 2MB, and 4KB pages) by maintaining a set of hash page tables for each page size.

To reduce parallel lookups, ECPT uses an in-memory data structure named Cuckoo Walk Table (CWT); each CWT maintains metadata (size and way) of ECPT translation entries. CWTs are cached in special MMU caches named Cuckoo Walk Caches (CWCs). During translation, if a requested page hits a CWC, the MMU can directly look up the specific page table (with the size) or the specific way.

2.2 OS Memory Management

The OS manages in-memory translation structures like page tables and other auxiliary structures (e.g., CWT in ECPT), defined by the hardware architecture. The OS is also responsible for managing translation data (virtual-to-physical address mappings and metadata like protection and dirty bits).

Translation information is consumed by almost all OS memory management operations. Hence, translation architectures have strong implications on OS performance. For example, recent work [108] shows that the majority of page migration cost is from OS memory management on translation-related operations like unmapping/remapping pages and demoting huge pages, instead of actual page copies.



Modern OSes separate *architecture-independent* OS memory management and *architecture-dependent* hardware support. Mach [25] designed a machine-independent memory manager where its architecture-independent code makes few assumptions about MMUs [91]; the design is inherited by BSD kernels [45]. EMT is inspired by Mach/BSD, but focuses on empowering new, experimental translation schemes.

Linux layers machine-independent/dependent code differently. It maintains a multi-level tree-based page table in the architecture-independent module. This design achieves high-performance memory management: 1) it enables optimizations that need to directly manipulate page tables and translation entries, and 2) it avoids overhead due to indirections. However, it lacks extensibility to different translation architectures especially those that do not fit its tree definition such as ECPT or even the conventional hashed page tables.[1]

3 The Need for a New OS Framework

Emerging memory technologies and research on MMU architectures pose a strong need of developing and evaluating OS memory management on new translation schemes. The current practice of evaluating new translation schemes mostly relies on hardware simulation, either using performance models to estimate OS overhead [28, 65, 77, 95, 109, 111], or replaying traces collected by running workloads on vanilla Linux [77, 95, 98, 109]. Such approaches can hardly capture complex OS-architecture interactions [29]. We argue that the lack of OS effort is largely due to memory management systems in commodity OSes not providing an extensible interface for new, different translation architectures.

[1] Hashed Page Tables (HPTs) was provided by architectures like IA-64 and POWER [1, 10], but Linux does not have native support for HPTs [105]. Linux maintains a software tree-based page table to store full virtual memory mapping and treats the HPTs as soft-managed extended TLBs. Such an approach leads to duplication of translation data and redundant maintenance.

```
1  void walk_pte_range(pmd, addr, end, wa
2    spinlock_t *ptl;
3    pte_t *pte = pte_offset_map_lock(mm, pmd, addr, &ptl);
4    ...
5    for (;;) {
6      err = ops->pte_entry(pte, addr, addr + PAGE_SIZE, walk);
7      ...
8      addr += PAGE_SIZE;
9      pte++;
10   }
11   ...
12   pte_unmap_unlock(pte, ptl);
13 } /* mm/pagewalk.c */
```

Figure 4: **Hardware-specific optimizations in Linux.**

Hardwiring Translation Schemes Is Untenable. Linux's memory management code is currently hardwired to a five-level tree. Without an extensible framework, it can hardly embrace new translation architectures that use different lookup structures such as hash tables [98, 99, 109], flattened or range tables [26, 65, 87], and hybrid schemes [27, 63].

Figure 3 shows a representative example in Linux, where a memory operation for unmapping a virtual address range at PMD level (`vunmap_pmd_range` in `vmalloc.c`) makes the following assumptions specific to Linux's tree definition:

- A translation entry of a 2MB virtual address range (PMD) can be found from the entry of a 1GB address range.
- An entry of a 2MB address range (PMD) either points to a 2MB huge page or a directory of 4KB pages.
- The translation entry of the next 2MB address range can be iterated by increasing the pointer.

Such implementation patterns are commonplace in Linux's current architecture-independent memory management module. Hence, supporting a different translation architecture would require heavy rewriting of existing Linux code.

In fact, it is also nontrivial for Linux to support translation schemes that use a different tree. Evidently, adding the fifth level took 715 lines of code changes across 23 files [97], all in the architecture-independent modules of Linux. Similarly, though FPT's design strives to limit OS changes [87], it still introduces nontrivial changes of Linux's architecture-independent code to fold the intermediate levels of the tree.

Furthermore, without a well-defined interface, memory management code becomes hard to maintain due to implicit assumptions and semantic overloads with continuous optimizations and fixes. In Figure 3, `pmd_none_or_clear_bad()` overloads three semantics, making the code hard to maintain.

Hardware-Specific Optimizations Are Desired. Inspired by Mach/BSD [13, 45, 91] that have clean separation of machine-independent and dependent code, we started from a pmap-like interface for Linux. In Mach/BSD, architecture-indepedent memory management code uses pmap interface to manage virtual memory mappings. pmap [91] represents a virtual-to-physical address map, which can point to a VAX linear page table [70] or segment registers in IBM RT PC. With pmap, different translation schemes can be supported by writing pmap modules. Typical pmap operations include creation, deletion, and update of address mappings [13, 91].

Unfortunately, we find that a map interface like pmap is not sufficiently expressive to write hardware-specific optimizations, especially in the Linux context. For example, pmap routines for inserting or finding a translation, only reference a virtual address without exposing translation entries. Figure 4 shows three common patterns of optimizations in existing Linux code: 1) batching with fine-grained locks for range operations, 2) in-place translation entry updates with no data copy, and 3) direct fetching of translation entries by offsets. None of them are easy to write using a map, as they need to directly manipulate translation entries. As optimizations of memory management are critical to Linux performance—27.8% of Linux kernel patches to memory management are for performance optimizations [59]—a simple map interface makes it hard to fully empower translation architectures.

Existing Frameworks Do Not Target Translation. Driven by new memory technologies like tiered memory, several new memory management frameworks [61, 92, 103] have been developed to improve the extensibility of Linux's memory manager. However, few of them concern hardware translation architectures, but focus on application-specific page prefetching and replacement policies. FBMM [103] proposes to reuse VFS [51] and write memory managers as file systems. It exposes the `page_fault` VFS callback for managing page table entries. However, FBMM relies on Linux's existing code that is hardwired to the multi-level radix tree structure, and thus cannot support different hardware translation schemes. Fundamentally, file system interfaces can hardly serve as an effective framework for memory translation.

4 EMT Design

Extensible Memory Translation (EMT) is an OS framework built atop Linux with the goal of empowering new, experimental memory translation architectures. Figure 5 gives a high-level overview of EMT. EMT currently focuses on supporting new memory translation architectures in the OS kernel, instead of exposing them to userspace [47]. The design and implementation of EMT achieves the following goals:

- **EMT is an architecture-neutral framework.** EMT is not hardwired to specific translation structures such as multi-level tree in Linux. Supporting a new memory translation scheme should not change architecture-independent code.
- **EMT enables hardware-specific optimizations.** EMT allows architecture-dependent code to customize routines for hardware-specific optimizations. The ability to customize differs EMT from high-level interfaces like pmap in Mach/BSD [91] and hat in SunOS [50].
- **EMT is modularized and improves maintainability.** EMT provides well-defined translation semantics and organizes them with an object-oriented design. The interface

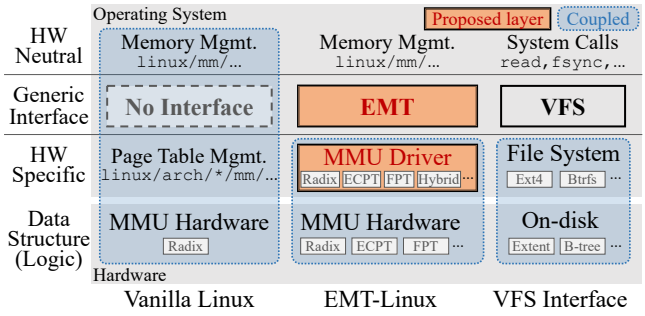


Figure 5: **Overview of the EMT framework, compared with vanilla Linux and analogized to VFS.**

eliminates architecture-specific or overloaded semantics. EMT also makes it easy to profile and analyze OS performance with regard to translation architectures.

- **EMT has negligible overhead.** EMT is carefully implemented with compiler optimization, cache efficiency, and the ability to inline functions. EMT-Linux serves as a performance baseline for new architectures or OS modules.
- **EMT accommodates modern hardware and OS complexity.** EMT aims to develop insights into complex OS-architecture interactions. EMT supports *all* Linux's memory management features related to CPU MMU translation such as huge pages, swapping, DAX memory, etc.

4.1 EMT API

EMT exposes an object-oriented API that organizes translation related kernel routines around three architecture-neutral primitives: 1) *translation object* that maintains all the information of a virtual-to-physical address translation, 2) *translation database* that stores translation objects of an address space, and 3) *translation service* that manages the MMU states.

In EMT, all architecture-dependent code is implemented in drivers for MMU architectures, referred to as *MMU drivers*. To support a new translation scheme on EMT-Linux, one needs to write the MMU driver that implements EMT API without the need to modify architecture-independent code.

A key design principle of the EMT API is to abstract the *functions* of translation for OS memory management from hardware-defined *shapes*. Despite many different translation architectures (§2), the essential function of memory translation is to output the virtual-to-physical address mapping and all associated metadata, which is abstracted as a *translation object* in EMT. EMT avoids assuming shapes of translation data like translation entry schema or translation data structures. How to encode translation information of hardware-defined shapes into the EMT API is the job of MMU drivers.

The EMT API is organized as 1) *basic functions* that must be implemented by each MMU driver for its supporting translation architecture, and 2) *customizable functions* that have a default implementation that is architecture-independent; the default implementation only uses basic functions and other

```
//// Translation Object
// Read the attribute of an object based on the attribute key
tobj_read_attr(tobj, attr_key) -> (error, attr_value)
// Update the value of a given attribute in an object.
tobj_write_attr(tobj, attr_key, new_val) -> (error, old_val)
...
//// Translation Database
// Find a translation object in a translation database
tdb_find_tobj(tdb, vaddr) -> (error, tobj)
// Update a translation object matching tobj's va
// by copying attributes of tobj.
tdb_update_tobj(tdb, tobj) -> (error, old_tobj)
// Remove the given translation object from the database.
tdb_remove_tobj(tdb, tobj) -> (error, old_tobj)
...
//// Translation Service
// Switch the translation database of the current address space
tsvc_switch_tdb(tdb) -> (error, out_tdb)
// Read the translation database of a given address space
tsvc_read_tdb(cpu) -> (error, out_tdb)
...
```

Figure 6: **Examples of basic functions in the EMT API.** EMT exposes 15 basic functions in total.

common code. These routines can be customized by MMU drivers for hardware-specific optimizations.

The basic functions represent the minimal set of functions to support a new translation architecture. Developers can start with basic functions to achieve a functional kernel and then iteratively add optimizations via customizable functions. Basic functions free developers from sophisticated optimizations in Linux; it leads to a more friendly development and test cycle.

4.1.1 Basic Functions

Basic functions are expected to be architecture-dependent and are required to be implemented by each MMU driver. Figure 6 gives examples of basic function APIs. The API design avoids assuming specific hardware schemes like the five-level radix tree (§2) or page table entry schema. It also prevents overloaded semantics like `pmd_none_or_clear_bad` (Figure 3) due to software evolution.

Translation Object. A translation object encodes a virtual-to-physical address mapping and all its associated metadata. For paged architectures, it encodes translation information stored in page table entries. For tree-based architectures, a translation object encodes information in page table entries that point to the physical page (see §5). A translation object can also represent segments or variable-length memory regions. Translation metadata are encoded as attributes such as size, protection, presence, swap, etc., which are queried by general OS memory management. EMT lets MMU drivers encode metadata into architecture-dependent bits. MMU drivers can also encode architecture-specific attributes and use them to implement architecture-specific features like protection keys and capabilities [19, 21, 107].

Translation Database. Translation objects of an address space are stored in a conceptual database. The database is commonly implemented by a page table (which can be of various shapes) in an MMU driver. It can also be implemented by multiple co-existing page tables (e.g., ECPT needs separate

```
//// Translation Object Iterator
// Return the current translation object and advance the iterator
tobj_iter_next(iter) -> (error, tobj)
...
//// Huge Page
// Check if a given virtual address range can be a huge page
thp_eligible(tobj, pg_size, vma) -> eligible
...
//// Address Range
// Check if the given virtual address range has no mapping in it
addr_range_void(tdb, start, end) -> is_void
...
//// Lock
// Get a lock to protect all translation objects in the range
addr_range_get_lock(tdb, start, end) -> (error, tlock)
...
//// Swap
// Get the Linux swp_entry_t from a translation object
tobj_to_swap(tdb, tobj) -> (error, swp_entry)
...
```

Figure 7: **Example customizable functions in the EMT API.** EMT exposes 35 customizable functions in total in 7 groups.

page tables for each userspace process and for a shared kernel space across processes; see §6), or by segments or VMA registers [63, 111]. EMT requires a translation database to return one and only one translation object for a virtual address, as the function of the database. EMT does not concern the shape of the database. Its basic functions abstract away architecture-specific structures.

The EMT API decouples translation objects from translation databases; the former does not concern how translation data are stored, while the latter does not interpret translation objects. The benefit is modularity, making it easy to reuse existing code (as shown by the FPT and ECPT MMU drivers).

Translation Service. A translation service abstracts the MMU of a system. It is the root of the EMT API, and manages the creation, destruction, and switching of address spaces. Upon a context switch, the translation service is called to switch the databases. Translation service decouples translation management from task management.

4.1.2 Customizable Functions

Customizable functions provide an interface for MMU drivers to implement hardware-specific optimizations. Each customizable function has a default architecture-neutral implementation using basic functions and other architecture-independent code. Figure 7 gives examples of customizable function APIs.

Customizable functions are exposed to MMU drivers via a combination of redefinable macros, following Linux's convention. The architecture-neutral version is wrapped in `#ifndef` so that it can be used if no architecture-specific implementation is available. If an MMU driver wants to implement a customizable function, it defines the customizable function name to its own implementation; otherwise, the `#ifndef` redirects the interface to the default implementation. Since customizable functions always have an architecture-neutral implementation, adding new customizable functions in EMT (if needed in the future) will not break existing MMU drivers.

In principle, customizable functions are those that can benefit from architecture-specific optimizations. The choice now is through high-level reasoning together with profiling that identifies performance-critical code. Currently, EMT exposes different groups of customizable functions, as exemplified by Figure 7. We discuss the iterator group as an example.

```
1  int tobj_iter_next(struct tobj_iter *iter, struct tobj *tobj)
2  { ...
3    int ret = tdb_find_tobj(iter->tdb, iter->va, tobj);
4    ret = tobj_read_attr(tobj, TOBJ_ATTR_SIZE, &size);
5    if (!ret) iter->va += size;
6    return ret;
7  } /* mm/emt-generic.c */
```

(a) Default (architecture neutral)

```
1  int tobj_iter_next(struct tobj_iter *iter, struct tobj *tobj)
2  { ...
3    // handling the most common case of iterating in a 2MB range
4    if (iter->ptep) {
5      tobj->va = iter->va;
6      tobj->pte = iter->pte;
7      if ((iter->va + PAGE_SIZE) & (~PMD_MASK)) {
8        iter->va += PAGE_SIZE;
9        iter->pte++; // Exploit radix's spatial locality
10       return 0;
11     }
12     // Cross 2MB boundary, update ptep based on pmd
13   }
14   ... // handling other cases.
15 } /* arch/x86/mm/radix.c */
```

(b) x86-64 radix MMU driver

Figure 8: **A customizable function of the iterator.**

Translation-Object Iterator. Iterating over a large number of translation objects is a common management pattern when the OS scans a memory region (e.g., for page migration [14] and huge-page promotion [16]). The performance of such operations is critical, e.g., an optimized iterator can reduce page fault handling cost by 52.5% (§8.4). EMT provides a translation-object iterator with customizable functions. Figure 8a shows the default implementation of the iterator's `tobj_iter_next()` function, which is not efficient—the OS needs to walk from the root to the leaves of the page-table tree in every iteration using `tdb_find_tobj`. Note that such OS walks cannot benefit from hardware caches like PWCs as they are done by software. Figure 8b shows the customized implementation of the x86-64 MMU driver that leverages spatial locality of the radix tree to directly increment the pointer to get the next object. We discuss the implementation of the ECPT MMU driver in §6.2.

EMT's iterator functions differ from Linux's page-table iterator [90]—it does not assume the radix tree structure. EMT's iterator does not return intermediate entries (which are specific to tree schemes), but returns translation objects.

4.2 Generality

It is hard to prove generality, but our effort on supporting x86-64 radix tree, FPT, and ECPT indicates that EMT can express different hardware schemes, and *all* related optimizations. These schemes represent tree- and hashing-based translation designs, which ground many emerging architectures. A few new architectures [27, 56, 63, 111] propose hybrid designs which often use a fast scheme for common patterns and a

slow scheme for correctness [56, 63, 111], or expose multiple schemes to userspace [27, 47]. For pure hardware-based fast schemes [56, 111], the translation is still the traditional one from an OS perspective (e.g., Midgard [56] uses radix tree as its backend). For architectures that use multiple schemes for different address space segments, the MMU drivers can manage multiple page tables under the hood of a database.

From a metadata perspective, EMT can support address translation schemes with coupled or separate metadata management. For metadata that are separately stored from translation structures, the MMU driver encodes and updates the translation entry and its metadata separately in the translation object. For example, EMT supports protection keys like Intel MPK [21] and hardware capabilities [107] by encoding keys as attributes of translation objects. EMT naturally supports capability-based translation [42, 107] which encodes permissions into capabilities (protected pointers).

EMT also supports mechanisms that manage cache modes like PAT [74] and MTRR [72]. EMT views the cache modes of a page as attributes of its translation object. When the cache mode of a page is changed, the MMU driver updates the attributes. For example, the x86 MMU driver will update the PAT, PCD, and PWT bits of its translation entry [82].

Limitations. EMT only concerns translation, and does not change operations on physical memory pages. EMT focuses CPU virtual-to-physical translation and does not target IOMMU translation for DMA requests. Linux code for IOMMU translation is also hardwired to the radix-tree scheme; the EMT approach can potentially apply. EMT assumes that programs run with virtual addresses; EMT currently does not support designs that make program use physical addresses directly [101, 102].

EMT currently only supports the native environment; virtualization support is on the roadmap. As the extended page table [19] (EPT) has a similar structure as the native page table, we plan to create a virtualization-specific MMU driver to manage EPT. The driver creates a translation database for each VM and handles tasks like changing EPTP registers upon VM switches and allocating EPT tables. KVM can call EMT APIs accordingly. We expect paravirtualization support (`pv_ops.mmu` [73, 75] in particular) to be encapsulated in the MMU driver: MMU drivers with paravirtualization support can call `pv_ops.mmu` for function patching.

5 EMT-Linux with x86-64 MMU Drivers

We develop EMT on Linux, referred to as EMT-Linux. Conceptually, it took four steps: 1) identifying memory management code in architecture-independent modules that are hardwired to x86-like, tree-based translation scheme; 2) rewriting them using the EMT API; 3) moving architecture-specific optimizations into the x86-64 MMU driver, and 4) writing default implementations of customizable functions.

The EMT implementation on Linux (v5.15) takes 9.5K

```
1  void walk_tobj_range(start, end, walk) {
2    struct tlock lock; struct tobj_iter iter;
3    struct tobj tobj; ulong size;
4    struct tdb *tdb = walk->mm->tdb;
5    err = addr_range_get_lock(tdb, start, end, &lock);
6    addr_range_write_lock(&lock);
7    err = tobj_iter_init(tdb, start, end, &iter);
8    ...
9    while (tobj_iter_has_next(iter)) {
10     err = tobj_iter_next(&iter, &tobj);
11     err = tobj_read_attr(&tobj, TOBJ_ATTR_SIZE, &size);
12     err = walk->ops->tobj(tobj, tobj->va, tobj->va + size,
       ↪ walk);
13     ...
14   }
15   tobj_iter_end(&iter);
16   addr_range_write_unlock(&lock);
17   addr_range_put_lock(&lock);
18 } /* mm/pagewalk.c */
```

Customizable split PT lock.

Customizable iterator can be implemented as ++ for performance.

EMT also allows in-place operations via low-level abstractions.

Figure 9: **Rewriting code in Figure 4 with EMT.**

lines of code changes (7.3K for interface refactoring and 2.2K for the x86-64 MMU driver) in 15 person-months. We changed 196 kernel functions in the `mm` directory of Linux—most memory management code interacts with the page table.

We use macros and inline functions to minimize interface overhead as per Linux's coding style [20]; `#ifndef`-based function redirections are used otherwise. Specifically, we turn functions no more than three lines into macro or inline functions. We ensure that EMT does not break performance characteristics, e.g., no increase of stack size or call stacks, and no decrease of instruction cache hit rates in most cases (§8.3).

Moreover, we preserve *all* of Linux's existing architecture-specific optimizations and realize them in the x86-64 MMU driver. Hence, EMT supports all virtual memory features of vanilla Linux and is *transparent* to user applications.

OS Memory Management with EMT. In EMT-Linux, OS memory management is no longer hardwired to specific translation schemes. Meanwhile, EMT-Linux reserves hardware-specific optimizations like in Linux—both basic and customizable functions can be instantiated by different MMU drivers. Figure 9 shows the code in EMT-Linux that implements the hardwired Linux routine in Figure 4. It uses the translation-object iterator (see Figure 8) to scan all the pages in a memory region. This is a common pattern used in many OS memory management operations such as page promotion and migration, as well as page eviction (e.g., using LRU and MGLRU).

Figure 10 shows a skeleton of the page fault handler in EMT-Linux. In vanilla Linux, the page fault handler walks down the page-table tree level by level to determine the type of faults and dispatch them to corresponding subroutines (e.g., a leaf-level PMD entry implies a 2MB page). Differently, EMT-Linux's page fault handler decouples page sizes from the translation data structures (the radix tree). It looks at the translation object and the corresponding page size based on the faulting address, and decides the subroutine to invoke.

Swapping operates on translation objects that map pages to be swapped. Different architectures may encode swap-page information differently. x86-64 MMU driver stores swap in-

```
static vm_fault_t __handle_mm_fault(vma, vaddr, flags)
{ ...
  struct tobj tobj;
  struct tdb *tdb = vma->vm_mm->tdb;
  err = tdb_find_tobj(tdb, vaddr, &tobj);
  err = tobj_read_attr(&tobj, TOBJ_ATTR_MAPPED, &mapped);
  ...
  if (mapped) {
    if (flags & FAULT_FLAG_WRITE) { // fix the write fault
      err = tobj_read_attr(&tobj, TOBJ_ATTR_WRITE, &write);
      if (!write)
        return do_wp_page(&vmf);
    }
    ... // many other fixes
  } else { // mapping does not exist;
    ...
    while (pg_size > BASE_PAGE_SIZE) { // try huge page
      if (thp_eligible(tobj, pg_size, vma)) {
        int ret = create_huge_page(&vmf, pg_size);
        ...
      }
      pg_size = dec_page_size(tdb, pg_size);
    }
    if(vma_is_anonymous(vma)) { // handle anon page fault
      struct page *page = alloc_page_vma(...);
      if (!page) goto oom;
      struct tobj old_tobj;
      err = tobj_update_attr(&tobj, TOBJ_ATTR_PA,
            page_to_pfn(page) << BASE_PAGE_SHIFT);
      ... // update other attributes like permissions
      err = addr_range_get_lock(tdb, vaddr,
            vaddr + BASE_PAGE_SIZE, &lock);
      addr_range_write_lock(&lock); // lock the range
      err = tdb_update_tobj(tdb, &tobj, &old_tobj);
      addr_range_write_unlock(&lock);
      addr_range_put_lock(&lock);
      return 0;
    }
    ... // handle other type of base page faults
  }
  ... // error handling (e.g., oom)
} /* mm/memory.c */
```

Figure 10: **Snippet of EMT-Linux's page fault handler.**

formation in a page table entry if the present bit is cleared; huge page swapping [44] is done by encoding PMD entries. ECPT and FPT use the same mechanism. EMT provides customizable functions if architectures need different encoding.

EMT encapsulates translation cache management in MMU drivers, as the cache structure is architecture-specific. For example, ECPT does not use x86-64 PWCs but has CWCs to cache page size and way information [98]. TLB-related code is handled with the same principle. The MMU driver performs TLB flushes and guarantees the consistency of cache state. Batch invalidation is supported by customizable functions.

x86-64 MMU Driver. For the x86-64 radix-tree translation scheme, our x86-64 MMU driver maintains the multi-level tree page table. The MMU driver encodes page table entries at all levels of the radix tree for a given virtual-to-physical address mapping in the translation object. This encoding enables the MMU driver to realize all the optimizations specialized for the tree-based x86-64 page table, while making architecture-neutral code agnostic. For example, the MMU driver can directly operate on the PMD or PUD entries to implement Linux's split page table lock [15] through the `addr_range_get_lock` customizable function (Figure 9). The MMU driver can also implement optimizations that leverage spatial locality of the tree structure, as exemplified by the iterator (Figure 8). Encoding attributes of x86 page table entries via translation object API is straightforward by reading/writing bits in the entries, and our x86-64 MMU driver supports hardware-specific features like Intel MPK.

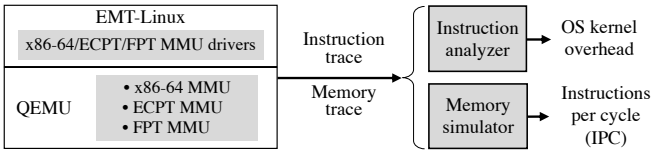

Figure 11: **Emulator toolchain for OS development and evaluation on experimental memory architectures.**

FPT MMU Driver. We implemented an MMU driver for a new translation scheme based on Flattened Page Table (FPT) [87]. The FPT design aims to minimize OS changes [106] and is based on the x86-64 radix-tree page table. Without an interface like EMT, it needs nontrivial changes to Linux's architecture-independent code, including changing macros that define bits in page table entries and checking if a level needs to be folded. The Linux prototype in the FPT paper [87] supports flattening of L3+L2 only. We wrote the FPT MMU driver by reusing the x86-64 MMU driver code with 664 lines of C code. With the EMT API, no architecture-neutral OS code needs to be changed. Our FPT MMU driver supports all three types of flattening patterns of tree levels, and it co-exists with the x86-64 radix MMU driver.

6 ECPT on EMT-Linux

6.1 Emulator-based Toolchain

It is challenging to develop OSes for new translation architectures without manufactured MMU hardware. We did not find an available toolchain for developing and evaluating OS kernels with experimental architectures like ECPT. The original evaluation of ECPT [98] collects memory traces from simulation using Simics [76] on *vanilla Linux* and replays traces in SST [94] that simulated an ECPT MMU. Simics is closed-source and only supports existing ISAs.

We develop an emulator-based toolchain using QEMU [5] (Figure 11). We use QEMU's software MMU mechanism [4] to develop an emulated ECPT MMU where we implement ECPT translation logic and hardware caches in 3.1K lines of C code. QEMU offers an emulated x86-64 MMU which serves as a baseline for performance evaluation.

Our toolchain can connect to trace-driven hardware simulators (QEMU provides no cycle-accurate simulation). We developed instruction and memory tracers using QEMU's TCG plugin [23]. The instruction trace helps analyze kernel and userspace behavior (§8.4), as well as hardware simulation.

6.2 ECPT MMU Driver

We implement an ECPT MMU driver on EMT based on the hardware architecture design [98]. We use a three-way

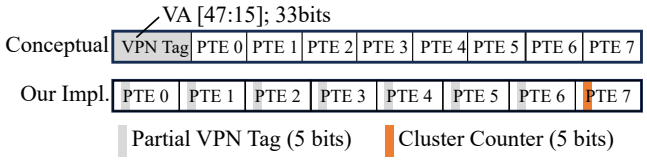

Figure 12: **Implementation of 64-byte PTE-ECPT entry clusters consists of eight 8-byte PTE entries.** Each entry contributes five bits for the VPN tag or a cluster count.

ECPT for each page size (4KB/2MB/1GB) so the translation database manages nine control registers, one per way; registers are updated upon a process context switch. The driver also manages nine registers for the kernel page tables (§7.1). The ECPT MMU driver takes 7.4K lines of C code.

The ECPT structures are implemented in the ECPT MMU driver. For memory efficiency, we allocate ECPTs of a specific size on demand. We follow the ECPT design of clustering eight translation entries into a 64-byte cache line to improve locality. To do so, we construct the VPN tag (Figure 2) with bits from multiple translation entries, as shown in Figure 12. For the PTE VPN tag, each entry contributes five bits so the first seven entries together make up the VPN tag, and the last entry contributes five bits as the count of valid entries in the cluster. The count is used to calculate occupancy (for table resizing) and for freeing the cluster. These metadata are managed by basic functions. PUD and PMD entries use the same design but with 24 bits and 15 bits for the VPN tag.

When a table's occupancy exceeds a threshold (0.6 as in [98]), a background kernel thread resizes the table and migrates entries from the old table to the new table gradually.

Except for the repurposed five bits for metadata, ECPT's translation entry by design follows x86-64 PTE format. We reuse the PTE encoding from the x86 radix MMU driver, enjoying the benefit of EMT's object-oriented design.

Cuckoo Walk Tables (CWTs) are implemented in the ECPT MMU driver, invisible to architecture-independent code. We follow the ECPT design [98] to use a 5-bit section header (a section is the address range translated by one ECPT translation entry) and cluster 64 headers into a 64-byte cache line. Each header is one byte and contributes three bits to encode the VPN tag and count of valid section headers.

Optimizations. We implemented a series of optimizations through the customizable functions, driven by benchmarking and profiling (§8.4). For example, we customize the iterator with architecture-specific optimizations to accelerate range operations. The idea is to exploit locality within a translation entry cluster: the iterator finds the next entry by pointer arithmetic, instead of hashing-based lookups, when the entry is not the last one in its cluster. One common optimization pattern is to minimize the cost of range operations—the default implementation (e.g., Figure 8a) often takes too many fine-grained hashing-based operations.

7 Reflection on ECPT Design

We show that building OS components is essential to understanding architecture designs. The efforts on developing and evaluating ECPT with EMT-Linux reveals OS challenges of using a fast translation scheme, which were unexpected (undocumented in the original hardware design).

7.1 Managing Kernel Page Tables

In modern OSes like Linux, the kernel address space is shared across processes [9]. In tree-based translation, sharing is realized by having high-level page table entries pointing to the shared subtree of the kernel address space [22]. This design does not apply to hashing-based translation. One option is to maintain one ECPT for each process containing both user- and kernel-space addresses. However, such a design is memory inefficient and leads to high overhead, e.g., once a translation of a kernel-space address is updated, the OS must update the corresponding entries in ECPTs of all processes.

Our ECPT MMU driver maintains a global kernel-space ECPT (kECPT) shared among processes and an independent user-space ECPT (uECPT) for every process. The kECPT has the same page size and way configuration as each uECPT. The kECPT and uECPTs are managed independently. When KPTI (kernel page table isolation) [22] is enabled, two independent global kECPTs are managed (a complete kECPT and a minimal kECPT). This design requires ECPT MMUs to expose another nine control registers that point to kECPT(s).[2]

Self-Reference Paradox. Managing kECPTs is more challenging than uECPTs. Different from uECPTs that are mandated by the kernel, the kECPT manages the kernel's own code and data—translations for kECPT management code and kECPT itself are stored in kECPT. This creates a challenge for ECPT which needs to move translation entries across ways for resolving hash collisions—in the moving window, if the entries map the kECPT itself or the kernel code for moving entries are missing, the kernel crashes due to missing translation of the kECPT or code, as shown in Figure 13. Frequent triggers are kernel's huge page promotion/demotion which remove entries and insert new entries in different tables.

We term the issue *self-reference paradox*. The root cause is a lack of hardware support for atomic updates on multiple memory locations. Radix-tree page tables do not face this paradox, because they do not move entries and the huge-page promotion/demotion is done by updating one PUD/PMD entry. In general, the self-reference paradox can happen in kernel page tables that need to move entries (many advanced index schemes need to move entries [36, 113]). Note that

[2] The cost of additional architectural registers is negligible; they add to less than 0.01% of the die area. The area overhead was measured with the same methodology as in [98, 100] using CACTI [30] with 22nm technology. The new design also distinguishes whether the target address belongs to the upper or lower half of the address space and directs the lookups to uECPT or kECPT. CWC is shared and has no additional cost.

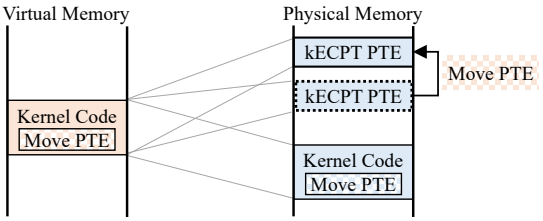

Figure 13: **An example of self-reference paradox caused by the need of moving kECPT entries that are needed to find kernel code for moving kECPT entries (§7.1).**

other kernel structures like forwarding table [112] do not face this paradox if they do not map kernel code/data.

We address the paradox via a series of software-hardware endeavors. First, we always copy the entry to the new location *before* removing it at the old location, which may cause duplicated entries but no missing entries. We instruct the MMU to handle duplicate entries that have the same virtual-to-physical address mapping and the same protection bits; the deduplication policy also works for huge-page promotion/demotion as it does not change the mapping or protection. We avoid location-changing read-update-write operations in OS code so that duplicated entries always have the same mapping and protection. For ECPT, any operation that may change the content of an entry can only be done after the entry is locked.

Atomic kECPT Switching. Another form of self-reference paradox manifests via KPTI [22]—when switching between the kernel space and the user space, the OS needs to switch between a full kECPT and a minimal kECPT. One potential implementation is to use multiple `mov` instructions to redirect control registers from the old kECPT ways to the new ways. However, this may lead to an inconsistent ECPT state during the switch window, where some registers point to new ways and the others point to old ways. This leads to issues when the translations of currently executing kernel code are stored in different ways across the new and old kECPTs. Note that simply keeping context switch code covered by both kECPT is not enough since the instructions can reside in different ways of the old and new tables. Instructions might not be successfully fetched when kECPT state is inconsistent.

Solving this problem needs a mechanism for atomic switching from all old kECPT ways to the new kECPT ways. Such an atomic switching mechanism can be realized with hardware support. Our solution is to add additional sets of kECPT control registers and the hardware switches between the two sets of control registers, in a similar vein as the `VMLAUNCH` and `VMRESUME` instructions of x86 on updating multiple registers together. The switch is a serializing instruction to ensure that all instructions after it will use the new kECPT.

7.2 Implications on OS Performance

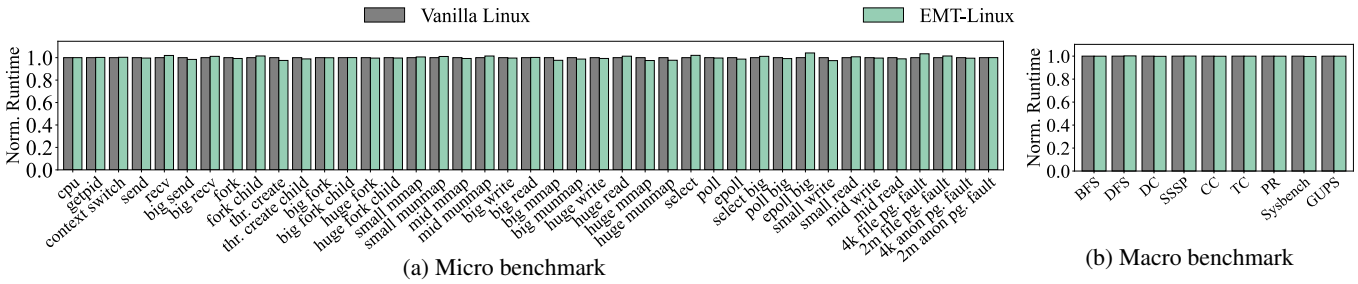
Managing Sparse Address Space. A fundamental efficiency property of tree-based page tables is the ability to manage sparse address space, which is critical for OS memory management which commonly needs to scan large, but sparse address ranges. In tree page tables, a high-level entry can encode properties of a large address range, e.g., a nonexistent PMD entry indicates no valid page allocated in the corresponding 2MB range. Hashed page tables have no such hierarchical relationship between entries; hence, the OS may go through all the possible entries in the large, sparse address range.

One optimization is to enable a similar property in ECPT by designing special entries that are not for translation, but for encoding states. The OS checks the entry to learn the states of the corresponding address range, e.g., the OS can query such an entry to check if the corresponding 2MB address range has any allocated page, instead of checking all possible PTE entries. The design would need to cooperate with the MMU.

Multicore Scalability. We find it nontrivial to implement efficient locking primitives similar to Linux's split page table lock [15] in ECPT, because the location of an ECPT entry can be moved due to insertion or rehashing. The movement of entries makes it prone to deadlocks, e.g., one thread t holding a lock l and inserting a new entry, thus consequently requires moving an existing entry e (see [83]) which is locked by another thread that waiting on l. One solution is to let t release all its acquired locks and retry later when deadlock. The complexity lies in recording and rewinding states changed by t. We are exploring an alternative design that introduces a separate lock table to provide the OS with the flexibility of implementing lock primitives, which has the semantic of locking both an address range and the related entries. Our implementation of the ECPT MMU driver has no correctness issue, as we use a coarse-grained lock.

8 Evaluation

8.1 Methodology



We validate the correctness of the EMT-Linux implementation using Linux tests. Since EMT supports all virtual memory features in Linux, EMT-Linux should pass any userspace tests.

We also measure the interface overhead of EMT by running the same set of performance benchmarks on EMT-Linux (§5) and vanilla Linux running upon the same hardware.

We then measure the performance of EMT-Linux on ECPT. We run EMT-Linux with the ECPT MMU driver on top of an emulated ECPT MMU using our emulation framework (§6.1). We compare the performance of EMT-Linux with the Radix MMU driver running on an emulated x86-64 MMU.

Benchmarks. We use LEBench [93] as a micro benchmark to measure the performance of core OS operations such as page fault handling, context switching, and system calls.

We use nine memory-intensive macro benchmarks that stress the TLB and need off-TLB translation. We use the same set of macro benchmarks from the ECPT paper [98, 100] except two where we failed to reproduce the working set.

(a) Micro benchmark (b) Macro benchmark

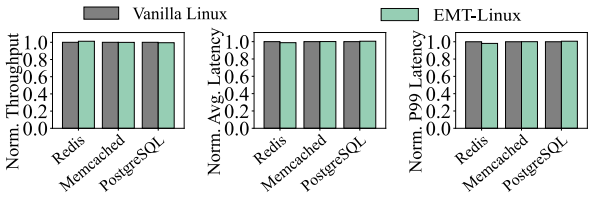


Figure 14: **Performance overhead of EMT-Linux over vanilla Linux (measured by the micro and macro benchmarks).**

The macro benchmarks include seven applications from the GraphBIG benchmark suite [80]: Breadth First Search (BFS), Depth First Search (DFS), Degree Centrality (DC), Single Source Shortest Path (SSSP), Connected Components (CC), Triangle Count (TC), and PageRank (PR); they use the LDBC-1000K dataset [2], with working sets of about 8.5 GB. We also run the GUPS benchmark [58] which issues random memory updates, and a memory test from Sysbench [66]. Both GUPS and Sysbench have 64 GB working sets.

We also evaluate three memory-intensive applications: Redis, Memcached, and PostgreSQL. Table 1 shows the workloads. All these applications are multithreaded programs.

Application	Working Set	# Records	Read:Write	# Requests
Redis	128 GB	536 M	50:50	60 M
Memcached	69 GB	56 M	80:20	10 M
PostgreSQL	64 GB	21 M	100:0	25 M

Table 1: **Application workloads used in the evaluation.**

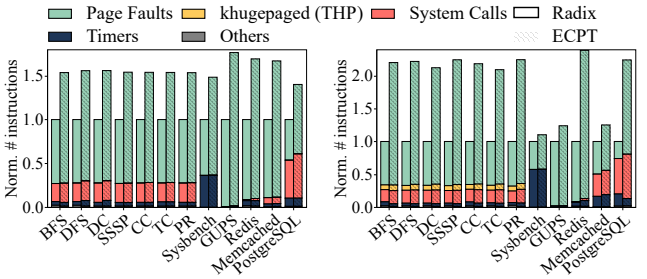
(a) Throughput (b) Avg. Latency (c) P99 Latency

Figure 15: **Performance overhead of EMT-Linux over vanilla Linux on real-world applications**

8.2 Functional Correctness

We show that EMT supports all memory management features of Linux by running Linux Test Project (LTP) [12] against EMT-Linux. We use the default kernel configuration for the generic kernel (5.15.0-125-generic) of Ubuntu 20.04. LTP includes 1,405 tests in total and 1,208 of them apply to the kernel configuration. EMT-Linux with Radix, ECPT, and FPT MMU drivers both pass all 1,208 tests which covers 376 system calls. We also cross-validated program outputs of the micro and macro benchmarks across EMT-Linux and vanilla Linux. We use testing as a continuous effort throughout our development, rather than a one-time effort, which helped capture bugs in a timely manner.

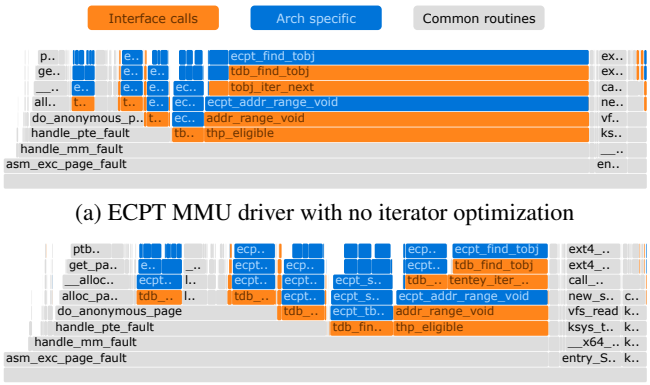
8.3 EMT Interface Overhead



EMT introduces negligible overhead. We run the benchmarks and application workloads on vanilla Linux and EMT-Linux running on the same hardware. The hardware is a dual-socket Intel Xeon Gold 6346 server at 3.10GHz with 16 cores and 256GB DDR4-3200 DRAM. We disable hyperthreading and fix core frequency to make the measurement stable. The overhead of EMT is calculated by normalizing the results of EMT-Linux to vanilla Linux. We experimented with various kernel configurations (e.g., enabling THP); the results are consistent.

Figure 14a shows the results of kernel micro benchmarks LEBench [93]. EMT-Linux exhibits an average normalized kernel-routine performance of 99.9% relative to vanilla Linux (with a standard deviation of 1.1%) across the 41 LEBench microbenchmarks. The largest overhead comes from the "epoll big" benchmark, where EMT-Linux slows the benchmark by 4.2%. It was caused by not inlining certain functions due to coding style restriction, which can be further optimized by restructuring the code or forcing inlining. Figure 14b shows that the overhead of EMT-Linux is less than 0.1% on the macro benchmarks. Figure 15 shows the normalized throughput, average latency, and tail latency of three real-world applications (with workloads in Table 1) on EMT-Linux, normalized to their performance on vanilla Linux. The measured differences of the three metrics are within 0.1%, 0.1%, and 0.2%, respectively. The results of the real-world application show that the EMT interface does not affect system responsiveness.

The negligible overhead is attributed to two kinds of endeavors. First, we carefully engineered the EMT interface to preserve the performance characteristics—we minimize increased stack size or deepened call stacks, and maintain cache efficiency. Instruction cache hit rates on EMT-Linux differ from those on vanilla Linux by at most 0.8%. Second, EMT enables us to implement all the hardware-specific optimizations in the MMU drivers.

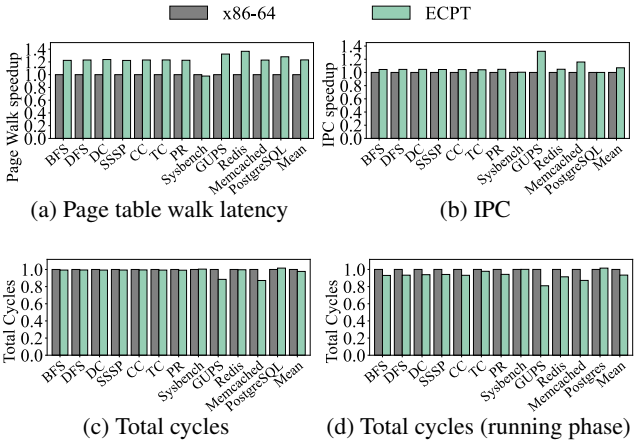


8.4 OS Performance on ECPT

We show that EMT enables us to understand OS performance on new translation architectures using ECPT as an example. We evaluate ECPT by running EMT-Linux with the ECPT MMU driver on our emulation framework and comparing

(a) 4KB (b) THP

Figure 16: **Distribution of kernel instructions of EMT-Linux with the Radix and ECPT MMU drivers.**



(a) ECPT MMU driver with no iterator optimization

(b) ECPT MMU driver with iterator optimization

Figure 17: **Flame graph of EMT-Linux kernel instructions when running GraphBig BFS (THP enabled).**

its performance with the x86-64 radix MMU driver. We run macro benchmarks and application workloads and record all kernel and user instructions (with both 4KB pages and THP).

Understanding OS Overhead of ECPT. Figure 16 shows the distribution of kernel instructions; most of them are for page fault handling. Compared with Radix, ECPT spends 1.74x more instructions on page fault handling on average for 4KB pages, and 2.59x more with THP enabled. When THP is enabled, ECPT leads to relatively more work than Radix because Linux's THP implementation uses a few expensive operations to check if there exist valid entries in a given address range. These checks are on the critical path of page fault handling when THP is enabled since the kernel needs to know if the 2MB range has any mappings before it can decide if a 2MB huge page mapping should be built. For Radix, these checks are cheap (0.39% of total kernel work) because a PMD entry has information on PTE tables. If the entry is not valid or present, then neither 2MB nor 4KB mappings exist; the huge-page bit tells if the entry points to a huge page or a directory of 4KB pages. However, these checks are expensive in ECPT, as ECPT's entries are independent, the kernel may need to check all 512 4KB entries of pages in the 2MB range, which requires many expensive lookup operations. We discussed the potential solution in §7.2.

(a) Page table walk latency (b) IPC

(c) Total cycles (d) Total cycles (running phase)

Figure 18: **ECPT hardware simulation results— Page Table Walk Latency, Instruction Per Cycle (IPC) and Total Cycles—with the ECPT system and the x86-64 system, running EMT-Linux.** All results are normalized to those of the x86-64 system as the baselines.

Effectiveness of Optimizations. EMT exposes optimization opportunities for MMU drivers using customizable functions. Figure 17 uses flame graphs to show the effectiveness of iterator optimization running GraphBIG BFS with THP. With the iterator optimization (§6.2), ECPT can save 49.0% of total kernel work, and 52.5% of the page fault handling work. The optimization drastically saves the work of hashing and lookups of the architecture-neutral default implementation, by incrementing the pointer to an entry directly, as long as the entry is within an entry cluster (Figure 12). Note that such kernel work as software overhead cannot benefit from hardware caches such as TLBs or PWCs.

8.5 Hardware Simulation

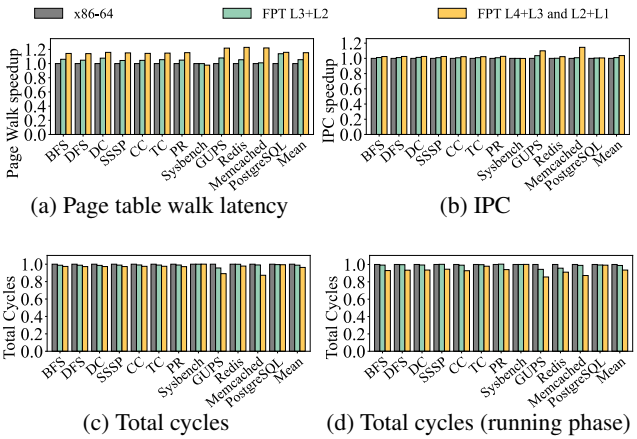
8.5.1 ECPT

EMT's emulator toolchain provides an open platform of hardware simulation for experimental architectures where silicon implementations are not available. To demonstrate this, we run hardware simulations for EMT-Linux with the x86-64 radix and ECPT MMU drivers using the DynamoRIO simulator [41]. We use the hardware configuration described in the ECPT paper [98]. For PWC configuration, we follow more recent works [77, 111] to use 3 levels of PWC with 2-4-32 entries per level. We use the macro benchmarks and the three application workloads described in §8.1.

Traditional Hardware Metrics. Our toolchain measures traditional hardware metrics, namely Page Table Walk Latency and Instructions Per Cycle (IPC), which are considered key performance metrics of hardware translation architectures (see [87, 98]). As shown in Figures 18a and 18b, ECPT has significant performance advantages over x86-64 (Radix). On average, ECPT speeds up page table walks by 23.1%, and

increases IPC by 7.0%. For most benchmarks, ECPT shows nontrivial page table walk and IPC speedups, as it directly accesses the last-level PTEs. The only exception is Sysbench whose workload has a high PWC hit rate of 99.8% at the PMD level on x86-64, i.e., the x86-64 page table walks skip most intermediate steps and directly accesses last-level PTEs; meanwhile, ECPT pays extra cycles for hash computation in addition to CWC accesses, so it slightly slows down Sysbench's page table walk by 2.2%

New Metrics with OS Overhead. We find that IPC, which measures instruction throughput, does not fully reflect application runtime—though ECPT increases IPC, our ECPT MMU driver introduces more kernel instructions than the x86-64 MMU driver (§8.4). Hence, we measure the total cycles for running macro benchmarks and applications, including the OS overhead (mostly page-fault handling as shown in Figure 16). Figure 18c shows that, on average, the ECPT system reduces total cycles by 2.3% across the workloads. GUPS and Memcached show major benefits, where the ECPT system reduces the total cycles by 11.5% and 12.9%, because page table walks account for over 66% of their execution time.



The aforementioned analysis shows that the OS can play an important role in application performance, which could be overlooked with hardware metrics. Without building the OS memory management, it is hard to evaluate OS overhead accurately. Prior work assumed that OS overhead is constant under different memory-translation architectures. In the initial modeling, the memory trace is collected from running benchmarks on vanilla Linux on x86-64; the trace is then replayed in a simulator of ECPT MMU. As shown in §8.4, memory translation architectures can have profound implications for OS performance. EMT aims to enable OS experience for new translation architectures. We believe that EMT effectively lowers the barrier to implement OS support for new memory-translation architectures by making the kernel developers focus on MMU driver implementations.

IPC as a metric aligns with application's execution time when OS overhead is minimal. All the evaluated workloads have two phases: a *loading phase* that loads data from the disk to memory, and a *running phase* that runs the computation or serves user requests. The running phase involves less kernel work with kernel instructions accounting for less than 1.3% of the total instructions. With only the running phase considered, ECPT improves IPC by 7.5% and reduces total cycles by 6.6% compared to the x86-64 system (Figure 18d).

The results could be different with different hardware simulators. We expect the impact of kernel instructions to become smaller when using SST [94] which models OoO execution more precisely. The SST evaluation remains future work.

8.5.2 FPT

We start with a FPT configuration that flattens L3+L2 tables (see Figure 1) which was implemented by the original OS prototype [87]. Our evaluation shows that the benefit of flattening L3+L2 is limited: only L3 entries were saved, which were cached effectively in x86-64. As shown in Figures 19a, 19b, 19c, compared with Linux on x86-64 (baseline), on average, the FPT-based system speeds up page table walk latency by 5.5%, IPC by 1.0%, and the total cycles by 1.1%.

(a) Page table walk latency (b) IPC

(c) Total cycles (d) Total cycles (running phase)

Figure 19: **Hardware simulation results of the FPT system and the x86-64 system, running EMT-Linux.** All results are normalized to those of the x86-64 system as the baselines.

We then implemented the FPT configuration that flattens both L4+L3 and L2+L1. This configuration was not implemented in [87] due to its difficulties of supporting 2MB huge pages. We implemented a 4KB-only version and evaluated it with only 4KB base pages (no huge page). With this configuration, compared with Linux on x86-64, the FPT-based system speeds up page table walk latency by 15.3%, IPC by 3.6%, and total cycles by 3.7% (Figures 19a, 19b, and 19c).

Flattening both L4+L3 and L2+L1 in FPT yields performance comparable to ECPT in the running phase. Compared with radix, ECPT and FPT reduce total cycles by 6.6% and 6.4%, respectively (Figures 18d and 19d). For hardware metrics (page table walk latency and IPC), the FPT-based system matched ECPT-based system's performance: ECPT is only faster than FPT by 2.4% in page table walk latency and 0.4% in IPC. On the other hand, ECPT inherently supports huge pages of varying sizes, unlike this FPT configuration.

9 Experience and Lessons Learned

Developing EMT-Linux and the MMU drivers together with the emulated MMU took extensive engineering efforts. Specifically, we had to develop interacting moving parts across the hardware-software boundary.

A key principle is to enable incremental, contiguous engineering practice. For example, when implementing ECPT, our first milestone is to write a basic per-process hashed page table (BHPT) using EMT, without features like collision resolution, elastic resizing, CWT/CWC, etc. We implement BHPT logic in both EMT-Linux and the MMU and have a running

system that only supports a tiny microbenchmark. Despite being basic, the running system serves as a foundation for gradually adding features and eventually evolving into a full-fledged system. For features that need both hardware and software support, we start from the hardware, which typically has simpler logic and mostly reads translation data.

We continuously test and evaluate our system, not only for correctness (§8.2) but also for performance. Continuous profiling helped us quickly observe performance regression over vanilla Linux; when developing ECPT, profiling helped us identify major inefficiencies compared to the radix-page-table-based system. We developed the instruction analysis with flame graphs [55] in our emulator toolchain. and use them extensively. We also added GDB support for the ECPT-based system (QEMU's GDB was hardcoded with radix).

We largely reuse the existing Linux compiler toolchain to keep the effort manageable. We leverage x86's model-specific registers (MSR) [19] as the control registers for ECPT, which is supported by GCC (x86's read/write MSR instruction allows access to arbitrary MSR with a 32-bit identifier). We use Clang's static analysis tools (e.g., clang-query [18]) to search for error-prone code patterns during refactoring.

One mistake we made was to start from Linux's boot-time kernel page table [6, 8], which is legacy code without debugging tools. Developing boot-time kECPT requires implementation in assembly and build mappings of kernel code/data from a bootstrap address space. We spent four months to understand the details of the boot-time kernel page table. Retrospectively, we should have started from runtime kECPTs (by switching the system to it after boot [7]) so we could have a running system quicker to parallelize our efforts.

10 Related Work

As memory translation has become a major bottleneck of emerging memory-hungry, irregular workloads such as generative models, graph analytics, and recommendation systems, translation architecture has been an immensely active research topic recently. Extensive efforts are made on new designs of TLB [33, 86, 88, 89] and page walk caches [32, 40], and more efficient huge page management [62, 69, 81, 84, 85].

To fundamentally resolve translation bottlenecks, recent work [53, 56, 63, 98, 109] is actively rethinking translation architectures; a common thread is to prioritize speed over space efficiency (with abundant memory) and use fast lookup structures to reduce tail latency (avoiding pointer chasing).

Memory translation architectures have profound implications on OS reliability and performance, but unfortunately have not been well explored in prior work. EMT is designed to enable development and evaluation of OS support for emerging translation architectures to formulate an OS perspective.

Note that memory management and its extensibility were well studied in OS research [24, 38, 47, 67, 91] and are continuously revisited, driven by the growth of memory capacity and the heterogeneity introduced by memory tiering [37, 61, 71, 78, 92, 103]. So far, extensibility refers to the ability for user space to customize memory management features, e.g., page fault handler. Few prior studies considered extensibility in terms of empowering memory translation architectures or studied their implications on OS performance.

We are inspired by machine-independent memory management designs in Mach [91] and SunOS [50]. The goal of EMT is to enable the OS development for emerging, experimental memory translation architectures and demonstrate the value with our experience. We attempted to simplify the EMT interface, e.g., to a map interface [50, 91]; however, we find it hard to balance architecture neutrality and low-level optimizations. One way is to add hints, but hints are not expressive for passing information to different MMU drivers.

Virtuoso [64] is a recent hardware simulation framework that considers OS overhead (mostly the overhead of page fault handling) using an imitated MimicOS in the user space. EMT and Virtuoso are fundamentally different but are complementary. Unlike Virtuoso which is designed for architecture-centric simulations, EMT is an OS interface for enabling OS developement and evaluation with regard to new translation architectures. EMT benefits architecture designs from an OS perspective by running real MMU drivers on Linux.

11 Concluding Remarks

EMT is an OS framework for developing and evaluating OS memory management for new memory translation architectures. Our work shows the importance of understanding hardware translation schemes from the OS perspective. Specifically, we show that fast translation schemes like ECPT can incur new challenges for the OS. We will release and make EMT and the emulator toolchains as an open platform and encourage new hardware architectures to experiment with modern OSes. With the significant diversity of emerging workloads and increasing heterogeneity of interconnected memory devices, it becomes harder to foresee a one-size-fits-all translation scheme. Hence, OS extensibility for different translation schemes is critical to enable specialized translation. We hope that EMT design starts a practical journey towards extensible OS kernels for translation of heterogeneous devices.

Acknowledgement

We thank the anonymous reviewers, and our shepherd, Haggai Eran, for their insightful comments. We thank Chloe Alverti, Ren Wang, Andrea Arcangeli, Jinghao Jia, and Kaiyang Zhao for their feedback and discussion. We are very grateful to Shanbo Zhang and Rubin Du who helped prepare the EMT artifacts and earn the Reproducibility badge. We also thank Divyam Arora, Logan Cudia, and Yuchen Tang for their participation. Tiered Memory Management Beyond Hotness

Jinshu Liu Hamid Hadian Hanchen Xu Huaicheng Li
Virginia Tech

Abstract

Tiered memory systems often rely on access frequency ("hotness") to guide data placement. However, hot data is not always performance-critical, limiting the effectiveness of hotness-based policies. We introduce amortized offcore latency (AOL), a novel metric that precisely captures the true performance impact of memory accesses by accounting for memory access latency and memory-level parallelism (MLP). Leveraging AOL, we present two powerful tiering mechanisms: Soar, a profile-guided allocation policy that places objects based on their performance contribution, and Alto, a lightweight page migration regulation policy to eliminate unnecessary migrations. Soar and Alto outperform four state-of-the-art tiering designs across a diverse set of workloads by up to 12.4×, while underperforming in a few cases by no more than 3%.

1 Introduction

Driven by the growing demands of memory-intensive workloads, such as graph processing and machine learning, tiered memory architectures that integrate a **fast-tier** (*e.g.*, DRAM) and **slow-tier** (*e.g.*, CXL memory) are becoming standard in cloud datacenters [1–5]. While this approach improves memory capacity scaling, it also introduces significant performance challenges. Effective data tiering is critical to mitigating the 2–3× performance disparity between tiers [6–12].

Existing tiering designs are grounded in the assumption that frequently-accessed ("hot") data is more performance-critical than cold data and should reside in the fast-tier. Thus, tiered memory management primarily focuses on hotness tracking, memory allocation, and migration policies to detect, allocate, and relocate hot data across tiers efficiently [4, 13–29].

We argue that hot data is not always performance-critical and can reside in the slow-tier without degrading performance (§2.1). In modern out-of-order CPU designs, latency mitigation techniques, such as memory-level parallelism (**MLP**), obscure the true cost of memory accesses [13, 30–32]. Not all memory accesses contribute equally to performance (vary by 4×, §3); overlapping requests (high MLP) often mask slow-tier latency penalties, leading to less pronounced slowdowns.

Although MLP is a well-established concept within the architecture community [30–32], its implications for tiered memory management have been largely overlooked. Prior classification efforts across objects, pages, and data structures [13, 19, 33, 34] often implicitly reflect the effects of MLP through coarse heuristics or indirect indicators of memory access costs. However, they do not *explicitly* model or quantify MLP impact. What remains missing is a principled, accurate, and MLP-aware performance metric that enables more effective, performance-driven tiering policies across online and offline scenarios, and generalizes to diverse workloads.

Existing tiering systems also suffer from heavyweight and imprecise hotness sampling and page migration mechanisms. Two key limitations are prevalent [1, 4, 16, 17, 19, 21–24, 35]: **(a)** *Suboptimal data placement.* Existing coarse-grained allocation policies prioritize fast-tier placement for newly allocated data, but under fast-tier pressure, performance-critical data is often displaced to the slow-tier, necessitating costly migrations later to correct the placement errors; **(b)** *Excessive migration overhead.* Existing systems often employ aggressive migration policies, incurring substantial overhead by frequently relocating non-critical pages. This overhead can erode or negate the performance benefits of tiering (§2.1).

We propose **Amortized Offcore Latency (AOL)**, a novel performance metric that accurately quantifies the performance impact of memory accesses by integrating memory latency and MLP. While latency measures the impact of individual memory requests, it does not capture the latency-masking effects of MLP. By considering both factors, AOL, expressed as "`Latency/MLP`" combined with CPU stalls, offers a more precise representation of the true performance contribution of memory accesses (validated across 56 workloads, §3).

We leverage AOL to redesign memory allocation and migration policies, introducing two novel tiering mechanisms: a static memory allocation policy, **Soar**, and a dynamic page migration regulation policy, **Alto**. Soar employs AOL-based profiling to rank objects by assessing their accumulative contributions to application performance. High-ranking objects are placed in the fast-tier, achieving near-optimal placement while eliminating runtime migration overhead. Alto adaptively regulates page migrations based on AOL, ensuring that only performance-critical pages are promoted, regardless of their hotness. Alto seamlessly integrates with four representative tiering systems with minimal code changes, including TPP [4], Nomad [22], Linux NUMA Balancing Tiering (NBT) [36–38], and Colloid [23].

We evaluate Soar and Alto across a range of realistic

graph, cloud, and HPC workloads on both NUMA and real CXL platforms, varying fast-to-slow tier ratios and bandwidth contention levels. SOAR outperforms Nomad, NBT, Colloid, and TPP by 14–547%, 4–79%, -1–68%, and 31–1242%, respectively; ALTO improves performance by -2–81%, 1–31%, -3–18%, and 2–471%. Negative improvements indicate that SOAR/ALTO underperform relative to baselines in a few cases (5 out of 182 in total). While SOAR and ALTO achieve strong results broadly, their performance gains are less pronounced under high bandwidth contention due to AOL inflation from queuing delays. Raising AOL thresholds can restore their performance gains but requires contention-aware tuning. We highlight this to clarify the scope of our approach and leave AOL tuning as future work.

In summary, we make the following contributions:

- We quantitatively demonstrate that hotness is an unreliable proxy for performance-criticality: the performance impact of memory accesses can vary by up to 4× across workloads.
- We introduce AOL, a performance metric that combines memory access latency and MLP, and leverages CPU stall cycles to accurately estimate tiered memory performance.
- We propose AOL-powered memory management policies: SOAR for near-optimal data placement and ALTO for adaptive migration control.
- We open-source SOAR and ALTO at https://github.com/MoatLab/SoarAlto.

The rest of the paper is organized as follows: §2 covers background and motivation, §3 introduces the AOL metric and predictor, §4–6 present SOAR, ALTO, and evaluation, followed by related work (§7) and conclusion (§8).

2 Background and Motivation

Hotness implicitly assumes that all memory accesses contribute equally to application performance, ignoring variations introduced by loaded latency and CPU-side latency-mitigation techniques [39]. A key dimension behind this disconnect is **memory-level parallelism (MLP)**. MLP quantifies the number of outstanding memory requests awaiting completion by the memory controller. It plays a critical role in reducing CPU stall time [30]. Under high-MLP access patterns, such as array traversals, the CPU can issue many concurrent requests to minimize stalls. In contrast, serialized access patterns, as in pointer-chasing with depedent requests, exhibit low MLP and expose latency more directly, leading to greater slowdowns [13, 40]. In tiered memory systems, this implies that placing hot data in the fast-tier does not guarantee performance gains.

2.1 The Case Against Hotness-based Tiering

We design a microbenchmark to quantify the performance impact of different memory access patterns and illustrate how hotness-based tiering policies can lead to incorrect page migration decisions and performance degradation. Later, we show these findings extend to real-world applications with more complex memory access behaviors in §6.

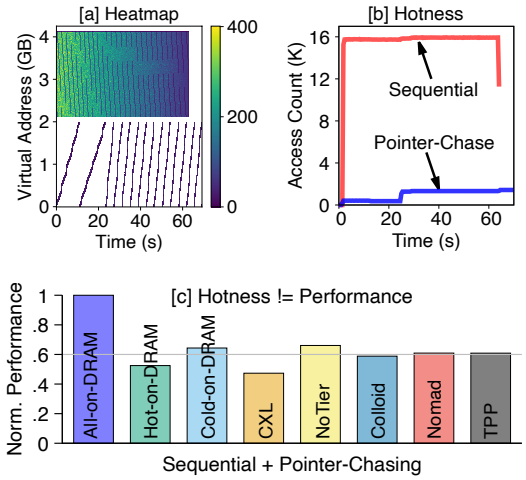

Figure 1: **Hotness vs. performance benchmark (§2.1).** *(a) presents the heatmap. (b) shows the access rates over time. (c) compares the performance of different tiering strategies (higher is better), showing that placing hot pages in the fast-tier can degrade performance when they are not performance-critical.*

The benchmark comprises two types of memory accesses: one thread performs sequential reads (high MLP, "hot", termed as **"seq"**), while the other executes pointer-chasing operations (low MLP, "cold", termed as **"pc"**). Each thread operates on a dedicated 2GB buffer. The "pc" thread issues 4 billion load instructions, while "seq" thread issues 26 billion, resulting in comparable runtimes for both (Figure 1a&b). This design prevents either thread from dominating overall workload performance in a tiered memory setup. The total runtime of both threads serves as the application's performance metric.

Figure 1a presents the heatmap highlighting the contrasting behaviors of the two memory access patterns. The sequential region (top half) demonstrates high memory access activity due to parallel memory reads (measured MLP=7 precisely), while the pointer-chasing region (bottom half) exhibits sparse memory accesses, reflecting its serialized nature (MLP=1). The difference is further quantified in Figure 1b, where "seq" pages are 13.6× hotter than "pc" pages on average.

Hotness-based tiering policies prioritize placing hot pages (in "seq") in the fast-tier, while cold pages (in "pc") are relegated to the slow-tier. Figure 1c shows the limitations of this approach. All the performance results are normalized to the fast-tier-only configuration (`All-on-DRAM`), where higher values represent better performance.

❶ Placing "seq" pages in the fast-tier and "pc" pages in the slow-tier (`Hot-on-DRAM`) degrades the performance to 52.4% of `All-on-DRAM`, nearly doubling the runtime.

❷ Placing cold "pc" pages in the fast-tier and hot "seq" pages in the slow-tier (`Cold-on-DRAM`) achieves a 34% performance gain over the "ideal" hotness-based placement in ❶.

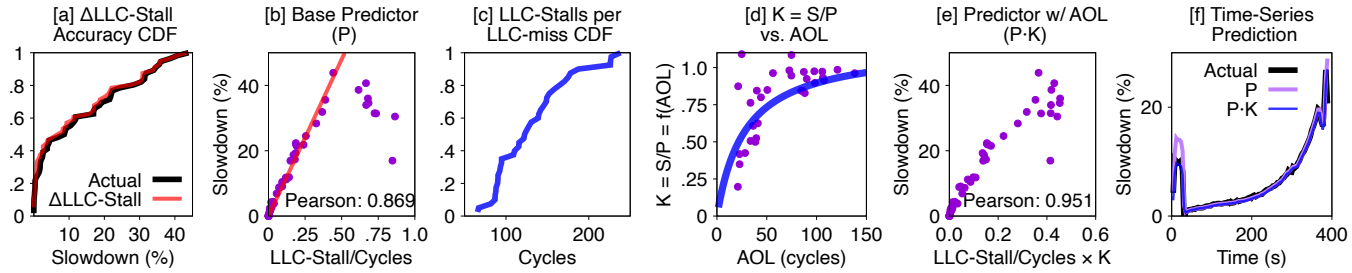

Figure 2: **AOL-based performance prediction (§3).** *(a) shows that LLC-Stalls effectively captures workload performance slowdowns on the slow-tier. (b) presents the base predictor (P) based on LLC-Stalls, but tends to overestimate slowdowns for high-MLP workloads. (c) reveals the average stalls per LLC-miss can vary by 4× across workloads. (d) models the workload-specific correction factor K as a function of AOL; the blue curve fits the observed hyperbolic relationship. (e) integrates K into the base predictor, yielding an AOL-based predictor that significantly improves prediction accuracy. (f) demonstrates that the AOL-based predictor generalizes to fine-grained time-series prediction.*

❸ When all pages are placed in the slow-tier (`CXL` bar), the performance is 47.4%, only slightly worse than ❶. Despite lower access frequency, the serialized nature of "pc" accesses dominates workload performance.

❹ State-of-the-art tiering designs such as Colloid, Nomad, and TPP underperform the `Cold-on-DRAM` setup, despite employing various optimizations.

❺ State-of-the-art also underperforms NoTier, a baseline that relies solely on the first-touch allocation policy without proactive page migrations. They fall behind NoTier by 12–14% and trail the ideal `All-on-DRAM` by 40%. This demonstrates that tiering can degrade performance due to the migration overhead and failure to identify truly performance-critical pages, which is not uncommon in real-world (§6).

The results highlight the inherent limitations of frequency-based hotness metrics and the corresponding hotness-driven tiering policies, where both incorrect data placement and migration overhead lead to suboptimal system performance.

3 Memory Performance Prediction

In this section, we define the Amortized Offcore Latency (AOL) metric for estimating the performance impact of slow-tier accesses, and demonstrate that AOL is accurate and adaptive across workloads at fine granularity.

3.1 Relating Slow-tier Performance to CPU Stalls

We begin with an offline slowdown analysis of 56 workloads from SPEC CPU 2017 [41] and GAPBS [42]. We measure the slowdown of each workload on the slow-tier compared to the fast-tier, and collect key CPU performance counters (Table 1) for intra- and inter-workload analysis.

We find that *performance degradation on the slow-tier is predominantly caused by increased CPU stalls due to LLC misses*, which we refer to as `LLC-Stalls` (or s_{LLC} for simplicity) [11, 43]. The slowdown (S) can be approximated as: $S = \frac{\Delta c}{c} \approx \frac{\Delta s_{LLC}}{c}$, where c is the number of CPU cycles on fast-tier, and Δs_{LLC} is `LLC-Stalls` increase on the slow-tier.

Table 1: **Intel PMU counters for AOL predictor (§3).** `ORO` is short for `OFFCORE_REQUESTS_OUTSTANDING`. Requests are demand reads.

s_{LLC}	`CYCLE_ACTIVITY.STALLS_L3_MISS`, # of LLC stall cycles
c	`CPU_CLK_UNHALTED.THREAD`, # of cycles
A_1	`ORO.CYCLES_WITH_DEMAND_DATA_RD`, cycles w/ pending requests
A_2	`ORO.DEMAND_DATA_RD`, # of pending requests per cycle
A_3	`OFFCORE_REQUESTS.DEMAND_DATA_RD`, # of requests to uncore

It is important to distinguish `LLC-Stalls` from LLC misses. While LLC misses count how often memory accesses reach fast-tier/slow-tier, `LLC-Stalls` measure the *actual stalled CPU cycles* waiting on such memory accesses. Thus, `LLC-Stalls` offer a more direct and actionable signal of slow-tier impact on application performance. Due to the 2–3× latency increase of the slow-tier [8, 22], each LLC miss results in more stall cycles, making `LLC-Stalls` a natural proxy for slowdown. Figure 2a shows the CDFs of actual and predicted slowdowns using $\frac{\Delta s_{LLC}}{c}$ for all the 56 workloads. Estimated slowdowns deviate by less than 4% from measured values, confirming that the added CPU stalls induced by slow-tier accesses largely explain workload slowdowns.

3.2 LLC-Stalls for Performance Prediction

While $\frac{\Delta s_{LLC}}{c}$ accurately estimates slowdown, computing Δs_{LLC} requires measuring workload performance on both the fast-tier and the slow-tier, limiting its use to offline settings. To enable online prediction, we simplify it using the fast-tier metric $\frac{s_{LLC}}{c}$ based on the following observation.

Our analysis shows that Δs_{LLC} and s_{LLC} are strongly correlated: workloads with high `LLC-Stalls` on the fast-tier tend to incur proportionally more stalls on the slow-tier. This allows us to approximate $\Delta s_{LLC} \approx k \times s_{LLC}$, where k is a constant. Substituting into the slowdown formula, we get $S = \frac{\Delta s_{LLC}}{c} \approx k \times \frac{s_{LLC}}{c}$. We define the base predictor P as $P = \frac{s_{LLC}}{c}$. Figure 2b shows that S and P are strongly correlated across 85% of workloads, with a Pearson coefficient of 0.869. The red line shows the fitted model; purple dots are measured slowdowns offline.

3.3 AOL for Accurate Prediction

Amortized Offcore Latency (AOL). P is accurate for low-MLP workloads but fails to model high-MLP workloads (outliers in Figure 2b). Upon further investigation, P tends to overestimate slowdown for high-MLP workloads (>4 on our platform). This overestimation stems from its implicit assumption that all LLC misses equally contribute to CPU stalls, ignoring the latency-masking effect of MLP. Figure 2c shows that the average `LLC-Stalls` per LLC miss vary significantly across workloads, ranging from 60 to 240 cycles (a 4× difference). High-MLP workloads exhibit fewer stalls per miss, reflecting reduced sensitivity to slow-tier latency.

While MLP's conceptual impact on performance is intuitive, its *quantitative* effect is much harder to model. Naively integrating MLP into the predictor (*e.g.*, $\frac{P}{\texttt{MLP}}$) yields poor correlation with slowdown. Moreover, MLP alone is insufficient for modeling slowdown. Its latency-masking benefits diminish as memory latency increases. To address this, we define $\texttt{AOL} = \frac{\texttt{Latency}}{\texttt{MLP}}$ and use it to enhance the predictor.

AOL-Based Prediction Model. We use AOL to refine the base predictor P by regulating its overestimation for high-MLP workloads. Specifically, we model slowdown as $S = P \times K$, where K **is a function of AOL that quantifies how MLP amortizes the base predictor's overestimation.** K-vs.-AOL is derived via offline cross-workload modeling following an empirical approach. For each workload, given the measured slowdown S and $P = \frac{s_{LLC}}{c}$, we compute $K = \frac{S}{P}$, resulting in the purple data points in Figure 2d (X-axis is AOL and Y-axis is K). The nonlinear relationship between K and AOL indicates that MLP does not scale down P by a constant factor. This aligns with intuition, doubling MLP from 2 to 4 does not yield a 2× performance gain, as modern CPUs employ various latency-hiding optimizations that complicate MLP's direct impact on slowdown.

Observing that K follows a hyperbolic trend with asymptotic growth behavior [44], we fit the curve using $K = f(\texttt{AOL}) = \frac{1}{a+\frac{b}{\texttt{AOL}}}$, where a and b are constants. The resulting fit is shown as the blue curve in Figure 2d. Importantly, a and b are hardware-dependent (*e.g.*, CPU and memory) but workload-independent. They can be calibrated offline using microbenchmarks with extreme access patterns (*e.g.*, sequential vs. pointer-chasing), which represent two ends of the MLP spectrum, as discussed in §2.1. Users do not need to repeat the extensive benchmarking process we performed to profile and model $K = f(\texttt{AOL})$. This makes the model easy to deploy across platforms, enabling fast and accurate online prediction with minimal profiling overhead. Figure 2e shows that AOL significantly improves prediction fidelity, achieving a Pearson correlation of 0.951 (closer to 1 indicates stronger linear relationship). While our model is not perfect, evidenced by an outlier in the bottom right of Figure 2e, it generalizes well across diverse workloads (§6). We leave more accurate modeling to future work [43].

Lightweight Measurement. All components needed for AOL and the AOL-based predictor are derived from just four hardware counters (Table 1): A_1, A_3, c, and s_{LLC}.

❶ $\texttt{Latency} = \frac{A_2}{A_3}$, where A_2 is the accumulative number of inflight requests per cycle and A_3 is total requests to uncore.
❷ $\texttt{MLP} = \frac{A_2}{A_1}$, where A_1 counts cycles with ≥1 inflight request.
❸ $\texttt{AOL} = \frac{\texttt{Latency}}{\texttt{MLP}} = \frac{A_1}{A_3}$.
❹ Base predictor $P = \frac{s_{LLC}}{c}$ measures stall pressure.
❺ We compute $K = \frac{S}{P}$ and model it with $K = f(\texttt{AOL}) = \frac{1}{a+\frac{b}{\texttt{AOL}}}$.
❻ Final predictor is

$$S = P \times K \approx \frac{s_{LLC}}{c} \times \frac{1}{a+\frac{b}{\texttt{AOL}}}$$

Here, AOL captures how MLP and memory access latency jointly shape performance.

AOL vs. Slowdown. We now present the properties of $K = f(\texttt{AOL})$ and how it relates to slowdown via $S = P \times K$, by analyzing the (blue) curve in Figure 2d. The observed AOL range spans mostly (0, 130] cycles, with K values in mainly (0, 1] on our testbed (§6). This formulation captures how AOL reflects the impact of CPU stalls on slowdown: as AOL increases (*i.e.*, high latency or low MLP), K approaches its upper bound of 1, making S nearly linear with P. Conversely, small AOL values (*e.g.*, high MLP) indicate that most stalls are masked, yielding smaller slowdowns with K closer to 0.

The curve also reveals diminishing returns at high AOL. For 70% of workloads with AOL below 90 cycles, K increases steeply from 0.2 to 0.8, indicating that P requires significant correction only when AOL is low. A small K (*e.g.*, 0.5) implies that P must be scaled down by 2× to match observed slowdown. In contrast, the remaining 30% of workloads with higher AOL require less than 20% adjustment, suggesting that raw stall time already tracks slowdown closely. When memory bandwidth is unconstrained and latency is stable, MLP becomes the dominant factor in AOL and thus drives K, quantifying its direct influence on slowdown.

AOL remains effective even under bandwidth contention. Under bandwidth pressure, queuing delays inflate latency, which raises AOL. This behavior reflects the growing performance cost, for both latency- and bandwidth-bound workloads.

Time-Series Prediction. Beyond workload-level modeling, the AOL-based predictor supports fine-grained, time-series slowdown prediction. This enables accurate performance estimation over short execution intervals, essential for adaptive, online/offline tiered memory management (§4–§5). Figure 2f shows the prediction results for a graph workload (`tc-twitter`). Compared to the base predictor P (pink), which fails to capture the dynamics, especially in the first ~50s, the AOL-based predictor $P \cdot K$ (blue) closely matches the actual slowdown (black), demonstrating its effectiveness for interval-level prediction.

Next, we show how AOL and its predictors can be used to guide data placement and migration in tiered memory systems.

4 SOAR: Rank-based Static Object Allocation

Existing tiered systems rely on the first-touch policy, supplemented by LRU-based page reclamation to maximize fast-tier usage [4, 45]. We argue *tiered memory allocation should prioritize performance-critical objects for fast-tier placement.*

We seek a **near-optimal** initial object placement strategy, *eliminating* the need for costly page migrations. Achieving this requires capturing object-level performance contributions across diverse object types and temporal dynamics. To this end, we introduce **SOAR**[1], an AOL-driven profiling-guided memory allocation policy based on object rankings according to their accumulative contribution to workload performance.

While AOL-based prediction (§3) is effective at the workload level, it falls short for individual objects due to the semantic gap between architectural events (Table 1) and object-level memory accesses. We develop a novel object-level profiling algorithm that refines AOL-based performance prediction to operate at object granularity. The key insight is to distribute CPU stalls across objects proportionally to their relative access frequencies based on the observed MLP and latencies, thereby approximating each object's performance impact to application performance accurately.

4.1 Object-Level Performance Profiling

Figure 3 (❶–❽) illustrates SOAR's profiling workflow, which periodically collects and processes three types of metrics: object metadata via object tracking, memory accesses via PEBS-based LLC-miss sampling, and temporal performance via AOL-based prediction. SOAR's key innovation lies in associating these data streams to derive a quantified per-object performance impact (a "score") for ranking. SOAR profiler runs the workload *once* on the fast-tier to gather all required metrics with minimal performance overhead.

4.1.1 Object Profiling

We now describe the three data flows used for SOAR's object profiling in detail.

Object Tracking/Flow (F_O, ❶→❷): We track object metadata to analyze usage patterns. Using `LD_PRELOAD`, we intercept (de)allocations via `malloc()/free()` and `mmap()/munmap()`. For each object, we record its lifespan ($[T_{\text{alloc}}, T_{\text{free}}]$), virtual address (`vaddr`), size, allocation `type` such as `malloc()` or `mmap()`. We group objects by call chain via `backtrace()`, treating those with identical call stacks as the same object type, as they originate from the same code path and share access patterns. (De)allocations are then matched by `vaddr`, with each object represented as a five-element tuple, forming the object flow (F_O).

Memory Access Tracking/Flow (F_M, ❸→❹): We use Intel Processor Event-Based Sampling (PEBS) to track the temporal and spatial distribution of memory accesses. Specifically, we sample LLC misses, recording the access timestamp (T) and virtual address (`vaddr`). High-fidelity sampling is unnecessary: a low sampling rate (*e.g.*, 3000) suffices, imposing negligible overhead and avoiding timing skew, which is critical for profiling short-lived objects. Each PEBS sample forms an entry in the memory access flow (F_M).

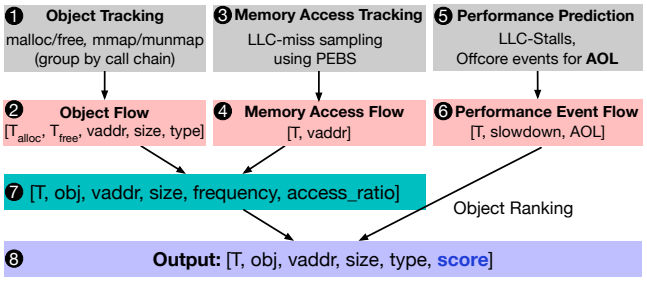

Figure 3: **SOAR profiling (§4.1).** *SOAR tracks multiple flows of information to derive object rankings based on performance impact.*

Performance Analysis/Flow (F_P, ❺→❻): We leverage AOL-based prediction to estimate memory access performance impact (§3). Performance is sampled periodically over workload execution (*e.g.*, every one second, configurable). Each sample forms an entry in the performance flow (F_P), including the timestamp, predicted performance, and AOL.

4.1.2 Unifying Object Flows

Next, we unify the three flows (F_O, F_M, F_P) for analyzing object characteristics and convert them into a comprehensive per-object performance profile.

We first merge F_O and F_M to associate memory accesses with objects. If the timestamp and address of a memory access in F_M fall within the lifecycle and address range of an object in F_O, the memory access is attributed to the corresponding object. All memory accesses in F_M are examined and matched to objects in F_O, constructing a memory access time-series flow (T_M) for each object (O).

For each object, the time-series flow (T_M, ❼) is generated over its lifetime. Each entry in T_M includes the timestamp, ID, address, size, and *access frequency* between the current and previous timestamps. After constructing all T_M data flows, the number of memory accesses (c) to each object during each profiling period can be computed. The memory access ratio (R) for each object is defined as $R = \frac{c}{\sum_i c_i}$. It represents the weight of an object's memory accesses relative to the total memory accesses, which will be used to assign object-level performance slowdowns (§4.2).

We then merge T_M with F_P to associate the predicted performance metrics with each object. The time-series predicted performance is derived from the performance events flow (F_P), where the predicted performance and AOL are computed for each time interval, along with the timestamp, forming the time-series performance flow (T_P). By combining T_M and T_P (Algorithm 1, §4.2), the predicted performance and AOL are associated with live objects during each time

[1] SOAR stands for **S**tatic **O**bject **A**llocation based on **R**anking.

Algorithm 1 Object scoring (every profiling period)

Input: 1) Access ratio (R); 2) Predicted perf (p); 3) AOL (l)
Output: Object score (s).

1: `factor` = $F(l)$ ▷ *Decide perf scale-factor based on AOL*
2: **if** $R < R_{min}$ and $l < L_0$ **then**
3: $s = R \times p \times$ `factor` ▷ *Low-MLP object*
4: **else if** $R > R_{max}$ and $l < L_0$ **then**
5: $s = R \times p$ / `factor` ▷ *High-MLP object*
6: **else**
7: $s = R \times p$ ▷ *MLP=1, even hotness*
8: **end if**

period. This process results in a comprehensive time-series object flow/profile (T_O, ❽) constructed for each object.

4.2 Object Ranking

The object ranking process quantifies each object's cumulative contribution to workload performance over its lifetime. For all active objects during a profiling interval, and given the predicted workload performance (§3.3), the core challenge is attributing performance impact to individual objects. This is non-trivial because modern hardware does not provide mechanisms to directly measure per-object performance contributions. While the AOL-based predictor accurately estimates slowdown at the workload level, it does not bridge this granularity gap. Furthermore, current CPUs do not expose per-access CPU stall information, making fine-grained attribution infeasible. Soar employs a simple yet effective heuristic: it estimates relative object contributions based on MLP and access frequency, detailed in Algorithm 1.

In an extreme scenario with no memory overlapping effect during the time period (*i.e.*, MLP=1), the predicted performance slowdown can be distributed proportionally to the memory accesses (c) for each object. Let the predicted performance slowdown for the period be p. The score for each object is then computed as $p \times R$ (Lines 6–7). This is true because each memory access contributes equally to the overall predicted performance slowdown under MLP=1.

When memory overlapping effects are significant (high MLP), objects with a higher number of memory accesses dominate the memory overlapping behavior. Their performance contributions (and scores) should be amortized to account for their likely higher MLP compared to other objects. This scenario corresponds to Lines 4–5 in Algorithm 1. Similarly, for objects with lower MLP, their average per-access performance contribution is higher than that of objects with higher MLP. Therefore, their scores should be scaled up to reflect this increased performance contribution (Lines 2–3).

R_{min} and R_{max} are used to differentiate high- and low-frequency accessed objects. The "hot" objects are more likely to be affected by memory overlapping when AOL is low, while the scores of "cold" objects need to be scaled up. For example, Figure 1b illustrates an extreme case: the score of a pointer-chasing object should be higher than that of a sequential object due to the low AOL. L_0 is the threshold used to determine whether the current time period exhibits significant MLP. This threshold is derived from our microbenchmark results, which establishes the relationship between K and AOL in Figure 2d. For instance, when AOL is more than 100 cycles, K stabilizes to a constant, thus we set L_0 to be 100.

The scale factor $F(l)$ (Line 1) adjusts per-object performance estimates based on access frequency (§3.3), analogous to how K in Figure 2d amortizes latency at the workload level. We use AOL to determine this scaling factor. When AOL is low, we set the factor to 8, corresponding to the MLP of access patterns with high parallelism (*e.g.*, the sequential microbenchmark in §2, which has MLP=7). Dividing an object's access count by 8 effectively cancels out the masking effects of MLP. For objects with very low access frequency (*e.g.*, pointer-chasing), we amplify their estimated performance impact by multiplying their access count by a factor between 2 and 8, determined by a stepwise function of the observed AOL (higher AOL corresponds to a larger factor). We later show that a similar approach is also effective for regulating page migrations in §5.

Aggregating per-interval scores across all time intervals for each object is straightforward: Once a score (s) is assigned to an object at a given time interval, it is accumulated over the entire lifecycle of that object type. This approach aligns with the memory allocator's primary objective, minimizing performance degradation when allocating objects by ensuring that all performance contributions are accounted for. This contrasts with online tiering policies, which often prioritize recent accesses by giving them more weight [17, 19].

After the entire process is complete, each object type is assigned a score s. To account for varying object sizes, a unit score is introduced as $s' = \frac{s}{\texttt{sizeof}(O)}$. When comparing two objects with the same score s, the larger object is less valuable to place on fast-tier due to its lower unit score.

4.3 Object Allocation

Soar allocation decision is based on the rank of objects by their unit scores. It aims to place the top-N objects in fast-tier, where it tries to maximize N while ensuring that the total size of the top-N objects does not exceed fast-tier size. Since fast-tier size does not always match the total size of the top-N objects, we attempt to bind as many top-ranking objects to fast-tier as possible from a sorted list of objects $(O_1, \ldots, O_n)$ with unit scores $(s'_1, \ldots, s'_n)$ in descending order, where $s'_i \geq s'_{i+1}$. For short-lived objects that may be interleavingly allocated with others, the sum of their occupied size on the fast-tier is taken as the maximum of their individual sizes. If free space is insufficient to fully accommodate the next top-ranking object when the request arrives, Soar falls back to the first-touch approach: the object is placed in the fast-tier first and spills over to the slow-tier when the fast-tier becomes full.

The sorting order of objects by unit scores does not necessarily correspond to the order of their allocation requests. For instance, the $(k+1)^{\text{th}}$ ranked object may be allocated before some of the top-k objects. In such cases, pages of the $(k+1)^{\text{th}}$ object are demoted to the slow-tier until enough space becomes available in the fast-tier for the top-k objects. Page demotion is triggered only when space is insufficient for objects that's destined to stay in fast-tier, making the total demotion overhead low as it occurs rarely. Objects that are neither fully nor partially allocated to the fast-tier are allocated to the slow-tier.

We use `numa_alloc()` from `libnuma` to overload memory allocation functions and bind allocations to the fast-tier/slow-tier. Objects that can be flexibly placed on either tier retain their original allocation path without being overloaded. This approach requires no changes to application code, making SOAR non-intrusive and easy to use. To identify which allocation should be redirected, SOAR inspects the call chain at each allocation site to distinguish object types. It supports various languages (*e.g.*, C/C++, Python) and does not depend on specific memory allocators. For example, SOAR can also integrate with heterogeneous memory-aware allocators such as `memkind` [46, 47], which mitigates potential fragmentation for small objects, as `numa_alloc()` operates at page granularity.

4.4 Use Cases and Limitations

Modern applications such as graph processing, ML/AI, and HPC often pre-allocate objects that persist for extended periods, making them ideal candidates for SOAR. Although SOAR adopts static allocation based on offline profiling, it can be extended to support online profiling for long-running workloads. One approach is to use past profiling data to predict future object performance.

Although SOAR requires a single run of the workload on the fast-tier for profiling object scores, profile-guided optimization is a widely adopted practice for improving datacenter efficiency [48–50]. Another limitation is that the current SOAR ranking algorithm assumes uniform memory access distribution across each object, leaving room for future optimizations for objects with heterogeneous access patterns.

5 ALTO: AOL-based Adaptive Page Migrations

In this section, we show that AOL can also address a key bottleneck in existing tiering designs: excessive page migrations that disregard performance impact, leading to unnecessary overhead and degraded performance. By prioritizing the migration of performance-critical pages and filtering out less impactful ones, AOL improves overall tiering efficiency.

5.1 ALTO Overview

Existing tiering designs adopt aggressive page migration strategies: when a "hot" page is detected, it is immediately promoted to the fast-tier, either because space is available or by demoting cold pages to make room. This policy has several drawbacks. *(a)* Migrating hot but non-performance-critical pages yields no benefit, as these accesses do not induce CPU stalls. *(b)* Page migrations are long-latency, blocking operations that impose substantial overhead. Per our measurements, migrating a page takes on average 12µs, during which application threads are stalled if they access the migrating page. *(c)* This challenge is exacerbated on CXL, where the latency and bandwidth gap with DRAM is narrowing, making tiering overhead more pronounced. Consequently, many state-of-the-art tiering systems underperform even naive first-touch-based baselines due to excessive migration overhead. *(d)* Worse, performance-critical cold pages are often ignored by access-frequency heuristics, missing opportunities for performance gains. These limitations call for a fundamental reassessment of assumptions in current tiering policies.

Ideally, pages should be migrated only when they are truly performance-critical, and unnecessary migrations should be avoided when the workload is insensitive to slow-tier accesses.

To address these issues, we propose **ALTO**[2], an adaptive tiering orchestration policy that dynamically regulates page migration intensity. ALTO leverages the AOL metric to detect periods of high memory access overlap, during which slow-tier accesses have minimal performance impact. By filtering out non-critical migrations, ALTO reduces overhead and improves overall performance. ALTO is lightweight and easily integrates into existing tiering systems, enhancing efficiency without requiring major architectural changes.

Non-Goal: While integrating AOL to track per-page performance and design AOL-centric migration policies is promising, it presents unique challenges, particularly in estimating page-granular performance using coarse-grained counters (out of scope for this work). We plan to explore the broader tiering design space enabled by AOL in future work.

5.2 ALTO Design

Leveraging AOL, ALTO regulates page migrations when the overlapping effect of memory accesses (high MLP) is evident. In other words, we can use AOL to identify non-performance-critical periods and adjust the intensity of tiering operations accordingly. The detailed ALTO page migration regulation scheme is shown in Algorithm 2.

Let us first consider the case where memory bandwidth is not a bottleneck, so offcore latency remains stable and low, making MLP the dominant factor in AOL.

(a) Low AOL: Low AOL indicates high MLP, meaning memory latency is largely masked and potential slowdown is minimal. In this case, there is less need for page promotions. ALTO limits the rate of hot page detection, page migrations, or both, to reduce unnecessary overhead.

(b) High AOL: High AOL suggests serialized, latency-sensitive memory accesses where correct page promotions

[2] ALTO stands for **A**OL-based **L**ayered **T**iering **O**rchestration.

Algorithm 2 AOL-regulated page migrations (*e.g.*, every 1s)

Input: $\texttt{AOL}_{\texttt{low}} \leftarrow 40$, $\texttt{AOL}_{\texttt{high}} \leftarrow 100$ ▷ *Profiled offline*
Output: Adjusted page migration ratio (`Scale`).

```
1: Profile the current AOL (l)
2: if l ≤ AOL_low then
3:     Scale ← 0                          ▷ Disable page promotions
4: else if l ≥ AOL_high then
5:     Scale ← 1                          ▷ Enable all page promotions
6: else
7:     Scale ← F(l)                       ▷ Partial page promotions
8: end if
```

can yield significant performance gains. Alto responds by enabling more aggressive page detection and migration to alleviate critical bottlenecks.

Based on the above observations, Alto employs two AOL thresholds to guide page migration regulations: a lower bound ($\texttt{AOL}_{\texttt{low}}$) and an upper bound ($\texttt{AOL}_{\texttt{high}}$). When AOL falls below the lower bound, Alto limits or disables tiering operations to reduce overhead (Lines 2–3). When AOL exceeds the upper bound, Alto enables full-speed tiering operations (*i.e.*, no change to the default tiering migration policy, Lines 4–5).

Since the impact of AOL on performance follows a hyperbolic curve (Figure 2d), where small changes near the lower bound can lead to large performance differences (§3.3), a more fine-grained approach could involve dynamically adjusting tiering intensity based on the observed AOL value. This enables more nuanced and adaptive tiering decisions to better capture workload dynamics. We use a stepwise function to adjust page migration intensity. Specifically, Alto gradually reduces the page promotion rate as AOL decreases while AOL falls within $[\texttt{AOL}_{\texttt{low}}, \texttt{AOL}_{\texttt{high}}]$ (Lines 6–7). The function $F(l)$ (Line 7) mirrors the procedure used to determine the performance scale factor $F(l)$ in Algorithm 1 in Soar (§4).

The AOL thresholds in Alto are derived from the blue curve in Figure 2d, modeled as $K = f(\texttt{AOL}) = \frac{1}{a+\frac{b}{\texttt{AOL}}}$. We use an empirical approach based on two microbenchmarks representing extreme MLP cases: a pointer-chasing workload for low MLP and a sequential workload for high MLP (§2). These benchmarks yield low/high AOL values of 40/100 cycles and 25/95 cycles on our two experimental platforms. We conduct detailed sensitivity studies on these values in §6.

5.3 Alto Integration with Existing Tiering Systems

Alto can be seamlessly integrated into existing tiering systems, such as TPP [4], NBT [36, 37], Nomad [22], and Colloid [23], to enhance their efficiency and reduce overhead. This integration is straightforward as Alto builds upon their existing policies. Below, we provide a brief overview of how Alto can be incorporated into these systems.

Alto+TPP. TPP is a state-of-the-art tiering design for CXL, which adopts page reclamations for pages demotions and NUMA hinting faults for page promotions with a set of aggressive heuristics to identify hot pages. We implement Alto+TPP by constraining the page promotion rate proportionally to AOL based on offline-profiled thresholds.

To gradually reduce page promotion rate as AOL decreases, in our implementation, Alto+TPP periodically ignores certain potential promotion candidate pages. For instance, if we aim to allow 20% of TPP-identified candidate pages to be promoted, we allow the first two pages of every 10 pages to go through.

To monitor AOL, we utilize Linux `perf` to collect the CPU counters periodically (Table 1), *e.g.*, every 1s. Subsequently, we calculate AOL based on these counters, enabling us to dynamically adjust the page promotion rate based on the observed AOL. Our user-level tool is lightweight and imposes no additional overheads. The kernel side only involves ~30 LOC changes to page migration policies in the Linux memory subsystem. We use a default AOL sampling period of 1s for Alto. While lower sampling period possibly enables more fine-grained Alto-based migration regulations and better performance, we find that 1s is sufficient to capture AOL and workload dynamics.

Alto+NBT, Alto+Nomad, and Alto+Colloid. Unlike TPP, NBT, Nomad, and Colloid adopt less aggressive page migration strategies. They rely on NUMA hinting faults for tracking page accesses, which functions similarly to standard NUMA balancing (*i.e.*, AutoNUMA [51]). Their page scanning mechanism sequentially examines all Virtual Memory Areas (VMAs) in each process. During VMA scanning, the system sets each page's flag to `PAGE_NONE`. Subsequently, when a page is accessed, a minor page fault is triggered. If the page resides on a node other than its preferred node, it is marked as a candidate for migration to the preferred node.

In both NBT and Nomad, only pages located in the slow-tier are scanned, with the fast-tier serving as the preferred node for all pages. To optimize this process, we implement Alto by limiting the number of pages set to `PAGE_NONE` during periods of significant memory access overlapping (low AOL), effectively regulating promotions. Colloid samples pages in both tiers following the same mechanism. For Alto+Colloid, we only regulate page migrations from slow-tier to fast-tier.

6 Evaluation

Our evaluation seeks to answer three key questions: (1) How do Soar (§6.2–§6.4) and Alto (§6.5–§6.7) compare to state-of-the-art tiering policies? (2) How sensitive are their performance gains to AOL threshold choices? (§6.8) (3) How do they perform under bandwidth contention? (§6.9–§6.10)

6.1 Experimental Setup

We evaluate Soar and Alto on two platforms. The first is a CloudLab dual-socket Intel Skylake server (**"SKX"**) with two 10-core CPUs and 96 GB DDR4 DRAM per socket [52]. We emulate CXL by lowering the uncore frequency and

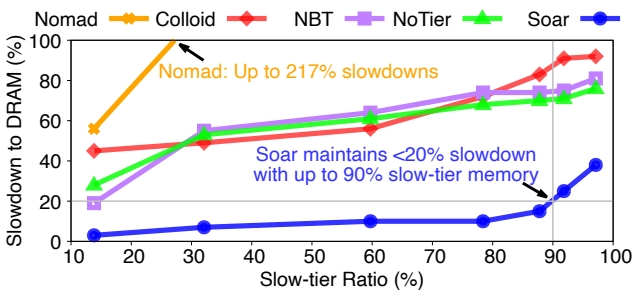

Figure 4: **Soar on SKX/NUMA (§6.2).** *Soar consistently outperforms all other schemes under bc-urand across various slow-tier ratios, whereas state-of-the-art approaches frequently underperform, even compared to NoTier, especially under higher slow-tier ratios.*

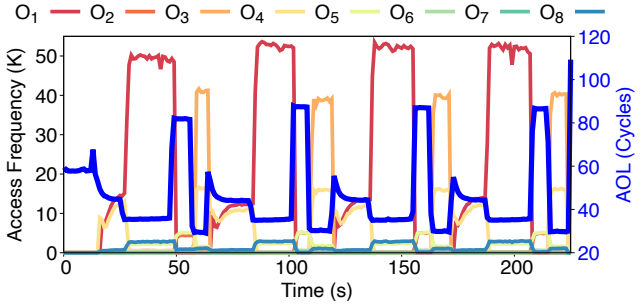

Figure 5: **Object-level accesses and AOL in Soar (§6.2).** *High object access frequency correspond to low AOL and cross-object access frequency correlates with MLP, which can be used to approximate object performance.*

disabling cores on one NUMA node, resulting in fast/slow-tier latencies of 90/190 ns (2.1×) and bandwidths of 49/17 GB/s. The second platform is a local Intel Sapphire Rapids server (**"SPR"**), with a 32-core CPU per socket, 192 GB DDR5 DRAM, and an ASIC-based 128 GB CXL memory expander (PCIe 5 ×8). Fast/slow-tier latencies are 114/271 ns (2.4×), and bandwidths are 218/26 GB/s.

We compare Soar and Alto against TPP [4], Nomad [22], NBT [36–38], Colloid [23], and a first-touch-only baseline ("NoTier"). NBT is the successor to AutoNUMA in Linux, with upstreamed optimizations from TPP. Colloid provides three implementations built on top of HeMem [17], Memtis [19], and TPP. We use the Colloid implementation built on top of TPP, which includes CXL-specific optimizations. **Performance is reported as slowdown relative to fast-tier-only (DRAM) performance**, which provides a fair and consistent comparison across various target systems. Lower slowdown (closer to 0) indicates better performance. None of the tiering systems outperform the fast-tier-only configuration.

Our workloads span graph analytics [42], machine learning [53], caching [54], and HPC [41], running under various fast/slow-tier ratios (mainly 10–90%, relative to workload's RSS). Each workload runs with 8 threads by default (unless otherwise noted), with bandwidth usage of 2.3–21 GB/s and RSS of 8–35 GB. We present detailed results for a few representative graph workloads and summarize the rest later.

6.2 Soar for Graph Processing

`bc-urand` is a betweenness centrality workload from the GAPBS benchmark suite [42], executed on a synthetic uniformly random undirected graph. We use the default configuration, which generates a graph with 134 million vertices and 2147 million edges. The algorithm estimates centrality by computing shortest paths from a subset of source vertices, resulting in irregular and sparse memory accesses. Its memory footprint is ~20 GB. The combination of large working set size (~17 GB) and random access patterns makes `bc-urand` a representative stress test for tiered memory systems. Figure 4 shows detailed Soar performance results compared to state-of-the-art tiering systems across various slow-tier ratios.

Table 2: **Soar object statistics and rankings (§6.2).** *The object information includes size, lifetime, access frequency, and computed Soar score. Rankings are provided based on three distinct criteria: First-touch (FT), Frequency (Freq), and Soar.*

#	Obj	Size	Time	Freq	Score	Ranking		
						FT	Freq	Soar
O_1	5fb2	536MB	139s	4.7M	$3.5e^{-8}$	8	1	1
O_2	6d68	536MB	208s	201K	$1.9e^{-8}$	6	6	2
O_3	6fe7	536MB	60s	1.3M	$1.8e^{-8}$	10	2	3
O_4	6d27	1073MB	208s	1.2M	$1.7e^{-8}$	5	3	4
O_5	b69c	1073MB	208s	420K	$1.4e^{-8}$	3	4	5
O_6	6cc3	536MB	208s	20.3K	$1.7e^{-9}$	4	7	6
O_7	6db6	536MB	208s	309K	$1.2e^{-9}$	7	8	7
O_8	b62e	17GB	223s	313K	$5.3e^{-10}$	2	5	8
O_9	5c24	327KB	14s	0	0	9	9	9
O_{10}	b5fb	1073MB	139s	0	0	1	10	10

Takeaway #1: *Soar outperforms all baselines under bc-urand across all slow-tier ratios. Soar maintains less than 20% slowdown even under 90% slow-tier memory, demonstrating robust performance under aggressive tiering conditions.*

In contrast, Nomad suffers up to 217% slowdown, and both NBT and Colloid degrade steadily (>60% slowdown) as the slow-tier ratio increases. Under high slow-tier ratios (>80%), all tiering baselines underperform NoTier by 10–20% due to excessive page migrations. Soar is the only system that outperforms NoTier consistently. We defer a detailed analysis of the inefficiencies in existing tiering designs to §6.5. These results highlight the effectiveness of Soar's performance-criticality-aware object allocation in maintaining good performance even under severe memory pressure.

Understanding Soar object rankings. Table 2 and Figure 5 summarizes the object-level statistics and rankings. The left five columns report each object's ID, address, size, lifetime, and access frequency. The "Score" column reflects the per-object unit-score computed using Algorithm 1, which determines Soar object rankings (Column 9). For comparison, we also include rankings based on first-touch (**"FT"**, Column 7) and frequency-only (**"Freq"**, Column 8) policies.

Table 3: **SOAR object placement (50% slow-tier ratio).**

	Fast-tier	Slow-tier
SOAR	O_1–O_8	O_8–O_{10}
FT	O_{10}, O_8	O_1–O_7, O_9
Freq	O_1, O_3–O_5, O_8	O_2, O_6–O_7, O_9–O_{10}

Object information is as follows: O_8 represents the graph constructed after reading the input data. O_5 is the index generated for the graph. O_1, O_3, O_4, and O_6 are vectors used by `bc` algorithm. O_7 is a shared queue among all threads. O_2 is a bitmap to record the successors of each node during the back-propagation phase. The bitmap is shared by all the threads, but since each thread accesses the entries of the bitmap independently, its access exhibits high MLP.

Table 3 shows that under a 50% slow-tier setup, SOAR places the top seven ranked objects (O_1–O_8) in the fast-tier, while the remaining (O_8–O_{10}) are assigned to the slow-tier (note that O_8 spans both tiers). In contrast, "FT" and "Freq" produce different object placement decisions. NoTier allocates O_{10} and part of O_8 to the fast-tier, while the top six most performance-critical objects are placed in the slow-tier. For frequency-based tiering systems, O_1, O_3, O_4, O_5, and part of O_8 are the likely targets for page promotion (per "Freq" rankings in Table 2). Meanwhile, some pages from O_8 are also likely to be selected for demotion. This simultaneous promotion and demotion of O_8 across tiers incurs unnecessary performance overhead due to the lack of object-level performance awareness.

The MLP characteristics of certain objects can mislead frequency-based ranking and cause incorrect page selection, resulting in additional migration overhead. Such effects are ignored by prior tiering designs. In particular, several objects that are ranked low by SOAR but high by "Freq" exhibit high MLP. For example, O_2 ranks 2^{nd} in unit score in SOAR, but is ranked much lower (6^{th}) by "Freq" and "FT" due to low AOL during its active periods (Figure 5). Prior tiering systems will incorrectly prioritize O_3–O_5 and O_8 over truly performance-critical objects like O_2, reducing the likelihood that these more important objects are promoted to the fast-tier.

Takeaway #2: *Performance-aware object placement in SOAR explains its advantage over state-of-the-art tiering designs, whose overhead is exacerbated by ignoring MLP effects.*

6.3 SOAR on CXL

Figure 6 presents the performance of SOAR and baselines on CXL for `bc-urand`, and the trends mirror those observed on the SKX/NUMA setup (Figure 4). SOAR consistently delivers the lowest slowdown across all slow-tier ratios. Nomad shows severe instability with up to 588% slowdown and Colloid experiences up to 92% slowdown, compared to the worst-case slowdown of only 42% in SOAR. Nomad, Colloid, and NBT lose to NoTier almost uniformly across all slow-tier ratios while SOAR is strictly better than NoTier. These results reaffirm that SOAR is effective and robust across both emulated and real CXL environments.

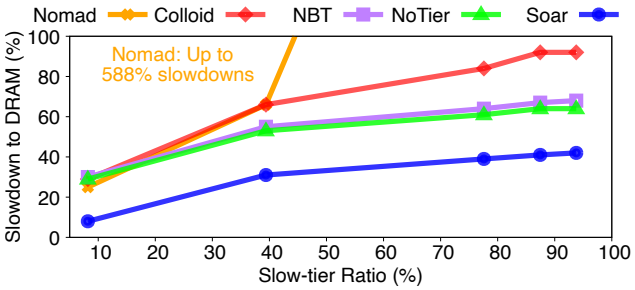

Figure 6: **SOAR vs. others for bc-urand on CXL (§6.3).** *SOAR performance on CXL is similar to that on SKX/NUMA, with SOAR consistently outperforming all baselines across slow-tier ratios.*

Table 4: **SOAR vs. others for more workloads (§6.4).** *SOAR is robust across workloads and consistently delivers better performance compared to existing tiering designs.*

	microbench	bc-urand	bc-twitter	bc-kron	sssp-kron	tc-twitter	603.bwaves
SOAR	34%	16%	7%	18%	14%	7%	4%
Colloid	60%	58%	26%	40%	25%	6%	43%
NBT	58%	68%	13%	59%	18%	11%	13%
Nomad	58%	123%	61%	105%	29%	24%	18%
TPP	58%	875%	495%	792%	760%	38%	1246%
NoTier	46%	67%	63%	55%	39%	9%	9%

6.4 SOAR for More Workloads

Table 4 shows that SOAR consistently achieves the lowest slowdown (up to 18%) across all realistic workloads under a 50% slow-tier ratio. In contrast, state-of-the-art suffer significantly higher slowdowns, with Colloid, NBT, Nomad, TPP, and NoTier reaching up to 58%, 68%, 123%, 1246%, and 67%. "microbench" represents the microbenchmark from §2.1. SOAR outperforms the next best system by 4–42% (except for `tc-twitter`). Even the baseline NoTier outperforms several tiering policies in many cases, highlighting the inefficiencies of page-based migrations. Among all the tiering baselines, no single approach consistently outperforms the others and their performance varies significant across workloads. These results further reinforce the effectiveness of SOAR's performance-aware object allocation across diverse workloads.

Takeaway #3: *SOAR's performance advantage over state-of-the-art and NoTier hold across workloads except for* `tc-twitter` *where SOAR loses by 1% to Colloid.*

6.5 ALTO Performance Evaluation

As the performance of existing tiering designs degrade with increasing slow-tier ratios, we evaluate ALTO with a fast-tier size that is sufficient to accommodate the workload's working set size, as determined by offline profiling, to demonstrate ALTO benefits. This configuration is biased in favor of existing tiering systems. Figure 7a&b compares ALTO with existing tiering policies across a range of workloads on both SKX/NUMA and SPR/CXL. In both environments, ALTO reduces slowdowns

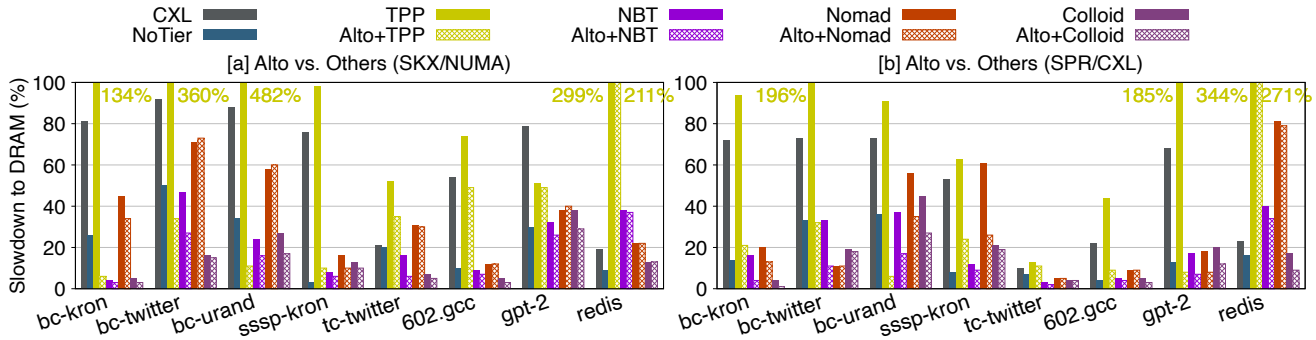

Figure 7: **Alto vs. TPP, NBT, Nomad, Colloid, and NoTier on SKX/NUMA and SPR/CXL across 8 workloads (§6.5–§6.7).** *(a) On SKX/NUMA, Alto+TPP outperforms TPP by 2–471%. Similarly, Alto+NBT outperforms NBT by 1–20%, Alto+Nomad surpasses Nomad by -2–11%, and Alto+Colloid achieves a performance gain over Colloid of 0–9%. (b) On SPR/CXL, Alto exhibits a similar trend to SKX/NUMA, outperforming TPP, NBT, Nomad, and Colloid by 2–178%, 1–23%, 0–35%, and 0–18%, respectively.*

Table 5: **Page promotion reductions of Alto compared to baseline (§6.5).** *Alto significantly reduces the number of page promotions by up to 127.4×.*

	bc-kron	bc-twitter	bc-urand	sssp-kron	tc-twitter	602.gcc	gpt-2	redis
TPP	127.4×	40.0×	83.9×	58.5×	1.5×	2.5×	2.7×	1.8×
NBT	3.5×	1.1×	1.7×	9.4×	1.2×	1.1×	1.9×	1.0×
Nomad	1.2×	2.3×	2.1×	1.4×	1.0×	4.4×	1.3×	1.4×
Colloid	14.9×	1.1×	2.1×	9.2×	1.0×	3.8×	3.7×	1.0×

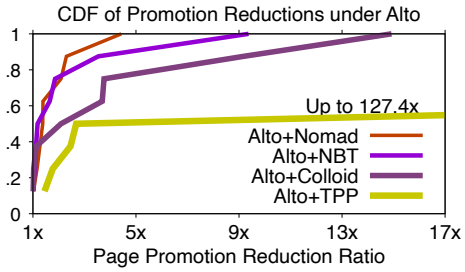

Figure 8: **CDFs of page promotion reductions in Alto (§6.5).** *Alto+Nomad promotion reduction is less than others.*

across all tiering systems (TPP, NBT, Nomad, and Colloid) for majority of the workloads, often cutting performance degradation by more than half. On SKX/NUMA (left), Alto eliminates extreme outliers, resulting in significantly better performance of only 2% slowdown in the best case. On CXL (right), the overall performance trend remains similar: Alto-enhanced policies outperform their baselines across majority of the workloads, highlighting Alto's relative robustness across different system configurations.

Among the four baselines, TPP exhibits the most aggressive migration behavior due to its intensive hot-page detection strategy. As a result, it performs poorly in our evaluation, reaching up to 482% slowdown, which is even worse than running the workloads entirely on the slow-tier ("CXL" bars).

Colloid focuses on balancing fast- and slow-tier latency under bandwidth saturation, based on the observation that fast-tier latency can exceed that of slow-tier in such cases. However, in our setup, none of the workloads saturate fast-tier bandwidth. By design, Colloid adopts a more aggressive page promotion policy than NBT, promoting hot pages not only to the fast-tier, but also to the slow-tier proactively. While this aggressiveness benefits certain workloads, it is not universally effective. As shown in Figure 7, Colloid performs worse than NBT on nearly half of the workloads.

Nomad adopts a non-exclusive page migration strategy, retaining pages in both tiers to avoid blocking migrations. As a result, reducing migration frequency has a more limited impact on performance compared to other systems. Additionally, Alto+Nomad regulates fewer page promotions than Alto with TPP, NBT, and Colloid, as shown in Table 5. These factors help explain the limited performance improvements of Alto+Nomad observed in several workloads. Alto+Nomad can underperform Nomad by up to 2% on several workloads, such as `bc-twitter`, `bc-urand`, and `gpt-2`. The underlying reasons are not yet clear to us and a deeper analysis is needed to understand the root causes as future work.

Alto's adaptive page promotion regulation allows it to filter out unnecessary page migrations, thus achieving better performance than the corresponding baselines. Table 5 and Figure 8 shows the reduction in page promotions achieved by Alto compared to the corresponding baselines across all eight workloads. Alto significantly reduces the number of page migrations by up to 127.4× while maintaining superior performance for most of the cases.

Takeaway #4: *Alto outperforms TPP, NBT, Nomad, and Colloid by 2–471%, 1–23%, -2–35%, and 0–18% across 8 workloads on NUMA and CXL by regulating unnecessary page promotions effectively. Alto+Nomad loses to Nomad for a few workloads by no more than 2%.*

6.6 Understanding Alto Performance

Alto's strength lies in the simplicity and accuracy of its AOL-based predictor, enabling it to significantly reduce page promotion overhead while improving performance. Figure

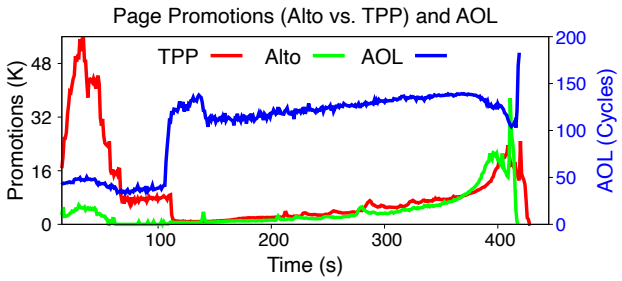

Figure 9: **Page promotions in Alto vs. TPP over time (§6.5–§6.6).** *Alto filters out unnecessary page migrations based on runtime AOL dynamically.*

8 shows the CDFs of reductions in page promotions for Alto compared to the baselines. Specifically, Alto reduces promotions by up to 127.4×, 9.4×, 4.4×, and 14.9× for TPP, NBT, Nomad, and Colloid, respectively.

To better understand this improvement, we zoom in on the `tc-twitter` workload and examine how Alto adaptively regulates promotion behavior. Figure 9 plots the page promotion rate and AOL over time for both TPP and Alto+TPP. Two key observations highlight Alto's effectiveness:

(1) Unlike TPP, which aggressively promotes pages in the first 100 seconds (red line) due to high LLC misses, Alto promotes far fewer pages (green line) during this phase. This is because AOL remains low (blue line), indicating high MLP and limited performance sensitivity to memory latency. By avoiding unnecessary migrations, Alto reduces the number of promoted pages from 1.6 million (in TPP) to just 190K, a reduction of 8.4×.

(2) As the workload progresses, Alto gradually increases its promotion rate in response to rising AOL values, whereas TPP simply follows access intensity without adaptive control. Ultimately, Alto outperforms TPP while migrating 3.5× fewer pages overall.

Other workloads in Figure 7 exhibit similar trends, demonstrating Alto's ability to maintain performance while minimizing migration cost through adaptive, AOL-guided tiering.

6.7 Alto on CXL

Figure 7b details Alto's performance on CXL, which closely mirrors the trends observed on the SKX/NUMA setup (Figure 7a). Across all workloads, Alto improves performance when layered over existing tiering systems, often achieving the lowest slowdown. The performance gains are even more stable on CXL due to improved bandwidth compared to the SKX/NUMA setup. These results highlight Alto's robustness and portability across different hardware configurations. Alto's performance benefits are similarly explanined as Figure 8. Note that while workloads run faster on SPR compared to SKX as the recent SPR CPU is more performant, the slowdown relative to DRAM performance is comparable, or slightly worse, due to the larger fast-tier/slow-tier latency gap (2.4× on SPR vs. 2.1× on SKX).

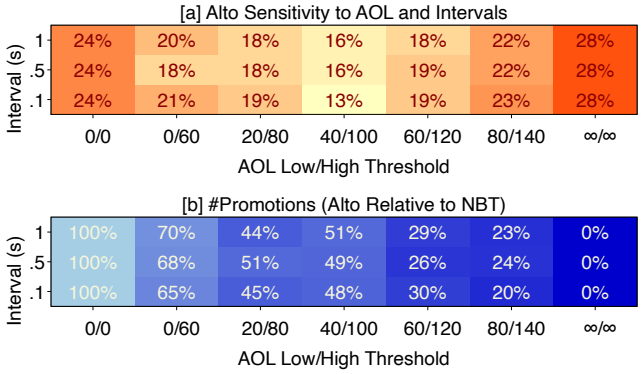

Figure 10: **Alto sensitivity to AOL and sampling intervals (§6.8).** *(a) Alto+NBT performance under varying AOL and intervals. (b) Relative number of promotions in Alto+NBT to NBT.*

6.8 Sensitivity Study

In this section, we study Soar and Alto's sensitivity to AOL and other parameters as well as justifying their default choices.

Soar. Algorithm 1 uses $R_{\min}$, $R_{\max}$, and L_0 as thresholds to incorporate MLP effects into object scoring. We evaluate the sensitivity of Soar to these parameters. Varying L_0 between 70, 80, 90, and 100 cycles results in minimal changes to the object ranking: only the ordering of O_2–O_4 in Table 2 differs. For a 50% slow-tier ratio in `bc-urand`, objects O_1–O_6 and part of O_7 are always placed in fast-tier, yielding identical performance across the full range of L_0 values. This indicates that the maximum AOL threshold in Algorithm 1 is robust.

Similarly, adjusting $R_{\min}$ and $R_{\max}$ to $(0.02, 0.6)$, $(0.03, 0.7)$, and $(0.04, 0.8)$ results in minor changes, only the ranking of O_2–O_5 differs. Since the top objects remain unchanged (under the same slow-tier ratio), the object placement and performance are unaffected, confirming that Soar's scoring is stable under reasonable threshold variations.

Takeaway #5: *Soar is robust to L_0 (from 70 to 100), $R_{\min}$, and $R_{\max}$ (from $(0.02, 0.6)$ to $(0.04, 0.8)$).*

Alto. We evaluate Alto's sensitivity to the AOL thresholds ($\texttt{AOL}_{\texttt{low}}$, $\texttt{AOL}_{\texttt{high}}$), and AOL sampling periods. Figure 10 shows the Alto results under a range of ($\texttt{AOL}_{\texttt{low}}$, $\texttt{AOL}_{\texttt{high}}$) threshold pairs and sampling intervals (100ms, 500ms, 1s).

In Figure 10a, we observe that Alto maintains stable performance across a wide range of threshold values. Slowdown remains within 16–22% for most parameter combinations, indicating robustness to threshold tuning. Extreme thresholds (*e.g.*, $0/\infty$) lead to degraded performance, highlighting the importance of filtering based on AOL to avoid over- or under-migration. Figure 10b shows the relative number of page promotions compared to Colloid. Across most configurations, Alto reduces promotions by 30–70%, while preserving performance. With more conservative AOL thresholds (*e.g.*, 60/120) and shorter sampling intervals, Alto eliminates majority of the page promotions (down to 30%) while still maintaining

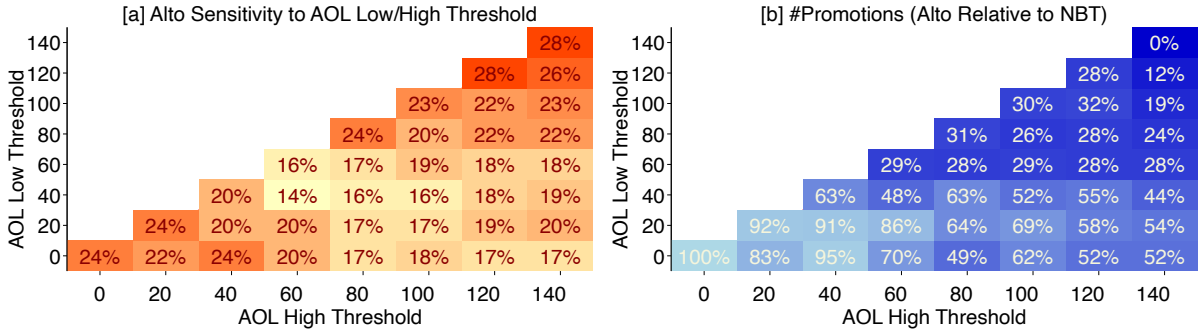

Figure 11: **Alto sensitivity to more detailed AOL low/high thresholds (§6.8).** *(a) Alto's performance can vary by up to 14% across different combinations of AOL low/high thresholds, and its default threshold setting is close to the optimal configuration. (b) Alto reduces page promotions according to AOL low/high thresholds.*

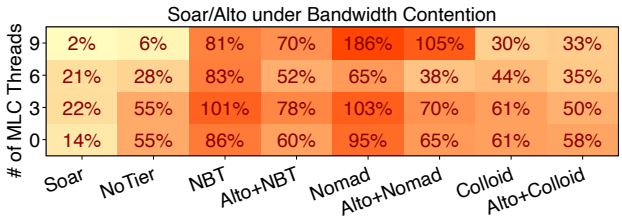

Figure 12: **Soar and Alto performance slowdown under bandwidth contention (§6.9–§6.10).** *Under bandwidth contention, Soar continues to outperform both NoTier and other tiering policies, and Alto+NBT, Alto+Nomad, and Alto+Colloid improve over their baselines by 11–26%, 27–81%, and -3–11%, respectively.*

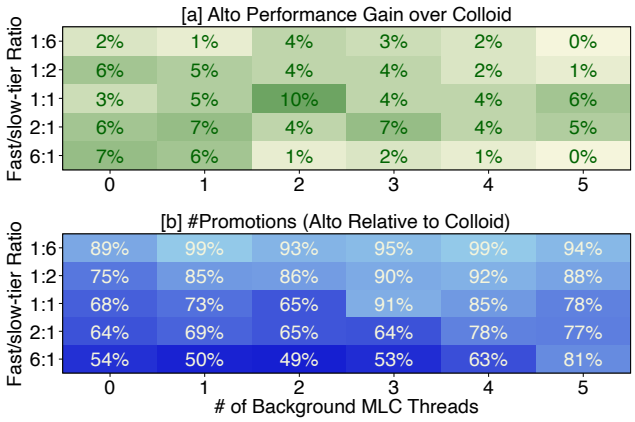

Figure 13: **Alto+Colloid performance gains over Colloid under bandwidth contention and different fast/slow-tier ratios (§6.10).** *Alto+Colloid outperforms Colloid by up to 10% under most fast/slow-tier ratios combined with bandwidth contention.*

acceptable performance (19% vs. 16% slowdown).

Figure 11 shows the sensitivity of Alto to varying AOL low/high threshold values, with combinations ranging from 0 to 140 (observed highest AOL). The two extreme cases (0/0 and 140/140) in Figure 11 represent no promotion regulation (*i.e.*, equivalent to the NBT baseline) and full regulation (*i.e.*, equivalent to NoTier), respectively. Across the threshold range from bottom left to top/bottom right, Alto's performance typically correlates with the degree of regulation: more page promotion regulation (smaller numbers in Figure 11b) generally leads to better performance (smaller slowdowns in Figure 11a). The default setting used by Alto (40/100 on SKX/NUMA) delivers reasonably good, though not optimal, performance (16% vs. 14% slowdown). We observe a maximum performance difference of 14% between 40/60 and 140/140 (NoTier). While the number of regulated promotions generally reflects Alto's efficiency, the exact performance impact of each regulation is hard to isolate and needs further investigation.

Takeaway #6: *Alto is robust to sampling intervals from 100ms to 1s, and its default AOL low/high thresholds are near-optimal, thanks to the accurate modeling of K and AOL.*

6.9 Soar under Bandwidth Contention

To evaluate the performance robustness of Soar to bandwidth pressure, we use Intel MLC [55] to generate memory traffic on the fast-tier by varying the number of threads from 0 to 9 on SKX. Each MLC thread sustains ~8 GB/s. The remaining 1 core is reserved for `bc-urand` with 50% slow-tier ratio. With 9 MLC threads, the bandwidth reaches 48 GB/s, which is 98% of the total bandwidth. Latency increases to 180 ns, 2× of the unloaded latency, demonstrating significant queuing delays.

Figure 12 shows that Soar outperforms the second best by 4–41% under bandwidth contention. As contention increases (0–9 MLC threads), Colloid consistently outperforms Nomad and NBT, but underperforms NoTier, with the performance gap widening under higher contention. This indicates that tiering becomes less effective in bandwidth-bound scenarios. Soar maintains its performance lead over NoTier (the second-best), though its gains diminish as contention intensifies (33% vs. 4% for 3 and 9 MLC threads).

Takeaway #7: *State-of-the-art tiering designs consistently underperform NoTier due to elevated migration overhead under bandwidth contention. In contrast, Soar outperforms all of them on bc-urand, though its performance gains decrease as contention increases, reaching up to 2× inflated latency.*

6.10 Alto under Bandwidth Contention

Figure 13a further compares Alto+Colloid and Colloid under varying fast/slow-tier ratios (ranging from 1:6 to 6:1) in a different MLC setup: 5 cores are reserved for `bc-urand`, and the remaining 5 cores run MLC threads. With 5 MLC threads, the system bandwidth reaches 40GB/s, approximately 81% of the total bandwidth, and latency increases to 140ns, which is 56% higher than the unloaded latency of 90ns.

Under moderate memory bandwidth contention in this case, even though overall system MLP increases, the background memory pressure does not alter the foreground workload's MLP behavior. While contention raises memory latency, it does not reduce the workload's inherent MLP (confirmed via our MLP measurements). However, as MLC threads increase from 0 to 5, the AOL range shifts from 30–140 to 40–250. Alto remains effective at regulating page promotions, as only 14.2% of the runtime experiences AOL above 100. Figure 13a&b supports this claim, showing that Alto+Colloid outperforms Colloid under bandwidth contention while migrating up to 51% fewer pages. While contention narrows the latency gap between tiers (*i.e.*, fast-tier latency approaches that of the slow-tier), the MLP-induced performance penalties of page promotion persist.

When further increasing the number of MLC threads to 9, Figure 12 shows somewhat diminished Alto performance gains over its baseline, in particular, Alto+Colloid vs. Colloid, with -3–81% improvement. Among all the baselines, Nomad shows the worst performance under extreme bandwidth contention, while Colloid performs the best (its target scenario). Note that `bc-urand` uses only 1 core here, as more cores are reserved for MLC, compared to 5 cores in Figure 13. Alto+Colloid falls behind Colloid by 3% under the 9-MLC-thread setup but outperforms it in all other cases. This behavior stems from increased fast-tier latency under bandwidth contention, which expands the AOL range from 40–140 (0 MLC threads) to 95–270 (9 MLC threads). With default AOL thresholds (40/100), Alto's regulation becomes less aggressive (Algorithm 2) when AOL falls out of the target AOL range, as shown in Figure 13b. Only 2.3% of runtime phases exhibit AOL below 95. As a result, Alto regulates only 1.6% of pages under 9 MLC threads, leading to 3% negative performance gains. However, adjusting AOL thresholds to 90/150 and 90/270 to match the runtime AOL range improves Alto+Colloid's slowdown from 33% to 23% and 20%, both outperforming Colloid (30%). Thus, adjusting AOL thresholds upward to match runtime AOL under high bandwidth contention can help preserve Alto's benefits. This requires tuning AOL thresholds based on contention levels. Developing an auto-tuning mechanism for AOL thresholds for such scenarios is an interesting direction for future work.

Takeaway #8: *Alto achieves improvements of -3% to 81% over Nomad, NBT, and Colloid for bc-urand under bandwidth pressure across various fast/slow-tier ratios. However, Alto's benefits diminish under extreme contention (e.g., 2× inflated latency), resulting in one case where Alto+Colloid underperforms Colloid by 3%. Raising AOL thresholds can help recover performance benefits in such scenarios.*

7 Related Work

Heterogeneous Memory Management. Soar shares its profiling-based design goal with prior systems [13, 34, 49, 56], but differs in its use of performance metrics, leading to different design choices. Unlike X-Mem [13], which classifies memory access to static types of patterns and ranks coarse-grained memory regions using offline-profiled latency, Soar leverages an AOL-based predictor that accounts for MLP and latency inflation for accurate slowdown prediction (§3.2). Soar is application-transparent without code changes and is lightweight, imposing neglible runtime overhead, making it applicable to a wide range of workloads.

