Message from the OSDI '26 Program Co-Chairs

Welcome to the 20th USENIX Symposium on Operating Systems Design and Implementation (OSDI '26).

We are grateful to our reviewers for their work, to our authors for theirs, to our artifact evaluation committee (co-chaired by Anand Iyer and Sara McAllister), to the poster session chairs (Daehyeok Kim and Shadi Noghabi), to the mentorship activity chair (Stephanie Wang), to the ever-ready USENIX staff, and to all attendees. A vibrant OSDI is a three-day celebration of the best in computing systems, and this one shouldn't disappoint.

OSDI '26 received 669 reviewable submissions, more than twice any previous year. Authors came from more than 30 countries. We pre-committed to accepting at least 20% of the submissions, and we met that commitment (barely), accepting 134—around 2.5x any previous year. (Two additional submissions were accepted via revise-and-resubmit from OSDI '25.) Roughly a third of the acceptances were conditional, subject to approval via stringent shepherding; thanks to heroic efforts from both authors and the PC, all conditionally accepted papers will be presented. Only a multi-track format could accommodate substantive presentations for so much great work, so this is the first multi-track OSDI.

We accepted two kinds of submissions, Research and Operational Systems. The reviewing process for Operational Systems papers focused on design, implementation, analysis, and experience in a real-world operational context. Nineteen accepted papers are designated as Operational Systems.

Beyond Operational Systems, we changed the review process by removing the author response period, replacing revise-and-resubmit with conditional acceptance, and reducing the minimum number of reviews per submission to two. These changes were broadly successful; our attempt to encourage concise submissions was not: only three accepted papers were submitted below the page limit.

Our program committee of 117 incredible researchers, drawn from all over the world, produced 1826 penetrating reviews and more than 4000 comments. Thank you.

Now, enjoy OSDI!

Eddie Kohler, *Harvard University*
Amar Phanishayee, *NVIDIA*
OSDI '26 Program Co-Chairs

20th USENIX Symposium on Operating Systems Design and Implementation (OSDI '26)

July 13–15, 2026
Seattle, WA, USA

Monday, July 13

KV Cache and Long Context

Strata: Hierarchical Context Caching for Long Context Language Model Serving 1
Zhiqiang Xie, *Stanford University and NVIDIA;* Ziyi Xu, *Shanghai Jiao Tong University;* Mark Zhao, *University of Colorado Boulder;* Yuwei An, *Carnegie Mellon University;* Vikram Sharma Mailthody, *NVIDIA;* Scott Mahlke, *NVIDIA and University of Michigan;* Michael Garland, *NVIDIA;* Christos Kozyrakis, *NVIDIA and Stanford University*

ECHO: Efficient KV Cache Offloading with Lossless Prefetching for Serving Native Sparse Attention LLMs 17
Guangda Liu, Wenhao Chen, Chengwei Li, and Zhenyu Ning, *Shanghai Jiao Tong University;* Jing Lin and Yiwu Yao, *Huawei;* Quan Chen, Shixuan Sun, and Jieru Zhao, *Shanghai Jiao Tong University;* Minyi Guo, *Guizhou University and Shanghai Jiao Tong University*

No Buffer, No Bottleneck: Efficient Zero-Copy KV Cache Offloading for Long-Context LLMs 39
Shutian Luo and Haiying Shen, *University of Virginia*

Simple is Better: Multiplication May Be All You Need for LLM Request Scheduling 55
Dingyan Zhang, Jinbo Han, Kaixi Zhang, and Xingda Wei, *Shanghai Jiao Tong University;* Sijie Shen, Chenguang Fang, Wenyuan Yu, and Jingren Zhou, *Alibaba Group;* Rong Chen, *Shanghai Jiao Tong University*

Prism: Cost-Efficient Multi-LLM Serving via GPU Memory Ballooning 75
Shan Yu, *University of California, Los Angeles;* Yifan Qiao, *University of California, Berkeley;* Mingyuan Ma, *Harvard University;* Yangmin Li, *Carnegie Mellon University;* Shuo Yang, *University of California, Berkeley;* Xinyuan Tong, *University of Edinburgh;* Yang Wang, *Intel;* Zhiqiang Xie, *Stanford University;* Yuwei An, *Carnegie Mellon University;* Shiyi Cao, *University of California, Berkeley;* Ke Bao, *LMSYS;* Deepak Vij, Xiaoning Ding, and Yichen Wang, *ByteDance;* Qingda Lu, *Alibaba Cloud;* Zhong Wang, *Tsinghua University;* Gao Gao, *Novita AI;* Harry Xu and Junyi Shu, *University of California, Los Angeles;* Jiarong Xing, *Rice University;* Ying Sheng, *University of California, Los Angeles*