Memory Performance Modeling. Prior work has focused on modeling memory performance using various metrics, including CPU stalls, LLC misses, memory latencies, etc., as well as ML-driven predictors [7, 8, 11, 21, 23, 57]. However, these approaches often fall short due to accuracy and complexity issues. While CPU stalls on the fast-tier can intrinsically capture memory access performance impact, they serve as a poor metric to predict slow-tier performance due to their inability to account for shifting memory-overlap effects caused by increased latency and variable MLP in the slow-tier. In contrast, our AOL-based predictor explicitly models CPU stalls, latency, and MLP. AOL amortizes the overestimated CPU stall increases, ensuring high prediction accuracy and serving as the key to Soar/Alto's effectiveness.

Memory Tiering. Memory tiering has been extensively studied from many angles, including efficient software- and hardware-based hotness tracking, memory allocation and migration policies across host and virtualized environments, and support for various slow-tier memory types [4, 13–28, 58, 59]. For instance, HeMem utilizes PEBS for fine-grained page access frequency sampling [17]. Most existing tiering systems rely on hotness for guiding data placement across tiers, ignoring the performance impact variability across memory accesses. Soar and Alto designs are orthogonal to existing tiering designs, acting as a general-purpose memory allocator and migration regulator that complements other optimizations such as better hotness tracking and migration policies.

8 Conclusion

Tiered memory management is becoming increasingly important with the rise of CXL, yet significant challenges persist. We demonstrate that hotness does not equate to performance, highlighting the need to revisit both the fundamental principles and strategies for memory tiering. We hope that our predictive metrics on AOL, static and dynamic tiering policies (Soar and Alto) will open up new directions for memory research.

Abstract

Large Language Models (LLMs) have resulted in a surging demand for planet-scale serving systems, where tens of thousands of GPUs continuously serve hundreds of millions of users. Consequently, throughput has emerged as a key metric that determines serving systems' performance. Due to large model sizes and memory-intensive self-attention, LLM serving has been commonly assumed to be memory-bound. Through a detailed analysis, we show that despite having memory-intensive components, end-to-end LLM serving is compute bound for most common workloads and LLMs. Alas, most existing serving engines fall short from optimal compute utilization, because the heterogeneous operations that comprise LLM serving—compute, memory, networking—are executed sequentially within a device.

We propose NanoFlow, a novel serving framework that exploits intra-device parallelism, which overlaps the usage of heterogeneous resources within a single device. NanoFlow splits inputs into smaller *nano-batches* and duplicates operations to operate on each portion independently, enabling overlapping. NanoFlow automatically identifies the number, size, ordering, and GPU resource allocation of nano-batches to minimize the execution time, while considering the interference of concurrent operations. We evaluate NanoFlow's end-to-end serving throughput on several popular models such as LLaMA-2-70B, Mixtral 8×7B, LLaMA-3-8B, etc. With practical workloads, NanoFlow provides 1.91× throughput boost compared to state-of-the-art serving systems, achieving between 50% to 72% of optimal throughput across popular models.

1 Introduction

Large language models (LLMs) based on transformers power applications like chatbots, search engines, and office software but are highly resource-intensive [21, 28, 41]. Reports indicate over 200 million weekly ChatGPT users, with API usage doubling after GPT-4o Mini's release [31, 35, 40]. Given the massive demand and limited GPU availability [11, 47], maximizing hardware utilization is critical. In particular, throughput, measured as tokens per device per second, has become a key factor in reducing serving costs [13, 17, 26].

LLMs are more resource-intensive than earlier DNNs due to unique characteristics. Their model sizes are vastly larger, for example, GPT-3 with 175B parameters requires five A100 80 GB GPUs to store weights in 16-bit precision, with some closed-source models even larger [7]. Moreover, LLMs' self-attention mechanism [51] scales total memory loading quadratically with the context length—the aggregate length of input and output sequences—during token generation. LLM serving systems often cache per-request state in a *key-value cache* (KV-cache), whose size can surpass the size of model weights [44], driving up memory demands. Moreover, each LLM iteration loads the entire model weights plus the KV-cache, while only producing one output token for each

decoding sequence, further increasing memory pressure. Due to these characteristics, LLM serving is commonly assumed to be overall memory bandwidth bound.

In this paper, we show that while the self-attention operation is indeed memory-bound, *LLM serving is often compute-bound when considered as a whole*. We provide a detailed analysis (which we also validate empirically) of the common operations used in current LLMs and find that: (1) Batching prefill and decode requests amortizes weight loading, making general matrix multiplications (GEMMs) compute-bound. (2) Although batched decode requests still need to load a unique KV-cache per sequence, novel optimizations such as grouped query attention [5] (GQA) can reduce the memory loads. (3) As model sizes grow, the compute operations from GEMMs tend to dominate compared to self-attention. Consequently, for many common workloads and LLMs, total compute operations dominate network and memory I/O.

However, in practice, we find that LLM serving engines are far from optimal in terms of compute utilization when measured end-to-end and compared to the hardware FLOPs. This is because LLMs use *heterogeneous operations*. For example, the self-attention is memory-bound during the decode phase. Also, when models are larger than a single GPU's memory capacity, GEMM is often split across multiple GPUs when using tensor parallelism, and thus requires network communication in addition to compute. We find that in current LLM serving engines, individual operations have high utilization of their bottlenecked resource ($\sim$ 80%). However, because each operation is executed one at a time, and different operations have different resource bottlenecks, the total compute utilization is only 40%, as shown in Section 6.2.

To address this gap, we present NanoFlow, a serving framework that aims to maximize utilization of the workload's resource bottleneck, when considered as a whole. The key insight is to leverage *intra-device parallelism for heterogeneous operations*. In particular, NanoFlow splits each input batch into *nano-batches* and duplicates operations across nano-operations, with each nano-operation processing a single nano-batch. Since nano-operations operate on separate nano-batches without dependencies, heterogeneous operations—such as memory-bound and compute-bound operations—can execute *simultaneously* rather than sequentially. This approach facilitates fine-grained pipelining across compute, memory, and network resources within a *single device*. As nano-operations duplicate each operation, this method increases memory I/O for weight loading. However, when the workload is compute-bound as a whole, the additional memory I/O can be hidden via pipelining.

To achieve efficient pipelining, NanoFlow executes nano-operations with a fraction of the GPU's resources. For instance, while most of the GPU resources can be assigned to a compute-heavy operation for high compute utilization, a memory-bound operation can still achieve considerable memory bandwidth usage using the remaining GPU resources.

Designing NanoFlow presents several major challenges. First, given the multitude and diversity of LLMs, determining the appropriate number of nano-batches, the input batch size for each nano-operation, and the execution order of nano-operations involves navigating a large search space. Second, when memory- or network-bound kernels run alongside compute-bound kernels, competition for GPU resources (e.g., execution units, caches) causes unpredictable performance interference, slowing down kernels running in parallel [43]. Balancing these trade-offs is critical. Allocating more resources to compute-bound kernels may excessively delay memory- or network-bound kernels, while prioritizing memory- or network-bound kernels could hinder overall throughput by slowing down compute-bound operations.

To tackle these challenges and efficiently explore the large search space, NanoFlow proposes *auto-search* to automatically construct an intra-device pipeline. The auto-search process reduces the search space by executing in two stages, which approximates the optimal solution balancing efficiency and accuracy. In the first stage, NanoFlow determines the initial pipeline schedule, including the number, size, and ordering of nano-operations, assuming no interference between kernels. In the second stage, NanoFlow refines the pipeline by profiling actual kernel interference and re-planning accordingly. NanoFlow also provides a runtime system to execute the optimized pipeline by efficiently forming nano-batches, allocating GPU resources, and managing the KV-cache.

We provide a detailed evaluation of NanoFlow on the LLaMA-2-70B model [49] using one NVIDIA 8×A100 DGX node [24]. For practical workloads including ShareGPT [1], LMSys [56] and Splitwise [32], NanoFlow achieves on average 1.91× greater throughput than state-of-the-art serving frameworks including vLLM [17], DeepSpeed-FastGen [13] and TensorRT-LLM [26], which is 68.5% of the theoretically optimal throughput we derive in §3. NanoFlow achieves similar latency compared with the best baseline TensorRT-LLM at a low request rate, while handling up to 1.64× higher request rates within SLO constraints. We also demonstrate NanoFlow's ability to automatically generate efficient pipelines for other models and architectures such as Mixture-of-Experts (MoE), by evaluating popular LLMs (LLaMA-3-70B, LLaMA-3-8B, QWen2-72B, Deepseek-67B, and Mixtral 8×7B). NanoFlow-generated serving pipelines achieve 50%-72% of optimal throughput, which on average reaches 2.66× throughput gain compared with vLLM.

In summary, we contribute the following:

- A detailed analysis and empirical validation of the workload characteristics and theoretically optimal throughput of LLM serving systems that shows modern LLMs operate in a compute-bound regime.
- NanoFlow, that comprises (1) an auto-search engine that automatically computes a pipeline for nano-batches to improve LLM serving throughput, (2) an end-to-end LLM serving runtime.

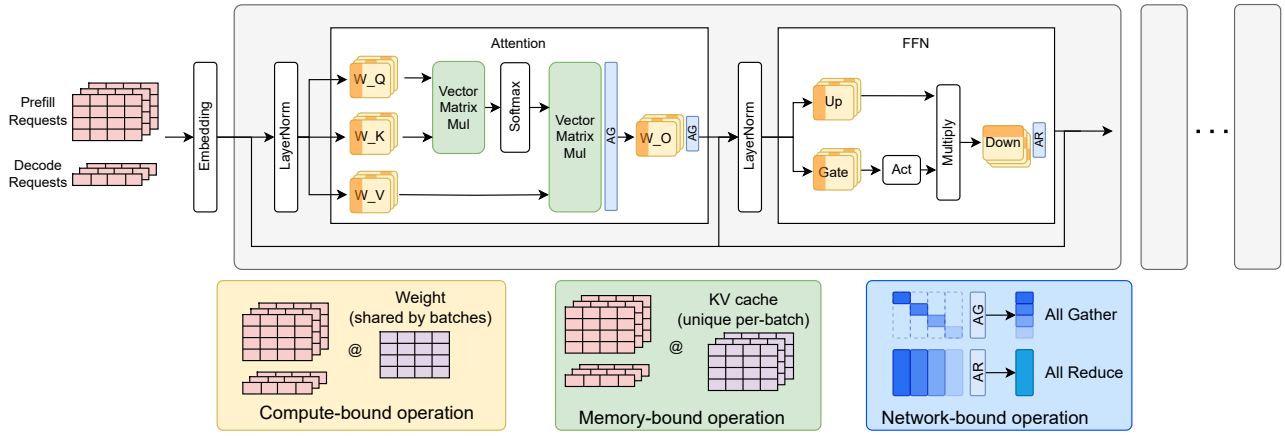

Figure 1: Transformer architecture. The operations in the yellow boxes have large batch sizes and share model weight parameters across requests; hence, they are compute-bound. Operations in green boxes require loading a unique KV cache for each request; hence, they are memory-bound. The blue box represents network operations that perform synchronization between operations.

- A comprehensive evaluation of NanoFlow that achieves 1.91× throughput gain compared to baselines and 68.5% of theoretical maximum throughput.

2 Background

2.1 LLM Inference Workflow

Recent LLMs like GPT-4, LLaMA, and Mistral [16, 29, 49] are based on the decoder-only transformer [51]. The inference process of these LLMs has two phases [53]: (1) *prefill*, which processes the input prompt all at once, and (2) *decode*, which generates output tokens one at a time autoregressively. The prefill phase initializes the *KV-cache* [34], which keeps the per-request state to speed up the decode phase.

Both the prefill and decode phases utilize the same inference workflow in Figure 1. Upon receiving an inference request, the input traverses identical *transformer layers* to produce the subsequent tokens. In each transformer layer, during the attention stage, the input is multiplied by weight matrices W_Q, W_K, and W_V to form Query, Key, and Value, with Key and Value concatenated into the existing KV-cache. The Query is then multiplied with the existing Keys and normalized to assess the similarity between the current token and all previous tokens. This similarity is employed to compute the weighted average of the Value, aggregating the context information. The outcome undergoes O-projection through a linear transformation using W_O followed by a layer normalization operation [6]. Subsequently, during the feed-forward network stage, the activation is multiplied by W_{up} and W_{gate} separately to generate o_u and o_g. Next, o_g passes through an activation function (e.g., SiLU [10]), followed by an element-wise multiplication with o_u. Finally, W_{down} is applied as the Down-projection to generate the output, which serves as the input to the next layer.

2.2 Operation Characteristics

According to the characteristics of the operations during inference, we can classify them into four categories.

Dense operations. The KQV generation, O projection, Up, Gate, and Down projection compute the multiplication of activations and model weights, which we define as *dense operations*. In the prefill phase, all tokens of new requests form a large batch for these dense operations. In the decode phase, batched decoding aggregates the activations from all the decode requests for dense operations [53]. Moreover, as the prefill phase and decode phase share weight matrices, the activations from both phases can be combined to further exploit the batching effect by amortizing the weight loading cost [3]. As a result, dense operations are *compute-bound*.

Attention operations. Transformers capture token relations through attention [51]. The prefill phase processes all input tokens simultaneously, making it *compute-bound*, while the decode phase generates one token per iteration, loading cached K and V vectors from the KV-cache, making it *memory-bound*.

Network operations. Collective communication operations including AllGather (AG) and AllReduce (AR) are *network-bound* and call for high bandwidth interconnection between nodes like NVLink [25].

Other operations. We classify the rest of the operations in transformer architecture, e.g., layer norms, positional embeddings, etc., as other operations, due to their short runtime compared to dense, attention or network operations.

2.3 Serving LLMs at Scale

With large models, multiple GPUs are required to provide enough resources, including both memory and compute, for efficient LLM serving [18]. Existing works [12, 38, 57] have comprehensive evaluations of different *inter-device paral-*

lelism paradigms:

Tensor Parallelism [38, 57] splits each weight matrix onto different GPUs and executes each operation collectively, avoiding weight duplication, thereby scaling compute capacity. However, frequent collective communications after operations are required to synchronize each operation's results, as shown in Figure 1.

Pipeline Parallelism [14] splits the model into stages by layers so that each GPU only needs to hold part of the weights. While all devices with tensor parallelism execute on the same batch of data, devices with pipeline parallelism operate on different micro-batches of data split by stages.

In practice, these parallelism paradigms are typically used in combination. Tensor parallelism is commonly applied across GPUs within a single node, where high-bandwidth interconnects are available, to support larger batch sizes. Pipeline parallelism, on the other hand, is employed across nodes to further scale the system.

3 Analysis

We now introduce the factors determining the throughput of LLM serving (§3.1) and model the cost of LLM serving (§3.2). We then classify modern LLM serving workloads according to our model (§3.3) and empirically validate this classification (§3.4), showing that popular workloads are compute-bound. Then, for the compute-bound scenarios, we determine optimal serving throughput (§3.5), explain why existing systems fall short of the optimal (§3.6), and how this motivates our proposed approach, intra-device parallelism (§3.7).

3.1 Key Factors of Serving Throughput

We define throughput as the *total throughput* of serving, which is the number of tokens processed per second by both prefill and decode phases. Throughput is affected by hardware properties, model configuration, user queries, and batch size.

Hardware specification. The following factors determine the available GPU hardware resources:

- N_{GPU}: number of GPUs
- $MemBW$ (GB/s): aggregate GPU memory bandwidth
- $MemSize$ (GB): aggregate GPU memory capacity
- $Compute$ (GFLOP/s): aggregate GPU compute capacity
- $NetBW$ (GB/s): aggregate GPU interconnect bandwidth

Model configuration. The following factors regarding the model architecture determine the computation, memory, and network demand when serving LLMs:

- D_{model}: hidden dimension size
- L: number of layers
- P_{Model}: number of parameters
- R_{GQA}: group size of GQA [1]
- S_{type} (Bytes): number of bytes (size) of the data type for model parameters (e.g., 2 for FP16)

User query statistics. The following user input statistics also affect the system throughput:

- p: average number of tokens in prompts to be prefilled
- d: average number of tokens in output to be decoded

Therefore, a serving request from a user corresponds to p prefill tokens and d decode tokens on average, for a total of $p+d$ tokens that we use when calculating the total throughput. Using user query statistics, total throughput (tokens generated per second) can be easily converted to other throughput metrics, for example, decoding throughput (decode output per second) is $\frac{d}{p+d} \times \text{Throughput}_{\text{total}}$, and request per second is $\frac{1}{p+d} \times \text{Throughput}_{\text{total}}$.

Batch size. An optimal throughput-oriented serving system needs to process large batches. For compute-bound dense operations, e.g., GEMMs, a larger batch amortizes the weight loading overhead and increases execution unit occupancy, which provides higher compute utilization. For memory- and network-bound operations, all requests share the same warmup cost (e.g., kernel launching overhead, pipeline setup overhead, network synchronization overhead, etc.), so a larger batch size leads to higher throughput. Therefore, when considering the optimal system throughput, we assume that the system always operates at the largest batch size at which the total available memory can hold the model weights and all the KV caches for the requests. [2]

3.2 Cost Model of LLM Serving

Under the assumption of maximum batch size, we derive the latency of an LLM serving iteration (where a batch of user requests are being processed by all the transformer layers) from the perspectives of required memory, compute, and network resources.

Memory. From the memory perspective, latency is:

$$T_{mem} = \frac{MemSize}{MemBW} \tag{1}$$

This is because the entire device memory content needs to be loaded into the GPU caches and registers once for each iteration (typical in modern serving systems [17]) when using the largest batch size. Although the model weights are shared between iterations, due to the long reuse distance, it is infeasible to cache the model weights and avoid loading from the device memory.

Compute. In LLM serving, all operations contribute to the total compute, while Dense operations produce the vast majority of computations for typical workloads (as we validate in §3.4). Therefore, we model the compute latency of dense operations below.

For every GEMM in dense operations, $2B_{Dense}N_wK_w$ computations need to be performed on weights and activations, where N_w and K_w are dimensions of the weight matrices, and B_{Dense} is the batch size for dense operations, which includes decode tokens from hundreds of requests and the prefill tokens from one or a few requests. Thus, the total compute for

[1] The number of Query attention heads that share one KV head [5].

[2] Activations occupy negligible (less than 5%) of the memory [17], thus we omit them for simplicity.

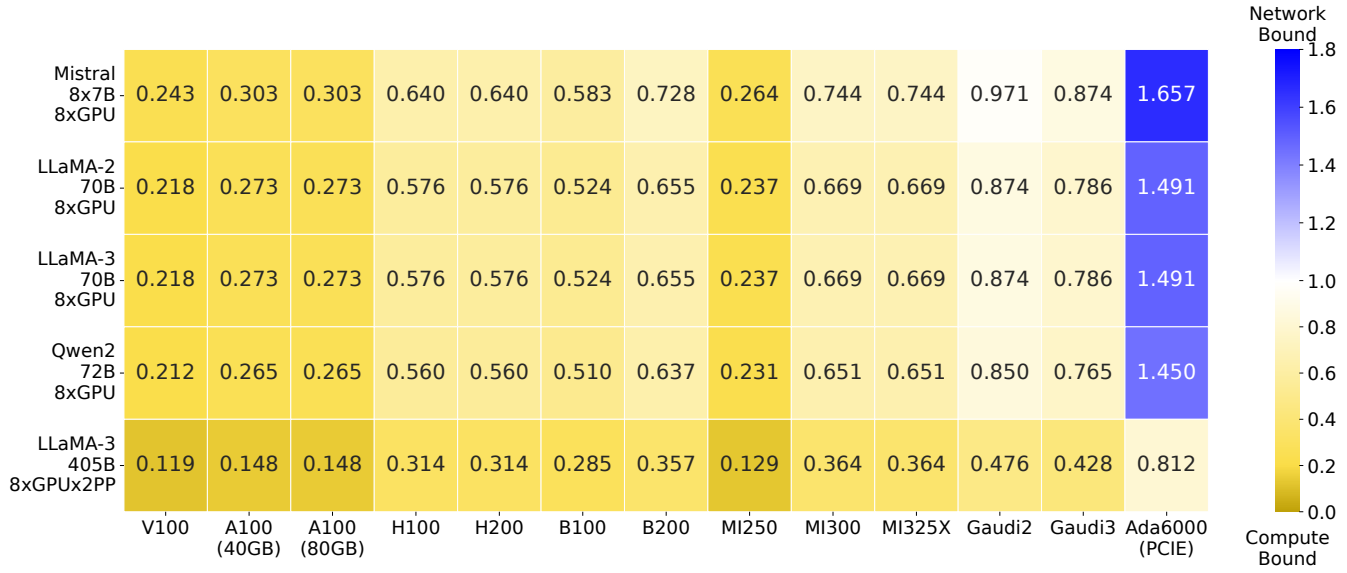

Figure 2: Comparison of network time and compute time. The closer to yellow, the more compute-bound the workload is, whereas the closer to blue indicates the workload is more network-bound.

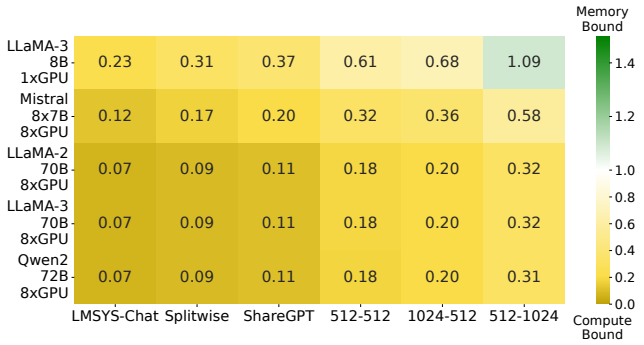

Figure 3: Comparison of compute time and memory time. The closer to yellow, the more compute-bound the workload is, whereas the closer to green the more memory-bound it becomes.

dense operations is $2B_{Dense}\sum N_w K_w$. Note that the $\sum N_w K_w$ term is the number of weight elements in all layers, which can be approximated using P_{Model} (the parameters in the model), thus, we simplify the expression as $2B_{Dense}P_{Model}$. Therefore, latency from the compute perspective is:

$$T_{Compute} \approx \frac{2B_{Dense} \cdot P_{Model}}{Compute} \tag{2}$$

Network. Finally, for tensor parallelism, collective network communication primitives are needed to synchronize the results after performing operations in multiple GPUs over different shards of data. The size of the data transmitted with collective communication equals the size of inputs for dense operations, which have dimensions $[B_{dense}, D_{model}]$. To support tensor parallelism, two AGs and one AR (or 2 ARs) are required [39]. An AR requires gathering outputs from other GPUs, performing local summation, and broadcasting results, thus it needs to transfer the activations twice, while an AG transfers activations once. Therefore, in both cases, we can estimate the total data movement for one GPU in bytes as $4 \cdot B_{Dense} D_{model} S_{type} \cdot L$. Thus, the latency from the network perspective is:

$$T_{net} \approx 4 \cdot \frac{(N_{GPU}-1) B_{Dense} D_{model} S_{type} L}{NetBW} \tag{3}$$

3.3 Classification of LLM Serving Workloads

We classify LLM serving workloads by comparing the latency of an iteration derived based on memory, compute, and network requirements.

First, we compare Equation 3 (network time) with Equation 2 (compute time). Their ratio can be calculated as

$$\frac{T_{Net}}{T_{Compute}} = \frac{2D_{model}L}{P_{model}} \frac{(N_{GPU}-1)Compute}{NetBW/S_{type}}$$

Note that $P_{model} \approx 12D_{model}^2 L$[3], thus $\frac{2D_{model}L}{P_{model}} \approx 1/(6D_{model})$. For models that need multiple GPUs (where T_{Net} is relevant), D_{model} is typically larger than 4096 [9, 16, 22, 48], making the term $\frac{2D_{model}L}{P_{model}}$ smaller than 1×10^{-5}. Due to the high bandwidth interconnect between data center GPUs (e.g., NVLink [25], Infinity Fabric [54]),

[3] $P_{model} = ((W_K + W_Q + W_V) + W_O + W_U + W_G + W_D)L \approx ((1/R_{GQA} + 1 + 1/R_{GQA})D_{model}^2 + D_{model}^2 + D_{model}I_{model} + D_{model}I_{model} + I_{model}D_{model})L) \approx (1+1+3.5+3.5+3.5)D_{model}^2 L \approx 12D_{model}^2 L$, where I_{model} is intermediate dimension, which is typically 3.5x of D_{model} [16, 22].

Table 1: Characteristics of accelerator models across various vendors and release years.

Vendor	Model	Release Year	MemSize (GB)	MemBW (GB/s)	NetBW (GB/s)	Compute (FP16 GFLOP/s)	$\frac{MemSize}{MemBW}$	$\frac{Compute}{MemBW}$	$\frac{NetBW}{MemBW}$

$\frac{N_{GPU}Compute}{NetBW/S_{type}}$ ranges from 1×10^4 to 1×10^5. Therefore, this ratio is typically less than 1, indicating that the network is not the bottleneck. We illustrate this ratio in Figure 2. For large models and data center GPUs, the compute takes more time than network.

We then compare Equation 1 (memory time) and Equation 2 (compute time) to finally determine the characteristics of the workload, namely, the following value

$$T_R = \frac{T_{Mem}}{T_{Compute}} \approx \frac{Compute}{MemBW}\frac{MemSize}{P_{model}}\frac{1}{2B_{dense}} \tag{4}$$

Modern models widely adopt Grouped Query Attention (GQA) as seen in LLaMA-3 [48], NeMo [4], and Qwen2 [9]. In GQA, multiple attention heads share a KV-cache, which effectively means that given the same memory capacity, batches can contain more requests. Consequently, B_{dense} tends to be larger. For example, when serving LLaMA-2 70B on $8\times A100$ GPUs, the maximum batch size of decode requests is on the order of 1024. Combined with the prefill tokens in the batch, B_{dense} can reach 2048 while a non-GQA model with the same size can only have $B_{dense}=256$. Thus, the ratio T_R is less than 1, and compute becomes the main bottleneck. Additionally, modern models tend to have increasingly large model sizes P_{model} (whereas the rest of the terms in T_R are constants given a hardware specification), further causing T_R to drop below 1.

Figure 3 shows the values of T_R with five representative models: LLaMA-3 8B [22] with 1×A100, Mistral 8×7B [16] with 8×A100, LLaMA-2 70B [49] with 8×A100s, LLaMA-3 70B with 8×A100s, Qwen-2 72B [9] with 8×A100s. As the heatmap figure shows, many of the workloads (Splitwise [32], LMSYS-Chat-1M [56], ShareGPT [1] as well as constant length inputs and outputs), are uniformly compute-bound, except in the case of the long decode (512-1024) workload on LLaMA-3 8B model, where the ratio T_R is around 1.

While the analysis is mainly conducted on an NVIDIA A100, the result remains similar for other accelerators. As shown in Table 1, compute/memory ratio and compute/network ratio are stable across vendors and generations, meaning the workload characteristics also remain largely unchanged.

To summarize, our cost model suggests that modern LLM serving workloads operate in a compute-bound regime, which we validate empirically in the next section.

3.4 Validation of the Cost Model

We validated our cost model on LLaMA-2 70B serving with 8 NVIDIA A100 GPUs and a dense batch size of 2048 requests. We computed the GFLOPs, memory movement, and network traffic for each operation (Table 2) and used these with our model to calculate $T_{compute}$, T_{mem}, and T_{net} based on hardware specifications[4]. The longest estimated time $T_{op}=\max(T_{compute},T_{mem},T_{net})$ indicates the most constrained resource. To validate these results, we measure the running time of different operations. For most operations, T_{op} aligns with profiling results. An exception is prefill attention, where the real measured time is larger due to the launching overhead of the associated kernels dominating the total time. The sums of all operations' $T_{compute}$, T_{mem}, and T_{net} values show that compute is the most constrained resource, which aligns with our model's finding.

3.5 Optimal Serving Throughput

Optimal throughput (measured in token/s/GPU) is achieved when the most limited resource, i.e. compute, is fully utilized. By applying Equation 2, the system's optimal throughput is:

$$\text{Throughput}_{\text{optimal}} = \frac{B_{Dense}}{T_{Compute}} = \frac{Compute}{2P_{Model}} \tag{5}$$

In the compute-bound regime, the optimal throughput depends *solely* on the aggregate computational capacity of the GPUs for the specific data type and the number of parameters in the model. Notably, other factors, including the GPU memory size, bandwidth, model data type, or the length of prefill and decode phases, do not have a significant impact on

[4]One-way network bandwidth was used for T_{net}

Table 2: Comparison of operation runtimes between cost model estimation and real-world measurements.

Operation	Compute (GFLOP)	Mem Load (GB)	Net Usage (GB)	Est. T_{comp} (ms)	Est. T_{mem} (ms)	Est. T_{net} (ms)	Real Time (ms)
KQV	27487.8	19.5	0	**11.01**	1.22	0	**16.08**

Total				**114.17**	45.09	31.33	

the theoretical optimal throughput, as long as the workload is overall compute-bound. We measure the GPU compute capacity by profiling the state-of-the-art GEMM vendor library, CUTLASS [46]. For example, when serving LLaMA-2 70B on 8×A100 GPUs, the profiled peak *Compute* is 280 TFLOPS for FP16, and the P_{Model} is 70B. Substituting these into Equation 5, yields an optimal throughput of 1857 tokens/s/GPU.

3.6 Gap to Optimal Throughput

As shown in Figure 7, existing serving systems fall far short of achieving optimal throughput. When serving offline requests, vLLM, DeepSpeed-FastGen, and TensorRT-LLM achieve only 22.0%, 22.9%, and 37.8% of the optimal throughput, respectively.

The main reason why existing serving systems fall significantly short of achieving optimal throughput is poor utilization of GPU resources. Figure 4 shows the execution flow of transformer operations within a GPU, using existing serving frameworks like SGLang [58], vLLM [17], DeepSpeed-FastGen [13]. These frameworks execute compute-, memory-, and network-bound operations sequentially on a single large batch in a device. This sequential execution flow forms multiple pipeline bubbles (denoted as "WASTED" in Figure 4), which cause the most constrained resource, compute, to be underutilized.

3.7 Intra-device Parallelism

Ostensibly, the advantage of existing serving frameworks when using a single large batch in a GPU is that they need to load model weights fewer times than if there were multiple smaller batches and corresponding operations.

However, the cost model and its validation that we outlined earlier in this section provides a valuable insight: Since modern models are largely compute-bound (by a factor of more than 2 as shown in Figure 3 and Table 2), creating and processing smaller batches may be justified, especially if compute utilization can be increased.

These observations motivate intra-device parallelism through nano-batching, which underlies the design of NanoFlow. NanoFlow creates multiple nano-operations, which are the same operations as the original operations, but operate on finer-grained batches that we call nano-batches. For example, for the original Up projection operating on a batch size of 2048, NanoFlow could create two nano-operations UP1 and UP2, operating on batches in ranges 0-768 and 768-2048, respectively, while performing the exact same projection. Different nano-batches do not have data dependencies. Therefore, nano-operations that use different resources—compute, memory, network—can operate on different nano-batches in parallel within a device to maximize the utilization of the most constrained resource, compute. Despite requiring repeated loading of model weights, we demonstrate that NanoFlow provides significantly more throughput than existing frameworks (1.91× on average), further closing the gap to optimal serving throughput (§6).

4 Design

We introduce NanoFlow's key components: the auto-search engine for automatic nano-batch pipeline computation (§4.1) and the LLM serving runtime for pipeline execution (§4.2).

4.1 Automated Pipeline Search

Deciding number of nano-operations, kernels, scheduling with intra-device parallelism, and resource allocation is challenging due to model and hardware diversity. To address this, NanoFlow proposes auto-search, which uses Mixed Integer Linear Programming (MILP) to obtain the nano-batch overlapping strategy, with a two-stage approximation for reducing the search space. We first outline auto-search prerequisites including kernel profiling and interference modeling (§4.1.1), then detail its two stages: pipeline structure search (§4.1.2) and GPU resource allocation (§4.1.3). Finally, we provide example pipelines for popular models (§4.1.4).

4.1.1 Kernel Profiling and Interference Modeling

Understanding the performance characteristics of different operations is key to automated pipeline search. For this, NanoFlow profiles GEMM kernels (used for compute-bound operations such as KQV generation), GEMV kernels (used in memory-bound operations as in decode-attention), and network kernels (used in network-bound operations such as AR and AG).

Determining the maximum dense batch size Given a specific model architecture and user input statistics (as described in §3.1), NanoFlow calculates the maximum *dense batch size* that can fit into the GPU memory (e.g., around 2048 for $8 \times A100$ serving LLaMA-2 70B). This dense batch size serves as an input to auto-search, which sets an upper bound of shapes in profiling.

Profiling interference-free kernels NanoFlow then determines the interference-free execution time of kernels, where each operation exclusively uses the GPU. NanoFlow profiles kernels with discrete input batch sizes from 128 to the dense batch size in multiples of 128, as 128 is a hardware-friendly shape for GEMM tiling. NanoFlow explores all possible kernel implementations varying the number of thread blocks, the

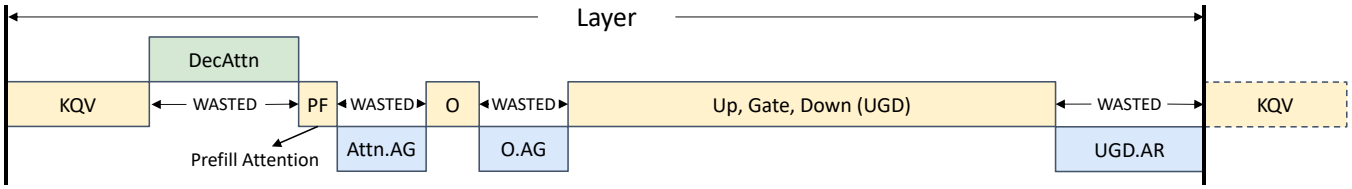

Figure 4: Execution pipeline of existing systems. The green, yellow, and blue operations correspond to memory-, compute-, and network-bound operations. Operations in the previous and next layer are denoted by dotted borders. "WASTED" shows the stages in the pipeline where the most constrained resource, compute, is underutilized. Small operations (i.e. layernorm, activation, etc.) are omitted for simplicity.

number of warps, and tile size for GEMM, GEMV, and network kernels to identify the implementation that provides the shortest execution time. The profiling outputs a mapping from (kernel, batch size) to its best implementation and execution time.

Profiling kernels with interference However, when two or more kernels execute in parallel on a device, they slow down compared to running separately. We refer to this as *kernel interference*, which is attributed to kernels competing for GPU hardware resources such as execution units, caches, power, and memory controllers [43]. Ideally, we would like to independently assign each nano-operation a fractional allocation of a single GPU's compute, memory, and network bandwidth. We call this fraction $R_{physical}$. Unfortunately, kernel interference is unpredictable, as NVIDIA GPUs do not give explicit control over compute, memory, and network bandwidth. Thus, we cannot directly control $R_{physical}$.

Instead, we use GEMM performance as a proxy R for $R_{physical}$ and model pairwise kernel interference. We define R in a GEMM-centric way since the compute-bound operations dominate and optimizing compute is the goal of NanoFlow.

In particular, we profile pairwise kernel interference patterns by measuring actual performance when overlapping between a compute kernel A and another kernel B. For example, if when overlapped, GEMM kernel A achieves 40% performance compared to its best performance when run individually, then we say that R_A=0.4. We then assume that the overlapped kernel is given the remaining resources, so we set $R_B = 1 - R_A$ =0.6.

Then, we model the interference by measuring the performance loss in the non-compute kernel B when R_A resources are allocated to kernel A. When overlapping A and B, we normalize A and B's performance to their peak performance when run individually. We call this value P. For the compute kernel A, P_A is equivalent to R_A by definition, while P_B captures the memory or network utilization when R_A resources are assigned to the compute kernel.

Intuitively, this process establishes an exchange rate between compute utilization R and memory or network performance P . The overall kernel interference model can then be captured in a table such as Table 3, which maps R to P for each kernel type.

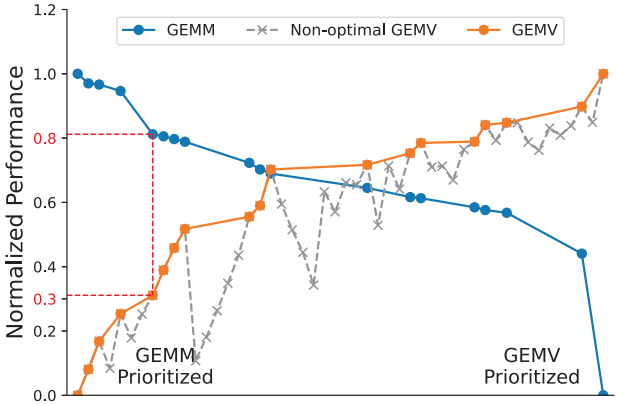

Figure 5: Interference characteristics between GEMM and GEMV kernels. The points on the x-axis correspond unique GEMM-GEMV implementation pairs. The y-axis denotes the GEMM and GEMV kernels' normalized performance P.

Nonetheless, profiling the mapping between R and P remains challenging due to the vast number of possible kernel combinations. While each operation may have only a few hundred kernel implementations, the combinations between different implementations of overlapping kernels exponentially expand the profiling space, resulting in millions of possible configurations. This immense complexity makes exhaustive exploration infeasible.

NanoFlow reduces the profiling space by limiting the thread block numbers for GEMV and network kernels to values between 8 and 128 (in steps of 8), as 128 blocks are sufficient to saturate their performance. It also excludes less efficient GEMM kernels, which have longer execution times while using more thread blocks. NanoFlow focuses on pairwise interference analysis—compute-memory and compute-network—rather than examining three kernel types simultaneously and assumes that the R to P mapping profiled with pairwise interference holds when overlapping three kernels.

Figure 5 shows NanoFlow's profiling results of GEMM-GEMV kernel pairs ($\sim$ 100 pairs, after the aforementioned simplifications) on an A100 GPU with GEMM shape $(M,N,K) = (384,4096,4096)$, GEMV batch size 384, and

Table 3: Performance P of GEMV and network kernels with different resource utilization R.

Operations	Resource Utilization (R)						
	0	0.1	0.2	...	0.8	0.9	1
GEMM (by definition)	0	0.1	0.2	...	0.8	0.9	1
GEMV	0	0.2	0.3	...	0.85	0.95	1
Network	0	0.3	0.5	...	0.9	1	1

sequence length 1024. These pairs are then sorted by descending GEMM performance, as shown in Figure 5. For instance, a normalized performance of 0.8 means the kernel's execution time is $1/0.8$ times longer than the fastest implementation. Pairs with higher interference on GEMM but worse GEMV performance (grayed-out in Figure 5) are discarded. This process identifies the best-performing kernel combinations at various GEMM-GEMV performance trade-off points.

Using interference profiles, auto-search generates a *resource mapping table* (Table 3). This table quantifies GEMV and network kernel performance (P) as functions of resource utilization (R). For example, as depicted by the dotted red line in Figure 5, achieving 0.3 GEMV performance requires sacrificing 0.2 GEMM performance (from 1 to 0.8). This implies a non-linear trade-off: 0.2 GEMM performance is exchanged for 0.3 GEMV performance, indicating that $R_{\text{GEMV}} = 0.2$ corresponds to $P_{\text{GEMV}} = 0.3$.

A sensitivity analysis of all GEMM shapes in the evaluated LLM models and 64 batch size combinations reveals that the R to P mapping is consistent, with a standard deviation within 5% of the mean. Consequently, Table 3 can be used to map R to P for all GEMV and network kernel implementations in subsequent auto-search analysis.

4.1.2 Auto-search Stage I: Pipeline Structure Search

In the first stage, auto-search takes as input the dense batch size, the operation dependencies (defined in the PyTorch implementation of a given model architecture), and the profiling of interference-free kernels, and then produces as output, the number, batch size, and order of each nano-operation using mixed integer linear programming (MILP). Stage I does not factor in the interference between nano-operations to simplify the problem, which is covered by Stage II. The MILP problem is subject to the constraints described below.

Optimization objective. The main objective of MILP is to remove pipeline bubbles (denoted by wasted in Figure 4) for compute operations to minimize execution time.

Constraints on the number of nano-operations. To overlap resources, each operation needs to be split into at least two nano-operations, each operating on an independent nano-batch. As splitting into nano-operations reduces the batching effect, the number of nano-operations should be minimized. Thus, auto-search begins its search by dividing all operations into two nano-operations and formulating the MILP problem to identify the batch size, execution time, and ordering of the nano-operations. If the temporary best solution has bubbles for compute, auto-search increases the number of nano-operations for operations near the bubble to improve resource utilization until MILP cannot produce better solutions.

Constraints on batch sizes and execution times. Auto-search forces the batch sizes to be chosen from 128 to dense batch size and uses the interference-free execution time of a nano-operation for a given batch size, as computed in §4.1.1.

Constraints on dependencies. The dependencies of nano-operations are determined by their parent operations (present in baseline implementations, e.g., in pytorch) and their input batches. Two nano-operations are dependent if and only if their parent operations are dependent (e.g., an O-projection depends on an attention operation) and their input batches intersect (e.g., ranges 0–255 and 128–383).

Constraints on overlapping. Overlapping kernels constrained by the same resource (e.g., compute) are unhelpful for utilization, so auto-search restricts the pipeline to overlap only operations constrained by different resources.

Constraints on operation transformations. Some network collectives have equivalent transformations with different performance characteristics and dependencies. For example, an AG can be converted into an AR with different weight partitioning approaches [39, 57]. NanoFlow explores all of these alternative transformations for network nano-operations and searches for the shortest pipeline design.

Due to the large search space, searching for an optimal pipeline would take hours or even days. However, a practical pipeline can be found in approximately 10 minutes by prioritizing searching a feasible solution instead of finding a provably-optimal solution.

4.1.3 Auto-search Stage II: Refining the Pipeline

The pipeline derived in the first stage does not factor in kernel interference, which is impractical for real deployment. In the second stage, auto-search refines this pipeline by considering kernel slowdown due to interference. This stage formulates a separate MILP problem, where the numbers, batch sizes, and ordering constraints of nano-operations remain the same (i.e., outputs of the first stage). Auto-search explores various resource utilization (R) allocations to individual nano-operations, and maps R to P using Table 3 derived in interference profiling. A specific resource utilization value R directly corresponds to kernel implementations as determined in §4.1.1. The goal of the second stage is again to minimize pipeline execution time.

Constraints on GPU resource utilization. As discussed in §4.1.1, concurrent kernels should compete for a total of 1.0 of GPU resource utilization R. Thus, auto-search forces the sum of R at any given time to be less than or equal to 1.0.

Constraints on execution times. Given the resource utilization R for a nano-operation, auto-search computes the execution time of the operation using D_{best}/P, where D_{best}

represents the best execution time without interference and P is derived using Table 3.

The auto-search is performed only when the model architecture or workload (input length, output length) undergoes significant changes. Compared to the long-running deployment times, the search time is negligible.

4.1.4 Example Pipelines

70B pipeline We apply auto-search to 70B-scale models, including LLaMA-2 70B, LLaMA-3 70B, Qwen2.5-72B, and Deepseek-67B. Compared to LLaMA-2 70B, LLaMA-3 70B features a larger vocabulary size of 128K, which increases the sampling time; Deepseek-67B has a slightly different number of layers and hidden dimension (D_{model}), Qwen2.5-72B introduces bias in KQV generation. However, none of these adjustments significantly change the performance characteristics, leading to similar schedules. We provide the NanoFlow-generated pipeline for LLaMA-2 70B as an example in Figure 6. Since three resources (compute, memory, and network) overlap at the beginning of a decoding layer (i.e., KQV generations), auto-search ends up using 4 nano-operations for this part, to reduce pipeline bubbles. Here, the decode attention operation has resource utilization 0.4 (i.e. reduces 40% GEMM performance) and reaches 80% of maximum decode attention performance. For the remainder of the pipeline, GEMM operations are prioritized, and only two nano-operations are used.

8B pipeline 8B models (e.g. Llama3-8B) do not require network operations as they fit in a single GPU. Thus auto-search splits all operations into two nano-operations, with decode attention overlapping with the Up Gate Down projection.

MoE pipeline Compared to 70B models, MoE models have different hidden dimensions and number of layers. Due to the imbalance between experts [16], NanoFlow uses tensor parallelism for MoEs, in which FFN is implemented using grouped-GEMM. FFN also involves an additional gate routing operation. Auto-search works similarly for an MoE model and automatically produces an efficient pipeline (§6).

4.2 NanoFlow Runtime

We now explain how NanoFlow executes the auto-generated pipeline by asynchronous scheduling (§4.2.1), and KV-cache SSD offloading for multi-round conversations (§4.2.2).

4.2.1 Request Scheduling

Batch formation NanoFlow assumes that auto-scaling, workload balancing, and priority-aware routing are managed by the control plane externally [15,33,45]. A NanoFlow instance assumes an abundance of requests and treats each request with equal priority. When requests are not abundant, the control plane should reduce the number of NanoFlow instances to maintain a sufficiently large per-instance batch size. Note that while the B_{dense}, i.e. the token batch size for GEMMs, is on the order of thousands (e.g., 1 prefill request of 2048 tokens and 256 decode tokens), this represents the combination of prefill and decode tokens. Therefore, the request batch size (e.g., 1 prefill and 256 decode requests) is on the order of hundreds, which is easy to attain in real-world large-scale serving.

When forming a batch, NanoFlow prioritizes unfinished decode requests and chunks prefill requests at a token granularity following SarathiServe [3] to exactly fill the remaining capacity of a pre-selected best-performing dense batch. This effectively reduces the tail latency as dense operations are performed over consistent batch sizes across iterations. Initially, the global batch contains only prefill requests (requests in prefill stages). As these requests complete the prefill stage, they transition to decode requests within the batch, and new prefill requests are introduced to maintain the fixed token batch size. As decode requests increase, the prefill token budget decreases, causing prefill requests to slow down. When decode requests begin completing, this frees space for more prefill tokens again, speeding up prefill. Thus, the number of decode requests and prefill requests will be stabilized.

To optimize GPU memory usage and avoid running out of memory, NanoFlow predicts peak future memory usage based on the status of user requests. NanoFlow tracks decoded tokens per request, estimates completion time using average decode length, and prefills new requests only if predicted memory usage stays within GPU limits. If the GPU runs out of memory, NanoFlow move a request to the CPU and reloads it once memory is available without recomputation.

Asynchronous scheduling Batch formation, including estimating memory usage, scheduling new requests, retiring finished requests, and adjusting the page table for PagedAttention [17], consumes a non-negligible amount of time on the CPU side [42]. In most serving frameworks [17,58], *only after* the GPU executes one iteration, the scheduler on the CPU is able to detect *EOS* tokens, remove the finished request from the batch, and refill the batch with new requests. However, GPU is under-utilized during this time. To avoid this waste, NanoFlow asynchronously schedules batch formation in parallel to the GPU executions. At any iteration i, NanoFlow forms the batch for the next iteration *before* the end of the current iteration. This means that NanoFlow cannot detect the *EOS* tokens generated at iteration i. After launching iteration $i+1$, NanoFlow forms the batch for cycle $i+2$, detects the *EOS* token from iteration i, and removes finished requests. Fortunately, since the average decode length surpasses 100 for typical workloads (See Table 4), the overhead of one extra decode token is negligible ($< 1\%$), given the benefit of hiding the batch formation overhead.

4.2.2 KV-cache Management

To efficiently serve multi-round applications, NanoFlow offloads the KV-cache of running requests to a hierarchical cache consisting of host CPU memory and SSDs, and loads a prior round's KV-cache when a new round arrives.

Simultaneous offloading. Instead of waiting for requests'

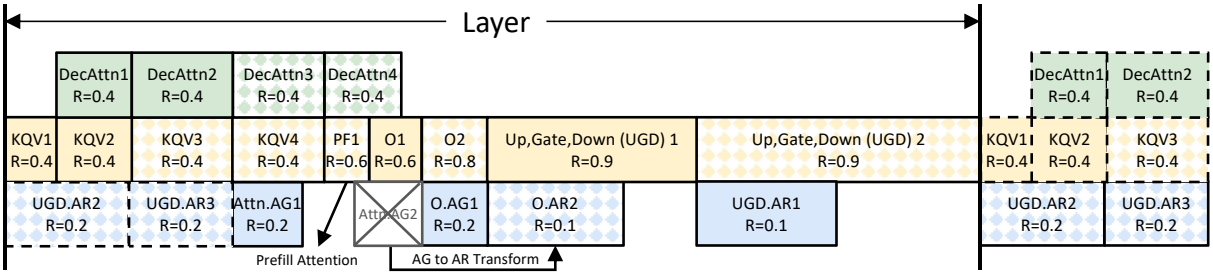

Figure 6: Execution pipeline of LLaMA-2 70B, automatically generated by NanoFlow. The solid background and shaded background represents input batch 0-768 and 768-2048, respectively. *R* stands for resource utilization. By overlapping the compute-, memory-, and network-intensive operations, NanoFlow increases compute utilization and improves the serving throughput.

completion, NanoFlow offloads the KV-cache of tokens directly after the KQV generation in each transformer layer before appending them to the KV-cache. The KV vectors output by KQV generation are naturally contiguous and the data size of the offload is balanced across iterations by design as NanoFlow's dense batches remain stable. As a result, the host and the GPU hold the same copy of on-the-fly requests' KV-cache. To minimize the offloading overhead, NanoFlow performs the device-host copy— an operation that uses minor GPU resources—during compute-bound operations in FFN. Moreover, NanoFlow reduces offloading time via NUMA-aware thread-binding.

Host KV-cache management. NanoFlow uses the LRU policy to manage the hierarchical cache of CPU memory and SSDs. For e.g., KV-cache are evicted to SSDs when the CPU reaches its memory limit and retrieved from either CPU or SSD to initiate the loading process when the next round conversation of a request comes in.

KV-cache loading and scattering. NanoFlow uses PagedAttention [17], therefore, the pages of the KV-cache reside in the GPU memory in a fragmented manner. In order to avoid copying to fragmented GPU page destinations, NanoFlow first copies the data to a contiguous space on GPU and then scatters the pages to their destinations. This achieves 7-10× higher bandwidth for host-to-device copy.

5 Implementation

We implemented NanoFlow for NVIDIA GPUs. NanoFlow consists of ∼10K lines of CUDA and ∼6K lines of Python.

Given the GPU resource requirements determined by auto-search, NanoFlow knows which kernels to launch for each nano-batch to achieve a given utilization level, based on its profiling results. NanoFlow launches nano-operations, respecting the ordering constraints from auto-search, on multiple CUDA streams and enforces ordering dependencies using CUDA events.

6 Evaluation

We now mainly answer the following questions:

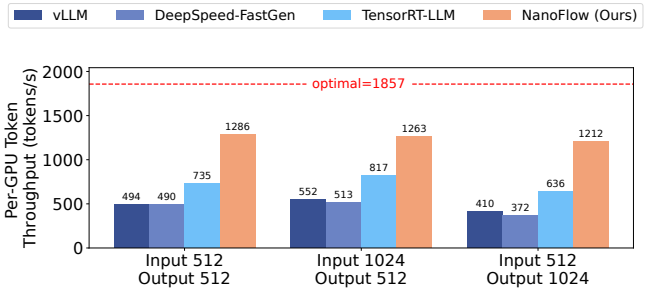
Dataset	Avg. Input (Std)	Avg. Output (Std)
Splitwise [32]	1155 (1109)	211 (163)
LMSYS-Chat [56]	102 (169)	222 (210)
ShareGPT [1]	246 (547)	322 (244)

Table 4: The average and standard deviation of input and output lengths in the sampled datasets.

- How much NanoFlow improves serving throughput compared to existing systems, and how does its throughput compare to the optimal serving throughput? (§6.2)
- What is the average serving latency under NanoFlow for different request rates, and how is it distributed? (§6.3)
- How do the various techniques proposed in NanoFlow contribute to the end-to-end throughput? (§6.4)
- What is the compute, memory and network resource usage pattern of NanoFlow? (§6.5)
- How does NanoFlow improve performance when applied to different popular LLMs? (§6.6)

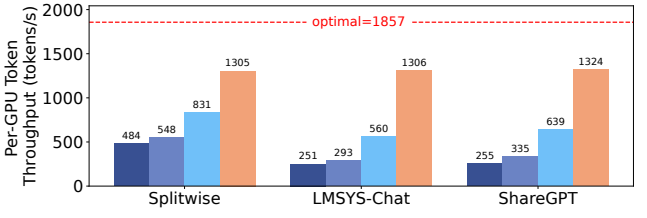
6.1 Experiment Setup

Hardware. We run our experiments on 8× A100 80GB SXM GPUs interconnected via NVLink.



Models. We provide a detailed evaluation of NanoFlow using the LLaMA-2-70B model, one of the most widely-used open-source LLMs. We also demonstrate the applicability of NanoFlow by evaluating it on 5 other representative LLMs. We use FP16 weights and activations for all models, as this is standard for data center-scale inference.

Baselines. We consider three widely-used serving frameworks as baselines.



vLLM[5] [17, 52] is a state-of-the-art serving system delivering high throughput. vLLM implements pagedAttention for increasing GPU memory utilization, as well as the chunked prefill for higher GPU compute utilization.

DeepSpeed-FastGen[6] [13, 23] is a serving framework de-

veloped by Microsoft. It dynamically composes prefill with decode requests to ensure that the engine is operating in a high throughput regime. We vary the `max-ragged-batch-size` to tune the batch size for highest throughput.

TensorRT-LLM[7] [26, 27] is a high-performance LLM inference engine built upon NVIDIA's TensorRT SDK. We set `max-num-tokens` by calculating the maximum capacity for the KV-cache in the GPU memory. We also enable paged KV-cache and dynamic batching optimizations when compiling.

Datasets. Splitwise [32] is a conversation trace collected from a real production environment at Microsoft, with a total of around 20000 requests. LMSYS-Chat-1M [56] is a large-scale dataset with 1 million real-world conversations from 25 different LLMs. ShareGPT [1] is a dataset with conversations collected from the ShareGPT API. We use the full trace from Splitwise and randomly sample 50,000 requests from ShareGPT and LMSYS-Chat-1M for our evaluation. Table 4 shows the average input length and output length in tokens for the sampled datasets we use.

6.2 Throughput

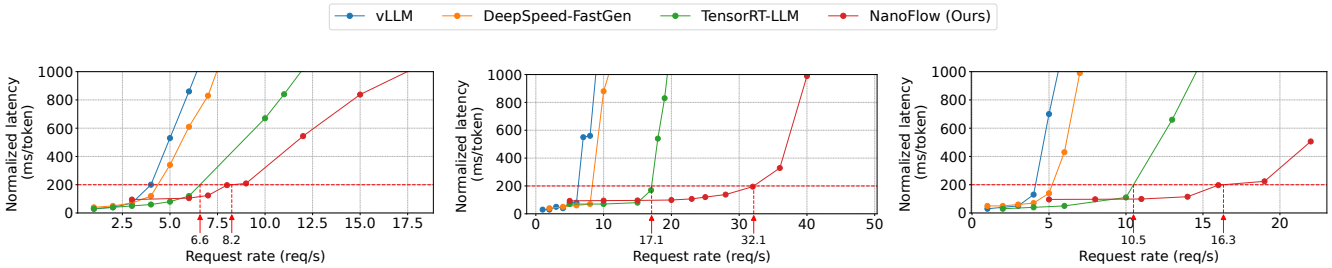
We first evaluate throughput to simulate use cases such as benchmarking, information extraction, data wrangling, and form processing [36]. We sample actual input (prompt tokens) and output (generated tokens) lengths from the datasets and add additional experiments with constant length. We then deploy a NanoFlow instance (with a dense batch size of 2048 in the case of Llama-2-70B, where NanoFlow delivers best performance) to measure the *total throughput* defined as the total number of input and output tokens divided by the execution time. We compare the performance of the NanoFlow instance with optimal throughput derived using Equation 5, where we measure the peak compute capacity using the state-of-the-art GEMM vendor library CUTLASS with a token batch size of 2048. Since the optimal throughput is independent of user query statistics, for all the experiments, the optimal throughput is 1857 tokens/s/GPU as computed in §3.5.

Figure 7 shows the throughput of the NanoFlow instance compared to the baselines. NanoFlow has the highest throughput in all settings and is able to achieve 68.5% of the theoretical optimal throughput in the best case. For constant lengths, NanoFlow has on average 2.62× higher offline throughput than vLLM, 2.78× higher than DeepSpeed-FastGen and 1.73× higher than TensorRT-LLM. When input and output lengths are drawn from the datasets, NanoFlow has on average 4.18× higher throughput than vLLM, 3.45× higher than DeepSpeed-FastGen and 1.91× higher than TensorRT-LLM.

6.3 Latency

We evaluate the latency of the NanoFlow instance, for which we model the request arrival interval via an exponential distribution, following prior work [17]. We generate 5 minutes of request traces from the datasets in Table 4 for various request rates. We then measure *normalized latency* by first calculating the end-to-end request latency divided by output length in tokens, then taking the average for all requests. For each framework, we gradually increase the request rate and measure the normalized latency. We select the SLO for average normalized latency as 200*ms* following prior works [59], which is also the typical human reading speed [8].

Figure 8 demonstrates the normalized latency of the NanoFlow instance compared to baselines at various request rates. At lower rates, the NanoFlow instance has comparable but slightly higher latency, because NanoFlow targets throughput-oriented scenarios and therefore employs a large dense batch size.



The NanoFlow instance is able to sustain a higher request rate within 200*ms* latency SLO compared to all other baselines across all the datasets. For example, for LMSys-Chat-1M dataset, the NanoFlow instance can achieve 1.64× higher request rate compared to TensorRT-LLM within 200ms normalized latency constraint.

Moreover, the NanoFlow instance's 99th-percentile latency is only 1.07× of the average latency at near-maximum throughput, as NanoFlow uses a constant dense batch size, helping it perform well even under tail latency SLOs.

6.4 Ablation Study

To showcase the overhead and benefit of the techniques that NanoFlow uses, including nano-batching, nano-operation overlapping, and KV-cache offloading, we compare the NanoFlow instance with baselines that share the same asyn-

[7] v0.8.0 (commit ID 5955b8a)

(a) Splitwise (b) LMSYS-Chat-1M (c) ShareGPT

Figure 8: Latency comparison. The x-axis shows the number of incoming requests per second, and the y-axis shows the normalized latency. NanoFlow handles higher request rates within 200ms SLO constraints.

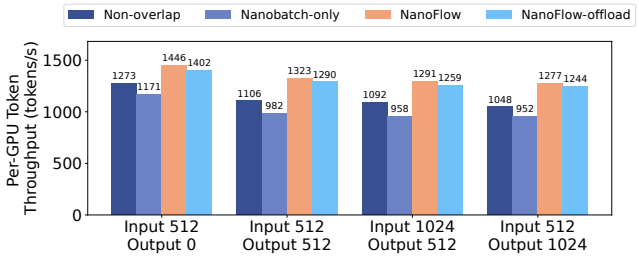


Figure 9: Ablation study results for NanoFlow. Nano-batching and overlapping improves NanoFlow's performance.

chronous request scheduling and kernel libraries.

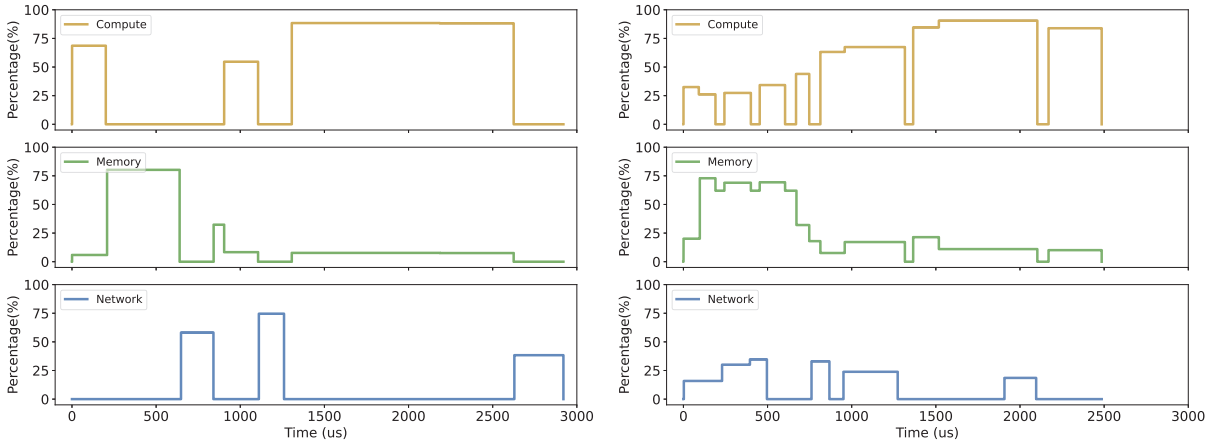
We created two baselines: a non-overlapping baseline processing inputs sequentially without nano-batches, and a nano-batch-only baseline that splits requests into nano-batches as in NanoFlow but executes them sequentially to assess nano-batching overhead. As shown in Figure 9, splitting into nano-batches alone reduces performance by 13.2%.

To estimate the benefit of overlapping network- and memory-bound kernels, we compare NanoFlow and baselines under various prefill-decode ratios, as shown in Figure 9. We use prefill-only workloads (Input 512, Output 0) to demonstrate the benefit of overlapping network-bound and compute-bound kernels. Additionally, we use decode heavy workloads (Input 512, Output 1024) to evaluate the benefit of overlapping both network- and memory-bound kernels. NanoFlow achieves 1.07× speedup by overlapping network-bound kernels and 1.17× speedup by overlapping both network- and memory-bound kernels compared with the non-overlapped baseline.

Moreover, we quantify the performance degradation due to offloading in Figure 9. Enabling offloading would slow down the pipeline by 3.0% due to kernel interference caused by KV-cache movement. However, offloading can reduce compute by 3.02× for multi-round LMSYS-Chat workloads.

6.5 Resource Usage

We demonstrate NanoFlow's effectiveness in terms of resource utilization in Figure 10. While the non-overlapping baseline sequentially executes operations, which mostly uses only one resource at a given time, the NanoFlow instance can concurrently utilize multiple resources and achieves 68.5% average compute utilization. Due to kernel interference, NanoFlow provides lower than optimal compute usage.



6.6 Performance on Other LLMs

We evaluate the throughput of NanoFlow instances for other LLMs with a constant length of input 1024 and output 512. All evaluations are done on 8×A100 80GB SXM GPUs, except for LLaMA-3-8B, which runs on a single A100 80GB SXM. The results are summarized in Figure 11. We find that NanoFlow improves throughput to between 50% and 72% of optimal throughput for these models, surpassing vLLM.

7 Related Work

LLM serving optimizations. Prior works have investigated optimizations for improving the serving throughput at different granularities. Orca [53] proposes request-level continuous batching, which refills the on-the-fly batch to maximize batch size at the granularity of an iteration. DistServe [59] and Splitwise [32] explore phase-level scheduling, which disaggregates the prefill and decode phases into different clusters. DeepSpeed-FastGen [13] and Sarathi-Serve [2] propose a chunked prefill policy, which splits a prefill request into multiple smaller chunks and batches decode and prefill requests together to improve overall utilization. However, these works do not perform scheduling at the granularity of operations. NanoFlow exploits intra-device parallelism, which features fine-grained resource management. Other works tackle the inference inefficiency by optimizing specific operations, including PageAttention [17], quantization approaches [19, 44, 55], etc. NanoFlow can easily adopt new operation implementations by profiling their performances and interference characteristics and integrating them into auto-search.

Operation-level parallelism. Some works focus on improving the efficiency of DNN workloads with operation-level optimizations. For example, Rammer [20] explores intra-operation parallelism by remapping the operations into different functional units. Unity [50] investigates the combination

(a) Non-overlap pipeline resource usage

(b) NanoFlow resource usage

Figure 10: The non-overlapping pipeline and NanoFlow's resource usage during inference of a single layer. NanoFlow achieves high compute usage across the whole pipeline by simultaneously utilizing memory and network bandwidth.

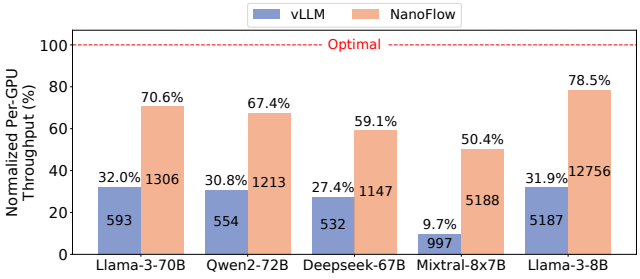


Figure 11: Performance of NanoFlow instances in terms of tokens per second per GPU for other models. Compared with vLLM, NanoFlow significantly increases throughput. NanoFlow achieves up to 78.5% of optimal throughput.

of parallelism and equivalent algebraic transformation of operations. However, these works do not consider the different resource demands of operations. ASPEN [30] and Welder [37] break the boundary between operations by constructing and compiling a tile-level data graph. Since tiles follow sequential dependencies, parallelism is still limited. Moreover, prior works require recompilation from scratch, which requires significant manual work. Compared with them, NanoFlow creates more overlapping opportunities through nano-batching.

8 Conclusion

In this work, we analyzed the characteristics of different operations in LLM serving and revealed the compute-bound nature of modern LLM serving workloads. We identified that compute is underutilized within a single GPU due to the sequential execution of compute-bound, memory-bound, and network-bound operations, leading to sub-optimal throughput. To address this, we proposed NanoFlow, a novel end-to-end LLM serving system that overlaps operations with heterogeneous resource usage through intra-device parallelism. NanoFlow automatically constructs a pipeline that overlaps nano-operations, with an auto-search that adapts to various LLM models. Our experiments show that NanoFlow achieves 1.91× throughput improvement over the state-of-the-art systems.

Abstract

To effectively utilize heterogeneous specialized hardware units in modern GPUs, such as TensorCores and Tensor Memory Accelerators, this paper introduces PipeThreader, a new DNN compiler. PipeThreader proposes shifting scheduling functionality from hardware to software so as to enable more efficient and sophisticated computation pipelining with minimal manual effort. This is achieved through sTask-graph, a new DNN computation abstraction, a hierarchical hardware abstraction that captures the capabilities of specialized units, and new scheduling primitives. As a result, PipeThreader can discover efficient pipeline scheduling for well-studied DNN architectures like FlashAttention, achieving comparable or even superior performance. Additionally, it can uncover novel pipeline schemes for emerging models like Mamba2, delivering significantly better performance compared to state-of-the-art hand-crafted implementations. The code is open-sourced at https://github.com/tile-ai/tilelang.

1 Introduction

The increasing size of deep neural networks (DNNs) imposes significant computation and memory pressure on modern AI accelerators, such as GPUs. To meet the growing compute demands, hardware vendors have introduced specialized heterogeneous hardware units, such as TensorCores [14–16, 20–22] and Tensor Memory Accelerators (TMA) [22]. Meanwhile, software developers tend to fuse multiple DNN operators, a compute-intensive unit such as matrix multiplication, into one single GPU kernel to maximize data reuse so as to alleviate memory pressure [27, 47].

However, these emerging hardware and software trends present new challenges for efficient DNN execution. First, maximizing utilization of the specialized hardware units requires careful scheduling of the DNN computation pipeline. Previously, GPUs relied on hardware schedulers for thread execution, amortizing potential stalls within individual pipelines through *massive* concurrent threads. However, this approach is no longer effective, as the number of available concurrent threads has decreased significantly due to the inherently larger tensor granularity required by specialized units to achieve higher computation density. Second, operator fusion introduces deeper computation pipelines. Hardware schedulers struggle to comprehend such sophisticated pipelines, making effective scheduling challenging. As a result, state-of-the-art DNN kernels, such as FlashAttention [26], are hand-crafted to carefully organize the execution pipeline. However, this approach is hard to generalize. New hand-crafted implementations are required for every GPU type, e.g., the NVIDIA Hopper GPU or AMD GPU [46], emerging DNN models, e.g., Mamba [31], and even new tensor shapes of DNN models, e.g., FlashAttention2/3 [26, 46].

Given the growing complexity of software and hardware pipelines, coupled with the inherent limitations of hardware scheduling, this paper proposes PipeThreader, a DNN compiler that supports *software-defined* pipelining for efficient DNN execution on modern GPU architectures with specialized heterogeneous hardware units. PipeThreader abstracts DNN computation as an sTask-graph. Each node in the graph denotes an sTask, a fine-grained task that can be scheduled to a specialized unit; and directed edges in the graph specify dependencies across sTasks. sTasks compute on *tiles*, which are portions of a tensor. The concept of tiling is widely adopted by modern DNN compilers [11, 23, 43, 49, 53, 54, 56]. Using the sTask-graph, PipeThreader can extract sophisticated computation pipelines that are well-suited for execution on specialized hardware units.

To expose fine-grained scheduling capabilities of hardware, PipeThreader abstracts the GPU device as hierarchical hardware units, including the virtualized homogeneous parallel execution units (i.e., EU) and the heterogeneous specialized units within each EU (i.e., sEU). An sTask can then be scheduled using three primitives, `append`, `wait`, and `propagate`, thereby enabling sophisticated pipelining through software. PipeThreader also incorporates a two-layer scheduling policy to find effective scheduling schemes, given the new optimization space defined by an sTask-graph and the new exposed hardware capabilities.

We have implemented PipeThreader with 8.5k lines of C++ and Python code, based on open-source DNN compilers: TVM [19] and Ladder [51]. Evaluation shows that PipeThreader can discover the pipelining scheme resembling that of FlashAttention in new hardware like NVIDIA H100 or AMD MI300X GPUs, achieving comparable or better perfor-

*Part of work is done during the internship at Microsoft Research.

mance without manual implementations. PipeThreader can also find effective pipeline scheduling for emerging models like Mamba2 [28], producing significantly better performance than the state-of-the-art hand-crafted implementation. We believe that PipeThreader is a further step toward defining a complete scope of tile-based software/hardware abstraction, which well aligns with modern tile-based programming efforts (e.g., Triton [49], CuTe abstraction from CUTLASS [23], etc.) and the evolution of new hardware architectures.

2 Motivation

The growing hardware and software complexity. The rapid growth of large DNN models, particularly large language models (LLMs) [44], has driven hardware vendors to develop specialized heterogeneous hardware units, such as TensorCores and Tensor Memory Accelerators (TMA), to meet the escalating computational demands. Meanwhile, sophisticated operator fusion techniques like FlashAttention [27] are increasingly employed to reduce memory overhead and maximize data locality (details in §3.3). While these trends enhance computational density and efficiency, they also introduce significant challenges in scheduling and execution, particularly on modern GPUs with heterogeneous units.

Under-utilization in traditional data-parallel GPU execution. Traditional GPU programming models like CUDA [3] dispatch threadblocks across Streaming Multiprocessors (SMs), treating each SM as a uniform, isolated execution unit. This abstraction assumes all SMs are interchangeable and hides their internal structure, which worked well for earlier architectures like NVIDIA V100 [20]. However, modern GPUs like the NVIDIA H100 [22] integrate heterogeneous components within each SM, including TensorCores for matrix operations, CUDA cores for general-purpose computation, and TMAs for memory movement. These components have distinct roles and execution characteristics. Uniformly dispatching threadblocks without awareness of these internal differences leads to inefficient resource usage. To fully exploit such architectures, it is crucial to be aware of the heterogeneous units within each SM and to coordinate task placement, scheduling, and pipelining accordingly. Without this level of control, significant performance remains untapped.

Figure 1 reports per-unit utilization on H100 across different implementations of MatMul, FlashAttention, and Mamba2. For MatMul, the TensorCore utilization is only 40% due to the bottleneck on memory movement without the pipelined execution, while expert-optimized cuBLAS achieves 97% TensorCore utilization. FlashAttention-3 [46] improves the utilization of TensorCore from 40% to 72% with manual optimizations compared to Triton-based FlashAttention2 [26]. Notably, evolving from FlashAttention-2 to FlashAttention-3 took nearly one year. However, the emerging manually optimized Mamba2 [28] still underutilizes the units with only

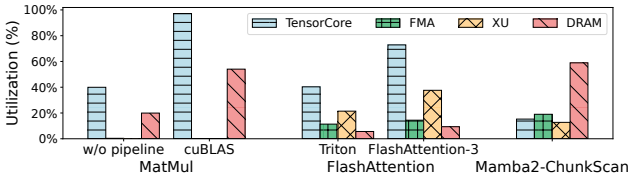

Figure 1: Per-unit hardware utilization on NVIDIA H100 for different implementations of representative AI workloads, including MatMul, FlashAttention, and Mamba2's ChunkScan. Each bar shows the utilization of individual hardware units for a specific workload implementation. Note that FMA and XU units are not used in MatMul.

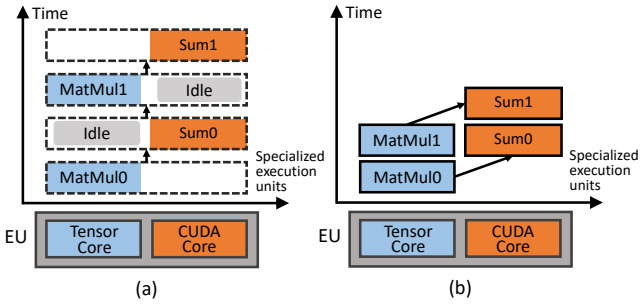

Figure 2: An illustration of (a) inefficient scheduling in existing approaches; (b) optimized scheduling that leverages pipelined execution across specialized execution units.

15% TensorCore utilization. Therefore, it is challenging to fully utilize the modern hardware for emerging DNN models.

Manually managing pipelined execution in kernels is notoriously challenging due to the vast and hardware-sensitive design space. Developers must carefully balance tile size and pipeline depth while adhering to tight on-chip resource constraints. These challenges are further amplified by architectural variability, including differences in memory hierarchies and specialized compute units. As manual reasoning quickly becomes intractable, automated inference and scheduling become essential for achieving both performance and portability. However, existing compilers such as TVM [19] and Triton [49] lack explicit mechanisms to express pipelined tile execution. By abstracting away low-level control, they limit the developer's ability to specify execution order, resource allocation, and compute-communication overlap—hindering the exploitation of full performance potential. Realizing efficient pipelined tile execution requires a new compiler that can systematically explore this design space, generate optimized schedules, and adapt across diverse hardware platforms.

Observations and opportunities. In light of these facts, we observe a unique opportunity to address the issue. Given that the new hardware units process data at a large granularity, such as tensor tiles, previous works [11, 23, 43, 49, 53, 54, 56] have demonstrated that tile-level execution can be efficiently scheduled at the software layer due to its deterministic performance at the tile level. By leveraging this trend, we advocate

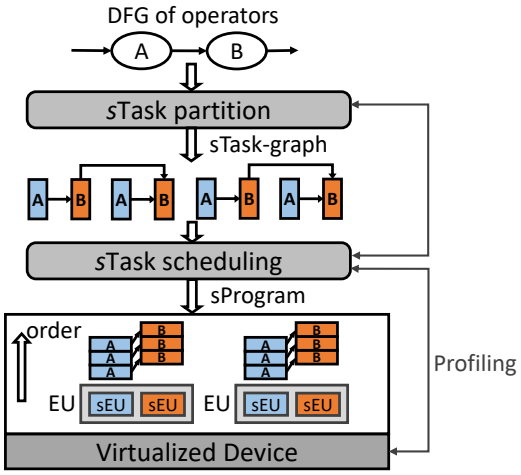

Figure 3: System overview of PipeThreader.

```

9      sEUType target_sEU;
10 };
11 class vDevice {list<EU> EUs;};
12 class EU {list<sEU> sEUs;};
13 class sEU {
14     bool is_async;
15     void Execute(sTask s);
16 };
```

Figure 4: The abstraction of sTask and sEU.

shifting pipeline scheduling from implicit hardware behavior to explicit software control. Here, pipeline scheduling refers not to low-level thread or warp dispatching by the GPU, but to the software-guided mapping of tile-level operations onto specialized units such as TensorCores, CUDA cores, or TMAs within each SM.

Figure 2(a) shows the execution of fused MatMul-Sum where MatMul is executed on TensorCore and Sum is executed on CUDA core. Due to the homogeneous abstraction in existing approaches, the scheduling serializes the execution despite the inherent parallelism between TensorCores and CUDA cores, leading to inefficiencies. In contrast, Figure 2(b) demonstrates the optimized scheduling that leverages specialized execution units, enabling pipelined execution and fully utilizing the heterogeneous hardware.

Unfortunately, neither the existing DNN model representations nor the hardware interfaces in existing GPUs explicitly expose the scheduling capabilities required for tile-level pipeline execution.

3 PipeThreader Abstraction

The observations in §2 motivate PipeThreader, a DNN compiler framework that integrates tile-based data parallelism with pipelined scheduling. Figure 3 provides an overview of the system. State-of-the-art DNN compilers (e.g., Triton [49], Roller [56], Welder [47]) abstract hardware accelerators as collections of homogeneous execution units (EUs) for SPMD-style parallelism. This approach overlooks the hardware heterogeneity inherent in modern GPUs. For example, TensorCores and CUDA cores within an SM are optimized for different workloads, a diversity that existing compilers fail to utilize. To address these limitations, PipeThreader introduces two key abstractions: *specialized tasks* (*sTasks*) and *specialized execution units* (*sEUs*). Starting with a data flow graph (DFG) of operators as input, PipeThreader converts these operators into sTasks, which are designed to exploit the heterogeneous capabilities of sEUs, enabling MPMD-style parallelism. Details of sTasks and sEUs are discussed in §3.1. sTasks preserve the data dependencies of the original DFG at task granularity, forming an *sTask-graph*. PipeThreader organizes the mapping of the sTask-graph to sEUs into an *sTask-program*, a structured representation for execution. With the *sTask-program* abstraction, PipeThreader opens up a new search space. Details of the sTask-graph, sTask-program, and search space are discussed in §3.2.

3.1 Specialized Tasks and Execution Units

sTask. PipeThreader introduces sTasks (short for specialized tasks) as the basic computation unit in an operator to be executed on a specific execution unit (sEU) of the accelerator device. The concept of sTask naturally aligns with the heterogeneous, specialized processors of modern DNN accelerators, e.g., TMA, CUDA cores, and TensorCores in H100 GPU. To maximize efficiency, the computation on such an accelerator needs to be divided into multiple parallel (heterogeneous) tasks for each type of specialized processor. Each type of these parallel tasks can be represented by an sTask, thereby exposing the potential task parallelism not only to specialized processors of the underlying hardware but also to the PipeThreader compiler.

As shown in Figure 4, an sTask processes a data tile sliced from the input tensors and produces a data tile in the output tensors, with its computation described by an index-based tensor expression. The `shape` (line 8) of an sTask is defined along each loop axis of the tensor expression `expr` (line 7). Additionally, the `target_sEU` (line 9) attribute specifies the type of specialized units on which the sTask can execute. In contrast, traditional tile-based tasks are not explicitly categorized, limiting their ability to exploit the parallelism of specialized processors. As illustrated in Figure 5, on a specific EU, a traditional MatMul-Sum task (a fused operation in FlashAttention) would sequentially compute a $[2 \times 2]$ data tile from A and a $[2 \times 2 \times 2]$ data tile from B, producing a $[2 \times 2]$ output tile for C. PipeThreader introduces two types of sTasks: `mma` sTasks executing matrix multiply-accumulate on TensorCores, and `Sum` sTasks running on CUDA cores.

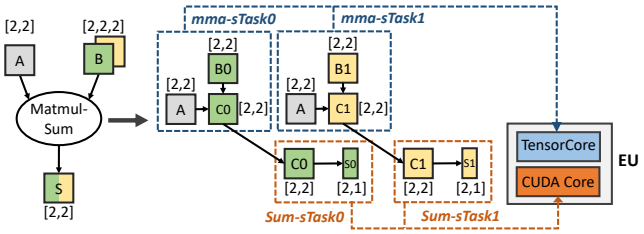

Figure 5: sTask MatMul-Sum on NVIDIA GPU.

This enables pipelining, as the second `mma` sTask, multiplying A with the partition $B1$ to produce $C1$ on TensorCores, can overlap with the first `Sum` sTask, reducing $C0$ to $S0$ on CUDA cores. This pipelined execution allows task parallelism, significantly improving hardware utilization.

sEU. Modern accelerators lack interfaces to map an sTask to a specific execution unit. To address this, PipeThreader explicitly exposes the execution units within GPUs and abstracts them as a hierarchical execution array, capturing both parallelism and the capability to support data-dependent execution with pipelining.

As illustrated in Figure 4, the abstracted device consists of multiple parallel execution units (EUs) (line 11), each containing several heterogeneous *specialized execution units* (*sEUs*) (line 12). These sEUs serve as the hardware foundation for PipeThreader to effectively schedule data-dependent tasks with pipelining. For instance, on a modern H100 GPU, a Streaming Multiprocessor (SM) is an EU that includes Tensor Memory Accelerators (TMAs) for `load` sTasks and TensorCores for `mma` sTasks. An sEU executes a given sTask using the `Execute` interface (line 15). The `is_async` attribute (line 14) specifies whether the sEU operates synchronously (e.g., CUDA cores) or asynchronously (e.g., TMAs). An asynchronous sEU can be executed concurrently with either asynchronous or synchronous sEUs.

3.2 From sTask-Graph to sProgram

To execute a DNN, PipeThreader transforms the input DFG into a specialized representation tailored to modern heterogeneous hardware. This process involves two key steps: constructing an *sTask-graph* that captures computation and dependency, and mapping this graph to specialized execution units (*s*EUs) as an *sTask-program* (*sProgram*), which orchestrates efficient execution.

sTask-Graph. As illustrated in Figure 3, operators from the input DFG are converted into *sTasks* via `sTask-partition`, forming an *sTask-graph*. This graph preserves the computation and data dependencies of the original DFG, with nodes representing sTasks and edges capturing their fine-grained dependencies at the task level. The `sTask-partition` process partitions each operator by configuring the `TileShape` (i.e., Map<Axis, Dim>) of sTasks, specifying their divisible dimensions and sizes. Traditional compilers primarily focus on spatial partitioning to achieve data parallelism. PipeThreader extends to support both spatial and reduction partitioning, unlocking new opportunities for pipelined execution. This flexibility allows PipeThreader to generate diverse sTask-graphs based on different partitioning strategies, enabling more versatile and efficient execution planning.

sProgram. Given the sTask-graph, PipeThreader maps it onto the hardware's sEUs in the form of an *sTask-program* (*sProgram*). The sProgram is a two-dimensional array, `sProg[sEU][order]`, where each entry specifies the assignment of an sTask to a particular sEU and its execution order. This structured representation facilitates efficient scheduling and execution of tasks. To maintain correct execution order for dependent sTasks, PipeThreader introduces *barrier-sTasks*, which synchronize execution by referencing a list of sTasks identified by `<EU_id, sEU_id, order>` in the program. A barrier-sTask waits for the completion of all referenced sTasks before proceeding.

Search Space. The search space of PipeThreader is structured as the set of sPrograms, where each is a two-dimensional array `sProg[sEU][order]` defining tiling size and execution order (with synchronization barriers) for each sTask in the graph. There might be many combinations of sTask ordering and tiling sizes. PipeThreader's search space includes all valid sPrograms where operators can be executed while respecting data dependency. For example, FlashAttention's search space includes 37,440 valid sPrograms. For complex fused operators, sTask scheduling often contributes more significantly to the search space. With more types of sTasks, there might be many valid sPrograms of different sTask execution orders. For example, in FlashAttention, there are 36 sTask size (i.e., tiling) configurations, but 1,040 sTask ordering configurations for each tiling size.

3.3 Running Examples

Mamba2. Mamba is a popular DNN model that processes sequences using chunk-wise scanning with a linear attention mechanism. Its linear attention comprises multiple modules; here, we illustrate its key ChunkScan operator.

Frontend. For the ChunkScan function, PipeThreader takes a simple IR represented in Figure 6(a) as input. It multiplies *cb* by the product of the exponential of *dA* and *dt* (line 6), then accumulates the result of the matrix multiplication of *cb* and *x* into *acc_o* (line 8). PipeThreader treats `load_cb` (line 3), `load_dA` (line 4), `load_dt` (line 5), `exp` (line 6), `load_x` (line 7), and `mma` (line 8) as individual sTasks.

sTask-graph. PipeThreader constructs a corresponding sTask-graph based on their dependencies. The sTask-graph can be partitioned along both spatial and reduction dimensions. Spatial partitioning (i.e., batch size) splits the graph into smaller subgraphs distributed across EUs for tile-based data parallelism. Reduction partitioning (i.e., sequence length)

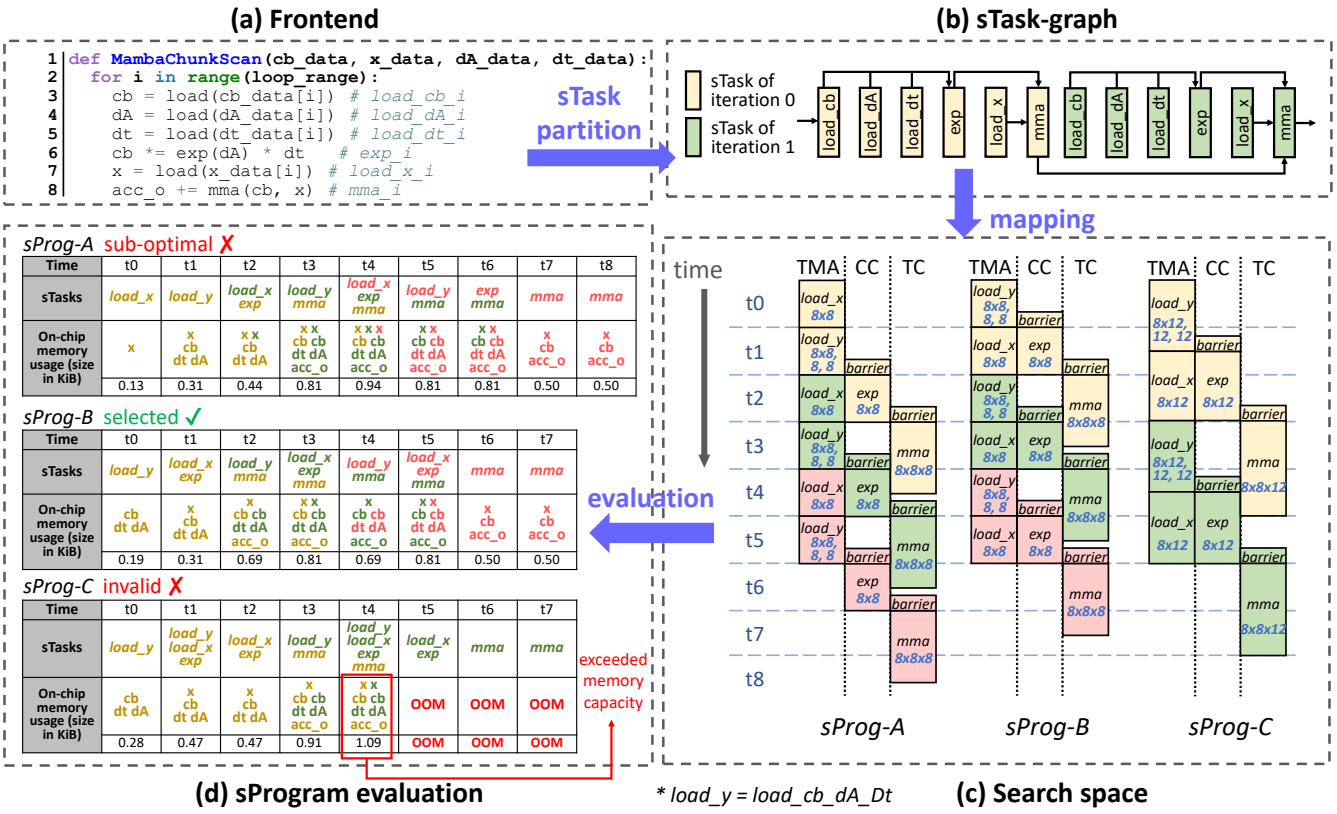

Figure 6: Running example of Mamba2-ChunkScan. (a) shows the user-facing frontend. (b) presents the sTask-graph constructed from (a), with colors indicating different iterations. (c) illustrates various sPrograms derived from the sTask-graph in (b), and (d) compares their evaluation to identify the most efficient sProgram.

creates finer-grained sTasks within an EU, exposing opportunities for pipelined execution. Given *acc_o* (line 8 in Figure 6(a)) of size (M,N) and X of size (K,N), PipeThreader partitions the spatial dimensions (M,N) as usual, assigning each sTask a tile of (m,n). It also partitions the reduction dimension (K) into *loop_range* iterations, allowing computations to overlap across iterations[1]. Figure 6(b) shows the sTask-graph derived from reduction-dimension partitioning.

sPrograms. Given the sTask-graph, PipeThreader can have different choices of mapping sTasks to sEUs in the form of multiple *sPrograms*. Figure 6(c) illustrates three sPrograms derived from the sTask-graph. In sProg-A, `load_x` is scheduled before other load sTasks, whereas sProg-B and sProg-C schedule these operations in reverse order. Compared to sProg-B, sProg-C employs a larger tiling size.

Evaluation. Figure 6(d) illustrates the evaluation of the three sPrograms. The table shows the sTasks running at each time step, along with the corresponding on-chip memory usage. Here, we assume an on-chip memory capacity of 1 KiB. In sProg-A, `load_x` is scheduled earlier, but since the `exp` sTask depends on the completion of `load_cb_dA_dt`, this results in delayed scheduling of `exp`, leading to lower overall efficiency compared to sProg-B. Although sProg-C employs larger sTasks, this increases the on-chip memory usage of its workspace. We observe that at time step t_4, the workspace exceeds the available on-chip memory capacity, rendering this sProgram invalid. Consequently, sProg-B is selected as the final scheduling strategy.

PipeThreader's task partitioning follows the principles of tiling but elevates new *reduction tiling* as a key optimization strategy. Traditionally, tiling prioritizes spatial partitioning for data reuse, while reduction tiling is often treated as secondary. PipeThreader, however, actively exploits reduction tiling to enable pipelining, improving execution efficiency. This ensures efficient pipelined execution while maintaining data reuse. By making reduction tiling a first-class optimization, PipeThreader unlocks performance improvements beyond conventional tiling strategies, particularly in pipeline-heavy workloads. Also, traditional tiling strategies tend to use larger tile sizes, which may conflict with increasing pipeline parallelism due to both demanding on-chip memory. PipeThreader further makes the trade-off between tiling and pipelining.

FlashAttention-3. FlashAttention is an efficient implementation of the original full attention mechanism, in which the input nodes of the DNN operator graph are three tensors: $Q, K,$

[1]Note here the sTask-graph does not fully unroll all the loops, it models iteration structures via scheduling a window of `MAX_STREAM` iterations.

```
1 def FlashAttention(q_data, k_data, v_data):
2     q = load(q_data)
3     for i in range(loop_range):
4         k = load(k_data[i]) # load_k_i
5         acc_s = mma(q, k)   # mma_qk_i
6         P = softmax(acc_s)  # softmax_i
7         v = load(v_data[i]) # load_v_i
8         acc_o = rescale(acc_o, param) # rescale_i
9         acc_o += mma(P, v)  # mma_pv_i
```

Figure 7: Pseudocode of the FlashAttention sTask-graph.

and V. First, a matrix multiplication `MatMulQK` is performed to compute $acc_s = QK^{\mathrm{T}}$. Next, acc_s is passed through a `Softmax` operation to produce P. Finally, P and V are used as inputs for the second matrix multiplication `MatMulPV` to compute the output O.

In FlashAttention, these three operators are fused into a single kernel. PipeThreader annotates the pattern to derive dependent sTasks, forming an sTask-graph (Figure 7). After partitioning, PipeThreader assigns `load_k` (line 4) and `load_v` (line 7) to TMA, `mma_qk` (line 5) and `mma_pv` (line 9) to TensorCores, and `softmax` (line 6) and `rescale` (line 8) to CUDA cores. PipeThreader applies its two-level scheduling policy to explore the space and generates an sProgram where sTasks execute in parallel on their respective sEUs, leveraging the asynchrony and heterogeneity of sEUs. It is worth noting that our scheduling space includes the pipeline plans of the latest FlashAttention-3 [46].

4 PipeThreader Scheduling

The sProgram abstraction opens up a large optimization space. PipeThreader aims to generate high-quality sPrograms in this space. To this end, PipeThreader separates the scheduling mechanism from its policy. On the mechanism side, it provides two capabilities: (1) Scheduling interfaces for a policy to generate a sProgram. (2) A profiler to supply profiling information requested by a scheduling policy. On the policy side, PipeThreader provides a two-layer policy that balances tiling and pipeline parallelism. This simple policy can already outperform the state-of-the-art, sometimes significantly. We believe this mechanism lays a foundation for future research into more sophisticated policies that further exploit the optimization space exposed by sPrograms.

4.1 Scheduling Interfaces

PipeThreader provides three interfaces to generate a high-quality sProgram in the new space, as shown in Figure 8. The `Append` interface assigns a specific sTask to a particular *s*EU within an EU. The `Wait` interface allows an sTask `s` to wait for sTasks in `list<sTask_uid>` to complete, which implicitly appends a barrier-sTask right before the sTask `s`. The above interfaces allow for explicit control of the placement and execution order of sTasks across sEUs (i.e., sProgram) to explore parallelization space.

```
1 void Append(sTask s, <EU u, sEU v>);
2 void Wait(sTask_id s, list<sTask_id> t);
3 void Propagate(sTaskGraph g, TileShape shape);
```

Figure 8: The scheduling interfaces.

PipeThreader provides a `Propagate` interface to explore the sTask partition space by automatically inferring the `TileShape` of each sTask in an sTask-graph. Starting from the output tile shape of the final sTask, `Propagate` performs a chain of shape inferences backward through the graph, determining the dependent input regions for each sTask based on its tensor expression and output tile shape. For example, if $[4 \times 128]$ output tile shape is required for a `Softmax` sTask, `Propagate` deduces that its input tile shape must also be $[4 \times 128]$. Treating this as the output tile shape of a preceding `mma` sTask, the input tiles are inferred as $[4 \times k]$ and $[k \times 128]$, where k is the reduction size.

4.2 Scheduling Policy

Our scheduling policy is inspired by the two-layer hardware abstraction described in Figure 3, where homogeneous EUs enable SPMD-style parallelism, and heterogeneous sEUs within each EU support MPMD-style parallelism. Figure 9 outlines the two-level scheduling algorithm used in PipeThreader. At the inter-EU level, the policy minimizes latency by partitioning the model into sTask-subgraphs, which are evenly distributed across EUs (lines 1-10). At the intra-EU level, the policy optimizes the execution cost of each sTask-subgraph on a given EU by constructing an efficient pipelining plan (lines 11-32). The inter-EU schedule is informed by execution cost estimates for each partition, as provided by the intra-EU schedule.

Initially, the policy represents each operator as one or more sTasks based on its computational stages (e.g., MatMul is split into `load` and `mma` sTasks). In the inter-EU pass, the scheduler enumerates different partitions of the output sTask in the function `GetsTaskPartitions` (line 2). For each sTask partition, the scheduler uses `Propagate` (line 4) to derive other sTask partitions across the graph and assigns sTasks evenly across EUs, leveraging their equivalent compute capability. This SPMD-style approach significantly reduces the complexity of inter-EU parallelism plans. The policy invokes the intra-EU pass to optimize the execution of assigned sTasks within an EU (i.e., an sTask-subgraph). During the intra-EU pass, the policy employs a greedy approach to schedule sTasks onto sEUs, iteratively performing the following steps until all sTasks assigned to the EU are scheduled: 1) selects the sTask t with the `endtime` earlier than the current time `cur_time` in `get_complete_sTask` (line 15); 2) identifies the set of ready sTasks whose predecessors have been scheduled (line 17-20) and dequeues the sTask u with the highest priority using `get_high_priority` (line 22); 3) appends the selected sTask to the sEU with `Append()` (line 23) and ensures sTask-level dependencies by invoking `Wait()` (line 25). We also call

```
1  Func InterEUScheduling(G:operator-graph, D:vDevice):
2      S = GetsTaskPartitions(out_op);
3      for out_tiles ∈ S.TileShape do
4          sTask_set = Propagate(G, out_tiles);
5          sTask_subgraph = Partition(sTask_set, D);
6          IntraEUScheduling(sTask_subgraph, EU, plan);
7          if Profile(plan).latency < best_latency
8              best_latency = Profile(plan).latency;
9              best_plan = plan;
10     return best_plan;
11 Func IntraEUScheduling(g:sTask-graph, EU, Plan):
12     scheduled_set =∅;
13     curr_time = 0;
14     while scheduled_set ≠ g.nodes do
15         t = get_complete_sTask(Plan, curr_time);
16         t.state = COMPLETE;
17         for n ∈ g.nodes \scheduled_set do
18             if all sTasks in Predecessor(n) are COMPLETE
19                 n.state = READY;
20                 ready_sTasks.add(n);
21         for ready_sTasks≠ ∅ do
22             u= get_high_priority(ready_sTasks, Plan, g);
23             P = Plan.Append(u, <EU, sEU>);
24             if check_valid(P)
25                 P.Wait(u, Predecessor(u).sTasks);
26                 if t ∉ Predecessor(u)
27                     P.Wait(u, t);
28                 u.endtime = max{sEU.time, curr_time} +
                     Profile(u, sEU);
29                 sEU.time = u.endtime;
30                 scheduled_set.add{u};
31                 Plan = P;
32         curr_time = curr_time + δ;
```

Figure 9: Scheduling algorithm.

`Wait(u, t)` to handle cases where the scheduling of u must wait for the completion of t to release memory (line 26-27). To improve pipeline efficiency, we prioritize scheduling asynchronous sTasks with *minimal dependencies on already scheduled tasks* and *high potential to unlock downstream sTasks*. As illustrated in Figure 6(c), scheduling `load_x` early delays the execution of `exp`, whereas scheduling `load_y` earlier enables `exp` to proceed sooner. As a result, our algorithm assigns a higher priority to `load_y`, naturally favoring the construction of `sProg-B` and `sProg-C` over `sProg-A`.

Increasing sTask overlap (i.e., pipeline parallelism) requires additional on-chip memory (e.g., shared memory and registers on GPUs) to buffer intermediate results between stages. However, this demand may conflict with the use of larger tiling sizes. Our method balances these competing demands through a joint search strategy guided by profiling feedback. To ensure memory feasibility, we invoke `check_valid` to verify (based on the current sProgram and profiler) whether a selected sTask fits within the memory constraints of the target `sEU` (line 24).

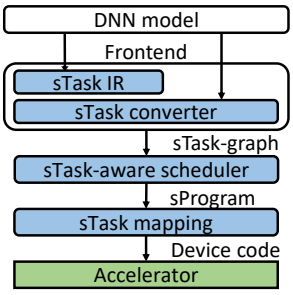

Figure 10: Implementation of PipeThreader.

Candidates that exceed the limit are skipped. For example, in Figure 6, `sProg-C` employs a larger tiling size, which exceeds the available on-chip memory. The `check_valid` step detects this violation and avoids generating such invalid schedules.

Profiler. PipeThreader introduces a profiler to guide efficient sProgram generation (Figure 9) in the search space. The profiler provides the following information of individual sTasks to generate a valid execution timeline of the sProgram: (1) the execution time of individual sTasks on specific sEUs, (2) the resource usage of sTasks, including local memory and register consumption, and (3) the overall execution time of the sProgram. The profiler automatically handles a new tensor expression by leveraging the code generation backend of existing compilers like TVM, and measures the execution time and resource usage of the device code of an isolated sTask. During scheduling, PipeThreader uses these profiling results to estimate when a task should be launched to maintain pipeline efficiency and minimize idle time. After completing sTask scheduling, the profiler also measures the performance of the entire generated schedule, providing the ground-truth latency. This profiling data informs the scheduling policy and guides the generation of efficient scheduling plans.

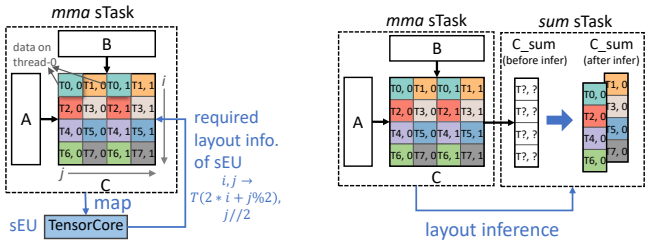
5 PipeThreader Implementation

PipeThreader is implemented with 8.5k lines of C++ and Python code, based on open-source DNN compilers: TVM [19] and Ladder [51]. Figure 10 summarizes the overall workflow of PipeThreader. The frontend produces the sTask-graph, which is then processed by the sTask-aware compiler (scheduler) to generate the sProgram. Finally, the mapping optimizer generates the device code for the sProgram.

5.1 Frontend

The PipeThreader frontend includes an sTask-IR for expressing the sTask-level DNN computations, and an sTask-converter to transform DNN model into sTask-graph.

sTask IR. The sTask intermediate representation (IR) provides the programmer and the compiler with a flexible way to express sTask-level computation that cannot be easily captured by the existing compiler IRs (e.g., expression-oriented



IR). The pseudocode in Figure 6(a) and Figure 7 can be viewed as a simplified form of the sTask IR. The pseudocode illustrates how complex deep learning kernels can be modeled as data-flow patterns, including memory operations (e.g., moving sTasks between DRAM and SRAM) and sequences of computations on sTasks.

sTask converter with sEU. The PipeThreader frontend can also convert the DNN model expressed by both sTask IR and ONNX graphs into an sTask-graph. In this process, we leverage Ladder [51], a state-of-the-art DNN compiler for operator fusion. The output of Ladder is a tile-graph, which is expressed in TVM's TIR as an intermediate representation. We annotate the `target_sEU` attribute of each tile-based task to transform it into sTasks based on sEU information. For instance, on the NVIDIA H100 GPU, we treat a Streaming Multiprocessor (SM) as an EU. Within each SM, the sEUs include the TensorCores for matrix multiply-accumulate `mma`, CUDA cores for general floating-point computations such as `reduce` and `parallel`, and the TMA for bulk memory `copy` operations between global and shared memory. These basic operations can be composed to represent data operations in most common deep learning kernels. For example, data movement is translated into a `parallel` operator which can represent arbitrary element-wise tile operations. Also, users can define customized functions to describe other sTasks.

Although programmers need to write a simple IR to generate kernels (e.g., Figure 7 for the FlashAttention kernel), they do not have to be aware of tasks, how to divide their graphs (or IRs) into sTasks, and which sTasks can run on which sEUs. PipeThreader can infer this information, for example, setting attributes such as tiling shape and target sEU in the sTask class in Figure 4. The sTask converter annotates each operation (e.g., `mma`) on which types of sEU to execute (i.e., `target_sEU` attribute). The scheduler then automatically determines how to divide it into sTasks (e.g., tiling shape) and which sTasks run on which sEUs (e.g., sEU assignment in sProgram). Therefore, PipeThreader can help reduce the tedious manual effort and strong domain expertise required for hand-crafted implementation. For the FlashAttention kernel, PipeThreader only needs 68 lines of Python code, as compared to 840 lines of CUDA kernel code from the hand-crafted implementation FlashAttention-3.

5.2 sTask Mapping on NVIDIA CUDA GPUs

For both TMA and TensorCore sEUs, the `is_async` attribute is set to true, as we can leverage the `cp.async.bulk` and `wgmma.mma_async` instructions. In contrast, the `is_async` attribute for CUDA cores is set to false because they do not support any asynchronous instructions. The fact that instructions for CUDA Cores and TensorCores can be dispatched simultaneously is officially confirmed by NVIDIA [8]. Interference can occur as both units utilize the same set of registers. We alleviate the potential interference by implementing double buffering on registers to overlap the execution of TensorCore and CUDA Core. We implement barrier-sTask using the `mbarrier` object in PTX [9]. To efficiently implement the `Execute` function in sEU, we decide how sTask operations and data map to different threads and physical memory through layout inference. We also use hardware-specific instructions (hardware intrinsics) to accelerate operations. PipeThreader does not require significant engineering effort to support different GPU models from the same vendor. When targeting different architectures such as A100 [21], H100 [22], or B100 [24], only lightweight updates to hardware-specific configurations, including sEU layouts, intrinsics, and resource limits, are needed. The core compilation and scheduling logic remains fully reusable.

(a) Align the sTask's layout with sEU requirements.

(b) Infer the layouts of connected sTasks on the sTask-subgraph.

Figure 11: An example of simplified layout inference for the `mma-sum` sTask-subgraph.

Layout inference. Efficient execution of sTasks on specialized execution units (sEUs) requires adherence to specific layout and thread-binding constraints. To address this, PipeThreader introduces a `Layout` object, which describes the data layout and thread-binding for sTasks. The `Layout` defines a mapping function and an iterator domain, specifying how logical data elements are translated to physical memory and, optionally, assigned to threads.

PipeThreader performs layout inference fully automatically, eliminating the need for manual specification. Figure 11a shows a simplified version of layout inference. The sTask `mma` is assigned to sEU TensorCore with strict layout constraints. Based on the layout constraints, we can derive the corresponding layout mapping function. Here, $\{T(m), n\}$ denotes the data element mapped to the n-th position of thread m.

In the sTask-graph, the layouts of connected sTasks must align to ensure compatibility. Using the layout requirements of specific sEUs, PipeThreader infers the `Layout` of sTasks and propagates these requirements throughout the graph. Conflicts between layouts are resolved through a priority-based inference algorithm, where high-priority sTasks, such as `mma`, dictate the layouts of dependent sTasks. For instance, in Figure 11b, the `mma` and `sum` sTasks are connected. Given that the layout of the `mma` sTask has already been determined, we can infer the layout of the `sum` sTask accordingly. In this example, the tensor `C_sum` needs to be duplicated.

Hardware intrinsic. For sTasks requiring bulk operations on sEUs, we lower the sTask into tile-level function templates. For example, matrix multiply-accumulate operations are lowered using the CUTLASS/CuTe templates, which integrate hardware-specific TensorCore intrinsics. Further instruction-level optimizations, such as register allocation, are delegated to low-level compilers like LLVM [38]. For NVIDIA H100, we apply Warp Specialization [17, 25] to optimize execution. This technique divides threads into producer and consumer warps, with each warp responsible for different pipeline stages. By allowing producer warps to release unused registers for reuse by consumer warps, Warp Specialization improves register allocation and efficiency. Based on the features of the TMA unit in H100, we assign the `load` sTasks, which copy data between global and shared memory, to producer warps. The remaining sTasks, such as `mma` and `Softmax`, are handled by consumer warps. Synchronization between producers and consumers is achieved using barrier-sTasks implemented with `mbarrier` to ensure correct data dependencies.

5.3 sTask Mapping on AMD ROCm GPUs

We also implement PipeThreader on MI300X [16], AMD's latest high-performance GPU. The MI300X GPU features parallel execution units known as compute units (CUs), analogous to NVIDIA's SMs. Each CU contains multiple sEUs, including MatrixCores for matrix multiply-accumulate, Arithmetic Logic Units (ALUs), and asynchronous copy units. Similar to CUDA GPUs, PipeThreader performs layout inference on ROCm GPUs to map sTask data to physical addresses and threads. Additionally, we explicitly utilize the `lgkmcnt` and `s_waitcnt` instructions to manage asynchronous barriers, enabling precise control over instruction dependencies and synchronization of memory operations.

6 Evaluation

In this section, we evaluate PipeThreader on both DNN microbenchmarks and end-to-end models by comparing with state-of-the-art DNN compilers, frameworks, and libraries to demonstrate the effectiveness of PipeThreader. We first summarize our findings: (1) PipeThreader can discover efficient scheduling for well-established DNN architectures (e.g., FlashAttention) and achieve performance comparable to or even surpassing state-of-the-art; (2) PipeThreader can uncover novel scheduling for emerging models (e.g., Mamba2), delivering significantly improved performance; (3) PipeThreader's abstraction and design are adaptable to hardware beyond NVIDIA GPUs (e.g., AMD MI300X), achieving notable performance gains.

6.1 Experimental Setup

Hardware platforms. We evaluate PipeThreader on both NVIDIA and AMD GPUs, as they are currently the most popular hardware platforms. Our evaluation includes two of the latest high-performance GPUs: the NVIDIA H100 (80GB) [22] and the AMD Instinct MI300X GPU (192GB) [16]. We use CUDA version 12.4 with the H100 GPU and ROCm version 6.1.0 with the MI300X GPU. Both GPUs are evaluated on the operating system Ubuntu 20.04.

Table 1: A subset of operator configurations in our microbenchmark.

DNN workloads. Our evaluation benchmark uses six typical DNN models, including LLAMA3-8B [29], LLAMA3-70B [29], Mamba2-1.3B [28], RetNet-65B [48], ResNet-50 [32], and UNet [45]. For large language models like LLAMA3-8B, LLAMA3-70B, and RetNet-65B, we perform tests using the (BS, SEQ) configurations of (1, 1), (32, 1), and (1, 4096); other models like ResNet-50 and UNet are evaluated with batch sizes of 1 and 128, which can comprehensively cover both online and offline inference scenarios. For Mamba, we evaluate BS=1 with sequence lengths of 1k, 2k, 4k, and 8k, and BS=32 or 128 with a sequence length of 1. These configurations are chosen because Mamba's primary advantage over transformers is its superior computational efficiency with long sequence lengths, and these settings represent the most commonly used scenarios. From each model, we choose the most frequent and expensive operations to construct our microbenchmark. Table 1 lists representative operators, their configurations, and corresponding abbreviations of each operator.

Baselines. We compare PipeThreader with DNN framework ONNXRuntime (v1.19.2) [7], as well as state-of-the-art DNN compilers such as Ladder [51] and PyTorch-Inductor (v2.4.0, with Triton v3.0.0) [10, 49]. PyTorch integrates bitsandbytes [30], an official backend in HuggingFace transformers, for $W_{FP4}A_{FP16}$ precision. Additionally, we evaluate PipeThreader against TensorRT (v10.0.1) [6], a vendor-specific inference library for NVIDIA GPUs. We also compare PipeThreader with libraries cuBLAS [2] and rocBLAS (on ROCm GPUs) [1] for MatMul, Ladder and bitsandbytes library for low-precision MatMul operations, MIOpen [36] for Conv2D, and expert-optimized FlashAttention-3 [46] kernel written using CUTLASS [5] templates for attention operation. For LLM

Figure 12: Operator performance on NVIDIA H100 GPU.

and Mamba models, we further benchmark PipeThreader against vLLM (v0.6.3) [37], the most popular library for LLM inference. Average performance metrics, such as speedup, are calculated using the geometric mean across all experiments. All evaluations begin with warm-up iterations, followed by repeated execution of each workload for a minimum of 5 seconds to ensure accurate and stable results.

6.2 Operator Performance on NVIDIA H100

Figure 12 shows the performance of all operator configurations in the microbenchmark. The x-axis represents different operators, and the y-axis indicates the normalized latency relative to PipeThreader.

MatMul. The first row of Figure 12 shows the performance of PipeThreader and other baselines on MatMul operators derived from LLAMA3-8B (M0-M7) and LLAMA3-70B (M8-M15). Although the existing compiler or libraries already provide well-optimized MatMul kernels, the result shows that PipeThreader still obtains a significant speedup. Compared to PyTorch, Triton, and Ladder, PipeThreader achieves average speedups of 1.24× (up to 1.40×), 1.13× (up to 1.26×), and 2.07× (up to 2.25×), respectively. This improvement stems from PipeThreader's ability to leverage its sTask abstraction to model MatMul as a pipeline of `load` and `mma` sTasks and fully explore advanced scheduling opportunities. Notably, PipeThreader matches cuBLAS MatMul performance, with an average speedup of 1.06×. It also achieves over 750 TFLOPS on most of these MatMul operators, approaching the theoretical TensorCore peak performance of the H100 GPU.

Convolution. PipeThreader implements convolutions using implicit GEMM [39], which also leverages the pipeline optimization of the `load` and `mma`. As demonstrated in the second row of Figure 12, PipeThreader significantly outperforms the baselines on the convolution operators derived from the ResNet-50 model (with batch sizes of 1 and 128). PipeThreader achieves an average performance improvement of 1.94× (up to 3.52×) over PyTorch and 2.56× (up to 8.66×) over Ladder, respectively. Since the official Conv2D implementation is not provided, we implement a Conv2D kernel using Triton and perform auto-tuning to achieve its best performance. Compared to Triton, PipeThreader delivers an average speedup of 1.85× (up to 2.47×).

Low-bit MatMul. The third row of Figure 12 shows the performance of low-bit MatMul operators derived from $W_{\text{FP4}}A_{\text{FP16}}$-quantized LLAMA3-8B (DM0-DM7) and LLAMA3-70B (DM8-DM15). As current TensorCores do not directly support $W_{\text{FP4}}A_{\text{FP16}}$ MatMul, the low-bit MatMul must first cast data to FP16 on CUDA cores, which introduces

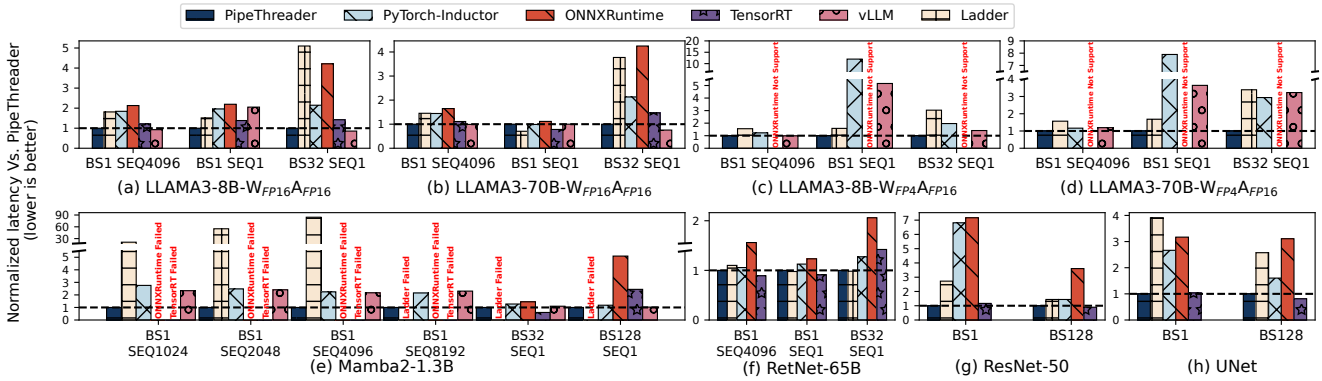

Figure 13: End-to-end performance on the NVIDIA H100 GPU.

Configuration	Pipe-Threader	PyTorch-Inductor	ONNX-Runtime	TensorRT	vLLM	Ladder
BS=1, SEQ=4k	3.29	6.06	7.01	3.99	3.05	5.96
BS=1, SEQ=1	0.29	0.56	0.63	0.40	0.59	0.43
BS=32, SEQ=1	1.29	2.78	5.47	1.84	1.11	6.62

Table 2: Latency (in milliseconds) of LLAMA3-8B-$W_{\text{FP16}}A_{\text{FP16}}$ on the NVIDIA H100 GPU.

an additional `dequant` stage. With more pipeline stages, we observe that PipeThreader gains larger speedups than the ones achieved on standard MatMul. For example, PipeThreader outperforms PyTorch (with bitsandbytes) and Ladder by 3.92× (up to 4.76×) and 2.48× (up to 3.81×) on low-bit MatMul, while the average speedups on standard MatMul are only 1.24× and 2.07×, respectively.

FlashAttention and FlashDecoding. Compared to MatMul and low-bit MatMul, FlashAttention involves even deeper computation stages, opening up a larger optimization space for PipeThreader. PipeThreader can automatically find effective scheduling schemes by exploring the new optimization space defined by an sTask-graph and the new exposed hardware capabilities. The fourth row of Figure 12 shows the performance of FlashAttention operators derived from LLAMA3-8B (FA0-FA9) and LLAMA3-70B (FA10-FA19). The evaluations cover sequence lengths ranging from 512 to 8k, with batch sizes of 1 and 64, including configurations with and without causal masking. PipeThreader demonstrates an average performance improvement of 1.36× (up to 1.50×) over Triton, compared to 1.13× (up to 1.26×) for MatMul operation. This highlights the system's ability to exploit the larger optimization space inherent in FlashAttention's more complex computation pipeline.

Such a general scheduling capability enables PipeThreader to achieve comparable performance to model-specific implementations optimized by experts, and in some configurations, even outperform them. FlashAttention-3, a manually optimized attention kernel tailored for NVIDIA Hopper GPUs, is an example of such an expert-designed approach. PipeThreader achieves an average performance improvement of 1.07× (up to 2.18×) over FlashAttention-3. As a hand-crafted approach, FlashAttention-3 cannot efficiently optimize for varying workloads. We observe that, particularly for smaller sequence lengths, FlashAttention-3 performs suboptimally due to fixed tile sizes. PyTorch uses the hand-crafted FlashAttention-2 kernel without incorporating finer-grained pipelining. Compared to PyTorch, PipeThreader achieves an average speedup of 1.82× (up to 2.29×).

FlashDecoding operators are selected from the LLAMA3-8B (FD0, FD1) and LLAMA3-70B (FD2, FD3) models with batch size set to 1 and context length set to 8192 to simulate decoding scenarios. Compared to FlashAttention-3 and Triton, PipeThreader achieves an average speedup of 1.12× (up to 1.23×) and 2.27× (up to 3.06×), respectively.

Linear Attention. The fifth and sixth rows of Figure 12 present the key linear attention operations of the Mamba2 model: ChunkScan and ChunkState operations, respectively. We compare PipeThreader with the official Triton implementation. The configurations we test have sequence lengths ranging from 1k to 16k, with batch sizes of 1 or 64. PipeThreader achieves average speedups of 1.71× (up to 1.99×) and 1.98× (up to 2.59×) over Triton for ChunkScan and ChunkState operations, respectively. Also, Triton fails on some configurations, such as sequence lengths of 8k (CC14, CT14) and 16k (CC7, CC15, CT7, CT15). These results emphasize PipeThreader's adaptability in handling emerging DNN operations, eliminating the need for hand-crafted implementations.

6.3 End-to-end Performance on NVIDIA H100

Figure 13 shows the end-to-end performance of all eight DNN models on the NVIDIA H100 GPU. Due to GPU memory constraints, we evaluate the inference latency of large language models like LLAMA3, Mamba2, and RetNet using a single decoder layer, which serves as a proxy for full-model performance, as all layers are identical and latency scales linearly with the number of layers.

LLM models. On the FP16-precision LLAMA3-8B and LLAMA3-70B models, PipeThreader achieves average

Pattern	Configuration	Triton	PT-Decouple	PT-Joint
ChunkScan	BS=1, SEQ=8k	0.158	0.198	0.108
ChunkScan	BS=64, SEQ=8k	13.332	12.150	6.981
FlashAttention	BS=1, SEQ=4k	0.639	0.851	0.438
FlashAttention	BS=64, SEQ=4k	41.681	48.762	30.416

Table 3: Latency (in milliseconds) comparison for decouple and joint sTask-graph optimization.

Pattern	Configuration	PipeThreader	Triton	CUTLASS
MatMul	M,N,K=8k,8k,8k	0.13	0.17	3.36
FlashAttention	BS=64, SEQ=8k	5.26	0.74	/
ChunkScan	BS=1, SEQ=16k	3.92	1.28	/
ChunkState	BS=1, SEQ=16k	3.71	1.05	/

Table 4: Compilation time (in minutes) on H100.

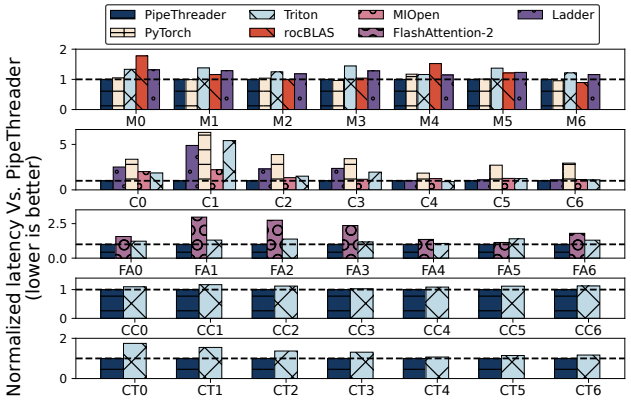

Figure 14: Operator performance on AMD MI300X GPU.

speedups of 2.17× and 2.45× over Ladder and ONNXRuntime, respectively. Ladder's schedule policy is unable to effectively represent and generate the FlashAttention kernel, while ONNXRuntime does not natively provide support for FlashAttention, leading to suboptimal performance. Although PyTorch-Inductor, TensorRT, and vLLM integrate industrially popular FlashAttention kernel as their backend, PipeThreader on average outperforms them by 1.79× (up to 2.15×), 1.28× (up to 1.47×), and 1.10× (up to 2.05×), respectively. This improvement is attributed to PipeThreader's ability to explore more efficient pipeline configurations tailored to operations in the model (e.g., MatMul and FlashAttention). In $W_{\text{FP4}}A_{\text{FP16}}$ quantization scenarios, PipeThreader outperforms Ladder, PyTorch-Inductor, and vLLM with an average speedup of 2.01× (up to 3.39×), 3.03× (up to 11.98×), and 2.16× (up to 5.16×), respectively, as it optimizes the pipeline scheduling for both low-bit MatMul and FlashAttention. We also include a subset of absolute performance in Table 2.

Linear Attention models. On the Mamba2-1.3B model, Ladder, ONNXRuntime, and TensorRT fail to generate efficient linear attention kernels, leading to memory errors under certain configurations. PyTorch-Inductor, which uses Triton as the backend, is capable of running fused linear attention but delivers suboptimal performance compared to PipeThreader. PipeThreader outperforms PyTorch-Inductor, ONNXRuntime, TensorRT, vLLM, and Ladder by 1.92× (up to 2.76×), 2.71× (up to 5.10×), 1.21× (up to 2.44×), 1.78× (up to 2.41×), and 45.93× (up to 84.41×), respectively, given its ability to explore more efficient pipeline configurations tailored to operations in the model.

For the linear attention model RetNet-65B, compared to PyTorch-Inductor, ONNXRuntime, TensorRT, and Ladder, PipeThreader achieves speedups by 1.16× (up to 1.31×), 1.60× (up to 2.12×), 1.06× (up to 1.46×), and 1.04× (up to 1.10×), respectively. On the RetNet-65B model, the speedup achieved by PipeThreader is relatively modest. This is because the RetNet-65B model's large attention head dimensions (256 for query and key, 432 for value) lead to high shared memory usage, limiting pipeline scheduling optimization.

CNN models. For ResNet-50 and UNet, by generating more efficient Conv2D kernels, PipeThreader achieves speedups of 2.01×, 2.54×, and 3.99× in end-to-end inference latency over Ladder, PyTorch-Inductor, and ONNXRuntime, respectively. Compared to TensorRT, PipeThreader achieves comparable performance (0.97×).

6.4 Evaluation on Scheduling Policy

Joint optimization. Our scheduling policy jointly optimizes partitioning and pipeline scheduling of the sTask-graph. To demonstrate the benefits, we create a variant of PipeThreader: "PT-decouple", which optimizes the partitioning (e.g., for high memory utilization in a single sTask) and pipeline scheduling (e.g., for high overlapping) in independent optimization passes. As shown in Table 3, on the Mamba2-ChunkScan (BS=64, SEQ=8k) operator, with the PT-decouple, the compiler focuses on maximizing data reuse and selects a larger tile shape (e.g., 64×128). However, this larger tile shape limits the sTask-graph's ability to achieve effective pipeline parallelism on one EU, resulting in an execution time of 12.150 ms. By jointly optimizing both the sTask-graph partitioning and scheduling, the compiler selects a smaller tile shape (e.g., 64×64), which facilitates more efficient pipelining and reduces the execution time to 6.981 ms.

Compilation time. The joint optimization would require a relatively longer compilation time. Table 4 presents the compilation times of PipeThreader for several typical configurations in FlashAttention and Mamba2. Since all task partitions are generated in line 2 of Figure 9, the scheduling process can be parallelized to accelerate compilation. For simple kernels with few pipeline depths, such as MatMul, PipeThreader compilation takes only 0.13 minutes, compared to 0.17 minutes and 3.36 minutes for Triton and CUTLASS, respectively. For complex fused kernels such as FlashAttention, PipeThreader still achieves a short compilation time of 5.26 minutes, even though it explores a large pipeline search space over Triton.

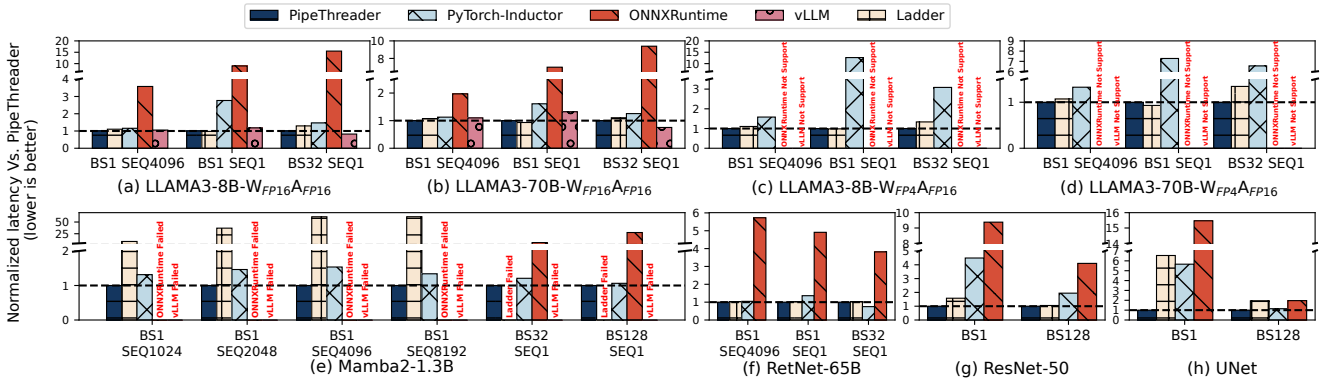

Figure 15: End-to-end performance on AMD Instinct MI300X GPU.

6.5 Evaluation on AMD ROCm GPUs

Operator performance. We benchmark the AMD MI300X GPU using a subset of operators selected from the microbenchmark suite originally designed for the NVIDIA H100 GPU. The evaluation focuses on key operators: MatMul (compared against PyTorch, rocBLAS, Triton, and Ladder), Conv2D (compared against PyTorch, MIOpen, Triton, and Ladder), FlashAttention (compared against FlashAttention-2 and Triton), and Linear Attention (compared against Triton).

Figure 14 shows that PipeThreader achieves speedups of 1.16× to 5.42× over Triton, and up to 6.21× over PyTorch, across different types of operators. PipeThreader surpasses rocBLAS and MIOpen on MatMul and Conv2D, with gains of up to 1.77× and 2.21×, respectively. PipeThreader also achieves up to 2.82× speedup over FlashAttention-2. Furthermore, PipeThreader outperforms Ladder with an average speedup of 1.45×, demonstrating its efficiency and scalability.

End-to-end performance. We evaluate PipeThreader on the AMD Instinct MI300X GPU against Ladder, PyTorch-Inductor, ONNXRuntime, and vLLM. Figure 15 shows the end-to-end performance results across eight models, including LLAMA3-8B and LLAMA3-70B in both $W_{\text{FP16}}A_{\text{FP16}}$ and $W_{\text{FP4}}A_{\text{FP16}}$ formats, as well as Mamba2-1.3B, RetNet-65B, ResNet-50, and UNet.

On the FP16-precision LLAMA3-8B and LLAMA3-70B models, PipeThreader achieves speedups of 1.48× (up to 2.77×), 6.33× (up to 15.51×), 1.02× (up to 1.32×), and 1.07× (up to 1.29×) over PyTorch-Inductor, ONNXRuntime, vLLM, and Ladder, respectively. On the $W_{\text{FP4}}A_{\text{FP16}}$ LLAMA3-8B and LLAMA3-70B models, PipeThreader achieves speedups of 3.97× (up to 12.66×) and 1.12× (up to 1.34×) over PyTorch-Inductor and Ladder, respectively, while ONNXRuntime and vLLM do not support $W_{\text{FP4}}A_{\text{FP16}}$ quantization on the ROCm platform.

For Mamba2-1.3B, PipeThreader achieves an impressive average speedup of 32.93× (up to 61.33×) compared to Ladder. This significant performance gain is primarily attributed to Ladder's inability to fuse the Linear Attention component. In comparison to PyTorch-Inductor, PipeThreader delivers an average speedup of 1.31× (up to 1.54×). On the RetNet-65B model, PipeThreader achieves speedups of 1.03× (up to 1.36×), 4.75× (up to 5.73×), and 1.01× (up to 1.02×) over PyTorch-Inductor, ONNXRuntime, and Ladder, respectively.

On traditional CNN models (ResNet-50 and UNet), PipeThreader achieves speedups of 2.74× (up to 5.66×), 5.84× (up to 15.47×), and 2.14× (up to 6.54×) compared to PyTorch-Inductor, ONNXRuntime, and Ladder, respectively.

MI300X GPU has relatively lower asynchronous capabilities and smaller shared memory than the NVIDIA H100 GPU, which reduces the potential performance (e.g., speedups over baselines) for pipeline parallelism enabled by PipeThreader.

7 Discussion

Advantages over hand-crafted kernels. PipeThreader demonstrates fundamental advantages over hand-crafted implementations, especially in automated pipeline scheduling and cross-architecture portability.

First, it eliminates the need for expert-level manual tuning. Designing efficient pipeline schedules by hand is error-prone, time-consuming, and sensitive to input configurations. Even expert-crafted kernels like FlashAttention-3 (FA3) initially lacked support for certain dimensions (e.g., head size 256), illustrating the difficulty. PipeThreader automates this process, systematically exploring the scheduling space under hardware constraints. It achieves up to 2.18× speedup over FA3 and outperforms vLLM's Triton-based Mamba2 by 2.41×.

Second, it generalizes well across hardware. While hand-tuned kernels are often tightly coupled to specific platforms, especially NVIDIA GPUs, PipeThreader can achieve significant gains on AMD hardware. Its abstraction also maps naturally to TPU-like architectures [34, 35] (e.g., TPU cores and DMA engines), enabling efficient pipelined execution.

Finally, it lowers the barrier to high performance. On Multi-head Latent Attention (MLA) [40, 41], PipeThreader delivers up to 5× speedup over Triton with only 80 lines of Python, matching DeepSeek's 500+ line CUDA implementation [4], but with far less development effort.

Scale to multi-GPU. PipeThreader can naturally scale to multi-GPU and interplay with collective communications introduced by tensor parallelism, through including the 1) communication units (e.g., RDMA, NVLINK, IB) between GPUs as sEUs, and 2) collective communications as sTasks. In this way, PipeThreader can reuse the policy to search for the efficient pipelining between collective communication and computation at the GPU kernel level, and scale to multi-GPU or multi-node environments. Current results show that PipeThreader performs on par with state-of-the-art systems such as TileLink [55] on common communication patterns.

Supporting new devices. We find that widely used hardware (e.g., NVIDIA/AMD GPUs or TPUs) aligns with the sEU abstractions, which contain even sets of all the sEUs. To compile sTask-graphs onto the device, the programming model only requires implementing the `Execute` interface of each sEU with their own load/store/compute instructions (Figure 4). The device virtualization resembles the hardware abstraction of Roller [56] and Welder [47], but further exposes the fine-grained heterogeneous sEUs.

MoE FFN kernels. PipeThreader can also support grouped MatMul in MoE FFN kernels. Unlike batched MatMul, each group can have a different shape. To handle this, PipeThreader can decompose each group into an independent sTask-subgraph with its own input shapes and apply policies separately, rather than sharing a single schedule.

8 Related Work

Deep learning compiler and frameworks. Most existing DNN compilers abstract hardware as homogeneous execution units (EUs). Rammer [43] introduces the concept of rTasks, designed for parallel execution across EUs, while Welder [47] focuses on holistic memory optimization through vertical fusion. In contrast, PipeThreader introduces sTasks and sEUs, explicitly exposing the heterogeneity of hardware to enable the optimization and scheduling of pipeline parallelism.