Memory Tiering and CXL

Break on Through to the Other Side: Pooling Memory Elastically with RamRyder 95
Yanbo Zhou, *University of California, San Diego;* Erci Xu, *Shanghai Jiao Tong University;* Dongjoo Seo and Adam Manzanares, *Samsung Semiconductor;* Steven Swanson, *University of California, San Diego*

MAC: Metadata Acceleration for Sustainable Performance in Big-Data Systems with CXL DRAM. 115
Dusol Lee, *Seoul National University;* Yan Sun, Houxiang Ji, Vinit Gupta, and Austin Antony Cruz, *University of Illinois Urbana–Champaign;* Inhyuk Choi, *Seoul National University;* Nam Sung Kim, *University of Illinois Urbana–Champaign;* Jihong Kim, *Seoul National University*

Finding NEMO: Nimble and Expressive Memory Observability 133
Shihang Li and Matthew Giordano, *University of Washington;* Tushar Garg, *Meta;* Rohan Kadekodi, *University of Washington;* Daniel S. Berger, *University of Washington and Microsoft Azure;* Baris Kasikci, Thomas Anderson, and Simon Peter, *University of Washington*

OBASE: Object-Based Address-Space Engineering to Improve Memory Tiering 151
Vinay Banakar, *University of Wisconsin–Madison and Google;* Suli Yang, *Google;* Kan Wu, *xAI;* Andrea C. Arpaci-Dusseau and Remzi H. Arpaci-Dusseau, *University of Wisconsin–Madison;* Kimberly Keeton, *Google*

MDK: Rethinking the data center memory reclamation problem 167
Shaurya Patel, *Google and University of British Columbia;* Suli Yang and Yawen Wang, *Google;* Kan Wu, *xAI;* Alexandra (Sasha) Fedorova, *University of British Columbia and MongoDB;* Margo Seltzer, *University of British Columbia;* Kimberly Keeton, *Google*

Sandboxing, Access Control, and Drivers

USEC: A User-Requirement-Driven Mandatory Access Control Framework for Operating Systems (Operational Systems) . . . 191
Yu Jiang, *Tsinghua University;* Wenhuan Liu, *Tsinghua University and UnionTech Software Technology Co., Ltd;* Fuchen Ma, Yuheng Shen, and Yuanliang Chen, *Tsinghua University;* Lei Zhang and He Li, *UnionTech Software Technology Co., Ltd.;* Quan Zhang and Chijin Zhou, *East China Normal University*

Mohabi: Disaggregating and Sandboxing the Firefox JavaScript Engine . . . 207
Abhishek Sharma and Anand Balaji, *The University of Texas at Austin;* Zachary Yedidia, *Stanford University;* Anthony Du and Taehyun Noh, *The University of Texas at Austin;* Iain Ireland, Jan de Mooij, and Matthew Gaudet, *Mozilla;* Tal Garfinkel, *Google;* Deian Stefan and Hovav Shacham, *University of California, San Diego;* Shravan Narayan, *The University of Texas at Austin*

Ichnaea: A Framework for Precise Tracking of Memory Objects . . . 229
Samad Haque and Sibin Mohan, *The George Washington University;* Aaron Paulos and Partha Pal, *RTX BBN Technologies*

Extracting Database Access-Control Policies From Web Applications. . . . 249
Wen Zhang, Dev Bali, and Jamison Kerney, *University of California, Berkeley;* Aurojit Panda, *NYU;* Scott Shenker, *University of California, Berkeley, and ICSI*

***iLand*: An Instruction-Level Dynamic Binary Instrumentation framework for iOS . . . 271**
Kaitao Xie, Yizhuo Wang, and Xiaolong Bai, *Alibaba Group*

LLM Training at Scale

Tessera: A Holistic Pipeline Parallelism Framework for Trillion-Parameter Heterogeneous MoE Training (Operational Systems). . . . 287
Weifang Hu, *Huazhong University of Science and Technology;* Langshi Chen, Man Yuan, Youyang Yao, Xiulong Yuan, Li Tian, Yong Li, and Wei Lin, *Alibaba Cloud;* Xuanhua Shi, *Huazhong University of Science and Technology;* Zhengping Qian and Jingren Zhou, *Alibaba Cloud*