Operator fusion has been widely adopted in DNN compilers such as TVM [19], Ansor [54], XLA [13], and TensorRT [6] to reduce memory overhead, resulting in deeper computational stages. Compilers like Triton [49], Welder [47], Roller [56], Cocktailer [52], TensorIR [11], ThunderKittens [12], FractalTensor [42], and Ladder [51] base their scheduling optimizations on tile abstractions. However, these primarily focus on spatial tiling to enhance data locality, enabling data parallelism across EUs but neglecting opportunities for pipeline parallelism across sEUs.

While efforts like Triton [49] and CUTLASS [5] incorporate pipelined execution, they rely on ad hoc rules for specific operators and fail to generalize across diverse workloads. PipeThreader addresses these limitations by introducing abstractions that enable automatic scheduling and optimization of pipeline parallelism.

Frameworks like ALCOP [33] focus on pipelining between data loading and computation to optimize memory hierarchy utilization. However, they fail to fully exploit the heterogeneity of modern computation units or to explore pipeline scheduling for workloads with deep computational stages, such as FlashAttention. PipeThreader addresses this gap by introducing finer-grained abstractions that enable comprehensive pipeline optimization across heterogeneous hardware components.

Optimizations for specific patterns. Due to the lack of sTask and sEU abstractions in existing compilers, pipeline parallelism optimization is often manually tailored to specific patterns. For instance, FlashAttention [46] and Hopper MatMul in CUTLASS [5] provide pattern-specific schedules but require significant manual effort. Additionally, FlashAttention provides separate schedules for different inputs, while CUTLASS [5] requires users to profile and select the best schedule. In comparison, PipeThreader generalizes pipeline parallelism by leveraging sTask and sEU abstractions, enabling automatic scheduling across a wide range of operators and configurations without requiring manual intervention.

Distributed deep learning frameworks. Centauri [18], PrimePar [50], and TileLink [55] improve communication-computation overlap through hierarchical scheduling, temporal tensor partitioning, and tile-based abstractions, respectively. PipeThreader can model communication and computation as separate sTasks, allowing it to represent the scheduling strategies proposed in these works, while enabling broader scheduling optimization.

9 Conclusion

As DNN models grow larger and specialized heterogeneous hardware units emerge, hardware schedulers are no longer sufficient for efficient pipeline execution. This paper introduces PipeThreader, a DNN compiler that enables software-defined pipelining via an sTask-graph abstraction and hierarchical hardware capabilities, combining virtualized EUs and specialized sEUs. With key scheduling primitives, PipeThreader automates pipeline scheduling, achieving comparable or superior performance to state-of-the-art methods like FlashAttention on H100 and AMD GPUs, while generalizing to emerging models such as Mamba2. We believe PipeThreader lays the groundwork for further advancements in compiler-based optimizations, paving the way for efficient utilization of evolving GPU architectures and DNN workloads.

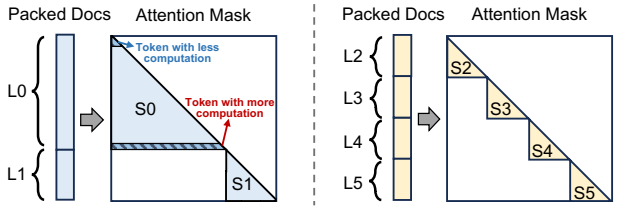
Abstract

In this work, we present *WLB-LLM*, a *W*ork*L*oad-*B*alanced 4D Parallelism for *L*arge *L*anguage *M*odel Training. We first thoroughly analyze the workload imbalance issue in LLM training and identify two primary sources of imbalance at the pipeline parallelism and context parallelism levels. Then, to address the imbalance issue, at the pipeline parallelism level, *WLB-LLM* incorporates a workload-aware variable-length document packing method to balance the computation and communication workload across micro-batches. Additionally, at the context parallelism level, *WLB-LLM* introduces a novel fine-grained per-document sharding strategy, ensuring each worker within a context parallelism group has an identical workload. Comprehensive experiments under different model scales demonstrate that *WLB-LLM* significantly mitigates the workload imbalance during 4D parallelism LLM training and achieves an average speedup of 1.23× when applying *WLB-LLM* in our internal LLM training framework.



1 Introduction

Large language models (LLMs) have been widely adopted as the backbone of various applications, such as coding assistants [27, 48], language translation [52], and chatbots [3, 31]. The remarkable capabilities and promising potential of LLMs have sparked a competition among big tech companies to train LLMs with higher intelligence and broader versatility [2, 6, 41]. As the scale of LLMs and length of context window continue to grow larger [14], the training of LLMs consumes a significant amount of computing power [33]. For instance, Meta reports that the training of the LLaMA3-405B model uses 16K H100 GPUs for several months [6]. The tremendous computational cost of LLM training makes every improvement in end-to-end training efficiency translate to substantial savings.

Unfortunately, a significant portion of GPUs are underutilized during large-scale LLM training jobs due to the workload imbalance issue. To illustrate this, Figure 1 (a) shows the normalized computation latency on each GPU during a 405B LLM training job executed across 8K H100 GPUs with a context window of 128K. It can be observed that the computation latency exhibits significant variance among GPUs. The slowest GPU suffers a computation latency that is 1.44× longer than the others. This disparity in computing latency causes a substantial degradation in training efficiency as the synchronized nature of training requires all other GPUs to wait for the slowest GPU to finish.

(a) Normalized computation latency in an 8K-GPU 405B LLM training job.

(b) Reason of imbalance: input-dependent nature of attention computation and the varying input document length.

Figure 1: Observed workload imbalance issue in large-scale LLM training jobs and the reason of workload imbalance.

The root cause of the workload imbalance lies in the input-dependent nature of attention computation and the varying input document length of the training data. As shown in Figure 1 (b), input sequences are composed of multiple input documents. To ensure model quality in long-context training, attention masks are applied to prevent attention computation between tokens from different documents within the same

sequence [6]. This approach introduces heterogeneity in per-token arithmetic intensity, as tokens at the tail positions of long documents require more attention computation. As a result, input sequences containing long documents incur significantly higher computation workloads, even with the same total sequence length.

However, existing LLM training frameworks [23, 26, 35, 38, 39] fail to recognize the heterogeneity in per-token arithmetic intensity. Specifically, state-of-the-art LLM training solutions employ a 4D parallelism paradigm that combines data parallelism (DP) [35], pipeline parallelism (PP) [25], context parallelism (CP) [30], and tensor parallelism (TP) [38]. The input documents are packed into sequences with fixed length at the DP and PP levels, and then sharded and distributed into chunks at the CP and TP levels. This fixed and static training flow treats all input tokens homogeneously and assigns each GPU an equal number of tokens, inevitably resulting in workload imbalance between GPUs. Furthermore, the trend of larger models and longer context windows exacerbates this issue, increasing the likelihood of an extremely long document appearing in the input batches, thereby delaying the entire training step.

An intuitive approach to address the workload imbalance issue is to shuffle and repack input documents to distribute the computation workload more evenly across micro-batches. However, this method is not effective and practical for two main reasons: *Firstly*, achieving effective balance through shuffling and repacking requires a sufficiently large packing window spanning multiple global batches. This impacts the randomness of data sampling and loading, which can potentially affect model convergence during training (as discussed in Section 3.3). *Secondly*, shuffling and repacking only address workload imbalances across micro-batches and cannot resolve intra-document imbalances caused by sequence sharding. In 4D parallelism training, input sequences are divided into chunks and distributed across different GPUs. Document chunks that include the tail end of a document incur a higher computational workload because their tokens must attend to more preceding tokens, causing an intra-document workload imbalance across GPUs.

To overcome the challenges mentioned above and address the severe workload imbalance issue in large-scale LLM training, we propose a flexible and input-aware document packing and sharding approach for the 4D parallelism training paradigm. The data packing and sharding will no longer output micro-batches with a fixed number of tokens. Instead, each GPU aims to get input tokens that have an equal amount of total computation and communication workload. Additionally, to minimize the impact on data randomness, we propose to only adjust the execution order of extremely long documents. This is based on our observation that the tokens of long documents account for only a small proportion of the total training tokens but have the most significant impact on workload imbalance.

Based on the above design insight, we build *WLB-LLM*, a *W*ork*L*oad-*B*alanced 4D Parallelism for *L*arge *L*anguage *M*odel Training. We begin by thoroughly analyzing workload imbalance in LLM training under 4D parallelism (§3), identifying two primary sources of imbalance across specific parallelism hierarchies: (1) Imbalance across micro-batches at the pipeline parallelism level and (2) Imbalance across document shards at the context parallelism level. To address these imbalances, *WLB-LLM* provides novel solutions tailored specifically to each parallelism level. **At the PP level**, *WLB-LLM* introduces variable-length document packing, allowing shorter documents to be combined to form longer sequences, thereby aligning the total computation workload to that of a single long document (§4). Additionally, *WLB-LLM* adaptively delays the execution of extremely long documents, achieving near-optimal workload balance across micro-batches while maintaining a relatively low per-token delay, thereby preserving the randomness of the data loader. **At the CP level**, *WLB-LLM* incorporates a novel per-document sharding strategy, ensuring each worker within a CP group has an equal workload (§5). Furthermore, we observe a tradeoff between kernel efficiency and sharding balance with per-document sharding. To maximize overall performance, we propose a heuristic algorithm that adaptively selects the most efficient sharding strategy based on the input sequence at runtime.

In summary, this paper makes the following contributions:

- To the best of our knowledge, we are the first to identify, analyze, and address workload imbalance issues in large-scale LLM training with 4D parallelism.
- At the PP level, we design a variable-length input packing and adaptive outlier delay strategy to achieve near-optimal workload balance across micro-batches, while minimizing impacts on data loading randomness and model convergence.
- At the CP level, we implement a fine-grained per-document sharding method with an adaptive sharding selection mechanism to achieve the most efficient sharding for each input micro-batch at runtime.
- We conduct comprehensive evaluations and demonstrate that *WLB-LLM* achieves an average speedup of 1.23× across various model scales and context window sizes.

2 Background

In this section, we provide the background of 4D parallelism LLM training and discuss the characteristics of input documents in long-context LLM training.

2.1 4D Parallelism LLM Training

Training extremely large LLMs with billions or even trillions of parameters is challenging, involving a significant amount

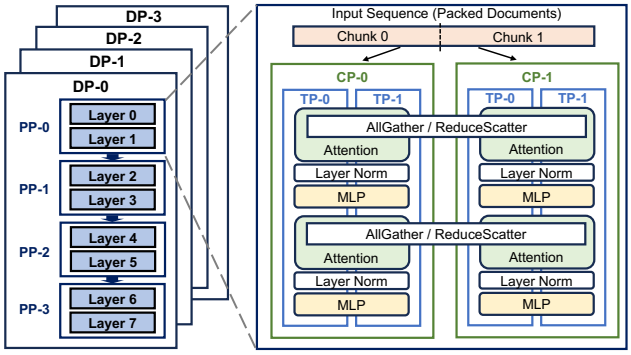


Figure 2: Overview of 4D parallelism for LLM training.

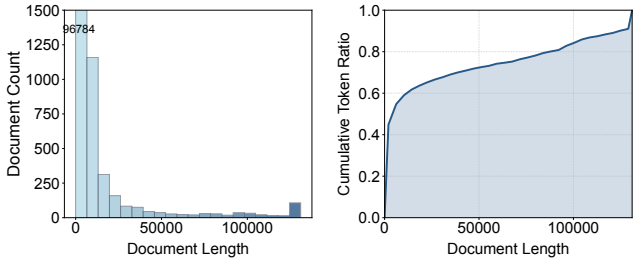

Figure 3: Characterization of input documents: Distribution of input document lengths (left) and cumulative token ratio by document length (right).

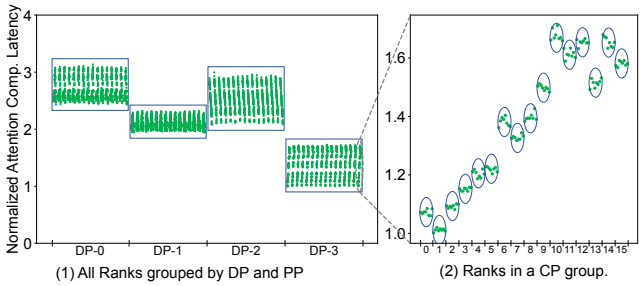
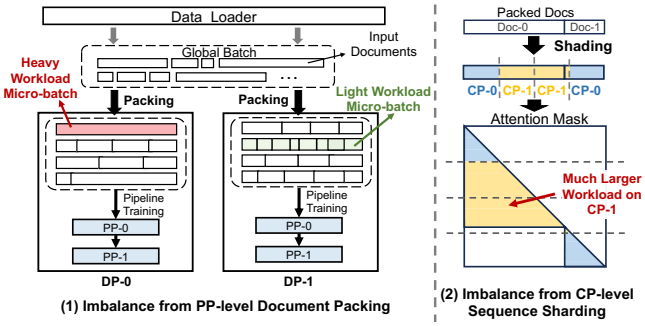
of engineering effort to tune the multi-level parallelism [55]. The state-of-the-art LLM training framework features a 4-dimensional parallelism [9, 12], including data parallelism (DP) [35], pipeline parallelism (PP) [25], context parallelism (CP) [30], and tensor parallelism (TP) [38]. Figure 2 presents an example of a (TP=2, CP=2, PP=4, DP=4) 4D parallelism.

Data Parallelism: In DP, the input global batch is partitioned and distributed across DP workers, with each worker owning a part of the global batch. By default, model parameters are duplicated across DP workers. Some advanced techniques like ZeRO [35] and FSDP [32] partition model parameters, gradients, and optimizer states across DP workers to reduce memory consumption. During training, each DP worker computes parameter updates using its local batch independently and then synchronizes gradients with other workers via AllReduce (or ReduceScatter when using FSDP).



Pipeline Parallelism: Within each DP worker, the devices are further partitioned into multiple PP workers through pipeline parallelism. In PP, the model is split in a layer-wise manner, with each PP worker owning several chunks of layers. The input batches of a DP worker are also divided into multiple micro-batches. During training, a micro-batch traverses through all PP workers from first to last, and then reverses direction in the backward pass. Peer-to-peer (P2P) communication is required to send activations and gradients during forward and backward passes, respectively.

Context Parallelism: CP is designed to address the large memory consumption of activations in long-context training. As shown in Figure 2, CP duplicates the model parameters but shards the input and activations along the sequence length dimension across CP workers. CP operates either in a ring-based manner using P2P communication [24] or involves AllGather communication during the forward phase to collect the KV (key and value) tensors of all tokens, and ReduceScatter communication for the gradients of the KV tensors in backward [6]. All other operators, such as Linear and LayerNorm, operate independently on all workers, similar to DP.



Tensor Parallelism: TP splits the model parameters within a layer (e.g., attention, FFN) and distributes them across multiple TP workers. TP is often applied in conjunction with Sequence Parallelism (SP) [15] to further split the input tensor and activations. In this paper, when referring to TP, we mean both TP and SP by default. With TP, each GPU only has part of the input and parameters, resulting in intensive AllGather and ReduceScatter communication during training. Therefore, TP is typically applied within a single node, while other levels of parallelism are applied across nodes.

2.2 Varying Input Document Length

In large-scale LLM training, the lengths of input documents could vary significantly, especially when using a large context window. To illustrate this, we profile the characteristics of training data in our 128K context length training job, as shown in Figure 3. **From a per-document perspective**, input document lengths distribution is highly skewed. As shown in the left part of Figure 3, the majority of input documents are relatively short, while some extremely long documents exist, with the longest reaching the full context window size. The presence of an extremely long document in an input batch can easily lead to significant workload imbalances across micro-batches. This observation highlights the need for an input-aware solution that dynamically balances workloads by accounting for variations in document length. **From a per-token perspective**, we compute the cumulative token ratio across different document lengths. As shown in the right part of Figure 3, the majority of training tokens come from relatively short documents. For instance, documents shorter than half the context window contribute over 75% of the total training tokens. Although long documents significantly impact workload balance, the tokens from these long documents constitute only a small proportion of the training dataset. This provides an opportunity to adaptively delay the execution of extremely long documents to mitigate workload imbalance, while minimizing the impact on data sampling randomness for the majority of tokens.

(b) Document packing at PP level and sequence sharding at CP level.

Figure 4: The workload imbalance comes from the PP-level document packing and CP-level sequence sharding.

3 Motivation

To motivate the design of *WLB-LLM*, we first conduct an in-depth analysis of workload imbalances across different parallelism hierarchies in 4D parallelism LLM training. We then introduce a baseline solution that shuffles and repacks input documents across batches. Lastly, we discuss why this baseline solution cannot fully eliminate workload imbalances and investigate the tradeoff between input packing balance and model convergence.

3.1 Imbalance Analysis

After analyzing the performance trace from our internal 8K-GPU, 128K context window training job for a 405B LLM, we identify two primary causes of workload imbalance: (1) workload imbalance among micro-batches at the PP level, and (2) imbalance across sequence shards at the CP level. To demonstrate this, we accumulate the attention computation latency on each GPU. The results have been given in Figure 4.

PP Level Imbalance: As shown in Figure 4 (a)(1), the attention computation latency across DP workers varies significantly. Within each DP worker, we observe "vertical lines" formed by the data points, each representing a PP worker within a DP worker. PP workers within the same DP worker exhibit nearly identical workloads, as they process the same

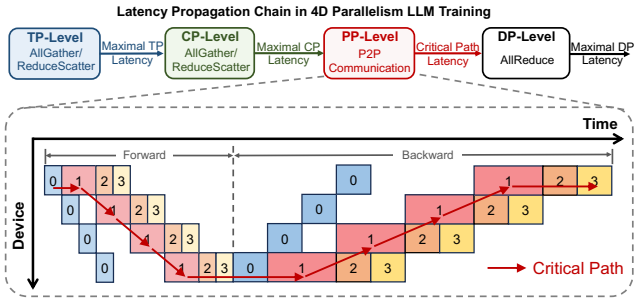

Figure 5: The process of latency propagation in 4D parallelism LLM training across different parallelism hierarchies. The impact of workload imbalance is enlarged at the PP level.

set of micro-batches. Based on the results shown in Figure 4 (a)(1), we conclude that the workload imbalance at both the DP and PP levels stems from the imbalance across micro-batches, which is caused by the input packing process. As illustrated in the left part of Figure 4 (b), input documents are packed into sequences (micro-batches) of equal length. While this fixed-length packing strategy ensures that each PP and DP worker processes the same number of tokens, variations in per-token computation intensity result in workload imbalances at these levels. For instance, a micro-batch containing only a single long document (highlighted in red) has larger workload compared to a micro-batch composed of multiple shorter documents (highlighted in green).

CP Level Imbalance: To better illustrate the imbalance at the CP level, we zoom in on a specific PP worker (also referred to as a CP group). As shown in Figure 4 (a)(2), significant workload imbalances are observed across CP workers (indicated by circles), while the TP workers within each CP worker exhibit similar computation latencies (data points within each circle). This imbalance across CP workers comes from the sequence sharding at the CP level. As shown in Figure 4 (b)(2), an input sequence is divided into chunks with an equal number of tokens, which are then distributed to CP workers. The state-of-the-art approach partitions the input sequence into $2 \times CP_size$ chunks. The i-th CP worker is assigned the i-th and $(2 \times CP_size - 1 - i)$-th chunks to achieve better load balancing [6]. This sharding strategy works well when the sequence only has a single document. However, if the sequence is packed with multiple documents, it may lead to significant workload imbalances across CP workers, as demonstrated in the figure. Although sequence chunks are further divided and distributed among TP workers, no imbalance is observed at the TP level. This is because, prior to computation, all TP workers perform an AllGather operation to collect the entire sequence chunk. As a result, each TP worker within a CP worker processes the same sequence chunk, eliminating imbalances at the TP level.

Imbalance Propagation: During training, the workload imbalance will be propagated from inner-level parallelism to

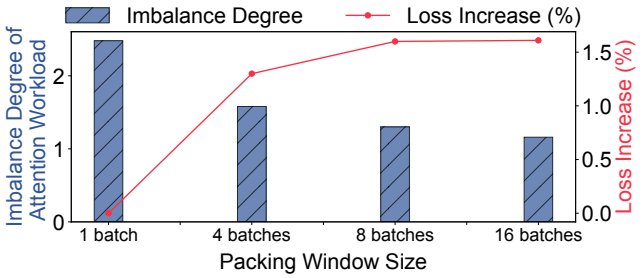

Figure 6: A larger packing window improves workload balance but leads to an increase in training loss.

outer-level parallelism. The imbalance will be accumulated and amplified, finally leading to a significant impact on end-to-end training latency. In DP, CP, and TP, collective communication [28] such as AllReduce, AllGather, and ReduceScatter is performed during training. All workers in these parallelism hierarchies work in a synchronized manner. As a result, the training latency of a given DP, CP, and TP group is determined by the slowest worker within that group. In contrast, at the PP level, different PP workers serve as producers and consumers of each other. As shown in Figure 5, the critical path of PP is the latency of the largest micro-batch traversing all PP workers plus the forward and backward passes of remaining micro-batches on the first PP worker. The distinct data dependency relationship between PP workers amplifies the imbalance, resulting larger impact on total latency. Due to the imbalance propagation, higher micro-batch training latency can arise from two main reasons: (1) Imbalances propagated from inner-level hierarchies (e.g., CP sharding imbalances); (2) Micro-batches with inherently larger workloads due to PP-level packing. This highlights the importance of eliminating the imbalance in all parallelism hierarchies.

3.2 Baseline Solution: Fixed-Length Packing

A potential solution to address the workload imbalance issue is to optimize the packing of input documents. Current 4D parallelism frameworks require all micro-batches to have a uniform sequence length [6], equal to the context window size, to enable efficient batching of input sequences. Building on this fixed-length requirement, we implement a baseline shuffling and packing optimization that packs input documents into micro-batches of equal size. Formally, given a set of input documents from one or more global batches, the objective is to pack these documents into several micro-batches with a fixed total length and balance the attention computation workload among all micro-batches. Without loss of generality, we use the causal mask as an example to calculate attention workload. With causal mask, the attention computation workload of a micro-batch is proportional to $\sum_{i=1}^{N} d_i^2$, where d_i is the length of each document within the micro-batch. The problem of searching the optimal document packing is NP-hard, as it can be extended from the classic Number Partition Problem [10] by adding a number sum constraint and a square-sum objective. To search for the optimal packing, we formulate the task as an integer linear programming (ILP) problem. Assuming we have N documents, each has length d_i, and we would like to pack these documents into M micro-batches, each with a total length of S. The objective is to minimize the maximum workload among the micro-batches:

$$\begin{aligned} \text{minimize} \quad & \max(\sum_{i=1}^{N} x_{ij} \cdot d_i^2),\ j = 1, \cdots, M \\ \text{subject to} \quad & \sum_{j=1}^{M} x_{ij} = 1, \qquad i = 1, \cdots, N \\ & \sum_{i=1}^{N} x_{ij} \cdot d_i \le S, \qquad j = 1, \cdots, M \\ & x_{ij} \in \{0, 1\} \end{aligned} \tag{1}$$

in which x_{ij} is a binary variable representing the packing plan. Specifically, $x_{ij} = 1$ means document i is packed into micro-batch j. With this ILP formulation, we then use a commercial solver [8] to obtain the optimal packing plan.

3.3 Tradeoff Analysis

Optimizing input document packing across more global batches could help achieve a higher degree of workload balance. However, it also manipulates the execution order of more input documents, affecting the randomness of data sampling and loading. This may negatively impact model quality and affect model convergence. To evaluate the tradeoff between packing balance and model quality, we pretrain a 550M-parameter model for 52K steps using various packing window sizes. We then assess the degree of workload imbalance of input batches after packing under different settings. The imbalance degree is calculated as $\frac{Max_Attn}{Avg_Attn}$, where Max_Attn represents the maximum attention computation workload in the global batch, and Avg_Attn denotes the average attention computation workload of all micro-batches in the global batch. As shown in Figure 6, when optimizing the packing across a single global batch, the workload imbalance across micro-batches still remains high. If the number of global batches increases, the fixed-length packing optimization could achieve a better workload balance. However, the final training loss increases as more global batches are involved in the packing optimization, due to reduced data loading randomness caused by repacking a larger number of input documents. These results indicate that naïve fixed-length packing optimization cannot achieve a good workload balance without compromising model quality, highlighting the need for more advanced solutions.

The tradeoff between packing balance and model quality motivates us to break the fixed-length constraint of micro-batches and design a more flexible packing strategy. In the following two sections, we will present the details of *WLB-LLM*,

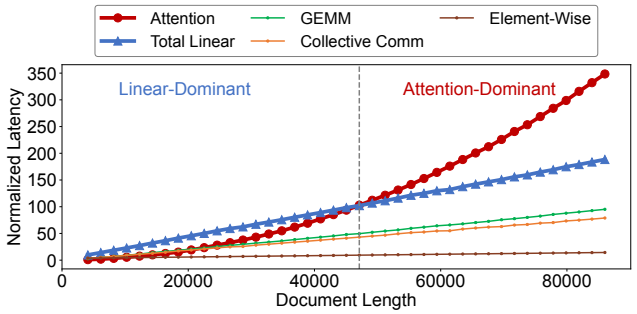

Figure 7: The relationship between operation latency and the input document length. (Total Linear is the sum of GEMM, collective communication, and element-wise operators)

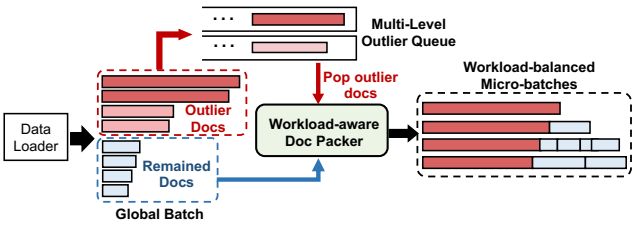

Figure 8: The process of outlier document delay combined with var-length packing.

including the PP-level variable-length packing and heuristic outlier document delay optimization (§4) and the CP-level fine-grained and adaptive sharding optimization (§5).

4 Var-Len Packing and Outlier Delay for PP

At the PP level, we focus on balancing the workload across micro-batches by repacking input documents in a workload-aware manner. **First**, we design a variable-length packing strategy to achieve a higher degree of workload balance within the same packing window size compared to fixed-length packing (§4.1). **Second**, we propose an outlier document delay method to adaptively delay the training of extremely long documents. This approach helps minimize the impact on data randomness while achieving near-optimal workload balance across micro-batches (§4.2). **Finally**, we design and implement an efficient heuristic algorithm to optimize packing at runtime with negligible overhead (§4.3).

4.1 Workload-Aware Var-Length Packing

The main limitation of the baseline fixed-length packing is that it cannot achieve balance if there is an extremely long document in a global batch. For example, if the length of a document equals the context window size, it becomes impossible to create another micro-batch consisting of shorter documents with an equal computation workload due to the quadratic complexity of attention computation. To address this limitation, we propose a variable-length packing strategy, which allows each micro-batch to have a different sequence length. The key insight behind our design is that the workload of a micro-batch is not solely determined by attention computation. Other operations, such as GEMM computation, element-wise operations, and collective communication (e.g., AllGather and ReduceScatter), also contribute significantly to the training latency and are influenced by the documents within each micro-batch. To demonstrate it, we present the relationship between operation latency and document length in Figure 7. The operation latency is measured from a training job of Llama2 7B model on 16 H100 GPUs and is normalized to the attention computation latency at a document length of 4096. It can be observed that attention computation latency increases quadratically with the length of input documents, while other operations, such as GEMM, collective communication, and element-wise operations, exhibit a linear relationship between operation latency and document length.

This relationship presents an opportunity to further improve workload balance beyond fixed-length packing. If a long document has significantly higher attention computation latency compared to other operations, we can pack multiple shorter documents together to extend the latency of other operations, thereby matching the total latency of the long document. Specifically, we extend the fixed-length packing to a variable-length approach. The optimization goal shifts from balancing only the attention computation workload to balancing the total workload, including all operations:

$$\begin{aligned} \text{minimize} \quad & \max\Big(\sum_{i=1}^{N}\big(W_a(x_{ij}\cdot d_i)+W_l(x_{ij}\cdot d_i)\big)\Big), \\ & \qquad\qquad\qquad\qquad j=1,\cdots,M \\ \text{subject to} \quad & \sum_{j=1}^{M} x_{ij}=1, \qquad\qquad i=1,\cdots,N \\ & \sum_{i=1}^{N} x_{ij}\cdot d_i \le S_{max}, \qquad j=1,\cdots,M \\ & x_{ij}\in\{0,1\} \end{aligned} \tag{2}$$

in which $W_a(\cdot)$ and $W_l(\cdot)$ are latency prediction functions that compute the attention computation latency and the latency of all other operations, respectively, based on document length. Both $W_a(\cdot)$ and $W_l(\cdot)$ can be derived from offline profiling. And S_{max} represents the maximum sequence length permitted by GPU memory constraints.

4.2 Outlier Document Delay

Our variable-length packing strategy enables a higher degree of balance by allowing short documents to be packed into a longer sequence that exceeds the fixed context window size. However, within a single global batch, the number of short sequences may be insufficient to fully balance the computation

workload across all micro-batches. To address this challenge, we propose adaptively delaying the execution of *outlier documents*, i.e., extremely long documents. This approach is based on our observation that, although these outlier documents have a significant impact on workload imbalance, they only contribute a small proportion of tokens for training (as described in §2.2). By selectively delaying the training of tokens from a few extremely long documents, we could achieve a more balanced workload across micro-batches while minimizing the impact on data randomness.

Overall Workflow: As shown in Figure 8, we implement a *multi-level waiting queue* for outlier documents. Assuming we have n outlier queues, each queue is associated with a hyperparameter L_i, which specifies the minimum length of documents in the i-th queue, where $L_1 < L_2 < \cdots < L_{n+1}$. When a new global batch arrives, documents with lengths greater than L_1 are considered as outliers and are added to the corresponding waiting queue i, where $L_i \leq d < L_{i+1}$, and d denotes the document length. The execution of documents in the outlier queue is delayed until the queue accumulates enough outlier documents. Once the queue size reaches the number of micro-batches in a global batch, the outlier documents are popped from the queue and added to each micro-batch. This ensures workload balance across micro-batches, as each micro-batch receives an equal number of outlier documents.

Tuning Hyperparameter L_i: The choice of hyperparameters L_i directly influences performance. A smaller gap between two consecutive hyperparameters L_i and L_{i+1} helps achieve a higher degree of workload balance, as it ensures that documents within the same queue have smaller differences in length. However, a smaller gap also causes documents within each queue to wait longer before accumulating enough documents to be processed together, thereby increasing the per-token delay. To select appropriate values for L_i, we sample a small subset of training documents and evaluate the packing algorithm (described later in §4.3) on this subset by measuring both the achieved workload balance across micro-batches and the resulting per-token delay. We then choose the optimal L_i values that maximize workload balance while maintaining a low per-token delay.

4.3 Heuristic Packing Algorithm

Although an ILP solver can derive the optimal packing for a given set of input documents, its solving time is impractically high to be paid at runtime. Optimizing document packing offline is also infeasible, as it would introduce significant storage overhead to store pre-packed datasets for different training configurations. To address this, we design a heuristic algorithm that combines variable-length packing with outlier document delay optimization to efficiently produce packed micro-batches with balanced workloads. As listed in Algorithm 1, the algorithm takes a dataloader D, a multi-level waiting queue Q for outlier documents operating in a FIFO manner, the number of micro-batches per iteration N, and the upper bound for sequence length S_{max} as input. The algorithm outputs a series of packed input batches with balanced workloads for each training iteration. The packing process begins by iterating over the input batches in the dataloader D and adding all outlier documents into the corresponding waiting queue in Q for delayed processing (Line 4-10). If any queue q in Q reaches size N, the documents in q are popped out and added to the pending document set for the current batch (Line 11-15). Packing proceeds in a greedy manner: it first processes the remaining documents, followed by the newly added long documents. For each document, the algorithm first attempts to pack it into the micro-batch with the minimal workload (calculated using $W_a(\cdot)$ and $W_l(\cdot)$ as defined in Equation 2), provided that the total length remains within the upper bound S_{max}. If this is not feasible, it then

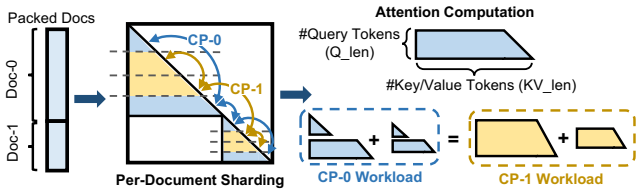

Figure 9: Overview of fine-grained per-document sharding.

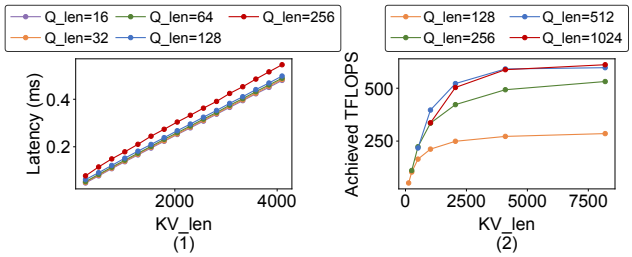

Figure 10: Attention kernel performance profiling: (Left) Attention forward latency; (Right) Achieved TFLOPs of the attention forward kernel.

attempts to pack the document into the micro-batch with the minimal current length (Lines 20-27). Documents that cannot fit within these constraints are saved for the next iteration (Line 29). Our heuristic approach effectively combines outlier document delay and variable-length packing to efficiently balance computational workloads across all micro-batches.

5 Fine-grained and Adaptive Sharding for CP

At the CP level, we aim to improve workload balance across document shards by implementing a fine-grained per-document sharding strategy, ensuring that each CP worker receives an equal computation workload (§5.1). Additionally, we observe a tradeoff between attention kernel efficiency and sharding granularity (§5.2). To maximize overall performance, we conduct an in-depth analysis and adaptively select the optimal sharding strategy for a given input sequence (§5.3).

5.1 Per-Document Sharding Design

At the CP level, the sequence of micro-batches is sharded across CP workers. Each CP worker works on an exclusive sequence shard. Existing CP implementation employs a **Per-Sequence Sharding** strategy, which equally shards the entire input sequence into $2 \times CP_size$ chunks. This method could easily lead to significant attention computation workload imbalance when the input sequence is packed with multiple documents. To eliminate the workload imbalance issue at the CP level, we propose sharding the sequence in a fine-grained manner. Specifically, we conduct **Per-Document Sharding** to divide each document into $2 \times CP_size$ document chunks. As shown in Figure 9, each CP worker takes a symmetrical pair of document chunks for each input document. With our fine-grained per-document sharding strategy, each CP worker not only receives the same number of tokens (ensuring workload balance in GEMM computation and collective communication) but also gets the same attention computation workload.

Avoid Padding: Our fine-grained per-document sharding strategy divides each input document into $2 \times CP_size$ document chunks. However, document lengths are not always divisible by $2 \times CP_size$, requiring extending the document length through adding some padding tokens. To avoid the redundant computation introduced by document padding, we design a padding-free per-document sharding method. Specifically, we split each document into two parts: one divisible by $2 \times CP_size$ and the remaining tokens. Assuming the length of the i-th document is d_i, where $d_i = e_i + r_i$, with $e_i = \lfloor \frac{d_i}{2 \times CP_size} \rfloor$. We apply the standard per-document sharding on the e_i part, while the tokens in r_i are distributed to CP workers in a round-robin fashion. Since $\sum_{i=1}^{n} d_i$ and $\sum_{i=1}^{n} e_i$ are both divisible by $2 \times CP_size$, it follows that $\sum_{i=1}^{n} r_i = \sum_{i=1}^{n} (d_i - e_i)$ is also divisible by $2 \times CP_size$. This ensures that each CP worker receives an equal number of tokens, thereby eliminating the need for padding.

5.2 Kernel Efficiency vs. Sharding Balance

Our per-document sharding strategy fully eliminates workload imbalance at the CP level. However, splitting each document into multiple shorter chunks may compromise kernel efficiency. The kernel efficiency may drop with fine-grained sharding due to two major reasons: **(1) Tile-level Computation Wasting:** The computation of attention is split into smaller tiles and distributed to different thread blocks for execution on GPU. For example, in the attention forward kernel of FlashAttention [5], the tile size is set to 128. If the number of tokens is less than the tile size, the thread block will still perform the full computation on 128 tokens, which will waste a significant amount of computation. To illustrate this, we profile the attention forward latency for query token lengths ranging from 16 to 256. As shown in Figure 10 (Left), when the number of query tokens (Q_len) increases from 16 to 128, the kernel latency remains constant. This is because all short documents with fewer than 128 tokens are padded to 128 tokens for computation at the kernel level. In contrast, as Q_len increases from 128 to 256, the kernel latency rises significantly. **(2) Inefficient Tensor Memory Accelerator (TMA) Usage:** TMA is a feature introduced in the NVIDIA Hopper architecture that enables asynchronous memory copying between global memory and shared memory on GPUs [1]. With large document lengths (e.g., $Q_len \geq 256$), multiple thread blocks process different Q tokens while sharing the same KV tokens of the document chunk. This allows KV tensor loading to be shared via the L2 cache using TMA load multicast,

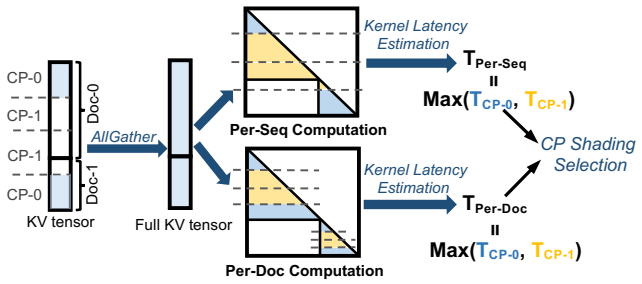

Figure 11: The process of adaptive CP sharding selection.

Model Size	Context Window	#GPU	4D Parallelism Configs (TP, CP, PP, DP)
550M	*64K*	*32*	*(2, 2, 4, 2)*
	128K	*32*	*(2, 4, 4, 1)*
7B	*64K*	*32*	*(4, 2, 4, 1)*
	128K	*64*	*(8, 2, 4, 1)*
30B	*64K*	*64*	*(8, 2, 4, 1)*
	128K	*128*	*(8, 4, 4, 1)*
70B	*64K*	*256*	*(16, 4, 4, 1)*
	128K	*256*	*(16, 4, 4, 1)*

significantly reducing the latency of transferring KV tensors from global memory to shared memory. As shown in Figure 10 (Right), when the length of the Query tensor increases from 128 to 256, the achieved TFLOPs increase significantly, demonstrating the impact of leverage TMA load multicast.

These profiling results clearly demonstrate the tradeoff between attention kernel efficiency and CP sharding balance. If per-document sharding is applied to input sequences composed of short documents, it can introduce redundant computation at the kernel level and reduce the achieved TFLOPs, ultimately leading to longer attention computation latency.

5.3 Adaptive Sharding Selection

Based on our analysis in Section 5.2, although fine-grained per-document sharding achieves optimal workload balance at the CP level, it does not necessarily guarantee better performance, as the attention kernel may become less efficient with the more fine-grained document chunks generated by per-document sharding. To address this issue, we propose to adaptively select the optimal sharding strategy for each micro-batch at runtime. As shown in Figure 11, during the forward pass at the CP level, an AllGather communication is performed across CP workers to collect the full KV tensor. We then calculate the input tensor shapes for the attention kernel (number of query tokens and key/value tokens) in the per-sequence and the per-document sharding cases. Finally, we predict the attention kernel latency and select the CP sharding strategy that yields lower attention computation latency.

To accurately estimate the attention kernel latency, we leverage the insights provided in §5.2. First, we calculate the total floating point operations required for the attention computation. The kernel-level padding is also considered by padding the document chunk to a multiple of the tiling size. Next, we estimate the achieved TFLOPs for the given tensor shape using the data collected from offline profiling which includes the impact of TMA usage. Finally, the attention kernel latency is estimated by dividing the amount of floating point operations by the achieved TFLOPs. By adaptively selecting CP sharding, *WLB-LLM* minimizes the CP level training latency.

6 Implementation Detail

WLB-LLM is built on top of a widely adopted 4D parallelism training paradigm, which integrates advanced distributed training techniques at each parallelism level. For DP, *WLB-LLM* leverages Fully Sharded Data Parallel (FSDP) [54], a state-of-the-art approach that uniformly shards model parameters across DP workers, significantly reducing memory requirements compared to traditional DP methods. For PP, *WLB-LLM* employs the interleaved 1F1B pipeline schedule [26]. To support variable-length packing optimization, *WLB-LLM* further implements a variable-length pipeline, which enables micro-batches to have variable sequence lengths. For CP, the per-sequence sharding baseline follows the AllGather-based CP approach used in Llama3 training [6], which performs an AllGather communication during the forward pass across all CP workers to collect the full KV tensors for attention computation. Building on this, *WLB-LLM* implements fine-grained per-document sharding by optimizing the document partitioning and distribution. For TP, *WLB-LLM* performs 1D tensor parallelism with sequence parallelism enabled [15, 38]. Additionally, *WLB-LLM* incorporates computation–communication overlapping to further improve TP training performance [46].

7 Evaluation

In this section, we evaluate *WLB-LLM* across various LLM sizes and 4D parallelism configurations, with model sizes ranging from *550M* to *70B*. We begin by presenting the improvements in end-to-end training latency. Next, we analyze the speedup contributions from individual optimizations at the PP level (§4) and the CP level (§5), respectively. Finally, we demonstrate that the optimizations of *WLB-LLM* do not compromise model quality or model convergence by comparing the training loss curve.

7.1 Experiments Setup

Hardware: We deploy *WLB-LLM* on a cluster with 32 nodes. Each node is equipped with 8× NVIDIA H100 SXM 80GB GPUs interconnected via high-bandwidth NVLink, while

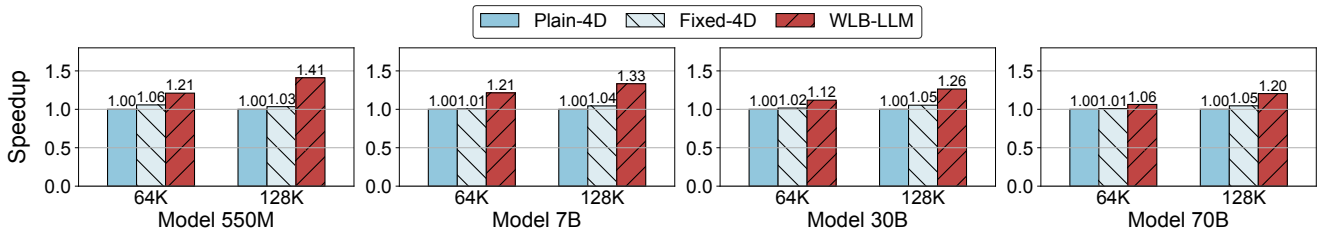

Figure 12: Training performance speedups of *WLB-LLM* and *Fixed-4D* over *Plain-4D* across various configurations.

cross-node communication is facilitated by RDMA over Converged Ethernet (RoCE).

Models and Parallelism Configurations: We conduct experiments on a series of our internal LLaMA-like models, spanning four different scales: 550*M*, 7*B*, 30*B*, and 70*B*. The 7*B* model shares the same architecture as the LLaMA2-7B model [42]. The other models retain the same architecture while proportionally adjusting the number of layers and model dimension size. For each model, we evaluated performance using two different context window sizes: 64*K* and 128*K*. Each model scale and context window size is associated with a corresponding 4D parallelism configuration. The global batch size is set to $PP_size \times DP_size$ and we use *bfloat16* precision for all evaluations. Details of the training setup and parallelism configurations are provided in Table 1. When mapping 4D parallelism to the hardware, inner-level parallelism dimensions (e.g., TP or CP) are prioritized for mapping to intra-node GPUs, leveraging the high-bandwidth NVLink for efficient communication. Outer-level parallelism dimensions, such as DP, are subsequently mapped across multiple nodes. Throughout the rest of the paper, we use *Model Size-Context Window Size* to denote a specific configuration. For instance, *7B-128K* refers to the 7*B* model with a 128*K* context window.

Baselines: We compare *WLB-LLM* with two baselines:

- **Plain-4D**: This is our internal codebase for large-scale LLM training, supporting 4D parallelism to enable efficient training and scaling up to 100*K* GPUs. *Plain-4D* directly uses input batches obtained from the dataloader for training without optimizing the input packing. For CP sharding, *Plain-4D* employs a per-sequence sharding method, which shards the input sequence at the whole-sequence level.

- **Fixed-4D**: *Fixed-4D* applies the baseline fixed-length packing optimization, as described in Section 3.2. To minimize packing overhead, a greedy algorithm is used instead of the solver, and the packing size is restricted to a single global batch to preserve data loading randomness and prevent an increase in training loss. For CP sharding, *Fixed-4D* utilizes a fixed sharding strategy throughout the entire training process, either per-sequence or per-document. We then select the better-performing result between the two sharding strategies and use it for comparisons.

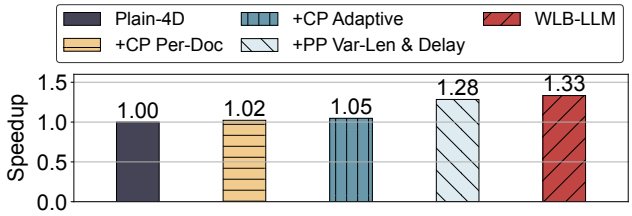

Figure 13: Performance breakdown of *WLB-LLM* on the 7B model with a 128K context window.

7.2 Training Performance

We run *WLB-LLM* and all baselines on diverse model size and context window size:

Plain-4D vs. Fixed-4D: As shown in Figure 12, *Fixed-4D* achieves only marginal improvements over *Plain-4D*, with an average speedup of approximately 1.03× across all settings. This limited gain is primarily because *Fixed-4D* adjusts document packing only within a single global batch and is constrained by the context window size. It fails to address the presence of outlier documents with extremely long lengths (e.g., a document with a length equal to the context window size). Given that attention computation scales quadratically with document length, packing multiple short documents within the constraints of the context window cannot match the computation workload of an extremely long document. Moreover, *Fixed-4D* employs either per-sequence or per-document sharding at the CP level for all input batches. This approach overlooks the tradeoff between attention kernel efficiency and sharding balance, resulting in suboptimal performance. These limitations constrain the improvements of *Fixed-4D* over the *Plain-4D* baseline.

***WLB-LLM* vs. Baselines**: Figure 12 shows that *WLB-LLM* consistently outperforms all baselines across various model sizes and 4D parallelism configurations. Specifically, *WLB-LLM* achieves speedups of 1.23× and 1.19× over *Plain-4D* and *Fixed-4D*, respectively. The significant improvement stems from two key optimizations in *WLB-LLM*. At the PP

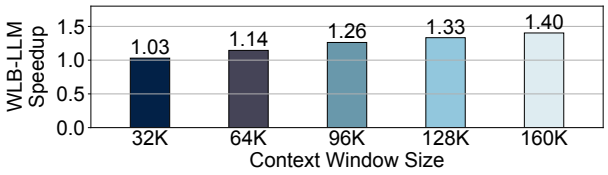

Figure 14: Speedups of *WLB-LLM* on the 7B model across context window sizes.

level, *WLB-LLM* employs a heuristic variable-length document packing algorithm that is not constrained by the fixed context window size. This algorithm also selectively delays the training of outlier documents, achieving a higher degree of workload balance compared to fixed-length packing. At the CP level, *WLB-LLM* combines per-sequence and per-document sharding, adaptively selecting the optimal sharding strategy for each micro-batch to maximize the performance.

Across Model Size and Context Window Size: As shown in Figure 12, *WLB-LLM* achieves slightly lower speedup on larger models. This is because larger models involve more GPUs for training, which increases the ratio of communication latency to computation latency, making the impact of workload imbalance in the attention layer less significant. On the other hand, increasing the context window size from 64K to 128K improves the average speedup from 1.15× to 1.30×, as longer contexts exacerbate workload imbalance issue. A more detailed sensitivity analysis on the context window size is provided in Section 7.3.

7.3 Breakdown and Sensitivity Analysis

In this section, we conduct a performance breakdown and sensitivity analysis. Specifically, we first report the performance breakdown to evaluate the impact of each optimization technique. Then, we perform a sensitivity study by measuring the speedups across different context window sizes.

Speedup Breakdown: We show the speedup breakdown in Figure 13 by separately applying each optimization technique proposed in *WLB-LLM* to *Plain-4D* for the *7B-128K* training configuration. By utilizing the fine-grained per-document sharding at the CP level, we observe a 1.02× speedup due to the reduced imbalance among CP workers. The speedup is limited due to the tradeoff between the kernel efficiency and the sharding balance. As a result, performing per-document sharding is not always beneficial and can potentially cause performance degradation. By adaptively selecting the per-document and per-sequence sharding strategies, we can improve the speedup to 1.05×. We then apply the PP-level optimizations on *Plain-4D* to study their effect. It can be observed that combining the heuristic var-length packing with the outlier documents delay offers a significant speedup of 1.28×. Finally, we incorporate both CP and PP-level optimizations to maximally reduce the workload imbalance across the all

Packing Method		Imbalance Degree	Packing Overhead (ms)
Method	**Config**		
Original Packing	/	1.44	0
Fixed-Len Greedy	#global batch=1	1.41	4
	#global batch=2	1.22	5
	#global batch=4	1.11	5
	#global batch=8	1.08	5
Fixed-Len Solver	#global batch=1	1.40	467
	#global batch=2	1.18	1488
	#global batch=4	1.09	25313
WLB-LLM	#queue=1	1.24	8
	#queue=2	1.05	20
	#queue=3	1.05	23

Table 2: Packing imbalance degree and overhead analysis.

parallelism hierarchies, leading to a final speedup of 1.33×.

Speedup across Context Window Sizes: We investigate the impact of context window size on the performance improvements delivered by *WLB-LLM*. Figure 14 shows the speedups over *Plain-4D* on 7*B* model across different context window sizes, varying from 32*K* to 160*K*. We observe that as the context window size grows, the achieved speedup becomes more significant, reaching 1.40× with a 160K context window. This is because a larger context window raises the likelihood of outlier documents appearing. Additionally, a larger context window also increases the proportion of attention computation and exacerbates the impact of imbalance on training latency. The trend of increasing speedups demonstrates the significant potential of *WLB-LLM* in handling the ever-expanding context window sizes today.

7.4 Optimization Analysis

In this section, we first analyze the effectiveness of the packing and sharding optimization in *WLB-LLM*. Furthermore, we demonstrate that the system optimizations in *WLB-LLM* do not compromise model quality or slow down convergence.

Packing Balance and Overhead Analysis: To assess the balance degree of computation workload across micro-batches with different packing strategies, we profile and compare the forward latency of each micro-batch in a *7B-128K* training job with different packing methods and configurations applied. As discussed in Section 3.1, the PP level latency is primarily determined by the largest micro-batch. Therefore, we use the following metric to represent the imbalance degree of a given batch: $\frac{Max_Latency \times PP_size}{Total_Latency}$, where $Max_Latency$ is the forward latency of the largest micro-batch and $Total_Latency$ is the total forward latency of all micro-batches. A lower imbalance degree indicates that the given batch is more balanced in terms of workload. The result of the imbalance degree and the packing overhead (per-batch packing latency) of different methods have been given in Table 2. We evaluate four different packing methods: (1) *Original Packing*, which uses the original input batch loaded from the dataloader; (2) *Fixed-Len Greedy* is the packing method used in *Fixed-4D* baseline,

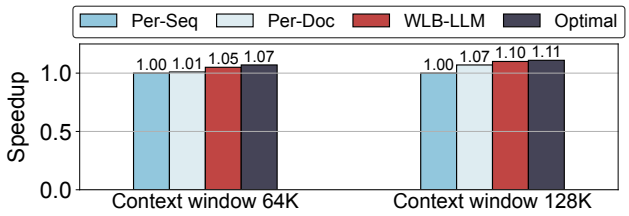

Figure 15: CP sharding performance comparison.

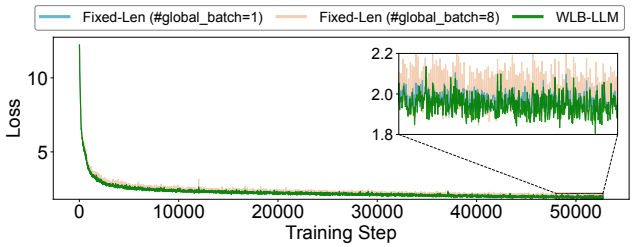

Figure 16: Training loss comparison on a *550M* model.

which shuffles documents in several global batches in a greedy manner to optimize workload balance across micro-batches; (3) *Fixed-Len Solver*, which employs an ILP solver [8] to solve Equation 1 and provides the optimal packing based on the given global batches; and (4) *WLB-LLM*, which utilizes var-len packing combined with outlier document delay. Additionally, we demonstrate the performance of *WLB-LLM* with different numbers of outlier document queues.

As shown in Table 2, *Fixed-Len Greedy* can slightly mitigate workload imbalance when packing across a single global batch. Packing across multiple global batches helps to achieve lower imbalance degrees, while it will incur higher training losses, as demonstrated in Figure 6. As for *Fixed-Len Solver*, it achieves lower imbalance degrees compared to *Fixed-Len Greedy* under the same number of global batches. However, the solver-based solution suffers from significant packing overhead. For instance, when packing across 4 global batches, the average packing latency for each batch exceeds 25 seconds. In contrast, *WLB-LLM* is the only solution which achieves both near-optimal imbalance degree and low packing overhead. For example, when having two outlier queues, *WLB-LLM* achieves 1.05 imbalance degree. Additionally, the per-batch packing latency is only 20 ms which is less than 0.65% when compared to the per-step training latency.

CP Sharding Performance Analysis: To demonstrate the effectiveness of per-document sharding and the adaptive sharding selection optimization at the CP level in *WLB-LLM*, we conduct a case study on a single transformer layer of a *7B* model with CP size of 4. We compare the forward and backward latency with different sharding strategies including: (1) *Per-Sequence Sharding (Per-Seq)*, (2) *Per-Document Sharding (Per-Doc)*, (3) *WLB-LLM*, which determines the sharding between *Per-Seq* and *Per-Doc* adaptively based on the given micro-batch at runtime, and (4) *Optimal*, which is the optimal result. It always chooses the sharding from *Per-Seq* and *Per-Doc* that yields lower latency.

As shown in Figure 15, *Per-Document Sharding* achieves a speedup of 1.01× and 1.07× over the *Per-Sequence Sharding* baseline under context window sizes of 64K and 128K, respectively. These results demonstrate the effectiveness of *Per-Document Sharding* in reducing the workload imbalance at the CP level. However, the fine-grained *Per-Document Sharding* may sacrifice kernel efficiency, particularly when the input sequence consists of many short documents. To overcome this issue, *WLB-LLM* leverages an adaptive sharding selection method to intelligently choose a better sharding strategy for each micro-batch at runtime. The results in Figure 15 show that *WLB-LLM* achieves a 7.5% and 3.4% improvement over static *Per-Seq* and *Per-Doc* sharding, respectively. Furthermore, *WLB-LLM* is very close to the optimal result, demonstrating the effectiveness of our adaptive selection method.

Model Convergence Analysis: *WLB-LLM* employs a heuristic variable-length packing optimization that adjusts document packing and delays the execution of outlier documents. To demonstrate that this optimization does not affect model convergence, we present the training loss curve of our *550M* model. As shown in Figure 16, packing across 8 global batches results in a noticeable increase in training loss (1.6% on average). This is because packing over multiple global batches disrupts the randomness of data sampling in the dataloader, which leads to a different data distributed per batch than desired. In contrast, *WLB-LLM* follows almost the same trend as fixed-length packing across a single global batch, since the heuristic variable-length packing algorithm used by *WLB-LLM* only delays outlier documents, which contributes to a small proportion of all input tokens. According to our profiling, each token is delayed by an average of 0.5 iterations in *WLB-LLM*. This minimal delay preservers original data distribution at best, allowing *WLB-LLM* to improve training efficiency without compromising model quality.

8 Discussion

In this section, we discuss the compatibility of *WLB-LLM* with other parallelism dimensions and potential opportunities for improvement in future work.

Compatibility with Expert Parallelism: Beyond 4D parallelism, expert parallelism (EP) [20, 53] is a complementary dimension tailored for Mixture-of-Experts (MoE) models [37]. In EP, different experts are distributed across workers, and each input token is independently routed to one or more experts at runtime, which can introduce load imbalance when expert capacity is exceeded [50]. Prior works mitigate this by adding a load-balancing auxiliary loss [7, 20] or injecting expert-wise bias into the routing scores [45]. Thanks to

these optimizations, state-of-the-art MoE training achieves dropless token routing [22], guaranteeing that every token is dispatched strictly according to its gating logits without any capacity-driven drops. Consequently, the packing and sharding optimizations in *WLB-LLM* will not affect EP routing decisions, making *WLB-LLM* fully compatible with existing EP load-balancing strategies.

Further Optimization Opportunity: The adaptive CP sharding selection in *WLB-LLM* is performed at the granularity of the entire input sequence, where either per-sequence sharding or per-document sharding is applied to the whole sequence. Although this approach already achieves near-optimal performance, there remains potential for further optimization. In certain cases, such as when an input sequence contains both extremely long documents and many short documents, it may be beneficial to combine both sharding strategies and apply them selectively based on document lengths. For instance, per-document sharding could be applied to long documents to balance the workload, while per-sequence sharding could be applied to short documents to maximize attention kernel efficiency. We hope this observation could motivate future work to further improve the efficiency of CP training.

9 Related Work

Distributed LLM Training Frameworks: To address the challenges of training extra-large LLMs, prior approaches primarily rely on 3D parallelism [15, 26, 38, 40, 43, 44, 55], which integrates tensor parallelism [15, 17, 38], pipeline parallelism [11, 19, 21, 26], and data parallelism [35, 36, 54]. Although 3D parallelism has proven its effectiveness in scaling model size, enabling the training of models with trillions of parameters [40], it struggles to scale context window size effectively. To address this limitation, a new dimension of parallelism called context parallelism has been introduced [30], forming the 4D parallelism training paradigm. Context parallelism splits input sequences into chunks, effectively reducing the memory bottleneck associated with extremely long documents. Initially, context parallelism employs a ring-based approach that overlaps communication and computation using P2P communication [24]. More recent approaches leverage collective communication methods (e.g., AllGather or AllToAll) to aggregate key and value tensors, offering greater flexibility and better support for various types of attention masks [6, 12, 30]. The introduction of context parallelism enables efficient training of LLMs with long context windows. However, existing 4D parallelism frameworks overlook the heterogeneity in per-token arithmetic intensity, leading to significant workload imbalances across GPUs.

Input Padding and Packing for LLM Training: The input of LLMs consists of samples with varying lengths. To batch input documents together and optimize GPU utilization during LLM training, the input documents must be organized into tensors of identical lengths. This can be achieved through two primary approaches: *Padding* [38] and *Packing* [16]. Padding involves adding zero padding to shorter documents within a micro-batch. However, this approach inevitably introduces redundant computation, communication, and memory overhead. To address this issue, prior works have designed more efficient kernels to reduce redundant computation [49, 51]. Other works, such as DynaPipe [13], optimize batching strategies to minimize padding. Although these approaches mitigate redundant computation, the overhead caused by padding cannot be fully eliminated. To further address this problem, recent works propose packing short documents together to form a single long input sequence [16, 47]. After packing, an additional attention mask must be applied to ensure tokens only attend to others within the same document [6, 18, 29, 34]. Due to its efficiency in avoiding redundant computation, packing has become the mainstream choice in LLM training. For example, LLaMA3 adopts input packing [6] in its training process, and state-of-the-art high-performance attention implementations (e.g., FlashAttention [4, 5]) also support efficient attention computation with document packing. *WLB-LLM* focuses on input packing and addresses the workload imbalance issue that arises when input documents are packed together.

10 Conclusion

In this paper, we present *WLB-LLM*, a workload-balanced 4D parallelism framework designed to enhance the efficiency of LLM training. *WLB-LLM* systematically identifies and addresses workload imbalances that arise across multiple parallelism hierarchies. At the pipeline parallelism level, *WLB-LLM* introduces a novel heuristic variable-length document packing algorithm combined with an outlier document delay method that effectively mitigates workload imbalance across micro-batches. At the context parallelism level, *WLB-LLM* proposes a fine-grained per-document sharding method with an adaptive sharding selection strategy to maximize CP training efficiency. Comprehensive experiments demonstrate that *WLB-LLM* outperforms existing 4D parallelism frameworks across various model sizes and parallelism configurations, achieving an average speedup of 1.23×.

A Artifact Appendix

Abstract

Our artifact provides an open-source implementation of the context parallelism optimization of *WLB-LLM*. It includes both the *Per-Sequence* baseline and the *Per-Document* sharding optimization proposed by *WLB-LLM*. This implementation differs from the internal version used at Meta. We develop this open-source version following the design proposed in *WLB-LLM*, using open-source frameworks. The goal is to make it easier for readers to experiment with and build upon the context parallelism optimizations presented in *WLB-LLM*.

Scope

This artifact provides a user-friendly interface to perform context parallelism training using both *Per-Sequence* and *Per-Document* sharding strategies. It enables quick performance comparisons between the two approaches, supporting the claims made in the *WLB-LLM* paper. It also serves as a good starting point for exploring further optimizations in context parallelism.

Contents

The repository includes the following components:

1. Implementation of both *Per-Sequence* and *Per-Document* sharding.
2. Code and scripts for verifying correctness.
3. Code and scripts for benchmarking the training efficiency of *Per-Sequence* vs. *Per-Document* sharding.
4. A detailed `README.md` with usage instructions and setup guidance.

Hosting

The artifact is open-sourced on GitHub at: https://github.com/Ash-Zheng/WLB-LLM-CP. We are actively maintaining the main branch of the repository to make it more comprehensive. Clear and accessible documentation will be continuously updated to reflect new features and improvements.

Requirements

We have tested and evaluated our artifact using the `nvcr.io/nvidia/pytorch:25.01-py3` Docker image, with PyTorch 2.6.0, FlashAttention 2.4.2, and CUDA 12.8. Our implementation has been validated on both NVIDIA A100 and H100 GPUs. To run performance comparisons between *Per-Sequence* and *Per-Document* sharding, a minimum of two GPUs is required.

DecDEC: A Systems Approach to Advancing Low-Bit LLM Quantization

Yeonhong Park* Jake Hyun* Hojoon Kim Jae W. Lee
Seoul National University

Abstract

Quantization of Large Language Models (LLMs) has recently gained popularity, particularly for on-device settings with limited hardware resources. While efficient, quantization inevitably degrades model quality, especially in aggressive low-bit settings such as 3-bit and 4-bit precision. In this paper, we propose DecDEC, an inference scheme that improves the quality of low-bit LLMs while preserving the key benefits of quantization: GPU memory savings and latency reduction. DecDEC stores the residual matrix—the difference between full-precision and quantized weights—in CPU, and dynamically fetches the residuals for only a small portion of the weights. This portion corresponds to the salient channels, marked by activation outliers, with the fetched residuals helping to correct quantization errors in these channels. Salient channels are identified *dynamically* at each decoding step by analyzing the input activations—this enables adaptation to the dynamic nature of activation distribution, thus maximizing the effectiveness of error compensation. We demonstrate the effectiveness of DecDEC by augmenting state-of-the-art quantization methods. For example, DecDEC reduces the perplexity of a 3-bit Llama-3-8B-Instruct model from 10.15 to 9.12—outperforming its 3.5-bit counterpart—while adding less than 0.0003% to GPU memory usage and incurring only a 1.7% inference slowdown on NVIDIA RTX 4050 Mobile.

1 Introduction

Recent advancements in Large Language Models (LLMs) based on the Transformer architecture [59] have shown great potential to reshape our daily lives [7,40,44,55,56]. However, their deployment costs pose a significant challenge, as large model sizes increase memory requirements and latency, limiting their use cases [60]. Quantization is a promising solution for reducing the LLM deployment costs [28, 69]. By lowering the model precision, quantization addresses both memory limitations and inference latency. The importance of quantization is pronounced for on-device deployments, where strict memory budgets often make model compression mandatory rather than optional. These scenarios typically require careful tuning of quantization levels to achieve an optimal balance between model size and quality [8, 14, 15, 58, 61].

While quantization may allow gigantic LLMs to fit into small-memory devices, it often leads to model quality degradation due to the inevitable loss of information. This is especially true for low-bit settings, such as 3-bit and 4-bit quantization, which are often used to accommodate the parameter sizes of LLMs [19,31,36]. This raises a key research question that this paper addresses: given a quantized LLM configured with the best possible effort under the memory budget, is there a way to recover the quality loss caused by quantization?

Leveraging external memory offers a potential solution to this problem. Specifically, on heterogeneous computing platforms where the CPU and GPU are connected via a PCIe interconnect—a common architecture in desktops and laptops—CPU memory becomes a viable option. Additional information that may be used to mitigate quantization errors can be stored in CPU memory and fetched at runtime, avoiding any additional GPU memory overhead.

However, utilizing CPU memory for GPU inference presents a critical challenge: the slow data transfer between the CPU and GPU can create a bottleneck for inference latency. To mitigate this issue, the volume of data transferred must be carefully controlled. Therefore, designing a system that effectively utilizes CPU memory requires the identification of the minimal set of additional information that can substantially enhance the quality of quantized models, while keeping the impact on latency minimal.

A clue for this problem comes from the well-known fact that not all channels in the weight matrix are equally important for quantization. Some channels, referred to as *salient channels*, are more critical, primarily due to the presence of activation outliers [6, 10, 25]. When certain input activation values are particularly large, the quantization errors in the corresponding weight channels—those multiplied by these large

*Equal contribution

activation values—are amplified, making the channels salient. By identifying these channels and selectively fetching error compensation terms from CPU memory, we can maximize the quality boost while minimizing data transfer.

Hence, the identification of the salient channels is essential for overcoming the bandwidth limitation, allowing for the transfer of only impactful information. Previous works that attempt to improve quantization algorithms by addressing activation outliers analyze the activation value distribution on a calibration data to predetermine the salient channels [10,27,33,36]. This approach is suboptimal as it statically designates certain channels as salient throughout the inference, while the real distribution of activation values—and thus the distribution of salient channels—changes dynamically at each decoding step. Accounting for this dynamic nature is crucial for the accurate identification of salient channels.

Thus, in this paper, we introduce DecDEC (**Dec**oding with **D**ynamic **E**rror **C**ompensation), an inference scheme for quantized LLMs that dynamically identifies salient channels and compensates for quantization errors in these channels, in real time. DecDEC enhances model quality while fully preserving the two main benefits of quantization: GPU memory savings and latency reduction. To achieve this, DecDEC stores the residuals of the quantized weight matrices in CPU memory, fetching only the parts that correspond to the dynamically identified salient channels for error compensation. Although small in size, these residuals provide a significant quality boost. This dynamic error compensation is performed concurrently with inference by an optimized GPU kernel, ensuring that all additional operations are seamlessly integrated into the existing workflow, minimizing inference slowdown. Below are the key contributions of our work:

- We provide an in-depth analysis on the dynamic nature of activation outliers in LLM inference.
- We present DecDEC, an inference scheme that enhances quantized LLMs by dynamically identifying salient channels and compensating quantization errors in them.
- We introduce a tuner for DecDEC that recommends system parameters to satisfy a target latency bound.
- We evaluate DecDEC across five different consumer-grade GPUs, demonstrating significant quality improvement with minimal memory and latency overhead.

2 Background

2.1 LLM Inference

Figure 1 presents a description of the modern LLM architecture and its inference flow. LLMs consist of multiple Transformer decoder blocks [59], each containing multiple linear layers, which account for most of the inference time, alongside other components like self-attention and normalization.

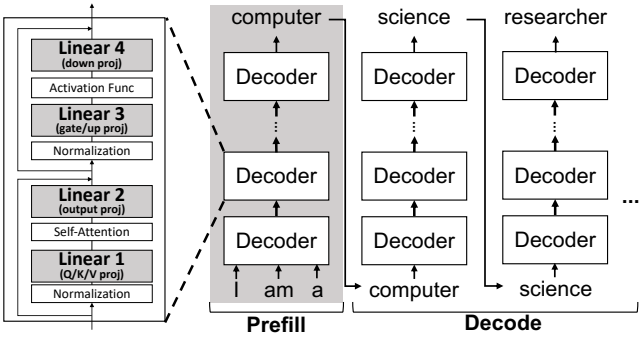

Figure 1: LLM inference.

LLM inference involves two phases: prefill and decode. In the prefill phase, all input tokens (e.g., 'I', 'am', 'a') are processed in parallel to generate a single output token (e.g., 'computer'). The decode phase begins subsequently, where the output token of the previous step is fed back into the model to generate the next token, repeated until the end of the sequence. This sequential nature of the decode phase makes it the primary latency bottleneck.

The decode phase is particularly memory-bound, as only one token is processed at a time, reducing the linear layers to GEMV operations. In data center settings, this issue can be alleviated by batching together multiple queries [32,66]. However, this usually cannot be applied to on-device inference, where LLMs serve only individual users.

2.2 LLM Quantization

Quantization for LLMs—a popular compression technique that reduces both memory usage and inference latency—can be categorized into two main types [28,69]: weight-activation quantization [10, 34, 37, 49, 64, 65] and weight-only quantization [9, 11, 12, 17, 19, 30, 31, 33, 36, 57]. Each are suited to different inference scenarios. Weight-activation quantization is primarily used in datacenter settings, where both memory and computational costs must be minimized to improve throughput. Quantizing both weights and activations allows for the efficient use of low-precision arithmetic units (e.g., INT4, INT8, FP8) available on modern GPUs [1]. In contrast, for on-device inference, weight-only quantization is the preferred approach [31, 69]. In this apporach, quantized weights are loaded from memory and dequantized on-the-fly to full precision (i.e., FP16), before being multiplied with the full-precision activations [23]. Though it only reduces memory traffic, this is sufficient to speed up on-device inference where memory is the bottleneck, as discussed in Section 2.1.

Weight-only quantization can be further divided into two sub-categories: quantization-aware training (QAT) [11,30,37], and post-training quantization (PTQ) [9, 12, 17, 19, 31, 33, 36, 57]. While QAT yields better results by retraining to reduce quantization errors, its cost makes it impractical for many end-

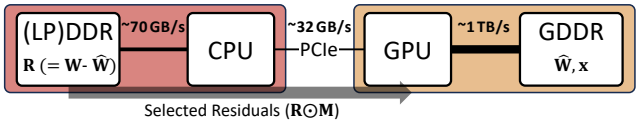

Figure 2: CPU-augmented inference for quantized LLMs.

users [31,69]. As a result, PTQ—requiring no retraining—has become the preferred method for on-device LLM inference. Therefore, in this paper, we specifically focus on weight-only PTQ for on-device inference.

3 Augmenting Quantized LLM with CPU Memory

In this section, we propose leveraging CPU memory—an often underutilized resource in LLM inference, as GPUs are the de facto standard processors for this workload—as a means to augment quantized LLMs. Section 3.1 introduces the concept of CPU-augmented quantized LLMs while Section 3.2 and Section 3.3 explore its opportunities and challenges.

3.1 Concept

Goal. We aim to leverage CPU memory to improve quantized LLM quality without additional GPU memory costs. Quantization trades model quality for a smaller memory footprint. In constrained settings, practitioners optimize this trade-off within a fixed GPU memory budget by selecting a uniform bitwidth or applying fine-grained strategies such as layer-wise [8,14,15] or channel-wise [58,61] allocation. Our goal is to then further improve quality post hoc by utilizing CPU memory, without increasing GPU memory usage.

Basic Mechanism. Figure 2 illustrates our concept of leveraging CPU memory to enhance quantized LLMs. We primarily target desktop or laptop platforms, where the GPU is connected to the CPU via a PCIe interconnect. As in conventional inference systems, the quantized weight parameters ($\widehat{\mathbf{W}}$) and activations ($\mathbf{x}$) are kept in GPU memory. The difference here is that $\mathbf{R}$—the residual between the original full-precision weights and the quantized weights—is stored in CPU memory. During the decode phase, residuals are fetched from the CPU to help compensate for quantization errors, potentially improving model quality. Due to the limited bandwidth of PCIe, which is typically an order of magnitude lower than GPU memory bandwidth (e.g., 32 GB/s vs. 1 TB/s), fetching the entire residual matrix would incur a prohibitive latency bottleneck. Therefore, only a small subset of residuals should be fetched in a selective manner. In short, this process augments each linear operation of quantized LLM from $\widehat{\mathbf{W}}\mathbf{x}$ to $(\widehat{\mathbf{W}}+\mathbf{R}\odot\mathbf{M})\mathbf{x}$, where $\mathbf{M}$ is a binary mask that sparsifies $\mathbf{R}$.

Key Research Question. A key research question in designing an effective CPU-augmented inference system for quantized LLMs is determining a subset of residuals, or mask $\mathbf{M}$. A good mask $\mathbf{M}$ should: 1) select portions of the residuals that contribute most to improving model quality within the bandwidth constraints, and 2) maintain a structured form that minimizes indexing overhead and ensures effective residual transfer, while enabling efficient processing on the GPU.

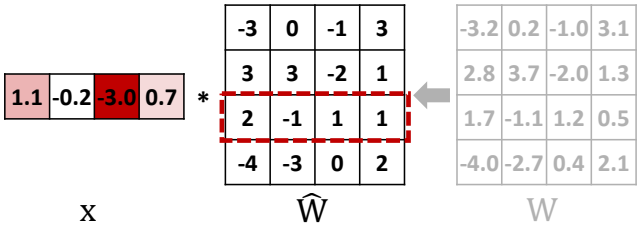

Figure 3: Activation outlier issue in weight quantization.

3.2 Opportunity: Not All Residuals Are Equally Important

Some residuals are more important than others—an opportunity that can be leveraged to determine $\mathbf{M}$. This opportunity arises from the presence of activation outliers (i.e., activation values with large magnitudes), a well-known phenomenon in LLM inference [6,10,25,27,33,36]. When certain activation values are noticeably large, even small quantization errors in the corresponding weight channels can be multiplied and amplified, leading to considerable perturbations in the output. Figure 3 illustrates this issue. In this example, the third input channel (third row) of the weight matrix is multiplied by the activation outlier, -3.0. We refer to such channels as *salient* channels. Constructing $\mathbf{M}$ at the input channel granularity based on the magnitude of input activations can satisfy two key conditions for an effective mask: selecting impactful portions of the residuals and maintaining a structured form.

Indeed, compensating for errors in salient channels using the corresponding residuals is highly effective. Figure 4 illustrates how the quantization error, defined as the mean squared error between the computation result with FP16 weights ($\mathbf{Wx}$) and quantized weights ($\widehat{\mathbf{W}}\mathbf{x}$), is reduced by sequentially replacing the input channels of the quantized weight with their corresponding FP16 values. For this analysis, we evaluate 3-bit and 4-bit versions of the LLaMA-3-8B-Instruct model [16], quantized using the state-of-the-art method AWQ [36], with a text sample from the C4 dataset [47] as the input prompt. All four linear layers in the 8th, 16th, and 24th decoder blocks are included in this evaluation. The quantization errors for both the 3-bit and 4-bit models drop rapidly when we progressively compensate for channels in descending order of their activation magnitudes (solid red and solid blue lines). This trend closely follows the activation magnitude distribution (solid black line), which represents the sorted activation magnitudes in descending order. In contrast, the reduction in

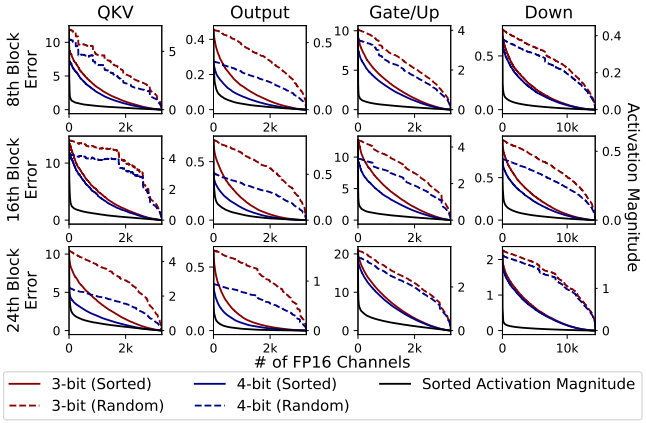

Figure 4: Quantization error reduction trends observed when replacing the input channels of quantized weights with FP16 values sequentially in sorted order (solid lines) and random order (dotted lines) for the 8th, 16th and 24th decoder block of Llama-3-8B-Instruct. The distribution of activation magnitudes in sorted order is also shown (black lines).

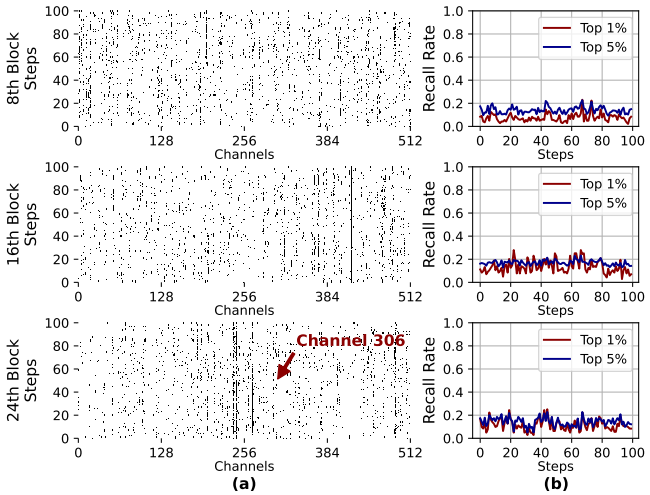

Figure 5: (a) Distribution of activation outliers (top 5%) and (b) Recall rate of static analysis-based outlier identification for the true top 1% and 5% outliers, across 100 decoding steps. The down projection layers in the 8th, 16th, and 24th decoder blocks of Llama-3-8B-Instruct model are used for profiling.

quantization error is significantly slower when input channels are compensated in random order, as shown by the dotted lines. This highlights the importance of prioritizing salient channels based on activation magnitude.

3.3 Challenge: Dynamic Nature of Activation Outliers

Identifying salient channels is challenging because the distribution of activation outliers changes dynamically by nature. While it is possible to infer salient channels by statically analyzing activation value statistics on a small calibration set [10, 27, 33, 36], such static approaches are suboptimal. Figure 5(a) shows the distribution of activation outliers—defined as activations with the top 5% magnitudes—in the down projection layer of the 8th, 16th, and 24th decoder blocks of the Llama-3-8B-Instruct model over 100 decoding steps, using a text sample for C4 dataset as the input prompt [47]. For visibility, only the first 512 channels are shown. While some channels (e.g., Channel 306 in 24th block, highlighted by an arrow) consistently exhibit high activation magnitudes and remain persistent outliers, the outlier distribution generally shows significant irregularity across decoding steps.

To quantify the dynamic nature of activation outliers, we calculate the recall rate of the top 1% and top 5% outliers identified through static analysis using a calibration set, compared to the true top 1% and top 5% outliers (ground truth) observed at each decoding step. We use a subset of the Pile dataset [21] for calibration, following prior work [36]. Specifically, we profile the average of the mean square of each activation value and use this as a metric for identifying outliers. Figure 5(b) presents the results, showing that the recall rate remains low (∼20%) for both the top 1% and top 5% outliers. This highlights a clear limitation of static analysis, as it misses the majority of outliers at runtime, emphasizing the need for dynamic identification of salient channels.

4 DecDEC Design

4.1 Overview

In this section, building on the opportunity outlined in Section 3.2 and addressing the challenge described in Section 3.3, we propose DecDEC, a CPU-augmented inference system for quantized LLMs that performs decoding with dynamic error compensation. Figure 6 presents an overview of DecDEC. During the decode phase, DecDEC augments each linear layer, essentially a GEMV operation, with dynamic error compensation. To produce the final output $\mathbf{o}$, DecDEC adds an error compensation term $\mathbf{o}_{\text{dec}}$ to the base GEMV result $\mathbf{o}_{\text{b}} = \widehat{\mathbf{W}}\mathbf{x}$. $\mathbf{o}_{\text{dec}}$ is computed by multiplying the input vector with a subset of weight residuals selectively fetched from the CPU. This selection is performed *dynamically*, fully accounting for the variability of input vectors. To maximize the number of residual values fetched under PCIe bandwidth constraints, DecDEC stores and retrieves a quantized version of the residuals ($\widehat{\mathbf{R}}$), comprising the quantized values $Q_r(\mathbf{R})$ and associated metadata, instead of the full-precision residuals ($\mathbf{R}$). Here, Q_r is a quantizer that maps full precision residuals to low-bit form and differs from the base quantizer used for the weights, Q_b.

The dynamic error compensation process consists of four sequential steps. ❶ First, by investigating the input activation vector, DecDEC creates `sc_indices`, a list of salient channel

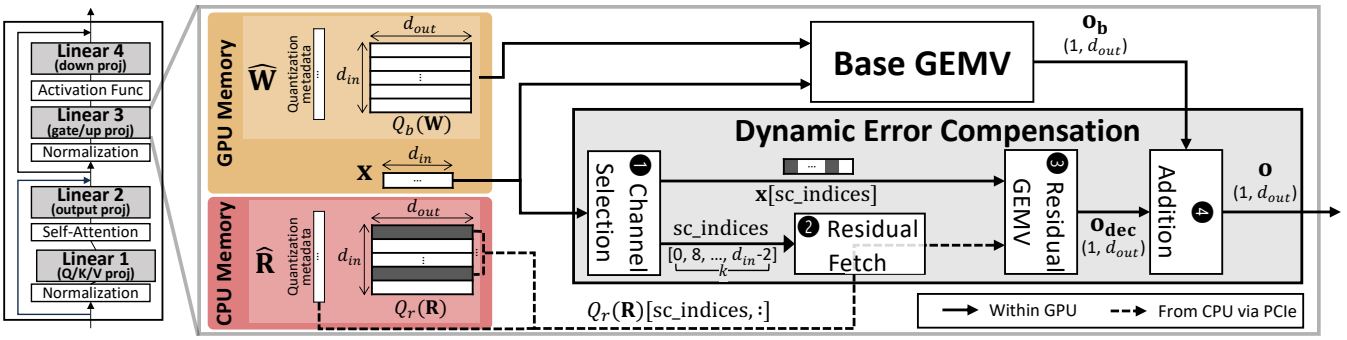

Figure 6: DecDEC overview.

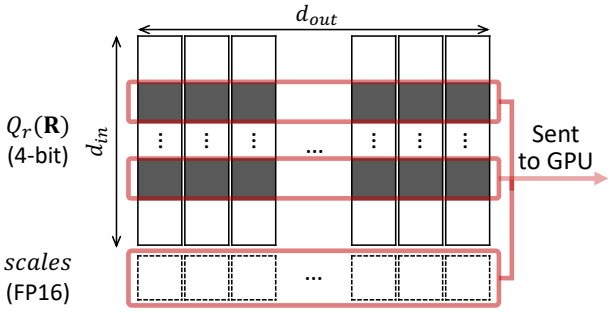

Figure 7: Quantization of weight residual.

indices. The number of salient channels to compensate, k, is a preconfigured parameter. This step is essentially a Top-K operation that selects the values in the input activation vector with the largest magnitudes. ❷ Next, a portion of the quantized residuals corresponding to the salient channels, $Q_r(\mathbf{R})[\texttt{sc_indices},:]$ (along with the necessary quantization metadata), is fetched from the CPU via PCIe. ❸ The fetched residuals are then multiplied by the sparsified activation vector ($\mathbf{x}[\texttt{sc_indices}]$), producing $\mathbf{o_{dec}}$. ❹ Finally, the resultant $\mathbf{o_{dec}}$ is added to the base GEMV result $\mathbf{o_b}$, producing the final output, $\mathbf{o}$. All steps run in parallel with the base GEMV on a different GPU stream, and must be highly efficient to remain hidden within base GEMV runtime.

The following sections provide details of each component of DecDEC. Section 4.2 explains how DecDEC performs the residual quantization. Section 4.3 details the GPU implementation of the dynamic error compensation. Section 4.4 illustrates how DecDEC configures system parameters, including k, the number of channels to compensate.

4.2 Residual Quantization

Figure 7 depicts the quantization scheme for the residuals. DecDEC employs 4-bit quantization for each output channel (i.e., column) of the residuals. To minimize metadata, symmetric uniform quantization is used. This approach requires only a single scalar scale factor as metadata for each output channel. The residual quantizer for the i-th output channel ($Q_{r,i}$) is defined as:

$$Q_{r,i}(r) = \text{clip}\left(\text{round_to_int}\left(\frac{r}{S_i}\right), -7, 7\right).$$

S_i, the scale factor, is determined through a grid search as the value that minimizes the mean squared error between the original and quantized weights.

Using this quantizer, each floating-point residual value r is projected to an integer between -7 and 7. At runtime, the selected input channels of the quantized residuals (highlighted in Figure 7) and all the scale factors are fetched from the CPU. Each input channel of the quantized residuals, as well as the scales, are stored contiguously in CPU memory, enabling coalesced data transfers.

4.3 Efficient Implementation of Dynamic Error Compensation

The top priority in implementing dynamic error compensation is ensuring low latency, allowing its execution to remain hidden within the base GEMV execution time. To fetch a sufficient number of residual channels within this short time window, DecDEC introduces three key software optimization strategies: 1) zero-copy residual fetching, 2) fast approximate Top-K for channel selection, and 3) kernel fusion.

Zero-Copy Residual Fetch. DecDEC leverages CUDA zero-copy [42], instead of commonly used API functions such as `cudaMemcpy()` or `cudaMemcpyAsync()`, to fetch the residuals from CPU. These APIs rely on the direct memory access (DMA) engine for data transmission, which is efficient at transferring large data blocks but suboptimal for smaller transfers due to the DMA setup overheads. Fetching residuals, however, falls into the latter category. The granularity of residual fetching occurs at the row level of the quantized residual matrix. With 4-bit quantization and typical row lengths of a few thousand to tens of thousands, each data block transfer is only a few tens of KBs. For optimal PCIe bandwidth utilization, the data block size should ideally be at least a few

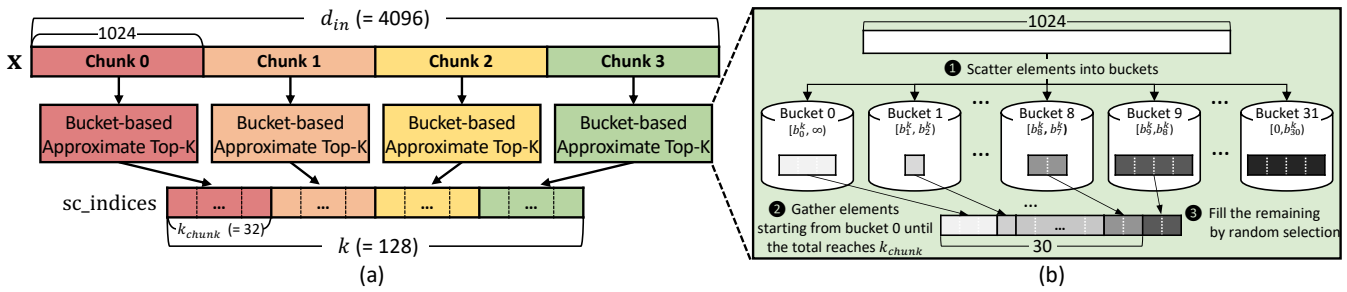

Figure 8: Fast approximate Top-K operation of DecDEC.

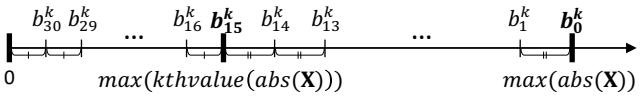

Figure 9: DecDEC 's approximate Top-K bucket boundaries.

hundred KBs (e.g., 256 KB) [41, 46]. In zero-copy access, the GPU directly sends cacheline-sized memory requests, making it suitable for fine-grained data access. While zero-copy access has the disadvantage of occupying GPU cores to generate memory requests—potentially slowing down other concurrently running kernels—this is not a major issue for DecDEC. The concurrent kernel for our case, the base GEMV, is typically memory-bound, so using fewer cores for this kernel is unlikely to have significant impact on its execution time.

Fast Approximate Top-K for Channel Selection. For channel selection, instead of an exact Top-K operation, DecDEC employs an approximate Top-K method that is fast and GPU-friendly while maintaining precision. Figure 8 illustrates the approach using an example where 128 elements are selected from a 4096-dimensional activation vector ($d_{in} = 4096$, $k = 128$). As shown in Figure 8(a), instead of a single global selection, DecDEC partitions the input into four contiguous 1024-dimensional chunks and performs a local Top-k_{chunk} selection within each chunk. In this example, $k_{chunk} = k/4 = 32$. The locally selected elements are then concatenated to form the final result. Although this introduces approximation, it significantly reduces latency by avoiding global synchronization—each local selection is handled independently by a thread block. A larger chunk size can improve efficiency but may increase the approximation error; we set the chunk size to 1024 to balance this trade-off effectively.

For each local selection, DecDEC uses a variant of the bucket-based Top-K algorithm [2]. Figure 8(b) illustrates this process. ❶ First, the 1024 elements in a chunk are scattered into buckets based on their magnitudes, with bucket boundaries (b_0^k, b_1^k, ..., b_{30}^k). The number of buckets is set to 32, matching the number of threads in a warp, allowing for efficient thread-level parallelism so that each thread processes a different bucket. ❷ Next, elements are gathered, starting from bucket 0, until the total count reaches k_{chunk}. ❸ If the number of elements in the current bucket exceeds the remaining spots for k_{chunk}, as in the case of bucket 9 in Figure 8(b), random selection is used to fill the remaining spots. This random selection adds an additional layer of approximation but significantly reduces latency by avoiding exact sorting.

Determining proper bucket boundaries is crucial to minimize the approximation error introduced by random selection (❸ in Figure 8(b)). DecDEC profiles the distribution of activation values using a small calibration set and aims to set boundary values that balance Top-K accuracy with the ability to handle a broader range of values. Placing finer-grained buckets around the expected k-th largest value generally improves accuracy, but limits the system's ability to handle out-of-distribution values. To address this, DecDEC uses an offline analysis to determine two key boundaries, b_0^k and b_{15}^k, from which the other boundaries are inferred (as shown in Figure 9). Let the distribution of activation values from the calibration set be $\mathbf{X} \in R^{N \times d_{in}}$, where N is the size of the set. The boundary b_{15}^k is set to the maximum of the k-th largest value across all vectors in $abs(\mathbf{X})$. The interval between 0 and b_{15}^k is uniformly divided into 16 buckets (b_{15}^k, b_{16}^k, ..., b_{30}^k), focusing on the range where the k-th largest value is most likely to occur. To handle out-of-distribution cases which can cause significant degradation in selection precision, DecDEC assigns an additional 16 buckets for values beyond b_{15}^k. Specifically, b_0^k is set to the maximum value in all $abs(\mathbf{X})$, and the range between b_0^k and b_{15}^k is also uniformly divided to form the remaining 16 buckets.

Kernel Fusion. DecDEC extensively fuses all dynamic error compensation operations into a single kernel. Figure 10 visualizes the execution flow of the fused kernel, using an example where two thread blocks process a weight matrix of size 4096×6144. In this example, only one channel is selected per each of the four chunks (i.e., $k_{chunk} = 1$, $k = 4$). Initially, each thread block sequentially processes two chunks, selecting a total of two channels (Step ❶ in Figure 6(b)). The indices for the selected channels (`sc_indices`) as well as the corresponding activation values ($\mathbf{x}$[`sc_indices`]) are stored in GPU memory. Thread blocks are then synchronized using the grid-wide synchronization feature of the cooperative group [43]. This synchronization is required because each thread block

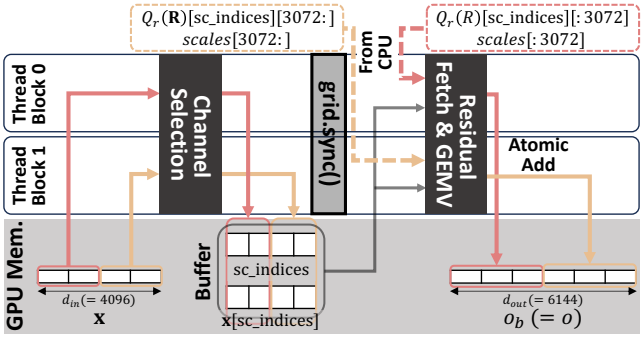

Figure 10: Fused kernel for dynamic error compensation.

processes a segment of all selected channels—not just a disjoint subset—when fetching quantized residuals from the CPU and performing GEMV (Steps ❷ and ❸ in Figure 6(b)). For example, thread block 0 processes $Q_r(\mathbf{R})[\texttt{sc_indices}][:3072]$ as opposed to $Q_r(\mathbf{R})[\texttt{sc_indices}[:2]][:]$. The thread block-level synchronization allows all thread blocks to have access to the complete set of `sc_indices` and $\mathbf{x}[\texttt{sc_indices}]$. This partitioning scheme allows for efficient reduction in the residual GEMV without requiring extensive global synchronization. The results from the residual GEMV are directly added to the result of the base GEMV ($\mathbf{o_b}$) using atomic primitives, yielding the final output ($\mathbf{o}$) (Step ❹ in Figure 6(b)).

GPU Memory Overhead. The buffer for `sc_indices` and $\mathbf{x}[\texttt{sc_indices}]$ in the fused kernel is the only additional GPU memory usage of DecDEC. Zero-copy from the CPU does not consume GPU memory. The bucket boundary values are not stored on the GPU; instead, only b_0^k and b_{15}^k are passed to the kernel as arguments. A single buffer can be reused for all linear layers if it is sized in accordance with the largest k. In the extreme case of fetching 10% of the channels across all layers in Llama-3-8B, the maximum k would be 1433, for the down projection layer. This calls for an 8.6 KB buffer ($1433 \times (4+2)$), which is less than 0.0003% of the model size, assuming 3-bit precision—essentially a negligible overhead.

4.4 Parameter Tuner

Necessity of Parameter Tuner. Effective use of DecDEC requires careful tuning two key parameters:

- n_{tb}: Specifies the number of thread blocks used for dynamic error compensation. Since DecDEC runs in parallel with the base GEMV, allocating too many thread blocks to dynamic error compensation can slow down the base GEMV computation, while allocating too few may underutilize PCIe bandwidth, as zero-copy transfers require GPU cores to issue memory requests.
- k_{chunk}: Specifies how many channels are compensated per chunk (1024 channels). A larger k_{chunk} improves model quality but may increase inference latency.

Choosing n_{tb} and k_{chunk} is challenging due to the large design space. The n_{tb} value for each type of linear layer (n_{tb}^{qkv}, n_{tb}^{o}, n_{tb}^{gu}, n_{tb}^{d}) has multiple viable candidates, constrained by the dimensions of the corresponding weight matrices. For example, in Llama-3-8B, there are 9 possible candidates for n_{tb}^{qkv} (1, 2, 3, 4, 5, 6, 8, 12, 24), while other layers also have multiple options. Selecting k_{chunk} presents a greater challenge due to its broader range of possibilities. The k_{chunk} value for each type of linear layer (k_{chunk}^{qkv}, k_{chunk}^{o}, k_{chunk}^{gu}, k_{chunk}^{d}) can be any integer less than a maximum determined by the available shared memory. Although platform-dependent, this upper bound is large (e.g., 367 with 48 KB per-block shared memory), leading to an expansive search space. This creates a combinatorial explosion of configuration options. Technical details on how to identify candidate values of k_{chunk} and n_{tb} for a given model and platform are presented at the end of this section.

To address this issue, we provide a DecDEC tuner that suggests n_{tb} and k_{chunk} values based on a target slowdown rate. The tuner maximizes k_{chunk} while keeping the total execution time—including base GEMV and dynamic error compensation across all linear layers—within the specified slowdown relative to the baseline (i.e., without compensation). This tuning is a one-time process for a given model-device pair.

Parameter Tuning Process. Figure 11(a) illustrates the tuning process, which consists of two phases: Phase 1 determines the n_{tb} values, and Phase 2 determines the k_{chunk} values.

In Phase 1, the tuner simplifies the search for n_{tb} values for each layer by replacing it with the search for a single metaparameter, n_{tb}^{max}. n_{tb}^{max} represents the upper limit on the number of thread blocks to use for dynamic error compensation. Each layer's n_{tb} is then set to the largest candidate below n_{tb}^{max}. Determining n_{tb}^{max} involves testing values up to half of the total SM count, to reduce the search space. In the example shown in Figure 11, the GPU has 56 SMs, so values up to 28 are tested. For each tested n_{tb}^{max}, a coarse-grained k_{chunk} search checks how many uniform increments to k_{chunk} can be applied across all layers without exceeding the target slowdown rate. Figure 11(b) shows an example of a coarse-grained k_{chunk} search for $n_{tb}^{max} = 24$ (i.e., $(n_{tb}^{qkv}, n_{tb}^{o}, n_{tb}^{gu}, n_{tb}^{d}) = (24, 16, 23, 14)$), yielding 19 valid steps. If no steps can be made for any n_{tb}^{max} value, the tuner fixes k_{chunk} to 0 for the layer with the smallest weight matrix and repeats the process, as smaller matrices are often most sensitive to increases in k_{chunk}.

After Phase 1, the tuner selects the n_{tb}^{max} with the most steps and proceeds to a fine-grained k_{chunk} search in Phase 2. Figure 11(c) shows the fine-grained k search for the selected $n_{tb}^{max} = 24$. In this phase, not all k_{chunk} values may increase together. At each step, the tuner increments k_{chunk} for as many layers as possible, prioritizing those with smaller increases in execution time. For example, in Step 1, k_{chunk}^{gu} is incremented first, followed by k_{chunk}^{d}. Step 1 stops at this point, as further increases to k_{chunk}^{qkv} and k_{chunk}^{o} would exceed the target; thus

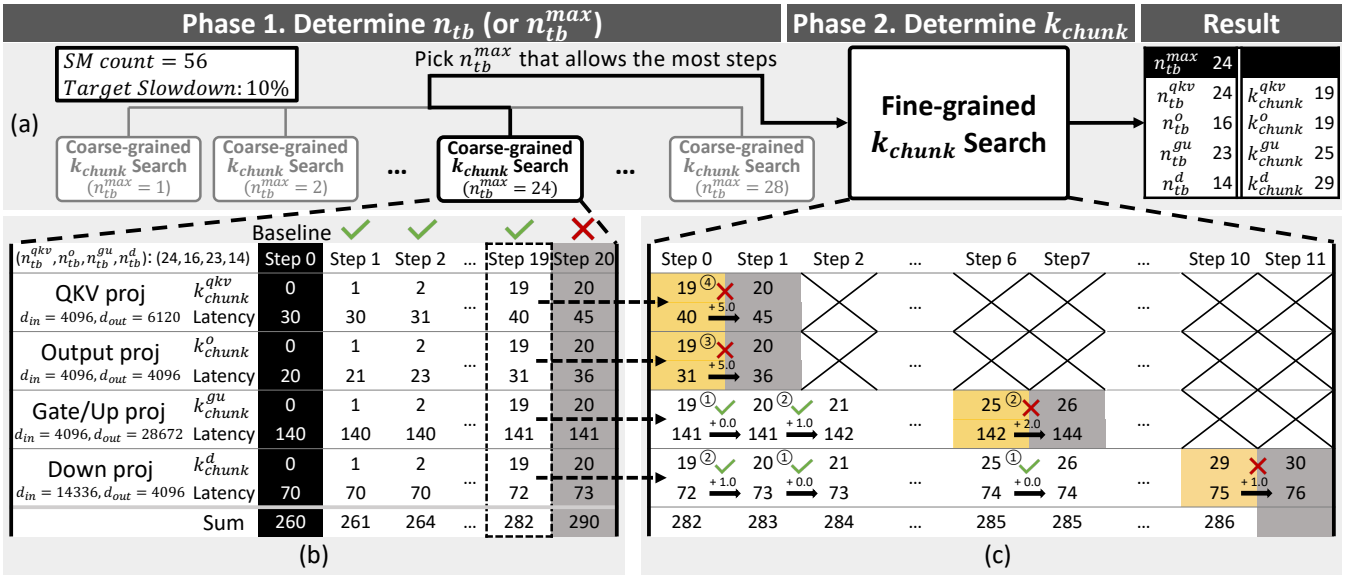

Figure 11: Parameter tuning process for DecDEC, assuming a total of 56 SMs and a target slowdown rate of 10%.

their final values are set (i.e., $k_{chunk}^{qkv}, k_{chunk}^{o} = 19$). This process repeats until no further increments can be made for any layer.

Technical Details: n_{tb} and k_{chunk} Candidates. The n_{tb} values considered during parameter tuning are those that have a meaningful impact on at least one of the two parts of the kernel execution: the approximate Top-K selection and the residual fetching. In the approximate Top-K selection part, the minimum processing granularity per thread block is one chunk. Therefore, increasing n_{tb} beyond the number of chunks does not have additional effect on performance. Thus, the set of n_{tb} values relevant to this part is:

$$A = \left\{ n \;\middle|\; 1 \le n \le \frac{d_{in}}{1024} \right\}.$$

For residual fetching part, 4-bit residuals are transferred over PCIe in coalesced segments of 256 values (128 bytes), resulting in a total of $s = d_{out}/256$ segments. These segments are distributed across n_{tb} thread blocks, with each block processing $\lceil s/n_{tb} \rceil$ segments. If multiple n_{tb} values result in the same number of segments per block ($\lceil s/n_{tb} \rceil$), only the smallest such value is considered and the rest are redundant. Excluding these cases, the candidate set relevant to this part is:

$$B = \left\{ n \;\middle|\; 1 \le n \le s, \left\lceil \frac{s}{\lceil s/n \rceil} \right\rceil = n \right\}.$$

The final candidate set for n_{tb} is the union of the two (i.e., $N = A \cup B$).

Meanwhile, k_{chunk} is bounded by the shared memory limit. During the approximate Top-K selection part of the kernel, shared memory usage increases with the value of k_{chunk}. Specifically, the shared memory usage for this part is:

$$128 + 128 \times k_{chunk} + 2 \times 1024 \text{ bytes}.$$

GPU Name	Memory Size	Memory BW	# SM	PCIe BW	R_{bw}
		Desktop			
RTX 4090	24 GB	1,008 GB/s	128	32 GB/s	32
RTX 4080S	16 GB	736 GB/s	80	32 GB/s	23
RTX 4070S	12 GB	504 GB/s	56	32 GB/s	16
		Laptop			
RTX 4070M	8 GB	256 GB/s	36	16 GB/s	16
RTX 4050M	6 GB	192 GB/s	20	16 GB/s	12

Table 1: GPU specifications.

Here, 128 bytes are used for integer counters that track the number of elements that fall into each of the 32 buckets; $128 \times k_{chunk}$ bytes are used to temporarily store the indices of elements assigned to each bucket; and 2×1024 bytes account for the input activation values in the chunk. The total must remain below the per-block shared memory limit (e.g., 49,152 bytes), which constrains the maximum allowable k_{chunk} value.

5 Evaluation

5.1 GPU Kernel Benchmarks

Methodology. In this section, we evaluate the DecDEC GPU kernel on three consumer-grade GPUs: two desktop GPUs, RTX 4070 Super (RTX 4070S) and RTX 4090, and one laptop GPU, RTX 4050 Mobile (RTX 4050M), with their specifications detailed in Table 1. Here, R_{bw} denotes the ratio of memory bandwidth to CPU-to-GPU (PCIe) bandwidth. The evaluation considers GEMV operations of output, gate/up and down projection layers in Llama-3-8B-Instruct [16], assuming 3-bit bitwidth. For the base GEMV, we use the LUTGEMM kernel, [23], a state-of-the-art GEMV kernel for uniform quantization. Kernel times are measured using NVIDIA Nsight Systems.

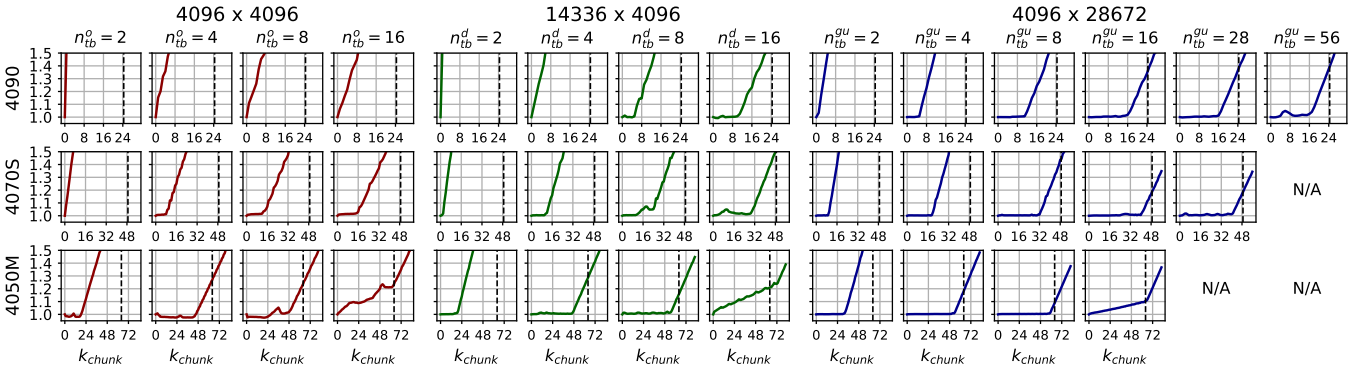

Figure 12: Execution time of base GEMV + DecDEC with varying k_{chunk} and n_{tb}, normalized to base GEMV execution time.

Expected Behavior. The execution time of the DecDEC kernel is expected to follow a piecewise linear function of k_{chunk} with two distinct segments. In the first segment, corresponindg to small k_{chunk} values, the latency remains nearly constant at the base GEMV time, as the compensation operations are fully hidden under the GEMV execution. In the second segment, once k_{chunk} exceeds a certain threshold—the knee point—the execution time linearly increases with k_{chunk}, inidcating that the compensation operations are no longer fully hidden. Theoretically, the knee point is expected to occur when $k_{chunk} = 1024 \times {}^{1}/_{R_{bw}} \times {}^{3}/_{4}$, representing the maximum amount of data transfer that can overlap with the base GEMV. Here, the base GEMV time is approximated by dividing the weight matrix size by the GPU memory bandwidth, and PCIe bandwidth is assumed to be fully utilized. The factor ${}^{3}/_{4}$ accounts for the 3-bit quantization; for other bitwidths, this factor should be adjusted accordingly (e.g., ${}^{4}/_{4} = 1$ for 4-bit quantization).

Results. Figure 12 shows the execution time of DecDEC kernel (base GEMV + dynamic error compensation), normalized to the standalone execution time of the base GEMV, across varying n_{tb} and k_{chunk}. Each subfigure also includes a vertical dotted line to mark the theoretical knee point derived from the analytical model (i.e., $1024 \times {}^{1}/_{R_{bw}} \times {}^{3}/_{4}$). All cases exhibit the expected two-segment piecewise linear behavior when n_{tb} is properly set, except for the 4096×4096 case on RTX 4090, the fastest GPU evaluated. In this case, the base GEMV execution time is so short that even a small k_{chunk} incurs overhead.

From the other cases, three key observations can be made. First, a lower R_{bw}—indicating lower memory bandwidth and higher PCIe bandwidth—shifts the knee point to the right. Thus, RTX 4050M, with the lowest R_{bw}, supports the largest k_{chunk} before the knee point, while RTX 4090, with the highest ratio, supports the smallest. This trend is consistent with the ordering predicted by theoretical knee points. Second, the knee point is highly sensitive to n_{tb}, highlighting the importance of careful tuning. Generally, higher n_{tb} values such as 8 or 16 delay the knee point. In contrast, small n_{tb} values (e.g., 2) cause the knee point to appear too early or disappear, leading to suboptimal performance. However, increasing n_{tb} can sometimes worsen results by slowing down the base GEMV, as discussed in Section 4.4. This effect is particularly noticeable on GPUs with fewer SMs, such as the 4050M. For instance, on the 4050M, $n_{tb} = 8$ yields the best results, whereas increasing n_{tb} to 16 leads to worse performance. Third, larger weight sizes enable higher k_{chunk} with minimal latency overhead, due to increased time slack. With sufficiently large weight sizes (e.g., 4096×28672) and a properly tuned n_{tb}, the actual knee point approaches the theoretical value. For example, on an RTX 4050M with a 4096×28672 matrix and $n_{tb} = 8$, the observed knee point is around $k_{chunk} = 60$, compared to a theoretical prediction of 64.

5.2 Impact on Model Quality

Methodology. We demonstrate DecDEC 's quality improvements on 3-bit, 3.5-bit, and 4-bit versions of two instruction-tuned LLMs: Llama-3-8B-Instruct [16] (hereafter referre to as Llama-3) and Phi-3-medium-4k-instruct (14B model, hereafter referred to as Phi-3) [40]. For the 3.5-bit version, we adopt a block-wise bitwidth allocation, applying 3-bit quantization to half of the decoder blocks and 4-bit quantization to the remaining blocks. This follows a KL divergence-based sensitivity metric from prior work [8].

As base quantization methods, we choose two state-of-the-art LLM quantization methods: AWQ [36] and SqueezeLLM [31]. AWQ is a *uniform* quantization method that mitigates quantization errors by applying per-channel scaling to protect salient channels, which are identified through an offline analysis on a calibration dataset. SqueezeLLM employs a clustering-based *non-uniform* quantization method that considers the sensitivity of each weight.

We evaluate DecDEC-augmented models across varying k_{chunk}, the number of channels compensated per chunk (1024 channels). We uniformly set k_{chunk} to 8, 16, 32, 64 and 128 for all layers. Based on the results in Section 5.1, values up to 64 fall within the practical range—where latency overhead from

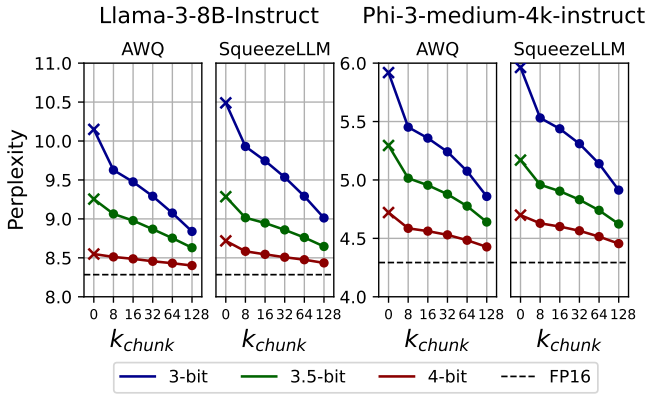

Figure 13: Perplexity on WikiText. The x markers correspond to baselines without DecDEC ($k_{chunk} = 0$). Lower is better.

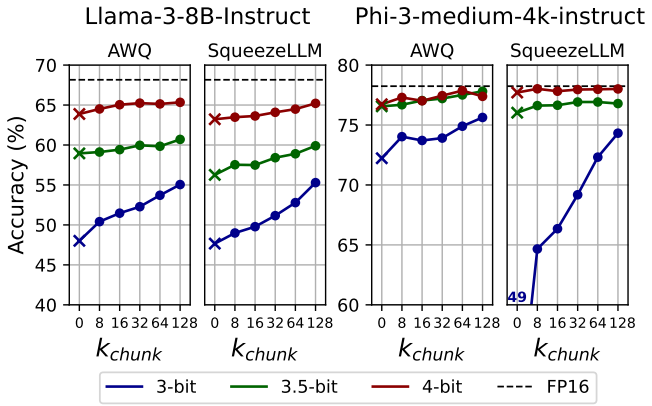

Figure 14: Accuracy on BBH. The x markers correspond to baselines without DecDEC ($k_{chunk} = 0$). Higher is better.

dynamic error compensation may remain low depending on the platforms—while $k_{\text{chunk}} = 128$ is included for completeness in evaluating upper-bound behavior.

Benchmarks. Following previous literature [9, 12, 31, 36], we use perplexity on WikiText [39] as the primary metric, as it reliably reflects quantized LLM quality [13, 36]. Additionally, we use BIG-Bench Hard (BBH) [54], a collection of 23 challenging tasks in BIG-Bench [52], to assess the models' capabilities in problem solving. Chain-of-Thought (CoT) is enabled for all BBH evaluations [62]. Lastly, we evaluate multi-turn conversation using MT-Bench [68], where a strong LLM judges 80 responses, scoring each from 0 to 10. We use GPT-4o as the judge and report the average of three runs.

Perplexity on WikiText. Figure 13 shows the perplexity results. Across all cases, a clear trend is observed: perplexity consistently decreases (i.e., model quality improves) as k_{chunk} increases. In particular, for 3-bit models, significant improvements occur even at $k_{chunk} = 8$. AWQ's perplexity decreases from 10.15 to 9.63 for Llama-3 and from 5.96 to 5.53 for Phi-3, while SqueezeLLM's perplexity drops from 10.49 to

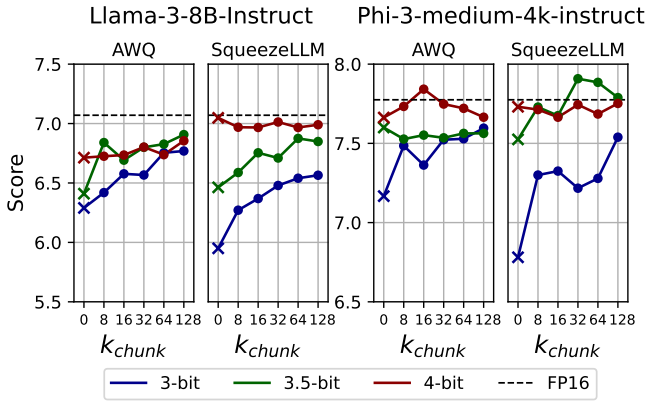

Figure 15: MT-Bench scores. The x markers correspond to baselines without DecDEC ($k_{chunk} = 0$). Higher is better.

9.93 for Llama-3 and from 5.92 to 5.45 for Phi-3. Meanwhile, the impact on 4-bit models is relatively less pronounced. This is expected, as 4-bit models are already close to full-precision, leaving less room for improvement. The 3.5-bit models follow an intermediate trend.

BBH and MT-Bench. Results on BBH (Figure 14) follow the same trends as the perplexity results. The MT-Bench results (Figure 15), on the other hand, demonstrate some different patterns. In cases where vanilla quantized models without DecDEC ($k = 0$) already achieve scores very close to those of the FP16 model—such as all 4-bit cases and the AWQ 3.5-bit model of Phi-3—the scores remain unchanged, oscillating around the baseline score. For the remaining cases, DecDEC significantly improves scores even with a small k_{chunk} (e.g., 8), like in other benchmarks; further increases in k_{chunk}, however, do not always yield noticeable improvements. These patterns may be attributed to the coarse-grained rubric of this benchmark, which assigns integer scores ranging from 0 to 10 for each task. This coarse-grained scoring may miss subtle improvements when the potential gain is small.

Effectiveness of DecDEC's Channel Selection. Figure 16 compares DecDEC with three variants using different channel selection mechanisms. To assess the benefits of dynamic selection, we include *Random* (blue line), which selects channels randomly, and *Static* (yellow line), which statically select channels by Hessian-based ranking with a calibration set (using exact sorting) following prior work [33]. To isolate the effect of DecDEC's Top-K approximation, we include *Exact* (red line), which uses true Top-K channels. Alongside perplexity results, we also report the average recall rate of Static and DecDEC relative to Exact.

While Static improves over Random, it underperforms DecDEC. DecDEC achieves lower perplexity than Static while using 4× or even 8× fewer channels (e.g., $k_{\text{chunk}} = 32$ or 16 vs. 128), highlighting the effectiveness of incorporating input-awareness. Meanwhile, the perplexity gap between DecDEC and Exact is minimal, with almost overlap-

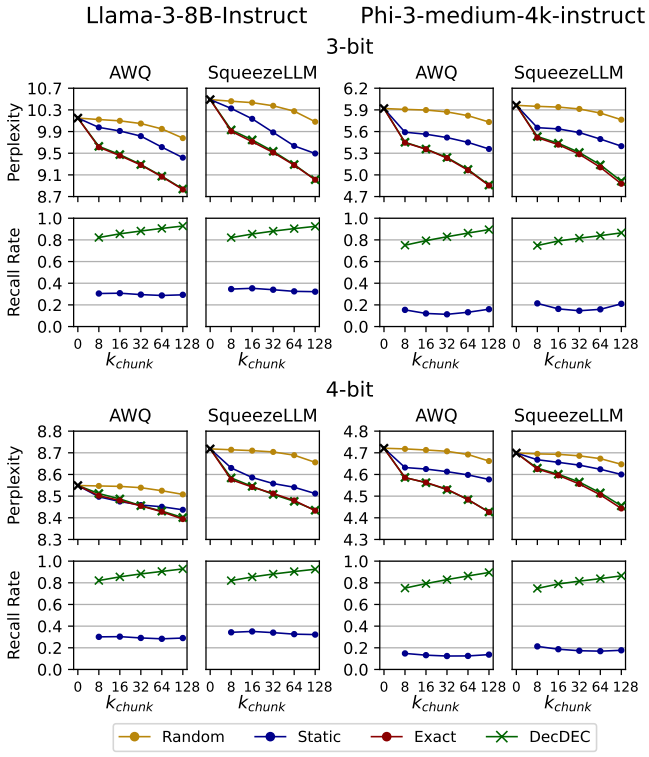

Figure 16: Comparison against random, static, and exact channel selection. Perplexity is shown on the top rows (lower is better), and recall is shown on the bottom rows (higher is better). The x markers in black correspond to baselines without DecDEC ($k_{chunk} = 0$).

ping curves. These results are explained by the recall rates: while DecDEC achieves around 80% recall relative to Exact, the recall of Static falls significantly short, at around 30% or below.

Impact of Residual Bitwidth. Table 2 presents the impact of residual bitwidth selection. In addition to the default 4-bit setting, we evaluate 2-bit, 8-bit, and full-precision (FP16) residuals with varying k_{chunk} for 3-bit models by perplexity on WikiText. Cells with the same color indicate cases where the total data transfer via PCIe is approximately equivalent. For example, $k_{chunk} = 8$ with 4-bit residuals requires a similar data transfer amount as the following combinations: $k_{chunk} = 16$ at 2-bit, $k_{chunk} = 4$ at 8-bit, and $k_{chunk} = 2$ at FP16. The best results within each color group are highlighted. Across all cases, a residual bitwidth of 4 either achieves the best or comes very close to it, supporting our default setting.

5.3 End-to-End Evaluation

Methodology. In this section, we present case studies demonstrating how DecDEC advances model quality while minimizing latency increases across three desktop GPUs—RTX 4090, 4080 Super (4080S), and 4070 Super (4070S)—as well as two

laptop GPUs—RTX 4070 Mobile (4070M), and 4050 Mobile (4050M). The specifications for these GPUs are listed in Table 1. We run the tuner for DecDEC with four target slowdown rates (2.5%, 5%, 10%, 20%), and evaluate perplexity on WikiText as well as end-to-end inference latency with the resulting configurations. For the base GEMV kernel, we use LUTGEMM [23] for AWQ and Any-Precision LLM [45] for SqueezeLLM—both state-of-the-art kernels for uniform and non-uniform quantization, respectively. We integrate DecDEC into a PyTorch-based inference pipeline optimized with the torch.compile feature [5] and measure the average time taken per token generation over 1024 tokens.

For the 3.5-bit models, we do not run the tuner separately. Instead, we construct the configuration by combining the tuning results with the 3-bit and 4-bit models. Specifically, we use the configuration from tuning with the 3-bit model for layers quantized to 3 bits, and the configuration from tuning with the 4-bit model for layers quantized to 4 bits—both assuming the same target slowdown rate.

Results. Table 3 lists the configurations obtained from the tuner along with the actual end-to-end slowdowns compared to the baseline. We report only the results for 3-bit as similar trends are observed for the 3.5-bit and 4-bit configurations. In all cases, the actual slowdown is below the target rate. This is expected as the tuner configures parameters conservatively. The tuner targets only the kernel times of linear operations, while other operations outside the linear layers (e.g., attention, normalization) also contribute to overall inference time. Consistent with the observations in Section 5.1, in general, selected k values are higher for GPUs with greater PCIe-to-GPU memory bandwidth ratio (4050M $>$ 4070M $\simeq$ 4070S $>$ 4080S $>$ 4090).

Figure 17 shows the trends of end-to-end inference latency versus perplexity. All Phi-3 cases, as well as AWQ 3.5-bit, 4-bit, and SqueezeLLM 4-bit cases of Llama-3 face out-of-memory issues on the 4050M, and are thus excluded. Similarly, the AWQ 4-bit case of Phi-3 for 4070M is also excluded. In each line in Figure 17, the x marker represents the baseline, while subsequent markers show the results for DecDEC on the four target slowdown rates, in increasing order.

For all cases, DecDEC demonstrates promising Pareto-optimal trade-offs between model quality and inference latency. The results for target slowdown rates of 2.5% and 5% are particularly impressive, while 10%–20% show diminish-

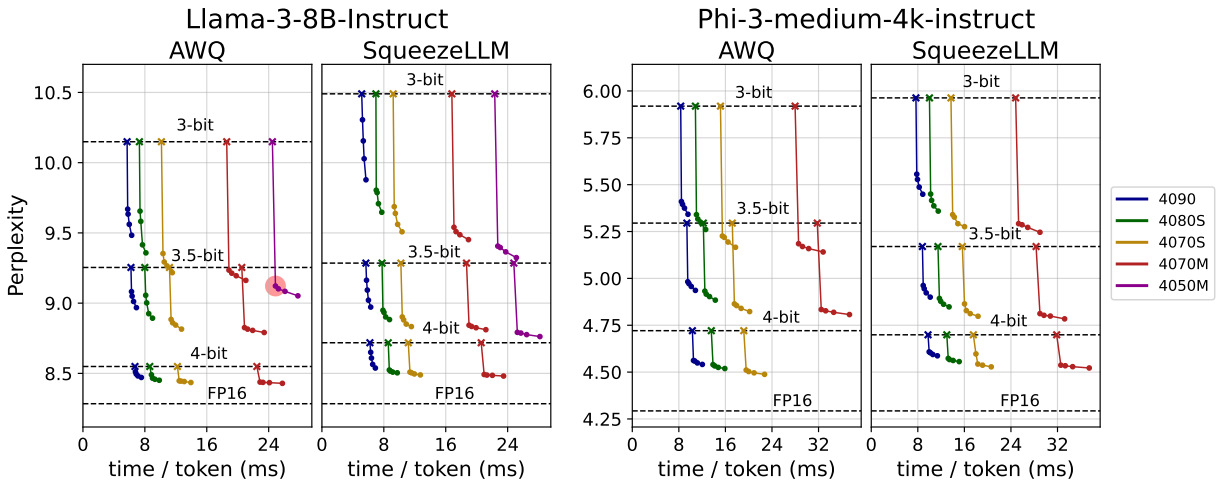

Figure 17: Perplexity against time per token on various NVIDIA GPUs. The x markers indicate baseline values, where DecDEC is not applied ($k_{chunk} = 0$). Subsequent markers show DecDEC results on target slowdown rates 2.5%, 5%, 10%, and 20%.

Table 3: Tuner results ($n_{tb}^{max}/(k_{chunk}^{qkv}, k_{chunk}^{o}, k_{chunk}^{gu}, k_{chunk}^{d})$) for four target slowdown rates (2.5%, 5%, 10%, 20%) and corresponding actual slowdown rates for 3-bit Llama-3 and Phi-3. Phi-3 is out of memory (OOM) on the 4050M GPU.

ing returns. On platforms with high PCIe-to-GPU memory bandwidth ratios, such as the 4070S, 4070M, and 4050M, DecDEC at 2.5% slowdown on 3-bit models sometimes outperforms 3.5-bit baselines. In these cases, DecDEC yields *Pareto-dominant* solutions by excelling in model quality, latency, and memory. Examples include AWQ Llama-3 (4070M, 4050M) and AWQ Phi-3 (4070S, 4070M). A particularly noteworthy case is the AWQ 3-bit Llama-3 on 4050M, where DecDEC reduces perplexity from 10.15 to 9.12 with only a 1.7% latency slowdown (highlighted by a red circle). This outperforms the 3.5-bit baseline, which is infeasible on 4050M without DecDEC due to memory limits. This case highlights DecDEC's effectiveness in pushing the boundaries of quantized LLMs within memory capacity constraints.

5.4 Evaluation across GPU Generations

We evaluate the robustness of DecDEC across GPU generations, as both GPU memory bandwidth and PCIe bandwidth, two key factors influencing its effectiveness, may increase with newer architectures. To this end, we use three consumer-grade GPUs from the same product class across different

(a) DecDEC Across GPU Generations (b) DecDEC on Server-Grade GPUs

Figure 18: Perplexity vs. time per token: (a) across different GPU generations and (b) on server-grade GPUs.

	Memory Bandwidth	PCIe Bandwidth	R_{bw}
RTX 5080	960 GB/s	64 GB/s	15
RTX 4080S	736 GB/s	32 GB/s	23
RTX 3080	760 GB/s	32 GB/s	24

Table 4: 80-class GPU specifications across generations.

generations—RTX 3080, 4080S, and 5080—whose specifications are listed in Table 4. The R_{bw} values (lower is better) remain essentially unchanged from the 3080 to the 4080S and even decrease from the 4080S to the 5080. Figure 18(a) plots the perplexity of AWQ-quantized Phi-3 with DecDEC augmentation against end-to-end latency on these GPUs, using the methodology described in Section 5.3. The improvements delivered by DecDEC are comparable across all three cards, confirming its robustness across generations.

5.5 Applicability to Server-Grade GPUs

Although DecDEC primarily targets single-batch inference on client (edge) devices, this section evaluates its effectiveness on server-grade GPUs. We measure perplexity versus end-to-end latency using an AWQ-quantized Llama-3-70B-Instruct model augmented with DecDEC on the H100 SMX5 and GH200, following the methodology described in Section 5.3. Both GPUs provide 3.36 TB/s of memory bandwidth; however, the GH200's 450 GB/s NVLink-C2C far exceeds the H100's 64 GB/s PCIe, yielding a much lower R_{bw}.

Figure 18(b) shows the results. DecDEC improves perplexity on both GPUs with minimal latency overhead. However, the GH200's advantage is smaller than the R_{bw} gap suggests. DecDEC assumes a DRAM-bound GEMV, where reallocating SMs for error compensation do not impact GEMV latency. On server GPUs, however, quantized GEMV (e.g., LUTGEMM [23]) is L1-bound, not DRAM-bound. Since L1 throughput scales with active SMs, reallocating SMs increases GEMV latency, limiting DecDEC's benefit despite low R_{bw}. Enhancing quantized GEMV kernels for server-grade GPUs by mitigating L1 bottlenecks could unlock further gains.

6 Related Work

GPU Implementations for Weight-Only Quantization. Numerous studies have proposed efficient GPU implementations tailored for weight-only quantization of LLMs. LUTGEMM [23] replaces the expensive dequantization with simple LUT operations. Marlin [20] supports FP16-INT4 GEMM across various batch sizes, and Quant-LLM [63] introduces a GPU kernel that efficiently handles non-power-of-2 bitwidths (e.g., 6-bit). FLUTE [24] provides a specialized kernel for non-uniform quantization. Any-Precision LLM [45] suggests a memory-efficient kernel for adaptive bitwidth selection. These implementations can seamlessly integrate with DecDEC, benefiting from its dynamic error compensation.

LLM Inference with External Memory. Several works address GPU memory limitations in LLM inference by leveraging external memories like CPU memory or disk. DeepSpeed-Inference [4] and FlexGen [50] focus on throughput-oriented, out-of-core LLM inference. Pre-gated MoE [29] retrieves the parameters of only the activated experts in MoE models from CPU memory. LLM-in-a-Flash [3] introduces a flash memory-based inference system exploiting activation sparsity. InfiniGen [35] offloads the key-value cache to CPU memory. PowerInfer [51] proposes a GPU-CPU hybrid inference engine that leverages activation sparsity in ReLU-based models. Though these approaches share the same goal as DecDEC in aiming to extend GPU memory, they address distinct scenarios with different challenges and opportunities.

LLM Compression Methods. In addition to quantization, pruning can improve the efficiency of LLM inference [18, 38, 53]. Other techniques, including knowledge distillation [22, 26] and low-rank decomposition [48, 67], offer additional ways to compress LLMs. These methods are orthogonal to quantization and, consequently, to DecDEC.

7 Conclusion

We propose DecDEC, an inference scheme for low-bit LLMs that improves model quality by correcting quantization errors through selective retrieval of residuals stored in CPU memory. By focusing on dynamically identified salient channels at each decoding step, DecDEC maximizes error compensation within a limited transfer volume. DecDEC significantly improves quality of quantized LLMs with minimal overheads.

Stripeless Data Placement for Erasure-Coded In-Memory Storage

Abstract

Erasure coding plays a crucial role in distributed storage systems to provide fault tolerance at a low storage cost. Conventional erasure coding schemes determine data placement based on stripes. However, placing data into stripes can incur non-negligible performance overheads that will manifest in emerging fast in-memory storage systems, making conventional erasure coding schemes suboptimal in such scenarios.

Aiming to eliminate such overheads, we present Nos, a *stripeless* placement scheme for erasure-coded in-memory storage. It lets each node *independently* replicate data to other nodes and encode received data replicas into parities with XOR. Thus, it avoids the overheads caused by stripes. To enable failure recovery, Nos uses a combinatoric structure called *symmetric balanced incomplete block design* (SBIBD) to decide primary-to-backup node affinities during replication. Atop Nos, we further build Nostor, a distributed in-memory key-value store. Evaluations demonstrate that Nostor achieves 1.61× to 2.60× throughputs with similar or lower latencies than stripe-based erasure coding baselines.

1 Introduction

Fault tolerance is crucial for emerging distributed in-memory storage systems whose nodes can experience multiple types of failures [24]. These systems, built atop the fast Remote Direct Memory Access (RDMA) networks, provide orders of magnitude faster access to numerous latency-sensitive hot data objects than disks [6,7,13,26,30,53]. However, they still need to reload data from the underlying slow storage upon failure recovery, during which the system can experience significant performance degradations [15,25,40] or data unavailability. Hence, in-memory storage systems need fault tolerance to preserve availability and performance during partial failures.

Redundancy is the key to fault tolerance. There are two major approaches to achieving data redundancy: replication and erasure coding. Replication is well-known for its simplicity but also high storage overhead. Erasure coding offers a tradeoff: it has much less storage overhead than replication, which comes at a cost in performance by incurring extra computation. Since main memory is significantly more expensive than disks, erasure coding becomes an appealing fault tolerance solution for in-memory storage systems as it allows accommodating much more objects than replication [47,56].

*Jiwu Shu is the corresponding author (shujw@tsinghua.edu.cn).

Stripe is a basal concept of virtually all existing erasure coding schemes. It consists of a set of chunks, some of which are data chunks and the others are parity chunks. Stripe requires that every piece of data must be assigned to *exactly one stripe*, and all methods to perform such assignments fall in two categories: intra-object [9,25,27] and inter-object [6,55]. Intra-object means that a stripe contains only one object, while inter-object means that a stripe contains multiple objects.

However, we find that on the fast main memory, the stripe concept tarnishes the performance-storage tradeoff by incurring high costs in the storage systems when they need to determine data placement. Here, existing erasure coding schemes either pay more on performance or save less memory:

- With intra-object methods, they must split objects into chunks, bringing significant overheads due to the high I/O fanout when accessing the objects.
- With inter-object methods, they either deploy a metadata service (MDS) to group objects into stripes, or they assign objects to stripes following a statically determined policy. The former introduces the MDS as a centralized bottleneck, while the latter wastes memory as there is no guarantee that objects are evenly distributed across stripes without any centralized coordination.