Hetu v2: A General and Scalable Deep Learning System with Hierarchical and Heterogeneous Single Program Multiple Data Annotations. . . . 305
Haoyang Li, *Peking University;* Fangcheng Fu, *Shanghai Jiao Tong University;* Hao Ge, Sheng Lin, Xuanyu Wang, Jiawen Niu, and Yuming Zhou, *Peking University;* Xupeng Miao, *Purdue University;* Bin Cui, *Peking University and Peking University (Qingdao)*

Syncopate: Efficient Multi-GPU AI Kernels via Automatic Chunk-Centric Compute-Communication Overlap . . . 331
Xinwei Qiang, Yue Guan, and Zhengding Hu, *University of California, San Diego;* Keren Zhou, *George Mason University and OpenAI;* Yufei Ding, *University of California, San Diego, and Meta;* Adnan Aziz, *Meta*

Teaching The Old Dog New Tricks: Building Efficient Data Pipelines for Large-Scale LLM Pre-training (Operational Systems). . . . 349
Luofan Chen and Chenhan Wang, *University of Science and Technology of China and ByteDance Seed;* Weidong Zhang, Jinxin Chi, Hequan Zhang, Zanbo Wang, Chenyuan Wang, Lishu Luo, Sijin Wu, Junqi Hu, Jun Wang, and Cheng Chen, *ByteDance Seed;* Lixin Huang, Liyang Zhao, Yong Tian, and Jun Guo, *ByteDance;* Youhui Bai, *University of Science and Technology of China;* Wencong Xiao, *ByteDance Seed;* Kang Chen, *Tsinghua University;* Cheng Li, *University of Science and Technology of China and Institute of Artificial Intelligence, Hefei Comprehensive National Science Center*

Cocoon: A System Architecture for Differentially Private Training with Correlated Noises . . . 367
Donghwan Kim and Xin Gu, *The Pennsylvania State University;* Jinho Baek, Timothy Lo, Younghoon Min, Kwangsik Shin, and Jongryool Kim, *SK hynix Inc.;* Jongse Park, *Korea Advanced Institute of Science and Technology (KAIST);* Kiwan Maeng, *The Pennsylvania State University*

Testing, Debugging, and Root Causing

ValScope: Value-Semantics-Aware Metamorphic Testing for Detecting Logical Bugs in DBMSs . . . 387
Li Lin, Liehang Chen, and Rongxin Wu, *Xiamen University*

The Abstention Protocol: RCA for Clos Fabrics (Operational Systems). . . . 405
Madhava Gaikwad, *Independent;* and Deepak Pandey, *Microsoft*

When Sampling Lies: Trustworthy Performance Profiling for Flat Workloads with Blink (Operational Systems) **423**
Rishikesh Devsot, *YScope;* ChenXing Yang and Yi Fan Yu, *YScope and University of Toronto;* Prabhdeep Singh Soni, Afshin Arefi, Bryan Chan, and Reza Azimi, *Huawei Technologies Canada;* Ding Yuan, *YScope and University of Toronto*

Breaking the Reward Barrier: Accelerating Tree-of-Thought Reasoning via Speculative Exploration **437**
Shuzhang Zhong, Haochen Huang, and Shengxuan Qiu, *Peking University;* Pengfei Zuo, *ByteDance Seed;* Runsheng Wang and Meng Li, *Peking University*

Controlling Opaque-Component Effects with Semisolates and Try **453**
Evangelos Lamprou, *Brown University;* Tianyu (Ezri) Zhu, *Stevens Institute of Technology;* Di Jin and Grigoris Ntousakis, *Brown University;* Georgios Liargkovas, *Columbia University;* Calvin Eng, *Brown University;* Konstantinos Kallas, *University of California, Los Angeles;* Michael Greenberg, *Stevens Institute of Technology;* Nikos Vasilakis, *Brown University*

Kernel Scheduling and Tail Latency

SBB: Eliminating Centralized Bottlenecks in Userspace Network Runtime **473**
Kang Hu, *Peking University and Zhongguancun Laboratory;* Shuqi Dong, *Peking University;* Chuandong Li, *Peking University and Zhongguancun Laboratory;* Ran Yi, *Peking University;* Zonghao Zhang, *Peking University and Zhongguancun Laboratory;* Yiming Yao, *Peking University;* Bo An, *Zhongguancun Laboratory;* Jie Zhang, Xiaolin Wang, and Yingwei Luo, *Peking University and Zhongguancun Laboratory;* Zhenlin Wang, *Michigan Technological University;* Diyu Zhou, *Peking University*