The main memory is fast and expensive, so we can afford the costs of neither choices. Still, the stripe concept forces us to choose one, putting us into a dilemma.

To circumvent these drawbacks, abandoning stripes seems like a good idea. However, precedent research has never taken this approach. Stripes are critical when they need to tolerate multiple chunk failures: failed chunks (within a threshold) can always be expressed as linear combinations of other living chunks and, thus, get recovered. Without stripes, this property might not hold, causing data loss risks.

In this paper, however, we argue that with a proper data placement policy, it is possible to tolerate multiple chunk failures without stripes. Thus, we can avoid stripe's drawbacks and make erasure coding's performance-storage tradeoff favorable for in-memory storage systems again. Without stripes, each node can independently replicate data chunks on it to other nodes; at the same time, they independently encode received data chunk replicas into their XOR sums, i.e., parity chunks. This greatly simplifies the write path.

Guided by the principle above, we present Nos, a *stripeless* data placement scheme for erasure coding. Like the famous

Reed-Solomon code [37], Nos has two parameters (k, p):

- Parameter p determines the fault tolerance threshold. Each data chunk is replicated for $(p+2)$ times – one primary and $(p+1)$ backups, to tolerate p node failures.
- Parameter k determines the storage overhead. Each node independently XORs k data chunk replicas into a parity chunk, bringing a storage amplification factor of $(p+1)/k$.

The key of Nos is that it selects backup nodes for each primary node according to a combinatoric structure called *symmetric balanced incomplete block design* (SBIBD). We prove that this model guarantees a successful recovery of any data chunk upon any p node failures. The amortized cost to reconstruct a lost chunk is no more than reading k chunks, also similar to the Reed-Solomon code.

Atop Nos, we build Nostor, a distributed key-value store. Nostor's server nodes store objects in their main memory and communicate via remote procedure calls (RPC) atop RDMA. Nostor employs Nos flexibly to achieve both low latency and high throughput. It also ensures data consistency for common-case I/Os, degraded I/Os, and node repairs with a versioning-based approach.

We implemented Nostor in Rust and make it open-source at GitHub. Our evaluation shows that, under real-world workloads, Nostor outperforms conventional stripe-based erasure coding schemes with 1.61× to 2.60× throughput improvements and similar or lower latencies. It consumes 18.7% to 57.4% less memory than primary-backup replication but is often as performant as it. Nostor also improves the node repair time by 16.4%. Nevertheless, as a performance trade-off, Nostor's degraded read latency can be 35.0% to 62.4% higher than conventional erasure coding in the worst case.

2 Background

2.1 Erasure Coding and Stripes

Erasure coding is an established data redundancy mechanism. Many distributed storage systems, both experimental [17, 41, 42] and productional [16, 18, 23, 32, 43, 50], have erasure coding enabled or provide it as an option for ensuring fault tolerance for data in them. Stripe is the fundamental concept of virtually all existing erasure coding schemes. We use the Reed-Solomon code [37], one of the most widely adopted coding schemes, as an example to elaborate on.

The Reed-Solomon code has two parameters: (k, p). Both are positive integers. The parameter p determines the fault tolerance threshold: the coding scheme can tolerate up to p simultaneous failures. The parameter k governs the storage overhead: the storage amplification factor is p/k.

Specifically, the Reed-Solomon code partitions all data chunks into groups of size k. Within each group, it multiplies a $p \times k$ encode matrix to the k data chunks to get p parity chunks. These k data and p parity chunks together form a stripe. The stripe can recover any p failed chunks by multiplying an inversion of the encode matrix to the remaining chunks.

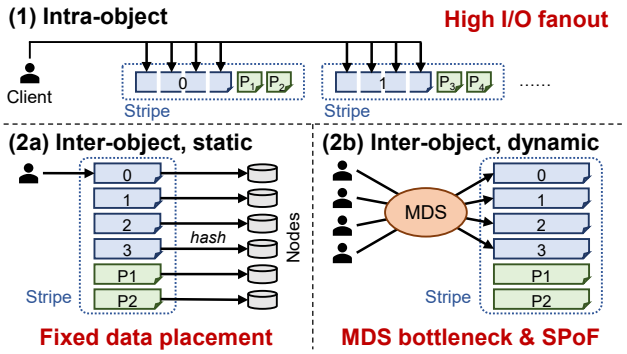

Figure 1: Summary of the drawbacks of stripes.

An essential characteristic of the Reed-Solomon code is that each chunk belongs to *exactly one* stripe. This characteristic is universal: it applies to all existing erasure coding schemes despite their diverse designs. Specifically, each data chunk must be assigned to a stripe, and each parity chunk originates only from the data chunks within the same stripe.

2.2 Drawbacks of Stripes

Stripe is the basic concept of erasure coding in conventional disk-based storage systems. However, when we move to the fast in-memory storage, its drawbacks start to manifest. The root cause is that *data placement is limited by stripes*. With a stripe-based coding scheme, determining data placement it is a difficult task that no existing solution can handle perfectly.

We still take the Reed-Solomon code as an example and focus on how it determines data placement in practice in an erasure-coded key-value store. There are two types of placement policies: intra-object and inter-object. We discuss them below and summarize their drawbacks in Figure 1.

2.2.1 Intra-object

Each object is first split into k chunks (each placed on a different node) and takes up an entire stripe. Data from different objects will not mix together in the same stripe. Examples include Ceph [50], EC-Cache [36], Giza [8], and Hydra [25].

For data availability, chunks in a stripe must be placed on different nodes, which means that reading or writing an object requires contacting k or $(k+p)$ nodes. Such a high I/O fanout can put significant strain on the network and cut down the maximum throughput proportionally (§6.2). Also, recent analyses revealed that small objects are prevalent in real-world workloads on in-memory key value stores [54]. It is unacceptable to access multiple nodes only to read/write a value that is smaller than 1 KB in around 80% of the cases [5].

2.2.2 Inter-object

Objects encode with each other; each stripe contains k objects. Examples include Cocytus [6] and LogECMem [9]. Here, we must assign k objects on different nodes to a stripe. There are two common assignment policies: static and dynamic.

Static assignment. For any object, we decide its belonging stripe only by its metadata (e.g., key hash) with a static policy. A significant drawback of this policy is that it does not respect the storage system's current state. In practice, this means that we cannot adapt to real-time placement constraints. For example, some nodes may suffer from temporary slowdowns, which can affect a wide range of user requests accessing objects whose primaries or parities are stored on these nodes.

Hash-based policies are also prone to the storage space waste caused by the empty chunks in stripes. It might, for example, hash objects 0, 1, 2, and 3 into the same stripe, but objects 1, 2, and 3 may never exist in the workload. This can cause the memory overheads to far exceed our expectations. Cocytus [6] alleviates this problem by manually allocating objects and encoding at virtual address level. However, in exchange, its allocation policy brings performance overheads (§6.2) and can cause memory wastes (§6.5).

Dynamic assignment. For any object, we dynamically decide its belonging stripe and placement at runtime, usually by consulting a metadata service (MDS) or proxy [9,27,55]. The MDS can choose a proper node (e.g., with the lowest load) to store the object and group it with other existing objects into a stripe, thus circumventing the drawbacks of static policies.

The problem is that we do not know an object's placement in advance, so every attempt to access the object has to first contact the MDS to get its metadata. This not only adds a network roundtrip's latency to the read/write critical paths but also makes the MDS a bottleneck and a single point of failure (SPoF). While replicating the MDS [9] solves the SPoF, it again aggravates the performance bottleneck due to the overheads brought by replication. Also, because objects are often small, the memory overheads brought by the (possibly replicated) MDS are non-negligible since the metadata size can be comparable to the object itself.

2.2.3 Summary

Stripes forces us to assign objects to them. However, every possible assignment scheme has significant drawbacks, making the stripe concept itself problematic.

3 Motivation

3.1 Abandoning Stripes

Stripe is the root cause of all the problems described in the previous section. Therefore, we can immediately solve them by abandoning the stripe concept. This is an unprecedented idea by now, but we can imagine how an erasure-coded storage system without stripes will look like:

- For availability, each object is stored on one *primary node* and replicated to multiple *backup nodes*. The primary node can independently and dynamically determine the object's backup nodes without having to consult a separate MDS.
- For low memory overhead, each node encodes received object replicas into parities. It can simply XOR the objects together instead of multiplying them with some complicated encode matrix. To recover a specific object, we find the parity encoding it, read all other objects encoded in the parity, and XOR them up to reconstruct the object.

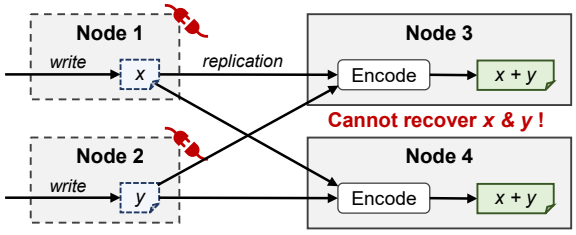

Figure 2: Demonstration of a strawman stripeless placement scheme. It risks data loss because it replicates data from two primary nodes to the same two backup nodes.

The imagination above is intuitively correct when only one node fails. But how can we perform failure recovery when multiple nodes fail simultaneously? Take the case in Figure 2 as an example. Objects x and y are stored on primary nodes 1 and 2, respectively, and they are both replicated to nodes 3 and 4 in case of two node failures. However, the system still risks data loss because if nodes 3 and 4 both XOR these objects together into $P_1 = P_2 = x \oplus y$, when nodes 1 and 2 fail, we cannot decode x and y from the remaining $x \oplus y$.

We find that the cause of this problem is that x and y, with different primary nodes, are replicated to the same two backup nodes 3 and 4. To eliminate this problem, we can assign different backup nodes for different primary nodes, so that *if two objects have different primary nodes, they cannot be replicated to the same two backup nodes.*

Formally, for a (symmetric) cluster of v nodes, we define a *primary-backup affinity matrix* $A_{v\times v}$ whose every element is 0 or 1. $A_{ij} = 1$ iff node i can replicate its primary objects to node j. Our requirement is: for any two rows r_1, r_2, there may exist at most one column c such that $A_{r_1 c} = A_{r_2 c} = 1$.

The final problem that remains is how to find the matrix A. Fortunately, it turns out that combinatorial mathematicians have already found it for us. Specifically, A should be a *symmetric balanced incomplete block design* (SBIBD). Below, we briefly introduce SBIBD and explain its connection with our stripeless data placement scheme.

3.2 SBIBD Primer

SBIBD is a combinatoric structure that was born in the 19th century [21,22,45] and can be found in most combinatorics textbooks today [4]. We only introduce necessary parts of the SBIBD theory here; more can be found in the textbooks.

SBIBD has three parameters: (v,k,λ). A (v,k,λ)-SBIBD is a 0/1 matrix $A_{v\times v}$. It has exactly k ones in each row and column; also, for any two rows r_1, r_2 in A, we have:

$$\left|\left\{c \mid A_{r_1 c} = A_{r_2 c} = 1\right\}\right| = \lambda$$

i.e., there are exactly λ column(s) with ones at both rows. We are particularly interested in the case where $\lambda = 1$, in which our requirement described in §3.1 is innately satisfied.

$(v,k,1)$-SBIBD has an important implication: v and k are not independent parameters. To show this, consider the number of ways to pick two rows r_1, r_2 and a column c such that $A_{r_1c} = A_{r_2c} = 1$. Since every column has k ones, this number is obviously $v\binom{k}{2}$. Also, by definition, for every distinct row pair (r_1, r_2) there exist exactly one such c, so the number is also $\binom{v}{2}$. Therefore,

$$\binom{v}{2} = v\binom{k}{2} \quad \Rightarrow \quad v = k^2 - k + 1 \tag{1}$$

i.e., the SBIBD must be a $(k^2-k+1, k, 1)$-SBIBD. We redefine $v = k^2 - k + 1$ hereinafter for convenience.

$(v,k,1)$-SBIBDs exist and can be efficiently computed for all $k = q+1$, where q is a prime power. As a result, they exist for most commonly-used k values in erasure coding, e.g., 3, 4, 5, 6, 8, 10, 12, and 14. To construct such a SBIBD, we first construct its topmost row r_1 and then cyclic-rotate it by $(i-1)$ units to get the row r_i [44]. Since SBIBD does not require an order among the rows in A, we can choose r_1 properly such that $A_{11} = 0$. This will ensure that A has a zero main diagonal. For example, when $k = 4, v = 13$, an SBIBD constructed by the method above is shown as follows.

	1	2	3	4	5	6	7	8	9	10	11	12	13
r_1	0	0	0	1	0	0	0	0	0	1	0	1	1
r_2	1	0	0	0	1	0	0	0	0	0	1	0	1
r_3	1	1	0	0	0	1	0	0	0	0	0	1	0
r_4	0	1	1	0	0	0	1	0	0	0	0	0	1
r_5	1	0	1	1	0	0	0	1	0	0	0	0	0
r_6	0	1	0	1	1	0	0	0	1	0	0	0	0
r_7	0	0	1	0	1	1	0	0	0	1	0	0	0
r_8	0	0	0	1	0	1	1	0	0	0	1	0	0
r_9	0	0	0	0	1	0	1	1	0	0	0	1	0
r_{10}	0	0	0	0	0	1	0	1	1	0	0	0	1
r_{11}	1	0	0	0	0	0	1	0	1	1	0	0	0
r_{12}	0	1	0	0	0	0	0	1	0	1	1	0	0
r_{13}	0	0	1	0	0	0	0	0	1	0	1	1	0

For example, for r_1, r_2, no column except $c = 13$ satisfies $A_{1c} = A_{2c} = 1$, verifiying SBIBD's property.

4 Nos

Nos[1] is an stripeless and inter-object data placement scheme for erasure coding, which is designed following the ideas discussed in the previous section. It tolerates $p < k$ failures in a cluster of size $v = k^2 - k + 1$. We first present its design (§4.1) and give it a demonstration (§4.2). Then, we briefly discuss its benefits and limitations (§4.3).

[1]The name stands for "no-stripe".

4.1 Code Design

Consider a cluster of v server nodes numbered $1, 2, \ldots, v$. Nos views a $(v,k,1)$-SBIBD as its primary-to-backup affinity matrix, which is in correspondence with our discussion in §3. Specifically, for an object whose primary is node i, we can send its replica to node j iff $A_{ij} = 1$. For any specific node j, the set $\{i \mid A_{ij} = 1\}$ is called its *replication source* set. Conversely, for any specific node i, the set $\{j \mid A_{ij} = 1\}$ is called its *replication target* set. Both sets have sizes of k.

Like the Reed-Solomon code, Nos has two parameters (k, p). Parameter k represents how many objects we encode into a parity and is co-dependent with the cluster size v following Equation (1). Parameter p represents the fault tolerance threshold. As a precondition, we require $k > p$. Most real-world storage systems naturally meet this precondition because $p \geq k$ would result in a relative storage overhead of at least 100%, which is usually undesirable.

The storage cluster must ensure data availability despite no more than p node failures. To this end, Nos stores each object on one primary node in its original form and encodes it with other objects on $(p+1)$ backup nodes using the following two-step erasure coding policy:

- The primary node replicates an object to nodes in its replication target set. There are k choices, and the primary node may select any $(p+1)$ out of them. This step is virtually equivalent to $(p+2)$-way replication. Since $A_{ii} = 0$ (zero main diagonal), object replicas are guaranteed not to be sent back to their primary nodes.
- Each node can receive object replicas from k other nodes. These replicas are temporarily buffered. In the background, when there is an object replica from every replication source node, the node collects one from each replication source and replaces them with their XOR sum, i.e., a parity.

Since the primary copy is the unchanged original data, Nos should be viewed as a systematic erasure coding scheme [29].

Primary nodes serve reads to the corresponding objects. If there are failed nodes, clients cannot directly access an object – let us call it x – whose primary node has failed. They need to contact living backup nodes of x to retrieve the parities and recover x. Each parity P of x is the XOR sum of x and other $(k-1)$ objects $x_1, x_2, \ldots, x_{k-1}$. If, fortunately, all these $(k-1)$ objects are alive, then the client can read them to decode x:

$$x = P \oplus x_1 \oplus x_2 \oplus \ldots \oplus x_{k-1}$$

We say x is *directly* recoverable by P in this case because P encodes only one failed object, that is, x.

However, when there are many failed nodes (no fewer than $(p+3)/2$, to be precise), every living parity P of x might encode some failed object y other than x itself, making direct recoveries impossible. In that case, we need to recursively recover y to finally recover x with P.

The key point is that because we select backup nodes according to a $(v,k,1)$-SBIBD, it is guaranteed that there exists

a P such that y is directly recoverable with it. As a result, even if we cannot recover x directly, we can still recover x in two steps: first, recover y; second, recover x.

Proof. Without loss of generality, let node 1 be the primary node of object x. Let $\mathcal{P}$ be the set of backup nodes where x is replicated to; $|\mathcal{P}| = p+1$.

To start recovery, node 1 must fail first. Each failed node in $\mathcal{P}$ can prevent up to two parities of x from being able to directly recover it (which we denote as *disabling* a parity below). For example, if $u \in \mathcal{P}$ fails, then a parity on u gets lost, and another parity that encodes x and an object from u now cannot directly recover x; by SBIBD's property, there cannot exist a third parity that encodes x and an object from u. This means that at least $1+(p+1)/2 = (p+3)/2$ failures are necessary to render x not directly recoverable.

Suppose we make f nodes in $\mathcal{P}$ fail such that x is no longer directly recoverable; let $\mathcal{F}$ be the set of these nodes. x now has $(p-f+1)$ living parities encoding it. Let $\mathcal{Y}$ be the set of failed objects other than x encoded in these parities. Consider any $y \in \mathcal{Y}$; let v be the primary node of y and P_{xy} be the parity that encodes both x and y. Object y also has $(p+1)$ parities encoding it; one parity might be on node 1 and get lost, and f parities are disabled by objects replicated from nodes in $\{1\} \cup \mathcal{F} - \{v\}$. By SBIBD's property, nodes in $\mathcal{F}$ except the one storing P_{xy} do not accept objects from node v. Therefore, there are $(p-f)$ remaining parities of y.

We still have a quota of $(p-f-1)$ further node failures. To prevent the recovery of x, we must select $(p-f+1)$ objects from $\mathcal{Y}$, one for each living parity of x, and make them not directly recoverable. These objects have $(p-f+1)(p-f)$ non-overlapping parities available. Similar to the discussion above, by SBIBD's property, each failed node not in $\{1\} \cup \mathcal{F}$ can disable up to two parities of a certain $y' \in \mathcal{Y}$; at the same time, it can also disable one parity for every other object in $\mathcal{Y}$. Hence, using the remaining node failure quota, we can disable up to $(p-f-1)(p-f+2)$ parities for the $(p-f+1)$ objects mentioned above. Because

$$(p-f-1)(p-f+2) < (p-f+1)(p-f)$$

we conclude that there exist at least one living parity of x, in which all failed objects except x are directly recoverable. Therefore, x is also recoverable. □

The proof's idea can also explain why Nos replicates objects to $(p+1)$ backup nodes. Intuitively, to tolerate p failures, each object should only replicate to p backup nodes. However, it can be shown that this can make the degraded read recursion infinite. An extra replica solves this problem.

4.2 Demonstration with $k = 4$

We demonstrate Nos with an example. Here, $k = 4$, $v = 13$, and we use the same SBIBD shown in §3.2. We assume that node 1 has failed, and a client now wants to access an object x whose primary node is node 1. Nodes 4, 10, 12, and 13 can accept backups of objects from node 1 and hold parities that encode x. Since we require $k > p$, p can only be 1, 2, or 3.

- When $p = 1$, the recovery is trivial: we can use any parity that encodes x since it cannot encode other failed objects.
- When $p = 2$, there can be one failed node other than node 1, which can prevent up to two parities from being able to directly recover x (e.g., if node 4 fails, the parity on it gets lost, and the parity on node 13 encoding an object from node 4 is also affected). Since we have three parities for x, one will be unaffected and can directly recover x.
- When $p = 3$, exhaustive search verifies that x is directly recoverable except when nodes 4 and 12 fail. In that case, x has two living parities: P_1 on node 10 and P_2 on node 13. They can both decode x, and we only discuss P_1 here for example. Besides x, P_1 encodes a failed object y from node 12, which we can directly recover with the parity on node 8 (encoding objects from nodes $\{5, 9, 10, 12\}$). Therefore, we can first decode y and then use P_1 to decode x.

4.3 Discussions

Nos aims at solving the drawbacks of stripes described in §2.2. It offers flexibility in data placement without an MDS by allowing the selection of backup nodes when replicating objects. It replaces matrix computation with XOR compared with the Reed-Solomon code, and hides parity encoding overheads in the background. The most important advantage is that despite the complex SBIBD theory behind it, Nos is easy to implement and deploy: primary nodes simply replicate data to backup nodes, and backup nodes encode received data into parities, both without any coordination with other nodes.

Nevertheless, such advantages come with some limitations, which we list and discuss below.

Ineffectiveness with slow storage. The goal of Nos is to accelerate fast in-memory storage systems. For conventional storage systems built atop slow disks, Nos can have limited benefits since the disks dominate their performance.

Incompatibility with large k values. Some code schemes, like the wide-stripe erasure codes [17], have large k values (e.g., ≥ 100). It would be hard for these codes to adopt the idea of Nos because Nos requires $\Theta(k^2)$ failure domains to function correctly, which is prohibitive when k is large.

Fortunately, Nos and wide-stripe erasure codes target distinct scenarios. Nos optimizes common-case I/Os for fast storage systems with frequent reads and updates, where values of k are moderate. In contrast, wide-stripe erasure codes aim at ultra-low storage consumption and recovery cost for cold storage systems with few reads or updates.

Further, modern datacenters can have tens of thousands of independent servers in a cluster [1, 48]. They can deploy Nos with reasonably large k values if they want. Still, this can be a challenging task as a large cluster face a lot more failure modalities than a small one. To keep the cluster small, one

may, for example, place two failure domains on each node, which halves the cluster size but doubles p.

Extra network bandwidth consumption. Nos consumes extra network bandwidth because of two intrinsic problems.

- First, in each write, Nos replicates data one more time than the Reed-Solomon code. Since the replicas can be transmitted in parallel, it has a limited impact on latencies. Future work may mitigate this problem by multicast to reduce outbound bandwidth consumption.
- Second, Nos needs to read $O(kp)$ objects to recover a desired object when direct recovery is impossible. Though there are no workarounds for this problem, as shown in §4.1, we can reconstruct other lost objects during the recovery. The amortized recovery cost (i.e., number of objects to read) of a lost object is still no more than k.

Also, fortunately, the extra bandwidth overheads are limited since objects are usually small in real-world workloads.

Rigid placement constraints. The most significant limitation of Nos is that it imposes a rigid data placement policy on the cluster. In a cluster of size v, each node can only send/receive data to/from $\Theta(\sqrt{v})$ nodes, leaving the remaining $\Theta(v)$ nodes unused. Also, since v depends on k, it can be difficult to use two coding schemes with different k values for different data in the same cluster. As a result, Nos is far less flexible than conventional coding schemes like the Reed-Solomon code. This is a consequence of the fact that Nos uses a raw SBIBD as its affinity matrix without modification. We hope future work can solve this problem with more advanced theory designs.

5 NOSTOR

To compare Nos with existing erasure coding schemes, we build NOSTOR, an in-memory key-value store prototype that employs Nos for fault tolerance. NOSTOR is implemented in Rust with around 16K lines of code.

5.1 Overview

NOSTOR adopts a C/S architecture. Servers maintain objects and parities in DRAM-resident hashmaps; for this, we use an existing implementation, DashMap [51], which is a sharded hashmap with each shard protected by a reader-writer lock. Clients and servers communicate via remote procedure calls (RPCs) atop fully-userspace RDMA.

Subclusters. NOSTOR employs a unified Nos policy in the entire storage system, i.e., with the same parameters (k, p) and SBIBD instance. There must be at least $v = k^2 - k + 1$ server nodes. If there are more nodes, NOSTOR will create *subclusters* in the entire cluster, each of size v. Subclusters may overlap with each other on some nodes, but NOSTOR will not encode objects from different subclusters together.

NOSTOR divides the key space by hashing for (1) subclusters and (2) primary nodes within each subcluster. Objects do not have predetermined backup servers; instead, primary servers decide backups for objects upon insertion.

Thread model. NOSTOR runs two types of threads on each server: foreground and background.

Foreground threads are RPC threads that perform reads and writes to primaries and dispatch backup write RPCs to other servers. For backup writes, foreground threads only push them into waiting queues to shorten the critical path, instead of digesting them synchronously. Each server maintains a *replication queue* (denoted as q_i) for each replication source i that buffers backup writes from server i. NOSTOR also maintains an index for items in the replication queues to query the yet-to-be-encoded objects during degraded reads.

Background threads pop items from replication queues and digest them. Its tasks include encoding new parities and updating existing parities. We will elaborate on the concrete jobs of background threads in §5.3.

5.2 Handling Client Requests

Client requests consist of `PUT`s and `GET`s. A client sends an RPC to the object's primary server to perform a request.

`PUT`. NOSTOR regards insertions, updates, and deletions as `PUT`s. It complies with the following contract: `PUT`s are committed (i.e., visible and fault-tolerant) by the time they return. To this end, NOSTOR employs a versioning mechanism:

- Each server locally maintains a monotonically increasing sequence number (SN) and assigns it to write requests. Each server also maintains a committed SN (CSN): all writes with SNs no larger than the CSN are committed.
- Instead of a single object, NOSTOR maintains a version queue for each primary object in the hashmap. Accesses to the queues are protected by reader-writer locks.

The detailed `PUT` procedure is as follows. ① Append to the object's version queue and fetch an SN. ② Compute the *delta* between the new value and its previous version. If this is an insertion/deletion, we regard the previous/new value as zero. ③ Replicate the delta to this object's $(p+1)$ backup servers. If this is an insertion, we first select the backup servers. Here, NOSTOR can run arbitrary selection policies and adapt to dynamic data placement requirements, e.g., avoiding unavailable or slow backup servers. ④ Update the CSN when replication finishes. Then, remove outdated versions of the object.

`GET`. The server first queries its hashmap for the object's version queue. If the queue is empty or the queue head is not yet committed (i.e., SN larger than the CSN), the server reports that the object is not found. Otherwise, it finds the object stored in the queue head and replies to the client.

5.3 Digesting Deltas

Background threads (BGTs) digest object deltas sent from their primary servers from the replication queues. To ensure failure consistency, BGTs only process committed deltas iden-

tified by their primaries' SNs and the CSNs, which are piggybacked in the RPCs. Uncommitted deltas will be pushed back into their corresponding replication queues.

Term definition. For convenience, we define several terms that we will frequently use in our following discussion.

- *Encodee* of a parity is an object encoded into this parity. In Nos, all parities should have exactly k encodees, but Nostor relaxes this constraint.
- *Full parity* is a parity with k encodees.
- *Partial parity* is a parity with fewer than k encodees. Nostor consistently attempts to convert partial parities into full parities to lower its storage overheads.

We elaborate on the jobs of BGTs as follows.

5.3.1 Encoding new objects into parities

Each BGT will repeatedly scan all replication queues and try to collect a delta from each queue to encode them together. Specifically, when it pops a delta from a replication queue, it first checks the hashmap for the delta's key. If no such entry exists, i.e., this is a new object, the delta is recognized as an insertion. The BGT will collect this delta and switch to the next replication queue. When it successfully collects k deltas, one from each queue, it will replace them with their XOR sum, i.e., a full parity. Finally, the BGT inserts the full parity, together with the keys of its encodees, into the hashmap.

Avoiding blocking. In practice, a server can temporarily block on some replication sources with no incoming new objects, which can prevent data in other replication queues from being digested and bloat Nostor's memory usage. To address this problem, BGTs do not wait indefinitely to receive from a replication queue; if they timeout, they will skip that queue and move forward. The timeout must be short to reduce CPU cycles wasted on waiting (10 µs in our implementation).

In this case, a BGT will collect fewer than k deltas when it finishes a round of scan, and the XOR sum will become a partial parity. Partial parities do not affect Nos's correctness since they add no extra dependencies among the objects. However, they must get converted into full parities as soon as possible. To this end, each server maintains a *parity queue*, denoted as $\bar{q}_i$, for each replication source i to record partial parities. $\bar{q}_i$ has the following admission rule: it holds partial parities whose encodees are *not* from primary server i. A partial parity can reside in one of all the valid parity queues.

BGTs will actively try to convert partial parities into full parities. Upon collecting a new object from the replication queue q_i, a BGT will first check whether $\bar{q}_i$ is empty. If not, it will pop a partial parity from $\bar{q}_i$ and encode the delta into it. The resulting parity will be pushed into another valid parity queue $\bar{q}_j$ if it is still a partial parity.

Handling concurrent PUTs. Multiple BGTs can concurrently digest deltas of the same object, of which only one may be recognized as an insertion. To this end, the BGT inserts a placeholder entry for the corresponding key in the hashmap if it recognizes a delta as insertion. Therefore, other BGTs will see this placeholder and recognize their deltas as updates. When the BGT finishes encoding the collected deltas, it will replace the placeholders with pointers to the encoded parity.

5.3.2 Updating existing parities

If a BGT pops a delta from a replication queue and finds a corresponding entry in the hashmap, it will recognize the delta as an update. The entry should (eventually) be a parity encoding the delta's belonging object. It will encode the delta into the parity, i.e., replace it with its XOR sum with the delta.

Handling deletions. Deletions can convert full parities into partial parities. Upon deleting an encodee from a full parity, the BGT inserts its metadata into a valid parity queue.

Will partial parities heap up? As long as objects are evenly distributed (which can be achieved with a good key hash algorithm), Nostor can prevent partial parities from heaping up because it is expected that every node will receive the same number of objects from its each replication source. Skewed update traffic will be non-blockingly digested into existing parities and, thus, is not a problem here.

5.4 Failure Recovery

Nostor needs to recover itself if there are failed servers in a subcluster. This task contains three jobs: ① ensuring failure consistency, ② providing degraded read service during the failure, and ③ repairing failed server nodes.

5.4.1 Failure model

Like previous work [6, 25, 36, 56], Nostor assumes fail-stop failures only. Partial network failures or network partitions will likely prevent Nostor from performing PUTs, but since Nostor has no centralized components, clients can still perform GETs on reachable nodes without worrying about split-brain. Byzantine failures are out of the scope of this paper.

5.4.2 Failure consistency

When a server i fails, Nostor must ensure the consistency of its replication targets. Replication target servers of server i do the following steps to ensure consistency. ① Notify all BGTs to stop digesting deltas in q_i and spawn a dedicated thread to collect the SNs of the deltas in q_i. ② Exchange the collected SN information with other replication targets. Thus, the server can find the largest CSN for server i. ③ Discard all deltas in q_i with SNs larger than the CSN. ④ Notify all BGTs to restart digesting deltas in q_i and wait for q_i to become empty.

Note that in step ②, replication targets of node i exchange all collected SNs, instead of the maximum, to correctly find all committed PUTs. After the steps above, all living replication targets of server i will reach a consistent state.

5.4.3 Degraded I/O

Nostor can serve degraded reads to objects whose primaries have failed as soon as Nostor completes the procedure described in §5.4.2 and reaches a consistent state. For simplicity,

Nostor disallows degraded writes. In other words, if a write request matches one of the following conditions, it will be blocked: ① the primary has failed, or ② it cannot replicate to $(p+1)$ living backup nodes.

To perform a degraded read to object x whose primary is server i (failed), the client sends a read RPC to any living server. The server performs the following steps. ① Send RPCs to all living replication targets of server i, which query their hashmaps for the given key and return the metadata of the parities encoding the corresponding object. If the object exists, at least one backup node should reply with non-empty metadata. ② Find the parity that encodes the fewest failed objects, which is the best parity to recover x. ③ Read the parity and all its encodees except x. This may trigger recursive degraded reads, but the recursion will not go deeper, as proved in §4.1. ④ XOR the parity and all the encodees together to decode x.

5.4.4 Node repair

When a new server joins the subcluster to replace a failed one, Nostor starts the node repair procedure. It becomes online and starts serving client requests only after it finishes the following two recovery tasks.

Recover primaries. The server contacts all its replication targets to get a complete list of objects to store a primary copy of. Then, it sends degraded reads requests to them to recover the objects and store the results. Since decoding is performed by other servers, the recovering server will not suffer from inbound network traffic bottleneck.

Recover parities. The server contacts all its replication sources to retrieve all objects that should have been replicated to it. Retrieved objects are pushed into the corresponding replication queues. Then, the server encodes them into parities in the same way as we have discussed in §5.3. There is no need for Nostor to encode objects into the same parities before the failure. The server can perform object retrieval and encoding in parallel to reduce the recovery time.

6 Evaluation

We seek to answer the following questions.

- How does Nostor perform in common cases, and whether it performs well or not, why (§6.2, §6.3)?
- How does Nostor perform in failure recovery (§6.4)?
- How much memory does Nostor use (§6.5)?

6.1 Experiment Setup

We evaluate Nostor on CloudLab [12]. The testbed consists of 16 `c6525-100g` nodes. Every node has the following hardware and software configuration:

- **CPU**: 1× 24-core AMD 7402P, running at 2.80 GHz;
- **RAM**: 128 GB (8× 16 GB 3200 MT/s);
- **NIC**: Mellanox ConnectX-5 Ex 100 Gb (one port);
- **OS**: Ubuntu 22.04 LTS, kernel version 5.19;
- **NIC Driver**: DOCA-OFED 2.10.0;
- **Coding Library**: Intel ISA-L 2.31.1 [19] (AVX2 enabled).

We run two servers on each node so that we can evaluate Nostor with up to $k = 6$ ($v = k^2 - k + 1 = 31$). Note that in deployment, each server should run on a separate failure domain; our setting is due to the lack of physical servers.

Baseline systems. We evaluate Nostor mainly against:

- `Cocytus`: An *inter-object* erasure-coded in-memory object store based on Memcached and TCP/IP network [6]. It uses the Reed-Solomon code. For fairness in comparison, we identified the main logic in its source code and ported it line-by-line into our evaluation framework. `Cocytus` has a similar write path with Nostor: compute the deltas, replicate them, and commit asynchronously. It differs from Nostor in encoding and stripe allocation.
- `PQ`: An *inter-object* object store similar to `Cocytus`, except that it switches from the Reed-Solomon code to the P+Q code in RAID-6 [33]. It uses XOR instead of matrix computation to encode data.
- `Split`: An *intra-object* scheme that splits each object into smaller chunks and encode them into a stripe. It represents Ceph [49, 50], EC-Cache [36], and Hydra [25].
- `Repl`: Ignores k and uses $(p+1)$-way replication for fault tolerance. It offers high performance at the cost of high memory consumption.

We evaluate the systems under three configurations: $(k, p) = (4,2)$, $(6,2)$, and $(6,3)$. Note that `PQ` does not work with $(6,3)$ since it only supports $p = 2$. All baselines use static data placement policies; we will explain this choice in §6.2.4.

Thread configuration. With hyperthreading enabled, we have $24 \times 2 = 48$ cores on each node. The two servers each use 18 cores, with 12 foreground and 6 background threads. `Repl` and `Split` do not need background threads to digest object deltas, so they use all 18 cores to run foreground threads. We run a client on each node that uses the remaining 12 cores, with 32 coroutines multiplexing each thread.

6.2 Microbenchmarks

We evaluate Nostor with the following microbenchmarks:

- 100%-`GET` and 100%-`PUT` with fixed value sizes;
- YCSB [10] A, B, and D (C omitted since it is 100%-`GET`).

The size of the key space is 50 million. Objects are accessed following a Zipfian-0.99 distribution.

6.2.1 100%-GET & 100%-PUT

Figure 3 shows the throughputs. For `GET`, all evaluated systems except `Split` perform similarly well because they only query the hashmap once per `GET`. With value sizes ≤ 256 B, Nostor's `GET` throughputs are 3.92× and 6.06× of `Split` for $k = 4$ and $k = 6$, respectively. These ratios are very close to k, implying that the network IOPS is the bottleneck when

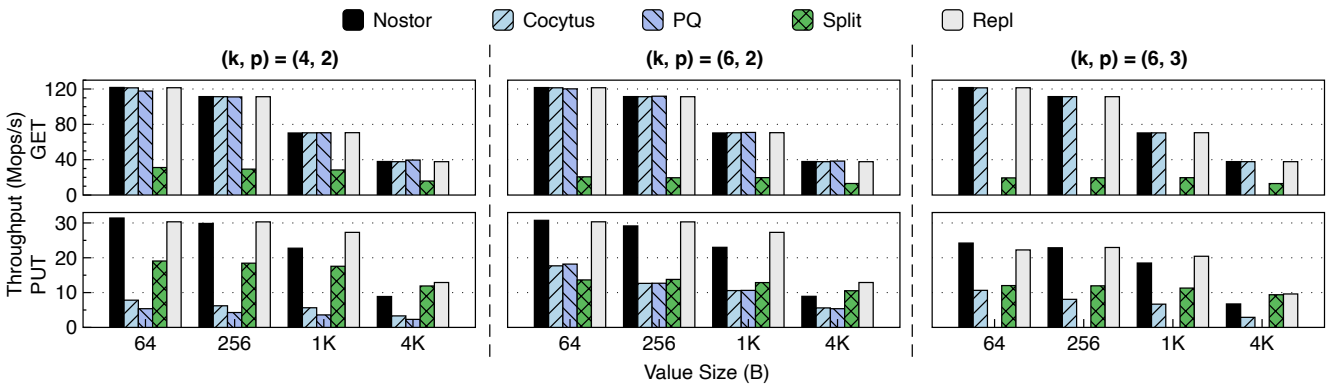

Figure 3: Performance of 100%-GET and 100%-PUT microbenchmarks.

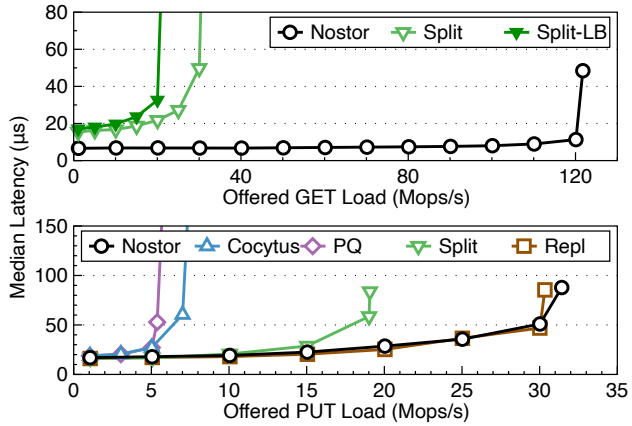

Figure 4: Latency-throughput curves under 100%-GET and 100%-PUT microbenchmarks.

objects are small and that we have pushed the systems to their maximum throughputs. For 1 KB and 4 KB values, the performance bottleneck shifts to the network bandwidth. Still, Nostor delivers 2.40× to 3.57× throughput of `Split`.

For PUT, as expected, `Repl` shows the overall best performance. Nostor performs similarly well for 64 B values; for 1 KB and 4 KB values, it delivers 87.4% and 69.7% throughputs to `Repl`, respectively. This is because the overhead of the one extra replica per PUT starts to manifest as value sizes increase. Also, due to the lowest network bandwidth consumption, `Split` outperforms Nostor for 4 KB values. `Cocytus` and PQ perform the worst (37.3% to 56.6% lower than Nostor on average); we find that it is the synchronized space allocation that hampers their performance the most. They allocate objects in one large stripe using the first-fit policy, serializing all PUTs and severely harming their performance. In Nostor, instead, objects are independent, and such synchronization overhead does not exist in the first place. Overall, Nostor achieves relatively good PUT performances.

Figure 4 shows latency-throughput curves with $(k, p) = (4, 2)$ and 64 B values. For GET, Nostor's curve also represents `Cocytus`, PQ, and `Repl`, which all deliver the best performance. `Split` has higher latencies and lower throughputs due to its high I/O fanout. For PUT, Nostor also has the lowest latencies; interestingly, it even slightly outperforms `Repl`. The reason is that Nostor stores fewer parities than `Repl`'s replicas, resulting in reduced pressure on the hashmap index.

We also make some additional comments to the baselines:

- For `Split`, previous work proposed late-binding, a GET latency optimization technique: fetch one more chunk in the stripe and use the first k that arrive to decode the original data. However, late-binding is unfavorable here because network is always the performance bottleneck, and late-binding can only aggravate it. With $(k, p) = (4, 2)$, `Split`'s throughputs decrease by 15.6% to 28.4% for different value sizes with late-binding. We draw a curve for `Split` with late-binding in Figure 4 (`Split-LB`) which shows that there is no improvement in median latency. Worse, the 99% tail latency even increases by more than 2.2×.
- For `Cocytus`, our implementation delivers 78.5% and 17.9% lower latencies for GETs and PUTs than the original implementation, respectively, with at least a 9.5× throughput improvement, even if we assume the original implementation has 100% scalability. Therefore, we believe that our implementation and evaluations of `Cocytus` are fair.

6.2.2 YCSB

Figure 5 shows the performance of YCSB workloads, where we use 1 KB values as in its original specification. For the write-intensive YCSB-A, Nostor performs similarly to `Repl` and significantly better than `Cocytus`, PQ, and `Split` due to its simplified write path. For the read-intensive YCSB-B and YCSB-D, all systems except `Split` have good performances. These results are all consistent with our conclusions drawn in §6.2.1. Also, overall, all evaluated systems deliver higher throughputs on the YCSB-D workload than on YCSB-B. This is because YCSB-D reads recently inserted objects, which should improve cache efficiency at the servers.

6.2.3 Sensitivity analysis

Figure 6 shows how the performances of the evaluated systems vary with different (k, p) parameters. We run YCSB-A workload under each configuration. Note that we cannot eval-

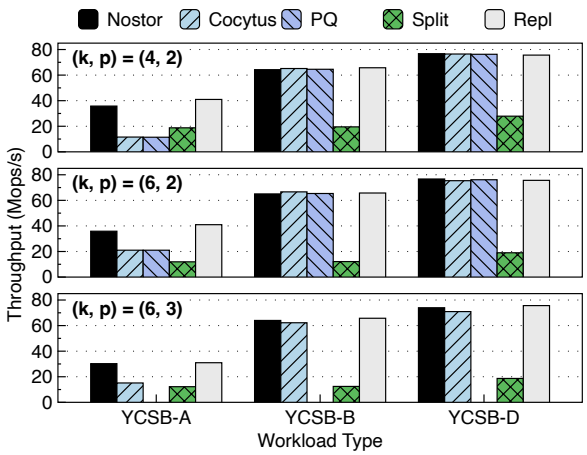

Figure 5: Performance of YCSB workloads.

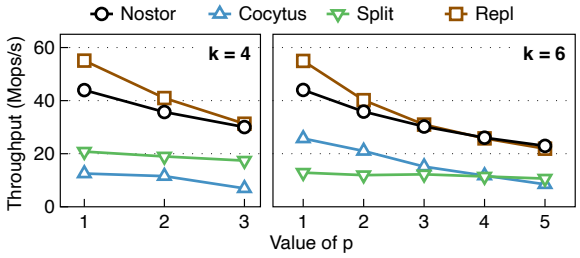

Figure 6: Performance with different (k, p) configurations.

uate PQ here since it only works with $p = 2$.

We make the following two observations. First, Nostor's performance highly depends on p, but k has little impact on Nostor's performance. This is due to Nos's design: its write critical path is similar to primary-backup replication and unaware of k. Second, as p becomes large, the performance gap between Nostor and `Repl` closes. This is because the impact of the extra replica of Nostor has diminishing marginal effects as the total number of replications increases.

6.2.4 How about dynamic data placement?

One may wonder why we only evaluate static data placement policies. To answer this question, we implemented a baseline that adds a dummy MDS to the I/O critical paths to simulate dynamic data placement policies. The MDS just adds a centralized point in the I/O critical paths and does nothing more. It must replace the position of a server (since there are no more cores), so we evaluated all other systems with one fewer server to compare them with it. Figure 7 shows the results. Bottlenecked by the MDS, the baseline delivers the lowest throughputs among the evaluated systems: 89.2% and 72.4% less than Nostor for GETs and PUTs, respectively. This convinces us that we must avoid the centralized MDS and opt for static data placement policies to achieve high performance.

6.2.5 Adaption to runtime data placement constraints

We evaluate how Nostor and other systems can adapt to dynamic data placement constraints at runtime. We run the

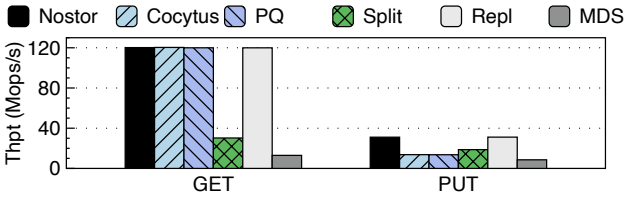

Figure 7: Performance comparison with a baseline system that has an MDS on its I/O critical paths.

YCSB-D workload under $(k, p) = (6, 2)$ and simulate a temporary node slowdown scenario, during which two nodes incur 1 ms extra latency for PUTs (by sleeping). The node slowdown information is broadcasted to every server. Figure 8 shows the results, in which the slowdown starts at $t = 10$ s and ends at $t = 35$ s. `Cocytus` also represents PQ since they are similar.

Nostor can avoid replicating objects to slow nodes in PUTs, so it only suffers from millisecond-level tail latencies caused by objects whose primary nodes are slowed down. In contrast, `Cocytus` suffers from skyrocketed tail latencies (48.2×) because it cannot dynamically place its stripe or circumvent the slow nodes. Due to the read-recently-inserted access pattern of the YCSB-D workload, `Cocytus`'s slow nodes also severely affect its `GET` operations and result in a significant throughput drop of 98.9%. `Repl` suffers from 25.0% lower throughput and 47.7× higher tail latencies due to similar reasons. `Split` is special here because it already suffers from high, millisecond-level tail latencies due to its high network IOPS pressure. The presence of the slow nodes decreases the pressure, causing no negative effects to the tail latencies. However, we observe significantly higher (10.8×) PUT median latencies. This is because `Split`'s PUT operation has a higher fanout than all other evaluated systems; thus, more PUTs are affected by the slow nodes.

Despite the results above, we find that it is possible for `Cocytus`, `Split`, and `Repl` to avoid replicating to slow nodes and, thus, reduce their performance penalties. Specifically,

- `Cocytus` and `Split` can allow dynamic placement of parity chunks in each stripe. For example, when $p = 2$, they can choose 2 nodes out of $(2 + s)$ candidates to place parity chunks, which allows us to tolerate s slow nodes. Here, s is the "degree-of-freedom" of node choices. We use $s = k - (p + 1) = 3$ in this experiment, the same as Nos.
- `Repl` can adopt strategies like hinted handoff [11] to avoid replicating data to slow nodes. Specifically, if an original backup node is slow, the primary node can hand off the object replica to another backup node. The new backup node monitors the state of the original backup node, and hand back the object replica when it becomes normal.

We implement variants of `Cocytus`, `Split`, and `Repl` with features above enabled (denoted as `Cocytus+`, `Split+`, and `Repl+`, respectively) to compare Nostor against them. They are plotted as dotted lines in Figure 8. During the slowdown event, the tail latencies of `Cocytus+` and `Repl+` are similar

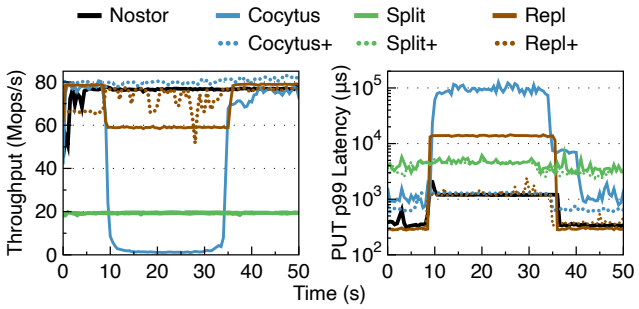

Figure 8: Performance with runtime data placement constraints (two nodes slowed down). *Latency is log-scale.*

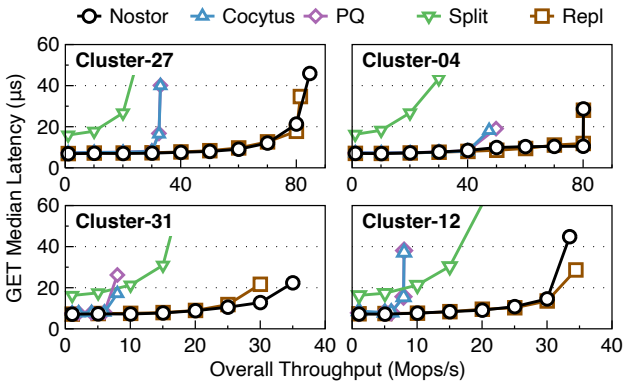

Figure 9: GET performance of Twemcache workloads.

to Nostor. Split+ performs nearly the same with its original version in the figure, while its PUT median latencies now remain stable. Nevertheless, these methods also incur other significant overheads. Specifically,

- Cocytus+'s memory consumption markably increases (16.2% to 62.6% with different object sizes) compared with its original version. This is because allowing dynamic candidates is equivalent to splitting each stripe in Cocytus splits into multiple new stripes with the same primary nodes but different backup nodes. With many more stripes, our worry in §2.2.2 about the static assignment policy becomes true: a stripe might, with a high chance, contain empty chunks and result in a significant memory waste.
- Split+ also consumes more memory because, to avoid aggravating the request fan-out problem, it need to store parity chunks' positions along with the object splits, so that it can retrieve them quickly during degraded reads. This leads to 6.1% to 78.4% extra memory usage.
- Repl+ suffers from two problems. First, its throughput is unstable during the slowdown event because hinted handoff causes load imbalance among normal nodes. Second, after the slow nodes recover, its tail latencies are 28.9% higher than Repl on average since the object hand-back traffic interferes with the client request traffic.

Overall, we observe that it is difficult to perfectly augment these baselines to gracefully tolerate slow nodes. In contrast, Nostor can achieve this goal with little extra efforts.

As a final comment, "broadcasting node slowdown to every server" is only for the convenience of this experiment. In practice, slowdown detection can work in a decentralized manner: each server monitors the performance of object delta replication RPCs and dynamically identifies slow nodes.

6.3 Real-World Trace Benchmarks

We evaluate Nostor with Twitter's Twemcache trace [54] with $(k, p) = (4, 2)$. We select four representative traces covering small/large objects and read/write-intensive workloads; see Table 1. Figures 9 and 10 show the median latency-throughput curves for GET and PUT operations, respectively.

Nostor consistently outperforms other erasure-coded systems with 1.61× to 2.60× throughput improvements. It also slightly outperforms Repl on Cluster-31 for the same reason described in §6.2.1. Nostor and Repl's median latencies are not significantly affected by object sizes: despite the two orders of magnitude difference in average sizes, most objects still fit in one MTU (9000 B in our testbed) and therefore have limited impact on networking overheads.

We observe that all systems except Split perform similarly when the load is low. As the load increases, Cocytus and PQ start to meet throughput bounds due to their poor PUT performance. This also explains why Cocytus and PQ deliver lower throughputs on Cluster-27 than Cluster-12, even if the former has much smaller objects: the higher write ratio significantly hampers their overall performance.

Due to space limits and the fact that Nostor does not specially optimize tail latencies, we omit the tail latency-throughput curve figures. Here, we present some important details about tail latencies. First, Nostor's PUT p99 latencies are superior to all baselines except Repl. On Cluster-31, Nostor outperforms Cocytus/PQ by 33.9% and Split by 6.4%; it underperforms Repl by 26.8%. On Cluster-12, Nostor outperforms Cocytus/PQ by 77.1% and Split by 23.4%; it underperforms Repl by 39.6%. Second, Nostor's GET p99 latencies are similar to Cocytus/PQ/Repl and 68.5% lower than Split. Third, in contrast to the median latencies, the p99 latencies are visibly affected by object sizes. From small objects (Cluster-27/31) to large objects (Cluster-4/12), Nostor's GET/PUT p99 latencies increase by 3.69× and 1.35× on average, respectively. This is because the object sizes shown in Table 1 are the average sizes, while p99 latencies are dominated objects larger than the average. Also, these large objects are more affected by temporary request bursts.

To sum up, Nostor is superior to all evaluated erasure-coded systems in both latency and throughput. It also delivers similar median latencies to Repl, but its tail latencies can sometimes be higher.

	Small objects	Large objects
Read-intensive	Cluster-27 (15% write, object size 74 B, $\alpha = 1.07$)	Cluster-04 (7% write, object size 2506 B, $\alpha = 1.10$)
Write-intensive	Cluster-31 (94% write, object size 56 B, $\alpha = 0.00$)	Cluster-12 (80% write, object size 1074 B, $\alpha = 0.30$)

Table 1: Summary of Twemcache traces used in evaluation. Object size = key + value (averaged). α is the Zipfian parameter.

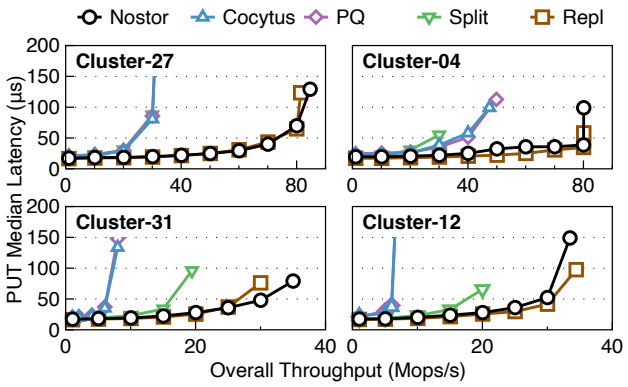

Figure 10: PUT performance of Twemcache workloads.

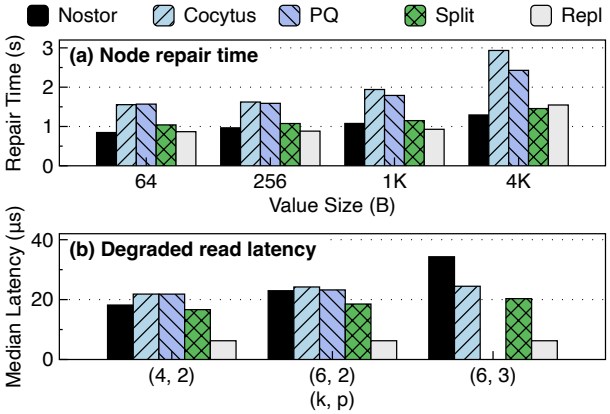

Figure 11: Recovery performance.

6.4 Recovery Performance

6.4.1 Node repair time

We make two servers fail under $(k, p) = (4, 2)$ and then restart them. Each server recovers itself as described in §5.4. Figure 11(a) shows the average time to recover a node. Other (k, p) configurations yield similar trends and are omitted.

Nostor and `Repl` have the highest node repair speed. `Repl` is fast because it does not need to decode any data; instead, it only reads object replicas from backup nodes. Nostor needs to perform decoding, but it has a smaller number of parities ($(p+1)/k\times$ object count) than `Repl`'s replicas ($p\times$ object count). This results in reduced performance overheads caused by inserting into the hashmaps, so Nostor is also fast.

For `Split`, `Cocytus`, and `PQ`, the amount of data to recover is the same. `Split` is slightly (16.4%) slower than Nostor because its data are split into finer-grained chunks, incurring more metadata-related overheads. `Cocytus` and `PQ` are more (88.2%) slower than Nostor because they naturally have low PUT performances. Also, `Cocytus` recovers (9.1%) slower than `PQ` with value sizes ≥ 256 B. We attribute this to their coding scheme difference: `Cocytus` decodes data with matrix multiplication, while `PQ` uses XOR. ISA-L performs XOR and matrix multiplication similarly fast on 64 B data, but when data is larger, XOR becomes 4.06× faster than matrix multiplication. This reduces the decode time of `PQ`.

6.4.2 Degraded read latency

We measure 64 B degraded read latency under each (k, p) configuration with p failed nodes. Figure 11(b) shows the results. `Repl` is the fastest since it only needs to read a replica. `Split` is the second fastest since the amount of data it reads is only $1/k$ to other erasure-coded systems. For $(4, 2)$ and $(6, 2)$ configurations, Nostor's degraded read latency is 16.5% higher than `Split` on average. However, it is also 11.0% faster than `Cocytus` and `PQ` because it only uses XOR to decode data (`PQ` also performs bit-shift and bitwise-AND).

For Nostor with $(k, p) = (6, 3)$, we carefully choose the failed nodes such that the worst case, i.e., recursive degraded read, will be triggered. In this case, due to an extra round of recovery, Nostor's degraded read latency rises to the highest, 35.0% higher than `Cocytus` and 62.4% higher than `Split`. Since such degraded reads should be rare among all read operations, we believe the increased latency is acceptable.

6.5 Memory Consumption

We populate the systems with 50 million objects and measure their memory consumption. Figure 12 shows the results, in which Nostor's memory usage (in GBs) is labeled above the bars. `Cocytus` also represents `PQ` since they are similar.

We make the following observations. First, Nostor incurs extra metadata overheads because it must store the encodees' keys along with each parity, which explains why it consumes more memory from $(k, p) = (4, 2)$ to $(6, 2)$. As the value size increases, the overheads become negligible. Second, `Cocytus`'s memory usage is the lowest with 64 B values but rises as the value size increases, showing that its memory allocator produces "holes" in the stripes and wastes memory: as value sizes increase, metadata overheads become negligible, and the wastes start to manifest. Third, `Repl` consumes 1.23× to 2.35× memory compared with Nostor. With the performance similarity of Nostor and `Repl` in mind, we believe Nostor offers a favorable performance-storage tradeoff over replication. Finally, even if we continuously apply a skewed (Zipfian-0.99) write-intensive workload to Nostor, its memory usage still keeps stable. This shows that Nostor can digest object deltas fast enough and avoid bloating its memory usage.

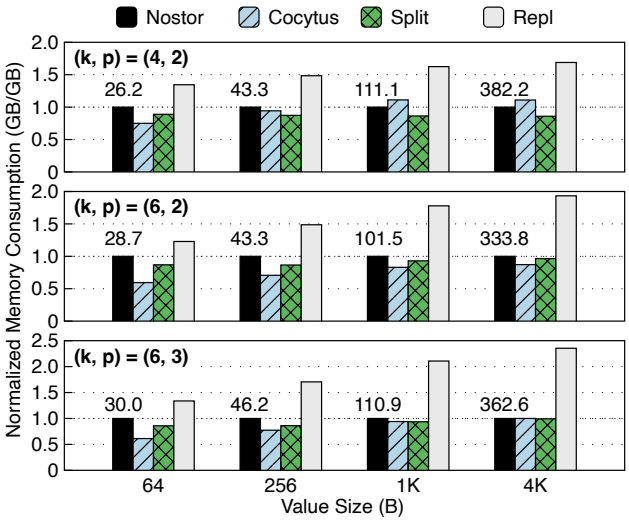

Figure 12: Normalized memory consumption.

In §6.2.5 we discussed slowdown-tolerant variants of the baselines, namely `Cocytus+`, `Repl+`, and `Split+`. Here, we discuss a bit more about their memory consumption. Compared to Nostor, `Cocytus+` consumes 30.9% less to 35.1% more memory. Its relative memory usage increases as the object size grows, consistent to our observation of `Cocytus` above. `Split+` consumes 9.4% less to 57.4% more memory. In contrast to `Cocytus+`, its relative memory usage decreases as the object size grows. The reason is that the amount of memory to store parity chunks' positions are constant, which becomes less significant when objects grows larger.

7 Related Work

Block designs and codes. Block design is a combinatorics concept with a long history dating back to the mid-19th century; the SBIBD used in this paper is a special kind of block design. In the 1950s, it became clear that block designs are strongly related to erasure coding and error-correcting codes (ECCs) [3, 35, 38]. For example, $(7,3,1)$-SBIBD corresponds to the well-known 7-bit Hamming code with 4 data bits and 3 parity bits. Other block designs can also be used to design codes like the Low-Density Parity-Check (LDPC) code [2].

While block designs have been used in the design of coding schemes since decades ago, their usage is still limited to conventional stripe-based codes. These coding schemes are unfit for new high-speed storage systems. To our knowledge, Nos is the first to use the block design theory to construct an erasure coding scheme without stripes.

Erasure coding for in-memory storage systems. There have been many efforts to apply erasure coding to in-memory storage systems. Some are similar to Nostor in that they ensure all returned writes are fault-tolerant. Cocytus [6] pre-allocates large empty stripes and allocates objects of different sizes within the chunks, which is shown to be inefficient. RE-Store [28] combines replication and erasure coding by replicating each object into two copies to reduce one parity. Though faster in recovery, this approach suffers from both replication's high memory consumption and erasure coding's computation overheads. EC-Cache [36] encodes each object into a stripe by splitting them into chunks. It mainly targets load balance in a system atop the relatively slow TCP/IP network, but falls short in performance-critical scenarios atop the fast RDMA network.

Other systems do not offer the contract that returned writes are committed. BCStore [27] buffers writes at clients until there is enough data to form a stripe, risking the loss of buffered data. Hydra [25] and Carbink [56] assume the far memory model, i.e., only one process running on a single node can access the storage system. Therefore, they do not need to encode data on the same node as the process. However, all data is immediately lost if that node or process fails.

Different encode methods. Erasure coding schemes mainly fall into two categories according to their methods of encoding data: matrix multiplication [17, 18, 20, 29, 37, 46] and XOR [14, 33, 34, 38]. In §6, we have shown with `Cocytus` and `PQ` that the encode method does not greatly affect the performance; instead, the write path design does.

From replication to erasure coding. Nos consists of a synchronous replication phase and an asynchronous coding phase. Many existing systems adopt similar ideas, including f4 [31], HDFS [43], HACFS [52], and RCStor [39]. In these systems, objects are first stored in a replicated storage pool and then moved to an erasure-coded pool in the background. Nos's approach differs from theirs in that it only has one storage pool and encodes object replicas directly into parities. This avoids the movement of the objects' primary copies and reduces the complexity of the entire storage system.

8 Conclusion

This paper proposes Nos, a stripeless data placement scheme for erasure-coded storage systems. It enables failure recovery by selecting backup nodes for objects according to a combinatoric structure called SBIBD. Atop of Nos, we build Nostor, a fault-tolerant distributed in-memory key-value store, to demonstrate the effectiveness of Nos. Evaluations show that Nostor outperforms existing erasure-coded systems on throughput and write latency.

Acknowledgment

We sincerely thank our shepherd for helping us improve the paper. We are also grateful to all reviewers of this paper for their helpful comments and feedback. This work is supported by the National Natural Science Foundation of China (Grant No. U22B2023). This work would not have been possible without the guidance of Prof. Yuchun Ma, who teaches Combinatorics at Tsinghua University with great dedication.

A Artifact Appendix

Abstract

The artifact consists of the Rust code of Nostor and baseline systems used in evaluation, runner scripts to validate their functionalities and reproduce the experiments, and related description files. It is intended for validating the claims made in the paper and facilitating further research on stripeless data placement in erasure-coded storage.

Scope

At a high level, the artifact allows its users to validate the following claims in the paper:

- Nostor outperforms stripe-based erasure-coded storage systems in terms of common-case performance.
- Nostor performs similarly with `Repl` (replication) with significantly less memory consumption.
- Nostor can recover from client failures.

These claims correspond to the questions raised at the start of the Evaluation section (§6).

The main purpose of the artifact is to validate the claims above. Aside from that, since the artifact contains full implementations of Nostor and baselines, it can be used as a starting point for further research on erasure coding and distributed in-memory storage systems.

Contents

The artifact contains source code, scripts, and other necessary components. Below, we explain the contents aside from the README. More detailed descriptions can be found in `HOWTOUSE.md` in the artifact repository.

Source code. The `nos` directory contains the source code of Nostor and baseline system servers. The `nos-cli` directory contains the source code of the client. Nostor's implementation is in `nos/src/objstore`, while the baseline systems are in `nos/src/bin`. Experiment infrastructure is in `nos-cli/src/runners`.

Scripts. The `scripts` directory contains runner scripts for running experiments and plotter scripts for visualizing the results. Scripts for validating the functionalities (i.e., AE scripts) are in the `ae-functional` subdirectory. Other scripts serve as building blocks of the AE scripts, such as running a single experiment. The configuration files used by the scripts are in the `config` directory.

Other components. The `trace-preprocess` directory contains the preprocessor for Twitter's Twemcache trace. For the real trace files, please refer to Twitter's original repository. After being processed, the traces can be consumed and replayed by the clients. The `rrppcc` directory contains the RPC engine implementation. The `data` directory contains the original data. Other directories and files are miscellaneous components, e.g., C library bindings and documentation.

Hosting

Nostor's artifact repository is hosted on GitHub at https://github.com/IcicleF/Nos on the `master` branch. The first usable commit version is the initial commit (`f6f9741`). However, due to possible future bugfixes and updates, please always use the latest commit.

Requirements

To reproduce the experiments, the testbed must have:

- At least 16 Linux servers with Internet access
- One server has password-less SSH access to all servers
- RDMA network + Mellanox ConnectX-5 or newer RNICs
- CPUs with AVX-2 support
- DOCA-OFED, which can be downloaded here
- Rust 1.86 or newer
- Intel ISA-L 2.31.1 or newer

Fewer servers or less advanced RNICs can be used if the user only wants to verify Nostor's functionalities. For detailed instructions, please refer to the README file in the artifact repository.

Abstract

Storage systems must maintain integrity even after rare and difficult-to-test-for conditions like power losses and media errors. Formal verification presents a promising avenue to ensure storage systems are resilient, but current approaches involve significant complexity and rely on verification constructs or forms of logic beyond what most verifiers natively support. In this paper, we present two new verification techniques that rely only on standard constructs provided by most verification tools such as Hoare logic, ghost variables, and quantifiers. First, we introduce PoWER (Preconditions on Writes Enforcing Recoverability), a novel approach to verifying crash consistency that encodes its requirements in the preconditions of storage API methods. Second, we present a new model of media corruption for provable corruption detection on any type of storage device. To demonstrate the power of these new techniques, we use them to build two verified storage systems using two different verification frameworks. We build and verify the key-value (KV) store CapybaraKV using Verus and the notary server CapybaraNS using Dafny. Both systems are built for persistent memory (PM), which we target due to new challenges it presents to building resilient storage systems. We develop new techniques to address these challenges, including the *corruption-detecting Boolean*, a new primitive for atomic checksum updates. Both systems verify in under a minute, and CapybaraKV achieves performance competitive with similar unverified PM KV stores.

1 Introduction

Storage systems must preserve the integrity of stored data even if rare events like power losses or media errors occur. However, ensuring that systems are crash consistent and can detect corruption is difficult. There has been extensive prior work on testing storage systems for these properties, but testing cannot guarantee the absence of bugs [14, 18–20, 35, 36, 44, 46–48, 50, 52, 69]. Program verification offers a promising alternative: use machine-checked proofs to ensure resiliency and correctness properties [1, 7, 9, 21, 22, 38, 57].

However, verifying that storage systems are crash-consistent and corruption-resistant is challenging for three reasons. First, verifying crash consistency requires specialized tools that exacerbate the learning curve for verification. Second, prior work on provably detecting corruption makes strong assumptions about data layouts that are not compatible with all systems [21]. Third, verified storage systems have not been able to achieve state-of-the-art performance thus far [7–9, 21, 57]. As a result, mainstream adoption of verification for storage systems has been low.

In this paper, we present a novel approach for verifying that storage systems (1) are crash-consistent and (2) can provably detect corruption. Our approach is tool-agnostic: it only relies on Hoare logic [17, 25], ghost variables, and quantifiers, features supported by most verification tools. This enables us to implement our approach in existing verification tools, such as Dafny [45] and Verus [43], without changing the tools themselves. Our model of corruption enables provable corruption detection without imposing restrictions on data placement.

To demonstrate our approach, we build two verified storage systems, a key-value store and a notary service, using two different verification frameworks. We show that the key-value store achieves performance competitive with similar unverified systems.

Verifying crash consistency. A key challenge when verifying crash consistency is reasoning about *intermediate system states* that may occur when an operation is interrupted by a crash [9]. This is difficult because Hoare logic [17, 25], the basis of most verification tools, trades the ability to describe these intermediate states for efficient modular verification. In Hoare logic, a function is specified by preconditions that must hold when it is invoked and postconditions that must hold when it completes. Its internal behavior is otherwise unconstrained.

Prior verified storage systems have introduced new frameworks and features, beyond what standard verifiers support, to facilitate reasoning about intermediate states. For example, the FSCQ file system extends Hoare logic with *crash conditions*, predicates about intermediate disk states of a function [9], in the Rocq proof assistant [11]. The VeriBetrKV key-value store adds TLA-style [41] reasoning to Dafny [45] to support *state machine refinement* proofs about crash behaviors [21]. These approaches, while powerful, all have a steep learning curve and are tied to certain verification tools.

We introduce PoWER (Preconditions on Writes Enforcing Recoverability), a new approach to reasoning about storage system crashes that, unlike prior work, relies only on standard

constructs provided by most verification tools. The key insight behind PoWER is that new forms of logic or TLA-style reasoning are not required to reason about crashes; we can instead add a precondition to methods that perform durable updates stating that all resulting crash states must be legal. This can be done with Hoare logic and quantifiers, which are supported by most verification tools. In PoWER, when developers call the write API, they are required to supply a proof that satisfies the precondition that the write will always leave the storage system in a crash-consistent state.

The need to write such proofs may seem daunting, but we show how it can be greatly simplified by turning common intuitions used by storage systems developers into a set of proof strategies based on system domain knowledge. These strategies are based on the insight that most crash-consistency proofs can be discharged only by reasoning about the *location* of the write, not its contents or specific crash states. For example, if a write only modifies bytes that are logically unreachable, it is clear that the write will not cause inconsistency.

PoWER does not sacrifice soundness for flexibility. We prove that its guarantees correspond to crash conditions in Crash Hoare logic [9] and to crash invariants in Perennial [6] using machine-checked proofs.

Verifying corruption detection. Many storage systems use cyclic redundancy checks (CRCs) to detect bit corruption due to media errors [4, 16, 21, 66, 67]. As with crash consistency, developers of verified systems must determine the expected model of corruption and CRC properties upon which to base their proofs. The only verified storage system supporting corruption detection, VeriBetrKV [21], assumes that the checksum is embedded with the data, and that both are updated atomically. This is not true of many real-world storage systems [58] (especially on byte-addressable memories), thus limiting its adoption.

We present a new model of data corruption based on the theoretical properties of CRCs and provide libraries and functions for developers writing verified corruption-detecting systems. Our model imposes no restrictions on where data and its checksum are stored and does not require them to be atomically updated together.

Verified systems. To demonstrate PoWER and our corruption model, we build two verified persistent memory (PM) storage systems: CapybaraKV, a key-value store written in Verus [43], and CapybaraNS, a notary service written in Dafny [45]. PoWER and our CRC model are not restricted to PM; we target PM because it presents novel crash-consistency and corruption-detection challenges not encountered with traditional storage.

One such challenge is that PM's fine-grained atomic write size (8 bytes) [64] makes it impossible to atomically update CRCs with data using standard techniques, which were developed for storage devices with much larger access granularity. We develop a new primitive, the *corruption-detecting Boolean* (CDB), to support provably crash-atomic CRC updates. We use CDBs in both CapybaraKV and CapybaraNS and find that they simplify many crash-consistency proofs.

To illustrate that PoWER is compatible with coarse-grained concurrency (if used with a tool like Verus or Perennial that supports concurrency), we extend CapybaraKV to support two forms of concurrency. One extension uses a reader-writer lock to permit concurrent readers or a single writer at a time, and another extension uses sharding to permit concurrent writers to keys falling in different shards.

We focus our evaluation on CapybaraKV and find that it achieves competitive performance with state-of-the-art unverified PM KV stores, outperforming them on many benchmarks. CapybaraKV is designed for an Azure Storage system that uses battery-backed DRAM, and has been integrated with a prototype Rust version of that system.

Our proposed approaches and systems have several limitations. First, PoWER relies on features that are present in most, but not all, verifiers. Highly-automated tools like Yggdrasil [57] and TPot [5] have limited support for quantifiers, which makes them incompatible with PoWER. Second, while PoWER can be used to verify concurrent systems like those discussed above, it does not support arbitrary fine-grained concurrency involving concurrent writes to the same storage region. Finally, as with all verified systems, the correctness of CapybaraKV and CapybaraNS depends on the correctness of their specifications and of the verifiers and compilers themselves.

In summary, this work makes the following contributions:

1. PoWER, a tool-agnostic way to verify crash consistency (§3.1);
2. A set of proof strategies and library functions to simplify crash-consistency proofs based on domain knowledge and natural intuitions about storage systems (§3.3);
3. A flexible and sound model of data corruption that facilitates proofs about the absence of corruption (§4.1);
4. The corruption-detecting Boolean, a useful new primitive for reasoning about CRC updates on persistent memory (§4.2); and
5. CapybaraKV and CapybaraNS, two new verified storage systems in different languages that demonstrate our new methods (§5).

2 Background and related work

In this section, we discuss how existing approaches establish crash consistency and corruption detection to motivate the need for our improved approaches.

2.1 Identification of storage system bugs

Crash-consistency and corruption-detection bugs impact even the most mature storage systems. Prior work on crash-consistency testing tools [36, 48, 52, 69] has found many previously undiscovered bugs in these systems.

Persistent memory (PM). Persistent memory devices provide byte-addressable durable storage at near-DRAM latencies [31, 68]. PM is generally mapped into an application or storage system's address space and accessed via memory load and store instructions [54, 64]. Unlike block devices, PM uses fine-grained atomic writes (8 aligned bytes [64]), and updates must be explicitly flushed from volatile CPU caches to ensure persistence. Recent research on PM storage systems has shown that they are prone to subtle crash-consistency bugs [14, 18–20, 35, 44, 46, 47, 50]. These bugs arise due to both PM's complex low-level interface and higher-level issues in new PM-specific design patterns.

Although PM is not yet widely deployed, cloud services like Azure Storage already use PM in production [40]. A variety of PM-related hardware offerings are currently in development [15, 24, 37, 63] and the CXL.mem protocol is expected to support PM [2].

2.2 Formal verification of crash consistency

Software verification tools are best suited for verifying properties encodable with Hoare logic [17,25], and crash consistency does not seem to fit this mold. In Hoare logic, one writes specifications for functions in the form of preconditions, which must be true when the functions are invoked, and postconditions, which must be true when the functions complete. However, crashes may occur partway through function execution, and Hoare logic does not let a developer directly specify conditions that must hold throughout the body of each function. For this reason, there has been much research proposing specialized methodologies for proving crash consistency.

Crash Hoare logic. Crash Hoare logic (CHL) is used by FSCQ [9], an xv6-like file system implemented and verified in Rocq [11]. CHL extends traditional Hoare reasoning with *crash conditions* that describe system state in the event of a crash. CHL's support for crash conditions is based on separation logic [53], which enables describing disjoint resources (e.g., different parts of a disk) with separate predicates. CHL is currently only supported by Rocq-based verification tools, which have a steep learning curve. Furthermore, Rocq programs can only be run by first extracting them to Haskell or OCaml, which limits their run-time performance.

CHL requires built-in language support or the ability to perform meta-level reasoning about the language's own semantics. Languages like Verus and Dafny would require a substantial overhaul, including changes to the core language, to support CHL. Indeed, some of us are part of the Verus development team, which has no plans to support CHL because it would require significant effort and would only be used by a small subset of users.

In contrast, PoWER can be used with any verifier that supports standard Hoare logic, ghost variables, and quantifiers, including verifiers like Verus [43] that produce fast code. Furthermore, we believe that PoWER would remain a valuable contribution even in the unlikely event that CHL support were added to Verus, because it could be used with *any* verification tool.

Crash invariants. GoJournal [7] and other systems built on top of Perennial [6] reason about crash safety as a form of concurrency, where a crash causes existing threads to stop executing and a new recovery thread to start executing. In particular, Perennial formalizes crash reasoning using *crash invariants* [6, §5.1], which are built on top of *atomic invariants*. Atomic invariants are properties that are verified to hold at the end of every atomic execution step. Many frameworks for verifying concurrent software (including Iris [33] and Verus) support such atomic invariants, but tools that do not handle concurrency (such as Dafny [45], Prusti [65], and Creusot [13]) lack this support. PoWER can thus be used even with tools that lack support for atomic invariants.

PoWER is also useful with tools that *do* support atomic invariants, but which make it cumbersome to directly state Perennial's logically atomic crash specifications [7, §6.2], such as Verus. Parts of the code requiring concurrency reasoning must use atomic invariants, but other code only needs to reason about PoWER specifications and can thus avoid the complexity of logically atomic crash specifications. (See §3.4 and §5.1.2.)

State machine refinement. State machine refinement was originally developed for verification of distributed systems in the IronFleet project [22]. VeriBetrKV [21] applies the technique to verify a key-value store based on the intuition that storage software interacting with a disk is similar to unreliable nodes interacting in a distributed system. Anvil [59] uses it to verify liveness properties of cluster management controllers. In these systems, each component (e.g., a single node, or a storage system journal) is modeled as a state machine and proven correct in isolation using Hoare logic assuming a synchronous and crash-free environment. Components are then proven correct via a series of state machine refinement proofs using TLA-style reasoning, which can also prove properties related to asynchrony, crash consistency, and liveness. IronFleet and VeriBetrKV are implemented and verified in Dafny with custom-built libraries for TLA-style reasoning.

These proofs require additional infrastructure on top of a TLA library. They are also labor intensive, since developers need to reason about low-level sequences of steps and write refinement proofs. In contrast, our techniques do not require additional infrastructure or separate refinement proofs, and let developers reason about their systems at a higher level.

Push-button verification. Push-button verification [51]

trades expressivity for the ability to verify code without writing any proofs. Crash refinement [57] is a technique for push-button crash-consistency verification in which the developer specifies a (finite) set of all possible crash schedules and requires that all executions obey the specification. This significantly reduces annotation and proof burden but is limited to simple, bounded systems. Other highly-automated verification techniques, such as the approach taken in TPot [5], have not been applied to storage verification.

Summary of comparisons. In contrast to the above, PoWER relies only on standard verification constructs, letting developers use whatever verification tool they feel is best suited for their project. Indeed, based on the recent influx of Rust-based verification tools, we expect that future improvements in verification tooling may come in the form of new languages and verifiers. Techniques that require developers to build complex frameworks or rely on specific language features will be less useful than approaches like PoWER.

2.3 Formal verification of corruption detection

VeriBetrKV [21] formally reasons about the use of checksums for corruption detection. However, its corruption-detection axiom strongly dictates how data must be checksummed and where the checksum must be stored. VeriBetrKV does not allow checksumming data across blocks, and precludes storing the checksum separately from the data. As we discuss in §4.1, this is overly restrictive for the systems we target. In contrast, our proposed model imposes no limitations on what data is checksummed or on where the checksum and data are stored. Moreover, it is difficult to determine what actual constraints VeriBetrKV's axiom implies for the underlying storage device, and whether it is sound, in contrast to our axioms that reason about the number of corrupted bits that CRC algorithms are designed to detect.

3 Verifying crash consistency using PoWER

This section discusses our novel, tool-agnostic technique PoWER for verifying crash consistency in storage systems. Unlike prior work, it can be used to concisely verify crash consistency with only basic verifier features.

3.1 PoWER

Our main contribution is Preconditions on Writes Enforcing Recoverability (PoWER), a way to verify crash consistency based on standard Hoare logic. This is challenging because while most verification tools let one specify what a method must satisfy upon completion (postconditions), one cannot generally specify what must be true *throughout* a method's execution, and crashes can happen at any point.

Overall idea. The idea behind PoWER is to give a method that performs durable updates a storage handle with a special API that ensures storage is always in a consistent, recoverable state. To do this, we add a single precondition to the API's write method, which requires all new crash states introduced by the write to be crash consistent.

```
1  pub exec fn write(&mut self, addr: u64,
2      bytes: &[u8], perm: Tracked<&Perm>)
3    requires
4      addr + bytes@.len() <= old(self)@.len(),
5      forall |s| can_result_from_partial_write(
6          s, old(self).durable_state,
7          addr as int, bytes@)
8        ==> perm@.permits(s),
9    ensures
10     self@.can_result_from_write(old(self)@,
11       addr as int, bytes@)
```

Listing 1: A simplified signature of an asynchronous `write` method used with PoWER in Verus

This is possible because one can describe all new crash states introduced by a write *before* it is invoked, even though asynchronous partial completion of those writes can occur at any time. By adding a precondition to the write method that forces the developer to reason about all such resulting crash states, we can ensure the developer cannot introduce crash-consistency bugs.

Modifying the API this way ensures correctness with no performance cost because all annotations involved in ensuring preconditions on writes are erased at compile time. The compiler generates an executable equivalent to what would exist with the standard, non-PoWER API.

The PoWER API. A standard storage API includes three main methods: `read`, which returns the most recently written bytes at a given address; `write`, which starts an asynchronous write but does not necessarily make it immediately durable; and `flush`, which ensures prior writes are durable. Their standard preconditions check properties like in-bounds addresses.

Listing 1 shows a simplified specification of a `write` method in the PoWER API in Verus. The `requires` clause specifies preconditions and the `ensures` clause specifies postconditions. `old(x)` is the contents of mutable reference `x` upon method invocation. `x@` is shorthand for `x.view()` and represents an abstraction of `x` (e.g., the current state of a storage device including outstanding writes). The new precondition introduced by PoWER is on lines 5–8; it requires that all newly introduced potential crash states are permitted. In Verus, we express the set of permitted states with an unforgeable ghost (i.e., erased by the compiler) permission token `perm`. The set of newly introduced potential crash states is defined by the storage model, which accounts for device properties like atomic write granularity and alignment; we now discuss that model.

Storage model. The storage model we use is based on the prophecy-based asynchronous disk model [62] used in Perennial [6,7]. This model eases reasoning about crashes by letting

```
pub struct PersistentMemoryRegionView { pub read_state: Seq<u8>, pub durable_state: Seq<u8> }

pub open spec fn chunk_corresponds(s1: Seq<u8>, s2: Seq<u8>, chunk: int) -> bool {
  forall |i: int| 0 <= i < s1.len() && i / chunk_size() == chunk ==> s1[i] == s2[i]
}
pub open spec fn can_result_from_partial_write(
  post: Seq<u8>, pre: Seq<u8>, addr: int, bytes: Seq<u8>) -> bool
{
  post.len() == pre.len() && forall |chunk| {
     ||| chunk_corresponds(post, pre, chunk)
     ||| chunk_corresponds(post, update_bytes(pre, addr, bytes), chunk)
}}
impl PersistentMemoryRegionView {
  pub open spec fn can_result_from_write(self, pre: Self, addr: int, bytes: Seq<u8>) -> bool {
    &&& self.read_state == update_bytes(pre.read_state, addr, bytes)
    &&& can_result_from_partial_write(self.durable_state, pre.durable_state, addr, bytes)
}}
```

Listing 2: Part of the specification used by the prophecy-based asynchronous storage model in Verus

proof code reason about possible future system states, akin to prophecy variables used in some refinement proofs [34, 42]. The Perennial authors have proven, in Rocq, that any system proven correct using the prophecy model is also correct using a natural model that cannot see the future [61]. We have also formally proven the soundness of our prophecy-based model by building it as a library atop a similar natural non-prophecy model, leveraging support for prophecy variables in Verus.

To explain the prophecy model, we first describe the natural model. Storage is divided into chunks with size equal to the atomic persistence granularity of the device. For instance, persistent memory uses a granularity of 8 bytes, while hard drives generally use 512 B or 4 KiB sectors. A read returns the last-written contents, even if the asynchronous writes that wrote them are still outstanding and may never become durable. A flush completes all outstanding writes. On a crash, each outstanding write operation is divided into chunk-granularity subwrites and some of the subwrites are durably performed. This model is tricky to reason about because the state includes both a current readable state and a set of outstanding writes.

The prophecy model, given in Verus in Listing 2, is simpler in that the state consists of only two byte sequences: the read state and the durable state (line 1). The read state reflects all writes performed so far, including outstanding updates that may be lost in a crash. The durable state reflects all subwrites performed so far that will *eventually* become durable, due to either a subsequent flush or a crash that will nondeterministically choose to render them durable.

A write operation applies the entire write to the read state and a nondeterministically chosen subset of chunk-granularity subwrites to the durable state. This is shown in Listing 2, with `can_result_from_write` (lines 13–15) specifying the possible prophesized results of a given write operation.

The flush operation's postcondition says that the read state matches the durable state, and that neither of these is changed by the flush. That is, the durable state does not *become* the read state as a result of the flush; rather, the flush confirms that the prophesized durable state matches the read state. The intuition for why this is valid is that when reasoning about instructions past a flush, one need not consider possible branching timelines in which some subwrites were lost.

We switched from the natural model to the prophecy model partway through development of CapybaraKV and found that it made proving crash consistency much simpler. One must still reason, when calling a PoWER `write`, about all the possible new crash states the write can introduce. But after the write, thanks to the prophecy model, one need only reason about the single prophesized resulting durable state.

Specifying prophecy variables in a storage model requires the use of ghost variables, which are a feature of most verification tools including Dafny and Verus. Ghost variables can contain information known at verification time even if it cannot necessarily be known during execution, which is what makes them a standard tool for prophecy variables.

Specifying crash-consistent states. PoWER, like all crash-consistency specifications [7, 9], requires that the specification writer formally specify the set of crash-consistent states. In theory, the developer may define this set however they like. We suggest the following approach, exemplified by Listing 3 which shows a simplified signature for a synchronous, crash-atomic append operation in an append-only log. Have the code define a recovery function `rec` that maps a sequence of bytes to an abstract state. Then, make the set of crash-consistent states be the union of two sets: (1) the set of states abstractly equivalent to the initial state, and (2) the set of states permitted by the postcondition. In other words, when crashing mid-operation, the code may either atomically execute that operation or do nothing.

Specifying crash-consistent transitions. Another way to specify crash-consistency properties is to specify a set of

```
pub exec fn log_append(&mut self, ps: &mut PoWERStorage, bytes: &[u8], perm: Tracked<&Perm>)
  requires forall |s| Self::rec(s) == Self::rec(old(ps)@) || Self::rec(s) == Self::rec(old(ps)@) + bytes@
    ==> perm@.permits(s),
  ensures Self::rec(ps@) == Self::rec(old(ps)@) + bytes@,
```

Listing 3: Signature for a log-append method that enforces crash consistency with PoWER

```
pub exec fn log_append(&mut self, ps: &mut PoWERStorage, bytes: &[u8], perm: Tracked<Perm>)
  requires forall |s1, s2| Self::rec(s2) == Self::rec(s1) + bytes@ ==> perm@.permits_transition(s1, s2),
  ensures Self::rec(ps@) == Self::rec(old(ps)@) + bytes@,
```

Listing 4: Signature for a log-append method that uses a single-use PoWER permission permitting a transition

legal *transitions* between crash states. That is, a permission can express not a set of legal crash states but a set of legal *pairs* of states (s_1, s_2). If the current durable state is s_1 then it permits introducing new crash state s_2.

A useful case of this is a permission to transition from any s_1 to s_2 if they both recover to the same abstract state. Another case is that for a mutating operation, one can grant permission to transition from s_1 to s_2 if s_2 recovers to a state that matches s_1 except that the operation has been performed. Listing 4 shows an example of this use.

Blanket vs. single-use permissions. Some scenarios call for a *blanket* permission, i.e., a permission that can be used repeatedly. A key case of this is permission to transition between recovery-equivalent states. Such permission can be granted to the system when it starts, so that it can make such transitions throughout its lifetime. This simplifies the specification by reducing the number of permissions that must be granted. Other scenarios call for *single-use* permissions. A key case of this is permission to perform a transition corresponding to a state-mutating operation that should only happen once.

Single-use permissions are straightforward to implement, by having a `write` operation consume or otherwise invalidate any single-use permission passed to it. In such an implementation, a blanket permission is a factory that can generate an arbitrary number of single-use permissions.

Statically partitioning into multiple PoWER regions. For some systems, it is convenient to statically partition storage into multiple parts, each with its own PoWER handle. We call each such part a *region*. Such partitioning can be done by using multiple physical or virtual devices, or by treating each file in a file system as a separate region. This modularizes reasoning about storage state since each region becomes a separate object with its own crash constraints and permissions.

3.2 Correspondence to other approaches

To demonstrate the soundness of the PoWER approach for specifying crash consistency, we use mechanically-checked proofs to show correspondence to two other approaches: CHL and crash invariants. These are among the current state of the art for verified storage systems, but require additional verifier features beyond Hoare logic and are thus not tool-agnostic.

Correspondence to Crash Hoare logic. To validate the soundness of our PoWER specification approach, we produce a mechanically-checked Rocq proof of its correspondence to CHL. We prove that any code satisfying a PoWER specification satisfies a corresponding CHL specification, encoded as a *crash weakest precondition* (WPC) in Perennial, whose crash condition states that, if the system crashes, the storage will satisfy the recoverability predicate. The details of this theorem statement, along with the proof, are available as part of this paper's artifact, described in §A.

Since we have not implemented PoWER in Rocq, this proof is metalogical and depends on a trusted translation of PoWER semantics into Rocq. This translation is fairly natural, so we feel confident in the correctness of this proof.

Correspondence to crash invariants. Crash consistency can also be specified using crash invariants, as in Perennial [6]. We prove that satisfying a PoWER specification implies the satisfaction of a crash invariant, in two steps. First, we implement the PoWER interface in Verus as a verified library on top of a lower-level interface that reasons about crash consistency using crash invariants. Second, we prove that, if an application adheres to the PoWER API, it implies that the PoWER library maintains a corresponding crash invariant on behalf of the application. We can do this because crash invariants can be built on top of atomic invariants, an advanced feature of some verification tools including Verus but not Dafny, Prusti [65], or Creusot [13]. Since both the PoWER interface and the invariant-based specification are in Verus, this proof is entirely machine-checked (unlike the CHL proof mentioned above). The details of this correspondence are available as part of this paper's artifact, described in §A.

3.3 Strategies for satisfying preconditions

We next discuss how a developer can prove their code matches a PoWER specification. The challenge is proving, immediately before each `write`, that all new crash states that can result from partial application of the write are permitted. In this subsection, we describe four design patterns that simplify this reasoning, and libraries we provide that make it easy to apply them. We classify durable updates into four categories—tentative, committing, recovery, and in-place—and provide

strategies to prove the crash consistency of each category.

Tentative writes. We call a write *tentative* if it has no effect on the abstract system state until some subsequent write happens. Tentative writes generally modify data at addresses that are unreachable during recovery (e.g., inodes unreachable from a file system's root), and do not change system state regardless of which subwrites become durable. Their contents only become relevant after a subsequent, non-tentative write (e.g., storing a reachable pointer to the address).

The developer need not prove anything about the specific bytes in a tentative write to prove crash consistency. They must only prove that the addresses modified by the write are unreachable during recovery. We provide lemmas in our Verus and Dafny libraries (see Listing 5 for the Dafny version) that the developer can call to satisfy the precondition of the PoWER API.

Committing writes. We call a write *committing* if it changes the abstract state of the system using a single crash-atomic write. For example, such a write might update a pointer that causes a tree of objects on storage to become reachable by the recovery function. A committing write is typically done after a flush to ensure that a crash does not cause the state to be invalid due to lost tentative writes.

For committing writes, the developer only needs to reason about two possible crash states: the states that result from the committing write being dropped or applied. We provide, in our library, a lemma that ensures that for a committing write there are only these two possible crash states.

Recovery writes. *Recovery writes* are writes done as part of a recovery procedure (e.g., replaying a journal). Such writes are not tentative, as they can change the abstract view, and they are not committing, as they may not match the atomic write granularity. To prove that such writes are crash consistent, a developer must prove that they only modify bytes that will be written to by a completed recovery procedure, and that recovery is idempotent. If the system crashes while recovering from an earlier crash, all modifications made during the first recovery will be overwritten by the second recovery, ensuring that any torn writes are fixed when recovery completes.

We have written a generic redo journal component in Verus. Internally, this journal must reason about intermediate crash states, but the user of the journal component (e.g., CAPYBARAKV) does not have to. The user just logs updates and eventually atomically commits (or aborts) the updates gathered in the log. The journal takes care of installing journaled operations on commit or when replaying its log after a crash.

In-place writes. *In-place writes* non-atomically modify user-visible state and can change the abstract state of the system. They thus leave the system in a nondeterministic abstract state. This may be reasonable for systems that provide weak crash-consistency guarantees, e.g., a file system that lets a read see a write that is then lost by a crash. Such a specification would permit a large set of possible crash states, so in-place writes could more easily be proven to produce states in that set.

We have not yet had experience verifying storage systems with weakly crash-consistent semantics, so we currently have no support in our libraries for reasoning about in-place writes. A developer of such a system would have to directly prove the PoWER preconditions.

3.4 Extending PoWER to concurrent contexts

So far, we have described how PoWER can verify non-concurrent storage systems, building on Hoare logic. Some verification tools have additional features for concurrency reasoning, and while PoWER does not require such features, it can leverage them to reason about some forms of concurrency.

PoWER can easily support systems that issue concurrent reads to storage, such as an implementation that uses a reader-writer lock to protect access. PoWER supports this pattern because it only adds a precondition for write operations and does not change how reads are done.

PoWER can also support systems that concurrently issue reads and writes to multiple statically allocated storage regions, as long as there is never read-write or write-write concurrency on a single such region. An example of this is a KV store sharded over multiple storage regions. To enable proving a linearizable specification for such a system, we introduce mechanisms to formally reason about the linearization order of operations across multiple storage regions. To do this, we extend PoWER to support Perennial-style reasoning about crash safety using atomic invariants, which are also supported in Verus. Specifically, we make the following two extensions to PoWER, which together we call *atomic PoWER*.

First, we introduce ghost state representing the durable state of persistent storage, based on Perennial's notion of durable resources. These durable resources can be owned by an atomic invariant, which enforces that some application-level recovery predicate always holds on the durable state (and in particular, this invariant can refer to the durable state of multiple storage regions), and therefore this invariant will be true when the system crashes and initiates recovery.

Second, we introduce the notion of a *completion* object returned when a write consumes a single-use permission. Logically, this captures the fact that a write matching the permission's `permits_transition()` was issued, and lets an application prove that its operation was applied to durable storage. For example, when an application invokes a KV store with a permission to create a new key, the KV store can return a completion proving that it wrote the key to storage, even if some concurrent thread has since deleted that key.

In atomic PoWER, permissions are no longer a trusted object but rather a verified wrapper around a Perennial-style proof (in Verus, a proof-mode callback) that opens the atomic invariant holding the durable resource and updates it when the write is applied. With this change, PoWER's API takes on the form of a *logically atomic crash specification* from

```
ghost predicate AddressesUnused<T>(s: seq<byte>, addrs: set<int>, rec: seq<byte> -> T) {
  forall s2: seq<byte> :: |s2| == |s| &&
    (forall i: int :: 0 <= i < |s| && i !in addrs ==> s[i] == s2[i]) ==> rec(s2) == rec(s)
}
lemma Lemma_TentativeWritePermitted<T>(ps: PoWERStorage, addrs: set<int>, rec: seq<byte> -> T,
                                       bytes: seq<byte>, start: int)
  requires forall s :: rec(s) == rec(ps.View().durableState) ==> s in ps.StatesPermitted()
  requires AddressesUnused(ps.View().durableState, addrs, rec)
  requires forall addr: int :: start <= addr < start + |bytes| ==> addr in addrs
  ensures  forall s :: CanResultFromPartialWrite(s, ps.View().durableState, start, bytes) ==>
           s in ps.StatesPermitted()
```

Listing 5: Dafny library lemma for proving that a tentative write satisfies the PoWER write API

Perennial [7, §6.2]. As a result, the application developer's job becomes to first state an atomic invariant about the durable ghost state, then to implement (perhaps using the library discussed in §3.2) permissions for any write operations they want to issue via a PoWER API. Intermediate layers between the top-level application atomic invariant and the low-level storage device are unaffected by these changes. For instance, we can reuse nearly all of CapybaraKV's single-threaded code for its concurrent variants because that reusable code satisfies a PoWER API and thus does not care how permissions it receives are implemented (see §5.1.2).

Limitations. The key limitation of PoWER's design, in terms of concurrency, is that it cannot reason about writes executing concurrently with other reads or writes to the same storage region. The constraint comes from the fact that the PoWER API requires the caller to logically know the current state of the region (`old(self)@` in Listing 1) at the time a `read` or `write` operation is issued. However, due to concurrent writes, the caller may not fully know that state.

4 Provably detecting corruption

Stored data may become corrupted over time due to media errors, so checking the integrity of data using cyclic redundancy checks (CRCs) is standard in many storage systems [4, 16, 66, 67]. A verified storage system should require that data read from the storage device is checked for corruption before it is used or returned to the user. In this section, we introduce a new model of media corruption, and a new corruption-resistant atomic primitive for persistent memory.

4.1 Modeling media corruption

To model possible data corruption, the postcondition of our `read` method specifies that the returned bytes may not match the last-written bytes, but rather are related to them via a `maybe_corrupted` predicate shown in Listing 6. The developer must perform a CRC check to prove that the returned bytes are uncorrupted before using them.

Our model of device corruption is as follows. The device has a corruption bitmask with one bit per storage bit. Where the bitmask is 0, reads return correct data. Where it is 1, reads return arbitrary bits, not necessarily the same on each read. The population count of the bitmask, i.e., the number of 1s, is bounded by a constant c that is opaque to the code to be verified. However, that code has access to a trusted fast CRC library [12] and an axiom stating that any two byte sequences with Hamming distance in $[1, c]$ have different CRCs. (For the ECMA variant of CRC-64 that we use, $c = 1$ for arbitrary-length data, i.e., it guarantees to catch any single-bit errors, but c can be higher for shorter lengths, such as $c = 3$ for data shorter than $\sim$1 GiB [39]. Our implementation currently does not take advantage of the higher c values for shorter lengths.) This means that, assuming c or fewer device bits are corrupted, the result of a CRC check on a given buffer definitively proves whether or not the buffer has been corrupted.

This model differs from VeriBetrKV's "corruption cannot produce a block with a valid checksum" [21]. Our model is more fundamental, describing the behavior of the media at a lower level. It is also more flexible, allowing the contents protected by a checksum to be noncontiguous and to not be in the same block as the checksum. This flexibility is required when building PM systems like CapybaraKV and CapybaraNS, as we discuss next.

4.2 Checking for PM corruption

Persistent memory presents new challenges for maintaining CRCs for corruption detection. Traditional storage systems often store a CRC of each block's contents within the block itself [58]. However, PM's finer write granularity (8 aligned bytes [64]) makes this technique crash-unsafe, as the hardware does not guarantee that the CRC will be written atomically with any non-trivial amount of data.

Prior work [44] on testing NOVA-Fortis [67], a corruption-resistant PM file system, shows that CRC management on PM is prone to crash consistency bugs. Furthermore, when trying to use and verify NOVA-Fortis's *Tick-Tock* algorithm for updating CRCs, we find it is not correct in either our model of corruption or VeriBetrKV's [21]. Tick-Tock maintains two

```
pub open spec fn maybe_corrupted(self, bytes: Seq<u8>, true_bytes: Seq<u8>, addrs: Seq<int>) -> bool {
  &&& bytes.len() == true_bytes.len() == addrs.len()
  &&& forall |i: int| 0 <= i < bytes.len()
    ==> exists |mask: u8| bytes[i] == (true_bytes[i] ^ (mask & self.corruption[addrs[i]]))
}
pub exec fn read(&self, addr: u64, num_bytes: u64) -> (bytes: Vec<u8>)
  requires self.inv(), addr + num_bytes <= self@.len(),
  ensures ({
    let true_bytes = self@.read_state.subrange(addr as int, addr + num_bytes);
    let addrs = Seq::<int>::new(true_bytes.len(), |i: int| i+addr);
    self.constants().maybe_corrupted(bytes@, true_bytes, addrs) })
```

Listing 6: Read method specification describing possible corruption of returned bytes

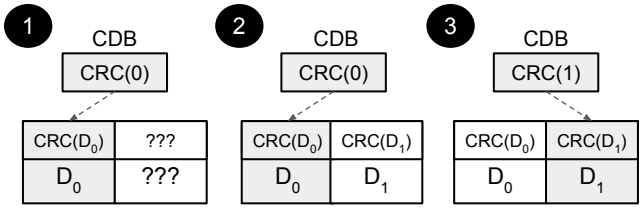

Figure 1: One way to use a CDB to atomically update a data structure and its CRC

copies (a primary and a replica) of each persistent data structure, each with its own CRC. To update the data structure, it updates the primary, then flushes, then updates the replica. On recovery, it uses whichever copy has a matching CRC, preferring the primary. However, CRC algorithms are designed to defend against media corruption in the form of a positive and bounded number of bit flips, not to distinguish between different user-level values. CRC collisions between such values, which can differ arbitrarily, are plausible (and indeed likely in scenarios where adversaries can manipulate values).

For example, suppose we begin updating a data structure with value D_0 to D_1. Tick-Tock writes D_1 and $\mathsf{CRC}(D_1)$ to the primary; suppose a crash occurs after D_1 becomes durable but before $\mathsf{CRC}(D_1)$ becomes durable, so the primary CRC remains $\mathsf{CRC}(D_0)$. Also suppose that the stored version of D_1 is corrupted into D_1' and that, by chance, $\mathsf{CRC}(D_0) = \mathsf{CRC}(D_1')$. Tick-Tock's primary CRC check will pass and it will not detect the corruption. This is plausible in both our and VeriBetrKV's models, since D_1' and D_0 may have an arbitrary number of bit differences.

To address this challenge, we propose the following new primitive that enables atomic updates on PM. The *corruption-detecting Boolean* (CDB) is an 8-byte integer that can only take on two specific values, one representing `false` and one representing `true`. These two values should be chosen carefully such that neither is likely to be corrupted into the other; we use $\mathsf{CRC}(0)$ and $\mathsf{CRC}(1)$. Since a CDB is 8 bytes, it can be written to PM atomically with respect to crashes. Since its valid values are statically known, it can be checked for corruption without needing to maintain a separate CRC.

Here is one way to use a CDB to implement an atomically mutable data structure D. Reserve space for an 8-byte CDB and two versions of D plus their CRCs. The CDB indicates which version is considered valid at recovery time. To update, tentatively write a new version and its CRC to the invalid location, then flush, then use a committing write to flip the CDB, then flush. Figure 1 illustrates this for the case where we start in step ❶ with D_0 as the valid version. In step ❷ we write the new version to D_1 and its CRC to $\mathsf{CRC}(D_1)$, then flush. In step ❸ we update the CDB to $\mathsf{CRC}(1)$ then flush. For the next update (not shown in the figure), we will go the other way: store the new version and CRC in D_0 and $\mathsf{CRC}(D_0)$, then flush, then update the CDB to $\mathsf{CRC}(0)$.

We find the CDB to be a useful primitive, and use it in several places in CapybaraKV and CapybaraNS to facilitate atomic updates. For instance, we use it in CapybaraNS to atomically update the counter and last hash, using the steps in Figure 1. To our knowledge, ours is the first proven-correct algorithm for atomic updates on PM with corruption detection.

5 Verified systems

To demonstrate our support for multiple verification tools, we implement CapybaraKV, the first verified PM key-value (KV) store, in Verus and CapybaraNS, the first verified persistent notary service, in Dafny.

5.1 CapybaraKV

CapybaraKV is an embedded PM key-value store with verified functional correctness, crash consistency, and corruption detection. It maps keys to values, where each value consists of an item and a list of elements. It is parameterized by key, item, and list-element types, with each of these types having a fixed size. It supports standard create, read, update, and delete operations on key-item pairs, as well as operations that update the list associated with a key. These list operations can append an element, trim a given number of elements from the front, or update the element at a given index. CapybaraKV supports crash-atomic transactions in which operations are visible immediately but not durable until committed.

Trait	Description	Generated code
`PmSafe`	Ensures safety of copying to storage	No methods; trivial `PmSafe` trait bounds on field types
`PmSized`	Ensures size known at verification time	Spec and exec `size_of` and `align_of` methods, and static assertions that their output matches compiler-generated type layout
`Clone`	Implements explicit copy method	Specification that copy equals original
`PartialEq`	Implements equality operator	Specification that operator is consistent with Verus equality

Table 1: Traits implemented by the `#[derive(PmCopy)]` macro in the `pmcopy` crate

Specification. Its abstract state is two maps from keys to values: the on-abort map and the on-commit map. The on-abort map represents what should result if an abort is requested or the system crashes. The on-commit map represents what should result if a commit completes. The abstract state's operations include abort, commit, create, read, update, delete, and various list-updating operations. The abort operation sets the on-commit state to the on-abort state, representing both the expected behavior if a transaction aborts or if the system crashes. The commit operation sets the on-abort state to the on-commit state, and every other operation affects only the on-commit state. In the event of a crash, the commit operation may either abort or commit the current transaction; all other pending operations must abort.

Implementation. CapybaraKV has four main durable components: a main table, an item table, a list-element table, and a journal. Each row in the main table contains a key, the address of the corresponding row in the item table, the address of the row in the list-element table containing the first list element, a CRC of the key, a CRC of the address fields, and a CDB (§4.2) indicating if the row is valid. Each row in the item table contains an item and its CRC. Each row in the list-element table contains a list element, the address of the next item in the list if any, and a CRC of each of these fields. An item row is considered valid if it is pointed to by a valid main table row. A list-element row is considered valid if it is pointed to by a valid main table row or list-element row.

CapybaraKV uses a physical redo journal. When a transaction is committed, we tentatively append a single CRC for all pending entries, then commit by updating a CDB. Log entries are replayed using recovery writes. Once all entries have been installed, we clear the journal. The journal is designed to be of general use beyond CapybaraKV.

New records are created in CapybaraKV by tentatively writing new main and item table entries to free rows, then journaling an update to the main table entry's CDB. Deletions only require journaling the invalidation of the target's CDB. CapybaraKV uses copy-on-write to update an existing item or list element, i.e., it allocates a new row in the appropriate table and journals an update to the row that points to it.

CapybaraKV also has a volatile index, implemented as a Rust `HashMap`, that maps all keys to their main table addresses. Each table also maintains a volatile free list used for allocation. These volatile structures are rebuilt at startup after log replay.

5.1.1 Safe reads and writes

In PM systems like CapybaraKV, PM's low access latency makes minimizing overhead essential. In particular, I/O latency can easily be eclipsed by software overheads, so many systems `memcpy` data structures between DRAM and PM with no serialization. However, such low-level operations risk crash safety and can lead to undefined behavior. For example, structures that contain references (e.g., file handles or virtual addresses) cannot safely be stored on PM, as a reference may be invalid after a crash. And, when reading stored data, we must ensure that data is placed in a properly laid-out buffer and checked for corruption before casting to a more useful data structure to avoid undefined behavior.

Unfortunately, these properties are difficult to verify because compiler-generated type and layout information is not available to verifiers. We tackle this issue by using the powerful Rust compiler to check properties that Verus cannot. We are inspired by Corundum [26], a Rust crate that uses various Rust language features to enforce safety properties in PM storage systems, and SquirrelFS [44], a PM file system with crash-consistency properties checked by the Rust compiler.

We have developed `pmcopy`, a trusted Rust crate that provides a macro to help developers check these crucial safety properties. It generates Verus ghost code to facilitate proofs that rely on type layout information and provides executable functions specified by this ghost code. It also adds compile-time assertions that are checked by the Rust compiler, not Verus, to check that axioms it synthesizes match compiler-generated information. CapybaraKV uses `pmcopy` to enforce safety properties about all durable data structures. We expect `pmcopy` will also be valuable in the development of other PM storage systems in Verus.

To use `pmcopy`, a developer need only include two annotations on the definitions of durable data structures. The first is the directive to use the C representation (`#[repr(C)]`), as the default Rust representation is intentionally under-specified and is not safe for operations that rely on a known type layout [56]. The second is `#[derive(PmCopy)]`, which causes `pmcopy` to generate an implementation of the `PmCopy` trait and several supertraits. Routines that copy to and from PM require that their parameters implement this trait. Table 1 de-

scribes four supertraits of `PmCopy` implemented by `pmcopy`. We assume that all Rust numeric types, `bool`, and `char` are safe to store on PM and mark them `PmSafe`. `PmCopy` can only be derived on structs and enums made up of `PmSafe` types.

Partway through development of CapybaraKV, an update to the Rust compiler changed the layout of `u128` and `i128`, which caused an inconsistency between compiler- and `pmcopy`-generated layouts. Thanks to the static assertions `pmcopy` generated, this discrepancy was immediately flagged.

5.1.2 Concurrent variants

In addition to the single-threaded CapybaraKV, we build two concurrent variants, one that uses a reader-writer lock to enable concurrent reads and one that uses sharding to also enable concurrent writes, representing the two forms of concurrency described in §3.4. The API shared by the two variants is a linearizable specification that is formalized using logical atomicity [32, 60] and encoded using proof callbacks in Verus. This shared API is non-transactional, consisting of single atomic operations that create, read, update, etc.

All three implementations use a single component, `UntrustedKvStoreImpl`, to implement the main KV-store functionality. This includes nearly all of the code, including setup, recovery, transactions, and individual operations. That component exports a transactional API that uses atomic PoWER. That is, it only stores and recovers state via a `PoWERStorage` object supplied by its wrapper, so it cannot perform writes unless granted permission for all possible resulting crash states. That wrapper, either the single-threaded CapybaraKV or one of its two concurrent variants, creates permissions and passes them to the `UntrustedKvStoreImpl` as needed. The sharded variant uses multiple instances of `UntrustedKvStoreImpl`, one per shard, each using a separate PM file as a storage region.

At startup time, each wrapper provides a blanket permission allowing any number of writes that do not change the abstract post-recovery state. The `UntrustedKvStoreImpl` saves this for repeated use throughout its lifetime, for recovery and for all operations except `commit`. For `commit` operations, the wrapper supplies a one-shot permission permitting transitioning from the on-abort state to the on-commit state.

The reuse of `UntrustedKvStoreImpl` demonstrates a development advantage of using PoWER for systems with coarse-grained concurrency like the two we describe here. Nearly all the code, including all the complex mechanisms for recovery and transactions, can be written within components implementing a PoWER specification. As a result, most of the time, developers only need to think about how to satisfy that simple specification. They only have to devise atomic invariants and reason about crash-consistent concurrency outside of the component, in the relatively small wrappers.

5.1.3 Discussion

CapybaraKV is designed for a particular use case, storing small keys, items, and list elements on a small amount (tens of GiB) of dedicated PM, in a production cloud storage service. In targeting this use case, we make several simplifying design decisions that streamline both implementation and verification but impose limitations on functionality.

CapybaraKV requires users to statically allocate storage space and specify at initialization the maximum number and size of keys, items, and list elements. It does not currently support dynamic resizing and will waste space if the number of records is smaller than initially specified. CapybaraKV uses a volatile index that keeps all keys in memory, which grows its memory footprint (especially if large keys are used) and must be rebuilt each time the system is started.

5.2 CapybaraNS

CapybaraNS is a notary service similar to the verified notary in Ironclad Apps [23]. It securely assigns logical timestamps to hashes so they can be conclusively ordered, and stores its state on persistent storage. We build and verify it in Dafny, with a trusted C# wrapper that provides external methods for CRCs, cryptography, and serialization.

Its abstract state consists of a current logical timestamp (a 64-bit unsigned integer) and a last hash. Its interface has two main operations: (1) `Advance` increments the timestamp and updates the last hash. (2) `Sign` uses the service's private key to sign a binding between the last hash and the timestamp. CapybaraNS uses the CDB algorithm from §4.2 to atomically update its storage state during an `Advance` operation.

5.3 Persistent memory model

We have written a model of PM in Verus and Dafny and use it to reason about potential crash states in CapybaraKV and CapybaraNS. This model uses the prophecy approach described in §3.1 and represents a PM resource using two sequences of bytes, a read state and a durable state. Our model is consistent with a storage API implementation that provides `write` and `flush` methods such that 8-byte chunks of a buffer written with `write` may be reordered until the next `flush` call. In our implementation, `write` calls a PMDK [30] function that uses non-temporal stores or `mov` followed by `clflushopt` or `clwb`, and `flush` performs an `sfence`.

There are two situations in which this model may overapproximate crash states. First, our model considers reorderings that are impossible if the implementation uses the strongly-ordered `clflush` instruction to flush cache lines. `clflush` is less performant than the weakly-ordered instructions described above, so typically PMDK will not use it. Even if it does, the instructions PMDK uses for each write are not known at verification time, so our model considers these reorderings to ensure it does not underapproximate crash states.

	Trusted	Spec+Proof	Impl
CapybaraKV			
PoWER framework	1698	1079	138
pmcopy crate	964	0	0
Journal	0	2234	611
Concurrency layer	1142	473	620
Sharding layer	395	265	332

Total	5244	14255	5531
CapybaraNS			
PoWER framework	266	118	4
Notary server	148	555	274
Total	414	673	278

Table 2: Lines of code in each verified system

Second, our model considers states including those that are only reachable by reordering 8-byte chunks on the same cache line. Current Intel systems guarantee that such updates will not be reordered by hardware, making some of these crash states impossible in practice [55]. We choose the current model because it is simpler and more portable than a model that is tied to specific instructions or low-level hardware guarantees. It also accounts for the possibility that the compiler may reorder independent `mov` instructions.

We note that PoWER is not tied to any particular storage model, so these overapproximations are not fundamental to the technique. A developer could use a different model for a system that always uses `clflush` and/or that never causes reorderings on the same cache line.

6 Evaluation

This section addresses the following questions: How much effort does it take to build and verify a new system with PoWER (§6.1)? How does CapybaraKV compare to similar, but unverified, PM key-value stores (§6.2)?

6.1 Verification effort

Table 2 gives the number of lines of code in major components of CapybaraKV and CapybaraNS, organized into trusted (i.e., unverified), specification/proof, and executable code. We count the unverified `pmcopy` crate towards CapybaraKV's trusted code, but we do not count the lines of code it generates. The CapybaraKV PoWER trusted line count also includes a mock PM region using a byte vector and PM backends for Windows and Linux. Both systems have a low proof-to-code ratio (2.6 for CapybaraKV and 2.4 for CapybaraNS).

Designing, implementing, and verifying CapybaraKV took approximately 1.5 years of work by a team consisting of both verification experts and newcomers. We built CapybaraNS when CapybaraKV was mostly complete, so its development benefitted from lessons learned when building CapybaraKV. It took less than one person-hour to port the PM specification to Dafny, about one hour to port the library supporting reasoning about tentative and committing writes, and about nine hours to implement and verify CapybaraNS in Dafny after writing its specification and C# wrapper.

Verification time. On one of our development machines (Linux v6.9.3, Intel Core i7-11850H CPU, 8 physical cores, 32 GB memory), it takes 54 seconds to verify CapybaraKV with 1 thread and 23 seconds with 8 threads. It takes 12 seconds to verify CapybaraNS with 1 thread; Dafny does not support multi-threaded verification.

6.2 CapybaraKV performance

We evaluate CapybaraKV against three unverified PM key-value stores: pmem-Redis [28], pmem-RocksDB [29], and Viper [3]. CapybaraKV is the first verified PM KV store, so we cannot compare to prior verified systems. VeriBetrKV [21], the most similar verified system, is designed for block devices.

Experimental setup. We run experiments on a two-socket machine with 32 physical cores, 128 GB memory, and one 128 GB Intel Optane DC PMM. The evaluation machine runs Debian Trixie and Linux 6.12.10. We run the pmem-Redis server and client on the same machine, enable its pointer-based append-only file, and configure it to store the AOF and all values on PM. We configure pmem-RocksDB to memory-map files for reading and writing and to use non-temporal stores when appending to its log. We set Viper to preallocate enough space for each experiment that dynamic resizing does not impact its performance. We use the sharded variant of CapybaraKV for all experiments, with one shard per thread.

Microbenchmarks. Figure 2(a) gives the average latency of various operations on items in the four evaluated KV stores with both sequential and random access patterns. Figure 2(b) gives the average latency of operations on lists in pmem-Redis and CapybaraKV; the other systems do not support lists.

Each experiment uses 25M records with 64-byte keys, 1 KiB values, and 8-byte list elements. The list "append" experiment appends a total of 16 list elements to all records, accessing the records in a random order. The "read list" operation returns the entire contents of the list as a vector, and "trim" removes all elements from the list. All operations except for list append are run once on each record.

Pmem-Redis has the highest latency on all operations due to communication overhead between its client and server. CapybaraKV achieves similar or better latency to pmem-RocksDB on all measured operations primarily due to its tiny (< 64 B) journal entries and its fast hash-map index. Pmem-RocksDB spends more time appending larger entries to its write-ahead log and managing its smaller but more

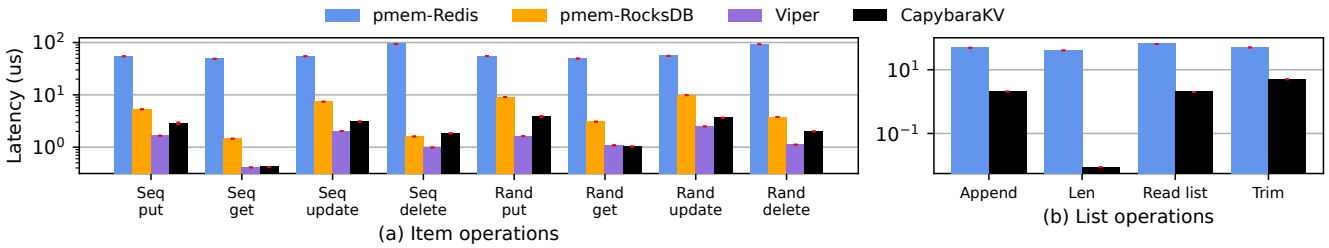

Figure 2: Average operation latency in microseconds. Note the log scale. Error bars show 95% confidence intervals.

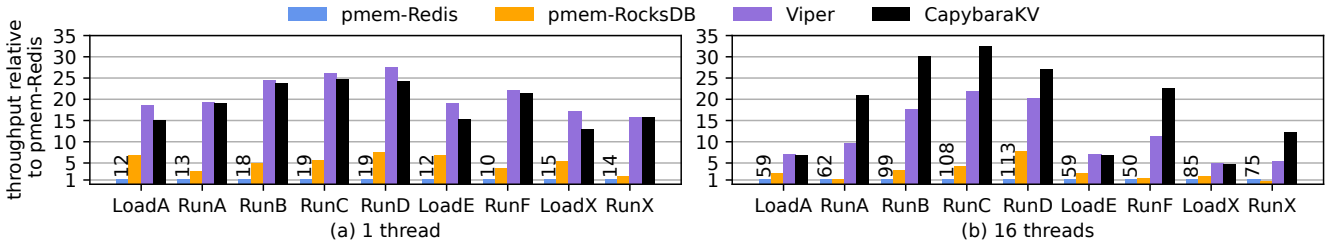

Figure 3: YCSB throughput relative to pmem-Redis. Numbers above pmem-Redis bars show absolute throughput in kops/s.

complicated in-memory MemTable and cache structures. Key lookups in pmem-RocksDB involve searching the MemTable and potentially multiple durable files.

CapybaraKV's random get latency is approximately 2× its sequential get latency in this microbenchmark because sequential loads are faster than random loads on Optane PM [31]. The sequential get workload runs on records that were inserted sequentially, whereas random get accesses keys that were inserted in a different random order.

Battery-backed DRAM. We also evaluate CapybaraKV in a testing environment in Azure Storage running Windows with 20 GiB battery-backed DRAM. We run the microbenchmarks shown in Figure 2(a) on CapybaraKV in this environment and find that operations are up to 2× faster on battery-backed DRAM and follow similar performance patterns. We are unable to evaluate the other systems in this environment as they do not support Windows.

Macrobenchmark: YCSB. We also measure each system's performance on several workloads from the widely-used YCSB benchmark suite [10]. CapybaraKV and Viper do not currently support range queries, so we skip the YCSB workload that includes them (RunE). Several workloads (RunA and RunB) involve partial value updates, which these systems also do not support, so we modify the workloads to always update full values. We also introduce workload X, which is based on a trace of traffic to a production service similar to CapybaraKV at Azure Storage and consists of 75% updates, 5% read-modify-write operations, and 20% reads with a uniform access distribution. All YCSB workloads use 15M keys and are executed 5 times on each system. The CapybaraKV instances in these experiments use 24-byte keys and 1140-byte values, both structured as byte arrays.

Single-threaded performance. Figure 3(a) gives the average throughput of each system using one thread relative to pmem-Redis. CapybaraKV significantly outperforms pmem-Redis and pmem-RocksDB and achieves similar performance to Viper on these workloads. Pmem-Redis is unable to achieve high throughput on these operations due to its high per-operation latency. Multiple factors contribute to pmem-RocksDB's lower performance: background threads performing LSM tree compaction slow down client threads; lookups and updates in its in-memory MemTable index take longer than in Viper and CapybaraKV's hash maps; pmem-RocksDB uses per-block CRCs that take longer to compute than CapybaraKV's smaller per-structure CRCs; and, unlike Viper and CapybaraKV, it logs all keys and values.

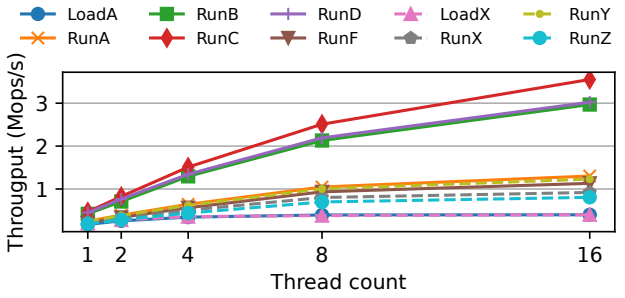

Figure 4: Sharded CapybaraKV YCSB throughput with different thread counts

Viper and CapybaraKV achieve similar performance on these workloads because they have similar architectures. Both use in-memory hash map indexes and use simple durable data structures. Viper also includes optimizations for running concurrent workloads on interleaved PM, but our experiments use a single non-interleaved NVDIMM.

Sharded performance. Figure 3(b) gives average throughput using 16 threads (the number of physical cores in each

	Startup time		Utilization (GiB)	
	Empty	Full	Memory	Storage
pmem-Redis	142 ms	-	12.3	22
pmem-RocksDB	9 ms	7 ms	2.0	17
Viper	9 s	75 s	1.1	23
CapybaraKV	7 s	53 s	2.8	18

Table 3: Startup times and memory and storage utilization on YCSB LoadA on 128 GiB Optane PM

NUMA node on our test machine) and 16 CapybaraKV shards. Each record is placed in a shard based on a hash of its key, which results in a roughly uniform distribution. We do not shard the other three systems in this experiment, as they already support multiple concurrent clients. Figure 3(b) shows that with our simple sharding protocol, CapybaraKV outperforms the other systems on concurrent workloads including, suprisingly, Viper. CapybaraKV uses coarser-grained concurrency control with lower overhead than Viper. We also find that Viper's performance in these workloads is impacted by the use of semaphores in its in-memory hash map implementation, CCEH [49]. CCEH protects hash buckets using per-bucket semaphores, and we observe via traces collected using magic-trace [27] that using these semaphores becomes slower with more workload threads (nearly doubling when going from 1 to 16 threads). CapybaraKV uses Rust's standard library `RwLock`, which does not have this issue.

Figure 4 gives average throughput of CapybaraKV on each YCSB workload with different thread counts. We omit LoadE for readability and because it has the same performance as LoadA. We introduce two new workloads, Y (50% reads, 50% updates) and Z (5% reads, 95% updates), which both use a hotspot access distribution where 90% of the operations access 10% of the records. Read-heavy workloads (Runs B, C, and D) scale well because the per-shard locks allow concurrent reads. The more write-heavy workloads experience more lock contention and do not scale as well. Since our sharding policy evenly distributes keys across shards, Y and Z perform similarly to the non-hotspot workloads.

Startup times. Table 3 compares how long it takes for each key-value store to start up on both an empty instance and a completely full instance on a 128 GiB PM device. To measure full startup times, we insert records with 64-byte keys and 1 KiB values into each system until it returns an out-of-space error, then repeatedly start each system on those records. Attempting to start the pmem-Redis server on a full instance fails with a memory allocation error. CapybaraKV and Viper take much longer to start on both empty and full systems than pmem-Redis or pmem-RocksDB because they need to initialize or reconstruct their in-memory data structures. Viper takes longer than CapybaraKV because it memory-maps more files and hashes each key before inserting it into the index.

Memory and storage utilization. Table 3 also reports DRAM and PM utilization in YCSB's LoadA workload. We use the same configurations as before for all systems but Viper, which starts with a 1 GiB pool and grows as keys are added. CapybaraKV uses more memory than pmem-RocksDB because it maintains all keys in DRAM. Viper only keeps hashes of keys in DRAM, which reduces its memory footprint. Pmem-Redis also keeps all keys in DRAM, but has high per-key overhead (almost 700 bytes as reported by the server).

18 GiB is the minimum space required by CapybaraKV to store these records; note that unlike the other systems, this CapybaraKV instance cannot grow any further. In an optimally-provisioned instance, CapybaraKV has low storage space overheads due to its simple durable layout and does not use much more storage than pmem-RocksDB. Viper uses more storage space because it checkpoints some system metadata for use in crash recovery. To achieve durability guarantees similar to the other systems, we configure pmem-Redis to store mappings from keys to durable values as well as the values themselves, which adds additional storage overhead.

7 Conclusion

This paper presents new techniques for proving crash consistency and corruption detection in storage systems. We introduce PoWER, a way to prove that a system is crash consistent using only basic verifier features like Hoare logic, and a new model of storage corruption that forces developers to properly perform corruption detection while giving them flexibility in how to do so. We develop a new primitive, the corruption-detecting Boolean, and show how to use it to implement a novel algorithm for atomic updates to PM data structures. To demonstrate that our approach is useful and tool-agnostic, we build two verified PM storage systems, CapybaraKV in Verus and CapybaraNS in Dafny. We evaluate CapybaraKV and find that its performance is competitive with unverified PM KV stores. CapybaraKV and CapybaraNS are available at https://github.com/microsoft/verified-storage.

Acknowledgments

We would like to express our great appreciation to our anonymous shepherd and reviewers for their helpful feedback on the paper. Their disappointment with a lack of concurrency support moved us to devise, implement, and verify concurrency mechanisms, which we feel have substantially improved the work. We are also grateful to Tej Chajed, Travis Hance, Jon Howell, Jialin Li, Bryan Parno, Upamanyu Sharma, and Joseph Tassarotti, with whom we had useful conversations about the work and its relation to Perennial and VeriBetrKV. Hayley LeBlanc and Vijay Chidambaram were partially funded by donations from Toyota.

A Artifact Appendix

Abstract

The artifact for this paper includes the source code for CapybaraKV and CapybaraNS and proofs of correspondence between PoWER and other crash-consistency verification techniques. It also includes instructions and code to run the experiments described in §6 and generate the corresponding tables and graphs.

Scope

The artifact can be used to validate all of the main claims of the paper. Specifically, it validates the following claims:

1. CapybaraKV and CapybaraNS are correct, crash consistent, and corruption resistant, and can be verified using Verus and Dafny, respectively;
2. CapybaraKV and CapybaraNS have low proof-to-code ratios and can be verified quickly;
3. CapybaraKV achieves competitive performance compared to state-of-the-art unverified PM key-value stores.

Contents

The artifact has three main parts:

1. The source code for CapybaraNS and instructions on how to build, verify, and run it. This part also includes information on how to manually audit CapybaraNS's specification.
2. The source code for CapybaraKV and for the three unverified systems we compare against, and scripts to compile these systems and to verify CapybaraKV. It also includes instructions and scripts to run the experiments and produce the figures and tables in §6, as well as information on how manually audit CapybaraKV's specification.
3. Soundness proofs in Verus and Perennial that establish the correspondence between PoWER and CHL/crash invariants, and information on how to understand the proofs and verify that they hold. It does not include the formalization of the soundness proof in Perennial, but describes how to find that formalization in the Perennial repository and how to check it.

Hosting

The artifact is hosted publicly on GitHub at https://github.com/microsoft/verified-storage/tree/osdi25-artifact/osdi25 and on Zenodo at https://doi.org/10.5281/zenodo.15306499. The Zenodo artifact and the `osdi25` directory in the `osdi25-artifact` branch on GitHub have the same contents and contain the version of the artifact used during the artifact-evaluation process.

Requirements

Verifying and compiling CapybaraKV, CapybaraNS, and the soundness proofs requires no special hardware and should work on most platforms. The CapybaraKV performance experiments are only compatible with Linux platforms, as the unverified systems we compare against only support Linux. The experiments are compatible with both real Intel Optane DC PMM hardware and emulated PM on DRAM; however, at least 128 GB of Intel Optane DC persistent memory is required to reproduce the results presented in the paper. To reproduce the results in the paper, we also recommend at least 128 GB of DRAM and at least 32 cores. The README files included in each part of the artifact describe specific requirements and recommendations in more detail.

A.1 Installation

To install the artifact, either clone the GitHub repository and check out the `osdi25-artifact` branch, or download and unzip the Zenodo artifact. Follow the setup instructions in `osdi25/capybaraNS/README.md` to install dependencies for CapybaraNS. Follow the setup instructions in `osdi25/capybaraKV/README.md` to run a script that will install dependencies for CapybaraKV and build the systems used in performance experiments. Checking the proof of correspondence between PoWER and crash invariants is done automatically when verifying CapybaraKV (see below). The proof of correspondence between PoWER and Crash Hoare Logic is part of Perennial's source code and can be checked by building Perennial; see `osdi25/soundness_proofs/README.md` for instructions.

We include several "mini" versions of the full performance experiments described in §6 that take about 15 minutes to run. We suggest running these experiments after setting up CapybaraKV to check for issues before starting the longer-running experiments.

A.2 Experiment workflow

The files `osdi25/capybaraNS/README.md` and `osdi25/capybaraKV/README.md` describe the workflow to compile and verify each system, obtain line counts, manually audit their specifications, run performance experiments, and validate the claims made in the paper.

A.3 Expected results

CapybaraKV, CapybaraNS, and the soundness proofs are expected to verify successfully using their respective verification tools. The time it takes to verify each system can vary significantly depending on the hardware being used; see each system's README file for more information on expected verification times. In general, we expect that verifying CapybaraNS will take under a minute, and verifying CapybaraKV will take one to two minutes with one thread and between 15 and 40 seconds with 8 threads. We expect the lines of code outputted by the provided line-counting tools to exactly match those in Table 2.

When run in an environment similar to the experimental setup described in §6, we expect the PDFs and tables generated by scripts described in `osdi25/capybaraKV/README.md` to look similar to those presented in the paper. The default experiments provided by the artifact are smaller than those used in the paper, so we expect some variation in data collected from the artifact. Using different hardware (e.g., emulated PM or a smaller PM device) may result in noticeably different results. We describe expected differences in `osdi25/capybaraKV/README.md`.

Fast and Synchronous Crash Consistency with Metadata Write-Once File System

Abstract

Low-latency persistent memory (PM) encourages file systems to pursue synchronous crash consistency. However, existing crash consistency approaches, such as *journaling* and *log structure file system*, incur many small, random, and ordered metadata I/Os, failing to exploit PM I/O potential. We propose a new file system model called *metadata write-once file system (WOFS)* to achieve fast and synchronous crash consistency. The key idea is to generate specific metadata for each file operation as a checksum-protected package and write it once with a single ordering point. The package is then managed to provide file abstractions through a package translation layer without extra writes. Using an array of techniques to generate, organize, and recover from packages, WOFS can provide practical, efficient, and reliable file system services. We implement WOLVES as a WOFS prototype in Linux kernel. Experiments using benchmarks and applications suggest that WOLVES can recover from crashes, improve operation throughput, and potentially reach PM I/O bandwidth limits.