Rakaia: Scalable In-Kernel Scheduling for TCP-Based RPCs **491**
Rui Yang, Konstantinos Prasopoulos, and Edouard Bugnion, *EPFL*

kSTEP: Characterization and Deterministic Testing of Linux CPU Scheduler Bugs **509**
Tingjia Cao, Shawn (Wanxiang) Zhong, and Caeden Whitaker, *University of Wisconsin–Madison;* Ke Han, *Purdue University;* Andrea C. Arpaci-Dusseau and Remzi H. Arpaci-Dusseau, *University of Wisconsin–Madison*

What Are You (M)Waiting For: The Hidden Cost of Idle in the Hyperscale Cloud (Operational Systems) **529**
Yun Wang, *Shanghai Jiao Tong University;* Xingguo Jia, *Alibaba Cloud;* Ben Luo and Kenan Liu, *Alibaba Group;* Shengdong Dai, *Alibaba Cloud;* Jingdong Han and Weihao Chen, *Alibaba Group;* Yicheng Gu and Xingzi Yu, *Shanghai Jiao Tong University;* Yibin Shen and Jiesheng Wu, *Alibaba Cloud;* Zhengwei Qi and Haibing Guan, *Shanghai Jiao Tong University*

Xkernel: Principled Performance Tunability of Operating System Kernels **547**
Zhongjie Chen, *Tsinghua University and Microsoft Research;* Wentao Zhang, *University of Illinois Urbana–Champaign;* Yulong Tang and Ran Shu, *Microsoft Research;* Fengyuan Ren, *Tsinghua University;* Tianyin Xu, *University of Illinois Urbana–Champaign;* Jing Liu, *Microsoft Research*

Agentic AI and LLM Operations

Murakkab: Resource-Efficient Agentic Workflow Orchestration in Cloud Platforms **567**
Gohar Irfan Chaudhry, *MIT CSAIL;* Esha Choukse, Haoran Qiu, Íñigo Goiri, and Rodrigo Fonseca, *Microsoft Azure Research;* Adam Belay, *MIT CSAIL;* Ricardo Bianchini, *Microsoft Azure*

ECO: An AI-Driven Code Efficiency Optimizer for Warehouse Scale Computers (Operational Systems) **589**
Hannah Lin and Martin Maas, *Google DeepMind;* Maximilian Roquemore, *Google;* Arman Hasanzadeh, *Google DeepMind;* Fred Lewis, Yusuf Simonson, Ameya Shringi, and Hongwen Dai, *Google;* Patrick Musau, *Google DeepMind;* Tzu-Wei Yang, *Google;* Amir Yazdanbakhsh and Deniz Altinbüken, *Google DeepMind;* Florin Papa, Maggie Nolan Edmonds, Aditya Patil, Don Schwarz, Satish Chandra, and Chris Kennelly, *Google;* Milad Hashemi, *Google DeepMind;* Parthasarathy Ranganathan, *Google*

StriaTrace: Efficient Tracing and Diagnosis for Online LLM Inference (Operational Systems) **627**
Haonan Wu, *Shanghai Jiao Tong University and Alibaba Group;* Yanqing Chen, Kun Qian, Xue Li, and Jingbo Xu, *Alibaba Group;* Erci Xu, *Shanghai Jiao Tong University;* Ennan Zhai and Wenyuan Yu, *Alibaba Group;* Guangtao Xue, *Shanghai Jiao Tong University and Shanghai Key Laboratory of Trusted Data Circulation and Governance and Web3;* Jingren Zhou, *Alibaba Group*

Diagnosing Performance Issues in Application-Defined Resources **647**
Yigong Hu and You-Liang Huang, *Boston University;* Haodong Zheng, *University of Washington and EPFL;* Yicheng Liu, *University of Washington and University of California, Los Angeles;* Dedong Xie and Baris Kasikci, *University of Washington*

Program Analysis

hS: Speculative Script Reordering at Subprocess Granularity 665
Georgios Liargkovas and Di Jin, *Brown University;* Tianyu (Ezri) Zhu and Dan Liu, *Stevens Institute of Technology;* A. Bolun Thompson, *University of California, Los Angeles;* Anirudh Narsipur, Seong-Heon Jung, and Siddhartha Prasad, *Brown University;* Diomidis Spinellis, *Athens University of Economics and Business and TU Delft;* Michael Greenberg, *Stevens Institute of Technology;* Konstantinos Kallas, *University of California, Los Angeles;* Nikos Vasilakis, *Brown University*