1 Introduction

Persistent Memory (PM) technologies, such as 3D-XPoint [1, 2] and CXL-SSD [3–5], have shown the merits to supercharge data-related scenarios [6–9]. Specifically, PM can be attached to the memory bus through specific protocols and accessed via CPU loads/stores without the block layer [4, 10–12].

While conventional block-based file systems require orchestrating I/O orders across many layers and using expensive disk flushes for durability [13–15], PM file systems enable fast synchronous I/Os by waiting for I/Os to reaching PM interfaces without intermediate layers. This encourages PM file systems to pursue synchronous crash consistency [16–29], which ensures file operations are immediately durable without explicit synchronization (*e.g.,* `fsync`), thereby promising to greatly simplify application crash consistency efforts [30–33].

Existing PM file systems follow two existing methodologies to achieve synchronous crash consistency. The first kind advocates **additional writes** for simplicity [34]. *Journaling file system (JFS)* is a representative approach [16,17,20,22,23, 35, 36], which reserves a contiguous PM area as the journal. JFS conducts an ordered metadata write to journal followed by an ordered commit block, and then issues multiple orderless in-place updates to file system metadata. As a result, system failures can be fixed by replaying metadata update backups from transactions. However, journaling with redundant metadata I/Os, even with optimizations such as transactional checksum [15, 20], reduces PM throughput dramatically.

The second kind carefully orders I/O sequences **without additional writes**. Approaches such as *log-structured file system* [21, 28] and *synchronous soft update* [25] enforce update ordering on different file system metadata (*e.g.,* inode, dentry, etc.). For instance, creating a file in SquirrelFS [25] involves first allocating and initializing a new inode, and then filling in a dentry to point to the inode. These ordering points [37] ensure that crash points are reasoned and can be fixed for recovery, thereby eliminating additional metadata writes; however, they unfortunately incur many small, random, and ordered metadata I/Os that hinder PM performance [10, 11].

Our motivational experiments on three representative PM file systems with different crash consistency techniques show that these metadata I/Os (for crash consistency) dominate more than 70% of the total I/O time, causing a severe PM bandwidth waste. We thus propose a new file system model, *metadata write-once file system (WOFS)*, which aims to minimize metadata I/Os and ordering points for fast and synchronous crash consistency. The key idea is to generate specific metadata for a file operation as a checksum-protected package and write it once with a single ordering point (*i.e.,* one synchronous I/O). Consequently, WOFS ensures that every metadata I/O (or package) is atomic and durable, and that WOFS can rely on replaying them for reliable recovery.

However, designing a file system that manages metadata as packages is non-trivial. We thus present a range of techniques: (1) to generate packages for various file system operations in Linux, we abstract packages for basic operations and use them to build complex operations; (2) to parse packages to provide metadata objects (*e.g.,* inode) for upper file/dir abstractions, we propose a *package translation layer* to gather fields from written packages; (3) to organize packages/data blocks in PM, we deploy a non-log layout and use reallocation to reclaim invalidated space; (4) to recover from packages after crashes, we propose *coarse persistence* to enable quick location of a group of packages for fast recovery. Consequently, these techniques make WOFS practical, efficient, and reliable.

We built WOLVES as a WOFS prototype on Intel PM. By applying two other techniques tailored to PM, *i.e., huge allocation* and *read ahead*, WOLVES further improves sequential I/O throughput. Finally, we port WOLVES to another PM platform (*i.e.,* an emulated memory-semantic SSD platform [3]) to show the generality of WOFS. Experiments

show that WOLVES can achieve 97.3%–99.1% PM I/O bandwidth under several write-intensive benchmarks. Using real-world RocksDB, we further show that WOLVES achieves 1.20–6.73× throughput compared to existing PM file systems.

In a nutshell, the contributions of this paper are three-fold:

- We make an in-depth analysis of existing crash consistency design principles atop PM (§2) and reveal that their many small, random, and ordered metadata I/Os squander fast PM bandwidth, and become bottlenecks for file operations (§3).
- We propose a WOFS model for fast and strong crash consistency. WOFS generates specific metadata for each file operation as a checksum-protected package and writes it once with a single ordering point. A series of techniques are proposed to generate, organize, and recover from packages, making WOFS practical, efficient, and reliable (§4).
- We have implemented the WOLVES file system to realize the efficiency of WOFS (§5). Experiments show that WOLVES can reliably recover from system crashes, outperform existing PM file systems across a range of workloads, and potentially reach PM I/O bandwidth upper limits (§6).

2 Background

2.1 Fast and Synchronous PM I/O Stack

PM characteristics. PM offers performance comparable to DRAM and data persistence similar to storage [1, 2, 4, 38, 39]. PM can be accessed via CPU load/store instructions through specific protocols (*e.g.,* DDR-T [10]). Compared to traditional HDDs/SSDs, PM is superior due to two unique characteristics: (1) *byte-addressability* that enables file systems to use direct access to bypass the block layer, and (2) a *persistent buffer* (*e.g.,* XPBuffer in Intel PM [10]) to ensure immediate durability when I/Os reach the PM interface [11, 40].

Fast synchronous PM I/O stack. The above PM features enable fast synchronous I/Os [25]: for each issued I/O request, PM file systems only require issuing a `PCOMMIT` (*i.e.,* CPU flush plus a memory barrier, such as `clwb+sfence`) to wait for the I/O to reach the persistent buffer (*e.g.,* 50–300 ns [11]). In contrast, traditional block-based file systems require waiting for data transfer across multiple layers to the media [13, 15], which is time-consuming (*e.g.,* tens of microseconds [41]).

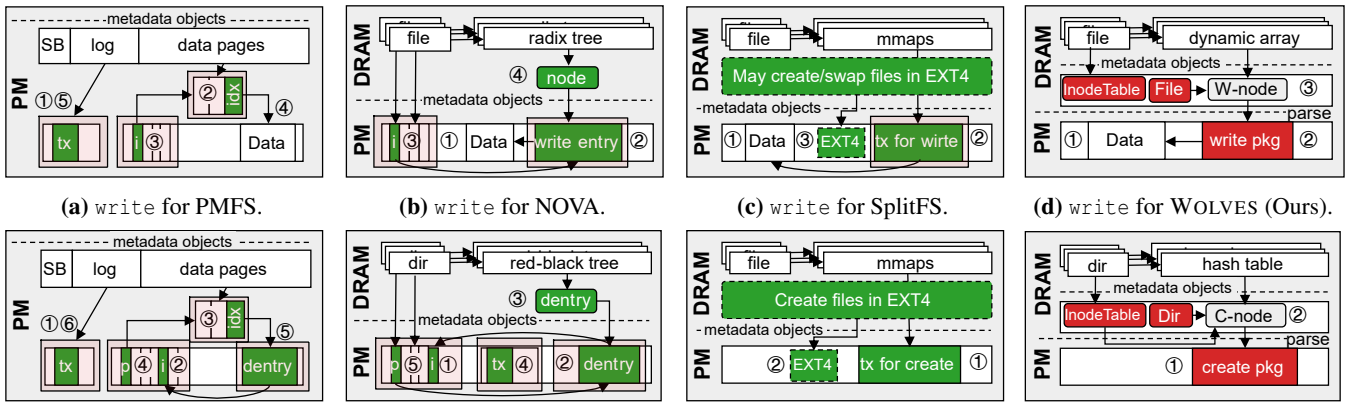
2.2 Synchronous Crash Consistency

With its fast synchronous I/Os, PM file systems pursue synchronous crash consistency [16–29]: each file operation is durable after its return without synchronization. This contrasts with the optimistic approach for slow disks [13, 15, 37], which allows operation loss for higher I/O throughput. Achieving synchronous crash consistency is important and charming as it can simplify application crash consistency efforts, especially for databases that suffer incorrect `fsync` behaviors [31, 32] and the strict NFS protocol that issues `fsync` for every operation [30]. Existing PM file systems follow two conventional methodologies for synchronous crash consistency, as below.

Tech.	I/O order (*e.g.,* `write`)	MOrd	MIOs	GC
JFS [22, 36]	$D \rightarrow J_M \rightarrow J_C \rightarrow M$[a]	3	> 3	Reuse
CK [20]	$D \rightarrow \overline{J_M \vert J_C} \rightarrow M$	2	> 2	Reuse
LFS [21]	$D \rightarrow (GC) \rightarrow m_e \rightarrow m_t$	≥ 2	≥ 2	Copy
SSU [25]	$D \rightarrow m_1 \rightarrow m_2 \cdots m_N$	N	N	Reuse
WOFS	$D \rightarrow \overline{J_M \vert J_C} \vert (m_{cp})$[b]	1	~ 1	Reuse

[a]: M is short for $m_1 \vert m_2 \vert \cdots \vert m_N$, where m_i is one metadata update.
[b]: m_{cp} denotes coarse bitmap persistence used for fast recovery (§4.5).

Table 1: Crash consistency techniques in PM file systems. *MOrd and MIOs denote the number of metadata ordering points and metadata I/Os. The line below CK separates techniques w/ and w/o additional writes. CK and SSU denote transactional checksum and synchronous soft update. WOFS is our proposed crash consistency method. The parentheses, e.g., (GC), indicate that the I/O does not always occur. The Copy-GC indicates that the file systems rely on data migration to reclaim invalidated space, while Reuse-GC indicates that the invalidated space is simply reallocated.*



Synchronous crash consistency with additional writes. These approaches back up metadata before updating them, which are simple but incur redundant writes. The most representative one is *journaling file system (JFS)*. JFS first writes data blocks (D), then wraps metadata updates as a transaction and writes it to a journal area (J_M). Afterward, JFS writes a commit flag (J_C) atomically to the journal. Finally, JFS conducts orderless metadata updates in place (M). This entails an I/O order of $D \rightarrow J_M \rightarrow J_C \rightarrow M$[1]. As a result, JFS can recover by checking and replaying transactions after crashes [13, 15]. Many PM file systems [22, 23, 36] leverage journaling for crash consistency.

To optimize JFS I/O, *transactional checksum (CK)* [42] is proposed. Specifically, CK writes J_M, J_C, and their checksum together without ordering (*i.e.,* $\overline{J_M \vert J_C}$[2]). As a result, incomplete writes can be verified by recalculating the checksum of J_M and J_C and comparing it with the stored one. Thus, CK has an I/O order of $D \rightarrow \overline{J_M \vert J_C} \rightarrow M$. Recent SplitFS [20] is a representative that leverages CK to accelerate journaling.

Synchronous crash consistency without additional writes. These approaches carefully order metadata updates to eliminate additional metadata writes. *Log-structured file system (LFS)* is the most representative one used in PM file systems, such as NOVA [21]. Specifically, LFS conducts metadata writes in an append manner [21, 43–45]. LFS regards the storage as a log and appends file/dir metadata to the log as a log entry (m_e); it then maintains *log tail* (m_t) to preserve the current write pointer. As a result, LFS can recover by scanning and checking log entries until the log tail. To accommodate the ever-growing log layout, LFS leverages the copy-based garbage collection (GC) to compact the valid log entries. As a result, the I/O order of LFS is $D \rightarrow (GC) \rightarrow m_e \rightarrow m_t$, where the parentheses indicate that the GC is not always triggered.

Another approach is synchronous soft update (SSU) proposed by SquirrelFS [25]. SSU is similar to LFS that performs

[1] $A \rightarrow B$ indicates that the persistence of B occurs after that of A.
[2] The overline indicates that J_M and J_C can be written concurrently.

(a) `write` for PMFS. **(b)** `write` for NOVA. **(c)** `write` for SplitFS. **(d)** `write` for WOLVES (Ours).

(e) `create` for PMFS. **(f)** `create` for NOVA. **(g)** `create` for SplitFS. **(h)** `create` for WOLVES (Ours).

Figure 1: Analysis of I/O ordering on write and create of existing PM file systems. *[i] and [p] are inode and parent inode; [tx] is transaction. The light-red squares indicate disaggregated in-PM metadata I/Os. The circled numbers denote update orders. PMFS, SplitFS, and NOVA represent JFS, JFS with transactional checksum, and LFS. Our WOLVES (§5) writes metadata once with a single ordering point.*

ordered updates on multiple different metadata objects (*e.g.,* inode, m_1, dentry, m_2, etc.) to satisfy three basic rules [34]: (1) never point to a structure before it has been initialized; (2) never re-use a resource before nullifying all previous pointers to it; and (3) never reset the old pointer to a live resource before the new pointer has been set. With these rules, SSU ensures that incomplete writes will never be visible to the file system, thus achieving crash consistency. Consequently, these rules form an I/O order as $D \rightarrow m_1 \rightarrow m_2 \cdots m_N$.

Summary. Table 1 summarizes existing crash consistency techniques, which suggests that these techniques incur multiple metadata I/Os and ordering points in critical paths.

3 Observations and Motivations

Nevertheless, unorchestrated I/Os and ordering points are essentially deficient in PM: (1) the coarse flush unit of persistent buffers (*e.g.,* 256-byte XPLine [10]) mismatches with small metadata, and thus can introduce I/O amplifications; (2) ordering points lead to wait for previous I/O operations, reducing I/O parallelism. Thus, we ask: *what exacts the toll on metadata I/Os in crash consistency processing for PM?* To answer this, we make an in-depth analysis of three PM file systems.

3.1 Analyzing I/O Path of PM File Systems

We analyze PMFS and SplitFS for JFS and CK with additional writes, and NOVA for LFS without additional writes. We omit SSU as it is similar to LFS, and we report SquirrelFS in §6.11.

PMFS I/O path analysis. PMFS is a classic JFS in PM [22]. It reserves a log space at the start of the PM for journaling, and the remaining space is organized as a B-tree for storing inodes and data blocks. For `write`, as Figure 1a shows, ① PMFS wraps metadata updates as a transaction (J_M), ② allocates blocks by traversing the B-tree and ③ updates the inode (M). Finally, ④ PMFS persists data (D) and ⑤ writes a commit entry to the log (J_C). The `create` is similar to `write` but needs to create a new inode (see ② in Figure 1e). Note that PMFS changes the original JFS order to $J_M \rightarrow M \rightarrow D \rightarrow J_C$, but its metadata I/Os and ordering points remain the same.

Workload	Avg. fsize	R/W size	R:W	#. files
FIO-SW	32GiB	0KiB/4KiB	0:1	1
FIO-RW	32GiB	0KiB/4KiB	0:1	1
Fileserver	128KiB	4KiB/4KiB	1:2	10K
Varmail	32KiB	1MiB/16KiB	1:1	10K
Webserver	64KiB	1MiB/8KiB	10:1	1K
Webproxy	32KiB	1MiB/16KiB	5:1	10K

Table 2: Characteristics of the evaluated six workloads. *The first two FIO workloads perform write operations. The last four Filebench workloads perform various open/create/write/read/-close/delete/fsync file operations to emulate real-world scenarios.*

NOVA I/O path analysis. NOVA [21] is the first LFS designed for PM. It associates each inode with a linked metadata log and leverages DRAM for fast indexing. For `write`, as Figure 1b shows, NOVA ① persists the data (D), ② appends a write entry to its inode log (m_e), ③ updates the log tail in the inode (m_t), ④ creates a DRAM node to index the entry. For multi-inode operations, such as `create`, NOVA introduces journals to protect the atomicity of affected log tails. As Figure 1f shows, `create` involves journal writes (④), inode updates (① and ⑤), and dentry appends (②). NOVA triggers GC whenever the log is full and needs to be extended.

SplitFS I/O path analysis. SplitFS is a user-space file system that utilizes transactional checksums for fast journaling [20]. It further accelerates data writes (D) via `mmap` provided by underlying EXT4, and EXT4 assists its metadata updates (M), as shown in Figures 1c (③) and 1g (②).

3.2 Analyzing Crash Consistency Overheads

Methodology. We break down the I/O path of PMFS, SplitFS, and NOVA (by inserting timing code around I/O operations) to

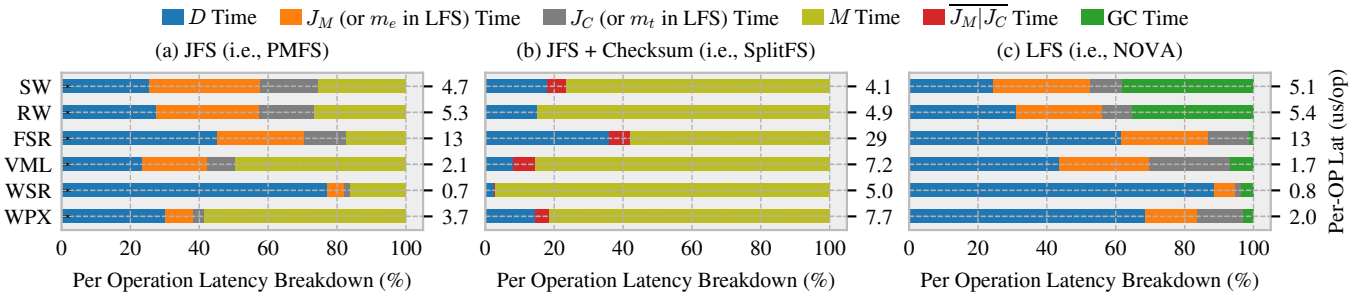


Figure 2: The study of crash consistency techniques in PM. *The right y-axis presents the average per-operation latency. Note that in RW and WSR, SplitFS does not write transactions (i.e., $\overline{J_M|J_C}$=0). SW and RW are FIO sequential/random 32 GiB write with 4 KiB per I/O and sync engine. FSR, VML, WSR, and WPX are short for Filebench workloads: fileserver, varmail, webserver, and webproxy. Note that NOVA's GC is significant in FIO workloads as it triggers GC upon log extensions [21]; consequently, larger files trigger more frequent GC, incurring higher overhead. In comparison, in Filebench workloads where files are small, GC overhead remains low.*

learn the overheads. We run six widely-used single-threaded micro- and macro-benchmarks [21, 22] as listed in Table 2.

Observation. Figure 2 suggests that metadata I/O time for synchronous crash consistency can even exceed the data I/O time. Specifically, PMFS, SplitFS, and NOVA spend 22.9%–76.5%, 63.8%–97.4%, and 11.3%–75.5% of the total I/O time on metadata in the six evaluated workloads. We find that these metadata overheads come from three main aspects:

- *Random metadata I/Os lead to persistent buffer hit misses, which causes I/O amplifications*. We study I/O amplifications of PMFS in the SW workload. Using *ipmctl* [46], we find that metadata I/Os of PMFS are increased from a theoretical ∼2.9 GiB (by calculating all issued metadata I/Os) to a measured ∼8.0 GiB, leading to 2.8× amplifications.
- *Ordered metadata I/Os lead to waiting for previous data transfer and limit PM I/O concurrency*. As Figure 2a and 2b show, PMFS spends 6.73%–49.2% metadata I/O time on transaction write and commit (steps ① and ⑤ in Figure 1a), while the overheads are reduced to 3.99%–6.27% in SplitFS with transactional checksum that eliminates ordering.
- *Increasing metadata I/Os further exacerbate the overheads*. For NOVA, the GC exacerbates metadata I/O numbers, causing an average of ∼13 metadata accesses per block I/O. This, as shown in Figure 2c, leads to ∼38.0% GC overheads. Meanwhile, metadata I/Os are increased from a theoretical ∼4.2 GiB to a measured ∼11.1 GiB (2.8×).

Significance. In a nutshell, many small, random, and ordered metadata I/Os lead to severe overheads. Consequently, in SW, existing PM file systems achieve less than 50% (not shown in the figure) of PM write bandwidth (∼2.26 GiB/s on our machine). This observation significantly challenges existing crash consistency techniques under the synchronous context.

3.3 Motivation

Intuitively, one solution to the above deficiency is to minimize metadata I/Os and ordering points for crash consistency.

Attempts. While many existing crash consistency designs attempt to achieve this goal, they ultimately fall short. Particularly, (1) transactional checksum achieves one $\overline{J_M|J_C}$ transaction write, but it fails to eliminate multiple, random, orderless metadata updates; (2) LFS successfully eliminates redundant journal writes via ordered log entry writes (m_e) and tail commit (m_t). However, further attempts to eliminate *GC* are failed as LFS must use a copy-based GC to compact the layout; (3) although SSU does not have to trigger GC [25], it still suffers from small, random, and ordered metadata I/Os as existing file systems manage multiple metadata objects (*e.g.,* inode) for file/directory abstractions, leading to significant I/O overheads (*i.e.,* ∼30% degradation as shown in Figure 15 in §6.11).

Insight. We note that existing crash consistency techniques struggle to *orchestrate and optimize I/Os across a range of metadata objects* (*e.g.,* inode, log entry/tail, etc.). This methodology, however, misaligns with the goal of minimal metadata I/Os and ordering points. Consequently, we are motivated to rethink file system metadata itself. Intuitively, by designing specific metadata for each file operation (similar to J_M) and attaching a checksum header to protect it (similar to J_C), the file system can write the metadata (*i.e.,* $m_{op} = \overline{J_M|J_C}$) once with a single ordering point: $D \rightarrow \overline{J_M|J_C}$.

Challenges. However, designing metadata for each operation is non-trivial, as reflected in four key questions: (1) How to practically design m_{op} considering various Linux file operations [47, 48]? (2) How to manage m_{op} to be compatible with traditional file/dir abstractions (*e.g.,* inode)? (3) How to organize m_{op} in PM efficiently? (4) How to recover from m_{op} reliably? We answer these questions in the next Section.

4 Metadata Write-Once File System Model

Motivated by §3, we propose *metadata write-once file system (WOFS)*. The key idea of WOFS is to generate specific, aggregated metadata for each file operation as a checksum-protected package (corresponding to the m_{op} described in §3.3), and write the package once with a single ordering point.

4.1 Overview and Design Principles

The WOFS overview is shown in Figure 3, as described below.

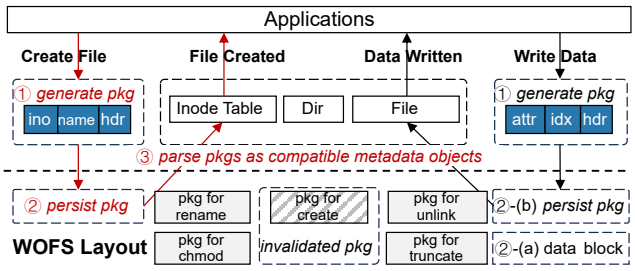

Figure 3: WOFS overview. *Each file operation corresponds to a package that contains necessary metadata fields, which can be written once. The packages are then parsed for file/dir abstractions.*

Package overview. In WOFS, a generated package contains necessary fields (denoted as J_M) for a file operation (*e.g.,* name for `create`). Further, a header is reserved for each package as a commit flag (denoted as J_C), which stores a *magic number*, a *type* for package type, a *timestamp*, and a CRC32 checksum[3] for package write once (*i.e.,* $\overline{J_M|J_C}$), as shown in Listing 1.

Workflow overview. As illustrated in Figure 3, for metadata operations such as `create`, WOFS ① generates a package for `create`, ② writes it once using a `PCOMMIT`, *i.e.,* $\overline{J_M|J_C}$, and ③ parses it to organize inode, inode table, and directory hierarchy. Data operations (*e.g.,* `write`) have a different I/O mechanism: WOFS first persists data (②-(a)) and then writes the package that references them (②-(b)), *i.e.,* $D \rightarrow \overline{J_M|J_C}$.

Crash consistency overview. With packages and the metadata write-once scheme, WOFS can achieve fast and synchronous crash consistency with minimal metadata I/Os and ordering points. First, metadata operations involve only $\overline{J_M|J_C}$; therefore, once a failure occurs, WOFS can detect incomplete packages by checking the checksum of J_M and J_C, and discard invalid ones during recovery. Second, data operations follow $D \rightarrow \overline{J_M|J_C}$; therefore, a crash before or during the $\overline{J_M|J_C}$ leads to an incomplete package, which can be discarded; meanwhile, as data blocks are not referenced by any valid package, they can be regarded as free space without consistency issues.

Design principles. The overall workflow and crash consistency principles of WOFS seem simple, but it requires further design considerations regarding packages, as guided below.

- *Generate minimal packages*. It is partially unnecessary to generate the specific package for each file operation as many operations share a similar semantic [47, 48]. Thus, WOFS aims to generate minimal packages that can represent or be combined to represent file operations (§4.2).
- *Parse packages to provide compatible metadata objects*. As packages upend the traditional file system metadata objects (*e.g.,* inode), WOFS aims to provide compatible metadata objects for efficient file/directory abstractions (§4.3).
- *Organize packages and data blocks in a non-log manner*. WOFS aims to allocate packages/data blocks across PM rather than in a log manner to avoid copy-based GC (§4.4).

[3]CRC32 is widely used for protecting file systems' metadata [20–22, 36, 45].

```
hdr = pkg->hdr;
hdr->type = WRITE; hdr->ts = current_time();
// fill other attributes inside pkg ...
hdr->CRC32 = CRC32(pkg, pkg->size); // checksum
// write package once with a single ordering point
PCOMMIT(pkg, pkg->size);  // clwb+sfence
```

Listing 1: Package write once I/O scheme. *WOFS uses the transactional checksum scheme [20, 42] to persist the package with a single ordering point (i.e., one `PCOMMIT`).*

- *Recover from packages after crashes efficiently*. The non-log layout complicates failure recovery as WOFS stores packages across the whole PM. WOFS aims to provide a coarse bitmap to quickly locate and check packages without frequent random I/Os to support fast recovery (§4.5).

4.2 WOFS Package Design

Considering 15+ file system operations in modern Linux [47, 48], it is partially unnecessary to generate the specific package for each file operation as many operations have similar semantics, which also increases complexity and reduces flexibility. Our goal is to abstract the most fundamental file operations, similar to CRUD operations in database [49].

Generate atomic package. We observe that file system operations can be categorized into CRUD: create (*e.g.,* `create`), read (*e.g.,* `read`, `lstat`), update (*e.g.,* `write`, `chown`), and delete (*e.g.,* `rm`). As read operations do not alter file system states, we omit read packages. For update operations, we find that they can be further divided into data (*e.g.,* `write`) and metadata modification (*e.g.,* `chown`). Therefore, we abstract the following four packages as the *atomic package*.

- *Create pkg* (256 bytes) for the operations that create new inodes, such as `create` and `link`. It contains 64 byte static file attributes, *e.g.,* create time and inode number (ino). The next 128 bytes store the parent ino, the linked ino, and the name entry. The remaining 64 bytes store the attributes of the parent inode (*e.g.,* link changes) and the package header.
- *Write pkg* (64 bytes) for the operations that allocate new data blocks, such as `write` and `fallocate`. It uses the extent [14, 21] to index the continuously allocated data blocks and records the time and size changes of the inode.
- *Attr pkg* (64 bytes) for the operations that change the attributes (*e.g.,* mode, uid, etc.) of an inode.
- *Unlink pkg* (64 bytes) for the operations that reduce the link of an inode. It contains the changed attributes of both parent (*e.g.,* time and size) and unlinked inode (*e.g.,* link counts and the inode number that is to be unlinked).

Generate compound package with crash consistency. We use multiple atomic sub-packages to represent complex file operations, *e.g.,* `rename` (=`link`+`unlink`). To ensure the crash consistency of compound packages, we reserve a *forward-pointer* in the package header to link sub-packages. We assign sub-packages an extra compound operation type to distinguish them from normal ones. For example, we assign

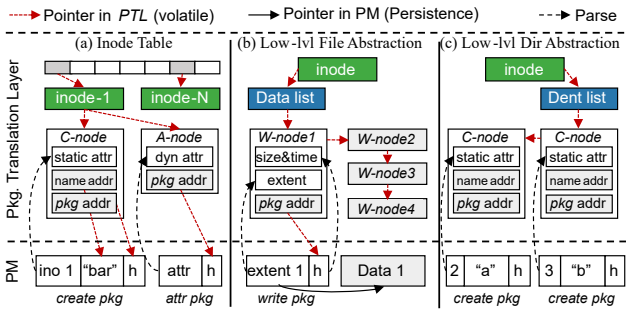

Figure 4: Package translation layer. *h is package header. PTL parses packages as pkg-nodes (*e.g., *C-node/A-node/W-node for the create/attr/write pkg) and organizes different pkg-nodes to provide compatible metadata objects for file/dir abstractions (§5.2).*

the type `CREATE|RENAME` to the *create pkg* used in a rename operation. Consequently, WOFS can write sub-packages without ordering points, *i.e.,* $P_1|P_2|...|P_N$, where P_i is short for a sub-package I/O (*i.e.,* $J_M|J_C$) and P_i points to P_{i+1}.

We run `rename` as an example. `rename` can be regarded as first hard linking a new file to the old one and then unlinking the old one [37]; therefore, it can be represented using *create pkg* (P_{create}) and *unlink pkg* (P_{unlink}). We now show that WOFS can safely issue $P_{create}|P_{unlink}$: If only P_{unlink} is partially written, WOFS can detect the incompleteness by following the *forward-pointer* in P_{create} and then discard `rename`. If only P_{create} is partially written, WOFS detects the incompleteness by determining that there is a P_{unlink} with *rename* type, but no P_{create} pointing to it. Note that using a *dual-pointer* can simplify this reverse detection, but it would misalign the atomic packages from the 64-byte cache line, which is currently avoided in our design. Finally, if both of them are partially written, WOFS cannot detect valid sub-packages, which is equivalent to the case where `rename` has never happened.

4.3 Package Translation Layer

By aggregating metadata of an operation as a package, WOFS upends the traditional metadata objects (*e.g.,* inode, dentry, etc.). Consequently, WOFS should parse packages to provide compatible file/directory abstractions. We introduce *package translation layer (PTL)* to achieve this goal. The basic management unit in PTL is *pkg-node*, which contains the parsed data from the package for fast access and the address of the package for reclamation (§4.4). These nodes are organized to form the compatible metadata objects, as shown in Figure 4.

- *Inode table*. To construct an inode, PTL combines the pkg-nodes of *create pkg* and *attr pkg* to represent its static and variable attributes. PTL maps the inode number to the inode as the inode table for fast search. An *inode manager* is introduced to allocate/free the inode number.
- *Low-level file abstraction*. PTL is responsible for locating data blocks to provide low-level file abstraction. As Figure 4b shows, PTL associates a list of *W-node*s for each regular file (*i.e., data list*), where the *W-node* contains the extent structure parsed from the *write pkg*. The upper file abstraction can reorganize these nodes for fast data access.
- *Low-level directory abstraction*. Similarly, PTL maintains a list of *C-node*s (*i.e., dent list*) to locate the sub-inodes under a directory. These nodes are further organized by the upper directory abstraction to provide high search performance (*e.g.,* using a hash table for name searching).

4.4 Non-log Layout and Package Reclamation

WOFS introduces a non-log layout that allocates blocks/packages across PM similar to *malloc*, which has two benefits: (1) allocate space anywhere to exploit PM fast I/O and erase-free nature [10]; (2) reclaim space via reusing (instead of heavy copy-based GC), which reasons invalidations by determining the causal-order of operations in the critical path, and reallocates invalidated space (similar to *free*), as follows.

- *Create pkg*. The deletion of a file (by writing an *unlink pkg*) invalidates its *create pkg*. After that, the space of *create pkg* recorded in the *C-node* (*i.e., pkg addr*) is marked as free and can be reallocated for new packages.
- *Write pkg*. Size change (*e.g.,* `truncate`) leads to the invalidation of the *write pkg* and corresponding data blocks. Overwrite might also lead to invalidation but it depends on the implementation. For example, if the file system adopts Copy-on-Write (COW) for data atomicity, overwrite will invalidate the old *write pkg* accordingly (see details in §5.2).
- *Attr pkg*. Any attribute changes result in the persistence of a new *attr pkg* of the file, which leads to the invalidation of the old *attr pkg* that belongs to the same file.
- *Unlink pkg*. WOFS checks whether to invalidate an *unlink pkg* during the creation of a file. This is because the *unlink pkg* cannot be reclaimed until its pointing *create pkg* is reallocated and overwritten, or WOFS might find a stale but valid *create pkg* during the recovery. Specifically, WOFS maintains an *order map* in the PTL, which maps the address of *create pkg* to that of *unlink pkg*. Whenever a *create pkg* is durable, WOFS looks up its written address in the *order map* to reclaim the associated *unlink pkg*.
- *Compound package* cannot be reclaimed until all the atomic packages are invalidated. To track this, we extend PTL by generating each compound package a *comp-pkg-node* and adding a reverse mapping from the *pkg-node* to the *comp-pkg-node* to notify the reclaiming of the atomic packages.

4.5 Fast Recovery with Coarse Persistence

For recovery, WOFS requires locating packages to check consistency and rebuilding PTL to manage packages. However, it is non-trivial to quickly locate packages as they are distributed across the PM due to the non-log layout design. We thereby first explore package locating approaches.

Locate packages with dump-restore. A naïve approach is *dump-restore (DR)* [21]: WOFS dumps the addresses of packages in a bitmap (where each bit for a 64-byte slot, as packages are 64-byte aligned) at the unmount time. During recovery,

WOFS uses this bitmap to locate and parse the packages. However, this approach still causes a PM scan after the system crashes due to the failure to timely dump the bitmap. *DR* can be optimized (*i.e., DR-OPT*) by "tagging" unallocated blocks during format, allowing them to be skipped during recovery, but it cannot avoid scanning allocated data blocks.

Locate package with coarse persistence. We argue that a centralized structure is a must for fast locating, but its impact can be minimized. We propose *Coarse Persistence (CP)*, which allocates a coarse *pkg-group* (*e.g.,* 4 KiB) to hold multiple packages and timely persists the address of *pkg-group* into the bitmap once it is allocated (*i.e.,* a bit for a group). Therefore, WOFS can scan the bitmap to locate the *pkg-group*, then probe to check valid packages, and finally rebuild PTL.

To ensure the crash consistency of CP, a straightforward approach is to insert an ordering point between bitmap update (m_{cp}) and the package I/O ($P = \overline{J_M|J_C}$), *i.e.,* $D \rightarrow m_{cp} \rightarrow P$. However, this ordering is unnecessary (*i.e.,* $P|m_{cp}$). Particularly, (1) if m_{cp} is durable, P can be detected through the bitmap and checked for completeness; (2) Otherwise, P cannot be accessed through the bitmap and is simply discarded. This is safe as m_{cp} occurs only when a new *pkg-group* is allocated; therefore, discarding P is equivalent to handling a normal data operation crash as described in §4.1.

Recovery with coarse persistence. After locating packages using CP, WOFS fixes inconsistencies and re-parses packages to rebuild the PTL. To fix inconsistencies, WOFS must identify and reclaim stale packages. It does so by determining the causal order between packages, treating logically reclaimed packages as invalidated, *e.g.,* a newer *unlink pkg* invalidates its corresponding older *create pkg*. Specifically, WOFS first detects successfully written packages using the magic number and checksum, then tracks their versions using timestamps in headers, and finally determines their causal order based on operation semantics (following rules similar to those in §4.4). Compound packages are checked and fixed using the forward-pointer mechanism, as described in §4.2.

Crash safety semantics. Consequently, WOFS's crash safety guarantees that packages preserve the same *causal order* as before the crash, rather than their *issue order*. For example, assume Thread-1 writes a *create pkg* C_1 for a file, followed by a *write pkg* W_1, and Thread-2 writes a *write pkg* W_2 to another file. These writes are issued in the order $C_1(t_1)$, $W_2(t_2)$, and $W_1(t_3)$, where t_i denotes the timestamp and $t_1<t_2<t_3$. A crash may leave W_2 partially written but C_1 and W_1 fully written; in this case, WOFS treats $C_1(t_1)$ and $W_1(t_3)$ as valid to preserve the correct causal order. On the other hand, WOFS does not require $W_2(t_2)$ for recovery since W_2 has no causal dependency on W_1 (*i.e.,* they operate on different files).

5 WOFS Implementation

We built WOLVES as a WOFS prototype in Linux kernel 5.1.0 with 12,000+ lines of C code. We also introduce several techniques to optimize I/O performance by leveraging Intel PM characteristics (*e.g.,* XPLine size and memory interface).

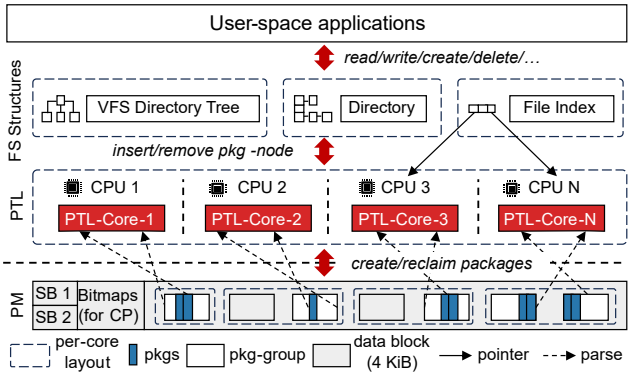

Figure 5: WOLVES file system architecture. *Packages are allocated within pkg-groups for fast recovery. WOLVES then writes packages with one* `PCOMMIT`. *PTL is then built to manage packages as traditional metadata objects for upper file/dir abstractions. To enable multi-core scalability, PTL is deployed in a per-core manner.*

5.1 Architecture and WOFS Properties

Data layout. As Figure 5 shows, WOLVES manages PM at a 4 KiB block granularity and reserves the first two blocks for *superblock* and its redundant copy. The subsequent few blocks are reserved for bitmaps that persist *pkg-group* addresses for fast recovery (§4.5). The rest of the space stores data blocks and packages. WOLVES allows only one type of package in a *pkg-group* to reduce bitmap size and simplify space management. Thus, WOLVES reserves $\frac{4}{(4096\times8)} \approx 0.012\%$ PM space for bitmaps, where "4" denotes four types of atomic packages.

Space management. WOLVES adopts a two-level allocator (*tl-allocator*) for space allocation on each CPU, and each allocator manages a contiguous area R where $R = \frac{PM\ Size}{NumOfCPU}$. Specifically, the allocator maintains a list of free data blocks in the current area using a red-black tree. If no blocks are available, WOLVES allocates space by consulting other core allocators in a round-robin manner. To reclaim a data block, since the allocated space never crosses allocator boundaries, WOLVES determines the corresponding allocator by simple address division, and reinserts the block number into it.

To allocate packages, *tl-allocator* first allocates a data block as the *pkg-group* and then allocates a package in the group. Specifically, *tl-allocator* tracks each allocated *pkg-group* with a memory node, which uses a small 64-bit bitmap to manage its space (*i.e.,* 64=4096/64). The memory nodes are maintained in a mapping where the key is the address of the *pkg-group*, and the value is the node itself. To reclaim a package, *tl-allocator* first calculates the address of the *pkg-group*, then finds the tracked node according to the mapping, and clears the associated bits for further allocation.

PTL implementation and space reclamation. PTL builds the inode table as a global hash table with fine-grained per-

bucket locks for concurrency. It manages the data list and dent list in a per-CPU manner similar to *tl-allocator*, where each core maps inode numbers to the corresponding list for fast access. To manage *pkg-nodes* (in these lists) across different cores, high-level file system structures (*e.g.,* file/directory) index *pkg-nodes* to produce a global file system view. These structures are protected by per-file locks (*i.e.,* inode locks), ensuring concurrent consistency. The effects of written packages remain invisible until these high-level structures are atomically updated to reference the *pkg-nodes* via locking. Finally, PTL reclaims space by reasoning about operations along the critical path (§4.4). Note that the reclamation overheads are negligible as no extra PM I/O is required: PTL simply notifies the *tl-allocator* that the space is available for reuse.

Concurrency model. WOLVES follows the causal-ordering concurrency protocol [50] to align with WOFS's crash safety semantics, meaning that the independent packages can be persisted in parallel even if they are ordered by timestamp (*e.g.,* create two files under two different directories). For causally related packages, such as deleting a file after creating it, WOLVES serializes them for correctness. This is consistent with the virtual file system (VFS) framework.

5.2 Handling File System Operations

Directory abstraction and operations. Overall, the file system name hierarchy is based on VFS `dentry`-formed tree, so that WOLVES only maintains the parent-child name hierarchy: It deploys a 128-slot hash table for the directory inode to reorganize *dent list* based on name hashes. The table size is configurable to meet different demands. Given this organization, the operations for creating an inode, such as `mkdir`, can be achieved by writing a *create pkg* once using a `PCOMMIT`, generating a *C-node* in PTL, and updating the parent's hash table. Deleting an inode can be similarly achieved by writing an *unlink pkg* and removing related memory objects. For inode deletion/creation, *order map* should be updated or checked to track and reclaim the invalidated *unlink pkg*; moreover, the *create pkg* should be reclaimed after inode deletion (§4.4).

File abstraction and operations. WOLVES adopts dynamic arrays [16, 51] for files to reorganize *data list*. Therefore, the `read` operation is simple: WOLVES calculates the array slot for the given offset and copies the data to the user buffer. We now introduce how WOLVES handles the `write` operations.

- *Non-overlap write*. Typically, a non-overlap write is done by writing data using non-temporal stores (*i.e., movnti*) to bypass CPU cache [11], writing a *write pkg* once, inserting a new *W-node*, and updating the dynamic array.
- *Overlap write*. WOLVES writes data in a COW manner [21]. After generating a new *write pkg* $[c,d]$ and a *W-node* $[c,d]$, the overlapped *write pkg* (pointed by *W-node* ranging $[a,b]$) is handled in three ways: (1) if $[c,d] \supset [a,b]$, WOLVES reclaims the old *write pkg* and data blocks; (2) if $c < a, d < b$ (or $c > a, d > b$), WOLVES reclaims the overlapped data blocks and modifies the old *W-node* to $[d,b]$ (or $[a,c]$); (3) if $[c,d] \subset [a,b]$, WOLVES modifies the old *W-node* to $[a,c]$, and generates a new *write pkg* and *W-node* for $[d,b]$.
- *Append write*. For an append-like operation (*i.e.,* `offset` = `size`), instead of creating a *write pkg*, WOLVES appends the new data to the blocks that are already allocated to the file, and writes the changed file size in an 8-byte atomic reserved field of the *write pkg* header without recalculating the CRC32. To verify the validity of a *write pkg*, WOLVES first assigns zero to the reserved field and then checks CRC32.

Ops	Package (§4.2)	Implementation Details
`create`, `mkdir`, `mknod`	*Create pkg*	① Persist *create pkg*, ② update *inode map* and parent's hash table, ③ check *order map* to determine whether to reclaim an *unlink pkg* (§4.4).
`read`	*None*	① Search the file index to obtain data addresses, ② copy the data from PM to the user buffer.
`write`, `fallocate`	*Write pkg*	① Persist *write pkg*, ② update *data list* and file index, ③ reclaim overwritten *write pkg* (§4.4)
`unlink`, `rmdir`, `rm`	*Unlink pkg*	① Persist *unlink pkg*, ② unlink *C-node* from the hash table and *dentry list* and free *A-node*, ③ update *inode map* and *order map* (§4.4).
`link`	*Create pkg*	Similar to `create`, but changes the linked inode of the name entry to the linked one (§4.2).
`chmod`, `chown`, `truncate`	*Attr pkg*	① Persist *attr pkg*, ② replace the newly generated *A-node* for the inode, ③ reclaim the old *attr pkg* associated with the file (§4.4).
`rename`	*Create* + *Unlink*	Reuse `link` and `unlink` operations with preallocated *create* + *unlink pkg*. Assign a forward-pointer from *create pkg* to *unlink pkg*.
`symlink`	*Create* + *Write*	Reuse `create` and `write` operations with preallocated *create* + *write pkg*. Assign a forward-pointer from *create pkg* to *write pkg*.

Table 3: Implementation of 15 typical file system operations. *This table shows the four atomic package abstractions are fairly enough for most of the file operations.*

Other operations. The implementations of 15 typical file system operations with packages are shown in Table 3. Other operations, such as `cp`, are omitted as they are handled by VFS once WOLVES has implemented the above operations. Note that the implementation of these file operations may vary. For example, if a file system needs to maintain timestamps for `read`, it can simply write an *attr pkg* to update the timestamps.

5.3 Recovery

Atomic package recovery. For atomic packages, WOLVES reasons their causal ordering to fix inconsistencies and rebuild PTL: It first scans the *create* bitmap to locate *create pkg* to rebuild the inode table and then the *unlink* bitmap to reclaim the invalidated inode. *Dent list* is rebuilt along with the inode table by parsing the name entry in the *create pkg*. Next, WOLVES scans the *write* bitmap to recover *data list*s. When constructing *data list*s, the overlaps of *write pkg*s are reasoned based on their timestamp, and *W-node*s are updated accordingly. Finally, WOLVES scans the *attr* bitmap to update the attributes of the inode and reclaims the truncated data.

Compound package recovery. For the compound packages, WOLVES verifies integrity by checking the forward-pointers:

the compound package is valid unless all the linked packages are valid. This verification is integrated into the package scanning process. As an example, we consider the `rename` operation, which combines *create* and *unlink pkgs*. For brevity, we denote the *create* and *unlink pkgs* as $P_{c|r}$ and $P_{u|r}$, respectively. The recovery of `rename` proceeds in two phases.

First, *validate the first package during the create bitmap scan.* If a $P_{c|r}$ is found, follows its forward-pointer. If it points to a valid $P_{u|r}$, the rename operation is successful, and a mapping from $P_{u|r}$ to $P_{c|r}$ is inserted into a temporary hash table. In this case, $P_{c|r}$ is treated like a normal *create pkg*. Otherwise, the pointed package is invalid (*e.g.,* broken checksum) or is not a $P_{u|r}$, the pointer is deemed stale, and the $P_{c|r}$ is discarded. This is safe since a compound package can be reclaimed only if all its components are reclaimed. Second, *validate the second package during the unlink bitmap scan.* If a $P_{u|r}$ is found but no $P_{c|r}$ points to it (by checking the hash table), it is reclaimed. Otherwise, it is processed normally.

A similar process applies to other compound packages, though it is integrated into different package scanning phases. For example, the `symlink` operation requires first verifying the *create pkg* (*i.e., create pkg* scanning), followed by the *write pkg* (*i.e., write pkg* scanning), to ensure integrity.

Allocator recovery. During package scanning, WOLVES recovers the allocators by marking all space as free, then restoring the allocated space for valid packages and data blocks.

5.4 Other Optimizations

Huge allocation (HA). WOLVES allocates 2 MiB huge blocks for append-like writes. Hence, smaller writes (*e.g.,* KV) can be appended to the huge block by updating existing *write pkg* (see §5.2), which reduces PM buffer pollution by increasing buffer hits. If huge blocks are not available, WOLVES allocates as many contiguous blocks as possible.

Read ahead (RA). For `read`, WOLVES can prefetch the to-be-read data in an XPLine (*i.e.,* 256 bytes) stride for acceleration. Specifically, to read `size` data at `offset`, WOLVES first issues a number of $size/256$ `prefetcht0` from `offset` with a 256-byte stride; then, it copies the data to the user buffer. This enables copy I/O to be overlapped with the prefetching I/O.

6 Evaluation

We design experiments on WOLVES (*i.e.,* our WOFS implementation) to answer the following questions:

- Can WOLVES achieve robust crash consistency?
- Can WOLVES fully release the I/O performance of the PM and achieve optimal metadata operation performance?
- How does WOLVES perform under the aged scenarios?
- How expensive are WOLVES recovery procedures, memory overheads, and storage space consumption?
- How does WOLVES compare to (synchronous) soft update?
- Does the WOFS/WOLVES design generalize to future platforms beyond Intel PM (*e.g.,* Memory-Semantic SSD [3])?

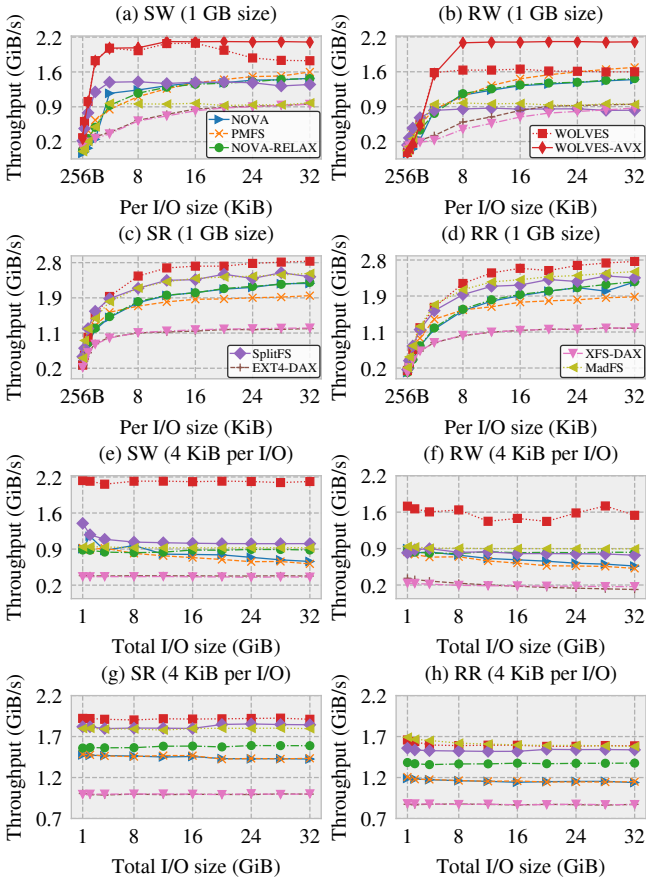

Figure 6: I/O performance comparison under different I/O patterns. *Sub-figures (a)–(d) study the I/O throughput varying per I/O size when populating a 1 GiB file. Sub-figures (e)–(h) study the I/O scalability under different file sizes with per I/O size 4KiB.*

6.1 Experimental Setup

Testbed. The experiments are conducted on a server with a 16-core Intel Xeon Gold 5218 CPU, 128 GiB DRAM, and 2×256 GiB Intel Optane PM configured in non-interleaved mode[4], running atop Linux Kernel 5.1.0 [52].

Competitors. We compare seven PM file systems that apply different synchronous crash consistency techniques: PMFS, NOVA, NOVA-RELAX (NOVA w/o data atomicity), SplitFS, MadFS, EXT4-DAX, and XFS-DAX. PMFS is equipped with a huge-page-aware technique from WineFS [18] to resist file system aging. SplitFS is configured in POSIX mode for the highest performance. MadFS [28] is a recent user-space PM LFS built atop EXT4-DAX. The last two file systems are production-ready and mounted in `ordered` mode. We also compare WOLVES with soft update file systems in §6.11, including (asynchronous) SoupFS [53], (asynchronous) HUNTER [51], and (synchronous) SquirrelFS [25]. Note that despite our best efforts, we only successfully run MadFS in FIO, single-threaded Filebench, and several FxMark work-

[4]Note that the interleaved mode shows similar performance trends. We thus only report non-interleaved mode due to page limits.

%ile (us/op)	WOLVES	NOVA	PMFS	SplitFS	MadFS
90%	2.21	5.22	5.00	1.76	1.70
99%	3.16	7.12	6.00	4.24	4.08
99.9%	12.84	19.38	21.00	951.09	1095.00
99.99%	18.92	23.27	329.4	1125.58	1302.53

Table 4: Tail latency comparison. *The table is measured under the single-threaded 32 GiB SW workload with 4 KiB per I/O.*

loads, using their provided configurations.

Methodology. We ran each test at least five times and reported the *average value*. The standard deviation was less than 5%, suggesting the experiments are repeatable.

6.2 Crash Consistency

We have used a formal logical model [37, 54, 55] to prove that WOLVES can provide robust crash consistency. The proof is attached to the Appendix A. In this subsection, we measure if WOLVES recovers correctly against crashes via three steps: (1) run workloads for specific I/O patterns, (2) trace I/Os and reorder them, and (3) create images with random crash points and remount WOLVES. We manually trace PM I/Os at the instruction level, including *store+clwb*, *movnti*, and *sfence*; traces are written to a file for reordering (between *sfences*) and replaying (until a random crash point).

Exhaustive crash consistency verification is practically infeasible due to the infinite space of workloads. Thus, we adopt three representative workloads, following OptFS [15] and BarrierFS [13], to show that WOLVES can recover from common random crash scenarios: an append workload that keeps appending 4 KiB data to a file, `create_delete` that creates then deletes 10 files, and `rename_root_to_sub` that creates and renames (mv) a file to a sub-dir. These workloads cover most I/O patterns in WOLVES: $D \rightarrow P|(m_{cp})$, $P|(m_{cp})$, and $P_{unlink}|P_{create}$. To see if WOLVES recovers to the latest consistent state, we create checkpoint for every file operation and compare the recovered system with the latest checkpoint. For each workload, we test 1000 random crash points. The results show that WOLVES consistently recovers to the latest consistent state prior to the crash, suggesting that it can correctly handle most common crash scenarios.

6.3 I/O Performance

We leverage FIO [56] to study WOLVES I/O characteristics.

I/O patterns. As Figures 6a–6d show, all file systems ramp up throughput with the per I/O size increases until the PM buffer is exhausted [10, 57]. For SW/RW, WOLVES shows significant benefits when the per I/O size is less than 16 KiB since it writes package once, but collapses afterward due to the deficiency of `movnti`, making data I/O dominated [23]. We address this by integrating *vmovntdq* into kernel (*i.e.,* WOLVES-AVX), and the throughput scales to PM bandwidth limits with the increasing I/O size. In SR/RR, WOLVES demonstrates the read performance of a kernel file system can even exceed that of user-space SplitFS thanks to the read-ahead (RA) technique. Notably, without RA (not shown in the figure), WOLVES has a similar `read` performance to other PM kernel file systems due to their similar `read` code paths.

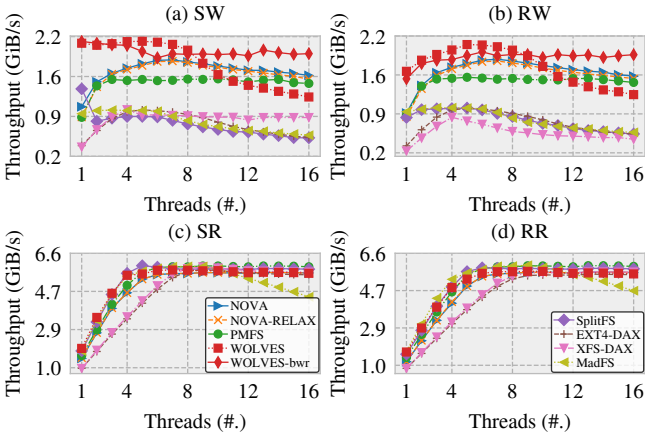

Figure 7: Concurrency performance comparison. *The experiment compares the 4 KiB per I/O write throughput of different PM file systems under 1–16 threads. Each thread populates a distinct 1 GiB file under the same directory.*

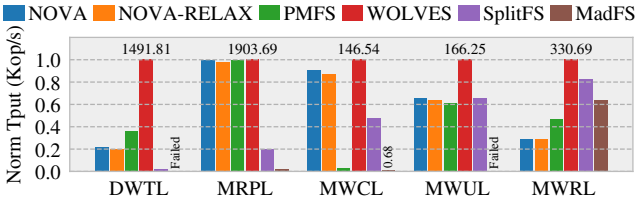

Figure 8: FxMark evaluation. *DWTL reduces the file size by 4 KiB; MRPL opens a file in five-depth dirs; MWCL creates an empty file; MWUL unlinks an empty file, and MWRL renames a file.*

File size scalability. As Figures 6e and 6f show, in the SW workload, the write throughput of WOLVES stabilizes at 2.20–2.24 GiB/s, achieving 97.3%–99.1% of the throughput of raw PM [2]. WOLVES fails to achieve similar performance in RW as RW cannot benefit from the huge allocation (HA), but it still achieves 1.65–9.44× throughput compared to others due to the minimized metadata I/Os and ordering points for the metadata write-once scheme.

Tail latency. As Table 4 shows, WOLVES achieves the lowest tail latency compared to NOVA and PMFS, but SplitFS and MadFS outperform WOLVES before the 99.0 percentile since they persist data in the user space. However, SplitFS and MadFS suffer severe tail latency afterward due to their occasional kernel metadata access, which becomes bottlenecks.

Concurrency. As shown in Figure 7, WOLVES outperforms competitors in 1–8 threads. Nevertheless, WOLVES suffers performance degradation when thread numbers ≥ 9. The observation is consistent with prior reports that PM has limited concurrency due to its hardware contentions [11, 16, 17, 51, 57]. To address this, we sample the I/O latency and insert delay when the I/O latency > 3000 ns to alleviate the contention

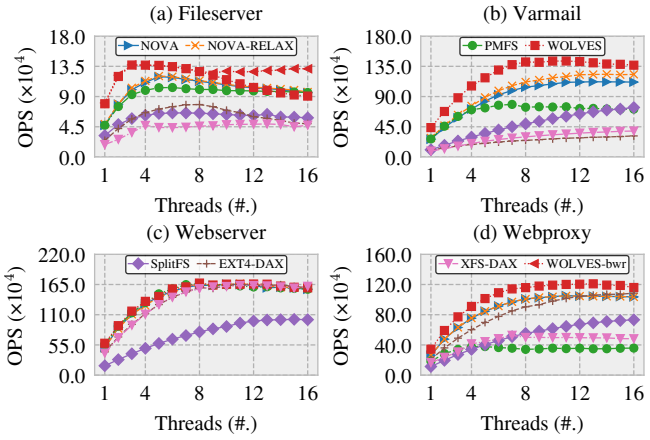

Figure 9: Filebench evaluation. *Each workload runs for 60 seconds under 1–16 threads. Operations per second (OPS) is reported.*

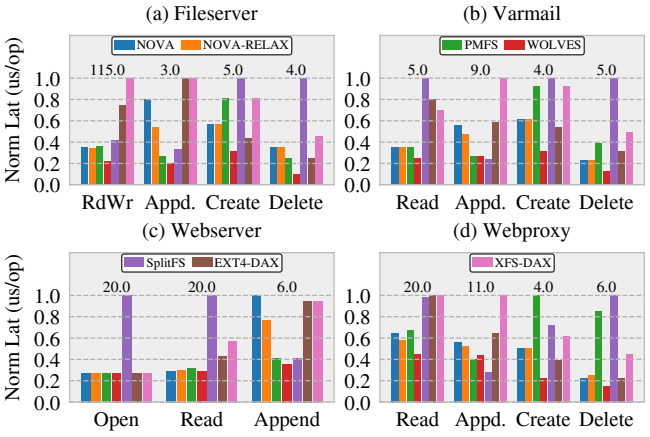

Figure 10: Filebench operation latency breakdown. *We report single-threaded performance breakdown. The numbers above the bars show WOLVES latency. Note that the open latency is similar under four workloads, and thus we only report it under Webserver.*

(*i.e.,* WOLVES-bwr). Consequently, WOLVES can scale to PM bandwidth limits with the increasing thread numbers.

6.4 Metadata Operation Performance

We study metadata operations using FxMark [58] under a single thread. For the concurrent metadata operations, VFS' locking scheme limits the parallelism [16,35], and optimizing its locking is beyond the scope of this paper. Figure 8 shows that WOLVES achieves the highest throughput for most metadata operations thanks to the metadata (*i.e.,* package) write-once scheme. In the MRPL workload, all the evaluated file systems, except for SplitFS and MadFS, show similar throughput since they rely on VFS directory traversing. SplitFS and MadFS, however, suffer from their own traversing and in-kernel traversing, thereby reducing the overall throughput.

6.5 Macrobenchmarks

We evaluate four workloads in Filebench [59] (see Table 2). As Figure 9 shows, WOLVES achieves the highest throughput under both write- and read-intensive workloads. In Fileserver, WOLVES can alleviate I/O contention by regulating bandwidth (*i.e.,* WOLVES-bwr). Figure 10 studies the latency breakdown of critical file operations. WOLVES achieves the lowest latency when performing file creation/deletion due to its metadata write-once scheme. We observe that PMFS has a similar append performance as WOLVES because PMFS uses a similar append approach. SplitFS, however, suffers severe metadata overheads due to its in-kernel metadata operations.

We also compare WOLVES with MadFS in Table 5 and find that MadFS suffers extremely low throughput due to its heavy metadata overheads, which is consistent with FxMark results.

Workload	MadFS	WOLVES	Speedup
Fileserver	5.57 Kops/s	80.4 Kops/s	14.4×
Varmail	7.13 Kops/s	438 Kops/s	61.4×
Webserver	63.6 Kops/s	581 Kops/s	9.14×
Webproxy	9.6 Kops/s	344 Kops/s	35.8×

Table 5: Filebench comparison with MadFS. *Here, we report single-threaded Filebench performance for MadFS.*

6.6 Performance Breakdown

I/O breakdown. Comparing Figure 11 with Figure 2, WOLVES reduces latency by 5%–86% compared to NOVA, SplitFS, and PMFS. Furthermore, *CP* overhead is less than 0.5%. Notably, in SW, WOLVES reduces data time by 42.2%; the reason is that the metadata write-once and HA reduce XPBuffer pollution; as a result, even the metadata time accounts for nearly 40%, it can achieve more than 97% of PM bandwidth. Using *ipmctl*, we confirm that WOLVES reduces per-operation metadata I/O by 70%–17.3× compared to PMFS and NOVA.

Technique breakdown. Figure 12 studies how the metadata write-once (WO), huge allocation (HA), and read ahead (RA) contribute to WOLVES. First, the metadata write-once scheme improves 1.01–1.66× and 72%–1.30× throughput under SW and RW compared to other PM file systems, which is the main source of performance improvement. We observe that sometimes WOLVES can reach 2.01 GiB/s under SW, primarily because the CPU has the potential to reorder *movnti*s (for data I/O, §5.2) to improve I/O parallelisms and reduce PM contention. Second, HA further improves throughput by 20.2% for SW, but it is less effective for RW due to the lack of sequential I/O patterns in RW. Finally, RA can improve SR and RR by 22%–27% due to the improved read parallelism.

6.7 Real-world Applications

LevelDB. Figure 13a shows the performance of different PM file systems on LevelDB using YCSB workloads (driven by built-in `db_bench`) [20]. WOLVES achieves the most significant improvement under write-intensive workloads (Load A, E, and Run A). On the read-intensive workloads, WOLVES's throughput is still higher than others, thanks to the RA.

RocksDB. Figure 13b runs RocksDB [23] (1M key-value pairs), which is configured with no preallocate. Despite our

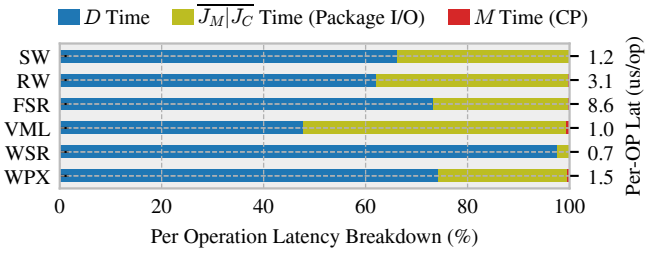

Figure 11: WOLVES I/O breakdown. *SW and RW are both 32 GiB with 4 KiB per I/O. FSR, VML, WSR, and WPX are short for fileserver, varmail, webserver, and webproxy running for 60 seconds.*

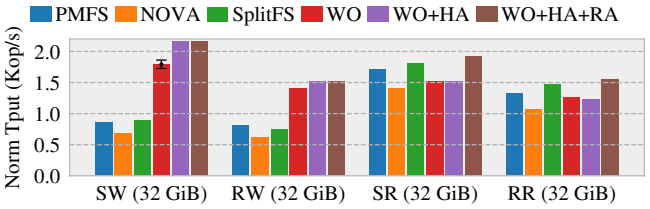

Figure 12: WOLVES techniques breakdown. *We show the single-threaded I/O performance with 4 KiB per I/O. WO denotes WOLVES without HA and RA. WO+HA+RA is the final WOLVES.*

best efforts, we fail to run SplitFS [20] on RocksDB. WOLVES has 1.26–6.73×, 1.36–5.21×, 1.26–3.93×, and 1.20–4.46× the throughput of other PM file systems for the Sequential Fill, Random Fill, Random Append, and Random Update.

6.8 Aging and Fragmentation

During frequent file creations/deletions (*i.e.,* aging), WOLVES incurs data/package fragmentation. To retrieve WOLVES aging performance, we use Geriatrix and widely cited Agrawal profile [60] to age WOLVES at 80% PM utilization until convergence in relative age distribution [61]. Following aging process, we stress SW and RW on WOLVES.

Figure 14a suggests that under the SW, (1) WOLVES has an unstable throughput 1.85–1.95 GiB/s due to fragmentation; (2) the performance degradation is minor as ∼50% of the Agrawal profile's files are ≥8 KiB, and their deletions free up many contiguous space (*e.g.,* more than 50% free contiguous block numbers are in $[19,384]$), which is then leveraged by HA to alleviate fragmented package writes. To show an extreme case, we set all files in the Agrawal profile to 4 KiB, resulting in an extremely fragmented space (*e.g.,* all available contiguous block numbers ≤8). However, even under this profile, WOLVES still outperforms NOVA and PMFS, and obtains 1.70–1.82 GiB/s throughput thanks to its metadata write-once scheme. Figure 14b shows that under the RW, WOLVES throughput is 1.31–1.44 GiB/s. Here, the performance degradation mainly comes from the fragmented packages as WOLVES has no HA optimization for RW.

In summary, though performance degradation occurs during aging, WOLVES still outperforms other PM file systems. Note that WOLVES does not apply any defragmentation techniques currently, which we plan to explore as a future work.

Category	Workload	NOVA	DR	DR-OPT	WOLVES
Large file	FIO-32G	24.2 s	70.1 s	60.4 s	2.61 s
Write intensive	Fileserver	2.48 s	71.9 s	45.8 s	3.99 s
Read intensive	Webserver	2.52 s	70.5 s	43.1 s	2.75 s

Table 6: Failure recovery time. *DR dumps package addresses into bitmaps when unmount; DR-OPT tags unallocated blocks during format and skips scanning them when recovery. Note that (write-intensive) Varmail and (read-intensive) Webproxy have similar results to Fileserver and Webserver, thus we omit them in the table.*

6.9 Recovery Overhead

Common scenarios. Table 6 compares the failure recovery time of NOVA, DR, DR-OPT, and WOLVES under three representative evaluated workloads. Thanks to *CP* (§4.5), WOLVES can only scan bitmaps and *pkg-group*s, thus achieving a failure recovery time comparable to that of NOVA. Note that the extremely slow recovery of NOVA under FIG-32G is due to its engineering deficiency: For files larger than 1 GiB, NOVA must scan its inode-log multiple times, as it can only replay entries for 1 GiB of data per pass.

Worst scenario. We build a worst-case workload to show that WOLVES can recover quickly thanks to the metadata-only scanning: We assume the file system is fully populated with non-empty files (*i.e.,* PM is fully occupied). Each file is written with a single data block, modified via `chown`, and eventually deleted. This process generates for each PM data block one 256-byte *create pkg*, one 64-byte *write pkg*, one 64-byte *attr pkg*, and one 64-byte *unlink pkg*, leading to the highest metadata (packages) scanning overhead. Even in this case, WOLVES scans only around (256+64+64+64)/4096=10.9% of the total 256 GiB PM space with ∼60 million files (which is similar to NOVA), and the overall recovery time for WOLVES is ∼21.6 seconds. We believe that this overhead is acceptable as it remains faster than the traditional fsck for SSD file systems, which can take more than 2 miniutes for 60 million files [62–64], thanks to PM's high read bandwidth (∼2 GiB/s).

6.10 Resource Consumption

Memory overhead. We measure memory usage by hooking in-kernel memory allocation. In Fileserver and Varmail, WOLVES and NOVA achieve comparable memory consumption: WOLVES uses ∼8.93 MiB and ∼10.82 MiB memory, while NOVA uses 10.48 MiB and 8.31 MiB memory. Unlike NOVA, which consumes no memory for closed files, WOLVES maintains 3.8 MiB–5.12 MiB of memory for PTL even when all files are closed. This modest memory overhead (*i.e.,* around 0.3%–1.6% of the workload's size) enables significant performance benefits, with WOLVES achieving 68% and 65% higher throughput in Fileserver and Varmail, respectively.

Space overhead. Adding headers for packages incurs extra space overheads, but we argue that it is acceptable: conducting a total of 128 GiB 4 KiB I/Os requires (1K+1)–(512K+1) *pkg-group*s for one *create pkg* plus 64K–32M *write pkg* (with or w/o HA), leading to 0.0015%–0.7% space in a 256 GiB PM.

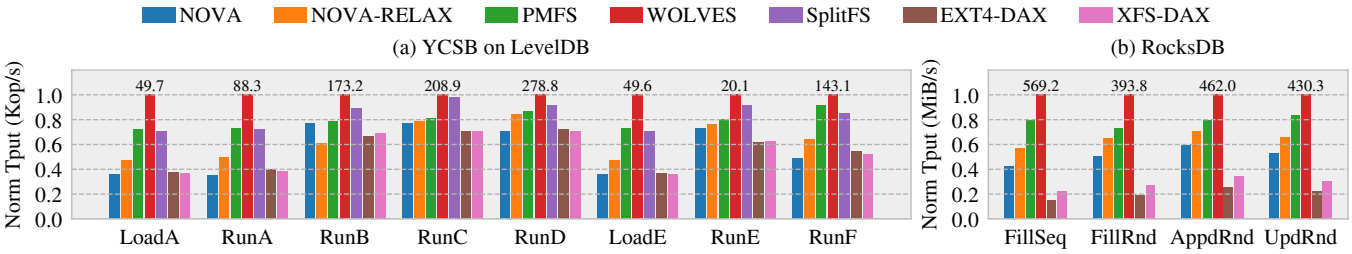

Figure 13: Real-world application performance comparison. *We measure the performance using the application's built-in db_bench tool. The numbers above the bars indicate the absolute throughput of WOLVES.*

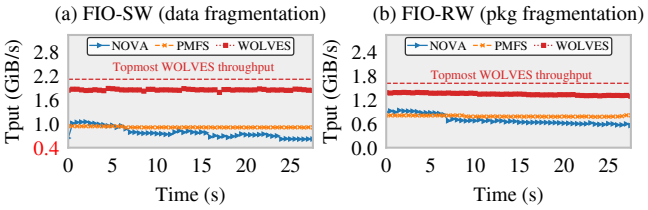

Figure 14: Aging/Fragmentation performance. *We measure the single-threaded sequential/random write throughput with 4 KiB per I/O under the Agrawal-profile-aged file system.*

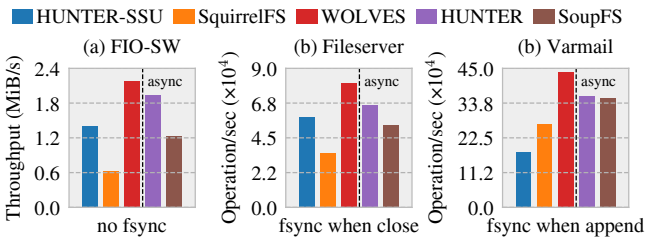

Figure 15: Comparison with (synchronous) soft update. *We hack HUNTER to support ordered synchronous soft update (i.e., HUNTER-SSU). SquirrelFS is written in Rust to support compile-time consistency check, and is measured under Linux kernel 6.3.0.*

6.11 Case Study: Beyond (Sync.) Soft Update

We use workloads with no/heavy/real-`fsync` to show that WOFS crash consistency outperforms SSU and even asynchronous soft update (ASU): (1) Figure 15a shows that ASU can outperform most of SSU, but WOLVES outperforms ASU as the former minimizes metadata I/Os while the latter periodically flushes metadata orderly, interfering with foreground I/Os. (2) By modifying FIO to issue `fsync` for every system call, we emulate the I/O behavior in RocksDB. The results (not shown) suggest that SSU has no performance degradation, while HUNTER drops to 762 MiB/s due to synchronization and I/O overheads. (3) Figures 15b and 15c show that WOLVES outperforms ASU by 21%–52% in workloads with occasional `fsync`, while other SSU suffers severe overheads due to many small, random, and ordered metadata I/Os.

6.12 Case Study: Memory-Semantic SSD

In this subsection, we show the generality of WOFS/WOLVES on Samsung Memory Semantic (MS) SSD [3], which is an emerging commercial PM backed by SSD. To simulate MS-SSD, we use *io_uring* [65] (with 128 depths) to emulate the byte-addressable interface, which allows the host to issue I/O to the *io_uring* buffers using loads/stores. The buffer is protected by a Castle UPS [66] and regarded as *persistent buffers*. The backend is a 1.6 TB Intel DC P4610 Series SSD; the issued I/Os are digested to SSD in a 4 KiB I/O unit through background threads (using `O_DIRECT`). Under this platform, the maximal write throughput is around 1900 MiB/s.

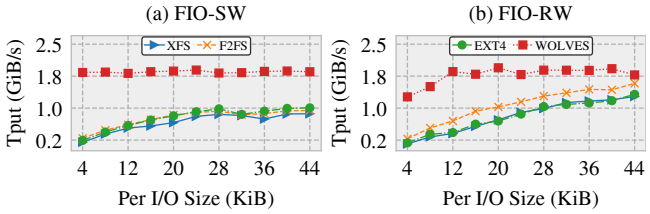

Figure 16: Performance comparison in MS-SSD. *We measure sequential/random write throughput in a single thread. The maximal write throughput of MS-SSD is ∼1900 MiB/s.*

We add several lines of code to emulate a PM-like interface, and thus porting WOLVES to the MS-SSD platform is trivial. We compare the write throughput of WOLVES with XFS, EXT4 and F2FS using FIO. For fairness, they are all configured to use direct-I/O and *io_uring* engine without `fsync` calls. Unsurprisingly, Figure 16 verifies similar results as in the Intel PM platform that WOLVES can achieve the highest write throughput thanks to the metadata write-once scheme.

7 Discussions and Future Work

Why do prior file systems manage metadata separately? Separating file system metadata with different responsibilities, such as inode, bitmap, and dentry, inherits the old wisdom of file system designs [67, 68]. Modern LFS, F2FS [45], also employs multiple tables (*e.g., SIT* and *NAT*) to manage metadata objects. Such design enables simplified crash consistency, easy/clear file abstraction, and avoidance of the wandering tree in flash memories [45]. However, it meets limitations for exploiting fast synchronous PM I/Os.

Distinguishing from LFS. The key novelty of WOFS lies in generating the specific, aggregated package for each file oper-

ation, which is different from the scattered metadata produced by modern LFSes, such as NOVA [21] and F2FS [45]. This write-once scheme minimizes metadata I/Os, resulting in a considerable improvement over LFS competitors. Moreover, WOFS's non-log layout and immediate package reclamation also distinguish it from LFS. These designs facilitate PM's relatively good random I/O (compared to HDDs/SSDs) and avoid significant GC overhead typically associated with LFS.

Shall WOFS eliminate data ordering? It is charming to eliminate data ordering via data checksum [15] (*i.e.,* $\overline{D|J_M|J_C}$). However, we find that data checksums, which cause user-to-kernel memory copies and computation overheads on large content, outweigh the benefits of eliminating ordering in fast PM. Specifically, we find that using CRC32 and faster xxHash [57,69] as data checksum inversely adds ∼40.1% and ∼32.3% overheads in the write path. Moreover, WOFS can already reach the PM bandwidth limit without data checksum. Hence, we leave exploring data checksums for future work.

Shall WOFS use checkpoint to accelerate recovery? Periodically checkpointing the PTL can alleviate package scan/rebuild overhead. However, we do not intend to use it for three reasons. First, checkpointing interferes with foreground PM I/Os, thereby degrading file system throughput [70], which we aim to avoid. Second, package/metadata occupy a small portion of storage, and scanning them is fast as no data block involved [21]. Finally, PM enables a much faster scanning performance than SSDs/HDDs, and reconstructing PTL is also fast as it merely manipulates DRAM. As a result, WOFS can recover in less than 30 seconds even in the worst scenario (§6.9). We do acknowledge the opportunity to checkpoint the PTL during system idle time, which we leave for future work.

Can memory overheads in WOFS be reduced? If memory overhead for PTL maintenance is a concern (*e.g.,* for memory-sensitive scenarios), it is feasible to use a PM-DRAM hybrid approach for PTL to reduce memory overheads while retaining performance, since PTL does not require flush/fence for ordering and durability. Specifically, we allocate 25%, 50%, 75%, and 100% of PTL metadata directly from PM and find that the performance degradation is negligible in SW, while only 3.1%, 6.3%, 8.8%, and 12.5% degradation in RW.

Performance considerations for compound packages. Currently, even the most complex operation [21], such as `rename`, involves only two packages, and the overhead of writing them concurrently with the forward-pointer is comparable to that of writing a single package. Figure 8 also shows that WOLVES's `rename` operation significantly outperforms existing PM file systems. Besides, such operations are infrequent. Particularly, `rename` operations account for ∼1%–10% of operations in many realistic/synthetic workloads [71,72].

8 Related Work

Optimizing ordering points. NOFS leverages back-pointers to eliminate the order between metadata and data [37]. OptFS introduces data checksum to eliminate the ordering between data and transactions for slow HDD [15]. BarrierFS redesigns the block I/O stack to enforce I/O order through multi-layer collaboration without waiting for persistence [13]. *Hardware Transactional Memory (HTM)* is an attractive hardware technique to eliminate software ordering. However, HTM-based crash consistency is currently only applicable on the eADR platform [24], which limits its usage. In contrast, our WOFS redesigns metadata as packages to minimize metadata I/Os and ordering points for fast synchronous crash consistency.

Metadata-optimized file systems. BPFS [73] novelly employs shadow paging that uses a COW scheme for metadata updates, but it leads to cascade of updates, which can be even more costly than JFS [21]. TableFS [74] and BetrFS [75] deploy write-optimized indexes to defer and batch small metadata writes [76]. Several works aim to use supercapacitors to protect asynchronous metadata I/Os, but these devices are not widely available [27,77]. In contrast, WOFS generates specific metadata for a file operation as one compact package to minimize metadata overheads without trading off durability.

Data-optimized file systems. OdinFS [17] and ArckFS [16] are two PM file systems designed to stripe data across multiple nodes to avoid single PM contention. However, these works follow traditional crash consistency mechanisms, leading to unorchestrated metadata I/Os. As a result, ArckFS (which even updates metadata in the user space) achieves only around 1400 MiB/s throughput under the single-threaded SW in our machine. We believe that these works are complementary to WOFS for machines with multiple nodes and PM arrays.

9 Conclusion

We introduce WOFS, a new file system model for fast and synchronous crash consistency. WOFS generates and manages specific metadata for a file operation as a checksum-protected package, and writes it once with a single ordering point. Experiments driven by various benchmarks and applications show that WOLVES, a WOFS prototype, outperforms existing file systems on PM platforms (*e.g.,* both Intel PM and MS-SSD), and can potentially reach PM bandwidth limits. The source code and test scripts are publicly available at `https://github.com/WOFS-for-PM/`.

A Proof of Crash Consistency in WOLVES

WOLVES achieves fast and synchronous crash consistency. In terms of crash consistency, there are three advanced levels: (1) metadata consistency that avoids dangling files, duplicate pointers, and storage leaks [37], (2) data consistency that further guarantees a file will not contain data blocks belonging to another file [54], and (3) version consistency that guarantees the version of metadata matches with the version of pointed data blocks [37]. This appendix focuses on formally proving that the proposed WOLVES based on the metadata write-once scheme can achieve both data consistency and version consistency[5] by using the existing logical framework [54, 55].

A.1 Notations

File system entities are *containers*, *pointers*, and *generations*. In WOLVES, package and data blocks are containers, which can be freed and reused. Containers are linked to each other by pointers (*e.g., write-pkg* maps data blocks). The *generation* of a container is incremented after each allocation while the

[5] Data consistency is a stricter form of metadata consistency [37].

epoch of a container is incremented whenever the contents are modified. Table 7 lists the notations. Specifically, we use *belief* to represent the in-memory and in-PM states of WOLVES, which are denoted as $\{\}_M$ and $\{\}_D$, respectively; we use *write()* to persist a container. We use before ($\ll$) and precedes ($\prec$) to indicate the ordering, for example, $A \ll B$ means A occurs before B, while $A \prec B$ means A occurs before B and holds until B occurs. Therefore, $A \prec B \Rightarrow A \ll B$.

A.2 Axioms

We reuse most rules in Sivathanu's logical framework [54] denoted by *S#*, as listed below.

- If a container B points to A in memory, its current generation also points to A in memory.

$$\{B^x \to A\}_M \Leftrightarrow \{g(B^x) \to A\}_M \tag{S1}$$

- If the on-disk contents of container A pertain to epoch y, some generation c should have pointed to generation $g(A^y)$ in memory followed by $write(A)$. The converse also holds:

$$\{A^y\}_D \Rightarrow \{c \to g(A^y)\}_M \prec write(A) \ll \{A^y\}_D \tag{S2}$$

$$\{c \to A_k\}_M \prec write(A) \Rightarrow \{A^y\}_D \wedge (g(A^y) = k) \tag{S3}$$

- If B points to A in memory, A is unshared and exclusive [54], a write of B will lead to the disk belief that B points to A:

$$\begin{aligned}\{B \to A\}_D \Rightarrow &\{B \to A\}_M \prec \\ &(write(B) \ll \{B \to A\}_D)\end{aligned} \tag{S4}$$

- A file system exhibits pointer ordering if it ensures that before writing a container B to disk, the file system writes all containers that are pointed to by B.

$$\begin{aligned}&\{B \to A\}_M \prec write(B) \\ &\Rightarrow \{B \to A\}_M \prec (write(A) \ll write(B))\end{aligned} \tag{S5}$$

We then present crucial axioms in WOLVES denoted by *W#* that govern the beliefs of WOLVES as follows.

- WOLVES believes that B logically points to A in PM only if B points to A physically with the correct checksum and no other entities are pointing to A with a larger timestamp.

$$\begin{aligned}\{B \to A\}_D \Leftrightarrow &\neg\forall C(\{C \dashrightarrow A\}_D \wedge ts(C) > ts(B)) \\ &\wedge \{B \dashrightarrow A\}_D \wedge ck(B)\end{aligned} \tag{W1}$$

- WOLVES ensures that if $\{B \to A_k\}$ and $\{C \to A_j\}$ hold in memory at two different points in time, container A should have been freed by persisting a newer C to invalidate B.

$$\begin{aligned}\{B \to A_k\}_M \ll \{C \to A_j\}_M \Rightarrow &\{B \to A_k\}_M \\ \ll &\{C \to A_j\}_D \wedge ts(C) > ts(B) \\ \ll &\{C \to A_j\}_M\end{aligned} \tag{W2}$$

Symbol	Description
$\&A$	set of entities that point to container A
A^x	the x^{th} version of epoch of A
A_k	the k^{th} version of generation of A
$g(A^x)$	the generation of the x^{th} epoch of A
$\{A^x\}_M$	the x^{th} version of A in the memory
$\{A^x\}_D$	the x^{th} version of A in the PM
$A \to B$	A logically points to B
$A \dashrightarrow B$	A physically points to B
$ts(A)$	the timestamp of container A (package)
$ck(A)$	the verification of checksum of A

Table 7: Notation used. *The table describes the basic symbols and operators used for consistency proof.*

- WOLVES ensures the data blocks A can be only pointed by one entity thanks to its CoW data update mechanism, which means:

$$\{B^x \to A^y\}_M \Rightarrow \{\&A = \{B^x\}\}_M \tag{W3}$$

A.3 Data Consistency

Data consistency ensures that a file will not contain data blocks belonging to another file [54]. Hence, we prove that if B points to A in PM (by scanning during recovery), then the generation of A is the same as the generation that was pointed to in memory, which can be reflected by the following rules:

$$\{B^x \to A_k\}_M \prec \{B^x \to A\}_D \wedge \{A^y\}_D \Rightarrow g(A^y) = k$$

We follow a similar process in §7.1 of [54]. We assume $g(A^y) \neq k$ (the content of A does not belong to generation k) and prove that this assumption leads to a contradiction, i.e.,

$$\neg(\{B^x \to A_k\}_M \prec \{B^x \to A\}_D \wedge \{A^y\}_D)$$

By applying eq. *S2*, we can obtain two possible sequences of the above assumption:

1. $\{B^x \to A_k\}_M \prec \{B^x \to A\}_D \ll \{C \to g(A^y)\}_M \prec write(A)$

2. $\{C \to g(A^y)\}_M \prec write(A) \ll \{B^x \to A_k\}_M \prec \{B^x \to A\}_D$

We then prove these two sequences lead to a contradiction.

- *Case 1*. Applying eq. *S1*,

$$\begin{aligned}\Rightarrow &\{g(B^x) \to A_k\}_M \prec \{B^x \to A\}_D \\ &\ll \{C \to g(A^y)\}_M \prec write(A)\end{aligned}$$

Applying eq. *W2*, we have

$$\begin{aligned}\Rightarrow &\{g(B^x) \to A_k\}_M \prec \{B^x \to A\}_D \ll \\ &(\{C \to g(A^y)\}_D \wedge ts(C) > ts(B)) \ll \{C \to g(A^y)\}_M \\ &\prec write(A) \\ \Rightarrow &(\{C \to g(A^y)\}_D \wedge ts(C) > ts(B)) \wedge \{A\}_D\end{aligned}$$

By applying eq. *W1*, it is easy to show that our initial assumption $\{B^x \to A\}_D$ (i.e., B points to A) and $\{C \to g(A^y)\}_D$ lead to a contradiction, as below.

$$\{B^x \to A\}_D \Rightarrow \neg\forall C(\{C \dashrightarrow A\}_D \wedge ts(C) > ts(B))$$

$$\{C \to g(A^y)\}_D \Rightarrow (\{C \dashrightarrow g(A^y)\}_D \wedge (ts(C) > ts(B)))$$

where $\neg\forall C(\{C \dashrightarrow A\}_D)$ means there is no entity C that points to A in PM, but $\{C \dashrightarrow g(A^y)\}_D$ means there is an entity C that points to $g(A^y)$ in PM.

- *Case 2*. Applying eq. *S1* and eq. *W2*,

$$\begin{aligned}
&\Rightarrow \{C \to g(A^y)\}_M \prec write(A) \\
&\quad \ll \{g(B^x) \to A_k\}_M \prec \{B^x \to A\}_D \\
&\Rightarrow \{C \to g(A^y)\}_M \prec write(A) \\
&\quad \ll (\{g(B^x) \to A_k\}_D \wedge ts(B) > ts(C)) \\
&\quad \ll \{g(B^x) \to A_k\}_M \prec \{B^x \to A\}_D
\end{aligned}$$

Applying eq. *S4*,

$$\begin{aligned}
&\Rightarrow \{C \to g(A^y)\}_M \prec write(A) \\
&\quad \ll (\{g(B^x) \to A_k\}_D \wedge ts(B) > ts(C)) \\
&\quad \ll \{g(B^x) \to A_k\}_M \prec write(B) \ll \{B^x \to A\}_D
\end{aligned}$$

Applying eq. *S5* (as WOLVES obeys pointer ordering, *i.e.,* all the pointed data blocks/*packages* are written before the pointers are written),

$$\begin{aligned}
&\Rightarrow \{C \to g(A^y)\}_M \prec write(A) \\
&\quad \ll (\{g(B^x) \to A_k\}_D \wedge ts(B) > ts(C)) \\
&\quad \ll \{g(B^x) \to A_k\}_M \prec (write(A) \ll write(B)) \\
&\quad \ll \{B^x \to A\}_D
\end{aligned}$$

By eq. *S3*,

$$\begin{aligned}
&\Rightarrow \{C \to A\}_M \prec write(A) \\
&\quad \ll (\{g(B^x) \to A_k\}_D \wedge ts(B) > ts(C)) \\
&\quad \ll \{A^y\}_D \wedge (k = g(A^y)) \\
&\quad \ll write(B) \ll \{B^x \to A\}_D \\
&\Rightarrow \{A^y\}_D \wedge \{B^x \to A\}_D \wedge k = g(A^y)
\end{aligned}$$

This again leads to a contradiction since this implies that the contents of A on PM belong to the same generation A_k, while we started out with the assumption that $g(A^y) \neq k$.

A.4 Version Consistency

Version consistency ensures that the version of metadata x matches with the version of pointed data blocks y [15], which is a stricter consistency than data consistency. Given an in-PM beliefs $\{B^x \to A\}_D \wedge \{A^y\}_D$, we need to prove that there exists an in-memory belief $\{B^x \to A^y\}_M$ before the crash. This can be reflected by the following rules:

$$\{B^x \to A\}_D \wedge \{A^y\}_D \Rightarrow \{B^x \to A^y\}_M \ll \{B^x \to A\}_D \wedge \{A^y\}_D$$

To prove this, we follow a similar process in Appendix of [55]. If the L.H.S holds, by applying eq. *S4* and *S2*, we have:

$$\begin{aligned}
\{B^x \to A\}_D \wedge \{A^y\}_D \Rightarrow &(\{B^x \to A\}_M \prec write(B)) \\
&\wedge (\{C \to A^y\}_M \prec write(A))
\end{aligned}$$

This also implies two possible sequences and to prove the version consistency, we need to show that both sequences lead to $\{B^x \to A^y\}_M \ll \{B^x \to A\}_D \wedge \{A^y\}_D$.

1. $(\{B^x \to A\}_M \prec write(B)) \ll (\{C \to A^y\}_M \prec write(A))$

2. $(\{C \to A^y\}_M \prec write(A)) \ll (\{B^x \to A\}_M \prec write(B))$

- *Case 1*. We show that $A = A^y$ and $C = B^x$. If $A \neq A^y$, by applying eq. *S1* and eq. *W2*,

$$\begin{aligned}
&\Rightarrow (\{g(B^x) \to A\}_M \prec write(B)) \\
&\quad \ll (\{C \to A^y\}_M \prec write(A)) \\
&\Rightarrow (\{g(B^x) \to A\}_M \prec write(B)) \\
&\quad \ll (\{C \to A^y\}_D \wedge ts(C) > ts(B)) \\
&\quad \ll (\{C \to A^y\}_M \prec write(A)) \\
&\Rightarrow \{C \to A^y\}_D
\end{aligned}$$

This leads to a contradiction in our start assumption $\{B^x \to A\}_D$. Therefore, $A = A^y$. On the other hand, using eq. *W3*

$$\begin{aligned}
&\{B^x \to A^y\}_M \Rightarrow \{\&A = \{B^x\}\}_M \\
&\{C \to A^y\}_M \Rightarrow \{\&A = \{C\}\}_M \\
&\Rightarrow B^x = C
\end{aligned}$$

Hence,

$$(\{B^x \to A^y\}_M \prec write(B)) \ll (\{B^x \to A^y\}_M \prec write(A))$$

Hence, $\{B^x \to A^y\}_M \ll (\{B^x \to A\}_D \wedge \{A^y\}_D)$.

- *Case 2*. If $A \neq A^y$, by applying eq. *S5* to $(\{B^x \to A\}_M \prec write(B))$,

$$\begin{aligned}
&\Rightarrow \{B^x \to A\}_M \prec (write(A) \ll write(B)) \\
&\Rightarrow \{A^z\}_D \wedge z \neq y
\end{aligned}$$

This contradicts the start assumption $\{A^y\}_D$. Therefore, $A = A^y$. At the same time,

$$\begin{aligned}
&\Rightarrow \{B^x \to A^y\}_M \prec (write(A) \ll write(B)) \\
&\Rightarrow \{B^x \to A^y\}_M \prec (\{A^y\}_D \ll write(B)) \\
&\Rightarrow \{A^y\}_D \wedge \{B^x \to A\}_D
\end{aligned}$$

Thus, we have shown case 2 also leads to $\{B^x \to A^y\}_M \ll \{B^x \to A\}_D \wedge \{A^y\}_D$. Hence, WOLVES achieves version consistency.

Decentralized, Epoch-based F2FS Journaling with Fine-grained Crash Recovery

Yaotian Cui[1], Zhiqi Wang[1], Renhai Chen[2], Zili Shao[1]

[2]*College of Intelligence and Computing, Tianjin University, China*

Abstract

F2FS, a log-structured filesystem, has gained widespread adoption in Android systems. However, F2FS relies on coarse-grained checkpointing for crash recovery. When triggered, this mechanism significantly degrades system performance by blocking file writes. Additionally, F2FS's checkpointing approach may not fully recover file data and metadata to a consistent state after a crash. Given these limitations, it is crucial to design a new journaling mechanism for F2FS that provides fine-grained crash recovery. While journaling methods are well-studied for in-place-update filesystems (such as JBD2 for EXT4), directly applying these state-of-the-art techniques to F2FS - an out-of-place-update filesystem - does not yield similar benefits.

In this paper, we propose a novel journaling technique, called F2FSJ, for F2FS with ordered journal mode. Catering to the out-of-place update features of F2FS, F2FSJ incorporate several innovative designs. First, in F2FSJ, only metadata changes are journaled and committed after data flushing, by which I/O and storage overheads can be mitigated. Second, we propose a decentralized journal design by embedding journal logs into inodes, which significantly reduces lock contention and interference when recording metadata changes. Third, we propose an epoch-based approach with a novel data/control-plane decoupling mechanism, which eliminates waiting times during journal period transfers. Finally, for journal apply, we propose a fast-forward-to-latest approach to consolidate multiple small updates into one update for reducing small writes. We have implemented a fully functional prototype of F2FSJ and conducted extensive experiments. Our experimental results demonstrate that F2FSJ can effectively reduce the checkpointing time by up to 4.9x and reduce the latency by up to 35% compared with F2FS. F2FSJ is open-sourced for public access.

1 Introduction

F2FS (Flash-Friendly File System) is widely adopted in Android systems due to its specially-tailored designs for flash storage such as append-only writes and hot/cold data separation with multi-head logging [10, 36, 39]. Despite the presence of battery power in Android smartphones, power failure remains a significant concern. For instance, Android smartphones may shut down in cold environments due to power-related issues [1, 13]. Furthermore, outdated applications or system updates can cause system freezes or crashes. As a result, ensuring effective crash recovery for F2FS is vital.

F2FS, however, relies on coarse-grained checkpointing for crash recovery, which once triggered, severely degrades the system performance by blocking file reads/writes, as all dirty data and metadata need to be written back to the disk as a checkpoint pack. For instance, as shown in §2.3, the worse-case latencies caused by checkpoints can be up to 293 ms, which is intolerable for user interaction or system responses. To address these issues, one effective approach is to utilize journaling that can mitigate these overheads by first recording file updates as logs and then applying logs to their original area. Thus, designing a new journaling mechanism for F2FS with fine-grained crash recovery is crucial.

Journaling mechanisms are well studied for in-place-update filesystems (e.g., JBD2 for EXT4 [7, 44, 45, 52, 53]). Nevertheless, directly applying these state-of-the-art journal methods for F2FS, which is an out-of-place-update filesystem, does not yield similar benefits. As illustrated in Figure 3, in an in-place-update filesystem, with fixed on-disk inode locations, in-memory changed inodes can be first journaled and then applied or recovered to on-disk inodes; by contrast, in F2FS, as inode locations are not fixed due to out-of-place-updates, by only journaling in-memory inodes, inodes cannot be correctly recovered due to outdated on-disk filesystem metadata. On the other hand, if both in-memory filesystem metadata and inodes are journaled, it incurs too much overhead as filesystem metadata and inodes need to be written twice.

In this paper, we propose a novel journaling technique, called F2FSJ, for F2FS with ordered journal mode. Ordered journal mode is widely adopted in practice by only committing changed metadata to the journal after data are flushed (each data flushing with its corresponding changed metadata is denoted as one journal period in this paper). To the best of

our knowledge, this is the first work to tackle F2FS ordered journaling.

In F2FSJ, we journal changes of filesystem and file metadata instead of the whole metadata pages employed in existing journal mechanisms such as JBD2. Specifically, F2FSJ includes several novel designs to address the following challenges: (1) How to organize a large volume of metadata changes so as to minimize lock contention with good scalability? (2) How to manage journal logging of each period and eliminate the waiting time when transferring from one journal period to another? (3) How to efficiently apply small changes recorded in the journal file and perform crash recovery with the change-based journaling for the out-of-place-update filesystem?

To address the first challenge, we propose a decentralized journal design by embedding journal logging into inodes. Specifically, for each inode, a per-inode log list is devised to record all of its related logging (i.e., file metadata changes from the inode and corresponding filesystem metadata changes from Segment Information Table (SIT), Node Address Table (NAT) and Segment Summary Area (SSA)). Compared with existing centralized approaches such as that employed by JBD2 in EXT4, our decentralized per-inode logging significantly reduces lock contention and interference among inodes when recording metadata changes, thus enabling higher efficiency and better scalability.

For the second challenge, we propose an epoch-based approach with a novel data/control-plane decoupling journal mechanism. Specifically, each journal period is associated with a new epoch; inside each epoch, journal's data and control planes are decoupled by logging metadata changes of an inode into its per-inode list (data plane) and only registering the inode information into the epoch (control plane). The data/control decoupling brings two benefits. First, it enables our decentralized journal design, i.e., for each new epoch, first storing metadata changes into per-inode lists and then collecting all changes of this journal period based on the registered inodes in the epoch for committing. Second, there is almost no waiting time when we transfer from one journal period to another. Particularly, when data flushing triggers the committing of the current epoch, we can immediately generate a new journal period with a new epoch to accommodate new metadata changes with negligible waiting time. On the contrary, the control and data planes are coupled with existing journal methods so the waiting time is inevitable during a period transfer (e.g., in JBD2, a new running transaction can only be issued after all file operations related to the current running transaction have been finished).

For the third challenge, when applying changes in the journal file, we adopt a fast-forward-to-latest approach to consolidate multiple small updates, caused by cross-epoch log records that operate on the same metadata, into one update, thus significantly reducing small writes. Specifically, we propose a new journal process design with a new page flag so a page with "dirty" metadata can be kept in memory without being flushed by the kernel page cache manager. Then when following the epoch order to apply changes, with a log record, we will directly flush its corresponding in-memory metadata and subsequently altering the page flag to "clean", thus avoiding future unnecessary flushing and enabling possible eviction as well. Note that our fast-forward-to-latest approach does not incur inconsistency due to the unique characteristic in out-of-place-update filesystems, i.e., old information will be kept without modification with out-of-place updates. Thus, in crash recovery, when there is no corresponding in-memory metadata when applying a log record, following the epoch order, metadata changes in log records can be applied one by one to the disk and finally reach to a consistent state.

We have implemented a fully functional prototype of F2FSJ and released the source code for public access. Our prototype involves minor changes (about 3,000 lines of C code) based on F2FS with Linux (Kernel Version 5.15). A series of experiments have been conducted to evaluate F2FSJ with benchmarks and real-world applications on both an Intel-based desktop and an ARM-based embedded development board. Experimental results show that F2FSJ can effectively reduce the checkpointing time by up to 4.9x and reduce the latency by up to 35% compared with F2FS. Additionally, F2FSJ, with its fine-grained crash recovery mechanism, can recover more files and data than F2FS checkpointing.

In summary, we make the following contributions:

- We for the first time propose a novel journaling technique for F2FS with ordered journal mode. F2FSJ eliminates the long checkpoint latency and provides fine-grained crash recovery.
- F2FSJ incorporates several innovative designs by leveraging the out-of-place-update features of F2FS as follows:
    1. F2FSJ only journals the changes of filesystem/file metadata so as to mitigate IO and storage overheads.
    2. In contrast to existing centralized approaches such as that employed by JBD2, a decentralized journal design is proposed to embed journal logs into inodes, which can significantly reduce lock contention and interference among inodes when recording metadata changes.
    3. An epoch-based approach with a novel data/control-plane decoupling journal mechanism is proposed to eliminate waiting times during journal period transfers that are inherent in existing methods (e.g., JBD2) with data/control coupling.
    4. A fast-forward-to-latest approach to consolidate multiple small updates into one update for reducing small writes in journal.

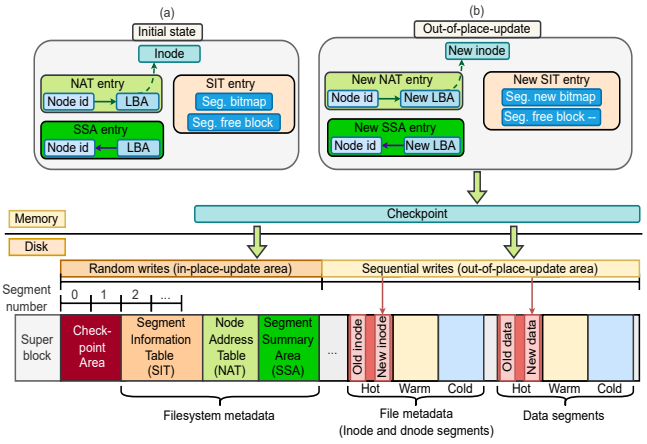

Figure 1: Overview of F2FS.

- We have implemented a fully functional prototype of F2FSJ in Linux kernel. The source code and detailed evaluation have been released for public access [8].

2 Background and Motivation

2.1 F2FS Overview

F2FS manages storage space at the unit of segments (e.g., 2MB per segment) and divides the whole space into the random writes area (in-place-update) and the sequential writes area (out-of-place-update). As shown in Figure 1, the random writes area stores F2FS filesystem metadata with fixed on-disk locations, such as SIT, NAT and SSA. Specifically, SIT records bitmap of each segment; NAT maintains the mapping from node IDs to logical block addresses (LBA) for node pages; SSA stores the number of valid blocks and the mapping from block addresses to node IDs. The sequential writes area stores file metadata and data in an append-only pattern. Specifically, inodes and dnodes (LBA of data blocks) are stored in node segments and data blocks are stored in data segments. F2FS separates node blocks and data blocks with three static temperatures (hot, warm, and cold) to exploit IO parallelism [28–30, 42] of multiple flash channels.

At runtime, on-disk filesystem metadata, file metadata and data are loaded into memory as illustrated in Figure 1(a). Then file operations can be performed. For instance, we can look up inodes by querying NAT and modify in-memory SIT and SSA for space management of each segment. In the sequential writes area, file metadata/data are managed using out-of-place updates. For instance, as illustrated in Figure 1(b), for regular file operations (e.g., file data writes) that modify file metadata and data, the updated inode is put to a new LBA rather than the original location.

In-memory and on-disk data/metadata will become inconsistent as they are first changed in memory. For instance, in Figure 1(b), to write the updated inode to a new LBA, a new LBA needs to be allocated, for which the in-memory NAT/SIT/SSA entries will be changed first, while the old versions are kept in the on-disk NAT/SIT/SSA. Such in-memory modifications will be lost if a crash happens before checkpointing.

2.2 Three Journaling Modes

In filesystems, there are typically three journaling modes, each offering a different level of data consistency and recovery capacity, as follows: (1) The first is ordered journal mode, in which only metadata are journaled and data flushing strictly precedes committing metadata journals. Ordered journal mode can ensure data integrity once metadata journals are committed to disk. (2) The second is writeback journal mode, which only journals metadata but the order of data flushing and metadata journals committing is not strictly enforced. Writeback mode can improve performance compared to the ordered mode since data can be written to disk quickly. However, it may introduce a risk of data inconsistency in a crash, as there is a possibility that the metadata journals may reach the disk before flushed data. (3) The third is data journal mode, in which journals both data and metadata. This mode ensures both data and metadata consistency during recovery. However, it has a performance impact due to the additional overhead of journaling data. In this paper, we focus on ordered journaling mode, which is widely adopted in practice (e.g., it is the default journaling mode in EXT4 [24]).

2.3 F2FS Checkpointing and Problem

F2FS utilizes checkpointing for crash recovery. Checkpoints can be triggered by either the thresholds of dirty in-memory metadata (e.g., the cached NAT entries or dirty node pages exceed a setting ratio) or a timeout (e.g., 60 seconds by default). When a checkpoint is triggered, all write activities will be blocked until it is completed. During a checkpoint, in-memory file data, file metadata and filesystem metadata (i.e., NAT, SIT, and SSA) will be flushed to disk in order to form a checkpoint pack that is stored in the on-disk checkpoint area as a snapshot. Based on F2FS checkpointing, for crash recovery, F2FS can roll back to a consistent checkpoint with its roll-back recovery mechanism. There are three critical issues associated with F2FS checkpointing.

Problem 1: Time Overhead. We have conducted preliminary experiments to reveal the overheads with the experimental setup in §5.1. In the experiments, four benchmarks, `mkdir`, `rmdir`, `create-4KB` and `unlink-4KB`, from filebench [9], are utilized, which all contain intensive file operations on filesystem metadata and file metadata, and the total execution time, the checkpoint time are measured. Figure 2(a) shows the time breakdown of the average execution time for F2FS and F2FSJ. It can be observed that with F2FS, as checkpoints are frequently triggered with intensive filesystem/file metadata operations, the checkpoint time occupies a significant proportion of the total execution time, ranging from 37.2%, 17.2%, 47.3% to 44.2%. By contrast, F2FSJ, with its fine-grained journaling, can significantly reduce the total execution time

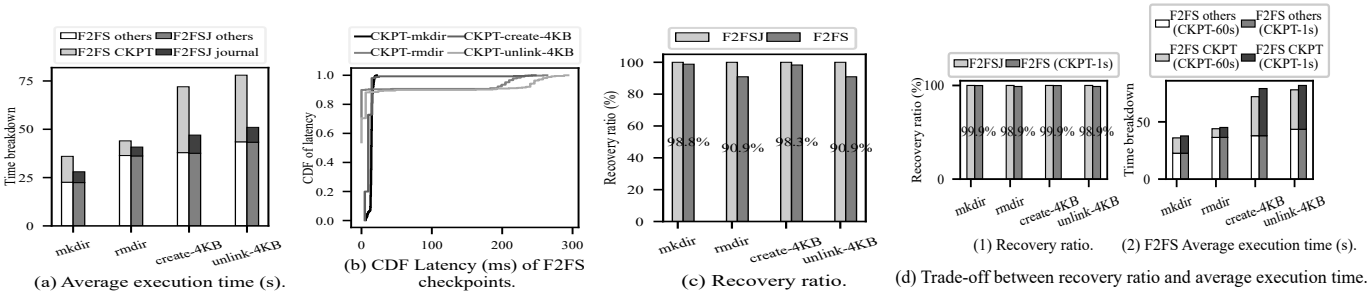

Figure 2: Preliminary experiments with the four benchmarks (mkdir, rmdir, create-4KB, unlink-4KB) from filebench, which contain intensive filesystem/file metadata operations. (a) Time breakdown of the average execution time for F2FS and F2FSJ. (b) CDF latencies of the F2FS checkpoints. (c) Recovery ratio comparison of F2FS and F2FSJ. (d) Trade-off between recovery ratio and average execution time: (1) Recovery ratio comparison of F2FS with the one-second checkpointing interval (denote as CKPT-1s) and F2FSJ; (2) Average execution time comparison of F2FS with the sixty-second and one-second checkpointing intervals (denote as CKPT-60s and CKPT-1s, respectively).

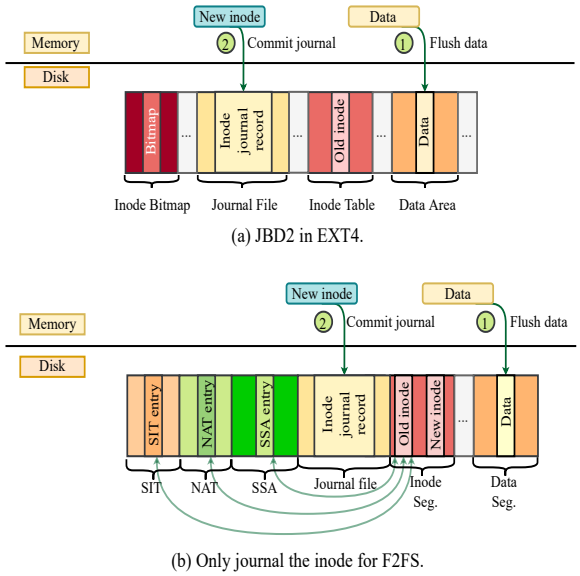

Figure 3: Journaling in EXT4 and F2FS. (a) In EXT4, as on-disk inode locations are fixed, a changed inode can be first stored in the journal file and then applied or recovered to on-disk inode. (b) In F2FS, inode locations are not fxed due to out-of-place-updates, so by only journaling in-memory inodes, inodes cannot be correctly recovered due to outdated on-disk fliesystem metadata.

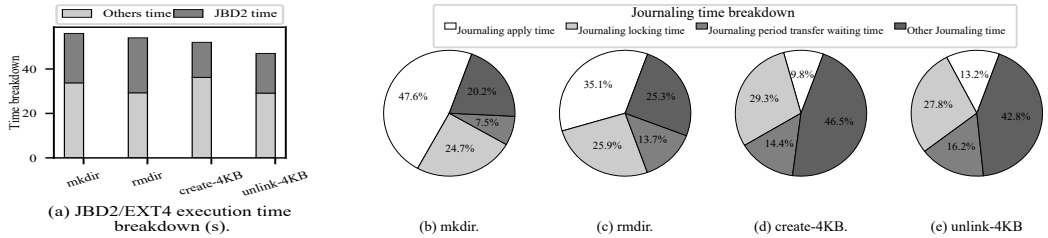
across the board.

Another critical issue for F2FS checkpointing is its long tail latency. Figure 2(b) shows the CDF (Cumulative Distribution Function) latencies of the F2FS checkpoints. For instance, the worst-case latency reaches to 247ms, 233ms, 293ms, 26ms for `create-4KB`, `rmdir`, `unlink-4KB` and `mkdir`, respectively, which is intolerable for user interaction or system responses.



Problem 2: Data and Metadata Loss. F2FS checkpointing is triggered by either the thresholds of dirty in-memory metadata or a timeout (e.g., 60 seconds by default), so only coarse-grained crash recovery can be performed and newly modified metadata and data are lost in a crash between two checkpoints. Note that in F2FS, `fsync()` will not trigger checkpoints for performance efficiency, so flushed file data could be lost. To demonstrate file data/metadata loss, we have conducted crash experiments for F2FS checkpointing and F2FSJ. Specifically, for F2FS, a sudden power failure is made after the last checkpoint is triggered, and for F2FSJ, at the same crash point, a power failure is made with `poweroff` [18]. Figure 2(c) shows the recovery ratio comparison of F2FS checkpointing and F2FSJ. It can be observed that F2FS with the default checkpointing interval (i.e., 60 seconds) incurs more data/metadata loss (up to 9.1%) compared with F2FSJ.

A simple solution to reduce data/metadata loss is to shorten the checkpointing interval, which, however, is a trade-off between metadata/data loss and performance degradation. As shown in Figure 2(d), when the checkpointing interval is set to one second, F2FS has less data/metadata loss (up to 1.1%). Nevertheless, it comes at the cost of the increased checkpointing execution time, i.e., the average execution time of checkpointing increases 12.2%, 14.5%, 21.2%, and 11.0% for the four benchmarks, respectively.

Problem 3: Inconsistency with Roll-forward Recovery. In F2FS, any persistent data or metadata beyond a checkpoint cannot be recovered in the event of a crash using its roll-back recovery mechanism. To address this limitation, F2FS implements a roll-forward recovery mechanism [4, 14, 15], which tags inodes and dnodes in fsync and utilizes this tag information for data and metadata recovery. However, in no-barrier and POSIX fsync modes, the unordered nature of the I/O stack [16, 31, 40, 55] can lead to inconsistencies, as the persistence order of file data and its associated inode/dnode tags is not guaranteed. For instance, if the inode/dnode tags are successfully written while the corresponding file data fails to persist due to reordering, the recovered state may become inconsistent - resulting in a newer inode pointing to outdated data.

2.4 Motivaton

To address the above issues of F2FS checkpointing, we propose F2FSJ that is a journaling technique with fine-grained crash recovery. Next, we first present the problems with existing journal methods in designing F2FS journaling and then introduce new challenges for applying our metadata-change-

(a) JBD2/EXT4 execution time breakdown (s). (b) mkdir. (c) rmdir. (d) create-4KB. (e) unlink-4KB

Figure 4: Preliminary experiments with the four benchmarks (mkdir, rmdir, create-4KB, unlink-4KB) from filebench for comparing the execution time with time breakdown on JBD2 in EXT4 (a), and journaling time breakdown for (b) mkdir, (c) rmdir, (d) create-4KB, and (e) unlink-4KB.

based journaling method in F2FSJ.

2.4.1 Problems with Existing Journal Methods

While journaling methods are well-studied for in-place-update filesystems (such as JBD2 for EXT4) [35, 37, 41, 47, 48, 51, 54], directly applying these state-of-the-art techniques to F2FS does not yield similar benefits. Specifically, as illustrated in Figure 3(a), for EXT4, as an in-place-update flesystem, its on-disk inode locations are fixed, so a changed inode in memory can be first journaled and then correctly applied or recovered to on-disk inodes without filesystem metadata modification. By contrast, for F2FS, as its inodes and data are managed using out-of-place updates, inode locations are not fixed. Thus, as shown in Figure 3(b), by only journaling the inode, it cannot be correctly recovered as the corresponding on-disk filesystem metadata (e.g., SIT/NAT/SSA entries) are outdated. On the other hand, if we store both in-memory filesystem metadata and inodes in the journal file, it incurs more overheads than JBD2, since both filesystem metadata and inodes need to be written twice.

Another problem in existing journal methods is to journal changed metadata based on pages (blocks). For instance, even if only the file size information is updated in an inode, JBD2 will journal the whole 4KB page that stores the inode. This incurs both runtime and storage overheads. First, at runtime, subsequent file operations that operates on the page will be held up when a journal commit involving that page occurs. As shown in Figure 4 (a), the average execution time of JBD2 accounts for a significant portion, ranging from 39.7%, 45.7%, 30.3%, to 38.8% for the four benchmarks, respectively. Second, not only more space is occupied in journal files, but also garbage collection will be triggered earlier, during which journal commit will be blocked so extra runtime overheads are introduced. In the journaling, time breakdowns are shown in Figures 4(b), 4 (c), 4(d), 4(e), it can be observed that JBD2 apply, which operates on journal files, occupies a big portion of the total journaling time, e.g., about 47.6% and 35.1% in benchmarks `mkdir` and `rmdir`, respectively.

2.4.2 Challenges for Journaling Metadata Changes

Motivated by §2.4.1, in F2FSJ, we propose a metadata-change-based journaling policy, in which we only journal the changed part instead of the whole page for in-memory metadata. However, designing F2FS journaling with such a policy poses new challenges as follows: (1) Lock contention; (2) Long waiting times during journal period transfers.

Challenge1: Intensive Locking. Existing journal methods utilize a centralized approach that leads to intensive locking contention. For instance, such an approach is employed by JBD2, in which a transaction is used to represent a journal period, and a global journal ticket (`t_updates`) and a log list is maintained for journaling management. Once a file operation triggers data or metadata to be journaled, it must first obtain a journal ticket, and then add the data/metadata pages into the log list of the running transaction. Correspondingly, two locks are provided for mutually exclusive accesses for the journal ticket and the journal log list, respectively. Lock contention for them becomes one of the performance bottlenecks in JBD2 [53]. Figures 4(b), 4 (c), 4 (d), 4(e) show the time breakdown of the locking overheads, in which (1) `j_state_lock` is the lock contention time for the journal ticket; (2) `j_list_lock` is the lock contention time for the log list. It can be observed that such lock contention occupies 24.7%, 25.9%, 29.3%, 27.8% of the total journaling time for the four benchmarks, respectively. Instead, in F2FSJ, we adopt a decentralized approach by storing logs into each inode (i.e., via per-inode log lists), thus significantly mitigating lock contention and interference among inodes.

Challenge2: Long waiting Times During Journal Period Transfers. Existing journal designs like JBD2 couples the control and data planes, thus incurring long waiting times during journal period transfers. For instance, in JBD2, a new running transaction cannot be issued when the previous one starts to commit. The reason is that for each transaction, the data plane (the log list) and the control plane (e.g., journal ticket, journal committing, etc.) are coupled, so a new transaction (for generating new data in the data plane) must wait for the completion of the previous one (for committing in the control plane). As shown in Figures 4(b), 4(c), 4(d), 4(e), in JBD2, the waiting time for the journal period transfers occupies about 7.5%, 13.7%, 14.4%, 16.2% of the total journaling time, respectively. In F2FSJ, this is solved by our epoch-based approach with data/control-plane decoupling.

3 F2FSJ Design

3.1 Overview

F2FSJ incorporates several novel designs. First, we employ epochs to manage control plane journaling, which can

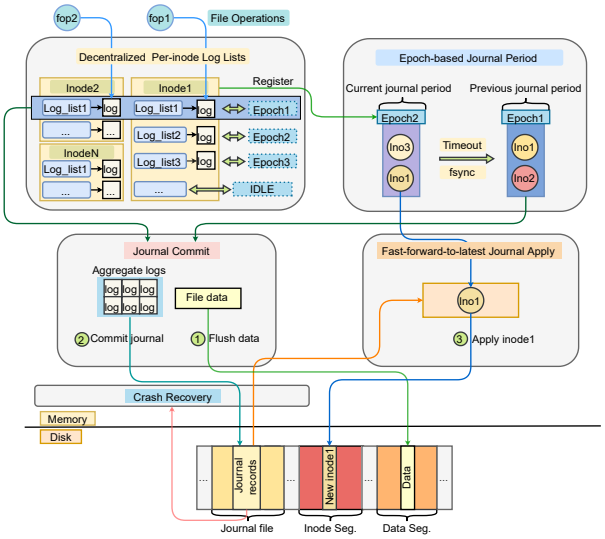


Figure 5: Workflow Illustration of F2FSJ.

effectively represent a journal period and decouple the control/data planes of journaling. Second, we adopt decentralized per-inode log lists to manage journaling data plane, by which metadata changes caused by file operations are inserted into corresponding per-inode log lists without intensive locking competition and inter-inode interference. Third, we propose an asynchronous journal commit mechanism that does not block ongoing file operations modifying the same metadata. Finally, we propose a fast-forward-to-latest journal applying scheme that can consolidate multiple small updates into one update for reducing small writes in journal apply.

Figure 5 illustrates the workflow of F2FSJ. First, when file operations modify metadata, metadata changes are inserted into inode log lists as log records and the inode information related to the changes is registered into the epoch of the current journal period (e.g., Epoch2 in Figure 5). Second, when an fsync or timeout is invoked, a new journal period with a new epoch (e.g., Epoch2) is generated to accommodate new metadata changes, while the changes can be aggregated based on the inode information in the previous epoch (e.g., Epoch1) and then committed after data flushing. Third, on-disk journals can be applied in epoch order, in which we adopt a fast-forward-to-latest approach by directly flushing in-memory metadata pages for the same metadata in logs. Finally, for crash recovery, we can replay on-disk journal records and reach to a consistent state.

3.2 Epoch-based Journaling

We use epochs to manage control plane journaling, and an epoch is represented with an ID that is a monotonically increasing number. Specifically, when an `fsync` or timeout is invoked, we will transfer to a new journal period with a new epoch and then the previous epoch can enter the commit phase. With a new epoch, for an inode, when its metadata changes occur for the first time in this epoch, its inode number is registered into the epoch (on the other side, in the inode,

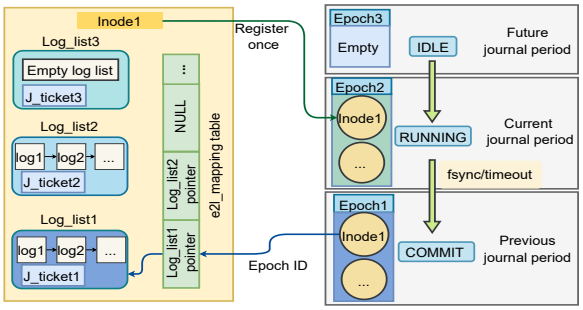

Figure 6: Illustration of epoch-based journaling and per-inode log lists.

based on the `e2l_mapping` table, with the epoch ID, the log list that stores metadata changes can be found as discussed in Section §3.3). In our implementation, inside an epoch, we utilize a linked list to record inode numbers and a lock is employed to ensure atomic inode registration. Note that for one epoch, inodes only need to register once (when its metdata changes occurs for the first time in this epoch). Thus, the lock contention overhead is negligible.

To align epochs with journal phases, each epoch has three states: (1) `IDLE` signifies availability for future journal periods without registered inodes; (2) `RUNNING` indicates that the epoch is being used for the current journal period; (3) `COMMIT` signifies that the epoch has entered the journal commit state. Specifically, as illustrated in Figure 6, each epoch maintains inode information, and the same inode can be registered in different epochs if it is involved in multiple journal periods. After inode registration, the logs can be efficiently stored in decentralized per-inode log lists. When an epoch is triggered to commit by `fsync` or timeout, it stops registering new inodes and transitions to the `COMMIT` state. Simultaneously, a new epoch is immediately issued for the next journal period, thus incurring negligible waiting times for journal period transfers.

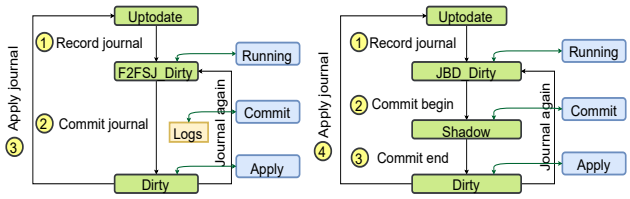
There are three benefits of utilizing epoch. First, by decoupling the data/control planes, an epoch only records the inodes involved in journaling, while metadata changes are stored separately in the data plane (i.e., per-inode log lists, as discussed in Section §3.3). With such a design, lock contention can be effectively reduced due to the small-sized and simplified control plane. Second, based on the decoupled control/data planes, the new epoch for the next journal period can be issued immediately without having to wait for ongoing file operations belonging to the current epoch. Third, the ACID property [25] can be ensured in journal committing as the logs belonging to the same epoch can be committed as a single transaction.

3.3 Decentralized Per-inode Log Lists

In F2FSJ, decentralized per-inode log lists are utilized to efficiently manage journaling data plane. Specifically, when file operations modify the metadata of an inode (e.g., the file size), based on the modified parts (i.e., metadata changes), log records are generated and inserted into the corresponding log list in the inode. An inode may contain multiple log

lists that are associated with different epochs, but only one log list is corresponding to the RUNNING epoch. Inside an inode, an epoch-to-log-list mapping table (i.e., `e2l_mapping`) is maintained, so for a given epoch ID, its corresponding log list can be found, as illustrated in Figure 6.

Based on `e2l_mapping` tables, we can do inode registration and store metadata changes as log records in per-inode log lists. Specifically, when inserting log records into an inode, based on the epoch ID of the RUNNING epoch, we first check the `e2l_mapping` table of the inode. If this is the first time to insert log records for this inode in this epoch, `NULL` will be returned. In this case, we first register the inode number into the RUNNING epoch, and then create a new log list (e.g., implemented by a linked list) and put the list address (e.g., the head of the linked list) into the `e2l_mapping` table, after which the log records can be inserted into the log list accordingly. Otherwise, if we can find the address of the log list from the `e2l_mapping` table, log records can be directly inserted into the list.



In F2FSJ, for filesystem metadata such as SIT, NAT and SSA, their changes are stored into per-inode log lists as well. Specifically, when collecting and storing metadata changes of an inode, if they are related to file data (e.g., data allocation, data deletion, etc.), the fliesystem metadata changes associated with the file data (i.e., SIT and SSA entries) will be recorded into the log list by associating with the corresponding metadata changes of the inode. On the other hand, the filesystem metadata of an inode (i.e., NAT, SIT and SSA entries of the inode) will be appended to journal records during journal commit (discussed in Section §3.5). As such, in journal apply and crash recovery, with both file and filesystem metadata in journal records, we can reach to a consistent state.

During epoch transition (from `RUNNING` to `COMMIT`), to determine whether file operations have completed journaling, a counter (e.g., `J_ticket` as shown in Figure 6) is associated with each log list, which represents the number of ongoing file operations. The commit thread can only aggregate the logs of a log list when the counter equals to zero.

Our design with decentralized per-inode log lists brings several benefits. First, it is convenient for log collection because each inode can naturally collect its own logs (i.e., metadata changes) in file-operation paths. Second, with our decentralized design, metadata changes are distributed to different inodes, thus eliminating the need for global locks in journaling data plane and significantly reducing lock contention and inter-inode interference. Third, the memory overhead is minimized as only metadata changes are journaled, and log lists are created on demand (only when metadata changes occur for inodes in epochs) and reclaimed after journal commit.

3.4 Non-blocking Journal Commit

`COMMIT` epochs are committed based on their commit order. Specifically, a journal commit process has two phases, namely, log aggregation and journal committing. In the first phase for log aggregation, log records are aggregated from the log list of each inode in the epoch for subsequent journal writes. Specifically, for each inode registered in the epoch, the commit thread locates the corresponding log list through `e2l_mapping` using the `COMMIT` epoch ID. Subsequently, the logs are aggregated together by iterating through the log list. Finally, the SIT/NAT/SSA entries of this inode will be appended to the end of the aggregated logs.

(a) Page state changes in F2FSJ. (b) Page state changes in JBD2/EXT4.

Figure 7: Journal process with page state changes.

The second phase is journal committing, by which aggregated logs in the first phase are written into an on-disk journal file with the following three steps. First, a journal descriptor block (JD) is written, which is a journal header that contains the metadata such as the epoch ID and the log-record length. Second, aggregated logs are persisted. Finally, a journal commit block (JC) is persisted to denote the completion of the journal committing. This three-step process can guarantee that all logs of one epoch can be applied or restored atomically.

In F2FSJ, we can provide non-blocking journal commit, meaning that journal committing does not block ongoing file operations that operate on the same metadata, since only metadata changes in log lists are journaled. By contrast, in JBD2, journaling is based on metadata pages that are locked during the DMA transfer in journal commit, so ongoing file operations on these metadata pages will be blocked.

3.5 Journal Apply

For journal apply, we adopt a fast-forward-to-latest approach, which can consolidate multiple small updates, caused by cross-epoch log records that operate on the same metadata, into one update. The key idea is to directly flush corresponding in-memory metadata instead of applying log records one by one. It consists of two components: (1) Journal process with page state changes, and (2) Fast-forward-to-latest journal apply, as follows.

Journal Process with Page State Changes. We propose a new journal process design with a new page flag so a page with "dirty" metadata can be kept in memory without being flushed by the kernel page cache manager. Specifically, in F2FSJ, each in-memory page has three states: (1) `Uptodate` that represents this page has the same content as its on-disk counterpart; (2) `F2FSJ_Dirty` that represents this page has been modified and the changes have been recorded but not committed, while the data has not been flushed to disk; and (3) `Dirty` that represents this page has been modified and the changes have been committed but not applied, while the corresponding data has been flushed. The state changes are

illustrated in in Figure 7(a). Particularly, the kernel page cache manger can only evict `Uptodate` pages, while it cannot do `Dirty` or `F2FSJ_Dirty` pages. During journal apply, `Dirty` pages will be utilized for reducing small writes as shown next.

For ordered journal mode, data should be persisted before metadata. For `F2FSJ_Dirty` metadata pages, their data have not been flushed, while after journal commit that happens after data flushing, metadata pages are changed to `Dirty`. Thus, `Dirty` metadata pages can be used for journal apply. Compared with JBD2, which uses two page states `JBD_Dirty` (before journal commit) and `Shadow` (during journal commit for preventing ongoing file operations from modifying the committed metadata pages) as shown in Figure 7(b), F2FSJ only requires one state (i.e., `F2FSJ_Dirty`), thus simplifying the design and implementation in journal apply.

Fast-forward-to-latest Journal Apply. In journal apply, following the commit order, for each journal record, by checking its corresponding in-memory metadata page, we perform as follows: (1) If the page is found in memory and its state is `Dirty`: we directly flush the `Dirty` page and subsequently altering its state to `Uptodate`; (2) If the page is not found in memory or the page state is `Uptodate`, we skip this record (based on our state changes, only `Uptodate` pages can be evicted so this is the case that its corresponding `Dirty` page has been flushed to disk); (3) If the page state is `F2FSJ_Dirty`, we apply the journal record by updating its on-disk data accordingly. Note that in journal apply, after an inode is updated, the filesystem metadata of the inode (i.e. SIT, NAT and SSA) may need to be updated as shown in Figure 8. Conceptually, only two states - `Dirty` and `Uptodate` - may seem sufficient. However, an additional state, `F2FSJ_Dirty`, is essential for implementing the fast-forward-to-latest approach. This state specifically indicates that an in-memory metadata page associated with a journal record is also involved in committing another ongoing journal record, making it unavailable for use. In such cases, the journal record in the journal file is applied directly, with the file data and metadata appended in F2FS.

An example is given in Figure 8. In Figure 8(a), we apply epoch1's journal record as follows: (1) Read the epoch1's journal record to memory and find that one log record of inode1 (i.e., 4KB file size) needs to be applied; (2) Use the inode number recorded in the log to find the in-memory `Dirty` inode1 (with 8KB file size); (3) Apply the in-memory `Dirty` inode1 to a new location to disk and change the page state of the in-memory inode1 to `Uptodate`; and (4) Update the corresponding NAT entry and write the new NAT entry to disk. In Figure 8(b), after applying epoch1's journal, we apply epoch2's journal record, in which after we read epoch2's journal to memory and find that one log record of inode1 (8KB file size) needs to be applied, we use the inode number to locate the in-memory inode1 and find its state is `Uptodate`, then we skip applying this log and move to next epoch.

Journal apply is conducted following the commit order. Specifically, we always start with the current epoch indicated

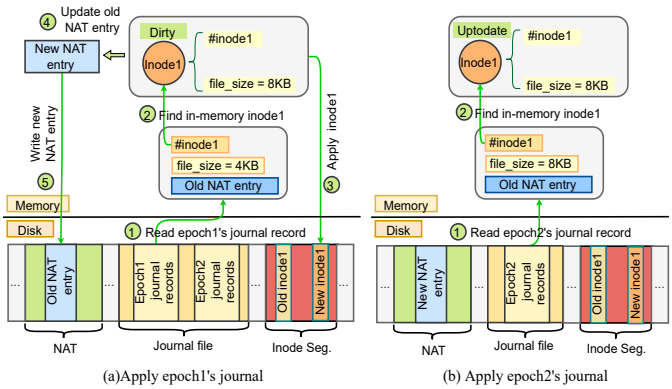


Figure 8: Illustration of the fast-forward-to-latest journal apply.

by the starting offset of the journal file that is recorded on disk. Only after all journal records of the current epoch have been applied, the offset can be updated so we can move to next epoch. Following this, with the unique characteristic in out-of-place-update file systems, i.e., old information will be kept without modification with out-of-place updates (e.g., Old inode1 is not replaced by New inode1 as shown in Figure 8), the fast-forward-to-latest approach does not incur inconsistency even with system crash. Journal apply is triggered and stopped based on the low and high watermarks based on the free space of the journal file. With a normal system shutdown, all journal records in the journal file will be applied before the close.

3.6 Crash Recovery

Crash recovery will be performed when we find there are journal records that are not applied during system booting. Similar to journal apply, we read journal records from the journal file and apply them one by one. However, in contrast to journal apply, we can directly apply journal records without checking in-memory pages. Specifically, based on the filesystem metadata of an inode (i.e., the SIT/NAT/SSA entries) recorded in the journal file, we can locate and read the old inode to memory, apply metadata changes based on logs and then update the new inode and its SIT/NAT/SSA entries to disk.

In the event of a crash during journal apply, the out-of-place-update mechanism in F2FS ensures that old data remains intact. This feature enables the filesystem to recover by replaying on-disk journals in epoch order, thereby maintaining data consistency and integrity. For instance, as illustrated in Figure 8(b), if a system crash occurs during epoch2, recovery will resume from epoch2. Using the filesystem and file metadata from epoch2's journal records, the system can then restore a consistent state.

4 Implementation

We have implemented F2FSJ with minor modifications to F2FS with about 3,000 lines of code, summarized as follows.

First, we define various log types and structures for different file operations, which contain the type of file operations

Categories	Name	Description
Metadata-intensive workloads with Filebench [9]	mkdir	Create 4M directories.
	rmdir	Delete 4M directories.
	create-empty	Create 4M empty files.
	unlink-empty	Delete 4M empty files.
Small-file-intensive workloads with Filebench	create-4KB	Create 4M 4KB-files.
	unlink-4KB	Delete 4M 4KB-files.
	copy-4KB	Create and copy 2M 4KB-files.
Data-intensive workloads for a 32GB-file with FIO [11]	Seq_write	Sequentially write.
	Rand_write	Randomly Write.
	Seq_read	Sequentially read.
	Rand_read	Randomly read.
	SeqWR_W	Write bandwidth of mixed Sequential writes/reads.
	SeqWR_R	Read bandwidth of mixed Sequential writes/reads.
	RanWR_W	Write bandwidth of mixed random write/reads.
	RanWR_R	Read bandwidth of mixed random write/reads.
Realistic applications with Filebench and APP commands	Varmail	Frequently create and delete small files with fsync.
	OLTP	Intensively write and append data to files.
	Fileserver	Intensively write and read small files.
	Webserver	Intensively read small files with fewer writes.
	Webproxy	Intensively read small files with fewer writes and deletions.
	git clone	Download a remote 4.7GB code repository.
	cp -r	Copy a local 3.9GB linux source code.
	make Linux	Compile Linux with local source code.
Android workloads with Mobibench [21]	Twitter	Replay I/O trace of Twitter.
	Facebook	Replay I/O trace of Facebook.
	SQlite	SQlite performance with varying journal mode.

Table 1: Benchmarks introduction.

and the contents of metadata changes. We implement interfaces for logging and integrate them into file operations.

Second, we modify `struct f2fs_inode_info` to implement per-inode log lists and `e2l_mapping` mapping tables. Specifically, for each log list, we set a journal ticket counter to record ongoing file operations. We also use an array to implement the `e2l_mapping` table and implement epochs with linked lists.

Third, we implement a kernel thread for journal commit that has a linked list for `COMMIT` epochs. We use another kernel thread for journal apply, which is triggered and stopped based on the low and high watermarks of the free journal space. Considering garbage collection (GC) may migrate inodes and data, thus changing the locations of old inodes, all journal records need to be applied before GC.

Finally, F2FSJ requires a contiguous disk area to store journal records, for which an on-disk journal file with a configurable size (e.g., 256 MB in our experiments) is created and utilized in round-robin fashion. During each epoch, metadata changes are collectively appended to the journal file, effectively avoiding random writes. Furthermore, by journaling only metadata changes instead of entire metadata pages, it significantly reduces write amplification.

5 Evaluation

In this section, we present evaluation results on F2FSJ and seek to answer the following questions: (1) Does F2FSJ eliminate the long tail latency of F2FS checkpointing? (2) Does F2FSJ provide better performance under various workloads than F2FS? (3) Does F2FSJ gain better performance compared with JBD2? (4) What are the overheads of memory, CPU and storage in F2FSJ?

5.1 Experiment Setup

Experiment Environment. All the experiments are performed on a desktop machine equipped with Intel's i9-10850K CPU (19 cores running at 3.6 GHz), 64 GB DRAM and a

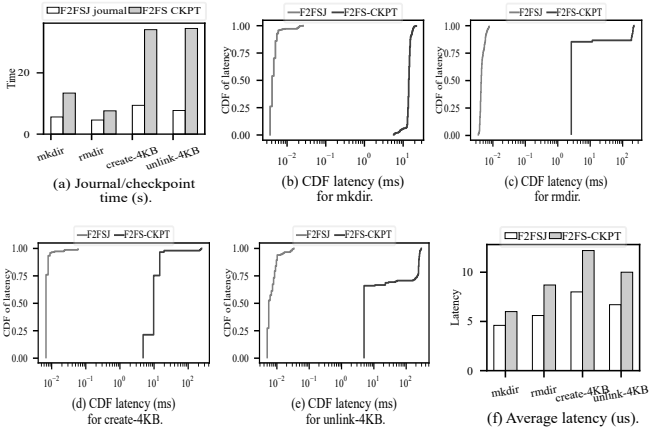

Figure 9: Journaling and checkpointing time comparison with filebench: (a) The journal time of F2FSJ versus the checkpoint time of F2FS checkpointing. (b)-(e) CDF latency comparison between F2FSJ and F2FS checkpointing for mkdir, rmdir, create-4KB and unlink-4KB. (f) Average latency comparison between F2FSJ and F2FS checkpointing for mkdir, rmdir, create-4KB and unlink-4KB.

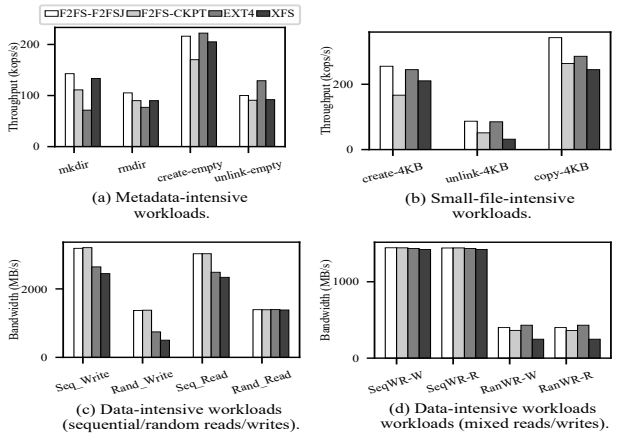

Figure 10: End-to-end performance: Throughput comparison with filebench for (a) Metadata-intensive workloads and (b) Small-file-intensive workloads. Bandwidth comparison with FIO for (c) Data-intensive workloads and (d) Data-intensive workloads with mixed reads/writes.

256GB Samsung 980pro PCIe 4.0 NVMe SSD [27, 57] that can provide up to 7.0 GB/s and 5.0 GB/s throughput for sequential reads and sequential writes, respectively. Clearlinux with Linux kernel v5.15.39 [20] is used as operating system.

Experiment Benchmarks. As shown in Table 1, we categorize the benchmarks into five classes, all of which have different file and directory access patterns, ranging from metadata-intensive workloads, small-file-intensive workloads, data-intensive workloads, realistic applications and Android workloads.

For evaluation results, all the tests are started with a clean filesystem and all reported numbers are the mean of at least ten runs and the standard deviation in all cases is less than 5% of the mean. We use `flame` [12], `perf` [22], and `bcc-tools` (eBPF based) [3], `Top` [19] and `Free` [17] to measure and breakdown the experiment results.

5.2 Journal and Checkpoint Time Comparison

We begin by comparing journal time and checkpoint time. In this context, journal time in F2FSJ refers to the execution duration of journaling for a specific benchmark, while checkpoint time in F2FS checkpointing represents the execution duration of the checkpointing process. Next, we evaluate latency, where latency indicates the execution time of a single operation, and average latency reflects the mean execution time of all such operations within a given benchmark.

We use four filebench benchmarks: `mkdir`, `rmdir`, `create-4KB`, `unlink-4KB`. As shown in Figure 9(a), F2FSJ has the minimal time overhead. For instance, the checkpoint time with F2FS checkpointing is 2.4x, 1.7x, 3.6x, and 4.9x longer than the journaling time with F2FSJ across the four benchmarks. Additionally, in Figures 9(b)-9(e), F2FSJ significantly reduces tail latencies compared to F2FS checkpointing, with the latter exhibiting tail latencies that are three orders of magnitude higher. Finally, as shown in Figure 9(f), F2FSJ outperforms F2FS checkpointing in terms of the average latency (e.g., 23%, 35%, 13% and 33% reductions for `mkdir`, `rmdir`, `create-4KB` and `unlink-4KB`, respectively).

5.3 End-to-end Performance

In this section, we use a diverse set of workloads, along with the throughput (operations per second) and IO bandwidth (MB/second) metrics, to assess and compare the end-to-end performance of multiple filesystem combinations. These combinations include F2FS integrated with F2FSJ (referred to as F2FS-F2FSJ), F2FS utilizing its checkpointing mechanism (denoted as F2FS-CKPT), EXT4 in conjunction with JBD2 (simply called EXT4), and XFS with logical journaling (simply named XFS). In addition, filesystems are set to the default working mode. Specifically, F2FS operates in POSIX mode, EXT4 with JBD2 runs in ordered mode, and XFS is configured with metadata journaling and asynchronous transactions. We first evaluate end-to-end performance using micro-benchmarks (§5.3.1) and real applications (§5.3.2). We then present the results for scalability (§5.3.3) and long-term/aged filesystem testing (§5.3.4).

5.3.1 Results with Micro-benchmarks

Metadata-intensive workloads. Figure 10(a) presents the throughput results. F2FS-F2FSJ outperforms F2FS-CKPT by 1.29x, 1.16x, 1.27x, 1.11x on `mkdir`, `rmdir`, `create-empty` and `unlink-empty`, respectively. For `mkdir` and `rmdir`, F2FS-F2FSJ (2.0x and 1.37x higher throughtput) and F2FS-CKPT (1.56x and 1.17x higher throughput) have better performance than EXT4. This is because EXT4 requires journaling 6 metadata pages for each create or delete operation, leading to more IO operations with more storage space. Additionally, file operations need to wait for JBD2 checkpoint in order to recycle space. But for `create-empty` and `unlink-empty`, EXT4 outperforms F2FS-F2FSJ (1.03x and 1.29x), because the longer query time on NAT is required in F2FS-F2FSJ and file operations will not be blocked by JBD2 checkpoint in EXT4. On the other hand, F2FS-F2FSJ outperforms XFS (i.e., 1.05x-1.17x higher throughput) for all benchmarks.

Name	Avg. file size	Num. of files	R/W/C/U ratio	Total file operations
Varmail	16 KB	1 M	2:2:1:1	128.8 K
OLTP	10 MB	3.2 k	1:10:0:0	33 M
Fileserver	128 KB	800 k	1:2:1:1	1.1 M
Webserver	16 KB	1.6 M	10:1:0:0	12.4 M
Webproxy	16 KB	2 M	5:1:1:1	3.8 M

Table 2: Filebench realistic workloads parameters. R/W/C/U represents the ratio of read, write, create and unlink, respectively.

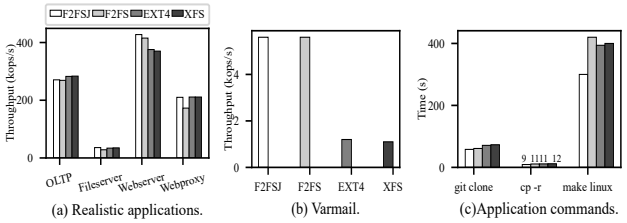

Figure 11: Throughput comparison with filebench for (a) Realistic applications and (b) Varmail. (c) Time comparison with APP commands.

Small-file-intensive workloads. As shown in Figure 10 (b), F2FS-F2FSJ outperforms F2FS-CKPT by 1.14x, 1.69x and 1.30x on `create-4KB`, `unlink-4KB` and `copy-4KB`, respectively. Compared to EXT4, F2FS-F2FSJ demonstrates similar throughput to EXT4 in `create-4KB` and `unlink-4KB`. However, it outperforms EXT4 in `copy-4KB`, benefiting from F2FS's inherent advantage in sequential read/write performance. Conversely, F2FS-F2FSJ consistently outperforms XFS across all tested scenarios, achieving 1.21x, 2.7x, and 1.40x higher throughput on `create-4KB`, `unlink-4KB` and `copy-4KB`, respectively. This advantage stems from F2FSJ's decentralized journal architecture and its decoupled control and data planes.

Data-intensive workloads. As shown in Figure 10(c), for `Seq_write` and `Rand_write`, F2FS-F2FSJ drives IO bandwidth comparable with F2FS-CKPT. The reasons are that F2FS-F2FSJ incurs additional journal I/Os during data flush, and large file writes do not frequently trigger F2FS checkpoints. For `Seq_read` and `Ran_read`, F2FS-F2FSJ and F2FS-CKPT have almost the same bandwidth because large file read operations only modify one inode, resulting in negligible overhead for both journaling and checkpoint processes. Due to the appending nature, F2FS-F2FSJ and F2FS-CKPT have higher throughput than EXT4 and XFS on `Seq_write`, `Rand_write` and `Seq_read`. For `Ran_read`, all four filesystems exhibit the same bandwidth performance. Then, for mixed workloads in Figure 10(d), all four filesystems demonstrate similar bandwidth performance on `SeqWR_W` and `SeqWR_R`. Conversely, for `RanWR_W` and `RanWR_R`, F2FS-F2FSJ outperforms F2FS-CKPT, while EXT4 attains higher bandwidth than F2FS-F2FSJ due to interference on NAT in F2FS.

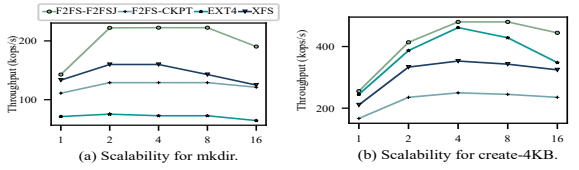

Figure 12: Scalability comparison for (a) mkdir and (b) create-4KB.

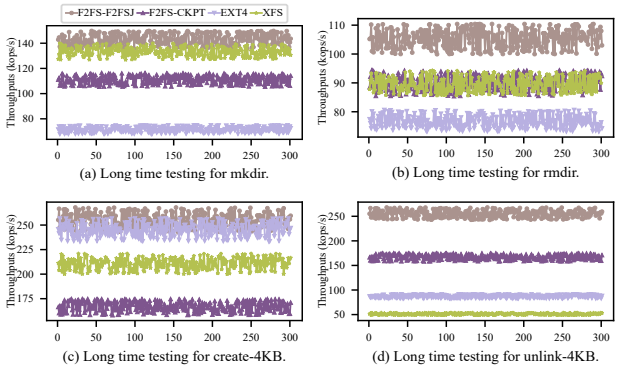

Figure 13: Long-term testing for (a) mkdir, (b) rmdir, (c) create-4KB and (d) unlink-4KB.

5.3.2 Results with Realistic Applications

Filebench workloads. Figures 11(a) and 11(b) shows the results with the filebench workloads. First, `OLTP` is a data-intensive workload and frequently invokes `fdatasync`, resulting in many I/Os to flush data. F2FS-F2FSJ has comparable throughput with F2FS-CKPT because checkpointing is not triggered frequently. Second, `Fileserver` is a small-file intensive workload, for which F2FS-F2FSJ shows 1.27x, 1.06x and 1.03x higher throughput than F2FS-CKPT, EXT4 and XFS, respectively. Then, `Webserver` primarily involves sequential read and write operations, for which F2FS-F2FSJ achieves 1.16x higher throughput compared to F2FS-CKPT, while both F2FS-F2FSJ and F2FS-CKPT demonstrate higher throughput than EXT4 and XFS due to F2FS's log structured design. For `Webproxy`,which is characterized by a high volume of file deletion and creation operations across 100 threads, F2FS-F2FSJ achieves 1.10x higher throughput compared to F2FS-CKPT but has lower performance compared to EXT4 and XFS. This is due to significant locking overhead in the filesystem metadata of F2FS, particularly in NAT and SIT, which leads to reduced performance. Finally, `Varmail` calls `fsync` every time after writes, incurring many I/Os to storage. For F2FS-F2FSJ and F2FS-CKPT, their performances are adversely affected by the frequent occurrence of I/Os during data flushing. EXT4 and XFS exhibits the lowest throughput due to the time overhead of journal period transfer.

Real-world applications. Figure 11(c) presents the results from real applications, including `git`, `cp` and `make`. First, for `git clone`, F2FS-F2FSJ incurs the lowest time cost and is approximately 5%, 18.3% and 21% faster than F2FS-CKPT, EXT4 and XFS, respectively. Second, for `cp -r` and `make linux`, which involve numerous reads and the creation of small files and directories, F2FS-F2FSJ achieves shortest

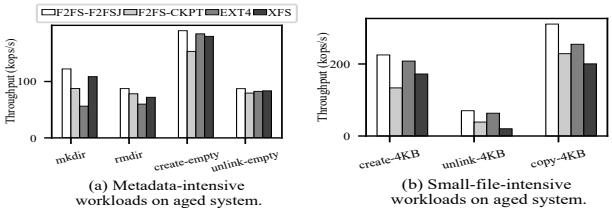

Figure 14: Throughput comparison on aged system for (a) Metadata-intensive workloads and (b) Small-file-intensive workloads.

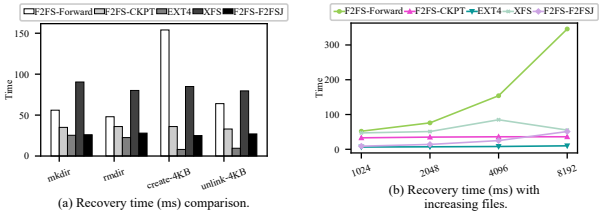
execution times compared to F2FS (14.0% and 22.1% reductions), EXT4 (18.8% and 23.% reductions), and XFS (22.2% and 25.0% reductions).



5.3.3 Scalability

We use `mkdir` and `create-4KB` to evaluate the scalability of F2FS-F2FSJ, F2FS-CKPT, EXT4 and XFS by setting the thread number from 1 to 16. Figures 12(a) and 12(b) show the results. For `mkdir`, F2FS-F2FSJ has the best scalability and throughput (e.g., 1.72x, 2.96x and 1.38x higher than F2FS-CKPT, EXT4 and XFS with 2 threads). Moreover, the performance of all filesystems begins to degrade when the number of threads exceeds eight [32, 46, 49]. For `create-4KB`, F2FS-F2FSJ has the best scalability and throughput (e.g., 1.92x, 1.03x and 1.35x higher than F2FS-CKPT, EXT4 and XFS with 4 threads). Conversely, F2FS-CKPT has the worst scalability because of its time-consuming and single-threaded checkpointing process.

5.3.4 Long-term and Aged Filesystem Testing

For long-term testing, we use four benchmarks: `mkdir`, `rmdir`, `create-4KB`, and `unlink-4KB`. We extend the original benchmark runtime by a factor of 300 (exceeding six hours for each long-term test). As shown in 13(a)–(d), the throughput performance of each filesystem remains stable, with fluctuations occurring within a consistent range throughout the long-term evaluation. Overall, F2FS-F2FSJ sustains the best performance without any sudden drops.

Aged filesystem testing is conducted using the Geriatrix [34] tool to simulate real-world fragmentation by distributing files of varying sizes across the filesystem. To evaluate performance under these conditions, we employ metadata-intensive and small-file-intensive workloads. As shown in Figures 14(a) and (b), F2FS-F2FSJ consistently outperforms F2FS-CKPT in an aged system environment, achieving 1.1x to 1.7x higher throughput. Furthermore, F2FS-F2FSJ demonstrates superior performance compared to EXT4 and XFS, as fragmentation significantly increases I/O overhead in JBD2 and XFS logging. Specifically, fragmentation causes excessive inode dispersion on the disk, leading to a rise in the number of bitmap pages requiring journaling. In contrast, F2FSJ's fine-grained journaling, which is based on metadata changes, remains unaffected by fragmentation.

(a) Recovery time (ms) comparison.

(b) Recovery time (ms) with increasing files.

Figure 15: Recovery time comparison for mkdir, rmdir, create-4KB and unlink-4KB: Recovery times for (a) creating or deleting 4,096 directories/files and (b) varying numbers of files.

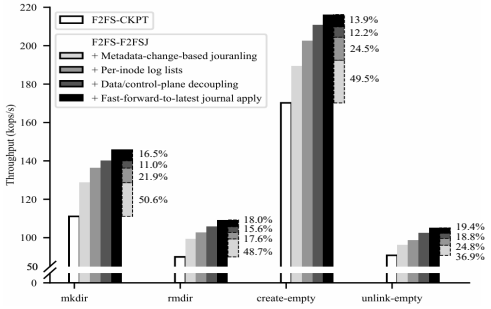
5.4 Crash Recovery

In this section, we assess the crash recovery performance of various file systems and mechanisms, including F2FS-F2FSJ (F2FS with F2FSJ), EXT4 (EXT4 with JBD2), and XFS (XFS with its logging). Additionally, we evaluate F2FS-CKPT (F2FS with its default checkpointing and rollback recovery mechanism) and F2FS-Forward (F2FS with its roll-forward recovery mechanism).

Recovery time comparison. We utilize four benchmarks: `mkdir`, `rmdir`, `create-4KB` and `unlink-4KB`. Specifically, we create or delete 4,096 directories or files, then execute a checkpoint/journal commit, followed by a power failure. As shown in Figure 15(a), F2FS-F2FSJ reduces recovery time compared to F2FS-CKPT and F2FS-Forward. Under the `create-4KB` benchmark, F2FS-Forward has an unusually long recovery time. This is because it compares inodes before and after tagging to restore the data index, generating random I/Os that degrade performance. EXT4 has the shortest recovery time, as it writes back journaled metadata pages directly without reading the original metadata from the disk. In contrast, XFS has the longest recovery time because it replays the log twice - first to identify canceled items and then to process the remaining log entries while skipping the canceled ones.

Figure 15(b) shows the recovery time comparison across file numbers ranging from 1K to 8K. As observed, F2FS-CKPT maintains a stable recovery time of approximately 35ms, as it only restores a limited amount of filesystem metadata recorded in the checkpoint pack. Compared to F2FS-CKPT, F2FS-F2FSJ recovers faster when the file count is below 4K but experiences a 1.4x increase when handling 8K files. Additionally, F2FS-F2FSJ journal recovery significantly reduces recovery time - by 5.4x to 6.8x - compared to F2FS roll-forward recovery. Among all tested systems, EXT4 exhibits the shortest recovery time, as it only writes back journaled metadata pages without reading additional disk data. Meanwhile, XFS has a longer recovery time than both F2FS-F2FSJ and EXT4. Interestingly, when the file count reaches 8K, XFS recovery time decreases due to its proactive mechanism to apply certain log entries.

Crash consistency. We use CrashMonkey [43] to validate the correctness of F2FSJ recovery. Specifically, we evaluate rename workloads (`renam_root_to_sub`) and create/delete workloads (`create_delete`). The recovery results confirm that F2FS-F2FSJ successfully passes all test cases, demonstrating its consistency performance.



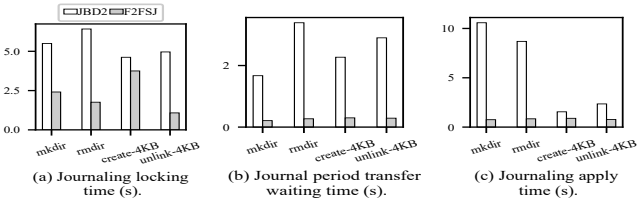


Figure 16: Throughput breakdown of each F2FSJ component for Metadata-intensive workloads.

(a) Journaling locking time (s).

(b) Journal period transfer waiting time (s).

(c) Journaling apply time (s).

Figure 17: JBD2 and F2FSJ journaling time breakdown: (a) Journal locking time. (b) Journal period transfer waiting time. (c) Journal apply time.

5.5 Breakdown Analysis of F2FSJ

In this section, we present a breakdown analysis of F2FSJ. First, we examine the contributions of its four components to the filesystem. Next, we compare the journaling time breakdown of F2FSJ with JBD2. Finally, we assess the impact of varying journal periods.

Effects of individual F2FSJ components. We analyze the throughput breakdown of each F2FSJ component using metadata-intensive workloads to assess their contributions. Figure 16 presents the throughput results of F2FS-CKPT (F2FS with default checkpointing) and F2FS-FSFSJ (F2FS with F2FSJ), highlighting the impact of each F2FSJ component: metadata-change-based journaling, per-inode log lists, data/control-plane decoupling, and fast-forward-to-latest journal apply. Among the total performance improvement, on average, metadata-change-based journaling contributes the most (approximately 49%) by leveraging fine-grained journaling to delay journal application, thereby reducing file operation blocking time. Per-inode log lists effectively minimize locking overhead during log collection, leading to a performance gain of approximately 21%. Data/control-plane decoupling reduces journal period transfer waiting time, resulting in a performance improvement of about 14%. Lastly, fast-forward-to-latest journal apply eliminates the overhead of across-epoch metadata application, contributing approximately 16% to overall system performance enhancement.

Journaling time breakdown. First, as shown in Figure 17(a), the locking time of F2FSJ is significantly reduced compared to JBD2, reduced by 18.8% - 78.2%. Second, the waiting time for journal period transfers in F2FSJ is noticeably less than that of JBD2, reduced by 86.8% - 92.0% in Fig-

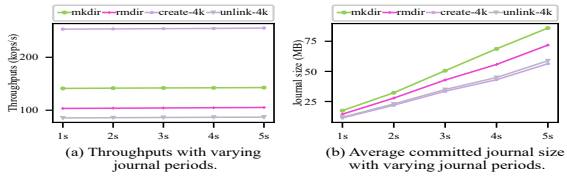

Figure 18: Throughput and journal size with varying journal periods.

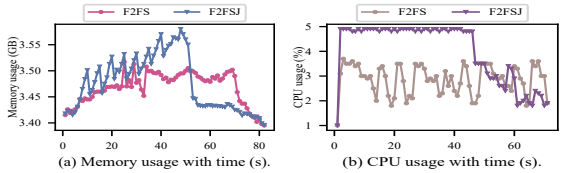

Figure 19: Overhead analysis: (a) Memory usage comparison. (b) CPU usage comparison.

ure 17(b). Third, in Figure 17(c), F2FSJ significantly reduces journal applying time (reduced by 68.4% - 95.3%).

Effects of varying journal periods. We evaluate the impact of varying journal periods on throughput and journal storage consumption. As shown in Figure 18(a), throughput across different benchmarks shows an increase (1.1%, 1.8%, 0.08%, and 1.6% for each benchmark) as journal periods extend from 1 second to 5 seconds, demonstrating that our decoupled control/data plane journal design imposes minimal overhead. In Figure 18(b), the average log size per journal commit exhibits an approximately linear increase, with maximum log sizes recorded at 85.9MB for `mkdir`, 71.8MB for `rmdir`, 56.4MB for `create-4KB`, and 58.8MB for `unlink-4KB`.

5.6 Overheads Analysis

In this section, we analyze the overheads associated with F2FSJ, specifically its impact on CPU usage, memory consumption, and storage utilization.

To assess CPU usage and memory consumption, we compare F2FSJ with F2FS checkpointing using `create_4KB`, which requires the highest memory and CPU resources. As illustrated in Figure 19(a), the memory usage of F2FS checkpointing ranges from 3.45GB to 3.50GB during the test, whereas F2FSJ exhibits a higher range of 3.50GB to 3.55GB, reflecting a modest 1.4% increase compared to F2FS checkpointing. For CPU usage, as shown in Figure 19(b), F2FS checkpointing averages around 3%, while F2FSJ reaches approximately 4.8% during the test. Consequently, F2FSJ exhibits 1.8% increase in CPU usage compared to F2FS checkpointing, which remains negligible.

For storage utilization, we compare F2FSJ (F2FSJ with F2FS) and JBD2 (JBD2 with EXT4), as both employ journaling mechanisms. In all the experiments discussed above, F2FSJ allocates 256MB for its journal file, representing only 0.1% of the total 256GB SSD capacity. In contrast, JBD2 requires 1GB of storage due to its page-based journaling approach. By leveraging metadata-change-based journaling, F2FSJ reduces storage usage to 25% of that required by JBD2.

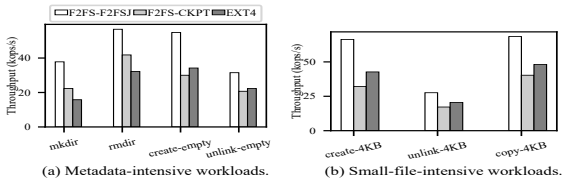

Figure 20: Throughput comparison for (a) Metadata-intensive-workloads and (b) Small-file-intensive workloads on ARM embedded board.

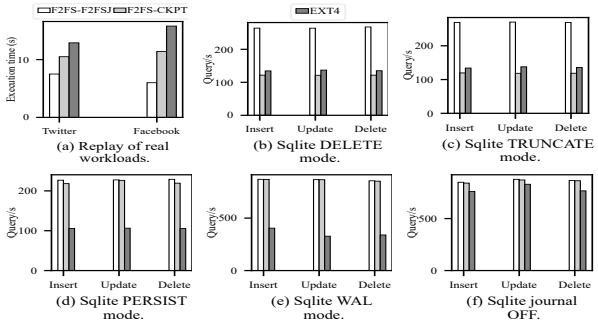

Figure 21: Real application experiments with Mobibench on ARM embedded board: (a) Execution time comparison for Twitter and Facebook workloads. Sqlite performance comparison for (b) DELETE mode, (c) TRUNCATE mode, (d) PERSIST mode, (e) WAL mode and (f) Journal-off.

5.7 Evaluation on ARM Embedded Board

For a more comprehensive evaluation, we expand our experiments to include micro-benchmarks and real-world Android applications on an ARM embedded board (Rockchip RK3588S [23]). This board features 4 Cortex-A76 and 4 Cortex-A55 CPU cores (8nm), 16GB LPDDR4 memory, and 128GB eMMC storage [6], running Linux kernel v5.10 and Android version 12 [2]. Specifically, we first compare the end-to-end throughput performance of F2FS-F2FSJ (F2FS with F2FSJ), F2FS-CKPT (F2FS with checkpointing), and EXT4 (EXT4 with JBD2) using micro-benchmarks. We then present results from Android applications, including execution time comparisons for Twitter and Facebook, as well as throughput comparisons for SQLite across different modes. Our evaluation shows that F2FSJ delivers superior performance improvements in micro-benchmark experiments compared to those observed in the desktop environment.

Metadata-intensive workloads. As shown in Figure 20(a), for metadata-intensive workloads, F2FS-F2FSJ significantly outperforms F2FS-CKPT by 1.70x, 1.36x, 1.83x and 1.52x and EXT4 by 2.39x, 1.76x, 1.60x and 1.41x for `mkdir`, `rmdir`, `create-empty` and `unlink-empty`, respectively.

Small-file-intensive workloads. As illustrated in Figure 20(b), F2FS-F2FSJ demonstrates significant throughput improvements compared to F2FS-CKPT, with gains of 2.06×, 1.60×, and 1.69× for create-4KB, unlink-4KB, and copy-4KB, respectively. Similarly, it outperforms EXT4 by 1.55×, 1.35×, and 1.42× for the same benchmarks.

Android workloads. First, F2FS-F2FSJ exhibits minimal time overhead for both Twitter and Facebook workloads, achieving time reductions of 28.5% and 47.3% compared to F2FS-CKPT, and 41.9% and 62.0% compared to EXT4, as

shown in Figure 21(a). Next, we evaluate SQLite throughput performance in terms of queries per second across different journal modes. Specifically, in Figures 21(b) and 21(c), F2FS-F2FSJ outperforms F2FS-CKPT by up to 2.24× and EXT4 by up to 1.96× for Insert, Update, and Delete workloads under both the DELETE and TRUNCATE modes. For the PERSIST and WAL modes, F2FS-F2FSJ demonstrates comparable performance to F2FS-CKPT while achieving up to 2.17× improvement over EXT4, as depicted in Figures 21(d) and (e). Finally, in Figure 21(f), F2FS-F2FSJ and F2FS-CKPT exhibit similar performance when SQLite journaling is disabled.

6 Related Work

JBD2. JBD2 utilizes a centralized approach with data/control coupling, where each epoch is associated with a global ticket and a lock. During file operations' journaling initiation/completion, acquiring the ticket lock to increment/decrement the ticket number is essential. Consequently, waiting times are inevitable during journal period transfers as the ticket lock must be obtained and the ticket number must become zero. In contrast, F2FSJ journals metadata changes in per-inode log lists, registering only the inode number in the epoch. Thus, it can issue the next epoch immediately during a journal period transfer without waiting for a global ticket.

NOVA. The per-inode log mechanism of NOVA [56] is tailored for NVM, which directly writes logs to the per-inode log area on NVM. In contrast, F2FSJ employs per-inode log lists for journaling, requiring different data organization and management mechanisms for log-structured filesystems.

WineFS. WineFS [33] is optimized for NVM. With undo journaling, it incurs more overheads for write transactions (i.e., record both old metadata/data); however, upon transaction completion, the associated logs can be discarded, eliminating the need for journal apply. This approach is effective for NVM, but slower I/O in flash storage may introduce more write overheads. In contrast, F2FSJ only journals metadata changes, enhancing journal write performance. Additionally, journal apply is not in the critical paths of data reads/writes, allowing it to be scheduled with minimal system impact.

BtrFS. Btrfs [50] optimizes updates to the copy-on-write trees [5] by journaling modified data and metadata related to a specific file in a dedicated log-tree. In contrast, in F2FSJ, we aim to design a novel journaling mechanism so as to provide fine-grained crash recovery for F2FS with different log organization and management schemes.

NV_LOG. NV_LOG [26] is a logging mechanism based on NVRAM (Non-Volatile Random Access Memory), which is not currently utilized in read-world products. In contrast, F2FSJ focuses on typical usage scenarios, offering a universal journaling approach tailored for flash storage devices.

I-journaling. I-journaling [48] enhances fsync performance through a hybrid journaling approach that combines JBD2 transactions with I-transactions. Per-CPU core I-transactions handle fsync operations, including the necessary metadata logs for crash recovery, while JBD2 transactions manage other file operations. This reduces fsync latency by committing I-transactions but still suffers from JBD2's locking overhead and extended journal transfer periods for non-fsync operations. In contrast, F2FSJ addresses these JBD2 limitations by employing a decentralized design and an epoch-based journaling mechanism, effectively eliminating locking overhead and journal transfer delays.

Z-journal. Z-journal [38] resolves JBD2's scalability challenges by introducing per-core journaling, allowing each CPU core to maintain its own transaction and using coherence commits for transactions that modify the same metadata pages. In contrast, F2FSJ separates journal data and control planes through per-inode log lists and epochs, achieving superior scalability and avoiding contention for journal operations on the same CPU core. Additionally, F2FSJ registers inodes into epochs, maintaining consistency without requiring complex coherence commits.

Fast-commit. Fast-commit [52] improves fsync performance and reduces I/O overhead in cloud environments by employing a hybrid journaling approach. JBD2 commits periodically (e.g., every 5 seconds), while Fast-commit logically journals filesystem updates within these intervals. It centralizes inode and dentry lists for journaling and uses compact logging to minimize journal size. However, as JBD2 continues running in the background, Fast-commit cannot fully eliminate JBD2's overhead and primarily optimizes fsync performance. In contrast, F2FSJ mitigates I/O overhead by journaling only metadata changes. Its decoupled data/control plane design enables fast journal period transfers, offering a more efficient solution than Fast-commit's hybrid approach.

7 Conclusion

In this paper, we propose a novel journaling technique, called F2FSJ, for F2FS with ordered journal mode. F2FSJ eliminates the long tail latency of checkpoint and provides fine grained crash recovery. F2FSJ incorporates several innovative designs. First, it only journals the metadata changes to reduce I/O and storage overheads. Second, it employs a decentralized journal design featuring per-inode log lists to minimize lock contention and interference. Third, it advocates an epoch-based strategy with decoupled data/control planes to eradicate waiting times during journal period transfer. Finally, it uses fast-forward-to-latest journal apply to consolidate multiple small writes. Evaluation results indicate that F2FSJ outperforms F2FS checkpointing.

Acknowledgments

We thank our shepherd, Kiran-Kumar Muniswamy-Reddy, and the anonymous reviewers for their constructive feedback and insightful comments. Abstract

The Okapi cluster file system decouples how data is spread across disks (data striping) for IO efficiency from how data is erasure coded together (redundancy grouping) for durability. Existing systems couple these two mechanisms' configurations, inducing significant inefficiencies. Decoupling allows grouping to be configured based on reliability and space efficiency goals, while simultaneously allowing striping to be configured based on performance goals. Decoupling also allows redundancy scheme changes from one EC scheme to another (e.g., to react to data temperature or disk failure rate changes) to occur without having to re-write data. Evaluation of an Okapi prototype shows that decoupling can be accomplished with <1% increase in metadata size and file manager memory, and minimal file creation and degraded read resource increase. Experiments demonstrate that decoupling can improve read throughput by 80% and reduce seeks per second by up to 70%, without yielding any data reliability, and reduce the overhead of redundancy transitions by up to 70%.

1 Introduction

Cluster file systems store data of a single file across multiple disks for IO efficiency and use redundancy to provide fault tolerance [7, 16, 50]. Although many environments use SSD caches and/or data replication for hot data, most data is stored via erasure codes on mechanical disks at lower cost-per-byte [4, 5, 48]. Generally speaking, k-of-n erasure codes (ECs) compute $r = (n-k)$ parity blocks over k blocks of data, and then store the n blocks on distinct disks. Such codes protect data from r failures at a space overhead of $\frac{n}{k}$.

Most existing systems spread each file's data across k data blocks, in units called *cells*, in a round-robin manner akin to RAID-4 [17]. This is called "striping". The size of a data block is typically 8MB or higher, and the size of a cell is typically 1MB. A file may consist of one or more of these arrays of k data blocks. Such striping improves degraded-mode read performance, decreases tail latencies, reduces buffer sizes for parity computation, and reduces capacity overhead for smaller files ($< k \times 8$ MB). The above described cell-level striping is used in Google's Colossus [25], Lustre [47], Ceph [11], HDFS [14] and many others [22, 39, 46, 57].

(a) Coupled: 4-of-6 grouping implies 4-wide striping

(b) Decoupled: 6-of-8 grouping while choosing 4-wide striping

Figure 1: 1a shows a file in a coupled architecture with a 4-of-6 EC scheme and 4-wide striping. Data is striped across 4 data blocks in a round-robin fashion as seen by the alternating light and dark colors. Parities are computed for every 4 data blocks. 1b shows the same file in Okapi's decoupled architecture with a 6-of-8 EC scheme and 4-wide striping. Data is striped across 4 data blocks, but parities are computed for every 6 data blocks. See Figures 3 and 4 for detailed examples.

In existing systems, each file's EC configuration (i.e., the values of k and r) dictates two decisions: how the file's data is spread across storage servers (i.e., data *striping*) and which blocks are encoded into the same parities (i.e., redundancy *grouping*). Specifically, data is striped over k blocks (stripe width = k), and those same k blocks (group width = k) are encoded together to form parities. Fig. 1a shows a file with 4-of-6 scheme where each row of 4 cells from 4 data blocks D1–D4, D5–D8 and D9–D12 are encoded to form parity cells (of the same size as data cells) in the two corresponding parity blocks. Thus, striping and grouping are tightly *coupled*. However, forcing stripe width and group width to be equal creates two fundamental problems: (1) an often too-limited set of options in a complex trade-off space between performance, space efficiency, and data reliability; and (2) worst-case re-encoding IO overhead when new circumstances dictate EC (grouping) changes.

First, with today's coupling, a file's values for k, r significantly affect its IO performance, space efficiency, and data

[*]Equal contribution

reliability. For instance, wider *stripes* (e.g., 30–96 wide [23, 25, 28]) allow higher bandwidth for huge sequential IOs, but can result in higher tail latencies and IO time used (due to extra seeks) when accessing smaller file ranges (e.g., <100MB), exacerbating the ever-worsening IO-per-TB-stored bottleneck [29]. Simultaneously, wider *groups* reduce storage overhead compared to narrower alternatives, such as 6-of-9 [13] or 10-of-14 [43], but increase reconstruction IO and can reduce data reliability. Many applications desire the performance benefits of narrow striping and storage overhead of wide grouping (such as video streaming services), or vice-versa. At Google, we observe many files use group width $k > 50$ to achieve space efficiency but suffer consequent IO inefficiencies, and other files use narrow schemes to reduce reconstruction overheads but suffer lower sequential bandwidth.

Second, coupling implies that changing a file's EC config, and hence group width (say from k_1 to k_2), requires re-*striping* its data contents. That is, all data units must be read and rewritten (striped across k_2 blocks), in addition to writing the newly computed parities. This overhead grows increasingly important as grouping changes become more common to reduce space overhead as data cools [29, 54], to maintain data reliability as disks age [25–27], and to address black swan events. One recent example of the latter at Google was a sudden failure rate increase of one disk make/model that dictated an emergency reduction of group width, overwhelming some storage clusters with a massive IO burst.

Recent work reported that millions of files transition to increasingly wider erasure codes every hour in Google clusters [29]. It highlights the massive scale of resulting IO demands and proposes efficient approaches to avoid them. However, unfortunately the IO savings are unrealizable for many systems using data striping because of the need for re-striping.

This paper introduces the Okapi cluster file system, which *decouples* each file's data striping configuration from its redundancy grouping configuration, enabling independent tuning. For example, Fig. 1b shows each range (e.g., 32 MB) of a file's data being striped over 4 data blocks (D1–D4, D5–D8 and D9–D12) while parities are computed over 6 blocks. And, if circumstances dictate a redundancy group width change (e.g., from Fig. 1b's 6-of-8 to Fig. 1a's 4-of-6 to increase data protection), it can be done without changing the stripe width or re-striping the data.

Achieving this increased flexibility requires careful design to avoid metadata blowup and minimize file creation and degraded read overheads, all without introducing complexities that might hinder adoptability. First, Okapi curbs metadata blowup by creating redundancy groups with sequential blocks of the file, which allows it to *infer* group constituencies from the existing stripe mappings instead of maintaining two different metadata structures. Second, Okapi uses *partial parities* to bound the client memory required during file creation. Specifically, when sequentially writing a file, computing parities can require data from multiple stripes containing data

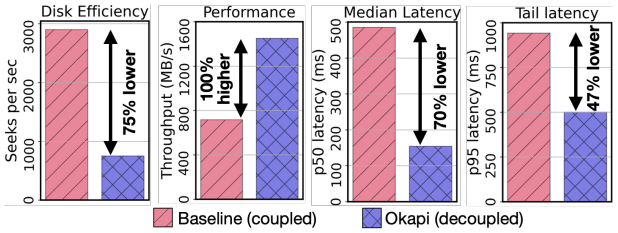

Figure 2: Decoupling improves cluster throughput, disk efficiency and workload latency. The graphs compare coupled and decoupled architectures for 8 MB reads on 12-of-15 EC files. While stripes are forced to be 12-wide in a coupled system, in Okapi, stripe widths could be optimally tuned independently of the EC scheme. See Sec 6 for detailed experimental setup.

blocks for a given group. Rather than caching all data until enough is written (which could easily be hundreds of MBs in wide groups), partial parities computed over accumulated data are kept instead. Third, Okapi smartly caches data during degraded-mode reads to limit read amplification.

We describe an implementation of Okapi in HDFS[1] to show how its concepts can be incorporated into an existing DFS that couples striping and grouping and to enable an apples-to-apples comparison to a coupled baseline. We note that other production scalable DFSs (e.g., Ceph, Panasas's PanFS and Google's Colossus) couple in a similar way, and could become decoupled with similar mechanisms. Experiments comparing to a coupled architecture with 6-of-9 EC scheme show that decoupling can increase read throughput by up to 80% (by reducing seeks by up to 70%) when matching stripe width to data access patterns, without compromising data reliability or space efficiency. With wider erasure codes such as 12-of-15 schemes, we observe up to 115% throughput improvement.

Fig. 2 shows a summary of performance benefits of tailoring stripe widths for 8 MB reads to 12-of-15 erasure-coded files. As a result of better IO efficiency, end-to-end client latency for a Google-derived read-only workload decreases by 36% when each file uses tailored stripe widths. Additionally, Okapi reduces IO for EC transitions by up to 50% compared to read–re-encode–write, and by up to 70% when used with other smart EC-transitioning techniques [29]. Analyzing a real emergency group width reduction scenario from Google and long-term disk-adaptive redundancy using failure logs from Backblaze production cluster confirm 38–45% less IO required for redundancy changes.

This paper makes five primary contributions. First, it exposes the unnecessary coupling of data striping and redundancy grouping in cluster file systems, analyzing resulting inefficiencies. Second, it provides insights into hyperscalar access patterns and workload trends through real-world application characteristics, and highlights the timely need to improve IO efficiency and reduce IO demand. Third, it introduces the decoupled approach, and identifies challenges in building a decoupled cluster file system—increased metadata, expensive file creation and degraded-mode access over-

[1] HDFS (Hadoop Distributed File System) is a popular open-source DFS, used in-production by more than 550 companies [10].

heads. Okapi overcomes them by (1) re-using existing structures and inferring EC group constituencies, (2) partial parity caching to curb client memory overhead, and (3) data caching to limit read amplification during degraded-mode reads. Fourth, it demonstrates that Okapi's ideas are easily adoptable in existing DFS by implementing them in HDFS. Fifth, via comprehensive evaluation on a real (academic) cluster using micro-benchmarks and Google-derived synthetic workloads, it shows that Okapi increases IO efficiency and reduces redundancy change costs.

2 Striping and grouping in cluster storage

Large cluster storage systems store exabytes of data on hundreds of thousands of mechanical disks (HDDs) housed in tens of thousands of servers. Data of a single file is divided into logically consecutive stripes. Each one of these stripes spreads its data in the cluster by *striping* the data across a number of disks and storing parities computed from that data *grouping* on other disks. This section serves to distinguish between striping and grouping in cluster file systems.

Striping: spreading data and accesses. Cluster storage systems break files into ranges and spread them among disks as discussed above. Indeed, most cluster storage systems go further, striping data among data blocks in a round-robin fashion within each range at a finer granularity (generally referred to as a *cell* or a *striping unit*) to improve performance without increasing metadata overheads. The number of data blocks a stripe spans across is called the *stripe width*. Fig. 3 shows a 64 MB file with a stripe width of 4 and a cell size of 1 MB. Note that 4 MBs can be read by fetching 1 MB from 4 disks in parallel.

The striping configuration (cell size and stripe width) dictates important aspects of disk efficiency and performance observed by clients. For every IO, a disk must position the read/write head (seek plus rotational latency) and then transfer the data to/from the disk surface. While both consume "disk time", a highly constrained and shared resource, only the data transfer part is useful. Thus, fewer larger transfers are more efficient, as they amortize positioning time over more useful work. Also, wider stripes can increase tail latency, since a client request is not complete until all involved disks are done. But larger transfers do take longer to complete, and thus can increase latency for clients when cluster load is low (i.e., when extra seeks wouldn't cause queueing delays). Generally, wider striping can be better at low load and worse at high loads, with the trade-off being most relevant for mid-sized requests. We define *mid-sized* requests as those that access more than one data cell but not so large that any choice will involve all disks containing relevant data blocks.

Grouping: erasure-code redundancy. Device failures are common in exascale cluster storage. Thus, data is stored redundantly to protect against permanent data loss. While certain hot data may be replicated, most data is erasure-coded

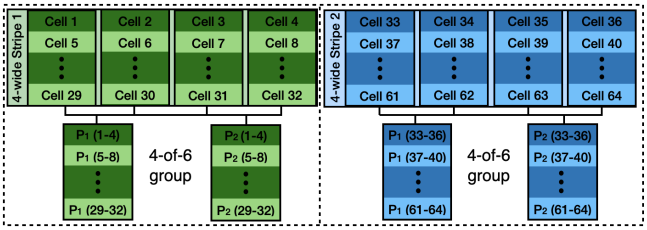

Figure 3: Coupled Architecture of a striped 64 MB *file* with 1 MB cells. Each column of cells is a data block, and data blocks of a stripe are stored on unique disks. The file consists of two stripes: blue and green. This coupled file is forced to use 4-wide striping due to using 4-of-6 grouping.

[13] with each group of data blocks encoded into parity blocks stored on other disks in the cluster (Fig. 3).

When using k-of-n Reed-Solomon erasure codes (EC), each of the k data blocks are encoded into $r = (n-k)$ parity blocks such that any k of the n blocks can provide all k data blocks. Naturally, when possible, a system will read the data blocks rather than using the parities to reconstruct.

The grouping configuration (k and n) dictates important aspects of data reliability, capacity efficiency, and reconstruction overheads. Parities add a capacity overhead of $\frac{r}{k}$. Unsurprisingly, more redundancy increases data reliability. In addition, reconstruction of missing data requires k of the n blocks of data. The reconstruction costs are therefore directly proportional to the value of k. In most environments, a lower bound of r (e.g., 3) is fixed due to factors such as datacenter makeup or planned maintenance outages [27, 28], while the group width (k) can vary. Widths like 6 [13] and 10 [43] and beyond [3] are now common, with 95 and 150 recently being reported [12, 28]. Data requiring higher reliability or being stored on more failure-prone disks is usually stored using *narrower* groups, accepting higher capacity overhead.

3 Why decouple striping from grouping?

Several factors related to IO efficiency determine the best stripe width for a given file, while independent factors related to reliability and space efficiency determine the best group width. Due to today's coupled striping and grouping, applications must choose among limited options (i.e., stripe width must equal group width) often inducing sub-optimal configurations for one or both widths. Furthermore, a coupled architecture forces all data to be re-written when changing EC schemes, inducing significant IO overheads. Emerging storage hardware trends, insights into datacenter workload access patterns, and modern redundancy management techniques further motivate the need for decoupling.

Storage hardware trends. HDDs are becoming denser without becoming proportionately faster [29]. Due to the decrease in IO-per-capacity, disk seeks and disk bandwidth are becoming an increasingly scarce resource. Thus, it becomes critical to improve both the IO efficiency of workloads (by tailoring stripe widths) and reduce IO from workloads that consume high disk bandwidth (e.g., EC transitions).

To demonstrate the impacts of coupling on IO efficiency, consider reading 12 MBs of data from a 6-of-9 erasure-coded file. Assuming 10 ms average positioning time (seek plus rotation) and sustained 150 MB/s data transfer rate, reading 2 MBs from 6 disks consumes 40% more aggregate disk time than reading 6 MBs from 2 disks[2]. To optimize for IO efficiency, if stripe width is set to 2, the file would need to use a 2-of-5 redundancy scheme (to be able to sustain 3 failures), resulting in an unacceptable 2.5× storage overhead.

Hyperscalar workload trends. As hyperscalars store more total data, the average temperature (popularity) of data in their storage clusters gets colder. The steady proportionate growth of cold data has promoted the adoption of *wide erasure codes* ($n \geq 20$) [3,28], which offers excellent capacity-efficiency but suffers from poor IO efficiency. This is especially true for *mid-sized* reads (>1 MB and ≤≈50 MB) where reading from wide EC incurs several 1-2 MB IOs, each one paying heavily in positioning time. At Google, we observe that such mid-sized requests contribute to 65% of total *bytes read* (see Fig. 6a for read-size distribution), which would immensely benefit if stripe widths are tailored to access patterns.

Moreover, we observe several real-world examples of this tension: (1) user-facing media streaming services want *narrow stripes* for IO efficiency and lower tail latency but *wide groups* for capacity efficiency; and (2) big-data processing workloads favor *wide stripes* to increase bandwidth for their large sequential reads but prefer *narrow groups* to reduce reconstruction costs upon failure. A coupled design locks in fundamental tensions between performance and capacity.

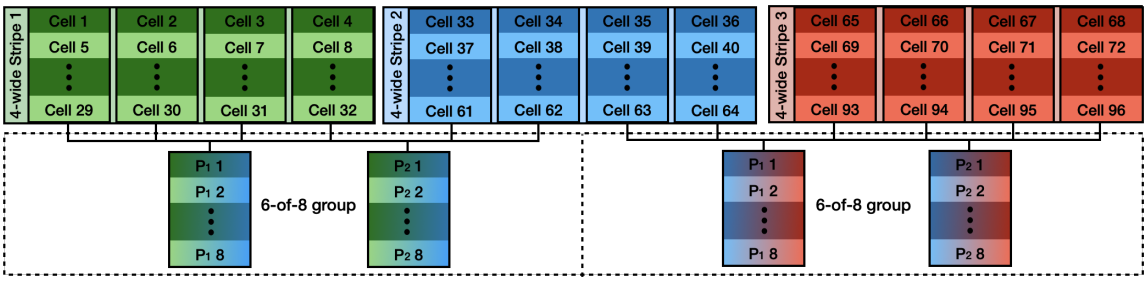
Redundancy adaptation trends. Recently proposed disk-adaptive redundancy systems [25–27] improve capacity efficiency by dynamically tailoring data redundancy to changing disk failure rates. Other systems [29] optimize transition IO overheads over a file's lifetime as it cools. However, these systems all fail to address the implicit degradation of IO efficiency due to these changes. For e.g., a 10 MB read to a 10-of-13 file after transition incurs a 2× increase in disk seeks v/s a 10 MB read to the same file in 5-of-8 before transition.

At Google, although the redundancy scheme of a file commonly changes throughout its stored life, the file's *access pattern usually remains constant*. We measured request-sizes of reads to uniformly sampled subset of files across three large Google storage clusters. Across these clusters, we found that 64%–94% of the sampled files were accessed using the *exact same read size* over a period of 150 days, whereas its EC scheme changed up to 4 times in the same duration. Furthermore, the per-file read size distribution exhibited very low variance with most reads heavily concentrated around the mean. This highlights the opportunity to tailor stripe widths of a file to improve throughput and resource efficiency. This result is unsurprising as most accesses in exascale cloud environments are issued by internal services or applications, which have known access patterns, and not direct user reads.

Increasing EC transitions trends. Transitioning data from one k-of-n scheme to another has become increasingly common. At Google, the most common transitions involve increasing group width for data as it cools. We observe over 100K EC-to-EC file transitions per day, resulting in multiple petabytes of disk IO every day in large clusters at Google.

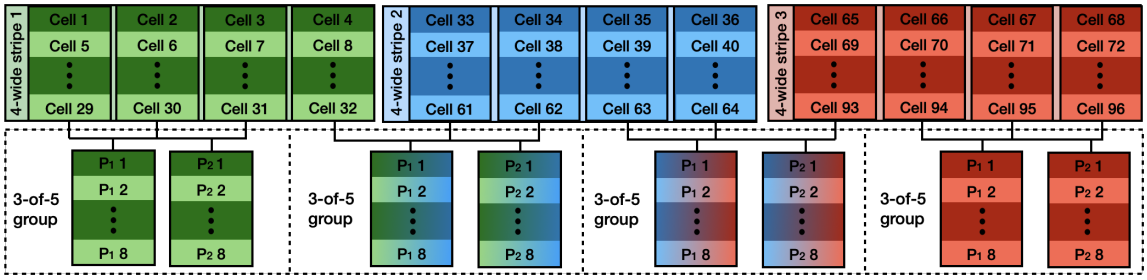
Bulk redundancy transitions can also happen in response to datacenter emergencies. For example, in late 2020, one exascale cluster observed sudden HDD failures (>4× the usual rate), triggering an unusually high number of data reconstruction events. To mitigate the issue, the data was transitioned from $k \approx 50$, which has high reconstruction-IO costs, to a smaller k (≈15) which is more reconstruction-IO-efficient.

The above redundancy adaptive systems heavily rely on redundancy transitions for realizing their benefits. These scenarios have elevated redundancy transitions to a first-class operation akin to reads and writes. However, despite the many optimizations proposed for reducing transition IO in the above systems [26, 29, 35, 36, 59], they are rendered inconsequential when files are striped in a coupled architecture since re-encoding forces re-*striping*. Not only does this reorganization make transitions costlier, it also induces unnecessary IO efficiency problems (i.e., the new stripe width can be less IO-efficient for the workload) as stated above.



We now present Okapi, a decoupled system that gracefully tackles the aforementioned trends.

4 Okapi's Design for Decoupling



The Okapi cluster file system allows independent configuration of data striping and redundancy grouping for *each file*. Okapi stripes a file across blocks and encodes blocks into parities like existing cluster file systems, but does not restrict group width to equal stripe width. Each file's contents are stored in one or more fixed-size blocks. Unlike existing systems, applications specify stripe width, in addition to grouping configuration (k and r). Data is striped MB-by-MB over each consecutive set of *stripe-width* blocks in a round robin fashion, and r parities are computed over each *consecutive* k blocks of the *same* file, no matter how the data is striped. For performance and durability purposes, Okapi requires blocks in a stripe *and* blocks in a group to be stored on unique nodes/failure domains. As described later in this section, such a design allows for lower per-file metadata, and curbs file creation and degraded-mode read access overheads. Fig. 4 illustrates the data layout for 4-wide stripes, but with two different grouping schemes: 6-of-8 and 3-of-5.

Next we describe key challenges involved with decoupling and how they are addressed in Okapi.

[2] 6×10ms for positioning plus 80ms of data transfer vs. 2×10ms for positioning plus 80ms of data transfer. Note that, in each second, each disk has one second worth of time divided between positioning and data transfer (and potentially idle time), neither of which get much faster with newer disks.

(a) 96 MB file with 4-wide stripes and 6-wide groups.

(b) 96 MB file with 4-wide stripes and 3-wide groups.

Figure 4: Decoupled Architecture: A 96 MB *file* striped 4-wide but shown with two different EC schemes - (a) 6-wide and (b) 3-wide. Each color—green, blue and red, represents a different stripe. Each 4-wide stripe is composed of **4** data blocks storing 32 MB. A group is composed of consecutive data blocks of the file, that may cross stripe boundaries. Block x is mapped to stripe $\lceil \frac{x}{\text{stripe width}} \rceil$ and group $\lceil \frac{x}{\text{group width}} \rceil$.

4.1 Challenges: decoupling stripes and groups

Increased metadata. Conventionally, EC file metadata contains the redundancy scheme configuration and location information (list of the disks) for each stripe. In a decoupled design, the DFS must also track the location information for each EC group. This additional metadata (usually stored in main memory) must have a small footprint, as memory is a valuable resource in any large-scale storage cluster.

Expensive file creation/appends. In a decoupled design, multiple groups can be incomplete at any given time while writing a new file, as opposed to just one in conventional systems. All data of incomplete groups need to be retained in memory until the parities are computed and flushed to the disk. This results in an increased client-memory footprint. A decoupled design must minimize memory requirements, and reduce unnecessary buffering of large amounts of data.

Increased work during degraded mode reads. During degraded mode reads, it is necessary to fetch at least k out of the n chunks from the group, even if they are not directly requested. This read amplification can be exacerbated in some decoupled configurations, since contents of stripes accessed is different from contents of groups required for reconstructing missing data. Such read amplification due to decoupling must have minimal impact on cluster throughput and latency.

Adoption-friendly design changes. Large-scale DFS usually take upwards of ten years to fully mature and become widely adopted. Proposing a design that warrants a DFS to be built from ground-up is therefore non-viable. A decoupled system should introduce straightforward design changes such that they can be readily incorporated into existing DFS.

4.2 Reducing metadata by inferring groups

Traditionally, DFS maintain the list of stripes that make up a file, along with the set of nodes where the data and parity blocks of each stripe can be found. Since stripes and groups are distinct in Okapi, we now need to maintain location information for both components separately, doubling the per-file metadata, which may be prohibitive.

Since redundancy groups in Okapi are comprised of *consecutive* data blocks, Okapi simply *infers* the redundancy group mapping from the existing data stripe mapping based on the stripe width and the file's EC scheme. Imagine the data blocks of a file (across all stripes) sequentially numbered from 1 to X. Then, data block x is mapped to stripe $\lceil \frac{x}{\text{stripe width}} \rceil$ and group $\lceil \frac{x}{\text{group width}} \rceil$ within a file. Given the ordered sequence of data and parity blocks, irrespective of the corresponding stripe information, Okapi can easily map the i^{th} set of k data blocks to i^{th} set of r parity blocks using simple modulo operations to identify redundancy groups of the file. We show the marginal metadata overhead incurred from using this inference logic in a live cluster instance in Sec. 6.

4.3 Partial parities for efficient file append

A common client access pattern is to create an EC file, write sequentially, and never modify the file once it is closed. Indeed, this access pattern is so dominant that popular DFS (e.g. HDFS, Ceph, Microsoft Azure) do not support modify or append operations on EC files [11, 14, 24].

In most DFS, when a file is written in this pattern, the system will wait to compute parities until all k data cells

of the row of a group are available. Although the written cells remain unprotected until the kth cell is received and the parities are computed and written out, this approach is much easier and more efficient than stricter durability semantics. Okapi retains the same semantic to allow for fair comparison with a coupled system to focus on the effects of decoupling.

To achieve the expected efficiency, the client must keep a copy of yet-unprotected cells in memory. For instance, consider writing the group shown in Fig. 3. The first 3 cells are written out to disks but also buffered in client memory until the 4^{th} cell becomes available to compute the first parity cell $P_1 1(1-4)$. Using this approach, decoupling can increase the load on client memory in some configurations. For example, for 6-of-8 groups with 4-wide striping as shown in Fig. 4a, the client would need to buffer the first 34 cells in order to compute the first parities. Okapi mitigates this overhead by computing intermediate *partial parities*. Rather than waiting for all data in a redundancy group to be written, Okapi greedily computes parity blocks with currently available data, which it keeps in memory instead of the more numerous data cells. We describe Okapi's partial parity computation below.

For a k-of-n erasure code, parity blocks for a vector of k data blocks are computed by using a $(n-k) \times k$ generator matrix. This generator matrix ($G_{(n-k)\times k}$) is simply multiplied with the data vector ($D_{k\times 1}$) over a Galois Field to produce the parity vector ($P_{(n-k)\times 1}$). For a simple 3-of-5 EC scheme, the parities are computed as follows:

$$G_{2\times 3} \times \begin{bmatrix} D_0 & D_1 & D_2 \end{bmatrix}^T = \begin{bmatrix} P_0 & P_1 \end{bmatrix}^T$$

Okapi breaks this into k *independent partial* computations.

$$G_{2\times 3} \times \begin{bmatrix} D_0 & 0 & 0 \end{bmatrix}^T + G_{2\times 3} \times \begin{bmatrix} 0 & D_1 & 0 \end{bmatrix}^T + G_{2\times 3} \times \begin{bmatrix} 0 & 0 & D_2 \end{bmatrix}^T = \begin{bmatrix} P_0 & P_1 \end{bmatrix}^T$$

A partial parity block can be computed for every data block as soon as they become available without needing any of the other data blocks. For example, for D_0

$$G_{2\times 3} \times \begin{bmatrix} D_0 & 0 & 0 \end{bmatrix}^T = \begin{bmatrix} P'_0 & P'_1 \end{bmatrix}^T$$

Rather than buffering all the data, Okapi instead buffers partial parities in *client memory*. Computed partial parity blocks are then simply added, as they become available, to eventually form the final parities. Breaking up the computation of parities by exploiting the associativity of a linear operation is an optimization that has been used in several prior contexts [32, 37, 40, 60]. Okapi re-uses the concept in the write path to mitigate the overhead introduced by decoupling.

Note that only the final parities are flushed to disk. Storing partial parities in client memory does not change or compromise the durability guarantees in the case of a client failure. In a coupled DFS, a client failure triggers a background recovery process which checks the last stripe in the file and generates parities if the stripe is under-protected. Similarly in Okapi, the recovery process checks for any under-protected redundancy groups and generates new parities for each by reading from data blocks. The recovery process in Okapi makes no use of partial parities and maintains the same durability semantics.

Distributed file systems such as HDFS and Okapi can be modified to support sync-on-write semantic, but doing so would hurt write performance substantially. Client write latency would not only see the time to receive a response for data written out to servers but also the time to send new data to update existing parities. Furthermore, the file system would need to support atomic read-modify-writes to incrementally update parities, either via shadow-paging or versioning. The required functionality and associated overheads would be necessary in systems both with and without decoupling.

4.4 Caching to reduce degraded read cost

If some blocks are unavailable during a read (e.g. due to a failed disk that is yet to be recovered), they have to be reconstructed on the fly at the client. Such degraded reads need to access both the data stripe (for read) and redundancy group (for reconstruction).

In a normal read operation, the client only reads the required cells. For degraded reads, at least k of n cells from the group containing the missing data need to be fetched, which may not have been read by the client otherwise, causing read amplification. In certain scenarios, Okapi's decoupling can increase this read amplification. Consider a 6 MB read in 6-of-8 EC file shown in Fig. 4a. Cells 1-6 need to be accessed (across two stripe rows). If the first block is missing, Okapi will read 12 MB of total data for on-the-fly recovery. A coupled system, with 6-wide group, would only read 6 MB. However, such an increase in read amplification occurs rarely.

For reads requesting less than one stripe row worth of data (small-sized requests), the degraded mode behaviour remains unchanged. For larger reads, in particular, reads spanning multiple stripes of data or an entire file (large sequential requests), the data required for reconstruction will either have been recently read by the client or will be fetched by subsequent reads. Okapi exploits this by anticipating a degraded mode read and caching the required data as it is read to avoid fetching the same data multiple times, eliminating read amplification.

For other mid-sized requests, although degraded-read performance in decoupled cases can be worse, we find that the overhead with Okapi's design is minimal and is an acceptable trade-off. We quantify these overheads in Sec. 6.4.

4.5 Re-grouping to minimize EC transition IO

EC transitions are commonplace in large-scale storage clusters (Sec. 3). We describe how Okapi's decoupled design helps in significantly reducing the IO cost of transitioning.

Storage clusters require sequential data to be written over consecutive stripes to exploit maximum parallelism and to ensure maximum disk efficiency while reading any range of bytes of data. In a coupled system, this strict restriction gets unnecessarily imposed on redundancy groups too. As a result,

when transitioning a file from k_1-of-n_1 to k_2-of-n_2, conventional file systems are forced to re-*stripe* the file - read the entirety of the file's contents and write them back according to the new striping layout like a new file. For example, if the stripe width of the file needs to be changed from 4 to 6 in Fig. 3, almost all the cells need to be moved from their original disk locations to different disks, incurring significant disk IO and network overhead.

A decoupled system allows us to instead *re-group* the file and change the EC groups without modifying the striping layout. Okapi simply determines which data blocks will make up the new groups and recomputes new parities for them without moving any of the data blocks. All data blocks are read, but only parities (and not data) are re-written. Consecutive sets of k_2 *data* blocks that may be spread across multiple stripes of the file are chosen to form $C = LCM(k_1, k_2)/k_2$ new redundancy groups. The amount of data to read can be further reduced with smart EC transitioning techniques [29].

In order to ensure maximum durability, the physical blocks that make up an EC group must exist on disks in different failure domains. When such re-grouping is performed, new groups may end up with multiple physical blocks that reside on disks in the same failure domain. In such situations, Okapi simply relocates those blocks such that a group is composed of blocks on distinct disks and incurs the cost of this extra data movement. However, these overheads can be completely eliminated by being cognizant of the possibility of redundancy transitions and allocating data of successive groups of a file to distinct disks during its creation. Such mindful placement mechanisms should be straightforward since mechanisms already exist to form n-wide groups.

4.6 Choosing stripe widths and group widths

Most data in hyperscalars are created and used by large applications/services that have engineers dedicated to maximizing their efficiency. Such engineers measure their system in operation and analyze trade-offs to tune their coupled stripe/group width configuration to meet desired reliability targets, minimize byte overhead, and achieve needed throughput/latency and disk-time efficiency [53, 55, 58].

At Google, for instance, engineers for large-scale data services periodically choose a space-efficient (coupled) EC scheme for their data that meets their reliability and performance SLOs. Reliability SLO is described using MTTDL. MTTDL, governed by the group width, can be calculated either analytically (using Markov chains) or experimentally (using Monte-Carlo simulations) [49]. Meeting the performance SLO on the other hand requires careful benchmarking. This entails generating artificial data using the proposed EC scheme using the application's preferred read size distribution. Average and tail read latencies are then calculated for normal reads and degraded reads performed by injecting failures. These reads are performed at normal *and* high cluster load to ensure that system performance continues to remain stable.

Okapi can make such selection processes easier in that a single width choice does not have to satisfy all reliability and performance goals. Our experiments indicate that a stripe width of $\lceil \frac{\text{median read request size}}{\text{block size}} \rceil$ works well in optimizing throughput and median latency with various group widths (which can be chosen for reliability), by amortizing seeks over substantial data transfer (see Sec. 6.5). But, *consistent with current practice*, we expect most applications/services to use benchmarking in configuring their (now-decoupled) stripe and group widths. We extract salient features from the aforementioned Google EC scheme selection process into *a* generalized strategy:

1. **Choose an EC scheme k-of-n.** Balance target MTTDL, byte overhead, and reconstruction costs [17, 20, 26, 27].
2. **Record IO patterns.** Randomly sample f representative application files. For each, log read request sizes over a representative time window that captures typical usage patterns, such as a full day during steady-state operation. Many organizations already have well-established observability infrastructure [51] which can be readily leveraged to collect and analyze I/O read sizes.
3. For each candidate stripe width x:
   (a) **Generate test files.** Create and write f files with group width k and stripe width x.
   (b) **Replay IO logs.** Issue the recorded read requests against test files in the same live cluster environment to capture realistic performance. Measure per-request latency.
   (c) **Analyze performance.** Measure median, tail latencies.
4. Choose the group and stripe width that satisfies all SLOs and offers the best balance of read performance (throughput, median latency, and tail latency) for future files to be created. Additional metrics such as seek count and write throughput may also be recorded and taken into account. There may be no single configuration that is optimal across all metrics; application engineers make subjective decisions based on which performance aspects are most critical for their specific use case.

Since IO requests to real, existing application files are sampled to collect the IO logs, access patterns, read size distribution and file size distribution are all inherently captured in this benchmarking process. If it is infeasible to record IO access patterns, or if IO access patterns are known to frequently change over time (a rare occurrence, see Sec.3), applications can default to setting stripe width equal to group width, performing no worse than coupled systems.

5 Okapi's Implementation

Okapi is implemented by modifying the Hadoop Distributed File System (HDFS). We use existing data structures and tried-and-tested pipelines as a conscious choice to not hurt the current performance or integrity of existing mechanisms

in HDFS[3]. This section describes how Okapi efficiently decouples stripes and groups, and the mechanisms that enable file read/write, data protection, and EC transitions. We briefly describe how decoupling can be implemented in few other popular DFS in Appendix A.

5.1 Simple, efficient decoupling

Traditional HDFS maintains metadata for a stripe of data blocks and its corresponding set of parity blocks in a data structure called striped block groups (SBG), which is tracked as a single entity in the Namenode's BlockManager.

Metadata. Okapi splits a conventionally coupled SBG into two structures: a data stripe and a parity group. A data stripe is a logical ordering of data blocks and a parity group is a set of parity blocks. This split allows the structures to have a O(1) lookup time in the BlockManager as they were for SBG's.

To minimize metadata overheads, Okapi saves 8 bits per block by eliminating the pointer to the EC policy and leverages the previously unused replication field instead. Additionally, it ensures sequential ordering of storage information, removing the need for internal physical block ordering in the new data structures. To minimize inode metadata, Okapi uses a single byte (max value=127, easily extendable) to track the stripe width per file in the header. This approach supports most widely published schemes to date [28].

Writes. Okapi allows files to be written with any arbitrary stripe width and EC scheme. It uses partial parities to avoid buffering large amounts of data between stripes. The partial parities are stored in a r-wide array of byte buffers, each of which stores data worth 1 block. This guarantees that the client will buffer at any point at most block size $\cdot\, r +$ cell size $\cdot$ k of data. When updating partial parities, Okapi multiplies only the relevant subsection of the encoding matrix with the data vectors to eliminate extraneous computation. This aspect of the implementation ensures that encoding and combining partial parities is computationally equivalent to encoding full parities in a single operation.

Normal reads. Normal reads in Okapi work exactly like in HDFS. Okapi simply looks at data stripes to inform clients where to read data from, similar to how SBG's are used, Parity groups are not needed and remain unused. This ensures that normal read performance in Okapi is not impacted at all by decoupling and that no additional necessary computation is required to retrieve physical block locations.

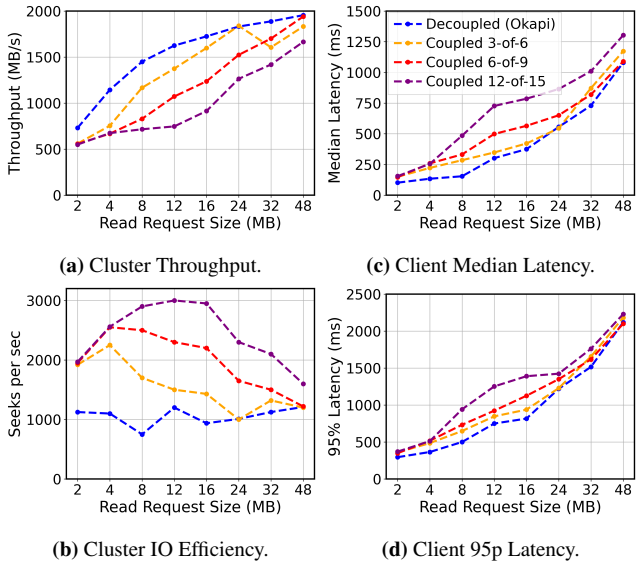
Degraded reads. A degraded read will infer the redundancy grouping for the failed block to reconstruct missing data. Okapi's design prioritizes efficiency and attempts to re-use any data that was already buffered in from the read when decoding the corrupt or missing data.

Under-replication detection and recovery. Data stripes and parity groups are managed in the exact same way as SBG's. Okapi therefore re-uses existing block reporting system for under-replication detection, with no loss in performance. The BlockManager lazily computes the redundancy grouping once under-replication is identified using constant time look-ups and modulo arithmetic.

Efficient and safe EC transitions Okapi computes new grouping based on the file's array of data stripes and the new EC scheme. After the new groups are determined, the new parity groups are added to the BlocksMap and the new grouping is sent to the Datanodes using HDFS's existing EC recovery pipeline. The new parities are encoded and reported by the Datanodes, and the old parities are atomically removed from the Namenode. This ensures that files are protected even during a transition as the old parity groups are available until the new parity groups are completed.

6 Evaluation

This section evaluates Okapi and confirms three main takeaways: (1) configuring a file's stripe width to match data access pattern provides significant IO efficiency improvements without compromising reliability. (2) decoupling stripe width from group width significantly reduces the IO required for EC scheme transitions. (3) Okapi does not introduce significant metadata, file creation or degraded-read overheads.



6.1 Experimental setup

Both Okapi and coupled experiments run on a 20-node cluster with one Namenode and 19 Datanodes. Each machine has a Quad-Core AMD Opteron Processor and 128 GB RAM. Each Datanode has a 1 TB Ext4 file system atop a 7200 RPM Hitachi Ultrastar HDD. The physical block size and file IO buffer size in HDFS are set to 8 MB (default block size at Google). The underlying Ext4 file system uses a 1 MB block size, which is the same as the cell size. Cluster nodes are connected via a 40GbE network. We measure throughput with DFS-perf [21]. For each workload, we measure aggregate throughput and median, p95, and p99 client request latency. We examine block device IO and disk seek behavior using blktrace [6] and seekwatcher [33]. We measure IO and CPU/memory costs by aggregating per-node data exposed by Ganglia [34]. We compare Okapi's performance with HDFS with micro-benchmarks and then with a synthetic trace generated using read-size distribution drawn from Google's cluster.

6.2 Decoupling improves IO performance

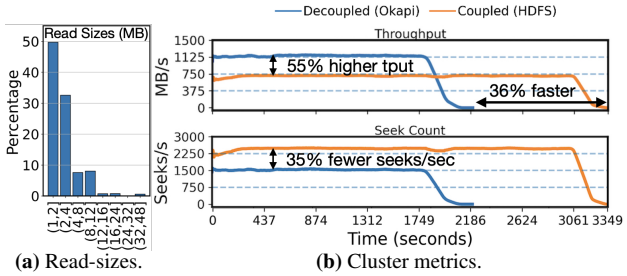
Our results demonstrate a significant benefit to total cluster read bandwidth and client latency when configuring the data striping to be tuned for their specific access patterns, without impacting factors such as storage overhead, reconstruction costs, which are controlled by grouping. We first compare read throughput and IO efficiency across varying access patterns

[3] Okapi is open-sourced at https://github.com/Thesys-lab/okapi.

(a) Cluster Throughput. **(c)** Client Median Latency.

(b) Cluster IO Efficiency. **(d)** Client 95p Latency.

Figure 5: Performance measurements for requests ranging from 2 MB–48 MB for files grouped 3-of-6, 6-of-9, and 12-of-15 (and thus striped 3-, 6-, and 12-wide respectively for HDFS) and pre-determined stripe width with 6-of-9 grouping for Okapi. Compared to 6-of-9 coupled configuration, throughput improves by up to 80% and seeks/sec reduce by up to 70% when decoupling with similar benefits to median and tail latency.



with/without decoupling. Then, we characterize the benefits of decoupling in a realistic read-only system workload. Finally, we show the impact of decoupling on write throughput.

Tuning stripe width improves read performance. We present cluster and client metrics of a read workload in which both HDFS and Okapi use 6-of-9 grouping (a popular EC scheme [13, 27]), which means that both systems have the same storage overhead. While this forces files in a HDFS to be striped 6-wide, Okapi faces no such limitation and allows clients to set the file's striping width based on its most common access pattern. In addition to 6-of-9 grouping, to evaluate alternate options, we include results for HDFS when files are grouped 3-of-6 (half the group width) and 12-of-15 (double the group width).

For our experiments, we benchmark throughput for different read sizes in the manner described in Sec. 4.6, and set stripe width for each read request size to optimize for cluster throughput and IO efficiency. For example, we use 1-wide and 6-wide stripes for 8-MB and 48 MB requests respectively.

Okapi provides high throughput at low byte overhead. Fig. 5a shows total cluster throughput with and without decoupling for each access pattern. For the configurations we examine, Okapi observes up to 80% increase in throughput and never performs worse than coupled 6-of-9 for any request size; without sacrificing any space efficiency or durability. Okapi performs the same as 6-of-9 coupled for only 48 MB requests, and same as 3-of-6 coupled for only 24 MB requests which is expected since Okapi's decision to stripe 6-wide and 3-wide coincides with the coupled cases' grouping width.

HDFS's poor throughput for smaller read requests sizes is a consequence of coupling data stripes and groups. For

(a) Read-sizes. **(b)** Cluster metrics.

Figure 6: Read performance for a realistic read-only workload. 6a shows the distribution of read-sizes >1 MB and ≤48 MB for erasure-coded files in Google's production storage cluster. 6b shows throughput and seek count for a trace of read requests pulled from the distribution in 6a.

example, a file is generally chosen to be written in 6-of-9 to provide a certain level of space efficiency. However, 6-wide striping for a 4 MB client read suffers from request fan-out and poor IO efficiency as it splits into four 1 MB disk reads, an unfortunate consequence of a decision made with only *grouping* in mind. A naive solution would be to ignore grouping and blindly choose a narrower group width, say 3-of-6. Not only does this increase storage overhead by 2×, but also the 3-wide striping still loses between 6–34% throughput compared to Okapi. Note that coupled 3-of-6 exhibits greater cluster throughput than coupled 6-of-9 for requests up to 24 MB, but eventually performs worse for larger requests since 3-of-6 requires an extra round-trip to Datanodes to retrieve data past the first data stripe, making 6-of-9 more favorable in these cases. If storage capacity dictates files must be grouped wider, say 12-of-15, then the coupled cluster loses up to half its bandwidth. Moreover, note that by decoupling, it is still possible to achieve 12-of-15 space efficiency *while meeting the same IO performance*.

Okapi reduces seeks dramatically. Fig. 5b shows the benefits in cluster's total seeks per second. Okapi promotes user's ability to choose a stripe width that maximizes sequential IO, thereby reducing the spindle usage by as much as 70% between Okapi and coupled 6-of-9. By tuning the stripe width to be suited for smaller sized reads, clients maximize sequential IO and enable disks to spend less time on seeks and more time on data transfer. The drastic reduction in total seeks promotes greater disk bandwidth, even when disk utilization is constant. Moreover, Okapi minimizes the variance in seeks/sec across different read sizes, reducing peak usage by up to 60% which significantly reduces resource provisioning costs.

Okapi lowers client response time. Fig. 5c shows Okapi provides a substantial reduction in median latency compared to both 3-of-6 and 6-of-9. This is a consequence of both improved cluster throughput and minimizing the fan-out effect. A similar, albeit less significant trend is observed in the 95th percentile latencies (Fig. 5d).

Okapi requires no compromises! Okapi does not sacrifice space efficiency or durability for these improvements. For example, to achieve the same read performance while maintaining durability for 16 MB reads in HDFS, the file would

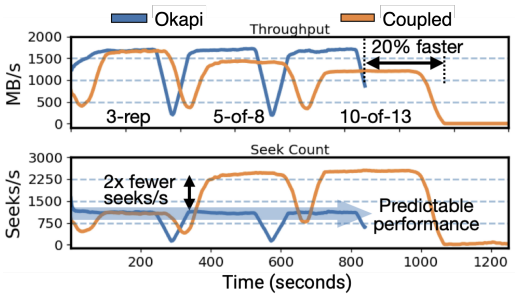


Figure 7: Performance and resource efficiency of file accesses as they transition to wider EC schemes over their lifetimes. Figure shows seeks/s and throughput observed for 16 MB file reads, first when files are in a 3-way replicated format, second in 5-of-8 and then in 10-of-13 EC scheme.

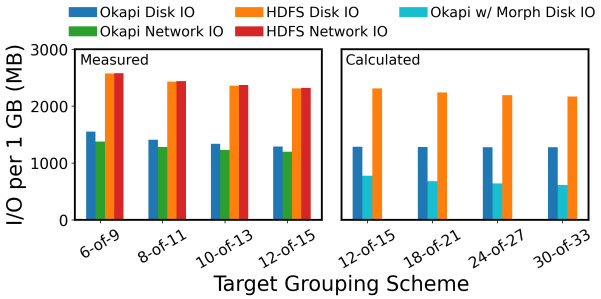

Figure 8: IO cost to transition 1 GB 6-of-9 files to varying target EC schemes. Left shows *measured* disk and network IO cost to transition to wider grouping schemes and then back to 6-of-9. Right shows *calculated* disk IO cost to transition to wider schemes.

need to be written in 2-of-5, which has worse space efficiency than 2-way replication. On the other hand, to achieve the same read performance while maintaining space efficiency in HDFS, the file would need to be written in 2-of-3, which has insufficient durability. Even when comparing against coupled 3-of-6, which has the same space efficiency as 2-way replication, most access patterns still perform noticeably worse than when decoupled. A coupled architecture simply cannot achieve the best of both worlds as Okapi can by decoupling these independent decisions.

Okapi enhances performance for a realistic workload. In this experiment, we measure the read performance in a testbed environment for a workload that uses the read-size distribution of EC files in a production storage cluster at Google as shown in Fig. 6a. We compare cluster performance in decoupled and coupled architectures while executing the same set of random-reads. In this scenario, we use 64 client threads each performing 10K reads. All files conservatively use a 6-of-9 grouping, although today's average EC group is typically wider for space efficiency. Since IO efficiency decreases for mid-sized requests with wider groups, we expect that in practice, the coupled case would actually perform worse than shown in our experiments for this workload.

Fig. 6b shows throughput, seeks/s, and end-to-end run completion time for a realistic read-only workload. Okapi shows a 55% increase in sustained throughput (MB/s) and 65% fewer number of total seeks (35% decrease in seeks/s) due to smarter striping decisions. Note that most read requests in Fig. 6a are smaller than 12 MB, a range of read-sizes that finds the most benefit from decoupling as seen in Fig. 5a. Despite both clusters running identical traces, Okapi's clients completed their work 36% faster than the HDFS's clients. The increase in throughput and decrease in end-to-end run-time shows how a decoupled storage cluster could handle both bursty and extended client traffic better than a coupled architecture.

Okapi maintains IO efficiency despite EC transitions. Morph [29] improves EC transition overheads but overlooks the impact on resource efficiency of accesses to such files. Accesses to same files post-transition to wider EC schemes result in poor IO efficiency. Unlike coupled systems, Okapi remains unaffected by EC transitions. We duplicate their experiment of file EC lifetime transitions from replication to 5-of-8 to 10-of-13 and measure throughput and seeks consumed for 16 MB read accesses to 25000 files in each phase of the file's lifetime. Okapi is able to achieve better throughput, uses 2× fewer seeks/s and achieves predictable performance and resource efficiency as shown in Fig. 7. This issue is further exacerbated in Disk Adaptive Redundant storage clusters, since even hot files can be transitioned to wider schemes, which directly impacts the latencies of user facing applications.

Okapi's benefits improve with median seek distance. The experimental setup has each disk filled with about 315 GB out of 1 TB of disk space. As the disk becomes more full, the median rotational and positioning latency would likely increase, further emphasizing the impact of each seek and making the reduction of seeks-per-second even more significant to cluster throughput.

6.3 Decoupling reduces EC transition IO

Redundancy transitions are common and have varying degrees of urgency and bandwidth/compute requirements. This subsection quantifies this benefit for three major sources of transitions and then experimentally compares Okapi's re-grouping to a coupled system's read-re-encode-write (RRW).

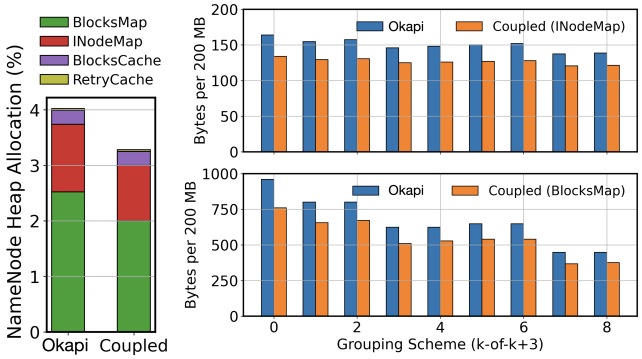
1. Making groups wider as data cools. Large storage clusters perform hundreds-of-thousands of transitions per day. Most of these transitions increase group widths to increase space efficiency for data that has cooled (in terms of access frequency). Okapi can reduce the IO required for such transitions by up to 50%. For example, for 100K 30 MB file transitions from 6-of-9 to 30-of-33 in a day, RRW would require 6.3 PB of total IO ($5 \times 6 \times 100K = 3$ PB of data read, 3 PB of data write and 300 TB of parity write). Regrouping in Okapi only requires 3.3 PB IO for the same transitions.

2. Urgent transitions to address emergencies. Sec. 3 describes an emergency bulk transition situation at Google caused by a sudden increase in the failure rate of a particular disk model. To avoid future reconstruction IO overload, all high-k data on those disks were transitioned to use narrower groups ($k \approx 50$ to $k \approx 15$).

Suppose 66% of the data was in ≈50-wide groups on

≈90K disks in the cluster.[4] Disks had an average capacity of 8 TB and capacity utilization of ≈75%. Transitioning to a 15-of-18 scheme using RRW requires 784.08 PB of transition IO (356.4 PB of data read[5], 356.4 PB of data *re-write*, and 71.28 PB of parity write). Assuming a 100 MB/s sustained disk bandwidth, with a 5% IO budget for EC transitions, 90K disks can transition at the rate of 90000×5 = 450000 MB/s = 0.43 TB/s. It would require over 21 days to transition all 784.08 PB without violating the IO budget. Even if we commission the entire cluster to perform transitions, with each disk issuing transition IO at 100 MB/s, it would take over 1 entire day! In contrast, Okapi incurs an IO traffic of 427.68 PB (45% less) for transitioning via regrouping, i.e. 12 days to complete without violating the 5% IO budget, and <14 hours if the entire cluster was commissioned.

3. Adapting group widths to disk failure rates. Disk-adaptive redundancy (DARE) systems use file transitions to maximize space efficiency based on observed disk failure rates, saving ≈ 20% of disk capacity [25–27]. As with other transition causes, Okapi reduces the IO required.



We simulate DARE for a production storage cluster (Backblaze [2]) over a period of 6 years to evaluate the transition costs of re-grouping versus RRW. Data is arranged into files, represented by an ordered array of redundancy groups, and the policies for reacting to failures and AFR changes were adopted from previous work [25]. When a group is marked for transition, the file that it is part of (and hence all groups part of the file) are transitioned together as described in Sec. 4.5.

The simulation showed that Okapi reduces mean disk transition IO cost by approximately 38%. This reduction is lower than earlier examples because it includes IO for block relocation to ensure that all blocks within each group are distributed across different failure domains even after transitions (Sec. 4.5). This overhead can be avoided by being cognizant of such potential re-groupings during file creation, and by placing blocks of adjacent groups of a file across different failure domains. We did not make any assumptions about failure domains in our simulation, placed blocks of a group randomly assuming each disk to be a separate failure domain.

Further, storage clusters typically rate limit background tasks like file EC transitions to prevent interference with foreground IO operations. However, these IO limits are sometimes violated for urgent transitions during risk of data loss. Assuming a 5% daily IO limit for EC transitions [26], we observe that RRW approach results in almost twice as many disks violating this IO cap when compared to Okapi.

Measured transition savings in Okapi. Okapi's regrouping approach for redundancy transitions is more efficient than the traditional RRW approach used in HDFS. In this experiment, we transition a 6-of-9 1GB file to wider groups and then back to 6-of-9. Fig. 8 (left) shows disk and network IO incurred in the two systems as measured in our experimental cluster setup.

[4] Although we cannot give the exact numbers, these are representative.
[5] 90000×8×0.75×0.66 TB = 356.4 PB

(a) Heap percentage **(b)** Byte overhead per file.

Figure 9: Calculated (a) total Java heap allocation overhead in the Namenode for decoupling 200 MB 6-of-9 files and measured (b) byte overhead of 200 MB files in the BlocksMap (bottom) and INodeMap (top) for increasing group widths. Metadata overhead decreases with increasing stripe and group width, eventually converging at very wide groups in both data structures.

Limited by available cluster size, we calculate results for transitions to wider groups analytically. Fig. 8 (right) shows calculated disk IO traffic for transitioning the same 6-of-9 1GB file using Okapi versus RRW.

We observe almost 50% decrease in disk and network IO across all transitions with Okapi. This decrease stems primarily from reduction in bytes written to disk. Note that Morph sees the same transition IO traffic as coupled in Fig. 8. Although Morph uses Convertible Codes to reduce IO overheads by computing new parities from old parites, it only helps when cell-striping is disabled; otherwise, re-striping the file necessitates rewriting it. Okapi overcomes the need to re-write file data, which can be combined with Morph to further reduce transition overheads by up to 70%.

Okapi uses slightly more disk than network IO. Okapi schedules new parity encoding on a target Datanode, so some new parities need not traverse the network. HDFS's RRW implementation instead does this on a client, in part because it must re-write the file data in addition to the new parities.

Okapi shows memory and compute savings. We compare memory and CPU utilization for the Namenode and client by performing 20 concurrent 200 MB EC transitions. With RRW, the client buffers file data in memory before writing to DFS and then clears its cache. With regrouping, the client uses no extra memory to make an RPC call. In Okapi, CPU utilization does not exceed 5.7% compared to 13.5% in HDFS, with ≈75% reduction of average CPU utilization.

6.4 Quantifying decoupling overhead

Namenode metadata memory overhead. We measure the memory footprint of decoupling by analyzing Java heap dumps on the Namenode process in Okapi and HDFS with 6-wide striped, 6-of-9 grouped 200 MB files. Fig. 9a depicts the metadata difference in total heap allocation. HDFS, by default, allocates 2% of the total Java heap to the BlocksMap

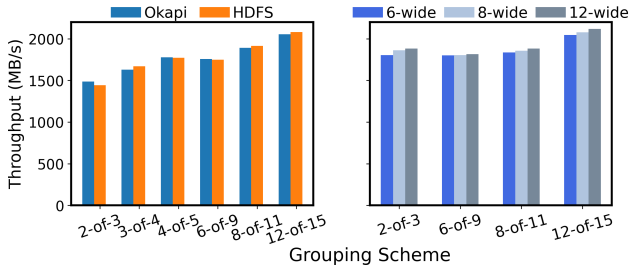


Figure 10: Measured (left) write throughput of files with stripe width equals group width in Okapi and HDFS and (right) decoupled write throughput of files in Okapi with varying stripes and EC schemes.

and 1% to the INodeMap. Okapi compensates for the increase in block objects by allocating 2.52% and 1.22%, respectively, for a collective heap usage increase of 0.74%. This increase allows Okapi to maintain the same number of objects and files in the cluster as conventional DFS with less than a 1% increase in overall Java heap usage.

Fig. 9b presents the memory footprint in the Namenode data structures per file. Okapi uses less than 1 KB per file in the BlocksMap and 170 B per file in the INodeMap, a respective 26% and 22% increase from their former values. These values shrink with wider groups as there are fewer blocks per file and, therefore, less overhead per block object. For example, if files were grouped 12-of-15 as opposed to 6-of-9, the overhead decreases to 20% and 18% respectively. These measurements reflect a reasonable increase in metadata per-byte which only improves with wider grouping schemes.

Minimal impact of decoupling on write throughput. Fig. 10 (left) shows write throughput across various EC schemes when stripe width equals group width. Despite the slight additional complexity in Okapi's decoupled write logic, we do not observe any noticeable decrease to write throughput between HDFS and Okapi.

Fig. 10 (right) compares write throughput with different stripe widths across varying EC schemes. There is no noticeable difference in performance as a direct result of decoupling. 6-of-9 grouping achieves the same write throughput with both 6-wide (coupled) and 8-wide striping (decoupled) despite the fact that 8-wide striping uses partial parities to compute the final parities. This result is consistent with Okapi's implementation, which guarantees the same number of linear operations to compute the final parities, regardless of stripe width.

Further, we observe a small increase in write throughput across all EC schemes as a result of increasing stripe width. A wider stripe can leverage a greater degree of parallelism when writing large amounts of data. However, we find that the difference in throughput across EC schemes can be primarily attributed to the amount of write amplification.

Client write memory overhead. Okapi uses partial parities to avoid buffering copious amounts of data in memory to write a complete group (Sec. 4.3). Fig. 11 shows the memory overhead when striping 6-wide with varying grouping schemes in a decoupled case and when striping/grouping 6-wide in HDFS. With decoupling, naive buffering of client data to eventually compute final parities requires clients to buffer up to 150 MB at 20-of-23. With partial parities, clients buffer at most an acceptable 25 MB.

In fact, the write memory overhead of Okapi with partial parities eventually converges with and passes (i.e., less memory required) coupled schemes beginning from 25-of-28 grouping. In conventional HDFS, the entire stripe of data must be buffered, even for extremely large groups, so the memory overhead scales with group width. With partial parities, however, the overhead is capped at $r \cdot \text{block size} + 1$.

However, when stripe width is greater than group width, in certain instances, it is more cost-effective to opt out of partial parities. This is because buffering all unprotected data cells is more economical than buffering partial parities of size $r \cdot$ block size. Okapi can dynamically determine at runtime whether to employ partial parities based on striping and grouping configuration.

Degraded mode read overhead. We show, both analytically and empirically, that degraded read overheads are minimal. Fig. 12 (left) quantifies the average read amplification and (mid) the average number of disks read during degraded-mode reads using 12-wide groups across varying stripe and read request sizes (assuming that reads can be made at any cell-aligned file offset with equal probability).

Case (1) when stripes are wider than groups. The read amplification is minor (3.23% worse on average for 18-wide stripes; and 4% *better* for 24-wide stripes). Although it may appear that the expected number of disks read is higher, the cause is the wider stripes(a conscious choice by file writer)—the number of *additional* disks read in degraded-mode is very small (2.73% more disks than coupled 18-wide groups).

Case (2) when groups are wider than stripes. Although read-amplification is higher in Okapi, probability of degraded-mode reads is proportionately lower (since fewer disks are accessed). The impact on total cluster throughput is hence commensurately lower. In addition, the required data is fetched from fewer disks (implying fewer seeks and higher IO efficiency), further amortizing the impact on cluster throughput.

Fig. 12 (right) experimentally compares single-failure degraded read latency for 6-of-9 EC files for Okapi (3-wide and 12-wide stripes) with coupled system (6-wide stripes). For small-sized (1 MB) and large sequential (96 MB) degraded-mode reads, Okapi observes no hit in performance. For mid-sized requests (24 MB), Okapi performs 33% worse with 3-wide stripes due to reading 2× more data. Note, however, that degraded reads occur half as often with 3-wide stripes than with 6-wide stripes. Okapi performs 16% worse with 12-wide stripes, because it is a poor stripe width for the given (24 MB) access pattern—it performs worse than 6-wide striping even for 24 MB non-degraded mode reads (see Fig. 5). Worst-case read amplification, and hence tail latency, may be worse in some striping configurations though the average read am-

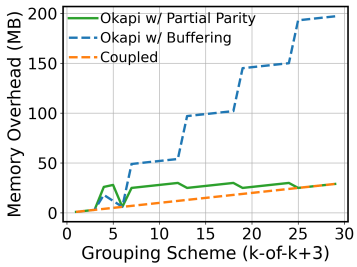

Figure 11: Maximum memory overhead during file creation for varying group widths. For coupled, we set stripe width = group size (k). For decoupled, we set stripe width = 6.

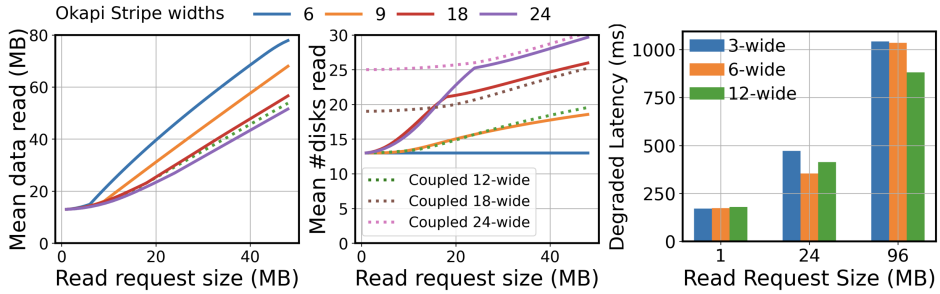

Figure 12: Expected total data read (left) and disks accessed (mid) during degraded reads for group width=12 and varying stripe sizes, with single block failures. The dotted lines refer to coupled configurations. Measured degraded read latency (right) for 6-of-9 files across stripe widths for three read sizes. Okapi's degraded-reads for 24 MB are 33% worse with 3-wide (but occurs half as often), 16.6% worse with 12-wide (due to poor stripe width choice).

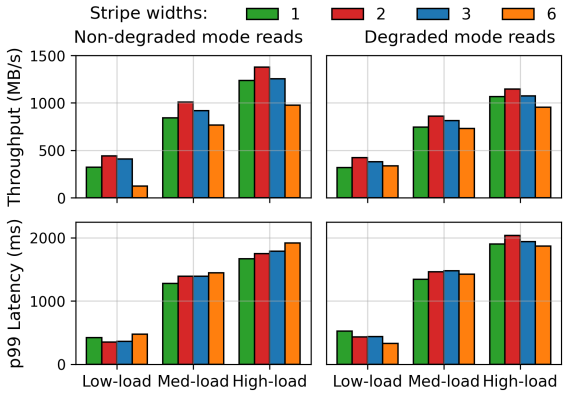
plification remains consistent. Benchmarking the stripe/group choices (Sec. 4.6) can help avoid unacceptable overheads.

6.5 Choosing group and stripe widths

This section follows the benchmarking process from Sec. 4.6 and presents performance results for 12 MB and 24 MB read requests under different cluster loads, for degraded-mode, and for different variances in request sizes. Based on our experiments, we recommend a stripe width of $(\lceil \frac{\text{median read request size}}{\text{block size}} \rceil)$ for optimizing cluster throughput and median latency. However, it may be sub-optimal for tail latency in some cases, such as with lots of degraded-mode reads. Application engineers must make a subjective trade-off based on which metric (e.g., throughput, median or tail latency) is most critical for their use case.

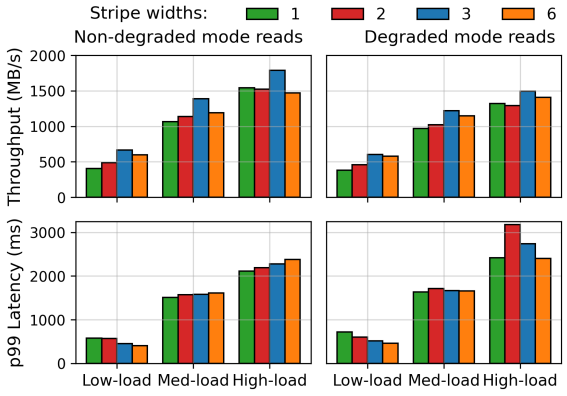
Fig. 13a shows throughput and 99th percentile tail latency for 12 MB reads to 6-of-9 erasure-coded files for four stripe widths (1,2,3 and 6) under different cluster loads. As described, the recommended stripe width of $\lceil \frac{12}{8} \rceil = 2$ maximizes throughput and minimizes median, p95, p99 tail latencies by reducing disk seeks and improving disk efficiency. For instance, under heavy load, stripe width of 2 yields ≈40% higher throughput than a coupled configuration (stripe width=6) and achieves 6.8% lower 99% tail latency.

Tail latencies grow with more degraded-mode reads, and degraded-mode reads with decoupled stripe/group widths can cause even greater read amplification and higher latencies. Fig. 13a shows throughput and tail latency for 12 MB reads when one of the nineteen disks has failed. Even in this extreme scenario, where 5% of the disks have failed, the recommended stripe width continues to be the best for throughput, median and p95 latencies, but p99 tail latencies are ≈9% worse than coupled. For latency-sensitive applications, the engineer may choose to stripe 6-wide, accepting ≈16.6% lower throughput to avoid a 9% increase to the tail. Another acceptable trade-off might be to use 1-wide stripes, which exhibit 1.6% higher p99 latency than 6-wide stripes, but only incurs 7% hit in throughput compared to 1-wide stripes.



We make similar observations with 24 MB requests in Fig. 13b. As with 12 MB reads, we find that the recommended stripe width of of $\lceil \frac{24}{8} \rceil = 3$ consistently maximizes throughput across load levels. For optimizing p99 latencies, 6-wide stripes generally turn out to be the best.

Fig. 14 shows throughput and latency when request sizes vary under heavy load. We assume request sizes to be normally distributed. We consider two access patterns, 12 MB and 24 MB, and vary standard deviation of request sizes (bounded between 0.5 MB and the file size) to files to study the performance impact. We observe that the recommended stripe widths consistently achieve the highest throughput although the improvements over other widths decrease with increasing variance. While the recommended stripe widths minimize p50 and p95 latencies, the best configuration for p99 latencies can vary depending on the variance in request-size. When request sizes follow a uniform distribution (a rare occurrence, see Sec.3), we observe little difference in performance with different stripe widths.



Although we used 8 MB blocks in our experiments, we observe similar trends for block sizes as large as 128 MB. Note that the performance trade-offs will vary depending on cluster setups, software implementations, HDD models, disk capacity utilization, stragglers among many other factors. To find optimal configurations, one must benchmark their applications in their clusters as described in Sec. 4.6.

7 Related Work

Data striping and redundancy grouping have long histories in data storage, beginning in the context of disk arrays [8, 15]. Most disk array configurations couple striping and grouping, such as by using an n-of-$n+1$ RAID5 scheme, with the stripe-unit choice being a target of optimization [9, 44]. One notable exception [19] proposed using parity (grouping) without data

(a) 12 MB reads

(b) 24 MB reads

Figure 13: Throughput (top) and p99 latency (bottom) for (a) 12 MB reads and (b) 24 MB reads to 6-of-9 EC files with stripe widths 1, 2, 3 and 6 for different cluster loads, during normal-mode read operation (left) and during degraded-mode read operation induced by disk failure (right).

striping, an extreme form of decoupling the two.

In both research [1,18,22] and production [13,24,42,47,57,61], DFSs couple stripes and groups. Various research efforts have proposed approaches to tune the striping+grouping configuration based on access patterns and data *-ability goals, given the trade-offs created by the coupling [53,55,58].

Many blob/object stores [24, 38, 41] pack several small objects into a single large file, which is in turn striped/erasure coded across disks. These systems *decouple* the user's view and filesystem's view of how data is stored to avoid small-file inefficiencies. This is orthogonal to Okapi's *decoupling* of stripe and group widths of the resulting large file to improve read efficiency and decrease EC transition overheads.

The prevalent architecture used by hyperscalers (e.g., Google, Microsoft, Facebook) and HPC (e.g., PanFS, Lustre, HDFS) involves the DFS layer managing both striping and grouping. But one could conceivably build a DFS that stripes data across blocks stored in a block-storage layer that separately uses parities to protect groups of blocks. This decouples stripes and groups by having each layer manage one of them. The closest example we can think of is Frangipani-atop-Petal,

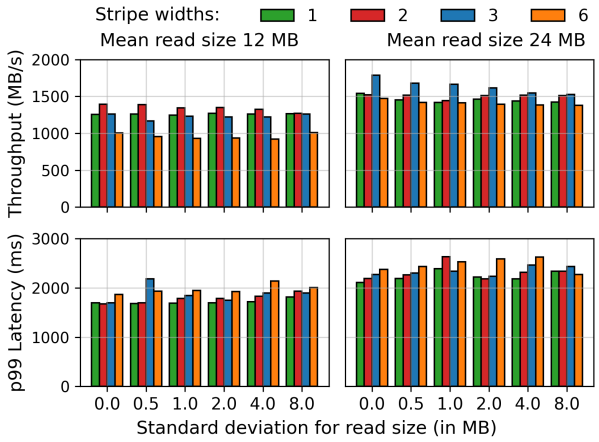


Figure 14: Throughput and p99 latency for reads to 6-of-9 erasure-coded files with different stripe widths as variance in request sizes increases. We consider two access patterns, where requests are normally distributed around (1) 12 MB (left) and (2) 24 MB (right), and vary standard deviation on x-axis.

where Frangipani [52] was a DFS that stored file contents in blocks stored in the Petal [31] replication-based (k=1) block store. However, such an architecture is not adopted by any of the popular DFSs due to its complexity when using EC (k>1) and the fact that it does not allow file-level control for important choices like EC configuration and data placement, all of which are key elements of modern DFS. Okapi retains the benefits of the current DFS architecture while allowing per-file, independent tuning of striping and grouping configurations.

8 Conclusion

Existing DFSs couple data striping and redundancy grouping, resulting in IO performance inefficiencies due to limited options in a complex trade-off space as well as high re-encoding IO overhead . Okapi overcomes these problems by decoupling stripes and groups. The design is simple and adoption-friendly. Experiments confirm significant improvement in IO performance (throughput, seeks and latency) and IO reduction for redundancy transitions.

Supplemental material for Okapi

The appendix is not peer-reviewed.

A Okapi can be easily adopted by other DFS

Most publicly-described distributed file systems, both open-source and proprietary, that we are aware of couple data stripes and redundancy groups. Okapi's design for decoupling is applicable to and beneficial for all distributed file systems that stripe their files. We describe below the coupled design of a few other contemporary distributed file systems, and show that Okapi's ideas can be adopted into their system.

Colossus File System (Google). The architecture of Colossus File System (Google's distributed file system) is similar to that of HDFS. A $k.r$ erasure-coded file stripe maintains r parity chunks for k (group width) data chunks. The data within the stripe is broken into small (typically 1MB) blocks which are spread across the k (stripe width) disks in round robin fashion [30]. The metadata of the file comprises of the list of file segments, and a mapping of the file segments to chunk locations, which indicate where each of $k+r$ chunks are stored in the storage cluster [45], just like in HDFS. Okapi's design can therefore be directly adopted into Colossus.

Panasas File System. Data is stored in *objects* that are spread across Object Storage Devices (OSDs). Files are striped across objects in a RAID-5 layout. Note that all RAID layouts inherently couple stripes and groups. In RAID-5, one parity chunk is maintained for three data chunks, and each row of blocks is spread across three chunks. Similar to HDFS, per-file metadata stores the storage map. The storage map maintains the striping strategy and location information for each object of the stripe. Okapi's design can therefore be directly adopted into Panasas.

Ceph. The reliability and layout of a file is dictated by EC *profiles* in Ceph. A profile, among other things, is defined by number of data chunks (k), number of parity chunks (m) and the stripe unit size. The stripe units refers to the logically contiguous pieces of data that get spread across the k data chunks in a round-robin fashion.

Unlike HDFS, which *stores* the mapping of chunk to node locations for each group, Ceph uses CRUSH [56], a near-uniform hashing function, to *compute* the locations of the chunks of an erasure-coded group. For an erasure-coded stripe/group of a file, CRUSH uses the file inode number and the index of the stripe (within a file) to compute $k+m$ unique node locations to store the chunks. Each chunk in a group (for durability), as well each chunk in a stripe (for optimal parallelism) must exist on a unique node. Since stripes and groups are no longer the same in Okapi, the algorithm must be modified to ensure node locations are unique across both stripes as well as groups. A naive way to achieve this is to use the existing CRUSH function to find $l = LCM(stripewidth, k+m)$ unique nodes. All chunks in each of the $l/stripe_width$ stripes and $l/group_width$ nodes will then be on unique nodes.

Compass: Encrypted Semantic Search with High Accuracy

Jinhao Zhu

Raluca Ada Popa
UC Berkeley

Abstract

We present Compass, a semantic search system for encrypted data that achieves high accuracy, matching state-of-the-art plaintext search quality, while ensuring the privacy of data, queries, and results, even if the server is compromised. Compass contributes a novel way to traverse a state-of-the-art graph-based semantic search index and a white-box co-design with Oblivious RAM, a cryptographic primitive that hides access patterns, to enable efficient search over encrypted embeddings. With our techniques, Directional Neighbor Filtering, Speculative Neighbor Prefetch, and Graph-Traversal Tailored ORAM, Compass achieves user-perceived latencies within or around a second and is orders of magnitude faster than baselines under various network conditions.

1 Introduction

An increasing number of user data systems, including WhatsApp [30], iCloud Backups [10], Telegram [121], Signal [110], and PreVeil [97], have adopted end-to-end encryption because of its strong security properties. In this setting, there has been a rich, decades-long line of work on encrypted search [24, 27, 31–33, 40, 44, 61, 62, 83, 88, 104, 109, 114, 116, 126], which enables the server to search over the encrypted data without learning the data or the query. Despite much progress, two challenges remain: *reduced security* and *low search accuracy*.

Security: The goal is to protect data, queries, results, and access patterns, against a *fully* compromised server. ***i) Leaky practical search.*** A long line of work allows the server to learn some information about the query or data [18, 19, 24, 50, 62, 67, 88, 116], such as search access patterns, to enable fast searches. However, leakage-abuse attacks [17, 55, 64, 74, 94, 96, 129] can reconstruct a significant amount of data or the query from this leakage. ***ii) Search with partial server trust.*** A line of work assumes trusted hardware enclaves at the server [5, 83, 118, 130], but hardware enclaves suffer from a wide range of side-channel attacks [16, 65, 128], including some that can entirely subvert remote attestation and their security [124]. Another line of work [27, 28, 109] assumes that the logical server consists of two or more trust domains, where at least one of them is trusted. However, it has been shown to be very difficult to deploy such different trust domains [26, 73], and attackers can still compromise both servers.

Meaning of social security numbers?

Keyword Search Result: Social Security Number Randomization. On June 25, 2011, the Social Security Administration changed the way Social Security Numbers are issued. Originally Social Security Numbers revealed information about their owners…

Semantic Search Result: Definitions for social security number. Social Security number is the number of a particular individual's Social Security account. Social security number is a nine-digit number issued to citizens, permanent residents, and temporary (working) residents under section 205(c)(2)…

Figure 1: Example of top-1 search results with the keyword search using a popular tool TF-IDF versus semantic search on the MS MARCO dataset. The keyword search result is skewed by the frequency of the phrase 'social security numbers,' and misses the question's focus on meaning, while the semantic search provides a more accurate answer.

Accuracy: Most of the works mentioned above have lower accuracy compared to state-of-the-art plaintext search systems. This is because they only implement the *lexical* search, which is less accurate than the *semantic* search used in modern systems. For example, some works above [3, 24, 27, 61, 62, 83, 114, 123, 126] implement an inverted index that maps each keyword to a list of documents containing that keyword. Such equality matching does not capture the meaning and intent of user queries (e.g., questions). State-of-the-art search systems such as Google products [47], Mac Spotlight [9], Dropbox Dash [120], Bing [81], and Elasticsearch [35] implement semantic search. Semantic search converts both the query and the content into embeddings in a high-dimensional space, which allows the search algorithm to compare the meanings of texts based on their proximity in this space, rather than just matching keywords. As shown in Fig. 1, semantic search is more accurate because it understands the intent and contextual meaning of the query. It also extends search capabilities to unstructured data such as audio, images, and videos.

In this work, through our system ***Compass***, we show that one can achieve the best of both worlds — namely, an efficient and accurate semantic search system without the server-side leakage or trust assumptions mentioned above. Compass

achieves search quality on par with *state-of-the-art plaintext search systems*. Moreover, search in Compass does not leak access patterns and does not rely on trusted hardware, while still protecting against a malicious server-side attacker (§4.8). Compass is designed for scenarios where a user wishes to privately search over their own confidential data, stored in encrypted form at a logical server. In this setting, Compass also enables secure retrieval over an encrypted RAG (Retrieval-Augmented Generation) [69] database.

The few prior proposals on secure embedding search are either inefficient or have weak security guarantees. For example, HERS [36] performs a linear scan using FHE over the entire data, while SANNS [20] combines heavy cryptographic tools like FHE, distributed ORAM, and Garbled Circuits. Other proposals suffer from weaker security assumptions, such as leaky search [11, 132], or relying on non-colluding servers [109]. Tiptoe [51] targets public databases and is thus unsuitable for private data scenarios. Specifically, its core homomorphic techniques depend on data being public to achieve efficiency. We elaborate further in §7.

To realize our goal of high accuracy, Compass aims to execute a powerful *state-of-the-art* semantic search index over encrypted embeddings. Graph-based algorithms currently have state-of-the-art accuracy on diverse workloads [12, 112], and Hierarchical Navigable Small World (HNSW) [79] is a top-performing and commonly-used index of this type [93, 98]. HNSW structures data as a multi-layer graph, with fewer nodes and edges at higher layers. The nodes at each layer are a subset of the layer below, with the bottom layer containing the entire dataset. Search starts from the top layer, traversing the graph using a greedy walk to find the local nearest neighbor, and then continues to the layer below.

Such complex graph traversal in the embedding space would be inefficient to perform with fully homomorphic encryption (FHE) [42] or GarbledRAM [77]. Instead, we build Compass on Oblivious RAM [90], specifically Ring ORAM [101]. Beyond access pattern protection, ORAM offers additional attractive properties for our system. With ORAM, Compass separates the computation from the storage: the embeddings and index are stored on the server in encrypted form, while the search algorithm runs locally on the client. The client interacts with the server only to retrieve the data needed during the search. Fig. 2 shows Compass's architecture. Unlike FHE, this allows us to support any distance metric, enabling a wealth of state-of-the-art embeddings. On the practical side, the efficiency of ORAM has improved significantly since it was first proposed. Additionally, supporting integrity checks on Ring ORAM is straightforward.

While the idea of combining a graph-based index with ORAM is alluring, the main challenge lies in efficiency. HNSW, like other graph-based ANN search algorithms, is optimized for efficient multi-hop traversal of a locally stored graph. A strawman solution that makes a remote ORAM request for every node visited during a search is highly inefficient due to *high bandwidth usage* and *excessive round trips*. Evaluating each candidate node requires fetching embeddings for all of its neighbors and computing their distances to the query. In HNSW, each node typically has tens to hundreds of neighbors. To achieve good accuracy, HNSW usually evaluates tens to hundreds of candidate nodes. As a result, data for thousands of nodes must be fetched remotely, and even with batching ORAM requests, it still requires tens to hundreds of round trips for a single query.

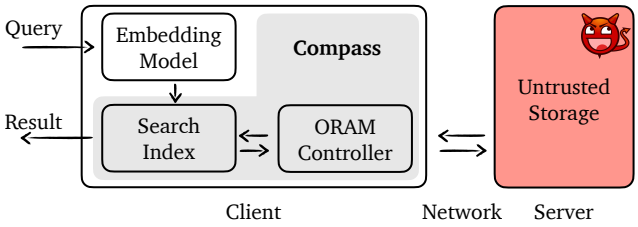

Figure 2: Compass Architecture

To address this challenge, we develop a new encrypted search index that *co-designs* a graph walk through embedding space and an ORAM backend for efficient graph search. Specifically, we introduce three techniques. We introduce *Directional Neighbor Filtering* to reduce bandwidth consumption. The key idea is, at every node in the graph walk, to only fetch the embeddings of a subset of neighbors that are in the same "direction" in the embedding space as the query. Compass determines this subset based on a small chunk of data, which is orders of magnitude smaller than the original dataset, cached locally on the client. Second, we introduce *Speculative Neighbor Prefetch*, which speculatively prefetches additional nodes that are likely to be visited in the future to reduce the total number of round trips required. Finally, we introduce *Graph-Traversal Tailored ORAM* that integrates the search index walk into a white-box "rearrangement" of the ORAM protocol, further improving the communication overhead and significantly reducing user-perceived latency.

Evaluation summary: We implemented and evaluated Compass on 4 popular datasets of different sizes and dimensions. Our results show that Compass's encrypted search matches the accuracy of the state-of-the-art plaintext semantic search algorithm across all datasets. Compass delivers up to 920× speedup over HSNW running on top of ORAM without our techniques and is orders of magnitude faster than two other evaluated baselines. Compass achieves user-perceived latencies of 0.57-1.28 seconds on a slow cross-region network across these datasets. In terms of memory consumption, client-side memory remains small (e.g., 5.5 MB, see Tab. 4) for personal data search scenarios. However, Compass is not yet scalable for global-scale web searches, as client-side memory usage increases to 0.5 GB (Tab. 4), a limitation we leave for future work. Overall, Compass makes encrypted search with high semantic accuracy practical for the first time without compromising security.

2 Background

2.1 Graph-based ANN Search

Similarity search is a core component of large-scale retrieval tasks. Commonly, entities, such as images, user profiles, audio, text, or products, are embedded into high-dimensional spaces with a chosen distance metric (e.g., Euclidean distance). The similarity search task then reduces to the nearest neighbor (NN) search problem: given a dataset D of points in a metric space, a query point q and a target result size K, we must efficiently retrieve the K closest points to q from D.

Since exact NN search is intractable on large, high-dimensional datasets [21, 106] and many applications can tolerate some accuracy loss, practical systems use *Approximate-Nearest-Neighbor (ANN) search*. These methods build indices over the dataset to support high search accuracy and efficiency. Proposed ANN algorithms include tree-based methods [13–15, 25, 53, 76, 85, 111], hashing-based methods [6–8, 43, 46, 54, 56, 71, 75, 92, 119], quantization-based methods [41, 48, 58, 59, 68], and graph-based methods [4, 38, 57, 79, 80, 86]. While each class of algorithms presents trade-offs between accuracy, efficiency, indexing time, and space footprint, graph-based algorithms have emerged as a popular choice due to their state-of-the-art accuracy on diverse workloads [12, 112]. ANN algorithms that do not use data-dependent traversal in the embedding space, like LSH [43, 54, 109], typically achieve lower accuracy with high-dimensional embeddings [12, 112].

HNSW [79] is a widely-used, top-performing graph-based index [12, 112]. It builds a hierarchical, multi-layer graph that has bounded node degrees. The HNSW search algorithm follows a simple iterative greedy search procedure. As shown in Fig. 3, the search begins from a pre-defined entry point. This entry point is chosen during the index construction and is a node on the uppermost layer. The search iterates over each layer, performing a greedy search, before dropping down to the layer below to continue its search. On each upper layer, the greedy search uses a dynamic candidate list of size one and greedily chooses a single node, which then becomes the entry point to the next layer below. Finally, upon reaching the bottom layer, the algorithm performs a greedy search using a dynamic candidate list of size ef and selects K nodes instead of just one. The parameter ef is typically larger than K and controls the trade-off between quality and efficiency, with higher values of ef corresponding to higher quality at the cost of higher search latency. In practice, one can choose ef by empirically generating the accuracy-efficiency trade-off curve over a benchmark dataset and choosing the ef value that meets the application's target accuracy at minimal search latency.

2.2 Ring ORAM

Oblivious RAM (ORAM) [45, 90, 116] allows a client to access data on remote storage without leaking access patterns. Path ORAM [116] is a practical, tree-based ORAM scheme that organizes server-side storage as a binary tree of roughly $\log N$ levels, where each node (bucket) contains Z blocks. Each block contains either real data or a dummy. A path is defined as the sequence of buckets from the root of the tree to one of the leaf nodes. Each block is randomly mapped to a path and resides either on that path or in the stash, a client-side buffer. The client also maintains a mapping of each block to its assigned path, which is called the position map.

We chose Ring ORAM [101], a follow-up to Path ORAM, for Compass because Ring ORAM has low bandwidth consumption (i.e., constant online bandwidth through the XOR trick). Even in a large client storage setting, as noted in [101], Ring ORAM remains competitive with other hierarchical ORAM schemes [29, 117]. Each bucket in Ring ORAM contains $Z+S$ blocks, where S is the number of slots reserved for dummies. Blocks in a bucket are randomly permuted before being written to the server, and the permutation is stored as metadata on the server. Ring ORAM's operations are:

- ReadPath(l,a): Unlike Path ORAM, Ring ORAM reads only one block, the target block a or an unused dummy, from each bucket on the path l. A block becomes invalid once it is read, which is reflected in the metadata.
- EvictPath: Eviction occurs every A ReadPath operations. The evicted path is selected in a reverse lexicographic order.
- EarlyReshuffle: A bucket must be reshuffled after S accesses because it contains only S slots for dummies. This operation reads the bucket from the server, shuffles it, and writes it back to the server.

To access a block a in Ring ORAM, the client first checks the position map to find the path l. Next, it reads the metadata of all buckets on l and uses this information to invoke the ReadPath operation. Thus, Ring ORAM requires two round trips per access. The online bandwidth is $O(\log N)$ and can be reduced to $O(1)$ via XOR operations by the server.

3 System Overview

Our system setup consists of a logical server and multiple clients. Each client owns a unique set of documents and an individual index, both stored on the server. Compass focuses on the case of a personal user searching their confidential data in the cloud, such as on Dropbox [120] or iCloud [9]. Data

sharing could be implemented by adding shared data to each relevant user's index. We do not focus on data sharing and leave optimizations to future work.

Compass's APIs are as follows:

- INIT($\mathcal{D}$): Given a set of documents $\mathcal{D}$, initialize the index.
- SEARCH(Q, K) $\rightarrow$ LIST(ID, SCORE): Given Q, the query embedding, return the top K relevant documents as a list of document IDs and their relevance scores.
- INSERT($\mathcal{F}$): Given a document $\mathcal{F}$, generate the embedding set $\mathcal{E}$ and store both the encrypted document and its embeddings on the server. The size of $\mathcal{E}$ depends on the document length and the model's context window.
- DELETE($\mathcal{F}$): Remove the document $\mathcal{F}$ and its embeddings.

Search, insert, and delete in HSNW are (poly)logarithmic in the number of documents, assuming the HNSW graph approximates a Delaunay graph [79]. Compass preserves the complexity of these operations. File updates are handled by deleting the old file and inserting the updated version. Large files are split into equal-sized chunks based on the embedding model's context length. Each chunk is treated as a separate file with its own embedding. For efficient ORAM initialization, one can use the bulk loading protocol from BULKOR [72].

3.1 Threat Model & Security Guarantees

Our system is based on a two-party model: a client and a (logical) server. The logical server may consist of multiple physical machines. The server is untrusted and can be maliciously compromised. Unlike some prior works that weaken the threat model by assuming multiple logical servers with at least one being honest [27, 103, 109, 125], we assume the entire server is untrusted. We also do not rely on uncompromised hardware modules or hardware trust assumptions at the server, like TEE-based systems [39, 83]. This means that the server in Compass can deviate from the protocol arbitrarily. Compass ensures that the server cannot learn any information about the user query, such as the query embedding, the IDs and lengths of the returned documents, or whether the query matches a previous one ("query access patterns"). Moreover, the server cannot learn the data contents from the search index or modify the search results without detection by the client.

Compass does not hide the type of operation, whether a user is performing a search, insert, or delete, on remote data. We do not protect against timing side-channel attacks based on the client's execution duration or the server's observation of timing patterns in user requests. We consider the system configuration parameters listed in §3.1.1 as public information. The server can roughly tell how large the data of each user is (e.g., how many GBs each user has), but Compass does not reveal to the server the size of query results. (Of course, these can be protected through padding [63] in time and space at a performance cost.) This strong model means that Compass protects against a plethora of attacks [17, 55, 64, 74, 94, 96, 129] on encrypted search that leverage access patterns or volume of results. Like much prior work [51, 83, 126], Compass does not protect against DoS attacks from the server. The server may drop the requests from clients at any time or even delete the client's data. We assume it is the server's business interest to maintain a good availability to attract more customers.

The client, who owns the outsourced data, is trusted with its own documents. That is, the client may search and read the contents of these documents. However, the client cannot access or perform a search on the documents of other clients, even if the client colludes with the server.

1. The challenger $\mathcal{C}$ chooses a uniformly random bit b.
2. The adversary $\mathcal{A}$ chooses two equally large datasets D_0 and D_1, as well as one set of public parameters param. The challenger initializes the system with D_b and param.
3. The adversary iterates as follows. At step i:
   (a) The adaptive adversary $\mathcal{A}$ chooses a pair of requests $q_{i,0}$ and $q_{i,1}$, which can be search, insert, or delete.
   (b) When the challenger receives a pair of requests, it first checks whether the type matches. If they are of different types, the challenger aborts. Otherwise, the challenger interacts with the adversary in the role of the server according to the Compass's protocol for request $q_{i,b}$. As part of this execution, the client protocol verifies the integrity of the data from the server. If any verification fails, the challenger aborts.
   (c) The challenger gets the request result r_i.
4. The adversary $\mathcal{A}$ outputs a guess b'.

Figure 4: Security game for Compass

3.1.1 Security Definition

Like prior work [107, 115], we provide an indistinguishability-based security definition. In our security game, there is a challenger $\mathcal{C}$ and an adversary $\mathcal{A}$ who acts as the client and the server of Compass, respectively. According to the threat model, the challenger is honest and the adversary is malicious, which means $\mathcal{A}$ can deviate from the protocol arbitrarily. The attacker wins the security game if it can either learn partial information about the query or data, or modify the search results without detection by the challenger (client).

Let param denote the set of public parameters in our system, including HNSW parameters M and ef, the number of cached layers, the size of the directional filter *efn* (§4.5), the size of the speculating set *efspec* (§4.6) used in our modified HNSW search. We define the security game in Fig. 4. The adversary $\mathcal{A}$ wins the game if the challenger $\mathcal{C}$ does not abort and one of the following two conditions is met: ***1)*** $b' = b$; ***2)*** the sequence of queries $(q_{i,b}, r_i)$ is an incorrect execution of plaintext Compass's search algorithm with param on D_b.

Theorem 1. *Assuming a collision-resistant hash function and an IND-CCA2 secure encryption scheme, for any probabilistic polynomial time stateful adversary $\mathcal{A}$, $\mathcal{A}$'s chance of winning in the security game in Fig. 4 instantiated with Compass's protocol is: less than half plus negligible for winning condition (1) and negligible for winning condition (2).*

Due to space constraints, we show a proof sketch in §4.10, leaving the full proof in the supplementary material §C.

4 Compass's Search Index

We now describe Compass's index. While we build Compass on top of HNSW, our techniques are generally applicable to other graph-based ANN indices. We primarily focus on the search since the insert algorithm in HNSW closely resembles that of the search, and the techniques described in this section apply to both. A summary of notation is shown in Tab. 1.

4.1 Data Layout

Before we dive into the details of each technique, we present Compass's data layout. The client holds:

- *ORAM-related data*: a stash for overflow blocks, a position map that maps each block to a path, metadata for each bucket, and a cached treetop for the ORAM tree (§4.7).
- *HNSW-related data*: metadata for HNSW search, including the dimension of the embeddings, the number of layers, and the degree bound M. If client-side caching (§5) is enabled, the client also stores the graph for the upper layers and the embeddings of nodes within these layers.
- *Quantized hints* that are a part of our Directional Neighbor Filtering technique, which we explain later in §4.5.

The server holds the ORAM tree in the Ring ORAM construction. Each node (bucket) of the tree contains $Z+S$ blocks. In our search index, each ORAM block corresponds to one node in the HNSW graph. The block corresponding to node x stores the embedding of x and its neighbor list, which consists of identifiers for the neighbors of x. Each bucket has a tree of hashes for the integrity check (§4.8).

4.2 Workflow overview

Fig. 2 shows the architecture and workflow of our system. Similar to a plaintext search on embeddings, the user's query is first transformed into a dense, fixed-dimensional vector using a pretrained embedding model. This query vector is then used to search within the embedded document corpus. Our search framework builds on HNSW and provides security guarantees by storing vector embeddings and the graph index encrypted on a remote server, accessed by the ORAM controller. During the search process, the client interacts with the server to retrieve the index and embeddings.

Symbol	Description
M	degree bound of traversed nodes in HNSW search
ef	size of dynamic candidate list in HNSW search
efn	size of directional filter
$efspec$	size of speculation set
Z	maximum number of slots for real blocks per bucket
S	number of slots reserved for dummies per bucket
A	eviction rate

Table 1: Summary of Notation

4.3 An initial attempt

We now present a natural way of traversing HNSW using ORAM: the client follows HNSW's search algorithm, making an ORAM request for each node visited. This solution is inefficient as it requires substantial bandwidth and numerous round trips. This inefficiency arises because HNSW is designed for local, multi-hop searches, while ORAM turns each node access into a non-trivial client-server request. It nevertheless establishes the foundation and terminology for our subsequent improvements in the rest of this section.

This HNSW greedy traversal is illustrated in Fig. 5a, which we now explain. Starting from the entry node (1), the algorithm fetches all its neighbors and adds them to the *candidate list*, namely, it visits them. We say that the algorithm *visits* a node if it retrieves the ORAM block of this node. In the subsequent iteration, the node in the candidate list closest to the query is selected as the next candidate node. The unvisited neighbors of this candidate are then visited and added to the candidate list. In Fig. 5a, it takes 7 search iterations to find the nearest node, with every node in the graph being visited. This algorithm works well when computation and storage are colocated. However, in our setting, the client has to retrieve neighbors' embeddings and neighbor lists from the remote server through ORAM requests, making it inefficient because of multiple costly network round trips and significant data transfer. In HNSW, the number of required round trips depends on ef, and each node's degree is bounded by M. Therefore, a search requires $ef \cdot M$ rounds of communication to retrieve the embeddings and neighbor lists of $ef \cdot M$ nodes. Empirically, in the final layer of HNSW, both M and ef range from tens to hundreds for sufficient accuracy, causing high search latency and bandwidth usage.

4.4 Towards Compass's search index

To understand our approach, it helps to first consider an attempt to reduce the number of sequential ORAM requests in the strawman above. The idea is to include the embeddings and neighbor lists of the neighbors in the neighbor list of a node within the ORAM block of that node. This will halve the number of ORAM requests and round trips as compared to the strawman. However, this strategy causes $M\times$ storage overhead on the server side because each node's embedding would

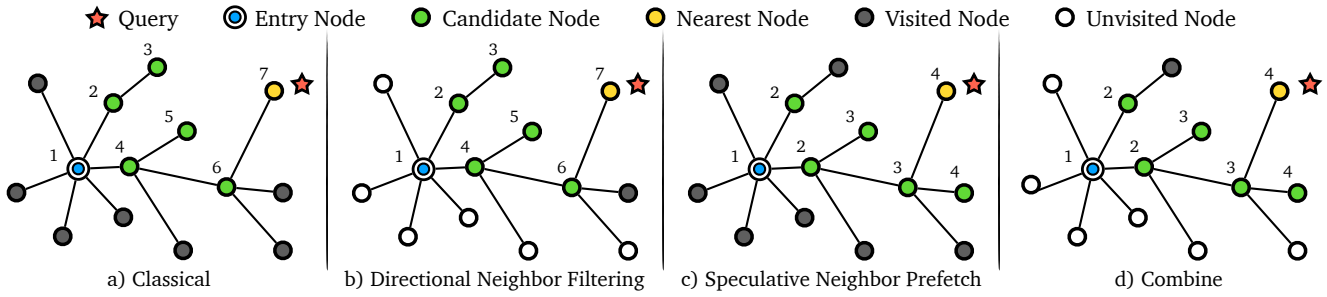

Figure 5: HNSW graph traversal followed by our ORAM-friendly traversal techniques. The search aims to identify the Nearest Node to the Query. The distance here is Euclidean distance. The numbers indicate iterations in the traversal, and which nodes are *processed* at each iteration. We say that a node is processed, if its neighbors are visited.

be stored both in its own ORAM block and in the blocks of its neighbors. Moreover, the increase in storage does not result in substantial bandwidth savings due to the larger ORAM block size.