Incr: Faster Re-execution via Bolt-on Incrementalization 683
Yizheng Xie, Evangelos Lamprou, Jerry Xia, and Nikos Vasilakis, *Brown University*

A Compilation-based Under-Constrained Execution Engine 701
Mingjun Yin, Zhaorui Li, Ju Chen, Haochen Zeng, and Chengyu Song, *University of California, Riverside*

Aletheia: Automated Detection of Data Integrity Violations in Microservices 721
Mafalda Sofia Ferreira, João Ferreira Loff, João Garcia, and Rodrigo Rodrigues, *INESC-ID, Instituto Superior Técnico, Universidade de Lisboa*

Synchronization

Arctic: a practical lock-free adaptive radix tree 739
Newton Ni, Nicolas Garza, Jenny Stinehour, and Michael Goppert, *The University of Texas at Austin;* Michal Friedman, *ETH Zürich;* Emmett Witchel, *The University of Texas at Austin*

Efficient and Scalable Synchronization via Generalized Cache Coherence 755
Yanpeng Yu, Seung-seob Lee, Lin Zhong, and Anurag Khandelwal, *Yale University*

Shaving the Peaks: Taming Tail Latency for Managed Workloads via Disaggregated Garbage Collection 773
Hongtao Lyu, Yuhan Li, and Mingyu Wu, *Shanghai Jiao Tong University*

DeLFS: A Decentralized Log-Structured File System for Manycores 793
Taehwan Ahn, Chanhyeong Yu, Sangjin Lee, and Yongseok Son, *Chung-Ang University*

Tuesday, July 14

RL Training at Scale

Weave: Efficient Co-Scheduling for Disaggregated RL Post-Training 809
Tianyuan Wu and Lunxi Cao, *Hong Kong University of Science and Technology;* Yining Wei, *University of Illinois Urbana–Champaign;* Wei Gao, Yuheng Zhao, and Dakai An, *Hong Kong University of Science and Technology;* Shaopan Xiong, Zhiqiang Lv, Ju Huang, Siran Yang, Yinghao Yu, Jiamang Wang, and Lin Qu, *Alibaba Group;* Wei Wang, *Hong Kong University of Science and Technology*

RLinf: Flexible and Efficient Large-Scale Reinforcement Learning via Macro-to-Micro Flow Transformation . . . 829
Chao Yu, *Tsinghua University;* Yuanqing Wang, *Infinigence AI and Peking University;* Zhen Guo, Hao Lin, and Si Xu, *Infinigence AI;* Hongzhi Zang, *Tsinghua University;* Quanlu Zhang, *Infinigence AI;* Yongji Wu, *University of California, Berkeley;* Chunyang Zhu and Junhao Hu, *Infinigence AI;* Zixiao Huang, *Tsinghua University and Infinigence AI;* Mingjie Wei, *Zhongguancun Academy;* Yuqing Xie, *Tsinghua University;* Ke Yang, *Zhongguancun Academy;* Bo Dai, *Beihang University and Infinigence AI;* Zhexuan Xu and Jiakun Du, *Tsinghua University;* Xiangyuan Wang, *Peking University and Infinigence AI;* Xu Fu and Letong Shi, *Infinigence AI;* Zhihao Liu, *Zhongguancun Academy;* Kang Chen, *Peking University and Zhongguancun Academy;* Weilin Liu, *Infinigence AI;* Gang Liu, *Tsinghua University;* Boxun Li, *Infinigence AI;* Jianlei Yang, *Beihang University;* Zhi Yang, *Peking University;* Guohao Dai, *Shanghai Jiao Tong University and Infinigence AI;* Yu Wang, *Tsinghua University*

DynaRL: Flexible and Dynamic Scheduling of Large-Scale Reinforcement Learning Training 847
Yuanqing Wang, *Peking University and Infinigence AI;* Hao Lin, Junhao Hu, Chunyang Zhu, Quanlu Zhang, and Zhen Guo, *Infinigence AI;* Yuchen Zhang, *Institute of Computing Technology, Chinese Academy of Sciences and Infinigence AI;* Xu Fu and Si Xu, *Infinigence AI;* Bo Dai, *Beihang University and Infinigence AI;* Zixiao Huang, *Tsinghua University and Infinigence AI;* Chao Yu, *Tsinghua University;* Boxun Li, *Infinigence AI;* Guohao Dai, *Shanghai Jiao Tong University and Infinigence AI;* Zhi Yang, *Peking University;* Yu Wang, *Tsinghua University*