Instead, we propose a novel way to traverse the HNSW graph designed for running on top of ORAM. Our traversal approach significantly reduces round trips and bandwidth usage via three techniques. The first two techniques make black-box usage of ORAM; *Directional Neighbor Filtering* (§4.5) reduces the network bandwidth overhead and *Speculative Neighbor Prefetch* (§4.6) reduces the number of network round trips required. Our third technique, *Graph-Traversal Tailored ORAM* (§4.7), makes white-box use of Ring ORAM to leverage the memory access characteristic in graph search to further reduce bandwidth and computation overhead.

4.5 Directional Neighbor Filtering

The key idea behind our Directional Neighbor Filtering technique is to consider only a subset of a node's neighbors during traversal because those closer to the query point are more likely to contribute to the final result; namely, to embed a sense of "direction".

One possible way to implement this idea is to store with every node, not only its own embedding but also the list of *compressed* embeddings of its neighbors. The intuition is to determine which compressed neighbors are closer to the query, and only fetch those from the ORAM, reducing bandwidth consumption. One can use compression techniques like PCA [60]. However, since a node does not have a large number of neighbors, we found that the compression is not effective in reducing the size of each ORAM block because there are not enough neighbors to amortize the space taken by the compression state (e.g., the transformation matrix).

Instead, we compress together *all the nodes* into a data structure we call *Quantized Hints*. The client stores the Quantized Hints, mapping each node ID to its quantized embedding. We find Product Quantization (PQ) [58] fits well here: it is a widely-used quantization method that is highly effective at compressing a large number of high-dimensional vectors. For example, we achieve 98% compression on various datasets (see §6.3.3) with a codebook size equivalent to 128 full coordinates, thus requiring a minimal amount of client storage. However, if we use PQ directly (namely, construct the index directly on quantized embeddings), there is a big accuracy drop because the closest quantized neighbor to the query is often not the closest full-coordinates neighbor.

Instead, our idea is to use the quantized nodes merely as "directional hints": for each node, we identify the top *efn* closest neighbors to the query based on the hint, and then fetch their *full* coordinates (the ground-truth) from the server to identify the next node to process. The intuition is that the closest *efn* quantized neighbors are very likely to contain the closest (full-coordinates) neighbor. By fetching only *efn* out of M neighbors, this technique reduces bandwidth usage by a factor of $\frac{M}{efn}$. We demonstrate in §6.4 that, with an appropriately chosen *efn*, the impact on search accuracy is negligible.

For clarity, we include an example of using directional neighbor filtering during the search in Fig. 5b. Assume we fetch only the top 2 closest neighbors in each iteration. At the beginning of a query, the Compass client computes its quantized embedding. Then, during each iteration in the traversal, let node A be the currently closest node to the query in the candidate list. The client iterates through A's neighbor ids, looking up their quantized embedding in Quantized Hints, and computing each neighbor's distance from the query in the quantized space. The client then only fetches the top $efn = 2$ closest neighbors from the server in a batched ORAM request (§4.7), and adds them to the candidate list. Compared to Fig. 5a, we can see in Fig. 5b that some of the neighbors of the nodes processed at (1), (4), and (6), which are not among the top 2 closest nodes to the query, are not visited. We thus avoid visiting 6 nodes in the graph, which approximately halves the bandwidth consumption.

4.6 Speculative Neighbor Prefetch

In speculative execution [66], the processor makes guesses of potentially useful instructions and executes them in advance to improve performance. Our Speculative Neighbor

Prefetch shares the same intuition. Each time the Compass client performs a round trip to the ORAM server to retrieve nodes that will be visited next by HNSW's search, the client also speculatively fetches additional nodes. This implicitly requires batching the access of multiple ORAM blocks into one request, which is introduced in §4.7. These additional nodes are not yet needed by the HNSW search algorithm, but are likely to be visited later. By retrieving these *likely-needed* nodes alongside the *currently-needed* node, we can reduce the number of future network round trips to ORAM during search. But how do we identify these nodes? Fortunately, the candidate list used in the greedy search algorithm is a good basis for speculation. The candidate list is sorted by the distance to the query. In our algorithm, we fetch the first *efspec* nodes' neighbors within one request. Once the response is received from the remote server, the candidate list is updated by evaluating the neighborhood of each node in the speculative set. With this technique, Compass reduces the number of round trips by a factor of *efspec*.

In Fig. 5c, we show an example of Speculative Neighbor Prefetch. In each iteration, the client extracts two candidates from the candidate list and visits their neighbors simultaneously. In this toy example, Compass reduces the number of iterations from 7 to 4. We show in §6 that implementing this technique on real datasets significantly reduces the search steps required while maintaining the same accuracy.

DiskANN [57] uses a similar speculative approach in the different setting of optimizing the interaction between memory and SSD. In DiskANN, they fetch a small number of extra nodes to balance the cost of computing and SSD bandwidth. However, in Compass, the cost model of fetching data from the disk and fetching data from ORAM over the network is different. In our setting, a key observation is that optimizing the number of round trips is much more important than optimizing bandwidth because the round trips directly affect user-perceived search latency and the bandwidth consumption is already in a reasonable ballpark. Therefore, depending on the dataset, for Compass, the size of the speculation set *efspec* can grow as large as 16 to achieve good overall performance.

Fig. 5d shows the final example of the search process when we compose both Directional Neighbor Filtering and Speculative Neighbor Prefetch. Compared to Fig. 5a, the algorithm in Fig. 5d achieves the same search results with three fewer network round trips and six fewer node retrievals.

4.7 Graph-Traversal Tailored ORAM

To reduce the cost of an HNSW traversal, or more generally a graph traversal, Compass optimizes how a graph is stored in ORAM and rearranges how ORAM requests are performed.

As mentioned in §4.1, each block in our ORAM stores both a node's embedding and its neighbor list. We now motivate this choice. Recall that graph storage consists of two parts: coordinates and neighbor lists. In each step of a greedy search, we first fetch the current candidate's neighbor list and then fetch the coordinates based on the neighbor list. A simple approach is to use two ORAMs, one for coordinates and another for neighbor lists. However, this requires two network round trips per search step, assuming that we batch the request for coordinates. Our design is based on the observation that the neighbor list belongs to a node whose coordinates we have already obtained in previous steps. By storing a node's coordinates and neighbor list in the same block, we fetch the neighbor list early to avoid an extra network trip. Let D be the dimension of the embedding and M be the degree bound. The bandwidth increases from $M*(D+1)$ to $M*(D+M)$. Typically, the degree bound is much smaller than the embedding dimension, so the increase is roughly 1.2 to 2×.

We build our system based on Ring ORAM and we make several white-box modifications to make it more efficient under graph traversal workload. The reader should recall the Ring ORAM background in §2.2. Each bucket's metadata is cached on the client to avoid extra round trips. As mentioned earlier, we use batching, a technique already shown to be effective [107, 126, 133], to reduce the number of round trips for parallel requests in the same search step. In Ring ORAM, evictions are scheduled after every A path access to keep the stash within a reasonable size. With batching, evictions are delayed if the batch size is larger than A.

Compass introduces ***multi-hop lazy eviction***: as the Compass client walks from hop to hop through the ANN graph to answer a query, the client performs a sequence of ORAM request batches without performing their associated eviction, responds to the user, and finally performs eviction. The advantages of multi-hop lazy eviction are substantial. In ORAM schemes, online bandwidth refers to the cost of reading data from the server, which affects response time, while offline bandwidth covers other costs like evictions. By delaying eviction until the end of a query, users experience lower search latency. This method works especially well in Ring ORAM, where offline costs are higher than online costs. For example, as mentioned in [101], for a set of properly selected parameters, the offline bandwidth is roughly $2-2.5\times$ smaller than the online bandwidth, and the online bandwidth is further improved by a factor of $\log N$ with the XOR trick. The downside of lazy eviction is that the buckets near the root run out of dummy budget quickly, leading to more frequent early reshuffles. We mitigate this with classic tree-top caching [101]: by caching the top t levels of the ORAM tree, we can delay 2^t evictions and keep the reshuffle rate reasonable.

With batching and multi-hop lazy eviction, the number of requests per batch and the number of batches per query introduce additional leakage. In a graph, the number of neighbors for each node can vary, which affects batch sizes, and the speed at which the greedy search converges can also be different, which affects the number of batches. We address this issue through a co-design with the graph algorithm. The main idea is to keep the number of search steps the same at each

layer of the HNSW graph and pad each node to have the same number of neighbors. We explain the details in §4.9.

Stash analysis: Another concern with delayed eviction is its impact on stash size, which can indirectly affect security. During a query, the client keeps all fetched blocks in the stash until the final eviction. As part of the eviction process, blocks from multiple delayed paths are fetched from the server. With a larger stash, eviction becomes inefficient if we perform a linear scan to find the candidate block for a specific bucket. To address this, we sort the blocks in the stash by their assigned path ID. This allows us to recompute the range of path indices for a target bucket and quickly locate candidate blocks in the stash. Insertion complexity increases to $O(\log N)$, where N is the size of the stash. However, it reduces the search cost for a bucket of size Z from $O(ZN)$ to $O(\log N)$, as the potential blocks are already grouped by path ID during sorting. We prove a stash bound for Compass's adaptation of Ring ORAM. In §B, we show that after the eviction is complete after the query, the size of the stash is upper bounded by the size of the stash in the original Ring ORAM.

4.8 Malicious server protection

A malicious server can alter ciphertexts, rearrange the layout of ORAM buckets, perform replay attacks, or provide incorrect query responses. To protect integrity and freshness, we follow the idea from the Path ORAM literature [102, 115] and construct a Merkle tree on top of the ORAM tree. If we label the buckets linearly, the hash of a non-leaf bucket is defined as:

$$\mathsf{H}_i = \mathcal{H}(\mathsf{B}_i || \mathsf{H}_{2i} || \mathsf{H}_{2i+1}), \tag{1}$$

where B_i is the "snapshot" of the i-th bucket, and H_{2i} and H_{2i+1} are hashes of the child buckets. For leaf buckets, the hashes of child buckets are omitted. In Path ORAM, B_i is simply the concatenation of all blocks in the bucket:

$$\mathsf{B}_i = b_1 || b_2 || ... || b_Z, \tag{2}$$

In Ring ORAM, however, each access retrieves only one block per bucket along the path. To avoid fetching the remaining blocks, we construct a secondary Merkle tree within each bucket, where the j-th leaf node is the hash of the j-th block in the bucket. Now, B_i is the root hash of the secondary Merkle tree of the i-th bucket. During the ReadPath operation, for each bucket, we retrieve $\lceil \log(Z+S) \rceil$ hashes from the secondary tree to reconstruct B_i, plus an additional hash for its sibling bucket. For EarlyReshuffle and EvictPath, since we already read Z blocks from each bucket, we only fetch S hashes of the remaining blocks. Note that for EarlyReshuffle, since we reshuffle individual buckets instead of entire paths, we must also retrieve the hashes of the target bucket's child buckets and the hashes of sibling buckets of its ancestors.

Algorithm 1: SEARCH($q, ep, ef, efspec, efn$)

Input: query q, entry point ep,
size of speculation set $efspec$,
size of directional filter efn,
number of nearest to q elements to return ef
Output: ef closest neighbors to q

```
1  V ← ep // set of visited nodes
2  C ← ep // set of candidates
3  W ← ep // set of found nearest neighbors
4  n ← ⌈ef/efspec⌉
5  for step ← 0...n do
6      E1 ← extract top efspec nearest nodes from C to q
7      E2 ← ∅
8      foreach e1 ∈ E1 do
9          foreach e2 ∈ neighbors(e1) do
10             if e2 ∉ V then
11                 E2 ← E2 ∪ e2
12     t ← efspec * efn
       // Based on quantized hints
13     E3 ← extract top t nearest nodes from E2
14     oram.batch_access(E3, t)
15     foreach e ∈ E3 do
16         V ← V ∪ e
17         C ← C ∪ e
18         W ← W ∪ e
19         if |W| > ef then
20             remove furthest element from W to q
21 return W
```

4.9 Putting it All Together

With the techniques above, we present our search algorithm for each layer in Alg. 1. In HNSW, the insertion is the same as the search, but it uses a different ef. To delete a node, the standard way is to search for the node and mark it as deleted.

Compared to vanilla HNSW, the main difference lies between line 4 and line 14. The number of search iterations, n, is determined by $\lceil ef/efspec \rceil$, as we extract the top $efspec$ nodes from the candidate list as the speculative set, E_1, in each iteration. In the first iteration, there is only one candidate, the entry point, so only one node is extracted from the candidate set. We then traverse the unvisited neighbors of the nodes in E_1 (referred to as E_2), ranking them based on their distance to the query, estimated using quantized local hints. The top t nodes from E_2 are selected as E_3, and a batch ORAM request is issued to retrieve their full coordinates and neighbor lists. The value of t is set to $efspec \cdot efn$, as we want efn neighbors per candidate. If the total number of nodes in E_3 is less than t, the batch ORAM request is padded to t for security. Once the full coordinates are retrieved, we insert each node in E_3 into the set of visited nodes V, the set of found nearest neigh-

bors W, and the candidate set C. The set W is dynamic, as the furthest element will be removed when its size exceeds ef. After completing n iterations, W is returned, and the first K nodes in W are the final search result of q. For search in upper layers, the ef is set to 1, and therefore we only apply directional neighbor filtering.

4.10 Security proof sketch

We provide a proof sketch covering the salient points, leaving the full proof in the supplementary material §C.

The integrity guarantee of our protocol comes directly from the Merkle tree on top of ORAM, which has already been proposed and proved [37, 102, 115]. Therefore, the attacker must respond correctly to all requests, with their only capability being to learn which items are accessed on the server during these requests. Prior works have already shown that batching of ORAM requests doesn't reduce security [126, 133].

Compass differs from these works in that our ORAM requests follow a multi-hop pattern. Each query in Compass triggers multiple batches of ORAM accesses, followed by lazy eviction at the end. For each type of query, the number of batches and the number of paths accessed per batch are determined by the public search parameters (see Alg. 1). During lazy eviction, the number of eviction paths depends only on the total number of earlier accesses, so it is also query-independent. Because the paths are chosen randomly, Compass does not leak the access pattern under the threat model described in §3.1. Different query types (e.g., search and insert) use different ef, so an adversary can still distinguish the operation type. As noted in §3.1, Compass does not try to hide which type of operation is being performed.

4.11 Fault Tolerance Considerations

In case of failure, Compass handles recovery similarly to prior work on ORAM fault tolerance [23]. At a high level, the client (1) persists its local state to disk and (2) periodically uploads this encrypted state to the server as checkpoints. At each checkpoint, the server stores a complete copy of the ORAM tree. Between checkpoints, the client prepares each ORAM operation (including access, reshuffle, and eviction) by persisting the associated information to the local disk. Specifically, it records the type of operation and the offsets of buckets and blocks that will be accessed on the server. Similarly, the server logs each ORAM operation before execution. If the client crashes, it first restores its local states from the latest checkpoint and then re-executes all ORAM operations performed after that checkpoint. This step is necessary to prevent the leakage of access patterns. Otherwise, if the same query is executed before and after the crash, the server could infer information because the accessed paths would be identical. Note that Compass fully protects against a malicious server only if the client-side disk remains intact, allowing recovery of local states and operation logs from disk. If the client's disk also fails, recovery relies solely on the server-provided state and logs. In this scenario, a malicious server might provide stale client states or an outdated ORAM tree, neither of which the client could detect.

5 Implementation

We implemented Compass in approximately 5k lines of C++ code. [1] We use the Faiss [34] library for HNSW construction and Product Quantization. We use AES-256-CBC to encrypt ORAM blocks and SHA-256 for hashing, via OpenSSL's EVP [2]. To save the cost of frequently visited nodes in upper layers, we cache all but the last two layers of the HNSW graph locally on the client. We set the number of search steps in the second-to-last layer to 1. Due to space constraints, we explain the reason behind the choice of cached layers and search steps in §A. We show the client-side overhead associated with layer-wise caching in §6.3.3. We follow the instructions from Ring ORAM [101] and choose $Z = 32$, $S = 64$, and $A = 36$ for our ORAM configuration. We use a slightly larger value for S and a smaller value for A compared to the bandwidth-optimal parameters recommended in [101] to reduce early reshuffles and the number of round trips.

6 Evaluation

In this section, we aim to answer the following questions:

- What is the search quality of Compass, and how does it compare to state-of-the-art plaintext search systems?
- What is the overhead introduced by Compass, and how does it compare to prior encrypted search schemes?
- How does Compass compare to an approach where the client downloads and stores the entire index locally?

6.1 Experimental Setup

We perform our experiments on the Google Cloud Platform with one n2-standard-8 instance (8 vCPUs and 32 GB memory) as the client and one n2-highmem-64 instance (64 vCPUs and 512 GB memory) as the server. We use Linux Traffic Control (tc) [1] to simulate network conditions. Following prior work [20, 109], we evaluate on two sets of network configurations to simulate same-region (fast) and cross-region (slow) networks. Specifically, the fast network has 3 Gbps bandwidth and 1 ms round-trip latency, and the slow network has 400 Mbps bandwidth and 80 ms latency.

We evaluate our system on four popular datasets widely used for ANN search: MS MARCO [22], TripClick [100], SIFT1M [58], and LAION [108]. The specifications for each dataset are presented in the upper half of Tab. 2. We build the HNSW graph with $M = 64$ for LAION and SIFT1M, and

[1] https://github.com/Clive2312/compass

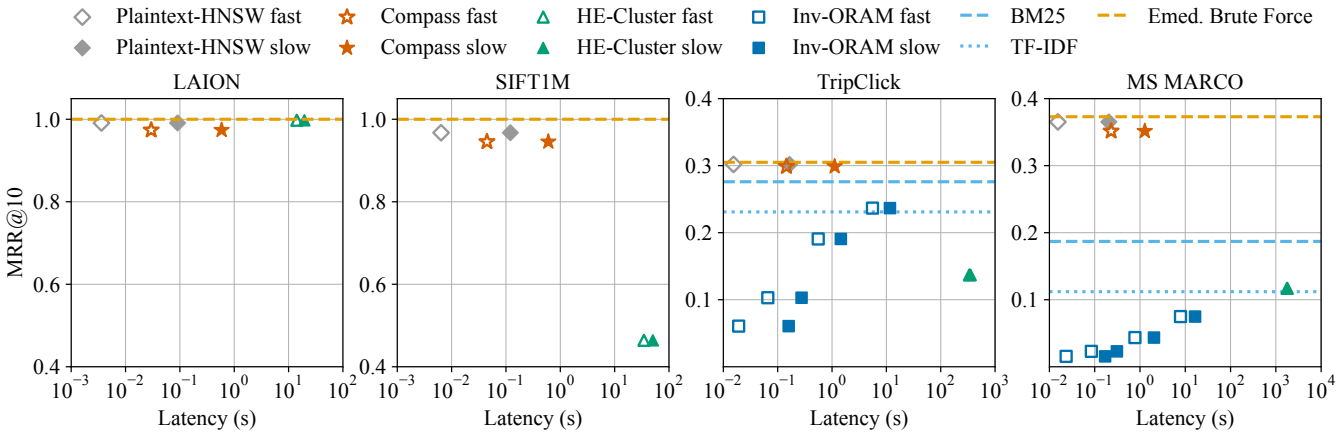

Figure 6: Comparison of Compass's search quality versus latency with Baselines. For TripClick, the results of the HE-Cluster under two networks are overlapped as the main bottleneck is the computation on the server. The search latency for HE-Cluster on MS MARCO is extrapolated due to memory limitation. (See estimated memory consumption in §6.3.3)

	MS MARCO	TripClick	SIFT1M	LAION
dim	768	768	128	512
# docs	8,841,823	1,523,871	1000,000	100,000
# queries	6,980	1,175	10,000	1000
ef	48	36	20	10
efspec	8	6	4	2
efn	24	24	12	12

Table 2: Specifications and parameters for each dataset.

$M = 128$ for TripClick and MS MARCO. For SIFT1M, each embedding is divided into 8 sub-vectors for PQ. For the other higher-dimensional datasets, we split the embeddings into 32 sub-vectors. The search parameters, shown in Tab. 2, are set to achieve a Recall@10 of at least 0.9.

6.2 Baselines

We compare our system with three baselines:

Inv-ORAM is a secure lexical search: an inverted index stored within ORAM [83, 126]. The inverted index maps each keyword to the documents that contain it. Relevance scores are computed using TF-IDF [99], a widely used algorithm in lexical search systems. Each *(keyword, document, score)* pair is stored inside an ORAM block. To avoid leakage of query length and keyword frequency, queries are padded to the longest query length (12 for TripClick and 16 for MS MARCO). Ideally, to hide keyword frequency, we would fetch the maximum number of documents a keyword maps to. However, as pointed out by [87], this can be worse than streaming the entire database. Therefore, following [83], we truncate each keyword's document list to a fixed size. The list is sorted by relevance score before truncation. To simulate OBI [126], we implement this baseline with batch ORAM access and our improved stash eviction algorithm. We evaluate this baseline on text-based datasets: TripClick and MS MARCO.

HE-Cluster is a secure semantic search based on homomorphic encryption and clustering. Tiptoe [51] demonstrates an efficient way to search for a private query on a *public* database by leveraging clustering to avoid linear communication overhead. This baseline is a natural extension of Tiptoe with the database also encrypted under homomorphic encryption. The clustering technique from Tiptoe directly applies here. However, other optimization methods from Tiptoe do not apply, as they were specifically tailored for a public-data scenario. Following Tiptoe, each dataset of size N is clustered into roughly $\sqrt{N}$ clusters using k-means, and boundary conditions are handled similarly. To prevent leakage of cluster size, each cluster is padded to the same size. The server-side computation for this baseline is parallelized across 64 threads.

Plaintext-HNSW is an insecure semantic search baseline in which the client sends a query to the server, the server executes a vanilla HNSW search on the plaintext data, and then returns the results.

6.3 Performance

We measure performance in two dimensions: search quality and latency. For search quality, we use the mean reciprocal rank at 10 (MRR @ 10), where the reciprocal rank is the inverse of the rank of the first relevant item in the results. For Compass, we report the user-perceived latency under the semi-honest setting. The end-to-end latency results, including those under malicious settings, are provided in §6.3.1. For the Inv-ORAM baseline, we set the truncated document list size to 10, 100, 1000, and 10,000, and report the results separately. The tradeoff is that a larger size results in better search quality but worse latency. In Fig. 6, we present the search performance of Compass along with that of the baselines. We also include the plaintext search accuracy using TF-IDF and BM25 [105], two widely used search algorithms, alongside the accuracy of the brute-force embedding search, which represents the highest

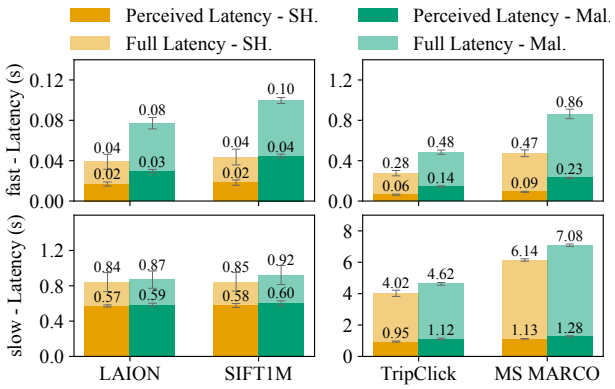

Figure 7: Breakdown of Compass's search latency. *SH* represents semi-honest and *Mal* represents malicious.

achievable accuracy with the current embedding model.

Overall, Compass outperforms both secure baselines in search quality, matching the accuracy of the brute-force embedding search in all four datasets. Compared to Plaintext-HNSW, the insecure baseline, Compass incurs a latency overhead of approximately 6–10×. For Inv-ORAM, the accuracy is affected by the size of the truncated list. Although a smaller truncated list allows Inv-ORAM to achieve lower latency than Compass, its search quality is significantly worse. To match the accuracy of plaintext TF-IDF, Inv-ORAM requires a larger truncated list, which significantly increases latency. The search quality of the HE-Cluster baseline varies across datasets. In the LAION dataset, the HE-Cluster achieves an accuracy comparable to Compass. However, in other datasets, its accuracy drops significantly and falls below that of plaintext TF-IDF on the TripClick dataset. This discrepancy is likely due to the health-related content of TripClick, where text sequence matching is particularly effective in identifying health-related terms. Compared to HE-Cluster, Compass is orders of magnitude faster in latency. While clustering reduces communication costs to sublinear, the server's computation cost remains linear. Although latency can be further improved with parallelization using more CPUs and instances, this is expensive and difficult to scale for multiple users.

6.3.1 Latency breakdown

In Fig. 7, we present the latency breakdown of Compass under various network and security assumptions. We report both user-perceived and full latency. The main contributor to user-perceived latency is ORAM operations. The overhead of distance computation and graph traversal is minimal, requiring less than 0.02 seconds even on MS MARCO. The full latency includes additional time spent on ORAM eviction.

With our lazy eviction technique and the XOR trick from Ring ORAM, the user-perceived latency is reduced by 1.5–5.6× compared to the full latency. For smaller datasets like LAION and SIFT1M on the slow network, the savings are less significant because the bottleneck shifts from bandwidth to round trips, as the graph traversal involves multiple rounds, whereas the eviction only takes two. The cost of integrity verification for malicious security is relatively low compared to the search, especially on larger datasets and slower networks.

Compass focuses on search over private data. For personal use cases, dataset sizes are typically comparable to smaller ones such as LAION and SIFT1M. The full latency for these datasets is under 1 second, even on slow networks. For a large-scale dataset like MS MARCO, the perceived latency is only 1.3 seconds. While eviction takes 5.8 seconds, this process can run in the background, overlapping with other application tasks, such as the subsequent generation step in the RAG pipeline. Overall, Compass achieves practical user-perceived latency across all four datasets and two network settings.

Under a more restrictive network such as 4G (50Mbps bandwidth, 100ms latency), the perceived latency remains acceptable as the primary communication overhead is from eviction. For example, the perceived latency is 0.94 seconds for SIFT1M and 2.03 seconds for MS MARCO in this case.

	Compass				HE-Cluster		Inv-ORAM	
	Per.	Int.	Full	RT	Full	RT	Full	RT
LAION	0.7	0.4	13.5	8	225.5	1	-	-
SIFT1M	1.1	1.0	12.2	8	737.2	1	-	-
TripClick	6.0	3.1	132.8	9	929.2	1	234.5	1
MS MARCO	8.9	5.1	226.4	9	2262.5*	1	300.1	1

Table 3: Comparison of communication cost (MB) and round trips per query. *Per.* represents non-eviction cost and *Int.* represents cost for interity verification. * indicates the result is extrapolated.

6.3.2 Communication

Tab. 3 presents the per-query communication costs and network round trips. For Compass, we additionally report the communication cost before lazy eviction and the cost for integrity verification. For Inv-ORAM, we use a truncated document list size of 10,000 for reasonable search quality. In Compass, the additional communication cost of the integrity check is minimal. Communication costs for LAION and SIFT1M in Compass are similar, even though SIFT1M has 10× more vectors. This occurs because LAION's embedding dimension is 4× larger than SIFT1M's. Compass achieves lower communication costs compared to the HE-Cluster baseline because communication complexity is (poly)logarithmic in Compass but $O(\sqrt{N})$ in HE-Cluster. Additionally, the FHE scheme used by HE-Cluster produces larger ciphertexts. Compared to Inv-ORAM, Compass requires similar communication bandwidth. Note that here we're comparing the total communication cost for a query. As we mentioned in §6.3.1, the main communication overhead in Compass comes from lazy eviction. For the non-eviction communication cost, which affects

	Embed. Size	Graph Size	Compass Server		Compass Client				HE-Cluster		Inv-ORAM	
			SH.	Mal.	Hints	ORAM	Graph	Total	Server	Client	Server	Client
	GB	GB	GB	GB	MB	MB	MB	MB	GB	MB	GB	MB
LAION	0.19	0.12	0.95	0.98	3.55	1.89	0.05	5.49	8.75	0.8	-	-
SIFT1M	0.48	0.51	6.19	6.69	7.75	27.87	0.21	35.84	15.6	0.71	-	-
TripClick	4.37	1.49	24.19	24.69	47.25	29.86	0.37	77.48	245.09	4.48	12	605.64
MS MARCO	25.33	8.55	193.50	197.50	270.58	225.99	2.07	498.65	1345*	11.14*	12	809.16

Table 4: Comparison of memory consumption. * indicates the result is extrapolated.

user-perceived latency, Compass requires less than 10 MB, even for the largest dataset, MS MARCO.

While both baselines are single-round protocols, Compass requires multiple rounds per query. We justify this for two reasons: First, Compass aims to match the quality of plain text search, and the additional round-trip overhead adds less than one second, even in slower network settings. In high-latency networks, the number of round trips can be further reduced by tuning the search parameters at the cost of a minor accuracy loss. Second, our Speculative Neighbor Prefetch limits the increase in round trips as dataset size grows. For example, MS MARCO and TripClick require the same number of round trips, despite MS MARCO having 6× more entries.

Compass's server is network-bound, primarily used for storage and lightweight XOR operations. In our experiments on the LAION dataset, the server achieves 436 queries per second with 26% CPU utilization under a 32 Gbps bandwidth and 25 concurrent client threads continuously issuing requests.

6.3.3 Memory Consumption

We report the breakdown of memory consumption in Tab. 4. The second and third columns show the sizes of plaintext embeddings and the HNSW graph for reference. We report the server-side memory consumption under both malicious and semi-honest settings. On the server side, Compass requires 3.2–6.8× more memory compared to storing the embeddings and the graph in plaintext. The main overhead here comes from ORAM, as a certain amount of dummy blocks is necessary for a smaller stash and fewer reshuffles. On the client side, the memory overhead consists of three parts: quantized hints, ORAM-related states (including the position map, metadata, and cached tree-top), and the cached layers of the HNSW graph. The main contributors to client-side memory usage are the quantized hints and ORAM-related states. Since the graph size in HNSW decreases exponentially as we move up the layers, the memory overhead for caching these layers is minimal. The size of the quantized hints is approximately 1% of the size of the original embeddings. Among the ORAM-related structures, metadata accounts for 60–80% of the overhead. We think this is a reasonable trade-off as we save 2× round trips by caching it. For a large-scale dataset like MS MARCO, Compass requires approximately 500 MB of client memory. For smaller, user-scale datasets, memory consumption is below 100 MB. When client-side memory is limited, Compass can further reduce memory usage by caching fewer layers of the graph and ORAM tree or by using less accurate hints, at the cost of additional round trips and bandwidth to maintain search quality. Compared to Compass, HE-Cluster requires significantly more server-side storage due to the size of HE ciphertexts. For MS MARCO, it needs over 1 TB of memory, which exceeds the capacity of our server instance. As a result, we extrapolated its memory and communication cost. Inv-ORAM requires a lot less server-side memory. This is because instead of storing an embedding vector per document, it only needs to store the IDs of keywords per document. Since passage lengths in MS MARCO and TripClick are usually under 100 words, the storage overhead is smaller.

6.3.4 Insert & Delete

We now briefly discuss how Compass compares to two secure baselines on insert and delete. For HE-Cluster, inserting or deleting a document securely is difficult without streaming the entire dataset; otherwise it could reveal which cluster the document belongs to. In Inv-ORAM, the truncation used for search can also be applied to insertion, and therefore the latency is similar to the search shown in Fig. 6. Deleting a document requires fetching the full list of documents for each keyword, which is expensive. In the HNSW graph, deleting a document is typically done by finding the node and marking it as deleted, which takes a similar time as a search. Insertion works like a search but uses a different candidate list size. For example, with a candidate list size of 160, Compass can insert a document in 19.2 seconds over the slow network and 2.6 seconds over the fast network on the MS MARCO dataset. There is a trade-off between insertion time and search speed. Faster searches usually require more time during insertion to build a better graph by carefully connecting to the best neighbors.

6.4 Ablation Study

We perform an ablation study to evaluate our techniques across all datasets under the slow network. The results are summarized in Fig. 8. Our study consists of three sets of experiments, each focused on evaluating one of our techniques. For Directional Neighbor Filtering, we fix the size of spec-

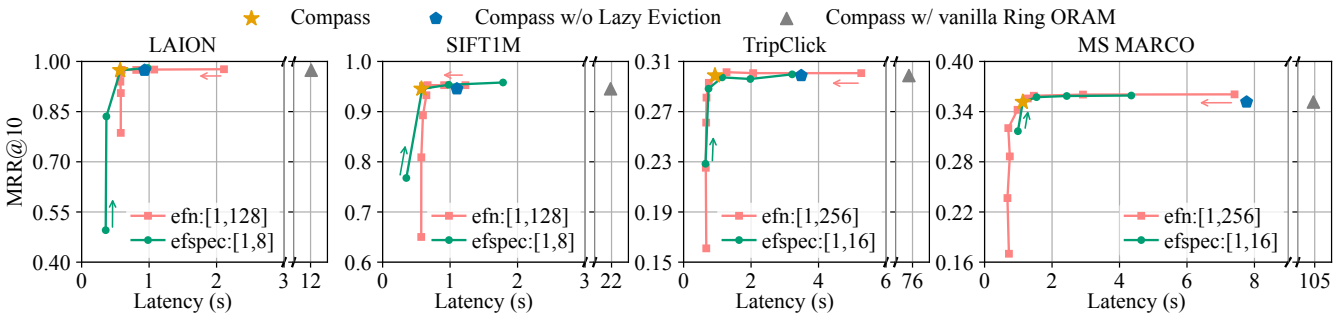

Figure 8: Ablation study on Compass's techniques. Each arrow denotes the direction of decreasing parameter values.

ulation set (*efspec*) to the value in Tab. 2 and vary the size of directional filter (*efn*), incrementally doubling it from 1 up to $2M$. Setting $efn = 2M$ disables this technique. Similarly, for Speculative Neighbor Prefetch, we fix the size of directional filter and vary the size of speculation set from 1 to twice its default value. When $efspec = 1$, Speculative Neighbor Prefetch is disabled. Finally, to evaluate Graph-Traversal Tailored ORAM, we first disable lazy eviction and then further disable batching. For each experiment, we compare the search quality and perceived latency against the default configuration specified in Tab. 2.

In Fig. 8, we observe that initially, a smaller *efn* reduces bandwidth usage by filtering irrelevant neighbors without compromising search quality. However, below a certain threshold, accuracy starts to drop significantly, and latency stops improving. This happens because relevant neighbors start being pruned, and bandwidth is no longer the bottleneck. A similar trend is observed for *efspec*. A very high *efspec* requires guessing more nodes prematurely during the search, leading to a greater impact on accuracy. In practice, the optimal *efn* and *efspec* can be determined by testing a small sample of queries after index construction, jointly with ef.

For Graph-Traversal Tailored ORAM, batching ORAM requests effectively reduces latency by 12–20×, due to far fewer round trips per query. Lazy eviction particularly benefits datasets like TripClick and MS MARCO, which have larger graph degrees and larger speculative sizes. These two datasets require accessing more paths per query, resulting in more frequent evictions if lazy eviction is disabled.

6.5 Comparison with Client-side Index

A strawman alternative to enable search over encrypted data is storing the entire index, including both the graph and embeddings, on the client device. In this setting, the server keeps a copy of the encrypted index, and the client initializes by downloading the entire encrypted index from the server. When the index is updated (e.g., through insertions or modifications), the client uploads these changes in encrypted form to the server. This allows other devices owned by the user, or the same device after disconnection (such as in a web setting), to retrieve the latest index. Uploading the entire new index for every update is expensive, so the client uploads only incremental changes and periodically merges these into a new (re-)encrypted index.

Compared to Compass, this approach allows faster queries after the client's initialization since all data is available locally. However, it requires large storage and memory on the client device, and it incurs a significant cold-start overhead to download the index. Such requirements affect its practicality, especially for users accessing the system via web or mobile devices. We empirically compare Compass with this alternative in terms of client storage and memory, as well as the communication costs associated with the first query.

Storage-wise, this approach requires the client to store the entire index. As shown in Tab. 4, this results in a 27–75× increase in client storage overhead compared to Compass. Moreover, efficient querying requires loading the entire index into memory. Such a large client storage requirement is problematic for mobile devices. According to recent surveys [122], mobile phones typically have around 384 GB of storage with 4 – 16 GB of RAM. Hosting a client-side index significantly restricts available storage and memory, limiting the number of applications users can run simultaneously during queries. Large datasets like MS MARCO, which requires 34GB of memory, cannot even fit directly into the RAM of typical mobile devices. While a separate line of research optimizes graph search between memory and storage [57, 113], it works best with at least several GB of memory.

In the web setting, the overhead of downloading the full index recurs whenever a user starts a new web session. To compare first-query costs, we initialize both systems without any client-side state, requiring each client to first download the state before executing a query. We report bandwidth and latency under the slow network in Tab. 5. For client-side indexing, the main overhead is downloading the index, and the latency increases to 12 minutes for MS MARCO. This initial connection delay is a significant disruption for users every time they have a new web session. In contrast, Compass achieves a consistently low latency of several seconds across all evaluated datasets. Moreover, client-side indexing incurs higher operational costs. For example, downloading the full MS MARCO index has an egress cost of $4.06, whereas Compass incurs only $0.058 for client states. The estimated

	Bandwidth		Latency	
	Client-Index	Compass	Client-Index	Compass
	GB	MB	(s)	(s)
LAION	0.24	6.23	5.2	0.73
SIFT1M	0.97	36.95	22.4	1.45
TripClick	5.84	83.49	121.7	2.84
MS MARCO	33.86	507.52	698.2	12.32

Table 5: Comparison of cold-start query communication cost and latency between Compass and client-side indexing.

cost in Compass (including compute and egress) is $0.01 per query. Each index download in the client-side approach is equivalent to roughly 375 queries in Compass.

Beyond these practical constraints, there are additional conceptual advantages for server-side indexing. First, as personal data volumes grow and embedding dimensions increase, the index will inevitably become too large for storage on any client device. With multimodal embedding models becoming increasingly powerful [127], users will likely include a broader variety of file formats beyond text and images. Furthermore, embedding dimensions are increasing to achieve better semantic understanding. For example, OpenAI's latest text-embedding-3-large model generates embeddings up to 3072 dimensions [89]. Second, according to a survey [27] of end-to-end encryption companies (for file storage, email, and chat), these companies preferred a server-side solution due to concerns about local resource consumption, limited web and mobile compatibility, and the difficulty of indexing large enterprise data volumes locally. In fact, Compass can be applied in the enterprise setting using the proxy model [23, 95, 107], where the company hosts an on-premise Compass client that enforces access control, while a remote server maintains the encrypted index and data.

7 Related Work

Lexical encrypted search: Searching over encrypted data has been a rich and fruitful line of work. Most existing work focused on lexical search, which generally delivers lower search quality compared to Compass. Furthermore, to achieve efficiency, many approaches reduce security in the following ways, whereas Compass does not make these compromises: ***i)*** Leaking access patterns [18, 19, 24, 50, 62, 67, 88, 114, 116], which can be exploited by leakage-abuse attacks [17, 55, 64, 74, 94, 96, 129]. ***ii)*** Assuming trusted hardware [5, 83, 118] that can be exploited by a wide range of side-channel attacks [16, 65, 124, 128]. ***iii)*** Assuming non-colluding servers or at least one trusted server [27, 28, 109].

Encrypted semantic search systems: Encrypted search over embeddings is a nascent line of work. HERS [36] uses FHE to perform a linear scan over embeddings, which results in a high overhead. Designed for the public database setting, Tiptoe [51] performs a more efficient linear scan over embeddings by crucially relying on the data at the server being public, so Tiptoe does not provide a solution for searching over encrypted data (nor for malicious security, integrity protection, and sublinear search) in contrast to Compass. Furthermore, Tiptoe's clustering technique reduces search quality, as discussed in §6. Pacmann [131] is a concurrent work, also designed for the public setting. Pacmann requires $O(\log N\sqrt{N})$ bandwidth and the client has to stream the entire database for preprocessing.

Other works attempt to build sublinear indices over embeddings, but sacrifice security. For example, the index traversal in [11, 132] is not privacy-preserving and leaks query information if the server has some knowledge about the plaintext. Preco [109], Riazi et al. [103], and Wu et al. [125] weaken security by relying on two non-colluding servers. Preco mentions the possibility of removing the non-colluding assumption by adopting a single-server PIR scheme but estimates that the resulting performance would become orders of magnitude slower.

Targeting at a different setting, SANNS [20] and Panther [70] combine several heavy-weight cryptographic tools, such as lattice-based homomorphic encryption, distributed oblivious RAM, and garbled circuits, for database privacy and therefore have higher performance overhead.

The line of work on ***secure inference*** [49, 52, 78, 82, 84, 91] is complementary to Compass; together, they can enable private Retrieval Augmented Generation (RAG) [69] on encrypted RAG data. RAG typically consists of nearest-neighbor retrieval in embedding space followed by model inference. Compass can be used for the retrieval part of RAG, and this line of work for the model inference part of RAG.

8 Conclusion

Compass is a search system over encrypted embedding data that achieves 1) comparable accuracy to the state-of-the-art search algorithm in plaintext, 2) strong security guarantees against malicious attackers, and 3) practical user-perceived latency at low server operation costs. Compass achieves these properties through a novel search index that co-designs the traversal of a graph-based ANN algorithm on top of Oblivious RAM via three techniques.

A Layer-wise Caching

Layer	3	2	1
LAION	-	1.8	3.19
SIFT1M	1.86	2.84	2.98
TripClick	1	1.99	2.78
MS MARCO	1.79	2.89	3.05

Table 6: Average number of search steps in each upper layer.

In HNSW, the upper-layer search uses a dynamic candidate list of size one, making it nontrivial to apply the Speculative Neighbor Prefetch directly. From the server's perspective, the memory footprint for upper-layer searches differs from that of the bottom layer. For security, it is necessary to set a separate bound for search steps in the upper layers when not all upper layers are cached locally.

To determine how many search steps in each layer are sufficient, we perform plaintext HNSW searches on the entire query set and collect the average number of search steps in each upper layer, as reported in Tab. 6. Layer 1 is the second-to-last layer. According to Tab. 6, the upper layers' search patterns are similar across all datasets, with an average of 1 to 3 steps per layer. Based on this observation and in order to reduce round trips, we empirically found that a single search step in the second-to-last layer is sufficient to maintain search quality when we cache all but the last two layers.

B ORAM Stash Size Analysis

In this section, we analyze how Compass's ORAM modification impacts stash size. Specifically, we are interested in two aspects of stash usage: the usage between queries and the peak usage during a query. The former helps us estimate memory usage when the Compass client is idle, and the latter indicates the maximum memory demand when processing a query. In the following analysis, we begin by proving the upper bound of Compass's ORAM stash usage between two queries and then analyzing the maximum stash growth during a query.

Now, we show that the stash usage of Compass after eviction can be bounded by the stash usage of the vanilla Ring ORAM. Assume that Compass's ORAM performs a lazy eviction every A' accesses. Let $\mathbf{s} := (\mathbf{a}, \mathbf{x}, \mathbf{y})$ be a sequence of ORAM accesses of size N, where $\mathbf{a} = (a_i)_{i=1}^N$ is the sequence of block addresses, $\mathbf{x} = (x_i)_{i=1}^N$ is the sequence of paths assigned to each address before the access, and $\mathbf{y} = (y_i)_{i=1}^N$ is the sequence of paths assigned to each address after the access. Without loss of generality, we assume that each a_i is unique, A' is a multiple of A, and N is a multiple of A'.

Theorem 2. *Let* $\mathsf{ORAM}_{\mathsf{Compass}}$ *and* $\mathsf{ORAM}_{\mathsf{Ring}}$ *be two ORAM instances with the same set of parameters (Z, S, A, and L).* $\mathsf{ORAM}_{\mathsf{Compass}}$ *is instantiated using Compass's ORAM protocol with a lazy eviction every A' accesses.* $\mathsf{ORAM}_{\mathsf{Ring}}$ *is instantiated with the vanilla Ring ORAM protocol. Let* $\mathsf{st}(\mathsf{ORAM}, \mathbf{s})$ *represent the stash usage. For a given* $\mathbf{s}$*,*

$$\mathsf{st}(\mathsf{ORAM}_{\mathsf{Compass}}, \mathbf{s}) \leq \mathsf{st}(\mathsf{ORAM}_{\mathsf{Ring}}, \mathbf{s}) \tag{3}$$

Following the definition of ∞-ORAM in Ring ORAM, we define $\mathsf{ORAM}^{\infty}_{\mathsf{Compass}}$ as an ORAM that has the same structure as $\mathsf{ORAM}_{\mathsf{Compass}}$, but with infinite bucket size. Similarly, we define $\mathsf{ORAM}^{\infty}_{\mathsf{Ring}}$. We reuse the algorithm G from Ring ORAM as the post-processing algorithm for both $\mathsf{ORAM}^{\infty}_{\mathsf{Compass}}$ and $\mathsf{ORAM}^{\infty}_{\mathsf{Ring}}$.

Lemma 1. *The stash usage of* $\mathsf{ORAM}^{\infty}_{\mathsf{Compass}}$ *after post-processing shares the same randomness as* $\mathsf{ORAM}_{\mathsf{Compass}}$ *after the same access sequence* $\mathbf{s}$*.*

Proof. We notice that delayed eviction can alternatively be viewed as a vanilla Ring ORAM with an increased eviction rate (larger means less frequent) and multiple paths selected per eviction. Ring ORAM's proof of Lemma 1 can be applied directly here to show that such equivalence also holds between $\mathsf{ORAM}_{\mathsf{Compass}}$ and $\mathsf{ORAM}^{\infty}_{\mathsf{Compass}}$ after post-processing. □

Let $\mathsf{h}(\mathsf{ORAM}^{\infty}, a_i)$ be the height of the bucket at which block a_i is stored in ORAM^{∞} after the execution of $\mathbf{s}$.

Lemma 2. *For any* $a_i \in \mathbf{a}$*, we have*

$$\mathsf{h}(\mathsf{ORAM}^{\infty}_{\mathsf{Compass}}, a_i) \leq \mathsf{h}(\mathsf{ORAM}^{\infty}_{\mathsf{Ring}}, a_i) \tag{4}$$

Proof. We know that in Ring ORAM:

$$\mathsf{h}(\mathsf{ORAM}^{\infty}_{\mathsf{Ring}}, a_i) = \mathsf{LCB}(\{p_i\}, \{y_i\}) \tag{5}$$

, where p_i is path selected in the later eviction operation covering the access of a_i and $\mathsf{LCB}(\cdot,\cdot)$ represents the height of the lowest common bucket of two input path sets. Similarly, in Compass, we have:

$$\mathsf{h}(\mathsf{ORAM}^{\infty}_{\mathsf{Compass}}, a_i) = \mathsf{LCB}(P_i, \{y_i\}) \tag{6}$$

, where P_i is the *set* of paths selected during the lazy eviction covering access of a_i. Since $p_i \in P_i$, the height of the lowest common bucket between P_i and y_i is at most $\mathsf{LCB}(\{p_i\}, \{y_i\})$. Therefore, Lemma 2 holds. □

Similar to Ring ORAM, we define T as a rooted subtree of ORAM^{∞}. A rooted subtree includes the root of the ORAM tree, and if a node belongs to T, all its ancestors must also be in T. We define $X_{Compass}(T)$ as the number of real blocks stored in T in Compass ORAM and $X_{Ring}(T)$ as the number of real blocks stored in T in Ring ORAM.

Lemma 3. *If Lemma 2 holds, we have*

$$\forall T, X_{Compass}(T) \leq X_{Ring}(T) \tag{7}$$

Proof. For a block a_i, let $\hat{\mathsf{b}_i}$ be the bucket in $\mathsf{ORAM}^{\infty}_{\mathsf{Compass}}$ that contains a_i and b_i be the bucket in $\mathsf{ORAM}^{\infty}_{\mathsf{Ring}}$ that contains a_i. From Lemma 2 we know that either $\hat{\mathsf{b}_i}$ and b_i are in the same position or b_i is an ancestor of $\hat{\mathsf{b}_i}$. By the definition of T, we know that for any node in T, its ancestors must be in T. However, descendant nodes are not necessarily included. If a block is in T in $\mathsf{ORAM}^{\infty}_{\mathsf{Ring}}$, it might not be in T in $\mathsf{ORAM}^{\infty}_{\mathsf{Compass}}$. Therefore, the number of real blocks in T in $\mathsf{ORAM}^{\infty}_{\mathsf{Compass}}$ is less than or equal to the number of real blocks in T in $\mathsf{ORAM}^{\infty}_{\mathsf{Ring}}$. □

Proof. Finally, it has been shown in Ring ORAM that the stash size exceeds R if and only if there exists a T where the number of real blocks in T is larger than $c(T)+R$, with $c(T)$ defined as the maximum number of blocks T can hold in a non-∞ ORAM. With Lemma 3, we can conclude that the stash usage in Compass ORAM is bounded by that of Ring ORAM. Therefore, Theorem 2 holds. □

After showing the stash usage bounds between queries, we now estimate the extra stash usage during a query. Each Compass query includes a sequence of batched ReadPath operations, followed by a single EvictPath operation. In each ReadPath operation, at most one real block is read from the server into the stash. After the batched ReadPath operations, the stash contains at most $ef \cdot efn$ new blocks. Unlike Ring ORAM, Compass evicts multiple paths simultaneously instead of one. The number of eviction paths is calculated by dividing the paths accessed during ReadPath operations by the eviction rate A, giving $\lceil \frac{ef \cdot efn}{A} \rceil$ paths. During eviction, the client reads Z blocks for each bucket on the selected paths. After reading selected paths, the stash grows by at most $\lceil \frac{ef \cdot efn}{A} \rceil \cdot Z \cdot L + ef \cdot efn$, where L is the number of levels in the ORAM tree. Following this analysis, the extra stash overhead is approximately 80MB on MS MARCO with the evaluation configuration. The actual overhead is smaller because paths share buckets, and not all buckets are full.

C Security Proof

In this section, we provide a formal treatment of the security of Compass. Our proof strategy is to consider two security games that are the original security game with only one of the adversary winning conditions and prove that an adversary cannot fulfill each condition separately more than the threshold allowed. Proving these two statements suffices to prove our theorem in our setting.

In this proof, as we demonstrated in §B, we assume that the main memory is sufficient for the stash during the execution of the protocol. For simplicity, our proof focuses on Compass's protocol within a single layer.

C.1 Condition 1

We begin by proving that the probability of the adversary winning under condition 1 is less than half plus negligible. Our strategy is to show that what the adversary observes when $b=0$ is computationally indistinguishable from what they observe when $b=1$. In the following proof, we omit the execution trace caused by the EarlyReshuffle operations. This is because the adversary knows exactly how many times a bucket has been accessed and therefore when and where EarlyReshuffle happens is public information.

First, we define what the adversary can observe during the game. During the security game, the challenger executes a sequence of queries:

$$Q_b = (q_{1,b}, q_{2,b}, ..., q_{i,b}, ...) \tag{8}$$

Let $O_{i,b}$ be the sequence of ORAM operations for the query $q_{i,b}$. According to Compass's protocol, each query consists of a sequence of batched access operations and an eviction operation at the end. Let m be the number of batches in a query, and we have:

$$O_{i,b} = \mathsf{op}_{\mathsf{access}}(B_1^{i,b}, s_1^{i,b}), ..., \mathsf{op}_{\mathsf{access}}(B_m^{i,b}, s_m^{i,b}), \mathsf{op}_{\mathsf{evict}}, \tag{9}$$

where $\mathsf{op}_{\mathsf{access}}(B_j^{i,b}, s_j^{i,b})$ represents the jth batch access operation of a set of blocks $B_j^{i,b}$ with padding requirement to size $s_j^{i,b}$, and $\mathsf{op}_{\mathsf{evict}}$ represents the eviction operation. Note that $B_j^{i,b}$ is the set of blocks requested by the search algorithm from the ORAM controller, not the set of blocks read by the controller from the remote server. For each block in $B_j^{i,b}$, the controller first checks the position map to find the path assigned to the block. It then looks at the metadata of the buckets along this path to find the block's offset in each bucket. A total of $\lceil \frac{\sum_{j=1}^{m} s_j^{i,b}}{A} \rceil$ paths are selected for eviction in reverse-lexicographic order. From each bucket on these paths, exactly Z blocks are read, and the non-dummy blocks are stored in the stash. Next, all buckets on these paths are updated with newly evicted blocks from the stash, padded with dummies, shuffled, and written back to the server.

Let $P_j^{i,b}$ be the *list* of paths for each block in $B_j^{i,b}$. This is a list because path assignments between blocks may collide. If $|B_j^{i,b}| < s_j^{i,b}$, $P_j^{i,b}$ includes additional randomly selected paths for padding so that $|P_j^{i,b}| = s_j^{i,b}$. Let $P_{evict}^{i,b}$ be the set of paths selected as eviction targets during $\mathsf{op}_{\mathsf{evict}}$, and $\mathcal{T}_{i,b}$ be the trace (or memory footprint) observed by the adversary for query $q_{i,b}$. We have

$$\begin{aligned} \mathcal{T}_{i,b} = {} & \mathsf{t}_{\mathsf{read}}(P_1^{i,b}), ..., \mathsf{t}_{\mathsf{read}}(P_m^{i,b}), \\ & \mathsf{t}_{\mathsf{evict_read}}(P_{evict}^{i,b}), \mathsf{t}_{\mathsf{evict_write}}(P_{evict}^{i,b}) \end{aligned} \tag{10}$$

Here $\mathsf{t}_{\mathsf{read}}(P_j^{i,b})$ means that for each path in $P_j^{i,b}$, one valid block is read from each bucket on the path. The subtlety here

is that if a bucket is part of multiple paths in $P_j^{i,b}$, it is read multiple times. For example, all paths share the root bucket. The Ring ORAM protocol ensures that different blocks are read from the bucket each time. $\mathsf{t}_{\mathsf{evict_read}}(P_{evict}^{i,b})$ means that for each bucket on paths in $P_{evict}^{i,b}$, exactly Z blocks are read, no matter how many paths this bucket belongs to. Similarly, $\mathsf{t}_{\mathsf{evict_write}}(P_{evict}^{i,b})$ writes $Z+S$ blocks (a new full bucket) to each bucket on the paths in $P_{evict}^{i,b}$.

Having defined what the adversary can observe during the game, we now prove that the following lemma holds for Compass.

Lemma 4. *For any pair of $q_{i,0}$ and $q_{i,1}$, if they are of the same type, Compass ensures the corresponding traces $\mathcal{T}_{i,0}$ and $\mathcal{T}_{i,1}$ are of **the same structure**.*

Before we prove this lemma, we first introduce the definition of **the same structure**.

Definition 1. *Two traces are structurally the same if they have*

- *the same number of operations*
- *the same type of operation at the same positions*
- *the same number of paths operated by the operation at the same positions*
- *the same number of blocks read from each bucket*

For example, consider a binary tree with 8 paths, which is labeled from 0 to 7, and the following 5 example traces:

$$\begin{aligned}
&\mathcal{T}_1 : \mathsf{t}_{\mathsf{read}}([1,2]), \mathsf{t}_{\mathsf{evict_read}}(\{3,4\}), \mathsf{t}_{\mathsf{evict_write}}(\{3,4\})\\
&\mathcal{T}_2 : \mathsf{t}_{\mathsf{read}}([1,2]), \mathsf{t}_{\mathsf{evict_read}}(\{3,4\})\\
&\mathcal{T}_3 : \mathsf{t}_{\mathsf{read}}([1,2]), \mathsf{t}_{\mathsf{evict_write}}(\{3,4\}), \mathsf{t}_{\mathsf{evict_write}}(\{3,4\})\\
&\mathcal{T}_4 : \mathsf{t}_{\mathsf{read}}([1,2,3]), \mathsf{t}_{\mathsf{evict_read}}(\{3,4\}), \mathsf{t}_{\mathsf{evict_write}}(\{3,4\})\\
&\mathcal{T}_5 : \mathsf{t}_{\mathsf{read}}([3,4]), \mathsf{t}_{\mathsf{evict_read}}(\{5,6\}), \mathsf{t}_{\mathsf{evict_write}}(\{5,6\})
\end{aligned} \tag{11}$$

If we take $\mathcal{T}_1$ as a reference, among $\mathcal{T}_2$ to $\mathcal{T}_5$, only $\mathcal{T}_5$ is considered to have the same structure as $\mathcal{T}_1$. $\mathcal{T}_2$ has a different length compared to $\mathcal{T}_1$. The second operation in $\mathcal{T}_3$ is a $\mathsf{t}_{\mathsf{evict_write}}$ while the second operation in $\mathcal{T}_1$ is a $\mathsf{t}_{\mathsf{evict_read}}$. $\mathcal{T}_4$ has the same length and operation sequence as $\mathcal{T}_1$. However, the first operation in $\mathcal{T}_4$ operates on 3 paths while the first operation in $\mathcal{T}_1$ operates on 2 paths.

Proof. Now we start the proof for Lemma 4. Take a search query as an example. As shown in Algorithm 1, a search consists of n iterations (line 5) and each iteration contains one batch access (line 14). Therefore, for each search request, the number of operations in the trace is $n+2$, with the extra 2 coming from the eviction. Since n is initialized with $\lceil ef/efspec \rceil$, the number of operations in the trace is fixed for a given set of parameters param. The trace always starts with n $\mathsf{t}_{\mathsf{read}}$ at the beginning and ends with one $\mathsf{t}_{\mathsf{evict_read}}$ and one $\mathsf{t}_{\mathsf{evict_write}}$. Next, we need to show that the number of paths accessed is the same for the same position. For each batch access, the number of requested blocks is padded to a fixed size of t (line 12 - 14), defined as $efspec \cdot efn$. Similarly, the final eviction always operates on $\lceil \frac{n \cdot t}{A} \rceil$ paths. Finally, we show that the same number of blocks is read from each bucket, which follows directly from the Ring ORAM's construction. Therefore, Lemma 4 holds. □

After knowing that $\mathcal{T}_{i,0}$ and $\mathcal{T}_{i,1}$ are structurally the same, we need to show the paths involved during a query, and the blocks we read from each bucket do not reveal any information. This comes directly from the original Ring ORAM construction. The path selected for $\mathsf{t}_{\mathsf{read}}$ appears random to the adversary because the path assignments are chosen uniformly at random. Eviction paths follow a fixed, reverse-lexicographic order, which is both public and static. Each bucket is randomly shuffled before being written back to the server, and any block that has been read becomes invalid until the next reshuffle. Therefore the adversary learns nothing from the position of blocks we read from each bucket.

The final step in our proof here is to invoke the security guarantees of the IND-CCA2 encryption scheme. For each pair of requests $q_{i,0}$ and $q_{i,1}$, the corresponding traces, $\mathcal{T}_{i,0}$ and $\mathcal{T}_{i,1}$, are computationally indistinguishable to the adversary. By the definition of our security games, if the challenger does not abort, Q_0 and Q_1 must have the same length and identical query types at corresponding positions. As a result, the execution trace of Q_0 is computationally indistinguishable from the execution trace of Q_1. Therefore, the adversary's probability of winning condition 1 is no better than random guessing, namely less than half plus a negligible.

C.2 Condition 2

We then show that the probability of the adversary winning in condition 2 is negligible.

Lemma 5. *Assuming that the underlying hash function $\mathcal{H}$ is collision-resistant, then the probability of the adversary winning through condition 2 is negligible.*

Proof. In Compass's protocol, the server operates as remote storage, either sending the client blocks at requested locations or updating its local storage based on the client's messages. Excluding the scenario where the server becomes unresponsive, the only way the server can deviate from the protocol is by sending the client an altered bucket's content. To ensure the integrity and freshness of the buckets that the client reads from the server, Compass uses a Merkle Tree built from collision-resistant hash functions. By the definition of collision-resistance hash functions, the probability of finding two different inputs that produce the same hash output is negligible. It is already well-proven by prior works that a Merkle Tree built with such hash functions ensures data integrity and the probability for an adversary to change the data in a way that the root hash remains the same is negligible.

Although Compass uses an HNSW graph as the underlying data structure rather than a tree, Compass ensures that each node's data, including the coordinates and neighbor list, is stored inside one of the buckets that form a binary tree on the server side. Therefore, the properties of the Merkle hash tree apply directly, which means that the probability of the server successfully forging a response that passes the client's integrity check is negligible. □

Weave: Efficient and Expressive Oblivious Analytics at Scale

Mahdi Soleimani

Anurag Khandelwal
Yale University

Abstract

Many distributed analytics applications offloaded to the cloud operate on sensitive data. Even when the computations for such analytics workloads are confined to trusted hardware enclaves, and all stored data and network communications are encrypted, several studies have shown that they are still vulnerable to access pattern attacks. Prior efforts to prevent access pattern leakage often incur network and compute overheads that are logarithmic in dataset size while also limiting the functionality of supported analytics jobs.

We present Weave, an efficient, expressive, and secure analytics platform that scales to large datasets. Weave employs a combination of noise injection and hardware memory isolation to reduce the network and compute overheads for oblivious analytics to a constant factor. Weave also employs several optimizations and extensions that exploit dataset and workload-specific properties to ensure performance at scale without compromising functionality. Weave reduces the end-to-end execution time for a wide range of analytics jobs on large real-world datasets by 4–10× compared to prior state-of-the-art while providing strong obliviousness guarantees.

1 Introduction

Public cloud platforms are increasingly used for storing and processing large volumes of data through distributed analytics frameworks [1–5]. MapReduce (MR) frameworks [1–3], in particular, ensure flexibility, efficiency, and scalability for analytics workloads but raise security concerns since they require trusting the cloud provider with sensitive data.

Ensuring data confidentiality requires protecting the data at rest (*e.g.*, on persistent storage), in flight over the network, and during processing. Early solutions [6, 7] addressed the first two requirements via authenticated encryption, and the third with trusted hardware enclaves (*e.g.*, Intel SGX [8], ARM TrustZone [9] and AMD SEV-SNP [10]). However, recent works [11, 12] have shown that such systems can still reveal sensitive information via *memory and network access pattern leakage*. Specifically, during the execution of map-reduce jobs, the volume of network traffic between pairs of workers (i.e., mappers and reducers) and the memory access patterns at each worker depends on the distribution of data items in the input dataset. An honest-but-curious adversary observing such access patterns can often identify individual data items even when all traffic is encrypted. As such, confidentiality requires secure MR frameworks to ensure these access patterns are *data oblivious*.

While data confidentiality is important for applications operating on sensitive data, security guarantees should not come at the cost of the expressiveness of MR frameworks or their performance at scale. We identify three main goals for secure MR frameworks:

- Strong security, including data confidentiality and protection against access pattern attacks, i.e., *obliviousness*.
- Minimal performance overheads compared to an insecure execution, especially at scale, i.e., for larger dataset sizes and with many distributed workers.
- Little to no restrictions on functionality, i.e., on the types of supported Map and Reduce functions.

We introduce a novel security definition to capture access pattern attacks on distributed analytics platforms by an honest-but-curious adversary in the cloud. The definition, named Indistinguishability under Chosen Dataset and Job Attack (or IND-CDJA, §2.2), informally requires that the distribution of network communications between workers and memory accesses inside workers observed during the execution of a secure MR framework is independent of the distribution of data items in the underlying input dataset. While this security requirement introduces a (provably) hard trade-off between arbitrary MR functionality and bounded performance overheads achievable by *any scheme* (§2.3), a practical assumption on the intermediate data generated by MR jobs (similar to prior works in this space [11, 12]) permits bypassing this tradeoff to achieve bounded overheads.

Unfortunately, existing approaches for mitigating access

pattern leakage in MapReduce frameworks either limit functionality beyond the assumptions required by IND-CDJA, incur high performance overheads, or both, to achieve security (§2.4). These approaches fall into two categories — sort-based (*e.g.*, Opaque [12]) and load-balancing (*e.g.*, Shuffle & Balance [11]). While those in the former category rely on cryptographic schemes like oblivious sort [13], those in the latter rely on oblivious shuffle [14]. Unfortunately, both schemes have well-known log-linear complexity, which translates to significant performance overheads in practice — often increasing the end-to-end job execution times by an order of magnitude or more than an insecure baseline (§5). Moreover, both approaches limit functionality beyond what is required to achieve obliviousness: the former on non-associative operations [12], and the latter on sort-based analytics [11].

We present Weave, an oblivious MapReduce framework that meets all three goals for secure analytics. Weave uses the load balancing approach as a starting point for network obviousness, but leverages principles of *noise-injection* explored in the context of oblivious storage systems [15–19] to achieve *constant* factor ($\sim 3\times$ or lower) overheads. Unlike prior approaches that employ data-agnostic shuffle mechanisms, our performance gains stem from Weave exploiting the distribution of data in the input dataset itself (§3). Specifically, Weave's shuffle phase estimates this distribution during execution and uses it to inject just enough "fake" network traffic so that the observable access pattern between pairs of workers is independent of the underlying distribution, i.e., network communications are *data oblivious*. Indeed, we show that Weave achieves the lowest network overhead achievable by any noise-injection scheme for oblivious communications in MapReduce frameworks. We also show that while the data structures employed by our noise injection mechanism can introduce memory access pattern leakage, judicious use of hardware-protected Enclave Page Cache (EPC) can avoid them with little to no overhead. We develop further optimizations and extensions to Weave that exploit dataset and workload-specific properties to improve its performance at scale and ensure rich functionality.

We show that Weave is secure under IND-CDJA, achieving strong security guarantees with obliviousness even with constant performance overheads (§4). We implement Weave atop Apache Spark [2] and evaluate it on several real-world workloads. Weave's execution times for these workloads is 4–10$\times$ lower than state-of-the-art systems with comparable security guarantees. Moreover, its performance scales linearly with dataset size and the number of workers (§5). The code for Weave, the datasets, and workloads used in our evaluation are available at `https://github.com/yale-nova/weave`.

2 Background and Motivation

We begin by outlining the secure MapReduce execution and threat model and demonstrating how sensitive information is leaked via network and memory access patterns even when the data is encrypted. We then discuss shortcomings of prior strategies in navigating the fundamental performance-functionality tradeoff in secure MapReduce execution.

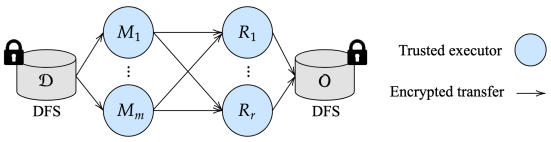

Fig. 1: **System model for secure MapReduce execution.** Tasks run in TEEs while data is encrypted in flight and at rest.

2.1 Secure Analytics Execution

We consider the secure execution of analytics jobs on a cloud-hosted MapReduce (MR) platform [1–3], as depicted in Figure 1. The MR platform reads and writes data from a cloud-hosted Distributed File System (DFS) [20, 21]. The client uploads an encrypted dataset D containing n equally-sized key-value pairs[1] to the DFS and submits a job to be executed on D using the MR framework. The MR framework runs the computations required for the job in secure enclaves — trusted containers of code and data isolated from the rest of the system — to ensure data confidentiality [6, 11, 12]. Data is only decrypted within the enclaves and re-encrypted before network communications and other I/O operations.

MR Job execution. An MR job is specified using a pair of map and reduce functions $(\mathsf{Map}, \mathsf{Reduce})$. Map takes a key-value pair as input and outputs a list of intermediate key-value pairs. Reduce takes as input an intermediate key and a set of values for that key. It combines these values using user-specified logic to output a new set of values.

MR frameworks comprise a centralized controller and multiple distributed workers. The controller receives job requests and schedules their execution across the workers in three sequential phases: map, shuffle, and reduce. In the map phase, the input dataset is divided into m splits, and a distinct worker ("mapper") processes each split in parallel. Each mapper executes Map on every key-value pair in their split to generate the intermediate key-value pairs. Next, the shuffle phase regroups mapper-generated intermediate key-value pairs into r partitions based on the intermediate key. The partitioning function (*e.g.*, hash or range-based) ensures that intermediate values with the same key are grouped into the same partition. Each partition is then processed in parallel by a distinct worker ("reducer") in the reduce phase, where each reducer executes Reduce on groups of values with the same intermediate key.

Threat Model. Similar to prior work on secure MR execution [6, 11, 12], we consider an honest-but-curious adversary that monitors the data at rest, the accesses to encrypted

[1] While plaintext datasets can have variably-sized records, we assume encryption pads them to the same size to avoid leaking record sizes [12].

memory pages inside MR workers, and the network communications between MR workers — the cloud provider is a typical example of such an adversary. We next detail the key components and assumptions of our threat model:

- **Computations.** All computations (*e.g.*, Map, Reduce executions) are assumed to run within Trusted Execution Environments (TEEs). TEEs provide attestation mechanisms so the adversary cannot deviate from the MR protocol. Moreover, the adversary cannot observe computations performed within the TEE.
- **Memory access patterns.** While memory access patterns within the TEE are generally visible to an adversary, each TEE is equipped with a small amount of Enclave Page Cache (EPC) [22] which ensures memory obliviousness, i.e., hides access patterns to data placed within them from the adversary. We defer the details of EPC security guarantees and their practical implementation to §3.3 and §3.6.
- **Network access patterns.** The adversary can observe worker communications (i.e., the size of traffic communicated between worker pairs) throughout a job's execution.
- **Data and code.** While the data handled by the MR framework is always encrypted at rest and in flight, the adversary can observe the size of the input dataset, the code for the functions Map and Reduce, and the allocation of datasets to workers. Polynomial-time computations can be performed on the above data to extract information about the underlying dataset.
- **Other side-channels.** Weave assumes enforced attestation and access control (*e.g.*, Azure CVMs [23, 24]), which constrain the attack surface and make sophisticated attacks (*e.g.*, hardware side-channel or physical access attacks) infeasible in practical cloud deployments [25]. Time and per record size difference channel attacks are out of Weave's scope. We discuss these channels further in §6.

Although secure analytics execution outlined above ensures that data is never stored or processed in plaintext during job execution, prior work [11, 12] has shown that worker communication patterns can still reveal sensitive data to an honest-but-curious adversary, as we detail next.

2.2 Access Pattern Leakages

Even in secure MapReduce frameworks, the communication patterns between workers for a given job can be related to the contents of the encrypted input, which an adversary can leverage to learn sensitive information about the input. We characterize this leakage using a simple MR job on chronologically ordered patient datathat counts cases per disease:

Map(patientID, (disease, date)):	Reduce(disease, $\{c_1, c_2, \cdots, c_j\}$):
Emit (disease, 1)	Emit (disease, $\sum c_i$)

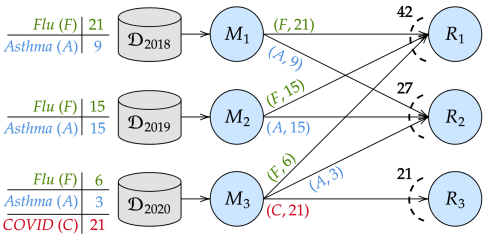

Fig. 2: **Example detailing mapper-to-reducer communication volume for an analytics job execution over medical records (§2.2).** The execution suffers from both split- and distribution-based leakage.

In the above job, Map extracts the disease and case count per record, and Reduce aggregates all case counts for a disease.

Figure 2 shows the access pattern leakage when executing this query on a medical dataset of patient records. We assume that the adversary knows the nature of the input: chronologically ordered medical records from 2019–2021, and wants to correctly label the communicated records between specific mapper-reducer pairs with the associated disease.

Split-based leakage. The set of intermediate key-value pairs generated by different mappers is often tied to how the key-value pairs may have been divided across input splits of the dataset. Since mappers split the chronologically ordered data, only some of the mappers' (M_3 in Figure 2) splits contain COVID-19 records, as cases were only diagnosed after 2019. While the adversary may not know which mappers will process COVID-19 cases, it knows that only a few mappers will process them. Since MapReduce semantics require all COVID-19 records to be processed on the same reducer, the adversary can identify which records correspond to COVID-19 cases based on the distinct communication pattern between mappers and reducers. Specifically, by noting that reducer R_3 receives records only from mapper M_3, even when all communications are encrypted, an observer can deduce that R_3 is most likely processing COVID-19 records.

Distribution-based leakage. The distribution of key-value pairs across reducers is tied to the distribution of intermediate keys generated during the map phase. If the adversary in Figure 2 knows the relative frequency of disease cases, then it can identify patients' diseases based on the number of records received by each reducer, *e.g.*, knowing Flu is $\sim 1.5\times$ more frequent than Asthma, the adversary can deduce that records sent to R_1 are for Flu, and those sent to R_2 are for Asthma.

In both examples, the adversary leverages public knowledge about the dataset to infer information about records sent between mapper-reducer pairs. While our examples are simplified for elucidation, prior work has shown that such attacks, combined with other side channels, can accurately reconstruct sensitive fields like age, marital status, and birthplace for individuals in US census data [11].

IND-CDJA. To capture the security of a MR framework

against such access pattern leakage-based attacks, we introduce a formal notion of security: Indistinguishability under Chosen Dataset and Job Attack or IND-CDJA. While we defer formal security definitions to §4, informally, a system is secure under IND-CDJA if the adversary cannot distinguish between the execution of a MR job on two different datasets of the same input size. In the context of access pattern leakage, the adversary cannot correlate the observed patterns of memory access inside workers and network communications among workers during execution to the distribution of data in the underlying private input dataset, i.e., an IND-CDJA-secure system ensures that the data distribution in the input (private) is independent of the access patterns (observable).

2.3 Performance-Functionality Tradeoff

A secure MR framework should support three main properties (§1): (i) *security* under IND-CDJA, (ii) *minimal performance overheads* relative to an insecure execution, and, (iii) minimal restrictions on *functionality*, i.e., the jobs that the framework can support. Unfortunately, IND-CDJA security exposes a hard tradeoff between functionality and the performance overheads that must be incurred to achieve this security:

Theorem 2.1 *No* IND-CDJA*-secure scheme can support arbitrary* MapReduce *jobs with bounded bandwidth overheads.*

Proof. Consider a MapReduce job, where the map function emits C intermediate key-value pairs ($C > 1$) if it encounters a particular key k^* and outputs one key-value pair otherwise. It is easy for an adversary to distinguish between two executions of the job, one on a dataset D^* that contains k^* and the other on a dataset D that does not (note, $|D^*| = |D| = n$). Specifically, while D^* causes $C+n-1$ intermediate key-value pairs to be exchanged between mappers and reducers, D results in n key-value pairs being exchanged.

To make the two executions indistinguishable, an IND-CDJA-secure must ensure both executions exchange *at least* $C+n-1$ records; exchanging fewer records will cause the output of the first execution (on D^*) to be incorrect. In other words, the bandwidth overhead of an IND-CDJA-secure scheme is *at least* $\frac{C+n-1}{n}$. However, since C can be arbitrarily large (*i.e.*, $C \to \infty$), the bandwidth overhead of an IND-CDJA-secure scheme will also be unbounded. ■

We note that the unbounded overhead in our proof's counterexample stems from the map function's ability to generate *arbitrary* number of intermediate key-value pairs. If the number of intermediate key-value pairs generated by a map function, c, is upper-bounded to a fixed constant C, then an IND-CDJA-secure scheme could achieve bounded performance overheads. Indeed, prior works in this space [11, 12] implicitly assume a bound C and achieve security that is semantically similar to IND-CDJA[2]. While we will discuss how prior approaches support $c = 1$ soon, we summarize their approach to supporting $c \neq 1$ below.

$c < 1$. These are common jobs that *filter* a subset of the dataset using some predicate. A simple approach for supporting such operations in an IND-CDJA-secure scheme is for Map to output exactly one intermediate key-value pair for every input record but append a 'valid' bit to the output. This approach requires the Reduce function to ignore invalid key-value pairs but always ensures $\hat{n} = n$ and allows IND-CDJA-secure to support this class with the same property as the $c = 1$ case.

$c > 1$. Theorem 2.1's proof leveraged a Map function in this class. With an upper-bound C on c, a secure scheme can add "filler" key-value pairs to the Map outputs (with invalid bits) to ensure exactly C intermediate key-value pairs per input record. Again, the Reduce function filters invalid key-value pairs. An adaptation of IND-CDJA-scheme for the $c > 1$ case can achieve bounded bandwidth, albeit with an additional $\frac{C}{c_{avg}}\times$ overhead, where c_{avg} is the average Map output size.

We provide a detailed analysis of various operations supported by MapReduce schemes, SQL frameworks built atop them, and typical MapReduce patterns that use them, along with the value of c they use in the full version of our paper [26]. Our key takeaway is that commonly used operations and application patterns employ ($c \leq 1$), which can be supported with low overheads (§3). Since the approach for supporting all of the above cases reduces to an IND-CDJA-secure scheme that can support $c = 1$, we restrict our focus to the $c = 1$ case (with $\hat{n} = n$) for the rest of the paper, unless explicitly mentioned.

2.4 Prior Approaches

Prior schemes for mitigating access pattern leakage in MR frameworks employ security semantically similar to IND-CDJA, and are either sort- or load-balancing-based.

Sort-based schemes use oblivious sort algorithms [13, 27] for intermediate key-value pairs exchanged between map and reduce phases. As a result, each reducer receives an equally sized contiguous segment of the sorted intermediate key-value pairs. Unfortunately, practical realizations of oblivious sort in MR frameworks suffer from two main shortcomings. First, they incur high compute and network overheads. Opaque [12], a representative sort-based approach, employs column-sort [13], which requires several rounds of processing and network shuffles, often resulting in long execution times (§5). Second, the use of oblivious sort makes the support for non-associative Reduce (*e.g.*, median) non-trivial. As such, systems like Opaque only support associative Reduce (*e.g.*, count), limiting functionality beyond the minimum restrictions for IND-CDJA-secure approaches.

Load-balancing schemes prevent distribution-based leakage by assigning equal numbers of intermediate key-value pairs to reducers. To this end, intermediate key-value pairs

[2] Details on differences in security guarantees are deferred to §4.

generated by mappers are first bin-packed using a first-fit decreasing approach [28] across reducers (with random assignment of bins to reducers). Then, all bins are padded to the same size, which depends on the frequency of the most popular intermediate key. To avoid split-based leakage, these approaches require the dataset to be obliviously shuffled before the map phase, *e.g.*, Shuffle & Balance [11], a representative load-balancing approach, uses Melbourne shuffle [14]. Unfortunately, these schemes also observe two shortcomings. First, while bin-packing is more efficient than oblivious sort (both in theory and in practice), oblivious shuffle observes log-linear network complexity [14, 29] and still presents a performance bottleneck (§5). Second, the bin-packing approach assigns intermediate key-value pairs to reducers based on key frequencies, obviating support for sort-based or any user-defined partitioning function — again, imposing more restrictions on functionality than an IND-CDJA-secure scheme must.

Other approaches include differential obliviousness [30, 31] and secure multi-party computations [32]. Although the former approach incurs overheads comparable to Weave, it employs significantly weaker security and remains susceptible to practical attacks like Figure 2's example. The latter approach, unfortunately, incurs impractically high performance overheads, making them unsuitable for MapReduce frameworks. We do not consider these approaches in our work.

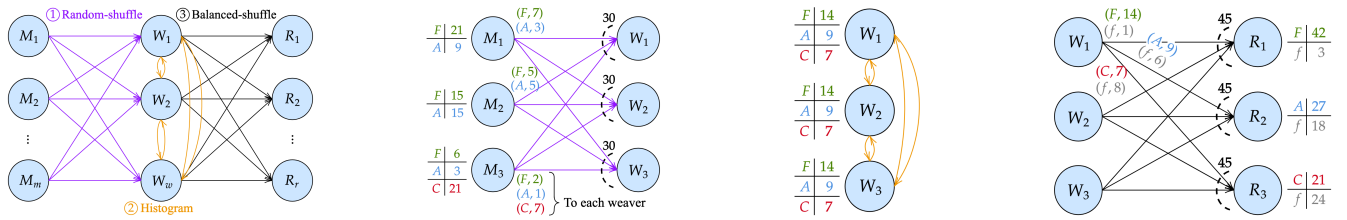
3 Weave Approach

Weave builds on the load-balancing approach and leverages principles of noise-injection employed in oblivious storage [15–18] to improve its performance and reduce its restrictions on MapReduce functionality. Weave decomposes analytics job execution into two parts:

Initialization. Weave first initializes worker nodes to be used as mappers, reducers, and for additional required processing to prevent access pattern leakage. It then generates secret keys for encryption and the pseudorandom generator (PRG), sharing them among the workers via secure channels. These are stored in each worker's secure enclave during the secure analytics job execution.

Job execution. Similar to secure analytics execution on prior MR frameworks [6, 11, 12] (§2.1), Weave's job execution still comprises the map and reduce phases, where workers run the Map and Reduce functions within TEEs with secure enclaves and memory oblivious accesses inside EPC sections. However, since the key source of access pattern leakage stems from an observer analyzing the communication volumes between mapper-reducer pairs (§2.2) during the shuffle phases, Weave replaces this phase with three new phases that prevent such leakage, namely the *random-shuffle*, *histogram*, and *balanced-shuffle* phases (Figure 3(a)). While random-shuffle only involves network communications, the histogram and balanced-shuffle phases involve both computations performed by workers and network communications. We refer to the w workers in these phases as *weavers* (W_i).

At a high level, random-shuffle (①) prevents any split-based leakage by randomly distributing intermediate key-value pairs generated by mappers to weavers in the next phase, effectively making the volume of network traffic between mapper-weaver pairs independent of how the data was distributed across splits (§3.1). The histogram (②) and balanced-shuffle (③) phases, on the other hand, collectively prevent distribution-based leakage by making the volume of network traffic between weaver-reducer pairs independent of the distribution of intermediate keys generated during the map phase (§3.2). Finally, while these phases ensure no access pattern information is revealed via network communications between workers, any leakage due to the memory accesses performed within the TEEs during these phases is prevented by placing the associated state within the Enclave Page Cache (EPC), an isolated memory region inside the TEE (§3.3). The following subsections describe these three phases in detail.



3.1 Preventing Split-based Leakage

As noted in §2.2, split-based leakage stems from intermediate key-value pairs generated by different mappers being tied to how input records may have been divided across input splits of the dataset. To prevent such leakage, Weave's random-shuffle phase requires each mapper M_i to route each intermediate key-value pair to a pseudorandomly chosen weaver W_j. Since the choice of the weaver processing a key-value pair is independent of how records were divided across the input dataset splits, Weave avoids split-based leakage (formal proof in §4).

An important consequence of such a shuffle is that each weaver receives a *proportionate* distribution of intermediate keys. In particular, if the map phase generates a total of $\hat{n}$ intermediate key-value pairs and $\hat{n}_k$ intermediate key-value pairs with key $\hat{k}$, then random shuffle ensures that each weaver receives, in expectation, $\frac{\hat{n}_{\hat{k}}}{w}$ key-value pairs with key $\hat{k}$. Figure 3(b) illustrates this on the simple example from §2.2.

3.2 Preventing Distribution-based Leakage

Distribution-based leakage, on the other hand, stems from the number of key-value pairs received by each reducer being tied to the distribution of intermediate keys generated during the map phase. Our approach for achieving both goals draws inspiration from prior literature on noise-injection [15–18] for oblivious storage, which employs principled use of fake queries to a storage system to make the observable access pattern across data items indistinguishable from a uniform random one. The histogram and balanced-shuffle phases in Weave realize a form of noise injection where the weavers leverage the histogram of intermediate keys to transfer fake and real intermediate key-value pairs to reducers. This allows Weave to ensure the volume of network traffic between

(a) Weave Overview (b) Random-shuffle phase (c) Histogram phase (d) Balanced-shuffle phase

Fig. 3: **Secure analytics execution in Weave.** (a) Weave replaces the shuffle phase with three new phases: ① random-shuffle, ② histogram and ③ balanced-shuffle (§3). (b-d) demonstrates Weave's execution on the example from Figure 2. (b) Random-shuffle distributes intermediate key-value pairs from mappers randomly across weavers: in our example, each weaver receives the same number of Flu, Asthma, and COVID-19 records. (c) Each weaver broadcasts a histogram of its received intermediate key-value pairs, informing all weavers of the global histogram of Flu, Asthma, and COVID-19 records (d) Balanced-shuffle assigns Flu records to reducer R_1, asthma to R_2, and COVID-19 to R_3. To ensure that each reducer receives $\texttt{kv_tot} = 45$ key-value pairs ($\alpha = 1.5$), each weaver sends fake key-value pairs (key f) to each reducer.

weaver-reducer pairs is roughly equal and independent of the distribution of intermediate keys. We detail these phases next.

Histogram phase. This phase aims to construct a global histogram of intermediate keys generated by each mapper at every weaver without leaking any information about the distribution of keys in the dataset.

To this end, each weaver W_i first creates a local histogram h_i over the $\hat{n}_i$ intermediate keys it receives from mappers in the random-shuffle phase. Since the random-shuffle phase ensures that $\hat{n}_i$ is independent of the underlying data distribution in the input dataset, the histogram h_i is padded to $\hat{n}_i$ entries to prevent any leakage based on histogram sizes. The padded histogram is then encrypted and broadcasted to all other weavers $W_{j\neq i}$. As such, weaver W_i also receives histograms h_j from all other weavers $W_{j\neq i}$, which it combines to construct a global histogram $\hat{\mathsf{h}}$ over all intermediate keys. By the end of this phase, every weaver has the same global histogram $\hat{\mathsf{h}}$. Figure 3(c) illustrates the histogram phase by continuing the example from Figure 3(b).

Balanced-shuffle phase. Having computed the global histogram, the weavers ultimately need to decide on the destination reducer (among all r reducers) for each intermediate key-value pair while satisfying two constraints. First, correctness requires all key-value pairs with the same key to be sent to the same reducer. Second, obliviousness requires the number of key-value pairs sent between each weaver-reducer pair to be independent of the data distribution in the input dataset.

The balanced-shuffle phase in Weave employs a form of noise injection; Algorithm 1 details this approach. Weave first fixes the number of intermediate key-value pairs (`kv_tot`) any reducer receives to a value independent of the intermediate key distribution. We set `kv_tot` to $\alpha \cdot \frac{\hat{n}}{r}$, where $\alpha > 1$ is independent of the key distribution. Weave then sends a combination of real and fake key-value pairs from the weavers to meet the fixed quota per reducer.

Algorithm 1 BalancedShuffle($\hat{\mathsf{h}}$)

At each weaver W_i:

1: $\texttt{kv_tot} \leftarrow \frac{\alpha \cdot \hat{n}}{r}$
2: $k \leftarrow$ first intermediate key in $\hat{\mathsf{h}}$
3: **for** $j = 1$ to r **do**
4: $\quad \texttt{kv_real}[j] \leftarrow 0$
5: $\quad$ **while** $\texttt{kv_real}[j] + \hat{\mathsf{h}}[k] < \texttt{kv_tot}$ **do**
6: $\quad\quad$ Assign all KV pairs for key k at W_i to R_j
7: $\quad\quad \texttt{kv_real}[j] \leftarrow \texttt{kv_real}[j] + \hat{\mathsf{h}}[k]$
8: $\quad\quad k \leftarrow$ next intermediate key in $\hat{\mathsf{h}}$
9: **for** $j = 1$ to r **do**
10: $\quad \texttt{kv_fake}[j] \leftarrow \texttt{kv_tot} - \texttt{kv_real}[j]$
11: $\quad$ **for each** $l = 1$ to $\texttt{kv_fake}[j]$ **do**
12: $\quad\quad d \leftarrow$ Roll a w-sided unbiased die
13: $\quad\quad$ **if** $d = i$ **then**
14: $\quad\quad\quad$ Assign a fake KV pair from W_i to R_j
15: Send all fake+real KV pairs from W_i to their assigned reducers

Assigning real key-value pairs: Weave first leverages the global histogram $\hat{\mathsf{h}}$ to greedily assign real key-value pairs with the same key across as few reducers as possible while ensuring (i) each reducer receives no more than `kv_tot` real key-value pairs, and (ii) intermediate key-value pairs with the same key are assigned to the same reducer (lines 2–8). Note that since all weavers have a roughly equal proportion of key-value pairs for each intermediate key ($\frac{\hat{n}_i}{w}$ key-value pairs with key k_i in expectation) due to the random shuffle phase (§3.1), each reducer R_j receives, in expectation, $\frac{\texttt{kv_real}[j]}{w}$ of the total $\texttt{kv_real}[j]$ real key-value pairs from each weaver.

Assigning fake key-value pairs: After assigning real key-value pairs, the remaining space in each reducer's fixed-quota (`kv_tot`) is filled using randomly generated fake key-value pairs (lines 9–14). Hiding distribution-based leakage requires that roughly the same number of intermediate key-value pairs are sent between each weaver-reducer pair. Since the proportion of real key-value pairs sent from various weavers to each reducer is already roughly equal, all that remains is to ensure that the proportion of fake key-value pairs sent from various weavers to a reducer is also roughly equal. This is

realized via the Bernoulli trials in lines 12–14 — a w-sided die is cast for each fake key-value pair, and the value of the roll decides which weaver gets to send that fake key-value pair. This ensures that each of the weavers generates, in expectation, $\frac{\texttt{kv_fake}[j]}{w}$ of the total $\texttt{kv_fake}[j]$ fixed number of fake key-value pairs received by reducer R_j. Combined with the real key-value pairs, each weaver sends, in expectation, $\frac{\texttt{kv_fake}[j]+\texttt{kv_real}[j]}{w} = \frac{\texttt{kv_tot}}{w}$ key-value pairs to each reducer R_j, ensuring obliviousness. Note that each reducer R_j receives exactly $\texttt{kv_tot}$ records.

A subtle issue in the above approach is that all weavers must agree upon the die roll values — otherwise, multiple weavers may send the same fake key-value pair at the same time, or no weaver may send it. One approach is to perform all die rolls at a centralized entity (*e.g.*, the centralized controller or a designated weaver) and disseminate their values to all weavers. However, this approach adds a potential scalability bottleneck. Weave opts for an even simpler solution — it distributes the same PRG to each of the weavers during initialization (§3), ensuring that each of the weavers independently generates the same die roll values and avoiding any runtime communication overheads for this purpose.

Finally, each weaver sends the real and fake intermediate key-value pairs to the reducers determined by the bin-packing and noise-injection approaches outlined above. The reducers, in turn, collect the intermediate key-value pairs from the weavers, decrypt them, and drop the fake entries. They then proceed with the reduce phase similar to traditional MR: applying Reduce to groups of intermediate key-value pairs with the same key and adding the results to the output with requisite padding and encryption.

Figure 3(d) continues the example from Figures 3(b) and 3(c) to show how the data records from a weaver are distributed across different reducers in the balanced-shuffle phase to prevent distribution-based leakage.

Choice of α. Clearly, larger values of α incur larger network bandwidth overhead, and therefore, the end-to-end execution time for MR jobs in Weave. While $\alpha > 1$ is a trivial lower bound, correctness mandates a larger α value:

Theorem 3.1 *For any $\alpha < \frac{2r}{r+1}$, there exist $\hat{n}$ intermediate key-value pairs that cannot be assigned into r reducers such that each reducer processes exactly $\frac{\alpha\cdot\hat{n}}{r}$ key-value pairs.*

Proof. Consider $\hat{n}$ intermediate key-value pairs with $r+1$ distinct keys, each with an equal number of intermediate key-value pairs, i.e., $\forall k, \hat{\mathsf{h}}[k] = \frac{\hat{n}}{r+1}$. If $\alpha < \frac{2r}{r+1}$, each reducer processes exactly $\texttt{kv_tot} = \alpha \times \frac{\hat{n}}{r} < \frac{2\hat{n}}{r+1}$ key-value pairs.

A single reducer must process all intermediate key-value pairs with the same key for correctness. As such, no reducer can be assigned intermediate key-value pairs for two or more distinct keys since $2 \times \frac{\hat{n}}{r+1} > \texttt{kv_tot}$. Accommodating all $r+1$ keys requires at least $r+1$ reducers, a contradiction. ■

Fortunately, $\alpha = \frac{2r}{r+1}$ is achievable, and can indeed be achieved by Algorithm 1 as we show next:

Theorem 3.2 *If $\alpha \geq \frac{2r}{r+1}$, $\hat{n}$ intermediate key-value pairs can be always assigned to r reducers such that each reducer processes exactly $\frac{\alpha\cdot\hat{n}}{r}$ key-value pairs, provided $\max_k \hat{\mathsf{h}}(k) \leq \frac{\alpha\cdot\hat{n}}{r}$.*

Proof. Consider a modified Algorithm 1 that permits intermediate key-value pairs for the same key to be split across two reducers in lines 2–8; note that since $\max_k \hat{\mathsf{h}}(k) \leq \frac{\alpha\cdot\hat{n}}{r}$, the intermediate key-value pairs associated with the same key may be split across at most two reducers. This assignment ensures all the key-value pairs will be assigned to $r_1 = \frac{\hat{n}}{\frac{2\hat{n}}{r+1}} = \frac{r+1}{2}$ reducers, regardless of the key distribution.

Let $\mathcal{K}_s$ be the set of intermediate keys whose values are split across two reducers. Note that $|\mathcal{K}_s|$ is at most $r_1 - 1 = \frac{r-1}{2}$. For each key $k \in \mathcal{K}_s$, the modified algorithm then reassigns all of k's key-value pairs to one of the $r - r_1 = \frac{r-1}{2}$ reducers that have not been assigned any keys yet. This is a feasible assignment, completing the proof[3]. ■

Note that $\alpha = \frac{2r}{r+1}$ still ensures that the traffic volume between weaver-reducer pairs is independent of the key distribution. However, as noted in Theorem 3.2's statement, this value of α requires the maximum number of intermediate key-value pairs associated with the same key (i.e., $\max_k \hat{\mathsf{h}}(k)$) must not exceed $\frac{\alpha\cdot\hat{n}}{r}$. Intuitively, this constraint captures Weave's requirement of the maximum intermediate key popularity being less than a single reducer's capacity ($\texttt{kv_tot}$) — a reasonable assumption in any MR job. Indeed, the maximum intermediate key popularity is much smaller than the reducer capacity in practice — no more than $\sim 5\%$ in our evaluations (§5). However, since α (and therefore, $\texttt{kv_tot}$) is a configurable parameter in Weave, it is possible to increase α (i.e., reducer capacity) to support a larger maximum key popularity — we analyze Weave's sensitivity to α in §5.4.

3.3 Avoiding Memory Access Pattern Leakage

While the random-shuffle, histogram, and balanced-shuffle phases prevent distribution-based leakage and split-based leakage, we note that *memory access patterns* during these phases can still leak sensitive information about data distribution. Similar to prior work [8, 10, 33–35], Weave leverages the Enclave Page Cache (EPC) [36, 37], a limited pool of oblivious memory that hides access patterns using a combination of hardware isolation and lightweight side-channel defenses (§3.6). We confine all memory-dependent sensitive states to this region and structure the design to minimize its footprint for scalability.

To facilitate this, Weave classifies memory accesses during the three phases into two classes: *data-independent* and *data-dependent*. Data-independent accesses (*e.g.*, scanning the entire dataset) do not reveal any distribution-dependent information about the dataset and can be kept outside EPC regions

[3] Algorithm 1 can always achieve the same overhead.

without affecting security (§4.1). In contrast, data-dependent accesses must use protected EPC memory:

Random-shuffle. Since random-shuffle scans through and pseudo-randomly assigns key-value pairs to different weavers, it performs no data-dependent memory accesses. As such, Weave does not use EPC memory during this phase.

Histogram. Since the histogram phase aggregates key counts in separate memory locations, the frequency of accesses to each location reveals the distribution of key-value pairs. Thus, each weaver stores its local histogram (h_i) and global histogram ($\hat{h}$) in the EPC.

Balanced-shuffle. In Algorithm 1, the buffers needed for the aggregation of the real and fake key-value pairs for reducer R_j at weaver W_i, and the `kv_real` and `kv_fake` counters that track W_i's real and fake key-value pair counts per reducer have data-dependent accesses and are kept inside EPC memory.

3.4 Weave Optimizations & Extensions

Sampled histogram for scalability. During Weave's histogram phase, each weaver broadcasts a local histogram containing $\sim \lceil \frac{\hat{n}}{w} \rceil$ entries to all other weavers; this presents a non-trivial overhead for large datasets, limiting Weave's scalability. To avoid this overhead, we observe that Weave's security against distribution-based leakage stems from the *indistinguishability* of traffic volume between weaver-reducer pairs. As such, weavers do not require *precise* knowledge of the global histogram $\hat{h}$; an *estimate* of $\hat{h}$ can be used as long as it can still ensure the indistinguishability guarantee. Weave thus builds the global histogram at each weaver using *random samples* of the intermediate key-value pairs. As noted in §3.3, histogram aggregations occur inside EPC; thus, sampling also reduces EPC memory requirement during histogram phase.

Specifically, each weaver only computes a local histogram over $s = \beta \cdot \frac{\hat{n}}{w}$ random samples out of the total $\frac{\hat{n}}{w}$ intermediate key-value pairs it receives, where $\beta < 1$ is the sampling factor. It then pads each local sampled histogram to $\lceil \frac{\beta \cdot \hat{n}}{w} \rceil$ entries and broadcasts it to other weavers. Each weaver aggregates the sampled histograms from other weavers and scales the key counts by $1/\beta$ to get an approximate global histogram.

We note that the approximation for the histogram can introduce variations in the weaver-reducer traffic during the balanced-shuffle phase that an adversary can observe. This requires additional noise (i.e., fake key-value pairs) to be added to weaver-reducer traffic to hide such variations. If we increase the traffic by a factor of $(1+\delta)$, then the Chernoff bound [38] allows us to ensure that the probability ε of successfully distinguishing the traffic volumes is $\varepsilon < \exp(-\frac{\beta\hat{n}\delta^2}{2})$, as captured in the following theorem:

Theorem 3.3 *For any polynomial-time adversary $\mathcal{A}$, if Weave's histogram phase samples $\beta\hat{n}$ intermediate key-value pairs and its balanced-shuffle phase sends $(1+\delta)\times$ more fake key-value pairs for some β and δ, $\mathcal{A}$'s advantage $\mathbf{Adv}^{ind\text{-}cdja}_{Weave}$ is negligible.*

Proof. Let the random variable X_i denote the number of sampled queries received by reducer R_i; since the sampled key-value pairs are each sent to a random reducer, $X_i \sim B(\beta\hat{n}, \rho)$ where ρ is the probability that a sampled intermediate key-value pair is sent to reducer R_i.

Given some small $\delta > 0$, the Chernoff bound [39] shows that the probability of ρ falling outside the bound of $[\frac{1}{r} - \delta, \frac{1}{r} + \delta]$ is an exponentially decreasing function of $\hat{n}, \beta$, and δ. Specifically, we obtain an upper-bound on the probability that our estimate $\frac{\alpha}{r}$ is off from ρ by more than δ if the sample size is $\beta\hat{n}$:

$$\Pr\left[\rho \geq \frac{\alpha(1+\delta)}{\hat{n}}\right] < \exp(-\frac{\hat{n}\beta\delta^2}{2}) \qquad (1)$$

Now, let us modify the balanced-shuffle phase (Algorithm 1) to send $(1+\delta)\times$ more fake intermediate key-value pairs to each reducer. Then, the advantage that a polynomial computation-bounded adversary has in distinguishing between the traffic distributions between weavers and reducers and a uniform random distribution is exponentially small, specifically, the probability of ρ being outside the bound given by Inequality 1.

Therefore, Weave is still IND-CDJA-secure if its histogram phase uses sample size $\beta\hat{n} \in O(\hat{n})$. ■

Our implementation uses a sampling factor β of 1% during the histogram phase and additional noise 5% (δ) during balanced-shuffle while still ensuring negligible ε.

Efficient support for associative reduce. Under our threat model, an adversary is aware of the nature of the analytics job being executed (§2.2). We can, therefore, employ targeted optimizations for associative reduce functions since this reveals no additional information to the adversary.

To this end, we modify the balanced-shuffle algorithm to *eliminate* any noise injection for associative reduce functions. Specifically, instead of moving on to the next reducer if all the key-value pairs for a particular intermediate key cannot be processed by a single reducer (line 5 in Algorithm 1), we permit *splitting* the key-value pairs associated with a key ('boundary key') across two or more reducers, similar to sort-based approaches [12]. This modification requires boundary processing to aggregate partial Reduce outputs for the boundary keys, where each reducer R_i must pass its boundary key and the corresponding aggregated Reduce output to the next reducer R_{i+1}, which computes the final aggregate for the boundary key. This allows us to use $\alpha = 1$ since no fake key-value pairs are required, with execution times comparable to insecure executions while preventing access pattern leakage (§5).

Supporting sort-based and user-defined partitioning. In Algorithm 1, intermediate keys are assigned to reducers in

the order in which they appear in the global histogram, $\hat{h}$. This makes the histogram a straightforward place to support sort-based and arbitrary user-defined partitioning functions. In particular, we order the keys in the histogram based on the user-specified partitioning function, overcoming a key functionality limitation in load balancing schemes (§2.4). If no partitioning function is specified, Weave still requires all weavers to agree on ordering keys in $\hat{h}$ so that they agree on the real/fake key-value allocations across reducers. As such, Weave uses a hash table with the same parameters (*e.g.*, hash function, load-factor, etc.) for $\hat{h}$ at all weavers.

3.5 Weave Overheads

Network bandwidth. An insecure MR framework uses $O(\hat{n})$ network bandwidth during the shuffle phase. In contrast, Weave's network bandwidth usage is $O(\hat{n})$ during the random-shuffle phase, $O(w(w-1)\cdot\beta\cdot\hat{n})$ during the histogram phase, and $O((1+\delta)\cdot\alpha\cdot\hat{n})$ during the balanced-shuffle phase. Note that the histogram phase only broadcasts *sampled key counts*, which are much smaller than actual intermediate key-value pairs. With Weave's default parameters, its network bandwidth overheads are $\sim 3.1\times$ (constant factor) of an insecure baseline: $1\times$ overhead due to the random-shuffle phase and $\sim 2.1\times$ overhead due to the histogram and balanced-shuffle phases (with $\delta = 0.05$ and $\alpha \approx 2$). These overheads are further reduced to negligible for jobs with associative reduce functions. In contrast, prior sort-based and load-balancing schemes incur $\log(\hat{n})$ factor network overhead relative to an insecure baseline, with even higher overheads in practice (§5).

Compute. Compared to an insecure MR framework, Weave incurs additional computations at the weavers during the histogram and balanced-shuffle phases. The computational complexity for the histogram phase is $O(\beta\cdot\hat{n})$ and $O(\hat{n})$ for the balanced-shuffle phase. Again, the added computational complexity for sort-based and load-balancing approaches is $O(\hat{n}\log(\hat{n}))$, with overheads being higher in practice (§5).

EPC Memory Overhead. Weave adds $O(\beta\hat{n})$ of EPC usage during the histogram phase to store $\hat{h}$, $O(\delta\hat{n})$ for padding records after sampling in the histogram phase, and $O(w)$ to hold `kv_real` and `kv_fake` during the balanced-shuffle phase. For non-associative workloads, an additional $O\left(\frac{r}{r+1}\hat{n}\right)$ is incurred to generate and keep fake records on weavers. We note that collectively, this remains a tiny fraction of the total dataset size. In our largest scale experiment with over a billion records, Weave consumes $< 5\%$ of EPC capacity (§5.2) — 0.1% for storing $\hat{h}$, `kv_real`, and `kv_fake`, 1.3% for padding records during the histogram phase, and 2.1% for storing the fake records. While Weave ensures datasets of virtually any size can be analyzed without exceeding EPC capacity in practical settings, Weave can also employ algorithmic techniques to provide memory obliviousness through software-based solutions when EPC capacity is exhausted, discussed in the full version of our paper [26].

3.6 Weave Implementation

Weave is implemented in Apache Spark [2] with an additional 1,500 lines of Scala code. To prevent access pattern leakage in MapReduce jobs, Weave's shuffle phases (random-shuffle, histogram and balanced-shuffle) replace Spark's default shuffle implementation, requiring no modifications to user code.

Weave leverages Gramine LibOS [40–42] for transparent execution atop Intel SGX enclaves. Gramine ensures execution integrity by (i) signing the enclave code, (ii) performing attestation, and (iii) encrypting/decrypting all memory accesses and network communications.

Handling MR jobs with $c > 1$. As noted in §2.4, to meet IND-CDJA security, Weave assumes an upper bound C for the number of intermediate key-value pairs c generated by a `Map` function. To support jobs with $c > 1$, Weave pads every `Map` function's output to C key-value pairs by injecting "filler" key-value pairs. The balanced-shuffle phase processes these filler key-value pairs as fake key-value pairs, i.e., they are distributed evenly among the reducers, where they are dropped without being processed. In our implementation, we assume the user provides this upper-bound C (*e.g.*, for functions like `flatMap`). While most MR jobs have $c \leq 1$, we evaluate the performance impact of $c > 1$ on Weave in §5.4.

Secure EPC design. While EPCs are designed to prevent leakage of memory access patterns, recent works have shown that current *commodity* TEEs such as SGX, SEV, or TrustZone [8–10] are vulnerable to side channel leakages like page-fault monitoring, cache contention, interrupt timing, branch prediction, and speculative execution [43–46].

To protect against such leakages, secure systems built atop publicly available TEEs leverage a *proxy*-based design, where a proxy encapsulates the "leaky" TEE and implements the mitigation of these attacks [33–37, 47–49], retaining memory obliviousness. In Weave, we adopt this proxy-based design, leveraging AEX-Notify [33] to mitigate single-step and interrupt-based attacks and core isolation (similar to Varys [34]) to limit cache timing attacks, all with constant overhead (less than 20%). Moreover, we rely on SGXv2's increased EPC size to minimize page faults for performance.

For more rigorous security guarantees, it is possible to use a formally verified TEE architecture with EPCs that guarantee zero leakage by design *e.g.* [50–52]. We leave the implementation of Weave atop such TEEs to future work.

4 Security Guarantees

This section describes our IND-CDJA security definition (§4.1), contrasts it against prior security models (§4.1), and shows Weave is secure under IND-CDJA (§4.2).

$\text{IND-CDJA}^{\mathcal{A}}_{b,\alpha,C}$:

$n, w, \mathsf{mem} \leftarrow \mathcal{A}_1$
$\mathcal{W} \leftarrow \mathsf{Init}(n, w, \mathsf{mem})$
$D_0, D_1, \mathsf{Map}, \mathsf{Reduce} \leftarrow \mathcal{A}_2(\mathcal{W})$
$o, \tau^N, \tau^M \leftarrow \mathsf{Execute}(D_b, \mathsf{Map}, \mathsf{Reduce}, \mathcal{W})$
$b' \leftarrow \mathcal{A}_3(o, \tau^N, \tau^M)$
Return b'

Fig. 4: $\text{IND-CDJA}^{\mathcal{A}}_{b}$ with adversary $\mathcal{A}$ and random bit b.

4.1 IND-CDJA

The IND-CDJA game, defined in Figure 4, is parameterized by an adversary $\mathcal{A}$, the constant α (which determines `kv_tot`), the maximum Map output size C, and a bit b. The bit b is kept secret from $\mathcal{A}$; the security of a scheme under IND-CDJA is contingent on an adversary not being able to guess b correctly.

In the game, the adversary $\mathcal{A}$ first chooses the input dataset size (n), the number of workers (w), and an array of fixed-size memory cells mem. Based on these parameters, the framework initializes a set $\mathcal{W}$ of w workers, each with the specified mem configuration. $\mathcal{A}$ then picks two challenge datasets D_0 and D_1 of size n, along with a MR job defined by $(\mathsf{Map}, \mathsf{Reduce})$. The framework executes the adversary's chosen MR job on D_b (determined by the random bit b) and generates o, the (partitioned) encrypted output of the job, and a pair of transcripts τ^N and τ^M, where τ^N contains all network communications sent between each worker throughout the job and τ^M contains all reads and writes to memory addresses in mem on each worker; these outputs represent the information that $\mathcal{A}$ can observe from the execution. Finally, given (o, τ^N, τ^M), the adversary $\mathcal{A}$ runs a polynomial-time algorithm to guess b, i.e., which challenge dataset was chosen, and outputs this guess as b'. The adversary "wins" if its guess is correct; conversely, if the guess is no better than a random coin flip, the execution framework is secure.

Prior security definitions. IND-CDJA provides a practical tradeoff between the two main definitions introduced in prior work for secure MapReduce execution. Intuitively, Opaque's obliviousness guarantee is requires the volume of network traffic between all worker pairs to be *exactly* equal. Our IND-based definition aims for more practical guarantees based on the observation that we do not need network traffic to be *identical* for different datasets, only *indistinguishable*. As long as the network traffic distribution is independent of the input data distribution, the adversary cannot infer any useful information. This allows IND-CDJA to cover a larger solution space of schemes, including Weave, without sacrificing security. Although we use a game-based definition in the main text for simplicity, we also provide a composable simulation-based version of IND-CDJA in the full version of our paper [26].

Meanwhile, the notion of 'strong hiding' in the Shuffle & Balance [11] is based on an indistinguishability game, not unlike ours. However, strong hiding allows the MR framework to leak the number of intermediate key-value pairs corresponding to the most popular key, which the adversary can use to infer the key skew of the underlying data and even identify the most popular key [53]. In contrast, IND-CDJA requires this information to be hidden, offering more robust security.

4.2 Proof of Weave Security

We establish the IND-CDJA security of Weave in the theorem below. Weave's security reduces to the pseudorandom security of the PRG shared by its workers, the real-or-random security of its encryption scheme, and the indistinguishability of the memory transcripts generated by its memory access mechanism. As noted in §3.3, Weave uses an oblivious memory pool within the TEE's EPC to secure its data-dependent computations[4]; we assume that the EPC ensures any sequence of accesses to this pool not visible to an adversary (i.e., $\tau^M_{EPC} = \emptyset$).

Theorem 4.1 *For any polynomial-time adversary $\mathcal{A}$ against Weave, there exist poly-time adversaries $\mathcal{B}, \mathcal{C}, \mathcal{D}$ such that*

$$\mathbf{Adv}^{ind\text{-}cdja}_{Weave}(\mathcal{A}) \leq \mathbf{Adv}^{prg}_{F}(\mathcal{B}) + \mathbf{Adv}^{ror}_{E}(\mathcal{C}) + \mathbf{Adv}^{ind}_{T}(\mathcal{D}),$$

where F, E, and T are Weave's PRG, encryption, and memory access schemes, respectively.

We defer the formal proof of security for Weave with optimizations to the full version of our paper [26], but provide an intuitive proof sketch for Weave without optimizations here. Our proof relies on the network traffic and non-EPC memory accesses of each worker following the same distribution, regardless of the dataset. We outline how each phase achieves this below:

Random-shuffle. Each mapper assigns its intermediate key-value pairs to a weaver uniformly at random, ensuring that the number of key-value pairs sent from each mapper to weaver is uniformly distributed. Also, mappers sequentially access intermediate key-value pairs regardless of their contents, resulting in indistinguishable memory transcripts between datasets.

Histogram. Each weaver broadcasts a histogram padded to the same $\lceil \frac{\hat{n}}{w} \rceil$-sized entries, ensuring that the same communication volume is seen for any dataset with the same number of intermediate key-value pairs. Also, since each weaver W_i keeps the histograms h_i and $\hat{\mathsf{h}}$ in EPC (§3.3), the memory transcript only contains accesses for scanning through the weaver's received key-value pairs for counting. Again, these are sequential and indistinguishable between datasets.

Balanced-shuffle. Consider the distribution of key-value pairs from each weaver across the reducers, where $\texttt{kv_real}[j]$ is the number of real key-value pairs assigned to reducer

[4] Similar to prior work [12], the EPC also ensures obliviousness of Map and Reduce function executions.

Dataset	Properties	Supported Workloads
Enron Email	137M records, 1.7M distinct keys 20B keys and 24B values	HistogramCount, Sort, InvertedIndex
NY Taxi	148M records, 262 distinct keys 4B keys and 4–10B values	HistogramCount, Sort, Median
Pokec Network	31M records, 1.1M distinct keys 4B keys and 4–10B values	PageRank

Table 1: Our evaluated datasets and workloads

R_j. The random-shuffle and balanced-shuffle phase together ensure that the number of real key-value pairs R_j receives from weaver W_i is a binomial random variable, $\hat{n}_{ij}^{real} \sim B(\texttt{kv_real}[j], 1/w)$. Moreover, Algorithm 1 (lines 12–14) ensures that the number of fake key-value pairs R_j receives from W_i is also a binomial random variable, $\hat{n}_{ij}^{fake} \sim B(\texttt{kv_tot} - \texttt{kv_real}[j], 1/w)$. The total number of key-value pairs R_j receives from W_i is then $\hat{n}_{ij}^{real} + \hat{n}_{ij}^{fake} \sim B(\texttt{kv_tot}, 1/w)$, the same distribution across all weaver-reducer pairs. For memory access patterns, each weaver keeps `kv_real`, `kv_fake`, and buffered key-value pairs destined for reducers inside its EPC, hiding any data-dependent accesses. Buffering in the EPC also allows the weaver to send all its key-value pairs at once in a random order, ensuring that the timing and order of transmitted key-value pairs are independent of the data distribution.

Security-correctness tradeoff and α. The game parameter α, which is visible to the adversary, determines the number of key-value pairs that Weave's Execute function sends to each reducer. Theorem 3.2 shows that α must be large enough to ensure correctness. In the unlikely event that maximum key popularity exceeds $\frac{2r}{r+1}$, Weave avoids leaking this information by sacrificing correctness. Specifically, it completes execution with incorrect results (securely notified to the user) by dropping the popular key's real key-value pairs. Weave can subsequently be reconfigured with a larger α. While this reveals that a highly popular key exists in the dataset, our threat model assumes that the adversary already knows the key distribution, i.e., no new information is revealed to it. IND-CDJA's key requirement instead is that *the popularity of individual keys* remains hidden, i.e., the adversary cannot determine *which* key is most popular. Weave thus preserves security as the IND-CDJA adversary cannot distinguish between executions on datasets of the same size and α.

5 Evaluation

We now evaluate Weave against state-of-the-art systems on real-world datasets and workloads.

Compared Systems. We evaluate Weave against three approaches: (i) Insecure baseline that runs tasks within TEEs but provides no network obliviousness guarantees and forms our no-overhead baseline, (ii) Opaque [12], a state-of-the-art oblivious sort-based approach, and (iii) Shuffle & Balance [11], a state-of-the-art load-balancing approach. We implement all approaches in Spark [2] atop Gramine LibOS [41] and make the entire EPC region available for all approaches, with enough memory to ensure memory obliviousness for all their data shuffling requirements. Our ported implementations of prior work closely match the respective system's reported performance results, ensuring a fair comparison.

Experimental setup. Our experiments are conducted on Microsoft Azure cluster with 3 to 20 Standard DC8s v3 instances, each with 8 vCPUs and 32GB of EPC memory. We run all systems inside Gramine LibOS with hardware memory isolation, encryption/decryption, and attestation. We use 10 workers and one controller (11 nodes) as our default configuration, except in our scalability study (§5.2).

Datasets and workloads. We use three real-world datasets: the Enron Email dataset [54], a corpus of corporate emails commonly employed in privacy research [55–58], the NY Taxi dataset, comprising extensive real-world taxi trip records from New York City [59], and Pokec graph dataset [60], comprising the graph for the Pokec social network. All datasets contain privacy-sensitive information with discernible distributions (*e.g.*, email keywords, trip destinations/times, and user profile data like gender and age in the social network) and are known to be vulnerable to access pattern attacks [11].

We employ five analytics workloads across these datasets, although only a subset applies to each dataset (Table 1). The HistogramCount query from the Puma benchmark [61] counts the frequencies of different keys. The InvertedIndex workload maps values in text data to their document occurrences for full-text search efficiency. The Sort job orders records by key. The Median job computes the median of the numerical values for key-grouped records. PageRank is a multistage graph processing workload. Our chosen workloads are representative of practical analytical jobs in privacy-sensitive settings and span diverse complexity ranges and functionality requirements from the MR framework (*e.g.*, non-associative Reduce in InvertedIndex and Median, sorting in Sort, etc.).

5.1 Weave Efficiency

Figure 5 compares the end-to-end execution time for all compared schemes across the various workload and dataset combinations outlined in Table 1 on a 10 node cluster. We note that non-associative jobs (Median and InvertedIndex) and sort-based jobs are not supported by Opaque and Shuffle & Balance, respectively (marked NA in the figure). As a baseline, TEE execution incurs a 1.9 to 2.8× overhead (compare Insecure Baseline with No-TEE Baseline), with the highest cost observed for the associative HistogramCount. The dominant overhead contributors are network and I/O operations, which involve enclave exits and data copies over enclave boundaries. However, these overheads are a necessary minimum for any secure solution.

Weave's execution times are within 1.65–2.83× of the in-

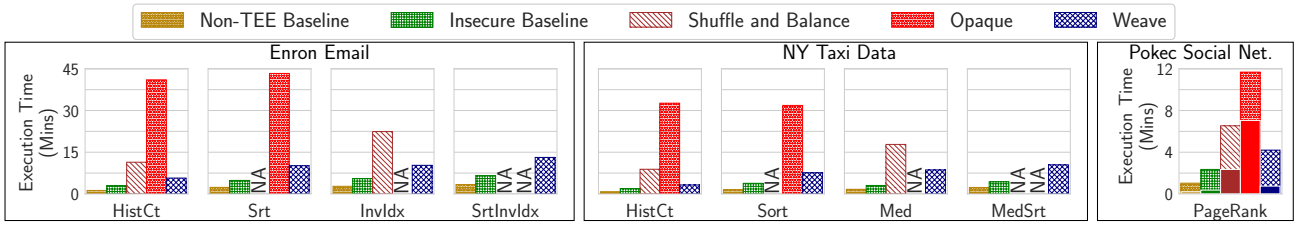


Fig. 5: **Execution time across compared systems & workloads (§5.1).** Jobs that an approach cannot support are marked NA. For PageRank, the solid bars show the time for the first round, while the hatched bars show the time taken for the subsequent 10 rounds.

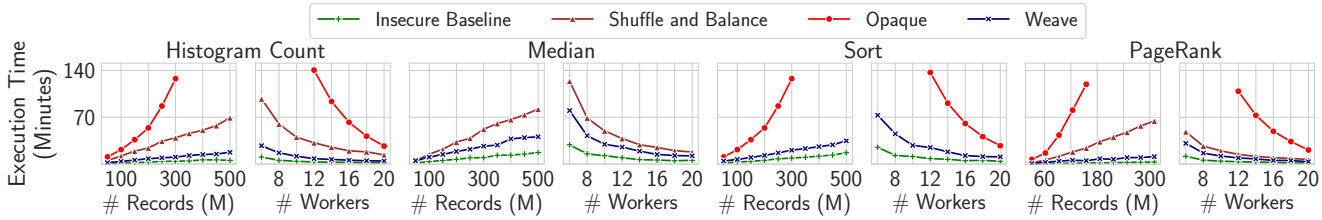

Fig. 6: **Performance scaling with dataset size and worker count (§5.2).** Weave and insecure baseline runtime scales linearly with dataset size, while Opaque and Shuffle & Balance runtime scales super-linearly. The runtime for all four systems reduces linearly with worker count.

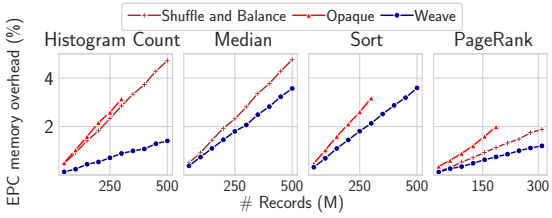

Fig. 7: **EPC memory overhead (§5.2)**w for secure shuffling relative to the insecure baseline scales linearly with data size for all schemes.

secure baseline, while the execution times for Opaque and Shuffle & Balance are 2.8–11.2× and 1.5–5.9× *higher than* Weave. At a high level, most of Weave's performance gains are due to its constant factor bandwidth and compute overheads relative to log-linear overheads seen in compared systems (§3.5). Analyzing the results further yields three interesting observations.

First, the major contributor to execution overheads across all compared systems for almost all workload-dataset combinations is their shuffle approach. Specifically, Weave sees the lowest overhead since Weave's random-shuffle, histogram, and balanced-shuffle phases permit a constant factor overhead relative to the insecure baseline's shuffle phase (1.5–2.7×; not shown in Figure 5). In contrast, Shuffle & Balance's single round of log-linear Melbourne shuffle incurs 3.9–8.3× overhead to insecure shuffles, while Opaque's four-round column sort observes an even higher overhead (7.2–20.2×; not shown in Figure 5). For PageRank, while the first round (solid bars) is dominated by the shuffle required for computing the graph's adjacency matrix, subsequent rounds only require broadcasting without any data shuffle in all systems. Thus, while Weave, Opaque, and Shuffle & Balance are 2.3×, 19.1×, and 9.8× slower than the insecure baseline in the first round, they take the same time for the remaining rounds.

Second, the associative Reduce optimization in Weave permits a 50% reduction in network overheads for associative jobs like HistogramCount. While Opaque employs a similar optimization, the end-to-end execution time remains dominated by its shuffle overheads. We also used mapper-side combiners for the insecure baseline for fairness, although Shuffle & Balance cannot use them since they break obliviousness.

Finally, a balanced distribution of intermediate key-value pairs across reducers in the secure systems, Weave, Opaque and Shuffle & Balance, results in fewer straggling reducers due to a more uniform work distribution across them, *compared even to the insecure baseline*.

5.2 Weave Scalability

We restrict our focus to the NY Taxi and Pokec datasets since they are much larger than the Enron dataset and permit larger-scale performance analysis. We omit Sort-variants for InvertedIndex and Median jobs since prior secure systems do not support them. For PageRank, we restrict our focus to one single round of rank aggregation on the Pokec dataset since subsequent rounds do not involve any data shuffle.

Scaling with dataset size (Figure 6). We fix the worker count to 10 and vary the number of records in the datasets, from 50 to 500 million records for NY Taxi data and from 31 to 310 million records for the Pokec graph data. As expected, the execution time for Weave and the insecure baseline scale linearly with dataset size across all jobs, since Weave incurs at most constant factor overhead relative to the baseline. The

log-linear scaling for Shuffle & Balance and Opaque is also expected due to their shuffle approaches; Opaque's overheads are somewhat higher due to the additional shuffle rounds required for column sort, which gets worse at larger dataset sizes due to memory thrashing during column sort in Spark.

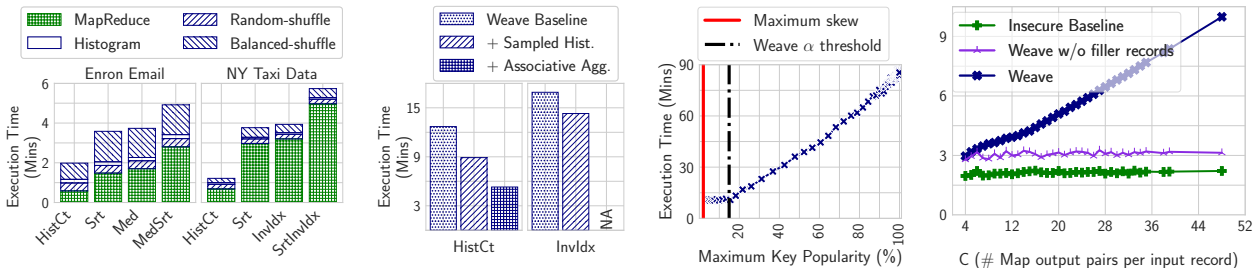
Across various jobs, the computationally light HistogramCount's scaling primarily depends on the shuffle overheads, resulting in a larger relative performance gap between Weave and compared systems. On the other hand, for the more computationally intense Median and Sort jobs, the gap between Weave and compared systems is smaller since the impact of shuffle is overshadowed by the time spent executing the Map and Reduce tasks. At 300 million records, Opaque and Shuffle & Balance observe execution times 9.3× and 2.7× longer than Weave on average, respectively.

Scaling with worker count (Figure 6). We fix the size of the dataset to 200 million records for the NY Taxi dataset and 310 million records for the Pokec social network graph data and vary the cluster size from 6 to 20 nodes. As expected, all four systems scale similarly to the number of workers, i.e., their execution time is reduced proportionally to the number of workers since each of them can split work and network traffic roughly equally among workers. As we saw for scaling with dataset size, the more computationally intensive jobs (Median, Sort) observe a lower performance gap between Weave and other systems in various worker counts, mainly because the impact of shuffle-based compute and network overheads is dwarfed by the time spent in tasks Map and Reduce. At 20 nodes, Opaque and Shuffle & Balance observe execution times 6.7× and 2.3× longer than Weave, respectively.

EPC memory overhead scaling (Figure 7). Our 10-node cluster hosts a total of 320GB of EPC memory. We see that the normalized EPC memory overhead for Weave, Opaque, and Shuffle & Balance — due to additional data structures that must be stored in EPC for each scheme — scales linearly with the number of records in the dataset. For Weave, despite linear scaling, the EPC overhead remains under 1.4% for HistogramCount and 3.6% for Sort on the NY Taxi dataset containing 500 million records, demonstrating that EPC overhead does not pose a scalability bottleneck for Weave.

5.3 Understanding Weave Performance

Weave execution breakdown (Figure 8(a)). The overhead incurred by the random-shuffle phase is purely due to network transfers and is linear in the dataset size. With our sampled histogram optimization, the network and computational overheads of histogram phase are negligible (< 1%). This leaves the balanced-shuffle phase, where the overheads vary by the job's nature and the dataset size. In particular, the balanced-shuffle phase overheads for non-associative jobs (InvertedIndex, Sort, Median) is much higher (up to 40% of the entire overhead) than for associative queries, where our associative reduce optimization all but eliminates compute overheads, and only incurs a network overhead linear in data size.



Impact of Weave optimizations (Figure 8(b)). We evaluate the impact of Weave optimizations for the InvertedIndex and HistogramCount jobs on the Enron Email dataset, using the same setup as §5.1. For the Enron Email Dataset, a sampling factor of 0.01 in the sampled histogram optimization reduces the communication time for the histogram phase by 220 seconds. As such, it reduces the execution time for InvertedIndex by 18% and HistogramCount by 30%. The associative reduce optimization only applies to HistogramCount, reducing its execution time further by 33% for a total of 63% reduction.

5.4 Sensitivity Analysis

Impact of α (Figure 8(c)). The choice of α ($\frac{2r}{r+1}$ by default) in Weave imposes a limit of $\frac{\alpha \cdot \hat{n}}{r}$ on the the maximum key popularity (§3.1). While all of our evaluated real-world datasets exhibit a maximum key popularity of < 5% (a small fraction of the threshold set by our default α), we artificially inflate the maximum key popularity in the NY Taxi dataset and evaluate the Median job execution on it to study Weave's sensitivity to larger α values. We use `LocationID` as the intermediate key, inflating the most popular key's popularity while keeping the total dataset size constant.

Figure 8(c) shows that as maximum key popularity (as a % of the entire dataset) increases from 4% to 99% (and consequently, the number of unique keys decreases), Weave's execution time increases by 7.9×. The two vertical lines are added for reference in the figure. The first line shows the maximum degree of skew (3%) in real-world social network datasets for Twitter follower network [62, 63]. The second line, at maximum key popularity of ∼ 14%, shows the point until which Weave's default value α (≈ 1.85) does not need to be increased; beyond this, the minimum viable α required to preserve IND-CDJA security increases linearly up to 13. Interestingly, at the point when Weave's default α needs to be increased, a single reducer ends up processing all intermediate key-value pairs associated with that key — nearly 14% of the entire dataset, and 45% more (real) key-value pairs than any other reducer — an unlikely scenario in real-world settings.

Impact of C (Figure 8(d)). For MR jobs where Map outputs $1 < c < C$ records, Weave (or any other IND-CDJA-secure scheme) must add $C - c$ "filler" intermediate key-value pairs to the Map output (§2.4), increasing its overhead by a factor by $\frac{C}{c_{avg}}$ (§2.4). We evaluate this impact on a Word Count job on the Enron Email dataset, where Map breaks down each sentence into multiple constituent words. We vary the required C by filtering out sentences with word counts over C and scaling up the rest of the dataset to the same size while preserving data distribution. Figure 8(d) shows that as C

(a) Weave execution time breakdown (b) Weave optimizations (c) Sensitivity to α (d) Sensitivity to C

Fig. 8: **Weave performance and sensitivity analysis (§5.3, §5.4).** (a) Random-shuffle phase overhead is linear in dataset size, histogram phase has negligible overheads and balanced-shuffle phase overheads are higher for non-associative jobs. (b) The sampled histogram optimization reduces Weave execution time by 18%–30%; associative reduce optimization reduces it further by 29%. (c) Highly skewed input distributions increase Weave overheads – the red vertical line shows the maximum skew (3%) we observed in real-world social network datasets for Twitter follower network [62, 63]. (d) Increasing C Word Count from 4 to 48 increases Weave runtime by up to 4.1×.

increases from 4 to 48, Weave's performance overhead relative to the insecure baseline increases from 1.32× to 5.34×. Moreover, an insecure variant of Weave (purple line) that does not insert filler records maintains a consistent 1.32× overhead as C increases.

6 Discussion and Future Work

We now discuss areas of future research.

Processing in batches. The complexity of random-shuffle in Weave is $O(\hat{n})$, a key factor in Weave's ability to provide IND-CDJA-security with constant overhead. This, however, requires all of the data generated by the map phases to be randomly shuffled *all at once*. If the data were instead sent in batches, an adversary with prior knowledge of how the input data is divided across them could identify specific data items sent to a weaver based on the batch they were sent in. This is particularly relevant to applications in streaming analytics [64, 65], where MapReduce jobs are executed on *micro-batches* of data. This requires adaptation of random-shuffle phase in Weave to ensure security even when applied to a series of such micro-batches. A possible approach to facilitate this is to adapt the dynamic distribution adaptation schemes and security models explored in prior work on oblivious storage [15, 18] to Weave for obliviousness *per micro-batch*.

Other communication patterns. Our work focuses on shuffle-based all-to-all worker communications in MapReduce analytics. Other analytics frameworks, such as distributed ML training or deep learning, employ different communication patterns, especially in collective operations such as broadcast, all-reduce, gather, all-gather, etc. These communications also suffer from similar access pattern leakages [66, 67] and can benefit from noise-injection-based obliviousness for efficiency and privacy.

Other side channels. While our work focuses on oblivious analytics execution by hiding network and memory access patterns, we consider two additional side channels outside our scope. The first is length-based leakage — similar to prior works [11, 12], we assume the key-value pairs in map-reduce communications are all fixed-sized or can be padded to the same fixed size. However, in real-world datasets, key-value pairs can have sizes that vary by several orders of magnitude, and padding can be prohibitively expensive [68]. Second, we do not consider timing-based attacks, where the duration of the computation can reveal information about the nature of the processing and the data to an adversary. While our security model assumes that the adversary already knows the job being executed, securing such timing-based channels becomes even more crucial when the jobs are secret. We leave the exploration of efficient schemes that can prevent leakage via both side channels to future work.

7 Conclusion

Weave is an efficient and expressive secure analytics platform that scales to large datasets. Weave applies the principles of noise injection to reduce the network and compute overheads for oblivious analytics to a constant factor. Weave reduces the oblivious execution time for analytics jobs on large real-world datasets by 4–10× compared to the prior state-of-the-art.

Paralegal: Practical Static Analysis for Privacy Bugs

Justus Adam Carolyn Zech Livia Zhu Sreshtaa Rajesh Nathan Harbison
Mithi Jethwa Will Crichton Shriram Krishnamurthi Malte Schwarzkopf
Brown University

Abstract

Finding privacy bugs in software today usually requires onerous manual audits. Code analysis tools could help, but existing tools aren't sufficiently practical and ergonomic to be used.

Paralegal is a static analysis tool to find privacy bugs in Rust programs. Key to Paralegal's practicality is its distribution of work between the program analyzer, privacy engineers, and application developers. Privacy engineers express a high-level privacy policy over markers, which application developers then apply to source code entities. Paralegal extracts a Program Dependence Graph (PDG) from the program, leveraging Rust's ownership type system to model the behavior of library code. Paralegal augments the PDG with the developers' markers and checks privacy policies against the marked PDG.

In an evaluation on eight real-world applications, Paralegal found real privacy bugs, including two previously unknown ones. Paralegal supports a broader range of policies than information flow control (IFC) and CodeQL, a widely-used code analysis engine. Paralegal is fast enough to deploy interactively, and its markers are easy to maintain as code evolves.

1 Introduction

Applications that handle sensitive user data must comply with privacy policies and legal frameworks like the GDPR [35], access control, and data retention limitations. Even within a single organization, the number of developers modifying a shared codebase on a daily basis makes it difficult to correctly implement and adhere to these requirements [36, 84]. Today, organizations rely on manual audits by privacy experts or external consultants to check if their code respects privacy properties. Such manual audits are laborious, error-prone, and unlikely to happen frequently [69, 72].

Paralegal is a program analysis tool that helps developers find possible privacy problems in their code before deployment. For example, an organization might want to check that all data associated with a user is deleted when they remove their account. With Paralegal, application developers provide meaning to abstractions like "user data" by annotating concrete code elements with *markers*. Privacy engineers meanwhile articulate a high-level policy saying that deletion functions must exist for all types that represent user data, and that the program must call those functions (e.g., "all types marked as user data must flow into deletion functions"). Paralegal models the application by generating its marked Program Dependence Graph (PDG), i.e., a PDG with markers propagated to the appropriate nodes. It then evaluates the policy against the PDG and reports violations to developers.

Paralegal aims to be a practical system for daily use by developers in an integrated development environment (IDE) or a continuous integration (CI) toolchain. While Paralegal is based on a rich literature on bug finding and policy enforcement tools, it contributes two key ideas that improve the practical applicability of such tools on real-world software.

First, Paralegal introduces *markers* as a layer of separation between policy and code that distributes the specification effort between respective experts. Privacy engineers author policies over markers as a vocabulary of semantically meaningful terms, but developers maintain the association of code elements to markers as the code base evolves. This results in policies that are easier to read and robust to code changes. It also allows Paralegal to precisely identify the code relevant to the policy, which it uses to optimize the analysis.

Second, Paralegal leverages the Rust programming language for scalability, precision, and reduced specification effort. Rust's ownership type system controls aliasing and mutation and allows Paralegal to approximate a function's effects by its type. Paralegal leverages such approximations to deal with third party library code when source code is unavailable or when the code is complex and hard to analyze, e.g., as is the case in standard library code. Both these cases traditionally require non-trivial, manual modeling effort. Paralegal further relies on these approximations for scalability. Since markers identify the policy-relevant parts of the codebase, Paralegal cheaply approximates a function's effects via its type signature if no marker is reachable in the function's body or its callees. Rust also encourages static dispatch via its trait system, and aliasing-restricted references via its ownership model. Both make data and control flow analysis, as employed

by Paralegal, more precise.

We have four success criteria for Paralegal: (i) Paralegal should find real privacy bugs, (ii) policies should be expressive, maintainable, and independent from the application code minutiae, (iii) policies should be auditable by non-developers, and (iv) Paralegal should scale to real-world applications.

We evaluate our prototype on eight real-world Rust web applications. Paralegal finds both known and unknown privacy issues in them: Paralegal would have caught five known bugs and found two previously unknown bugs. We compare Paralegal's approach with IFC and CodeQL, a practical code analysis tool supported by GitHub [15]. We find that Paralegal can express a broader range of policies than IFC, that Paralegal finds bugs more reliably than CodeQL, and that Paralegal's markers reduce the complexity of policies compared to CodeQL. We also investigate Paralegal's maintenance effort in evolving applications by applying it to 1,000+ commits spanning 2.5 years of development of Atomic [5], and find that marker changes are rare and no modifications to the policy were needed to keep enforcing it. Finally, we find that Paralegal's optimizations to reduce PDG size allow it to run in seconds, making it suitable for frequent and interactive use.

Paralegal is open-source [33] and our prototype is currently being evaluated for use at a large internet company. This company already has extensive static analysis tooling, but sees value in Paralegal as a complement to it. Specifically, teams at the company are exploring applications of Paralegal to ensure secrecy of cryptographic keys, to enforce encryption-at-rest, and to check that mitigations for speculative execution attacks are executed in hypervisor code.

In summary, this paper makes four key contributions:

1. The Paralegal static analyzer, which checks high-level properties against low-level, evolving code bases.
2. The marker abstraction to decouple policies and code; and techniques to efficiently generate precise marked PDGs from Rust code and model the behavior of library code.
3. A flexible policy framework that compiles policies in a high-level language into queries on marked PDGs.
4. Case studies reporting on our experience of applying Paralegal to eight real-world Rust web applications.

Paralegal has some limitations. As a static analyzer, it can only reason about information known at compile time and must abstract over all possible executions. Paralegal's policy flexibility also means that there is no universally sound approximation during PDG construction. As such, Paralegal's soundness and completeness are policy-dependent (see §4.1.3).

2 Motivation and Background

A practical privacy bug finder must be ergonomic for developers and deal with the realities of real-world codebases, including widespread use of libraries and frequent code change.

Specialized tools achieve practicality by targeting a single domain or type of policy. These systems operate on widely-used programming languages (e.g., Java, Python, Javascript, or SQL) and bake an understanding of the domain into the system—e.g., Android apps in DroidSafe [42], tabular data analytics in PrivGuard [77], or ORM-based MERN (MongoDB, Express.js, React.js, NodeJS) apps in RuleKeeper [38]. Importantly, this domain modeling helps these systems understand the semantics of API functions, libraries, and frameworks without having to analyze their code. However, these tools are limited to checking domain-specific properties and cannot support libraries outside their domain model.

At the other extreme are general **security-typed programming languages**. This category includes languages designed for information flow control [47, 63, 67] and security-typed ORMs [49], as well as proof assistants that encode security policies into dependent types [11]. These languages generally require a purely-functional programming style or extensive annotations on application and libraries, may require manually-authored proofs, and are not widely used in practice.

Prior **code analyzers** let users encode policies as queries over an Abstract Syntax Tree (AST) or a flow-based model of a codebase. Systems that target common programming languages (e.g., C [79], Java [46], PHP [10], Node.js [57], and Ethereum contracts [73]), exist, but all suffer from practicality limitations around library code and policy ergonomics. All of these systems either ignore library code or require developers to provide and maintain manually-written models to convey its behavior. For example, consider CodeQL [9], a "semantic code analysis engine" maintained by GitHub that has backends for languages including C++, Java, and Python. CodeQL's developers maintain extensive, manually-written models of C++ libraries such as `std` and `boost` [16, 17], and users must equally model other libraries they use. Code analyzers also rarely integrate with the codebase being analyzed, but instead encourage policy writers to query syntactic code constructs. For example, CodeQL policies often use regular expressions over identifiers to select source code elements. While helpful for use cases where the goal is to identify syntactic patterns (e.g., retry loops [71]), this design makes CodeQL brittle for enforcing custom semantic properties over changing code.

Paralegal targets Rust, a mainstream programming language whose ownership type system provides Paralegal with the ability to usefully approximate the effects of external library code. Paralegal thus avoids domain-specificity or a need for pervasive flow models to enforce policies over data flowing in and out of library code. Paralegal decouples policies and source code using lightweight markers that developers attach to program elements and maintain with their code.

3 Paralegal Overview

Paralegal catches privacy bugs in Rust programs by extracting a model of the dependency relationships between values at compile time and checking whether this model satisfies a policy written by a privacy engineer. We illustrate Paralegal's workflow using an example based on a real-life bug in Plume,

```rust
#[paralegal::marker(user_data)]
struct Comment { ... }

impl Database {
  #[paralegal::marker(make_delete_query, arguments = [id])]
  fn prepare_delete(&mut self, id: u32, table: &str) {...}
}

impl User {
  #[paralegal::analyze]
  fn delete_user(&self, db: &mut Database) {
    let my_data: UserData = self.get_my_data();
    db.prepare_delete(self.id, "users");
    for post in &my_data.posts {
      db.prepare_delete(post.id, "posts");
    }
    for comment in &my_data.comments {
      db.prepare_delete(comment.id, "comments");
    }
    db.execute();
  }
}
```

Figure 1: *Paralegal alerts developers to missing code (red) to delete a user's comments when deleting their account in Plume [66]. (Code simplified and error handling omitted.)*

```
Somewhere:
1. For each "user data" type marked user_data:
  A. There is a "source" that produces "user data" where:
    a. There is a "deleter" marked deletes where:
      i) "source" goes to "deleter"
```

(a) *The initial Plume user deletion policy.*

```
Somewhere:
1. For each "user data" type marked user_data:
  A. There is a "source" that produces "user data" where:
    a. There is a "deleter" marked make_delete_query where:
      i) "source" goes to "deleter"
      and
      ii) There is a "execute" marked executes where:
        A) "deleter" goes to "execute"
```

(b) *The revised Plume user deletion policy.*

Figure 2: *Example specification for user data deletion written in Paralegal's policy language (§4.3). **Policy clauses**, "variables", and markers are highlighted.*

a federated blogging application [66].

Plume lets users create posts and comments. If a user deletes their account, the application must delete their posts, comments, and the user metadata. Figure 1 shows the user deletion code. `delete_user` on `User` takes a database handle as an argument. It constructs deletion queries for the user themselves and each of their posts and comments, then executes those queries. This function contained a privacy bug: the code in red was missing, so user comments were not deleted [64]. Given a suitable privacy policy, Paralegal catches this bug.

First, a privacy engineer formalizes a policy in Paralegal's policy language (Figure 2a). They express the policy in terms of *markers*. Here, the marker `user_data` describes the concept of personal data, and `deletes` describes the concept of deleting data. Markers allow privacy engineers to formulate the policy at the level of the design of a program, rather than its concrete implementation. The privacy engineer produces the policy in Figure 2a and sends it to a developer.

The developer leverages her application knowledge to apply the policy's markers to relevant program entities. She applies the `user_data` marker to the types `Post`, `Comment`, and `User`. When she tries to apply the `deletes` marker, however, she discovers that there is no correct place to put it. If she applies it to the `prepare_delete` function, the policy would pass if a deletion query is simply *constructed*; nothing ensures that the application actually *executes* the query. She cannot put it on `execute` either: `execute` is a generic function that handles all types of queries, so applying the `deletes` marker here would allow *any* executed query to satisfy the policy.

Since the privacy engineer is unfamiliar with implementation details, they wrote a policy that does not quite fit with the application logic. The developer is faced with a choice: she can either refactor the application to work with the policy as written, or she can work with the privacy engineer to revise the policy. She goes back to the privacy engineer, explains the problem, and both together revise the markers and write a new policy—for all types of user data, there must exist a query to delete them, *and* that query must be executed (Figure 2b). The developer applies the new markers to the application. This give-and-take between privacy engineers and developers is a common Paralegal workflow.

The developer then regularly runs Paralegal to check the policy as she works on the application (e.g., in CI or as an IDE plugin). When faced with the erroneous `delete_user` function, Paralegal reports the error shown in Figure 4. Internally, Paralegal produced the marked PDG shown in Figure 3 and detected that there is no path from a node marked `Comment` to a node marked `make_delete_query` (and from `make_delete_query` to `executes`). The developer fixes the bug by adding the red code in Figure 1, and Paralegal's check passes again.

4 Design

Paralegal is comprised of three components: PDG construction (§4.1) as an abstraction of the program, markers (§4.2) as a semantic vocabulary, and policies (§4.3) that constrain how marked entities in the program can interact.

4.1 Program Dependence Graph

The PDG [37] is a generic representation of a program that can be reliably extracted for applications in any domain. For example, Figure 3 shows a simplified PDG for the Plume application in Figure 1. Paralegal constructs this PDG from Rust's MIR, a control-flow graph (CFG) intermediate repre-

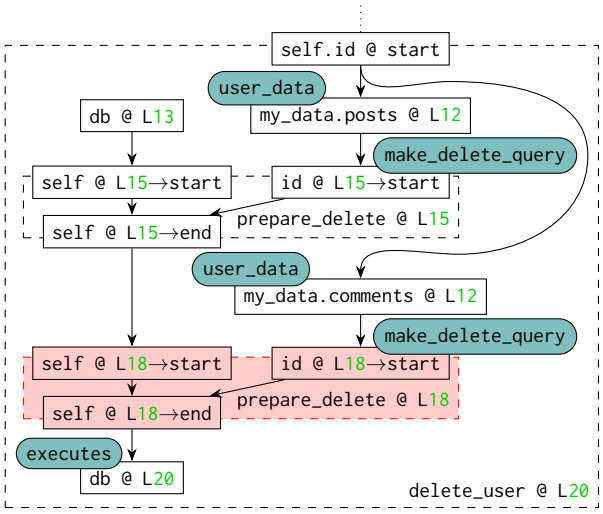

Figure 3: *Partial and simplified PDG for the Figure 1 example. Solid rectangles are PDG nodes, dashed rectangles are function scopes, and teal bubbles are markers. The red subgraph represents the missing comment-deletion code. "Lk" = line k in Figure 1. "start" and "end" refer to the function entry and exit locations, respectively.*

sentation in the Rust compiler.

To check policies on realistic codebases with reasonable accuracy, the PDG must be sensitive to dependencies at a fine granularity. Specifically, the PDG needs three properties:

Flow-sensitivity allows the PDG to distinguish between the values of data at different program locations. For instance, the value of `db` at Line 13 is not the same as the value of `db` on Line 20, so the PDG has separate nodes for each. By contrast, a flow-*insensitive* PDG would represent `db` with a single node, only reflecting the value of `db` at the end of the program, once all of the queries have been prepared and executed. This single-node representation would allow a program that calls `execute` *before* preparing the queries to pass the policy, even though such a program would not actually delete any data.

Context-sensitivity allows the PDG to distinguish between different calling contexts to the same function. Without context sensitivity, the PDG would represent the body of the `prepare_delete` function only once. This would mean that, for instance, its `self` argument is only one PDG node. Each call to `prepare_delete` (Lines 13, 15 and 18) then connects its inputs to that one `self` node in the PDG. It would therefore appear as though `self.id`, `post.id`, and `comment.id` are *all* arguments to the first `prepare_delete` call (Line 13), even though only `self.id` is. As a consequence, the policy could not detect a bug where a developer moves the `execute` call to Line 14.

Field-sensitivity allows the PDG to distinguish between different fields of a structure. For example, a field-sensitive PDG distinguishes `posts` and `comments`, even though they belong to a single variable, `my_data`. A field-*insensitive* PDG would not be able to detect the original bug (shown in red),

```
1  'Deletion Policy' not satisfied.
2  No entrypoints satisfied rule                1.A.a.i
3  Entrypoint `delete_user'
4    Did not satisfy                            (Rule 1.A.a.i)
5      "source" goes to "deleter"
6    for this "source":                         (Rule 1.A)
7      12 | let my_data = self.get_my_data();
8         |     ^^^^^^^
9    for the "user data" type: "Comments"       (Rule 1)
10   Help: There is a "deleter" here:
11     13 | db.prepare_delete(self.id, "users");
12        |                   ^^^^^^^
```

Figure 4: *Paralegal's error for the Plume deletion bug.*

because `my_data` (and therefore `comments`) does flow to `delete`.

Each kind of sensitivity increases the cost of PDG generation for both runtime and memory consumption. Paralegal mitigates these costs with the optimizations discussed in §4.1.2.

4.1.1 Definitions

Formally, the Rust CFG follows a superset of the grammar in Figure 5 (left). In this simplified model, instructions are either assignments, unconditional jumps, conditional jumps, or returns. The left-hand side of an assignment is a *place*, or an expression that refers to a specific region of memory (a variable, a field of a place, or a dereference of a place). The right-hand side can be constants, places, operations on places (including address-of), or function calls. The actual Rust CFG contains more details such as array indexing, but this subset is sufficient to illustrate Paralegal's behavior.

The Paralegal PDG follows the exact grammar in Figure 5 (right). A node in the PDG is a place p at a call string cs, and an edge is an operation of kind ek at a call string. A call string represents the sequence of locations $\ell_0 \dots \ell_k$ that uniquely identify a given instruction in a call tree.

The fundamental goal of the Paralegal PDG is to encode *dependence* within a Rust program. Dependence is a hyperproperty [14] of a program: informally, a variable y depends on a variable x if there exists two executions of a program such that changing x as input changes y as output, with all else held equal. There are two kinds of dependencies: data-dependencies, where the value of x directly affects y (such as $y = x + 1$), and control-dependencies, where the value of x indirectly affects y (such as **`if`** x **`then`** $y = 0$ **`else`** $y = 1$).

A PDG represents dependencies as paths between nodes. Say a PDG contains the edge:

$$p_{\mathsf{src}} \mathbin{@} cs_{\mathsf{src}} \xrightarrow{ek \mathbin{@} cs_{\mathsf{eff}}} p_{\mathsf{dst}} \mathbin{@} cs_{\mathsf{dst}}$$

then it should be the case that p_{dst} at cs_{dst} directly depends on the value of p_{src} at cs_{src} due to the effect ek at cs_{eff}. For example, a PDG for the instruction $y = x + 1$ would contain the edge $x \xrightarrow{\mathsf{data}} y$ (ignoring call strings). If there exists a path from p_{src} to p_{dst} in the PDG, or more formally:

$$p_{\mathsf{src}} \mathbin{@} cs_{\mathsf{src}} \xrightarrow{*} p_{\mathsf{dst}} \mathbin{@} cs_{\mathsf{dst}}$$

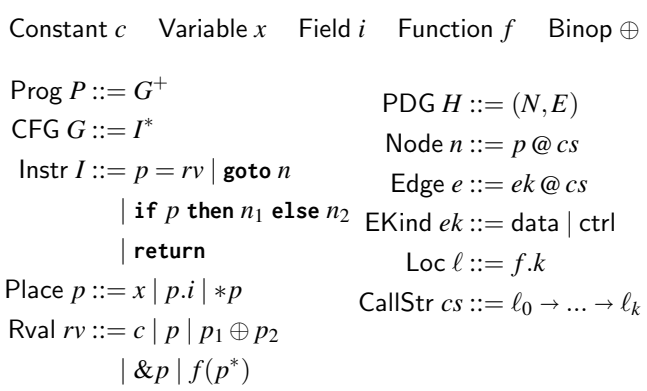

Figure 5: *Grammar for a core subset of the Rust CFG (top and left) and for the Paralegal PDG (right).*

then it should be the case that p_{dst} at cs_{dst} transitively depends on p_{src} at cs_{src}. We use the phrase "it should be" to indicate that this is the ideal case where the PDG faithfully represents dependencies. Paralegal's PDG contains all true dependencies for programs that use no unsafe features (e.g., FFI or pointer arithmetic). §4.1.3 discusses cases outside this guarantee.

4.1.2 Analysis

To construct a PDG, Paralegal statically analyzes each instruction that is reachable from the entrypoints of the analysis. Much of the PDG construction is standard practice—for details, see Ferrante et al. [37]. Our analysis benefits from the choice of Rust as a host language in three key ways.

Monomorphization. Given a function call $f(p_1, \ldots, p_n)$, Paralegal must determine which function f refers to. For example, the expression `x.to_string()` dispatches the trait method `to_string` based on the type of `x`. Paralegal monomorphizes function calls using context-sensitive statically-available type information. For example, if `x` has type `i32`, then Paralegal recursively analyzes the implementation of `<i32 as ToString>::to_string`. Here, Paralegal leverages Rust as the target language for analysis. By design, Rust strongly encourages the use of static over dynamic dispatch—most popular Rust libraries do not use dynamic dispatch at all [74]. Therefore, Paralegal can frequently monormophize function calls, which increases precision around libraries.

Modular approximation. For third-party libraries without source code available, Paralegal cannot know the implementation of f. In these cases, prior systems have either asked users to manually model the behavior of f (e.g., CodeQL maintains a large model of the C++ standard library), or made unsound assumptions about the behavior of f (e.g., Pidgin [46] assumes such functions have no side effects).

Paralegal instead uses the Rust type system to approximate the behavior of f soundly and precisely. At its core , the approximation conservatively assumes that all arguments to a function will influence all outputs of the function. However, Paralegal builds on the technique used in the Flowistry information flow analyzer for Rust [28], which provides two key pieces of information that refine this approximation:

1. *Mutability:* In Rust, a program is not allowed to mutate data accessible from an immutable reference. Paralegal can therefore assume that function calls do not mutate values behind immutable references, which limits the set of plausible outputs and therefore the data flows introduced by the approximation. For example, Rust's `HashMap<K, V>` has a method (slightly simplified) for removing a value:

   ```
   fn remove(&mut self, key: &K)
   ```

   Paralegal can assume that `HashMap::remove` only mutates `self` and not `key`.
2. *Aliases:* In most languages it must be assumed that, in addition to the described data flows, a function may introduce arbitrary aliasing relationships on pointers it has access to. In practice, such an assumption causes too many false positives to make for a useable analysis. In Rust however, all references (the most common pointer-like type) are annotated with a *lifetime* that indicates a precise, limited set of possibly aliased objects. For example, `HashMap<K, V>` has a method for getting a value by key:

   ```
   fn get<'a, 'b>(&'a self, key: &'b K) -> Option<&'a V>
   ```

   This method returns a reference to a value of type `&V`. Because the reference has lifetime `'a` and not `'b`, Paralegal can assume that `&V` points to `self` and not `key`.

This *modular approximation* of a function's behavior is highly accurate compared to precise analysis with access to the function's source code [28]. Therefore, this technique helps Paralegal retain precision while reducing developer burden.

Similarly, resolving function calls with dynamic dispatch is challenging. Paralegal leverages the same modular approximation to approximate the effects of a function behind dynamic dispatch; with additional engineering, Paralegal could analyze all possible function bodies to improve soundness [4].

Function cloning. Paralegal achieves context-sensitivity via function cloning [78], where each call-site duplicates the sub-graph of the called function. This technique is maximally precise, but it risks exponential growth in the size of the call graph. We found in practice that PDGs for realistic Rust applications are nonetheless small enough such that Paralegal runs reasonably fast, even for codebases with 198k LOC (§7.4). Two key factors enable this scalability. First, Paralegal uses markers to reduce PDG size, which we will describe in §4.2. Second, Paralegal uses a context-insensitive alias analysis based on Rust's lifetimes, which allow Paralegal to reuse the PDG for a function across all call sites to that function.

4.1.3 Limitations

Paralegal's PDG construction is similar to most static analyses in that it may include false dependencies by abstracting away relevant details of the code. For example, Paralegal will assume a branch could always reach both targets. This causes

a false dependency in cases like `z = if e { x } else { y }` where `e` is an expression that always evaluates to false. The impact of such inaccuracies on soundness or completeness depends on the policy being checked. For example, including a false dependency can cause a false-positive for policies like "secure sources *cannot flow* to insecure sinks," while it may cause a false-negative for policies like "user data *must flow* to a deletion function."

Paralegal errs on the side of including false dependencies rather than omitting true dependencies. Specifically, Paralegal's guarantee is that in Rust code without unsafe blocks, all true dependencies will be reflected in the PDG.

In general, developers should treat Paralegal output similar to that of a linter or bug finder. That is, a developer should not assume, "if Paralegal says my app is okay, then it is 100% secure or bug-free." Rather, the developer should assume, "if Paralegal says my app contains a policy violation, then I should investigate it." Some sources of inaccuracy are incidental and can be addressed with further engineering (see §5). Others are fundamental and discussed next.

Unsafe code. Rust uses `unsafe` blocks to permit operations that cannot be verified safe by the compiler, including FFI (e.g., calling C libraries) and use of raw pointers (as opposed to compiler-checked references). Paralegal may omit true dependencies induced by unsafe code, such as aliases induced by pointer arithmetic, because Paralegal reasons about aliasing via Rust's lifetimes.

Paralegal mitigates this limitation by using its type-based approximation. A common pattern in Rust FFI is to carefully encapsulate unsafe code within an API presenting a safe interface. Paralegal can analyze such an API just at the interface level without observing the unsafe internals.

Interior mutability. Rust provides "interior mutability" primitives like `RefCell<T>` which permit mutating data behind an immutable reference—that is, one can turn an `&RefCell<T>` into an `&mut T`. This special case violates the assumption of the type-based approximation that a function cannot mutate immutable references. Therefore, Paralegal may omit true dependencies when approximating calls to functions using interior mutability. This limitation also extends to shared-memory constructs, such as locks and mutexes.

This limitation is mitigated by two factors. First, interior mutability is rare in idiomatic Rust. For example, the largest application in our evaluation (HyperSwitch, about 198k LOC) contains no interior mutability in its application logic. Second, interior mutability impacts Paralegal's type-based approximation, not the dependency analysis. For example, a directly observed mutation `*cell.borrow_mut() = 1` *is* registered correctly as mutating `cell`, but if it takes place in `fn foo(cell: &RefCell<T>)` and `foo` get approximated, it is not.

External effects. Paralegal may omit true dependencies induced by effects on external systems like a file system, OS, or database. For example, if `f` is a `File` called `foo.txt`, then Paralegal understands that `f.write(bytes)` affects `f` because `write` requires a mutable reference to `f`. But Paralegal does not understand that `f2 = File::open("foo.txt")` is effectively an alias on `f`, and that `f2.read()` should depend on `f.write(bytes)`.

4.2 Markers

To articulate privacy policies in terms of a PDG, privacy engineers need to refer to nodes of interest. Most prior systems keep policy-related information entirely outside the codebase, and consequently require policies to embed direct references to functions or types. Such direct references make policies more complex and brittle, as §7.2.2 will show.

Paralegal instead uses *markers* to abstract categories of related nodes in the PDG. A marker is an abstract label, such as "sensitive data" or "public sink." Application developers attach markers to code elements, either via source-level annotations (e.g., `#[marker(user_data)]`) or an external configuration file. Developers can mark functions, function arguments, return values, and type definitions. The basic concept of a marker is relatively straightforward, but the subtleties lie in two areas: how Paralegal propagates markers to the PDG, and how Paralegal uses markers to optimize PDG generation.

Marker propagation. After generating the PDG, Paralegal assigns markers to the concrete nodes in the PDG that represent the abstract marked code elements. A parameter p of f, marked with m is a straightforward case. Paralegal assigns m to all PDG nodes that represent the *actual* parameter p at call sites of f. Paralegal handles markers on return values of functions analogously.

The type case is more complex. The simplest situation is as follows: say a marker m is attached to a type τ, and say a node $n = p \,@\, cs$ has $p : \tau$. Then Paralegal propagates m to n.

However, this algorithm may not always capture a privacy engineer's intent. For example, say a `Password` type is marked `sensitive`, and a `User` struct contains a field of type `Password`. Then say the code has a variable `u : User` and calls `f(&mut u)` on some black-box function f. The modular approximation will create one node for u at this call site, but not a node for every field in u.[1] The simple propagation strategy therefore neglects to attach m to n_u. However, the privacy engineer likely expects that because `Password` *could* have been mutated by f, the node n_u should be treated *as if* it were of type `Password`. To capture this expectation, Paralegal's actual algorithm propagates the marker. Say a node has $p : \tau'$. If marked type τ appears anywhere within τ' (e.g., the `User` struct, or $\tau' =$ `Vec<`τ`>`), Paralegal propagates m to p.

Adaptive Approximation. In Paralegal, policies can only talk about application entities that are marked. Paralegal may therefore soundly assume that only code interacting with marked entities influences policy enforcement outcomes. Paralegal leverages this assumption when analyzing an instruction that calls a function f by checking if there are markers reach-

[1] Such an approach would work, but increases the size of the PDG and leads to no additional precision, since function signatures are not precise enough for a field-sensitive approximation.

able from the body of f, and if not, approximates f's effects via type signature instead of generating its subgraph. Paralegal determines reachable markers by visiting all code reachable from f with a cheap call graph traversal. Paralegal fully monomorphizes f and all other functions during the traversal to prevent ambiguity as to what code is called for trait methods. Paralegal caches and reuses the results of marker-reachability traversals for each function. This optimization substantially improves PDG generation speed (§7.5).

4.3 Policies

Paralegal policies are assertions about either necessary or impermissible paths in the marked PDG. For example, a high-level privacy policy such as "a user must be able to delete all of their user data" can be encoded as the assertion "for all types marked `userdata`, there must exist a path from a node with that type to a node marked as a deletion function."

To express such assertions, Paralegal provides a policy language with a controlled natural language syntax that mimics the structure of legal documents. Paralegal compiles policies into Rust programs that use a low-level API to query the marked PDG. The primitives of the DSL are markers, variables, and PDG relations. Primitive relations include:

- `a "value" marked sensitive`
  binds PDG nodes marked `sensitive` to the name "value".
- `"value" goes to "sink"`
  Checks if a *data flow* path from `"value"` to `"sink"` exists in the PDG.
- `"value" affects whether "operation" happens`
  Checks if `"operation"` has a *control flow* dependency on `"value"`.
- `"value" goes to "sink" only via "disclosure"`
  Holds if every data flow path from `"value"` to `"sink"` contains at least one node in the set `"disclosure"`. This primitive allows policies to describe instances of declassification.

Privacy engineers than compose these primitives in first-order logical formulas. For example, a formula like this:

$$\forall x \in X.\ \exists y \in Y.\ P(y) \implies (P(x) \vee S(x,y))$$

is expressed in the policy language as the program on the left, which Paralegal compiles into the Rust code on the right:

```
1. For each "x" in X:
  A. There is a "y" in Y where:
    a. If P("y") then:
      i. P("x")
      or
      ii. S("x", "y")
```

```
X.iter().all(|x|
  Y.iter().any(|y|
    !P(y) || P(x)
          || S(x, y)))
```

The policy language requires policy writers to delineate the scope of each line in their policy with clauses (e.g., 1, A.). This structure of nested clauses, inspired by legal writing, seeks to achieve readable and unambiguous properties. The policy language is decidable because all primitive relations are decidable (the PDG is finite, so reachability is decidable), all quantifiers are decidable (they range over finite subsets of nodes), and recursive policies are inexpressible. Appendix A.3 has the full grammar for the policy language.

Paralegal allows policy writers to author policies as graph queries using the low-level Rust API. This primarily helps policy writers customize error messages, for example by emitting traces and paths through the PDG.

4.4 Error Messages

Paralegal's error reporting helps developers diagnose a failing policy. Error messages print the violated rules and the source code location that instantiated a given quantified variable (as in Figure 4). Paralegal reports them with a diagnostics framework inspired by the Rust compilers's error messages, relating graph nodes to snippets of the source code. Policies written with the low-level API can use this diagnostics framework directly to create customized error messages.

5 Implementation

Our Paralegal prototype consists of 15.1k lines of Rust and is implemented as a Rust compiler plugin.

Multi-crate support. Paralegal extends analysis across multiple crates by persisting the Rust MIR, the "outlives" relationships of lifetimes, output of the Rust type checker, and any Paralegal marker annotations. In one of our largest case studies (the social media application Lemmy [55]) this metadata for all crates combined is 411MB. (For context: `rustc` produces 258MB of metadata for the same application.) During PDG construction, Paralegal lazily loads the MIR for reachable functions and generates their PDG if markers are reachable. Paralegal's PDGs can span all crates for which `cargo` initiates compilation in the process of building the target application. Developers can limit this set for performance. This approach preserves source location information and error messages may reference locations in any loaded crate. A PDG cannot extend to external shared or precompiled libraries; in such cases, Paralegal uses the modular approximation.

Await. Paralegal deliberately discards all *control flow* introduced by the state machine created by `await`. This control flow is needed for Rust's async runtime, but it causes confusing false positives because privacy engineers do not expect these dependencies due to their transparent nature. The consequence of removing them is more predictable policy behavior at the cost of being unable to check for certain malicious async patterns, such as futures that hang indefinitely.

Marker limitations. Paralegal's marker annotations currently only support functions, function arguments, function return values, and type definitions. While these represent the common boundaries for semantic meaning of source code elements, policies would be more ergonomic if Paralegal allowed markers to be attached to fields of a type or global constants. Expanding the set of markable elements is feasible with additional engineering.

6 Case Studies

We now discuss our experience applying Paralegal to eight real-world Rust applications. We tried to pick popular, pro-

Application	Type	LoC	Policies	Unique Markers	Marked Locations	Entry pts.
Atomic [8] (v0.34.2)	Graph DB	9.6k	Access Control	4	4	1
Contile [27] (v1.11.0)	Advertising	4.9k	Purpose Limitation	3	5	1
Freedit [41] (v0.6.0-rc.3)	Social	6.6k	Data Retention/Expiration	5	5	4
Hyperswitch [44] (v0.2.0)	Payments	198.9k	Credential Security, Limited Collection	6	7	3
mCaptcha [59] (v0.1.0)	Authentication	10.6k	Data Deletion, Limited Collection	5	5	2
Lemmy [55] (v0.16.6)	Social	31.4k	Access Control	8	145	72
Plume [66] (v0.7.2)	Blogging	21.4k	Data Deletion	7	7	1
WebSubmit [68] (v1.0)	Homework	1.6k	Data Deletion, Access Control	11	18	3

Figure 6: *Case study applications with code size, policies, and Paralegal marker statistics. "Marked Locations" indicates the number of source code entities (arguments, returns, etc.) we marked; "Entry pts." is the number of analysis entry points.*

duction-level Rust applications that cover a range of domains and coding styles (Figure 6). The source code for these applications exercises language features and data-structures typically found in realistic software, including loops, traits, type parameterization, closures, higher-order functions, error handling, vectors, hash maps, strings, and async. We marked between four and 145 program locations, roughly proportionally to the amount of application code covered by policies.

Policies cover privacy properties from classic access control and security to data deletion and expiration, as well as purpose limitation (rules about what purposes data can be used for). We formalize 11 policies (1–2 per application), each with several clauses and nesting up to three quantifiers per clause (median: 3). The source code for all case studies, as analyzed in this paper, is available in our artifact [3].

6.1 Policies

We initially developed policies by examining source code, then directly writing policies about the expected flows in the PDG. But these policies used more markers and were more closely tied to source code than necessary. Hence, we switched to defining the policy first, using application functionality and documentation (as a privacy engineer would), then applying those policies to source code.

We found this approach made it easier to define policies, and that these new policies were clearer, more concise, and more portable to other applications. Privacy-related properties of applications are often obvious from the UI, functionality (e.g., account deletion), or documentation. By contrast, navigating a large, unfamiliar codebase to search for privacy-relevant sections is much harder. This experience inspired us to design the policy DSL. In two of eight cases we studied (see §6.3) our DSL policies, written without knowledge of source code, matched application semantics without revision.

We found that Paralegal is expressive enough to represent all the policies we wanted to check. Two applications (mCaptcha and Plume) use identical data deletion policies, except for their application-specific marker names. For policies that are fundamentally dynamic, we were able to define static approximations. For instance, Freedit, a social media platform, stores a user's viewing history, but deletes the data after three days. Since the current time is only available at runtime, Paralegal cannot directly verify that Freedit obeys the three day expiration limit. However, it can approximate this policy by checking that `viewing_history` flows to an `expiration_check` and that `expiration_check` has control flow influence on a `deletes`.

6.2 Markers

We found it easiest to apply markers to applications with modularized code that has clearly defined semantics. Applications with specialized delete or authorization check functions were simpler to apply markers to than applications that inline such logic inside large functions. We also found that many of our markers (e.g., `user_data`) could be applied to types alone. Idiomatic Rust programs often define fine-grained, custom types that are clearly named for the type of data they represent.

We mainly made two types of source code change. The first is because our prototype cannot apply markers to constants or to fields of a type, so we defined no-op functions `mark_{marker_name}(&data)`, whose sole purpose is to apply the appropriate marker to `data`. Second, if applications inlined privacy-critical functionality inside a larger function, there was no way of applying a marker to just the relevant lines. While this is not fundamental—a more complex policy could handle it—we extracted the logic into a helper function and marked that function. Via this process, Paralegal encouraged us to cleanly demarcate privacy-relevant code.

Appendix A.2 describes four other minor changes we made.

6.3 Selected Experiences

Two cases in our experience of developing policies stand out.

Atomic is a graph database that lets users create, edit, and share graph-structured data [5, 8]. Each time a user modifies a database resource, Atomic stores a signed *commit* record. Before creating a commit, the application must verify that the user has permission to modify that resource. Crucially, this authorization must happen *before* updating the database resource [7]. Our Paralegal policy asserts that a resource that will be modified first flows to an authorization check, which has control flow influence on the modification.

When we first ran this policy on the application, it failed,

Application	Bug Description	Reference	Paralegal Policy
Plume [66]	Comments and Media not deleted when a user is deleted.	commit 19f1842, issue 806	If a user flows into a delete function, all types marked as user data flow into a delete function.
Atomic [8]	Users can grant themselves write access to data without prior access.	commit 46a503a	Write permissions must be checked before a resource is updated.
Lemmy [55]	Banned or deleted users can log into a server.	commit b78826c	(1) A user deletion check and a ban check must influence every database access, except those reading the active user. (2) Community deletion check and user ban check must influence every database write to a community.
	Deleted users can perform actions in a server.	commit 2966203	
	Users can write to a deleted community.	commit 2402515, issue 2372	
	Banned users can act in communities.	issue 2372	

Figure 7: *Paralegal found seven bugs, including two previously unknown ones, in three applications: Plume [66], Atomic [8], and Lemmy [55]. The rightmost column summarizes, in prose, the Paralegal policy we used to find each bug.*

even after the developers fixed the bug. Upon investigation, we realized that we had missed an edge case: if a resource is new, the application *first* modifies the resource to set default permissions, *then* executes the permission check. We missed this logic initially because it was unclear in the application's documentation. In this situation, we had two options: *(i)* change the policy to exempt modifications that don't depend on user-provided data; or *(ii)* extract this benign modification into a helper function with an exception marker, and exempt this marker in the policy. The first choice burdens the policy with matching a specific code pattern; the second (which we chose) exempts only a specific code instance and clearly delineates the exception in the code itself.

mCaptcha is a proof-of-work (PoW) CAPTCHA service focused on privacy [59]. Website owners register sites with mCaptcha and embed mCaptcha API calls into their sites. mCaptcha's PoW algorithm features a tunable "difficulty", designed to balance security and latency.

In addition to adding a data deletion policy, which we reused from Plume (Figure 2a), we observed that mCaptcha collects optional consent to "gather performance statistics [...] and make them available to other mCaptcha installations" for difficulty tuning [45]. We wrote a policy to enforce that mCaptcha checks whether a user has opted in before storing their data, but the code failed this policy.

On discussing the issue with the mCaptcha developers, it turned out that we had misinterpreted their privacy goals—statistics are always collected, even if website owners don't opt into sharing them. The developers, however, indicated that they would be open to reconsidering this choice [58]. In addition, the discussion helped the mCaptcha developers find a (related) data integrity bug: they deleted all statistics when a user revoked their opt-in consent, rather than just the consent. This illustrates how the discipline enforced by Paralegal helps developers reflect on their code and find issues.

7 Evaluation

Our evaluation of Paralegal seeks to answer five questions:

1. Does Paralegal find bugs that result in privacy violations in real applications? (§7.1)
2. How does Paralegal compare to IFC and CodeQL in terms of expressiveness, practicality, and ergonomics? (§7.2)
3. Does Paralegal's decoupling of code and policies improve ergonomics for evolving applications? (§7.3)
4. Is Paralegal fast enough for interactive use, and how does its runtime scale with the amount of code analyzed? (§7.4)
5. How does Paralegal's adaptive approximation optimization contribute to its effectiveness and speed? (§7.5)

Setup. All experiments run on a server with an Intel Xeon E3-1230v5 CPU (3.4 GHz) and 64 GiB RAM, on Ubuntu 20.04 using Rust nightly-2023-08-25.

7.1 Finding Privacy Bugs with Paralegal

We applied Paralegal to eight applications (Figure 6) to investigate its ability to discover bugs. A good result for Paralegal would show that it finds previously reported bugs as well as new bugs, without generating many false positives.

Figure 7 summarizes the bugs Paralegal found: Paralegal found two previously unknown privacy bugs that were confirmed by the developers, as well as five previously known privacy bugs that the developers had already fixed.

Atomic and Plume. Paralegal found three known bugs in Plume and Atomic [6, 64, 65]. In Atomic, the policy passes Paralegal after the fix [6]. In Plume, however, the policy still fails after the developers' fix [64], since even though the application now deletes comments correctly, it still fails to delete users' uploaded media (a separate, known bug [65]).

Lemmy. We ran Paralegal on 72 HTTP endpoints in Lemmy. Paralegal found two bugs previously fixed by the Lemmy developers and two new additional bugs.

Known Bugs. A user may not access a Lemmy instance if their account has been banned or deleted. However, Lemmy's helper for authorizing already logged-in users omitted a check for whether their account is deleted [50]. Consequently, Paralegal flagged the instance authorization policy in all endpoints. After the fix [30], 71 endpoints passed the policy, but Paralegal still reported a failure in the login endpoint. Since the the login endpoint doesn't use the authorization helper for logged-

in users, it still did not check for account deletion [53]. The login endpoint was also missing a check if the user had been banned. After a second fix by the Lemmy developers [31], all 72 endpoints passed the policy.

New Bugs. Lemmy prohibits users to write in deleted communities: if a community was removed for problematic content, for example, users must not be able to make new posts. The Lemmy developers already found missing community deletion checks in five endpoints [32, 51], but Paralegal found 16 further endpoints lacking these checks.

In addition, a banned user should not be able to write to a community. Paralegal reported that some Lemmy controllers are missing these community ban checks. This allows bypassing access control: for example, a banned community moderator can immediately unban themselves. The Lemmy developers confirmed both bugs [52, 54].

7.2 Comparison with Related Work

Next, we evaluate how Paralegal's expressiveness and ergonomics compare to prior approaches, using the eleven policies from our case studies. We consider two baselines: *(i)* classic IFC based on a lattice of security labels; and *(ii)* CodeQL, a recent code analysis engine deployed at GitHub [15]. We tried to express the policies of our case study applications for both baselines. In IFC, this boils down to imposing a label hierarchy and determining declassification points. For CodeQL, we implemented appropriate queries.

7.2.1 Comparison with IFC

In classic IFC, labels applied to data form a lattice, and the system ensures that data with low-security labels is free of influence from values with high-security labels (the "non-interference" property). Some security and privacy concerns fit into this model, but its expressivity is limited compared to generic tools (CodeQL and Paralegal). As such, we expect IFC to be able to express some, but not all policies.

Figure 8 shows that IFC can enforce six of the eleven policies. Two properties, in Contile and Hyperswitch, directly fit IFC's notion of restricting flows of high-security values into low-security sinks. Policies in Lemmy, Atomic, Hyperswitch and mCaptcha require access control or consent checks prior to operations on data, which IFC can approximate via selective declassification. However, this strategy requires code changes beyond the usual addition of annotations (🔧); in this case, turning the check into a data flow operation, as IFC cannot declassify (i.e., remove a label) via control flow. WebSubmit's Access Control policy is a complex, data-dependent property that requires a list to contain only "blessed" receiver email addresses. Since IFC never prohibits upgrading a security label (e.g., from the low security "external" to high security "blessed"), IFC alone is insufficient to enforce this policy. Disciplined use of data types, combined with IFC, can enforce this property, but would require a substantial code rewrite. (Freedit's Data Retention policy contains a similar pattern.) Finally, Data Deletion and Retention policies rely on a "must reach" pattern that requires a value to reach a sink (i.e., deletion). IFC can enforce safety but not liveness properties, i.e., it can only check the absence of prohibited flows, but not mandate the existence of data flows. Thus, IFC fails to express and enforce these policies.

7.2.2 Comparison with CodeQL

CodeQL extracts a program's AST and derived information into a database, and developers write queries against it in a Datalog-like language. Since CodeQL lacks support for Rust, we translated the relevant parts of each application into C++, the most similar language to Rust with CodeQL support. Two applications (Hyperswitch and Contile) have policies that touch large amounts of code (1.3–1.5k LoC, plus library functions), so we omit them. For Lemmy, we translate one representative endpoint, but omit 71 structurally similar ones. Our ports seek to faithfully reproduce the control and data flow of the Rust code, but replace Rust's `Result` with C++ exceptions. We implement the queries using CodeQL's libraries for data flow [18] and control flow analysis [19].

CodeQL's query language can express all eight relevant policies, but its analysis engine fails to enforce some of them; when this happened, we debugged the issue sufficiently to pin it down to one or more limitations in CodeQL or its libraries, and stopped investigating further (i.e., our analysis may have missed further problems masked by the initial failure).

Policy Effectiveness. Figure 8 shows the outcome of each CodeQL policy. Plume's Data Deletion policy works; as do mCaptcha's policies (with caveats, see below) and Lemmy's Access Control policy in some versions of the code. Other properties fail due to combinations of limitations in CodeQL,

identified by symbols:

(†) Control flow analysis in CodeQL is not inter-procedural. This causes a false positive with Lemmy's access control policy, which uses a helper function for access control checks. CodeQL's control flow analysis also (intentionally [21]) ignores certain complex control flow patterns [22], which causes a false positive in Atomic.

(‡) CodeQL assumes no data flows exist through library calls whose source code is unavailable. This affects Websubmit's Data Deletion policy, which hinges on detecting data flow into a value-type constructor provided by a database library; similarly in Freedit's Data Retention, CodeQL misses data flow through a database method. While CodeQL allows developers to write manual models for library functions, this is onerous and error-prone.

(*) Taint propagation to fields within a structure and from fields to the structure itself requires manual modeling [20]. This complicates policies over markers on a structure that expect to detect flows of that structure's fields into a sink; or policies over markers on elements of a container that expect to detect flows of the container itself. The CodeQL developers manually model taint propagation for collection elements for some standard library data structures but do not (yet) model `std::unordered_map`, which Atomic and Websubmit's Access Control use.

(A) CodeQL currently lacks an alias analysis for C++, due to performance issues [24]. As a workaround, the developers manually model methods, e.g., for `std::vector::push_back`, but CodeQL lacks a default model for initializer lists, which show up in Websubmit's code checked by the Data Deletion property, and require reasoning about aliasing.

(T) Our C++ ports replace trait-constrained Rust types with C++ templates. CodeQL cannot analyze code with uninstantiated template parameters [23], even when constrained by concepts. By contrast, Paralegal can analyze uninstantiated, parameterized code by exploiting trait constraints with the modular approximation.

(¶) C++ has no language-level async support, but provides an `async` library function. When we use it in place of Rust's async, CodeQL misses data and control flow dependencies through this function [25], causing false positives and false negatives in Atomic, mCaptcha, and Lemmy. As a workaround, we use synchronous C++ code.

The last two limitations in part result from impedance mismatches between C++ and Rust, so we report them in Figure 8, but still consider the affected policies to succeed.

By contrast, Paralegal has an inter-procedural control flow analysis, models the effects of unknown library code via modular approximation, collapses taints in and out of structures without developer effort, and relies on Flowistry's modular alias analysis for Rust. It also handles uninstantiated type variables constrained on traits by approximating the effect of trait methods, and handles async Rust. As a result, Paralegal successfully expresses and enforces all these policies.

Policy Structure. Paralegal is designed to distribute work between markers, program analysis, and policy. CodeQL does not have markers (or a marked PDG), and it provides only low-level program analysis primitives. Therefore, we investigated how much of a CodeQL query corresponds to work done by Paralegal outside of the policy. We answered this question by qualitatively labeling each chunk of a CodeQL query (precisely, a CodeQL *predicate*) as either "policy" or "not policy" code. For instance, this CodeQL predicate in the Plume policy to find deletion functions is labeled as "not policy" because it serves the same function as a Paralegal marker:

```
predicate is_delete(DataFlow::Node n) {
  n.asParameter().getFunction().getName()
   .regexpMatch(".*deleteAny.*") and
  n.asParameter().getIndex() = 0
}
```

To check the reliability of this qualitative judgment, two authors of this paper independently labeled 30 predicates and, after resolving one conflict, achieved 96% agreement.

Across all CodeQL policies, we labeled only 36% of predicates as policy code. From our observations, the remaining 64% of code fall roughly into three categories: *(i)* predicates identifying code elements (i.e., markers), *(ii)* predicates defining the semantics of external code (i.e., models), or *(iii)* predicates defining primitives for code analysis. This result shows that Paralegal's design effectively separates concerns that are otherwise mixed together in existing systems.

7.3 Developer Ergonomics

We now evaluate the maintenance effort Paralegal imposes on developers as a codebase evolves. A developer may need to update her Paralegal configuration as follows:

1. she may need to move a marker, e.g., because argument order changes or a function is renamed;
2. she may need to add markers to new code elements;
3. she may need to adjust marker names because of changes to the semantic meaning of a code element; or
4. the privacy engineer may need to change the policy because it made assumptions about application semantics that no longer hold or because the policy goal changed.

Mechanical marker movement is easy, but changes to what markers mean impose higher cognitive developer burden, and policy changes require involving the privacy engineer.

To evaluate this, we run Paralegal on all commits of Atomic, starting with the introduction of the (buggy) permission model, using the same policy and markers as in §7.1. A good result for Paralegal would show that changes to markers are rare and the policy code is robust—i.e., that the policy is abstracted away from code details, and that the markers are at a granularity that avoids frequent changes.

The experiment covers 1,024 commits between June 9, 2021—when Atomic introduced the feature that our policy targets—and March 26, 2024. 87 commits failed to compile

and we skip them. The code Paralegal analyzes for the policy is a subsection of the entire application, but changes over the course of the experiment. We confirmed with the developers that the intent of the policy remains the same throughout. Since all markers assignments are within Atomic's workspace crates, only changes to code in the workspace can require adjustments to markers. On average, Paralegal's analysis touches 907 lines of within-workspace code (min: 411, max: 1,196). Within the 936 functional commits, 66 commits modify one or more analyzed lines, with 60 lines changed on average. Over the entire codebase, Paralegal's analysis touches 22k lines of code affected by 84 commits, with a mean of 1,165 lines changed per commit.

Paralegal detects the permission bug in each commit before the developers' fix (`46a503a`, 186/936 commits in; June 27, 2021) and passes on every commit thereafter. We found two commits that impacted markers: *(i)* a renaming of the marked function (`aba49fe`); and *(ii)* replacing a previously-marked function with one that takes additional configuration arguments (`e0cf2d1`). The former commit required no developer intervention[2] and the second commit caused Paralegal's policy checks to fail. Hence, Paralegal would have alerted the developer even if she neglected to move/adjust the markers previously. The policy itself required no modifications to accommodate code changes—unlike what might be expected if the policy targeted syntactic elements. This indicates that Paralegal's policy/code decoupling is robust.

7.4 Performance and Scalability

We now investigate Paralegal's performance and scalability on the eight case-study applications (Figure 6). We explore three setups that are representative of how we imagine Paralegal will be used in practice: *(i)* running locally on a project's workspace ("Workspace Only"); *(ii)* running interactively on a specific subset of code (e.g., in an IDE plugin); and *(iii)* running across a project's code and its entire dependency tree ("All Dependencies", e.g., in CI). These setups represent different trade-offs in terms of performance and soundness: the first two prioritize low latency, while the third minimizes false negatives as it check properties over all reachable code.

Paralegal is a `rustc` compiler plugin that operators on Rust's MIR. As a consequence, creating PDGs for a target crate requires first compiling all dependencies to make metadata and MIR for each function available. The applications with the largest dependency corpus (Lemmy and Hyperswitch) each take about two minutes to compile. This time is independent of Paralegal configuration and incurred only once, unless dependencies change. Most of this time is in `rustc` and applies to any compiler plugin: at most 4% of time is related to Paralegal-specific tasks, such as persisting the MIR to disk. In the following experiments, we omit this one-off cost and focus on the time Paralegal spends generating the PDGs and checking policies over them.

[2] A renamed marked function retains its marker if developers attach the marker via inline annotation. With markers attached via external configuration, the policy would fail and alert the developer.

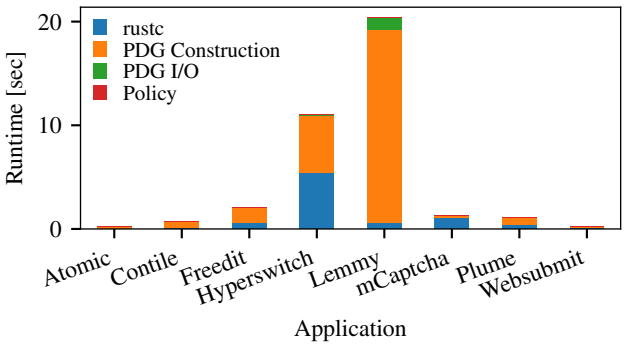

Figure 9: *In the "Workspace Only" setup, which runs Paralegal's analysis only over crates in the current workspace, Paralegal's end-to-end runtime is under 2.2 seconds for most applications. The two exceptions are Lemmy, which has many analysis entrypoints (72) and Hyperswitch, which is a large crate (≈200k LoC). PDG construction dominates runtime.*

We ran all performance experiments ten times. Variance is generally low, with maximum outliers deviating 0.1 seconds from the mean in the "Workspace Only" configuration and 1.2 seconds in the "All Dependencies" configuration.

End-to-End Runtime for "Workspace Only". Most policy-relevant code is usually concentrated in a few crates, such as the workspace a developer is actively working on. In the "Workspace Only" configuration, we set Paralegal to only include code from the current workspace in the PDG and use the modular approximation for functions from other crates. Focusing the analysis on the workspace potentially sacrifices some precision, as it will miss markers assigned in crates outside the workspace, but reduces latency as PDGs are smaller and faster to construct in this setting than when considering all dependencies. Paralegal finds all bugs reported in §7.1, even in this less-precise setup. There are no false positives except in Contile, where adaptive approximation causes a loss of field sensitivity for a helper function, leading to overtaint. Paralegal offers a mitigation strategy for this case, where a developer can configure the analysis to include k^+ more layers of the call tree than adaptive approximation would include in the PDG. In this and all further experiments, we run Contile with $k^+ = 1$, which eliminates the false positive at the cost of 0.3 seconds (9%) additional end-to-end runtime.

We separately measure the time spent in various stages of the analysis: *(i)* `rustc` time outside of the compiler plugin, *(ii)* PDG construction time, *(iii)* time spent (de)serializing PDGs, *(iv)* time spent checking policies over the PDGs. A good result would have Paralegal run in seconds.

Figure 9 shows the results. Most applications finish in under 2.2 seconds, with the exception of Hyperswitch at 12 seconds and Lemmy at 22.5 seconds. This is likely sufficiently fast for

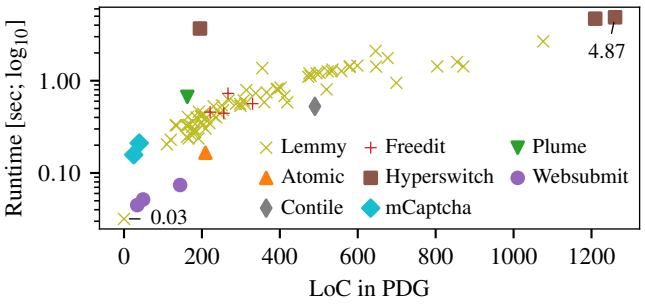

Figure 10: *Paralegal takes a mean of 0.8 seconds per endpoint and around five seconds in the worst case (Hyperswitch), enabling interactive use. Note the* log *scale y-axis.*

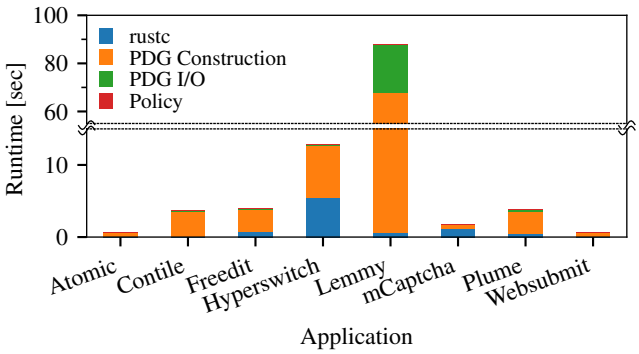

Figure 11: *In the "All Dependencies" setup, which runs Paralegal's analysis over the full codebase (including libraries), Paralegal's end-to-end runtime remains under 20 seconds for all applications except Lemmy (94 seconds), where Paralegal must construct a large PDG for each of the 72 entrypoints.*

interactive CLI or IDE use by a developer.

However, the restriction to workspace crates trades soundness for speed, as a missed marker in a dependency could result in properties spuriously passing (a false negative). While none of our case studies encounter this situation, even simple changes can introduce false-negatives when analyzing only workspace code. For example, Contile's metric data sending logic uses a crate-local error handling function that we marked; if the Contile developers were to switch to an equivalent error handling function provided by a library, Paralegal would miss the marker. Hence, Paralegal deployments might choose to complement quick, local analysis in the "Workspace Only" setup with a CI job that runs the analysis over the full dependency set, as described below ("All Dependencies").

Per-endpoint Runtime. In an interactive setting like an IDE plugin, Paralegal only needs to run on the code that changed at any given time (e.g., the endpoint the developer is editing). We therefore measure the per-endpoint runtime for the "Workspace Only" configuration, and report it as a function of the number of lines of code analyzed. The runtime for each endpoint excludes the overhead of running `rustc` on the target crate, as an IDE setting would use an incremental compiler such as rust-analyzer.

Figure 10 shows the results. Most endpoints take a few seconds (mean: 0.8 seconds), and runtime generally grows with the size of the analyzed code. Hyperswitch has the most expensive endpoints, caused by the policy requiring Paralegal to build a large, slow-to-construct PDG, but remains under five seconds. These results suggest that Paralegal, with incremental compilation, is fast enough for interactive use.

End-to-End Runtime for "All Dependencies". We now consider Paralegal's runtime when analyzing all reachable code, including all dependencies for which source code is available. In our example applications, this results in Paralegal analyzing between 88 and 878 crates (mean: 540). Paralegal still uses the modular approximation for the Rust standard library (`std`, `alloc`, etc.), because the `cargo` package manager uses a precompiled version by default. All runs use the adaptive approximation optimization (§4.2) to reduce the size of the PDG. A good result for Paralegal would show CI-appropriate runtimes of at most several minutes.

Figure 11 shows the results. Most applications finish in less than five seconds and PDG construction dominates runtime in all applications except for mCaptcha. Hyperswitch and mCaptcha have the largest target crates, so `rustc` time is highest for them. Lemmy takes about 94 seconds, as its large number of endpoints (72) results in Paralegal constructing many PDGs (72 PDGs at ≈1.3 seconds each). Overall, the runtime of Paralegal's "All Dependencies" configuration is acceptable for a CI setting.

7.5 Drilldown Experiment

Finally, we measure the impact of Paralegal's adaptive approximation optimization (§4.2).

The optimization determines the smallest prefix of the call tree[3] to be included in the PDG, such that all markers are reached. Paralegal approximates all function calls deeper in the call tree by their type signature. We compare this approach to a setup where the prefix is instead determined via a global depth limit, k. To achieve the same policy accuracy as with adaptive approximation, we assume an (unrealistic) oracle that, for each application, returns the minimal k such that Paralegal reaches all markers. In our setup, the oracle is the maximum depth observed in the adaptively-created PDG. This approach compares Paralegal's adaptive approximation to the strongest possible baseline, since any larger k will result in strictly longer runtime and no improvement in precision. A good result for Paralegal would show that adaptive approximation substantially reduces end-to-end runtime.

In the "Workspace Only" configuration, the gains from adaptive approximation are small, with a 10% mean speedup.

[3]Call graphs can have cycles, but Paralegal breaks cycles via its type-signature-based approximation on recursive calls. This ensures a tree shape.

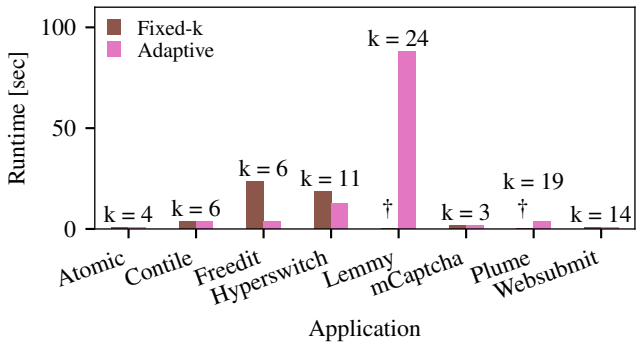

Figure 12: *The adaptive approximation optimization reduces end-to-end runtime by 35% on average and is necessary for Lemmy and Plume to terminate. The label on each bar indicates the oracle-provided minimum k call string length value to match the precision of adaptive approximation. † indicates that the fixed-k version times out after 15 minutes.*

Adaptive approximation makes a much larger difference for the "All Dependencies" configuration. Figure 12 shows the results for this setting. We label each bar with the oracle-provided k value used in the baseline. Most importantly, the adaptive approximation is necessary for PDG construction to terminate in two cases: Lemmy and Plume time out after 15 minutes the fixed-k setting, indicated by a dagger (†) in the figure. For Plume, the buggy version of the application finishes PDG construction in tens of seconds, but the fixed version times out, as it contains more code. In the other applications, the adaptive approximation reduces runtime by 35% on average compared to the idealized fixed-k baseline, with greater gains for applications with larger PDGs.

These results show that adaptive approximation, while always beneficial, is particularly critical when running Paralegal over the full codebase of large applications and their dependencies (e.g., in CI).

8 Related Work

§2 covered closely-related prior work in static analysis tools; we now discuss other approaches that relate to Paralegal.

Information Flow Control (IFC) enforces security policies by attaching security labels to values and propagating them through the program. Static IFC [47, 63, 67] is most comparable to Paralegal, but on its own fails to express important privacy properties (§7.2) and is difficult for developers to adopt [34]. Dynamic IFC can increase precision [13], enforce policies that depend on runtime knowledge, and handle languages which are difficult to analyze statically [76, 80, 82]. However, the tracking incurs runtime overheads which increase with the level of precision used and requires a runtime buy-in. In addition, violation cases lead either to crashes or confusing application behavior in deployment. Paralegal uses static analysis avoid both of these problems.

Bug-finding tools intelligently explore the state space of a program or API to find bugs. Bug finders are easy to adopt and handle a variety of code styles but are usually specialized to a domain such as concurrency [70], distributed systems [75], or file systems [12, 48, 62], and while some offer customization, such as the file-system bug finder eXplode [81], their properties are ultimately hard-coded. Paralegal requires some annotation effort, but allows checking flexible policies while retaining the compatibility with arbitrary code styles.

Code linters identify issues by looking for syntactic patterns such as AST fragments [61] or function names [56]. This approach is simple and practical, but limited in expressiveness and precision. Paralegal uses a more semantic model of the code (a dependency graph) to permit more expressive policies and more robust enforcement.

Policy enforcement tools check policies over data, usually based on runtime mechanisms. The often target domain-specific problems, such as preventing buggy queries [60, 83] or serverless functions [43] from leaking data. Sesame [29] enforces more general policies by leveraging Rust's types and limited static analysis, but requires runtime mechanisms. Paralegal is general and entirely based on static analysis.

9 Conclusion

Paralegal is a practical static analysis tool for checking high-level privacy properties against Rust applications. Paralegal extracts a marked Program Dependence Graph (PDG) from Rust programs annotated with markers, and checks privacy properties written in a high-level DSL against it.

Our evaluation shows that Paralegal finds privacy bugs in real Rust programs, requires modest developer effort as code evolves, and runs in tens of seconds, making it suitable for interactive and CI use. Paralegal is open-source software and available at: `https://github.com/brownsys/paralegal`.

Acknowledgements

We thank Kinan Dak Albab, Nicholas DeMarinis, Franco Solleza, and the members of the ETOS and Systems groups at Brown for their helpful feedback on drafts of this paper. David Fryd contributed several improvements to Paralegal and completed the mCaptcha case study; Tim Nelson helped with an initial version of Paralegal that was based on Forge [39]; and Tim Edgar provided input that inspired the original idea for Paralegal and its auditable, human-readable policy language. Feedback from the anonymous reviewers and Clément Pit-Claudel, our shepherd, greatly improved the paper.

A Appendix

A.1 Case Studies In Depth

(1) Atomic is a graph database server that lets users create, edit, and share graph-structured data [5, 8]. It uses the Actix web framework [1].

Each time that a user modifies a database resource, Atomic stores a signed *commit* record. Before creating a commit, the application must verify that the user has permissions to modify that resource. Earlier "parent" commits for the resource specify permissions for later commits. For instance, a commit that creates a new resource must also specify which users are allowed to edit that resource. For each commit, the application must check the permissions on the commit's parent. Crucially, this authorization must happen *before* updating the in-memory copy of the database resource [7]. If the authorization check happened *after* applying the commit, the user could first change their parent commit to one that gives them the requisite permissions, thereby guaranteeing that they pass the permission check.

To encode this policy in Paralegal, we define a `commit` marker for the `Commit` type. We then create a `modify_resource` marker for all operations that modify in-memory references to resources. We add a `sink` marker to the write operation that flushes the modified resource back to the database. Finally, we add an `auth_check` marker for checking the user's permissions. The Paralegal policy enforces that if a `resource` flows to a `modify_resource` then to a `sink`, the `resource` flows to an `auth_check`, and there is a control flow influence from the `auth_check` to the `modify_resource`.

(2) Contile is the backing server of the Mozilla Tile Service, which serves as an intermediary between advertisers and the landing page of the Firefox web browser to "ensure customer privacy" in the advertising context [26]. Contile services small ads, called *tiles*, to Firefox users.

The information available to the application is centered around the `Tags` struct, which features the following comment referencing the fields `tags` and `extra` of the struct:

> Not all tags are distributed out. ‘tags‘ are searchable and may cause cardinality issues. ‘extra‘ are not searchable, but may not be sent to [Metrics].

The Paralegal policy ensures that the data from the `extra` field is withheld from advertiser search and that it is never sent to the metrics server. We marked the `extra` field as sensitive data. We then marked the sinks to which `extra` should not flow: the first argument of both `MetricsBuilder::try_send` from the `cadence` library and `RequestBuilder::send` from the `reqwest` HTTP library.

(3) Freedit is a forum application that supports both Twitter and Reddit-like interaction modes [41]. Freedit's code comments state that it only retains a user's viewing history for three days [40].

We write two Paralegal policies. The first requires that when page view data is stored, a timestamp for its expiration date is stored alongside it. The second requires that there exists code that checks the database for expired page view data and deletes it. We marked the identifier for the table that stores pageview data for a user. We also marked the library functions that insert and delete data from the data store, as well as a library function for getting the current time.

(4) Hyperswitch is a payment router that provides a unified interface for interacting with common payment processors.

Hyperswitch's UI asks users to opt-in to saving their credit card information for future transactions. We write a policy that mandates the user's selection determines (via control flow) whether the credit card details are indeed stored. Hyperswitch's documentation also states that plain-text API keys are only available at creation. We write a Paralegal policy that states that an API key may only be released once to the user creating it, and that it can only be access through its hash afterwards.

We marked the type identifying credit card details and the function returning the user's storage decision. Additionally, we marked the API key type, the permissible hash function, and the response type for the key's initial creation. We also marked the return values of all endpoints to ensure that Paralegal captures all data sent to users. We analyze the the controller that creates API keys and two controllers that handle credit card data.

(5) Lemmy is a federated Reddit-like platform [55]. Rather than providing a single centralized website, anyone can create an instance tailored to their interests and moderation preferences. Users create communities within those instances and post content to them.

Our Lemmy policies focus on its access control rules: *(i)* if a user is banned or deleted from an instance, they may not read nor write data in that instance; and *(ii)* if a user is banned from a community or the community is permanently removed, users may not write data to that community.

We define four authorization check markers: one for an instance ban check, one for an instance deletion check, and two more for the respective community checks. We define `instance` and `community` markers for database accesses pertaining to data relevant to instances or communities respectively. Authorization checks need to happen in 72 HTTP endpoints in Lemmy that perform database reads and writes. Our policy stipulates that respective authorization checks need to take place in each controller where instance or community database accesses take place and that such checks must happen before the access and have a control flow influence. In addition to the bugs we report, we also found two more controllers that violate this policy. The controllers in question create new sites or communities. In this special circumstance, a limited number of database accesses are performed before the checks to complete the initial setup of the new site or community. We manually verified that performing these accesses is safe and then marked these locations as exceptions from the policy.

(6) mCaptcha is a proof-of-work based CAPTCHA service focused on privacy [59]. Website developers register their sites with mCaptcha and invoke the mCaptcha service API when end-users visit those sites. If a developer deletes their mCaptcha account, mCaptcha must remove all data associated with it. We realize this with a policy similar to §3's example and mark the `Identity` type from `actix_identity` as well as the `delete_user` method.

mCaptcha's PoW based algorithm features a tunable "difficulty factor", designed to balance security and accessibility to legitimate users. To optimize this parameter, mCaptcha can share statistics with other mCaptcha installations. Publishing this data requires explicit developer opt-in [45]. We initially wrote a policy to enforce that performance data could only be collected from websites that opted in. This verify-before-collect policy failed, and after discussing the issue mCaptcha developers, it turned out that we misinterpreted their privacy goals: statistics are always collected, even if developers don't opt into sharing them. A corrected verify-before-sharing policy passes Paralegal. However, the discussion helped the mCaptcha developers find a (related) data integrity bug: they deleted statistics when a user revoked their opt-in consent, even though they didn't intend to [58]. This illustrates that Paralegal-induced discussions can be helpful to developers.

(7) Plume. Plume is a federated blogging service [66], and the basis of our example in §3. If a user deletes their Plume account, the application must delete their personally identifiable data. We formalize this policy with Paralegal by marking the user and the types of user data: `Comment`, `Blog`, `Post`, `Media`, and `Notification`. Additionally, we placed a marker on the `delete` function in the `diesel` database ORM, for a total of seven markers.

(8) WebSubmit [68] is a homework submission system deployed at a U.S. university and written in 1.6k LoC of Rust using Rocket.rs. We consider three policies: *(i) data deletion*, which tests compliance with a GDPR-style "right to be forgot-

ten" by ensuring that an endpoint for deleting all of a user's data exists; *(ii) scoped storage*, which ensures that the user's identity is stored alongside their data; and *(iii) authorized disclosure*, which encodes the access-control policy: students may view their own answers, TAs and instructors may view all students' answers, and instructors may view course feedback.

We marked the data type containing student answers, deletion functions, the return value of each controller (to cover externalizing data), user identifiers provided by the framework as well as functions that retrieve instructors and TA's from the config.

The analysis covers the endpoint that stores student submitted answers and the deletion controller.

A.2 Source Code Changes

The following table lists, for each application, how many no-op functions we had to introduce to attach markers and how often they needed to be called.

Application	# Marker Functions (calls)
Contile	2 (5)
Freedit	1 (4)
mCaptcha	1 (1)
Hyperswitch	1 (1)
WebSubmit	2 (2)

In addition, we had to make the following adjustments to make analysis feasible or work around prototype limitations:

- **Contile**: We inlined one call to `Result::map_err`. This is a small function critical to the policy, but because it is in the (precompiled) standard library our multi-crate analysis could not access its code.
- **Hyperswitch**: We changed the type `PlaintextApiKey` to use an explicit `prefix` and `key` fields instead of a single string and a marked accessor function for the sensitive `key` field.
- **Lemmy**: We created (generalized) model for `actix::web::block` to ensure the closure it receives can be analyzed without having to deal with the `unsafe` code of `block`.
- **mCaptcha**: We stubbed compile time generated code by the "cachebust" utility as it failed to run on our machine and is irrelevant to the policy.
- **Freedit**: We moved the `user_cron_job` function (11 LoC) from the binary to the library. This works around a limitation in the `Somewhere:` policy scope, which can currently only see the entry points from one crate at a time and was causing a false positive.

We also made the following changes to be able to express a cleaner policy, as described in §6:

- **Atomic**: We factored a benign modification of the parent of a commit into a helper function that we marked.
- **Freedit**: We factored a comparison used for checking expired data into a helper function that is explicitly marked.
- **Lemmy**: We added calls to a `policy_exception` function that exempts a limited number of accesses from the policy check as described in Appendix A.1.

A.3 Policy DSL Grammar

⟨*paralegal policy*⟩ ::= `Scope:` ⟨*scope*⟩

B Artifact Appendix

Abstract

Our artifact contains the code for the Paralegal analyzer, policy compiler, supporting libraries, the set of applications we evaluate on, the benchmarker used to run evaluations, and the plotting script to generate the figures in the paper.

Scope

The artifact allows reproducing the following results:

1. Comparison with CodeQL (column three in Figure 8).
2. Policy structure and coding claims (paragraph "Policy Structure" in §7.2.2).
3. Bugs found by Paralegal (§7.1).
4. The ergonomics report from §7.3.
5. All claims made in performance evaluations in §7.4, such as Figures 9 to 12.

Contents

The artifact contains:

1. Source code for the Paralegal code analyzer, policy compiler, and supporting libraries for annotations and the low-level Rust API for policies.
2. The source code for all case study applications mentioned in the paper, as well as their Paralegal policies.
3. C++ translations for the case study applications and the CodeQL policies we tried on them.
4. Source code for the benchmarker used to run the evaluations.
5. The plotting script used to generate the figures in the paper.

The Docker container version of the artifact additionally contains the CodeQL version we used and all dependencies needed for any software that runs or is analyzed during the benchmarks.

Hosting

We provide two versions of the artifact: a Docker image hosted on Zenodo [3] and a GitHub repository [2] (tag: `final`).

The container is intended as an everything-included solution that allows for validation without any (online) dependencies.

The GitHub repository contains only the immediate source code for the programs and use cases, as well as instructions and lockfiles to replicate the environment used for the evaluation.

Requirements

Please refer to the README distributed with the artifact for detailed explanations of the requirements for both artifact versions. The Docker container version requires an x86_64 machine with Docker.

B.1 Installation and Experiment Workflow

We provide detailed instructions for installation, running experiments, and interpreting results in the README files for both the Docker/Zenodo and GitHub versions of the artifact.

Abstract

Today, many applications are hosted by cloud providers. In order to isolate the workloads of different clients, cloud enterprises mostly rely on containers rather than standard processes, since the latter are able to exercise a lot of ambient authority. Containers counter this deficiency by sandboxing processes. To this end, they use dedicated security mechanisms such as `seccomp-bpf`. However, these mechanisms add complexity to the kernel and increase its attack surface, thus prompting new security challenges.

Processes in microkernel-based systems do not have ambient authority. Thus, they do not require additional security mechanisms to build sandboxes. In this paper, we try to answer the question whether a microkernel-based OS architecture enables a leaner and more secure container infrastructure. Based on a CVE analysis, we show that the conceptual simplicity of containers on microkernels results in a better security posture than that typically found on monolithic systems.

We furthermore demonstrate the practical feasibility of implementing containers on state-of-the-art microkernels by building MettEagle, a prototype container service running on L4Re. We found that applications running in containers on L4Re expose performance characteristics comparable to that of containers on Linux for both synthetic and real-world benchmarks. In some cases, the container implementation of L4Re even outperforms Linux, accelerating container startup latency and improving network performance.

1 Introduction

Currently, virtual machines (VMs) and containers are the two prevalent mechanisms for isolating untrusted workloads running on a shared system. Generally speaking, containers are a more lightweight approach to isolation as they do not attempt to emulate an entire computing platform. Instead of spawning distinct operating system instances, multiple containers running on the same host share a single kernel and only expose separate instances of userland to applications. This allows them to achieve runtime performance close to that of the bare metal system [48]. Moreover, starting a container is much faster than booting a virtual machine [42]. These advantages made containers the premier choice for isolating workloads in settings such as serverless computing [38].

Interestingly, when looking at containers from the perspective of an OS engineer, they are only little more than hardened processes (or process groups) that are restricted in their resource utilization through dedicated in-kernel mechanisms such as `cgroups` or `seccomp-bpf` [1]. These facilities however, add a lot of complexity to core OS abstractions. This additional complexity in turn harms cross-container isolation by exposing a larger in-kernel code base that is shared between distrusting containers [4, 5].

In fact, the intricacies of implementing an isolation mechanism equivalent to that of containers on traditional, monolithic OSes largely stems from the fact that these architectures do not adhere to the principle of least authority (PoLA) by design. Hence, on such systems, the implementation of containers needs to prevent applications from exercising ambient authority that they should not have in the first place. One example of this problem is the use of `seccomp-bpf` to retroactively restrict the set of system calls (and their parameters) that is available to a container. This does not only add complexity to the kernel but also introduces a slight performance penalty since the respective checks need to be carried out at runtime [34]. Even though this overhead has been reduced recently [2], it will never disappear completely.

Modern microkernel-based OS designs [35, 37], in contrast, enforce PoLA by default. On such systems, processes have to explicitly request access to any system service like drivers or file systems instead of implicitly having the authority to use them. As a consequence, implementing container-style isolation on such platforms does not require additional resource constraining mechanisms as the OS itself provides strong compartmentalization of processes by default. Hence we argue, that on a microkernel-based OS, the use of processes can provide better isolation properties than containers on monolithic systems.

From a security perspective, a microkernel design can signif-

icantly decrease the amount of code that mutually distrusting containers need to share since the core system that each process has to rely on is small. Moreover, as all other system services are implemented as separate processes in userspace, the trusted computing base (TCB) of a container running on a microkernel only includes services that it actually uses [30]. This is different from monolithic approaches where kernel parts that are only used by some containers contribute to the TCB of all clients running on the same machine. Consequently, microkernels enable container implementations with an improved security posture.

However today, microkernel-based OS architectures are mostly used in embedded systems with statically configured workloads. First, this raises the question of how well microkernel concepts scale to large hardware platforms – the type of hardware that containers are usually deployed on. Second, to the best of our knowledge, the performance implications of using capability-based microkernels to host highly dynamic workloads like serverless computing services have not been studied so far.

In order to answer these questions and investigate the cost and benefits of our concept for containers on microkernels, we built a prototype container engine on top of L4Re [27], a state-of-the-art microkernel-based OS. We show how to provide container-grade isolation, including resource restriction and the necessary system services on such a system. Following a detailed discussion on the security properties of the resulting approach, we analyze its performance for both microbenchmarks as well as in a function-as-a-service (FaaS) setting, using the SeBS benchmark suite [16] as an evaluation platform.

In summary, this paper makes the following contributions:

- An analysis of what is needed to provide container-grade isolation to applications (Section 2).
- The design (Section 3) and implementation (Section 4) of a container-style isolation mechanism on L4Re, a microkernel-based OS. This includes modifications of L4Re to improve its performance when facing dynamic workloads on server-grade hardware.
- A detailed evaluation of our approach from both a security perspective (Section 5) as well as from a performance angle (Section 6), with a particular focus on a comparison to standard frameworks for lightweight virtualization on Linux, namely runC and Firecracker.

2 Background

Containers or lightweight virtual machines are used for isolating workloads in cloud environments. In the following we will discuss their general properties and implementation on monolithic OSes. Afterwards, we introduce L4Re and its capability-based access-control mechanism which we leverage for our secure container architecture.

2.1 Containers on a Monolithic OS

Broadly speaking, a container is an OS mechanism that virtualizes the execution environment of applications while sharing a single kernel. Examples for such facilities can be found on a variety of operating systems such as BSD (*Jails* [33]), Solaris (*Zones* [52]), and Linux [22]. Even though the exact implementation differs, containers on all platforms rely on three common kernel mechanisms with respect to security: 1. Deny access to unnecessary (kernel) interfaces. 2. For necessary interfaces, the visibility of resources is restricted. 3. Where resources have to be shared, resource accounting is enforced.

Interface Restrictions: As shown by Canella et al. [14], many cloud applications indeed only require a fraction of the rather large kernel interface exposed by monolithic OS designs. Container implementations exploit this fact to increase security by preventing a container from executing certain system calls, thus reducing the attack surface of the shared kernel. Current solutions like `seccomp-bpf` on Linux are built on top of the Berkeley Packet Filter (BPF) [43] and allow administrators to specify small filtering programs that the kernel executes upon every system call of a container to determine whether it adheres to the container's security policy.

Visibility Restrictions: Containers typically impose additional visibility restrictions on top of traditional processes. By using kernel features like Linux' `namespaces`, the administrator is able to hide certain parts of the system from applications running inside a container.

Within the scope of containers, visibility restrictions are applied e.g. to the file system by setting a separate root directory using the `chroot` system call. Container implementations often use visibility restriction mechanisms to virtualize network interfaces, process IDs, and mount points. Also, visibility restriction measures assure that processes running inside a container cannot communicate across container boundaries.

Resource Restrictions: For reasons of performance isolation, operating systems also restrict the resource usage of containers using dedicated mechanisms. One prominent example of such resource constraining frameworks is Linux' `cgroups` feature. Resource restriction frameworks for containers are often capable of organizing restrictions in a hierarchical manner, allowing containers to pass on a fraction of their already constrained resource budget [10]. Furthermore, they can prioritize access to system resources, thus guaranteeing a minimum share of a certain resource to each container.

Beyond these three core mechanisms, most implementations of containers also provide an ecosystem for managing containerized applications. For instance on Linux, a *high-level container runtime* like containerd [24] manages container images and the resources that a container requests for

execution such as access to the network. The Open Container Initiative (OCI) provides standards for the container runtime interface and container images, which allows OCI-compliant container managers to interact with any OCI-compliant *low-level container runtime*. Low-level container runtimes like runC [32] are responsible for setting up a container by configuring the lightweight virtualization mechanisms provided by the OS. After a container is launched by the low-level container runtime, the container manager takes over monitoring and life cycle management of the container.

2.2 Lightweight Virtual Machines

Virtual machines (VMs) provide a higher degree of isolation than containers, as distrusting applications do not share a kernel instance. Lightweight virtual machine implementations like Firecracker [7] and Cloud Hypervisor [6] try to overcome traditional performance shortcomings of VMs by optimizing virtual machine monitors for use cases like serverless computing, thus providing performance close to that of containers [9]. For instance, reducing the hardware emulated by the hypervisor is one way how Firecracker optimized its boot time.

The use of unikernels as a VM guest [42] is another way to increase the performance of VMs, as unikernels run in a single privilege level, saving context switches during execution. Furthermore, a unikernel can strip unused parts from the OS and userspace components, reducing the size of the TCB [54]. However, the missing isolation between the OS components and the application inside a unikernel contradicts the objective of a multi-layered security approach.

2.3 A Primer on the L4Re Microkernel OS

Being a microkernel, the L4Re kernel itself only implements functionality that cannot be realized in userspace, such as page table manipulation or mechanisms for inter-process communication (IPC). The L4Re microkernel (also known as the `Fiasco` kernel) represents each of the abstractions that it offers to userspace processes as *kernel objects*. Prominent examples for kernel objects are threads, IRQs, the scheduler and *IPC gates* which represent an IPC channel to a process.

Every other component of the operating system such as the memory management or device drivers run as processes in userspace (dubbed *tasks* in L4Re). During bootup the L4Re microkernel starts a *root task* called `moe`. `Moe` provides the basic system abstractions of L4Re such as RAM allocation or access to the read-only boot file system to other applications. `Moe` allows defining quotas for resource allocations, thus being able to constrain the resource consumption of application tasks. After initialization, `moe` starts `ned`, a service task that loads actual L4Re applications as specified by a startup script which is a part of an L4Re boot image. The components of L4Re we base our system on have single-threaded implementations.

2.4 Capabilities

L4Re, like most modern microkernel-based operating systems, uses capabilities [18] for implementing access control. A capability is an unforgeable token of authority, that grants the possessing process the power of carrying out operations on objects. For instance such an operation could be an IPC call to another process.

A central feature of capability-based access control is the absence of ambient authority. Tasks in L4Re start with no authority, i.e., no capabilities by default. This is crucial for a secure container infrastructure. To perform useful work and interact with the system, tasks must be granted the required capabilities explicitly. Other parts of the system cannot be accessed and are in fact not even visible to said task. Sharing object access is simple, as the owner of a capability is free to grant it to other tasks (*delegation*) with equal or less *rights* (for example, restricting read/write to read). Contrary to delegation, the owner of a capability can *revoke* (i.e., void) it, preventing its future use for authorization.

In L4Re, capabilities manifest as the permission to interact with a certain kernel object. Depending on the type of the respective object and the rights of the capability pointing to it, such interactions may configure the CPU scheduler, send an IPC message to another thread via an IPC gate, or destroy a kernel object. With L4Re, a capability can be delegated by sending it over an IPC gate connected to another process, whereupon the kernel takes care of copying the capability into the target process of the IPC. Similarly, the owner of a capability can instruct the kernel to revoke it at any time. Consequently, the L4Re microkernel is responsible for maintaining the system's security by shielding the capabilities of all processes against unauthorized manipulation.

3 Containers on L4Re

This section describes how the functional features and the security properties of Linux containers can be implemented on a microkernel-based OS like L4Re. In the following, we will use the term *compartment* for referring to an entity with container-style isolation running on L4Re, differentiating it from the Linux equivalent which we keep calling *container*. We start with an overview of our architecture and exemplify the interaction of the components by walking through the life cycle of a compartment. Finally, we explain how the isolation mechanisms used by containers on Linux can be transcribed to a microkernel-based OS, and whether these mechanisms already exist in L4Re, need to be introduced, or can be omitted entirely.

3.1 L4Re Compartment Architecture

Figure 1 depicts the components of our microkernel-based compartment system, which runs on top of the L4Re base system. This base system contains the L4Re microkernel and

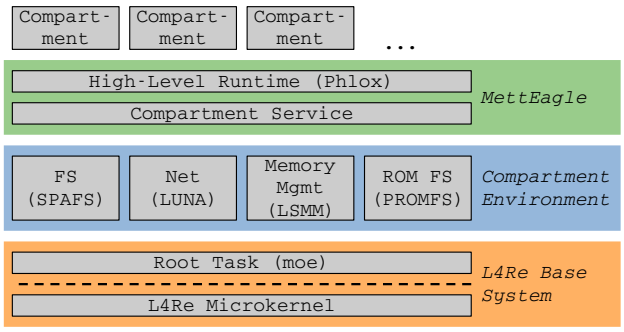

Figure 1: A sketch of L4Re's compartment architecture. Each gray box represents an L4Re process (*task*).

the root task `moe` which manages initial memory allocations to our services at system boot and provides other L4Re system primitives. The *compartment environment* contains all services required to run applications inside L4Re compartments. This includes services for file systems, networking, and scalable memory management.

The management of compartments on L4Re is handled by a *compartment engine* called *MettEagle*. Similar to the container stack on Linux, MettEagle comprises two subservices. The *compartment service* sets up the OS mechanisms required for running a compartment and manages the tasks associated with it. In Linux terminology, the compartment service is similar to a low-level container runtime like runC.

The compartment service is accompanied by a high-level runtime called *Phlox*. Phlox provides a more abstract interface to the compartment engine and implements a FaaS API that allows to spawn compartments remotely via network. For simplicity, we use the term *compartment engine* to refer to the service pair consisting of both the compartment service and the high-level runtime.

As common for microkernel architectures, each of the services depicted in Figure 1 runs in a separate task, yielding strong isolation between them as well as modularity. Note however, that a microkernel design does neither reduce the complexity of these services nor the effort of implementing them.

3.2 Life Cycle of a Compartment

Upon receiving a request for launching a compartment, MettEagle first gathers the resources that the respective compartment needs to run. In detail this means that Phlox creates new sessions with each of the system services in charge of managing the requested resources. For instance, this could be a network or a file system service. As a result of creating a new session with a system service, Phlox receives a capability to a new IPC gate via which the compartment is going to access the system service.

Now, Phlox instructs the compartment service to launch the compartment. Along with this request, Phlox sends the compartment service the set of capabilities gathered during the resource allocation phase. As shown in Figure 2, the compartment service delegates this set of capabilities to each task of the new compartment. These initial capabilities allow the tasks of a compartment to access the system services required for running an application. Now, the compartment service launches the compartment's tasks and monitors their exit status.

As the last step in the life cycle of a compartment, the compartment service collects the artifacts left over from the execution of a compartment. This includes closing all remaining sessions allocated for a compartment by revoking the corresponding capabilities. This in turn triggers the deletion of the associated kernel objects and frees the resources attached to them. MettEagle finally reports the compartment's exit status and optionally statistics on the compute time consumed by a compartment.

3.3 Isolating Compartments

With the general operation of MettEagle clarified, we now detail how microkernel-based compartments differ from Linux' containers.

Visibility Restrictions: Just as with Linux, at the core, a compartment on L4Re consists of a set of processes. All tasks of a compartment share a set of capabilities, hereinafter called the *compartment's capabilities*. These capabilities define which parts of the system are visible to the tasks of the compartment. Thus, by carefully choosing which capabilities are delegated to a compartment, MettEagle can restrict the system surface exposed to a compartment in a manner similar to Linux' `namespaces`. MettEagle can for instance constrain the set of processes a compartment can communicate with, or the network interfaces that are accessible to a compartment.

Another cornerstone for providing visibility restrictions in MettEagle is the absence of globally shared resources and identifiers on L4Re. For example, L4Re has no notion of PIDs or shared memory keys. Instead in L4Re, the respective objects are referred to by capabilities. As a consequence, MettEagle does not need to implement the respective virtualization layers found in visibility restriction mechanisms on monolithic kernels.

In order for an application to easily discover the parts of the system accessible to its compartment, we leverage L4Re's `namespaces` that allow a task to refer to a capability using a name. Similar to `namespaces` on Linux, this abstraction provides some form of virtualization as the compartment engine can set the mapping of names to capabilities for each compartment individually. For instance, two compartments could both see a capability named "`/usr`", but for each compartment the capability linked to the name could grant access to a different file system service. This mechanism enables MettEagle to present different views of the system to compartments. Each compartment on L4Re has access to

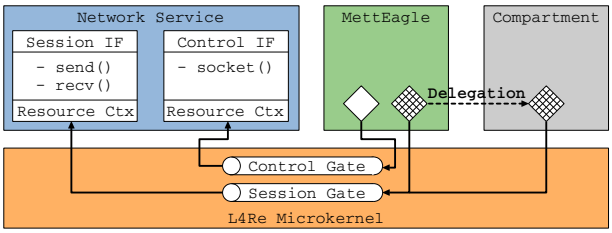

Figure 2: Example for an L4Re system service exposing different interfaces (IF) in multiple sessions (white boxes). The diamonds represent capabilities to the respective IPC gates.

a `namespace` containing its initial capabilities. `Namespaces` can be extended at runtime by adding new mappings to them, e.g. for capabilities that a compartment receives during its lifetime. Contrary to Linux' `namespaces`, which require to be integrated for various resource types, L4Re's implementation uses capabilities — a generic OS mechanism — to provide namespaces for any kind of resource.

System Call Restriction: Dedicated mechanisms for restricting the system interface available to a compartment (such as `seccomp-bpf` on Linux) are not required with L4Re. Instead, system services limit the interface they offer to a certain group of clients via dedicated IPC gates. This is possible because a system service in L4Re can securely identify a client based on the IPC gate used by the client for sending messages [37]. As shown in Figure 2, system services often expose a dedicated IPC gate for invoking control plane operations like the creation of a new session. In the context of compartments, only the compartment engine gets access to such gates, as untrusted applications running inside a compartment must not be able to spawn arbitrary sessions and thus get access to arbitrary resources, e.g. by creating unrestricted sessions. The compartments receive capabilities to session-specific gates that merely expose data-plane operations such as sending or receiving data from the network. This scheme allows for a fine-grained limitation of the API accessible to a compartment.

Resource Budgets: The secure identification of clients furthermore allows L4Re services to implement resource constraining mechanisms similar to Linux' `cgroups`. Usually, system services on L4Re create a dedicated IPC gate for each client session. During a session creation request, the caller specifies the resource restrictions of the new session and receives the capability to a session-specific IPC gate in return. Depending on the type of service, the session resource restrictions could be a bandwidth limitation, a priority, or a limit for memory allocations. The system service reflects the resource restrictions of a session by attaching a resource consumption context to the session's IPC gate as shown in Figure 2. Whenever a request arrives via a certain gate, a service first decides on whether to admit it by examining the remaining resource budget in the resource consumption context of the corresponding IPC gate.

As explained in Section 3.2 the compartment engine takes care of creating sessions with each system service required by a compartment before launching it. While doing so, the compartment engine adds a description of the respective resource limits to each session creation request and delegates the resulting capabilities to the new compartment. Reusing a session for multiple compartments and thus letting them share a common resource limit is possible as well. Note that unlike with `cgroups`, there is no uniform resource constraining mechanism across all L4Re system services. Instead, our compartment engine provides a transparent way to translate a compartment's resource limits into service-specific session creation requests.

4 Implementing a Prototype Compartment Infrastructure

This section describes the implementation aspects of components necessary for supporting compartments on L4Re.

4.1 The L4Re Compartment Environment

One option to implement the services of the compartment environment would be the use of a paravirtualized Linux (*L4Linux*) VM running on top of the L4Re base system. L4Re integrates such an L4Linux instance as a system service, allowing the latter to donate functions like device drivers to other L4Re applications [31].

In the context of compartments however, we chose to reimplement the required system services as native L4Re applications to avoid the drawback of the huge TCB that is entangled with using a single Linux VM as a provider for functionality. Mitigating this problem would be possible by spawning a dedicated L4Linux VM per compartment, but we discarded this approach as it would foil the benefits of lightweight virtualization. We thus started from L4Re's public development repository[1] and extended the L4Re base system with the multiple components to enable compartments.

First, we wrote an in-memory file system service called `SPAFS`. Unlike L4Re's ROM FS, `SPAFS` has write support and implements directories. These changes also required extending L4Re's VFS to support `SPAFS` functionality.

In order to make the MettEagle service accessible remotely, we equipped L4Re with a native network stack. To this end, we ported the driver for a 10 GBit Ethernet NIC from the Ixy driver framework [20] to L4Re. We also designed and implemented `LUNA`, a network service that multiplexes a NIC between multiple applications and implements a simple UDP/IP stack.

For the purpose of demonstrating compartments with an end-to-end benchmark, we integrated a simple FaaS agent into the Phlox high-level runtime. Phlox allows remote users to execute

[1] https://github.com/kernkonzept

code on an L4Re system. To do so, a function needs to be registered with MettEagle by uploading a code archive and assigning a name to it. Later on, users can instruct MettEagle to execute this function with input sent over the network. MettEagle sandboxes each function instance in a separate compartment.

Often, FaaS clients use interpreted languages for implementing function code [16]. We thus ported `python3` to L4Re to offer some form of standardized and widely used runtime that is also found with major cloud providers. `Python3` for L4Re was built using a novel cross-compiler that generates L4Re executables from standard Linux source packages.

Lastly, we implemented parallelized versions of both `moe`'s memory management (called `LSMM`) and its ROM FS (dubbed `PROMFS`) to increase the performance of L4Re on large machines. To this extent, we ported the LLFree page frame allocator [55] to L4Re and wrapped it in a user-level service in charge of managing the majority of the system's memory. The use of both `LSMM` and `PROMFS` is transparent to compartments, letting them act as a refinement of selected services usually offered directly by `moe`. We also enabled `moe` to run on multiple cores, avoiding cross-core IPC when interacting with it. As L4Re implements cross-core IPC synchronously using inter-processor interrupts (IPIs), this modification increases the overall system performance. However, unlike with `LSMM` and `PROMFS`, the internals of `moe` are still serialized and protected by a single lock.

4.2 Implementing Compartment Restrictions

As pointed out in Section 3, MettEagle implements visibility restrictions and virtualization by providing a minimal set of capabilities to compartments. If a compartment requires networking, MettEagle spawns a dedicated session with `LUNA` and passes the resulting capability to the compartment. `LUNA` sessions are bound to a specific address upon creation, forcing the compartment to use a fixed network endpoint.

For each compartment, MettEagle spawns a separate file system instance for data that the respective compartment needs to modify. In the future, this could be optimized by implementing overlay file systems. Read-only files (e.g., the `python` binary for executing the scripts of function) are hosted in a file system shared between all compartments.

Resource restrictions are implemented using quotas. In the current implementation, MettEagle can configure limits on resources like CPU allocation, memory consumption, or network bandwidth for each compartment. The concrete resource restriction mechanism is implemented in the system service that manages a resource. For instance, the scheduler in the L4Re microkernel allows to configure the set of CPU cores the threads of a task can use. MettEagle leverages this mechanism to restrict the CPU core allocation of a compartment according to a user-defined policy.

4.3 Lessons Learned

When implementing MettEagle, we came across a number of performance issues in the implementation of L4Re. We describe selected issues here which we consider generally insightful for the development of microkernel-based OSes.

Callbacks and Resource Pools: It turned out that L4Re's policy of having only a single reply capability limits performance. As the implicit reply capability of a thread voids when receiving the next IPC message, a server thread in L4Re can only serve one client at a time. Thus, each request arriving at the compartment service requires spawning a new thread for the execution and monitoring of a compartment. We avoided this overhead by using a callback mechanism. Upon invoking the compartment service, a client specifies a capability to an IPC gate to which the service communicates the result of the operation. The client then waits for messages on this gate to receive an answer from the compartment service.

Resource Reclamation on Critical Path: We observed that `unmap` (i.e., capability revocation) operations dramatically slow down the system when occurring on the critical path. The reason for this is the RCU-based implementation of the L4Re kernel. Threads revoking a capability can be blocked for an entire scheduling tick (10 ms by default) to ensure that a safe time point for deleting a kernel object is reached. Consequently, we implemented the compartment service and the auxiliary system services in a way to never carry out revocations on the hot path. We mitigated this issue by reusing system resources. For example, in the compartment service, instead of spawning new threads for monitoring the exit status of a compartment, we deployed thread pools to avoid the recurring overhead of spawning and deleting monitoring threads. Likewise, we carried out deletion operations in dedicated threads that do not block the actual service interfaces.

Locking of Capability Data Structures: We noticed a scalability bottleneck in `map` and `unmap` operations (i.e., capability delegation and revocation). For a delegation, the task structures of the source and destination task were locked, preventing parallel mapping from one task to multiple other tasks. We removed the lock for the source task due to the fact that the affected capabilities are already locked in the kernel's capability data structures. A similar optimization could be done for the `unmap` operation. However, even with these optimizations `map` and `unmap` do not scale well for highly parallel workloads, requiring further improvements. This demonstrates that even on a microkernel, sophisticated fine-grained locking strategies are needed to provide good performance for parallel workloads.

Component of MettEagle	SLOC
L4Re kernel	41,406
Sigma0 (root pager)	1,249

5 Security Evaluation

To the best of our knowledge, there is no hard and precise metric on the *trustworthiness* of a computing base. First, by the very nature of it, one does not know how many undiscovered security bugs are present in a given system. Second, it is hard to judge how many of these security bugs would be (partially) mitigated by the isolation architecture of a given platform. And third, the real-world security posture of a code base also depends on the activeness of development and the thoroughness with which bugs are investigated.

Because of these difficulties, we decided on using two proxy metrics as evidence that a container infrastructure based on a microkernel is more secure compared to Linux implementations. We provide a rough estimate of overall TCB *size* by counting lines of code and a vulnerability study based on past CVEs. At the end of this chapter we furthermore give insights on how a microkernel-based container architecture can mitigate timing-based attacks.

5.1 Trusted Computing Base Comparison

Table 1 and Table 2 list the TCB sizes of the MettEagle and Linux container implementations. We show source lines of code (SLOC, generated using SLOCCount [53]) as an established proxy metric for TCB complexity. Although SLOC does not directly measure the likelihood of code vulnerabilities, it gives an order-of-magnitude impression of the relative differences between the two systems. A significantly smaller number of code lines indicates that a software project might contain less bugs and it might be easier to uncover bugs as there are fewer moving parts. For our approach, we list the L4Re kernel and the userspace components `sigma0`, `moe`, `ned`, and `IO` as fundamental L4Re services. The network service `LUNA`, the `SPAFS` file system, and both MettEagle services constitute new components developed for this paper. On the Linux side, a kernel 6.7.4 was measured, limited to those C files actually contributing to the running kernel binary. In addition, the NIC driver module is listed. Contrary to L4Re, these components all run in kernel mode. We also mention the two pieces of container infrastructure `containerd` and `runC` (Go code counted using cloc [17]), although caveats apply as these components clearly offer more functionality compared to our research prototype. However, splitting that functionality in multiple isolated components, where only some are part of the core infrastructure TCB, may be possible.

In general, the microkernel implementation runs less code in CPU privileged mode compared to Linux. The small size of the kernel makes it easier to reason about it as part of a certification process. For instance, L4Re is certified according to both security (EAL4+ [13], SECRET level by the the German Federal Office for Information Security [12]) and safety (ASIL B [26]) standards. Outside the kernel, microkernel-based systems benefit from the absence of an all-powerful root account, and capability-based access control which encourages a system design following the principle of least authority.

5.2 Vulnerability Study

The small TCB size and privilege-reduced components of MettEagle should result in a better security posture. To demonstrate this point, we conducted a study of existing vulnerabilities in container infrastructure on Linux. Our approach is inspired by Biggs et al. [11]. We evaluated Common Vulnerabilities and Exposures (CVEs) collected by NIST [46], which describe known cybersecurity vulnerabilities in present and past software versions and assign vulnerability scores. The scoring follows the Common Vulnerability Scoring System (CVSS) [3], ranging from 0 (low) to 10 (critical).

To find relevant CVEs, we searched the NIST database for the terms ‘linux kernel seccomp’, ‘bpf’, ‘ebpf’, ‘linux kernel namespace’, and ‘linux kernel cgroups’. We limit our study to isolation compromises between containers, which we consider to be the highest impact vulnerabilities. The most prominent avenue are severe kernel-level exploits, so we filter our search results for Linux kernel exploits with high (CVSS 7.0–8.9) and critical (CVSS 9.0–10) scores according to CVSS scoring system v3.1.

The resulting list of 33 vulnerabilities is shown in Ta-

CVE	Cat.	Eval.	CVE	Cat.	Eval.	CVE	Cat.	Eval.
CVE-2023-39191	sc	FM	CVE-2021-4197	cg	PM	CVE-2017-18509	ns	FM

Table 3: List of CVEs classified by category (Cat.) and evaluation (Eval.). The categories consist of `seccomp` and / or `eBPF` (sc), `namespaces` (ns) and `cgroups` (cg) on Linux. The evaluation is marked as FM (fully mitigated), PM (partially mitigated), and N (not mitigated).

ble 3. This number may seem small, but these are potential high-severity exploits as they directly affect the Linux kernel. Mistakes in the userspace container infrastructure may contribute additional vulnerabilities, but these are not considered here as our FaaS runtime is not feature-comparable to the Linux implementation. For the 33 vulnerabilities considered, we categorize our findings the following way:

Fully Mitigated by MettEagle (FM): We do not see a possibility how a similar exploit could be constructed on our microkernel-based system.

Partially Mitigated by MettEagle (PM): If a similar implementation mistake is made, a similar vulnerability may exist in our system. However, immediate, total container-isolation compromise would not occur.

Not Mitigated by MettEagle (N): Our system would be affected the same way as the Linux system. In the following, we will discuss some sample vulnerabilities individually.

5.2.1 seccomp-bpf

`Seccomp-bpf` uses the extended Berkeley Packet Filter (eBPF), to restrict available system calls at kernel level [1]. With eBPF being a code interpreter at kernel level and `seccomp-bpf` using eBPF to express its filter rules, security issues can arise from flaws in either `seccomp-bpf` itself or the underlying eBPF. MettEagle does not require such filtering mechanisms. Only interfaces, for which capabilities are granted are visible to a container. To bypass this access control, the capability implementation itself would need to be compromised, which is part of the microkernel. While implementation bugs in the capability management may exist, we consider these less likely due to the lower complexity compared to a complete code interpreter and checking mechanism as required for `seccomp-bpf`. To substantiate this claim we gathered the SLOC count for the BPF directory in the Linux source. We counted 50,200 lines of code which is more than our entire microkernel (41,406 SLOC). While the SLOC of the BPF directory includes BPF debugging tools in addition to the eBPF interpreter and checker, we note that the microkernel also includes much more than the capability management. We found six CVEs directly related to `seccomp-bpf` and two CVEs related to eBPF in the Linux kernel. We argue that all of them are fully mitigated by MettEagle as the capability system provides `seccomp-bpf` functionality.

5.2.2 namespaces

We found 22 CVEs related to Linux `namespaces`. Out of these, we classified four as fully mitigated by MettEagle, 13 as partially mitigated, and five as not mitigated. Two more CVEs are actually related to `cgroups` and are therefore included in Section 5.2.3. As an example, we consider CVE-2018-18955 to be fully mitigated by MettEagle. It describes a vulnerability in the implementation of `namespace` restrictions, allowing privilege escalation via mishandling of nested user `namespaces`. In L4Re, resource access is enforced by capabilities, so such an escalation can only occur by compromising the capability system itself. Other vulnerabilities are only partially mitigated. An example is CVE-2018-16884, a vulnerability in the Linux kernel's NFS41+ subsystem, in which NFS41+ shares are simultaneously mounted in different network `namespaces`. We consider this to be a bug in the NFS component, causing it to misconfigure the isolation afforded by `namespaces`. Such misconfigurations by a resource provider component like NFS can occur in MettEagle as well. However, this specific CVE on Linux causes memory corruption and privilege escalation in the kernel. On MettEagle, such a mistake would only compromise a userspace component and thus does not immediately allow containers to access each other's memory. Inter-container isolation on MettEagle still holds, thus our ranking as partially mitigated.

CVE-2022-24122 is an example of the third category, *not mitigated*. It describes a use-after-free bug in the implemen-

tation of unprivileged user namespaces. This could lead to compromise of the Linux kernel. Equivalently, the L4Re could contain a memory bug in the code for capability management, compromising the kernel. However, the smaller size and certification of L4Re suggest that these kinds of bugs are less likely to occur.

5.2.3 cgroups

We found three CVEs related to Linux `cgroups`. These can all be partially mitigated by MettEagle. CVE-2022-0492 for instance describes an exploit, where a container can escalate privileges and bypass `namespace` isolation due to a flaw in a `cgroups` feature, allowing to execute arbitrary code with root privileges. In MettEagle, resource restrictions are implemented by resource contexts in userspace components. As these components may exhibit similar implementation flaws, resource restrictions may be equally evadable. However, such a compromise would only affect a single resource and would not result in breaking the kernel or inter-container memory isolation due to root privilege escalation as there is no all-powerful root on a capability-based OS.

5.3 Timing-Based Attacks

In this section, we discuss classes of security problems that are related to time, which are underrepresented in the CVE analysis. These issues include performance-related denial-of-service and timing side-channel attacks. In general, these problems can occur when an attacker and a victim share some state in a system for which timing properties can change based on the behavior of tenants.

One example of such an attack is KernelSnitch [41]. This attack can leak process information by observing the variance in access time to Linux kernel data structures. This variance in access time is due to the variable occupancy of such structures depending on the behavior of other processes. Similarly, Patel et al. [47] use this correlation to attack the performance of victim processes. They strategically trigger worst-case execution time of operations on kernel data structures. The attack described by Mergendahl et al. [44] targets a different, but also shared, component, the scheduler. The authors discovered that a low-priority adversary can arbitrarily delay a specific scheduling instance of an attacked thread by exploiting non-constant operation latency in scheduling data structures on seL4.

There are also shared data structures in L4Re, like the scheduler or capability inheritance trees. Consequently, similar attacks might also exist for L4Re. However, two properties of L4Re make it more resilient to these kinds of attacks. First, the L4Re kernel is real-time capable. Thus, many kernel operations are guaranteed to have bounded execution time, which reduces the likelihood of cross-process timing influences. Second, the microkernel approach offers fewer opportunities for such attacks than traditional systems as the amount of data structures that applications inevitably share can be reduced by careful system design, e.g., by using a separate instance of each system service per compartment. A downside of such mitigation strategies is their increased memory demand. However, the extent of this overhead is to be evaluated in future studies.

The idea of using separate system service instances for each container can also be extended to the kernel itself. For example, Ge et al. [25] implement temporal isolation of applications by running them in fully cloned kernel instances. Thus, we believe that the architecture of MettEagle can provide a better resilience against timing-based attacks compared to Linux-based approaches.

6 Performance Evaluation

In the following, we compare the implementation of compartments on L4Re with standard solutions for lightweight virtualization from a performance perspective. As we want to focus on the bare OS mechanisms, i.e. the isolation and virtualization of containers, we did not deploy warm start optimizations such as provisioning of standby containers with pre-initialized runtimes. In our evaluation we answer the following questions:

- What is the startup time of compartments on L4Re compared to their Linux counterparts?
- Is it possible to build I/O services on L4Re with a performance competitive to monolithic systems?
- What is the end-to-end performance of an application benchmark using standard runtimes running in L4Re compartments?

As a comparison for L4Re compartments, we measured Linux stock processes, runC [32], and Kata Containers [23] with Firecracker [7]. While Linux processes do not guarantee container-grade security properties, they represent an optimal baseline with respect to performance. RunC is the OCI's reference implementation for a low-level container runtime on Linux. It deploys the aforementioned Linux mechanisms like `seccomp-bpf`, `cgroups`, and `namespaces` to create sandboxed execution environments. Firecracker is a lightweight VM framework that builds on top of KVM. It is used with cloud providers like AWS. In our setup, both runC and Firecracker use containerd [24] as high-level container runtime. To integrate Firecracker in a containerd-based system we used Kata Containers [23] as a backend.

6.1 System Setup

All measurements were done on two identical dual-socket servers that are equipped with two Intel Xeon Platinum 8358 CPUs (32 cores per CPU) and 500 GiB of main memory each. For all benchmarks, we disabled both hyperthreading (SMT) and temporary overclocking (TurboBoost). We furthermore

set the CPU's pstate configuration to maximum performance mode. Additionally, the servers both feature a 10 Gbit (Intel 82599 / Intel X540) Ethernet NIC.

The results for benchmark setups running on Linux were recorded using kernel version 6.7.4, runC version 1.1.10, containerd version 1.7.9 and Kata version 3.3.0 with a small patch to enable the measurement of startup times in Firecracker. As `SPAFS` currently lacks a disk backend, we used in-memory file systems on all platforms.

6.2 Container Startup Latency

First, we measured the startup latency of a container. In this benchmark, the containers started consist of a single process and do nothing but recording a timestamp directly after booting. For runC the startup latency reported includes the setup of `cgroups`, `seccomp` filters, and file systems. To measure best-case performance, we set empty `seccomp` filters. For Kata Containers with Firecracker we measure the time from starting the microVM until the container inside prints its first message. To ensure a fair comparison, meta operations for spawning a compartment on L4Re, such as creating a new session with the MettEagle service, contribute to the startup latency.

Figure 3 shows the cumulative distribution function (CDF) of container cold start latency when starting multiple instances in parallel. The benchmark launches N containers at once and then waits for all containers to terminate before starting the next iteration. Note that in practice, many workloads are less extreme with regards to concurrency and rather launch containers in a staggered fashion, making the results shown in Figure 3 an estimation of worst-case performance.

Linux processes have an almost constant startup time, independent of the number of processes spawned in parallel (roughly 200 μs). Similarly, Kata Containers remain constant in their startup latency, albeit at a higher level, as the setup of a VM is more costly than launching a process. On L4Re, it takes 1 ms to start a container on an empty and idle system (N = 1). This startup latency gradually increases when more containers are launched in parallel peaking at 100 ms for 64 parallel launches. With runC, it takes around 70 ms to start a single container. Like with L4Re compartments, this number grows with increasing parallelism, reaching up to 200 ms when starting 64 containers in parallel.

The difference between the cold start latency of a Linux process and an L4Re compartment for N = 1 largely stems from the fact that L4Re loads two binaries when starting a task. Due to the implementation of L4Re's memory management, a task always starts with executing a common helper binary. This helper runs in the first thread of a task and in turn loads the binary of the actual application, effectively doubling the startup overhead. Note however, that this procedure is not intrinsic to a microkernel OS and could be optimized e.g. by running the helper's code directly in the application threads.

The reasons for the growing startup latency of L4Re compartments when facing increased parallelism are rooted in system components not optimized for parallel workloads. We verified that the increase in startup latency is not a consequence of growing IPC latency. However, the L4Re kernel uses coarse-grained locking on its internal data structures which affects the performance of carrying out capability delegation and revocation operations in parallel, which occur a lot when spawning a compartment. A similar issue can be found with `moe`, which uses a single lock to protect its internals. While `LSMM` and `PROMFS` parallelize the memory management and the boot file system, `moe` is still needed for creating objects like scheduling quotas, causing another bottleneck.

In addition to our previous benchmark, Figure 4 shows the startup latency of a single container as a function of idle containers that are present in the system. In this context *idle* means that all threads of the respective containers are blocked. The container whose startup time is measured and the idle containers are not started in parallel. Figure 4 thus gives insight into whether the management data structures of a specific container engine or OS themselves become a bottleneck when many containers are present. The results of the benchmark show that on all platforms, the number of idle containers does not significantly impact their startup latency.

6.3 I/O Performance

To evaluate I/O performance, we compare the network performance available to L4Re compartments to that of Linux processes and containers. We measured the latency of a UDP-based ping-pong benchmark over a 10 GiB/s Ethernet interface. The remote host that was pinged ran Linux, while the latency was recorded on the respective platform. On all platforms the latency was roughly the same with an average value of 40 μs.

Figure 5 shows the bandwidth achieved using multiple sockets in parallel. As expected, Linux and runC perform similarly as they use the same network stack. With a low degree of parallelism, Linux achieves a higher bandwidth than L4Re (900 MiB/s vs. 350 MiB/s) since L4Re does not implement advanced NIC features such as receive side scaling, and all driver processing is done on a single core, which is also used by the first thread of the benchmark. With increasing parallelism and thus more threads sending traffic from different cores, this effect diminishes. While L4Re was able to achieve throughput at line rate using many sockets, Linux performance decreased when using the NIC in parallel. Our efforts to tune Linux' network stack did not significantly improve its performance. This is surprising as a bandwidth test using `iperf` [21] achieved line rate throughput for many parallel TCP connections but yielded results similar to our custom benchmark when using UDP.

6.4 Application Benchmark

We chose SeBS [16], a client for benchmarking serverless execution environments, to simulate an application workload.

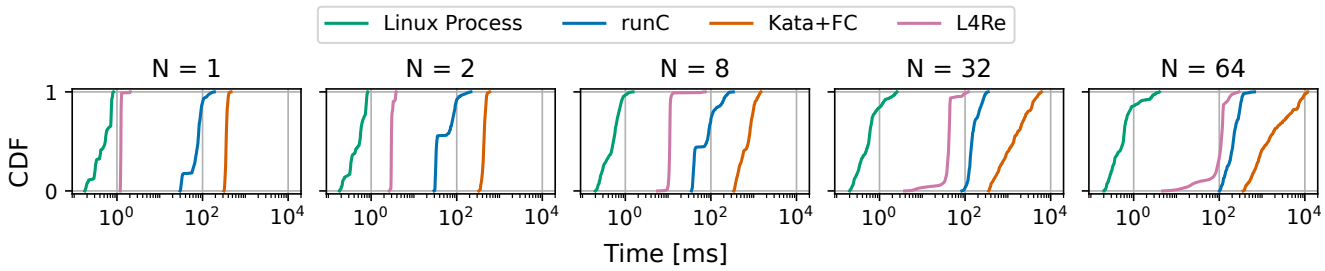

Figure 3: Cumulative distribution function of the container startup latency when launching N containers in parallel. The leftmost subplot (N = 1) shows the startup latency of a single container on an empty system.

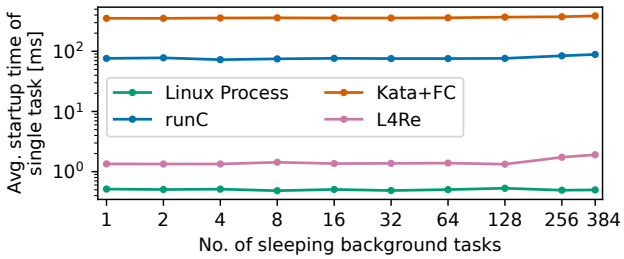

Figure 4: Average startup latency of a single container as function of the number of idle containers present in the system.

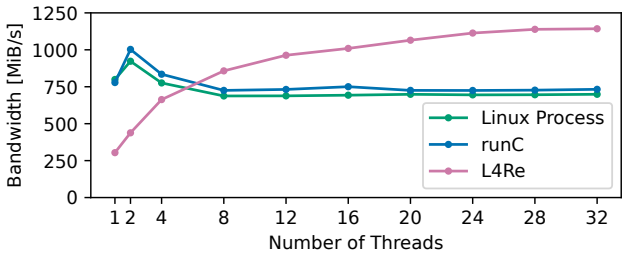

Figure 5: Bandwidth for transmitting data over a 10 GBit Ethernet interface (using 1472 B UDP packets) as a function of the number of parallel data streams.

SeBS deploys a set of benchmarks written in `python` to benchmark a FaaS server running on a remote machine. To avoid performance advantages for L4Re due to missing functionality, we implemented service similar to MettEagle's FaaS agent on Linux. This custom FaaS agent executes the benchmarks as a process, a container, or a Kata Container using a Firecracker backend respectively.

The use of a `python`-based benchmark yields multiple insights: First, it demonstrates that L4Re is capable of running a standardized runtime. This allows for executing unmodified code written for a platform like Linux on L4Re, giving a hint on how to deploy existing applications in compartments. Second, `python` is a program that makes heavy use of OS services. During startup, `python` interacts with dozens of files and performs a lot of memory allocation and deallocation. Due to their intrinsic communication overhead, microkernel OSes are known to have performance deficits for such operations. Hence, from a microkernel perspective, the use of a `python` benchmark approximates a worst-case example with respect to performance, allowing us to explore L4Re's limits.

In the following, we present results for a subset of the SeBS benchmark suite. We omitted benchmarks for uploading data to cloud storage, as this workload does not relate to our work. Also, we refrained from porting both the `pytorch` machine learning library and `squiggle`, a python library for DNA visualization to L4Re. Both benchmarks are compute-heavy and thus do not exercise the operating system. Lastly, we also had to omit an FFMPEG benchmark since it assumed support for the `fork` system call which does not exist on L4Re. In the end, we evaluated benchmarks for executing an empty `python` function, HTML manipulation, file compression, and several graph processing algorithms, whose dependencies were ported to L4Re.

Whenever possible, we ran the SeBS benchmarks with both a standard problem size as well as with a *tiny* problem size. While the tiny size is too small to represent a real-world use case, it provides us with an approximation for the runtime initialization overhead introduced by `python`, which differs for each benchmark due to a different set of `python` modules being loaded. The empty function and the file compression benchmark do not offer a configurable problem size.

Figure 6 depicts the latency for sequentially executing the SeBS benchmark. For all benchmarks except ZIP, the end-to-end performance of L4Re compartments is at most 15% worse than that of runC. When running the HTML benchmark, L4Re was 10% faster than runC. The right subplot reveals that the pure execution time spent in `python` (execution time of python code with module loading, excluding the startup latency of the core interpreter) is higher with L4Re compartments than on any other platform. However, the fast startup latency of compartments levels out this disadvantage, leading to a comparable end-to-end latency of function execution. For all benchmarks, the end-to-end latency for Kata was the highest which we attribute to the slower startup of

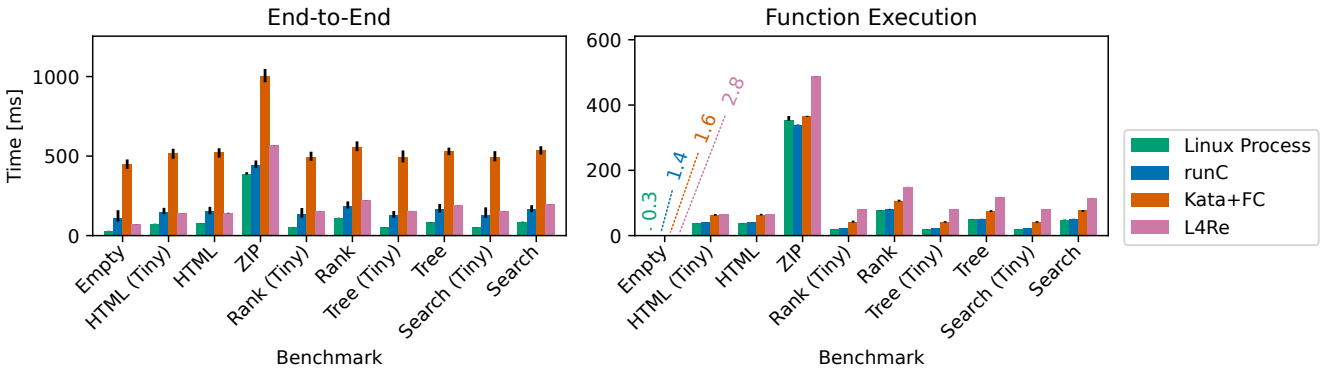

Figure 6: Median latency for sequential execution of the SeBS serverless benchmark. The left subfigure depicts end-to-end latency as observed by the client, while the right subfigure shows the execution time in python. Benchmarks run with the tiny size are marked by the *Tiny* suffix. The whiskers show the 5th and 95th percentile, respectively.

the VM and the fact that the container images Kata is copying into the VM upon initialization are much larger for a `python` benchmark than those used in the microbenchmark.

Interestingly, the absolute difference in execution time between L4Re and the other platforms is the same for both benchmark sizes, regardless of the benchmark type. For instance, the latency difference between running the page rank benchmark (Rank) in L4Re compartments and runC is around 45 ms for both the tiny benchmark size (graph with 10 nodes) and the standard size (graph with 10,000 nodes). Since the benchmark function script itself loads several modules and this time is included in the function execution latency, it is likely that the performance disadvantage of L4Re is caused by a slower initialization of `python` modules. This in turn indicates that the execution of `python` code on L4Re is not slow per se.

While investigating the numbers for `python` on L4Re, it turned out that L4Re's file system performance is much worse compared to Linux. For instance, a single call to `stat` takes around 4 μs on L4Re, but only 460 ns on Linux. This roughly tenfold performance disadvantage also applies to other file-related operations such as `open` or `read`. As even running an empty `python` script involves hundreds of calls to these functions, L4Re's shortcomings in file system performance strongly influence the benchmark as a whole. This also explains the weakness of L4Re in the ZIP benchmark, which executes many file operations also after the initialization phase.

Lastly, Figure 7 shows the results for running the SeBS benchmark in burst mode. In this mode, the client triggers 16 function invocations in parallel, leading to the parallel execution of 16 container instances with `python` on the server side. In general, all platforms performed worse than in the sequential setting. Comparing runC and L4Re, the end-to-end latency for an empty function and for the HTML benchmark is again similar. The ZIP and the graph processing benchmarks, however, take one to two times longer on L4Re than on runC. Yet again, the performance deficits are not caused by the compartment mechanism itself, but rather by the execution of the `python` code. However, L4Re consistently outperforms Kata containers.

As with the sequential pattern of the SeBS benchmarks, our file system implementation accounts for a large share of the performance deficits of L4Re compared to runC. The increase in function execution latency of the graph benchmarks (rank, tree, and search) is caused by the dynamic loading of shared objects required by the `python` scripts. Surprisingly, loading shared objects from within different tasks in parallel appears to slow this procedure as a whole. The exact reason for this is still subject to investigation.

7 Discussion

As the performance evaluation in Section 6 has shown, the implementation of containers on microkernels is feasible. Also on large machines, a microkernel-based container framework is able to provide performance competitive to standard solutions for most workloads. While the microkernel architecture introduces some intrinsic overhead, we believe that implementation optimizations could further improve the performance of L4Re compartments significantly. For example, L4Re's file system overhead could be reduced by deploying a file system design similar to approaches used with persistent memory where most file operations are implemented as accesses to shared memory instead of IPC [15].

Also, the FaaS agent of MettEagle currently lacks warm start optimizations [8, 19] found in current production-grade lightweight virtualization solutions. We do not see conceptual limitations that would prevent the adaptation of these optimizations with the compartment framework of L4Re. In fact, microkernels conceptually offer means of optimization even beyond those of monolithic kernels. On a microkernel-based system, different compartments could be using separate

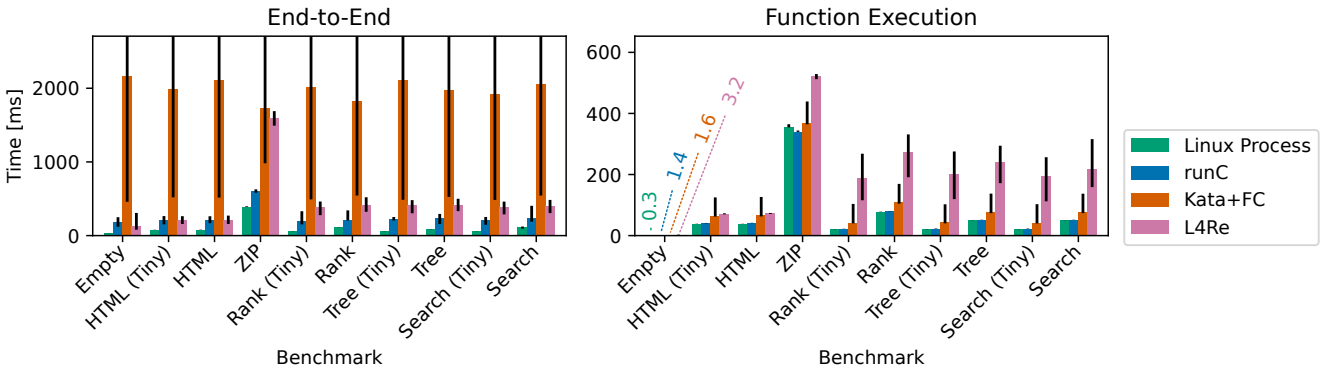

Figure 7: Median latency for starting 16 functions of each SeBS benchmark in parallel. The left subfigure shows end-to-end latency as recorded at the client. The right subfigure depicts the pure execution time in python. Benchmarks run with the tiny size are marked with a corresponding suffix. The whiskers denote the 5th and 95th percentile. The whiskers for Kata+FC in the left subplot extend to values between 3000 and 4000 ms but have been cropped to improve readability of the plot.

instances of system services such as storage or network stacks. Each instance could be tuned to its specific container workload, offering bespoke interfaces and abstractions. We did not explore such optimizations in MettEagle, but its overall architecture can be adapted to support such container-specific service instances.

In terms of interfaces, MettEagle currently does not support the execution of compartments loaded from OCI-compliant images. With an effort to enhance L4Re's POSIX Compatibility Layer, there are no fundamental limitations that prevent supporting OCI images on L4Re. However, this requires a lot of implementation and standardization effort, as OCI containers rely on many Linux-specific features like certain *sysfs* files.

Lastly, we believe that the findings of this paper could also be transferred to other microkernel platforms. For instance implementing containers on seL4 would work similarly on a conceptual level and grant additional security benefits as the seL4 kernel is formally verified [35]. The researchers developing seL4 also showed that their system is able to provide protection against a variety of timing-based side-channel attacks [28], which is of particular concern when running containers of mutually distrusting clients on the same hardware.

8 Related Work

The emergence of microservices motivated research for optimizing lightweight virtualization with respect to performance and security. For container-based systems, Cntr [51] introduced a mechanism for dynamically adding rarely used tools to production container images, reducing their size and deployment time. On the security side, dedicated interest groups work on hardening containers on Linux [40]. Additionally, chestnut [14] allows for automatically generating `seccomp-bpf` filters from application binaries, only granting access to system calls the application needs. Many such Linux-related container-hardening techniques become superfluous with MettEagle because a capability-based approach like L4Re promotes adherence to the principle of least authority.

Nakata et al. proposed to mitigate attacks exploiting the weaker security guarantees of containers by transplanting Linux containers across different OS types, thus thwarting attacks that only work when running on specific kernels [45]. The same reasoning applies to running containers on L4Re.

BlackBox [29] implements secure container execution on an untrusted operating system. Containers are shielded against the operating system using virtualization and system call sanitization. Although BlackBox achieves a small TCB for confidentiality, the otherwise large, untrusted operating system needs to be relied on to guarantee availability. The same applies to MettEagle, albeit with a much smaller TCB contributing to availability.

In pursuit of increasing the security of lightweight virtualization, lightweight VMs gained traction. Shen et al. used a library OS as a guest operating system running in lightweight VMs, increasing their performance by saving mode and context switches in the guest [49]. Their approach also reduced the interface between the guest OS and the hypervisor, shrinking the attack surface of the latter. For frameworks like Kata, Li et al. proposed runD [39], a set of optimizations for reducing the performance impact of container isolation mechanisms like `cgroups` when an application is already isolated in a lightweight VM. Manco et al. demonstrated the use of unikernels together with carefully designed VM infrastructure, yielding startup times and application performance even better than that of containers on Linux [42]. We believe that MettEagle also offers a high degree of isolation, like VMs do. The attack surface between containers and the microkernel is far smaller than under a monolith, like Linux. But in contrast to unikernel-based VMs, containers in MettEagle have native access to

operating system features like multithreading for performance and address-space-based compartmentalization for security.

Lastly, Koller and Williams argue that FaaS applications are less dependent on the Linux environment than traditional applications [36]. As an example, Szekely et al. required little effort to port FaaS applications to their new σOS API [50]. We argue in a similar way that porting real-world FaaS code to MettEagle will be manageable and not hinder adoption.

9 Conclusion

MettEagle has demonstrated the feasibility of implementing containers on the L4Re microkernel. Due to the fundamental security benefits of microkernels, our container design awards a more robust security posture compared to containers on Linux. While Linux needs to implement additional restriction mechanisms for providing container-grade isolation to processes, such mechanisms are either not needed or conceptually much simpler on a capability-based microkernel, since it fully isolates processes by default. We have demonstrated this security advantage with a study of past CVEs, many of which are mitigated on L4Re because the attacked restriction mechanisms are not present.

Further, we have shown that the simplicity of microkernel-based systems can even result in improved performance. Although some performance deficiencies remain, these are mostly caused by implementation issues rather than being inherent to the microkernel-based design. While we applied only limited optimizations for server-grade workloads to L4Re, we still achieve raw container startup times outperforming Linux containers. With these results, we believe a microkernel-based cloud infrastructure is worth developing further, as the security benefits are apparent and performance is competitive.

Acknowledgments

We would like to thank our shepherd, Yuvraj Patel, and the anonymous reviewers of SOSP'24 and OSDI'25 for their helpful suggestions. This research was funded by the German Research Council DFG through grants 502457159 (FOSSIL) and 501887536 (ParPerOS). The project was furthermore partially supported by the German federal ministry of research, technology, and space (BMFTR) within the MANNHEIM CeCaS project.

A Artifact Appendix

Abstract

The artifact contains every custom component that is needed to recreate the measurements presented in the paper. It is a bundle of source files of the individual projects created for this paper. This includes the MettEagle software and benchmark code. However, external, unmodified software (like Linux or Firecracker) is not included.

Scope

The artifact strives to achieve *artifact available*. It only contains source files and some documentation but no all-in-one script for fitting all the individual projects together. Thus, this artifact does not claim easy *functional* evaluation. Unfortunately, due to the large number of moving parts and long compilation times, setting up the benchmark environment takes some time. If any question arise while using the provided artifact, please contact the authors.

The artifact contains the code of the MettEagle FaaS runtime including the surrounding L4Re. It is thus possible to run MettEagle using this artifact. Furthermore, all the benchmark scripts for exercising MettEagle are included. Most importantly, a modified version of the SeBS benchmark suite is included to run functions on MettEagle. All code used to create comparative benchmarks on Linux is also included.

Contents

For a precise description of the provided artifacts, please refer to the `README.md` inside of the artifact.

Hosting

The artifact is available via Zenodo: https://doi.org/10.5281/zenodo.15211297.

Requirements

The artifact is designed for the x86-64 architecture. It is tested to run inside of Qemu and on the machine described in Section 6.1. The network benchmarks can either run via emulated NICs in Qemu or via connecting two physical machines.