RollArt: Disaggregated Multi-Task Agentic RL Training at Scale 863
Wei Gao, Yuheng Zhao, and Tianyuan Wu, *Hong Kong University of Science and Technology;* Shaopan Xiong and Weixun Wang, *Alibaba Group;* Dakai An and Lunxi Cao, *Hong Kong University of Science and Technology;* Dilxat Muhtar, Zichen Liu, Haizhou Zhao, Ju Huang, and Siran Yang, *Alibaba Group;* Yongbin Li, *Tongyi Lab, Alibaba;* Wenbo Su, Jiamang Wang, Lin Qu, and Bo Zheng, *Alibaba Group;* Wei Wang, *Hong Kong University of Science and Technology*

Seer: Online Context Learning for Fast Synchronous LLM Reinforcement Learning. 883

Abstract

Long-context large language models (LLMs) enable applications that reason over hundreds of thousands to millions of tokens, but serving these workloads efficiently is challenging. Modern systems cache key-value (KV) states and rely on hierarchical context caching across GPU HBM, CPU memory, and SSDs. We show that naïve designs often become I/O-bound: fragmented KV layouts lead to small transfers that underutilize bandwidth, cache loading stalls prefill, and schedulers that ignore cache-loading latency and delay hits (concurrent requests for the same context during a cache miss) suffer severe throughput degradation.

We present Strata, a hierarchical context caching framework for long-context LLM serving. Strata introduces a GPU-assisted I/O mechanism that decouples GPU and host layouts to enable efficient large transfers, and a cache-aware scheduler that mitigates delay hits, balances batches to hide cache-loading latency, and opportunistically overlaps complementary work. Implemented as part of SGLang and deployed in production, Strata improves throughput by up to 5× over vLLM-LMCache and 3.75× over NVIDIA TensorRT-LLM, without hurting short-context performance.

1 Introduction

Large Language Models (LLMs) represent a significant advancement in machine learning, achieving remarkable proficiency in understanding and generating natural language. Their adoption is now widespread, and they are rapidly evolving towards more robust problem-solving capabilities. A prominent trend in this evolution is the expansion of context windows, allowing LLMs to parse longer input prompts. This has enabled an important set of applications that require understanding large amounts of text, including coding assistants [6], retrieval-augmented generation (RAG) [27], document analysis [49], and conversational AI agents with memory modules [40]. Leading models, including Google's Gemini series [18], Anthropic's Claude 4 [7] and the Qwen series [46], already support context windows of up to one million tokens, with expectations of two million tokens emerging soon. Other frontier models like DeepSeek-V3 [12], Llama-3.1 [3] and Llama-4 series [4] also offer substantial context lengths, typically in the range of 128K to 200K tokens.

While long contexts enable new capabilities, recomputing attention over them from scratch is prohibitively expensive. Caching previously computed key-value (KV) states offers a practical solution, as these prefixes and sources are frequently reused across applications. This technique, often referred to as context or prefix caching [5, 11, 17, 41, 53], avoids redundant prefill computation and significantly reduces response latency. However, the memory footprint of cached KV states is substantial. For example, 40 GB of GPU high-bandwidth memory (HBM) can hold only roughly 0.3M tokens for Llama-8B, which can be quickly consumed by a handful of documents or a few hundred conversation turns. The capacity constraint of GPU memory leads to frequent cache eviction, resulting in low cache hit rates and expensive recomputation. As a result, production systems adopt hierarchical caching, storing KV states in CPU memory [52], local SSDs [14], or even remote memory pools [19,43] to extend capacity and preserve context cache reuse benefits.

However, transferring large cached contexts back to the GPU introduces a major performance bottleneck. Bulk KV transfers often cause memory stall, directly inflating Time To First Token (TTFT) and degrading throughput. Figure 1 illustrates this effect: when serving the LooGLE dataset [28] with SGLang offloading KV caches to CPU memory, configured in line with standard practices reported in prior work [14], 74% of prefill time is blocked on KV transfers (the red curve), resulting in up to a 4× throughput reduction. In these cases, I/O delays rather than compute become the dominant limiting factor. We observe that this inefficiency arises from two main sources.

First, KV cache layout leads to I/O inefficiency. As context lengths grow, the volume of KV data that needs to be moved between memory tiers (e.g., CPU memory to GPU HBM) increases substantially, yet current systems achieve only a

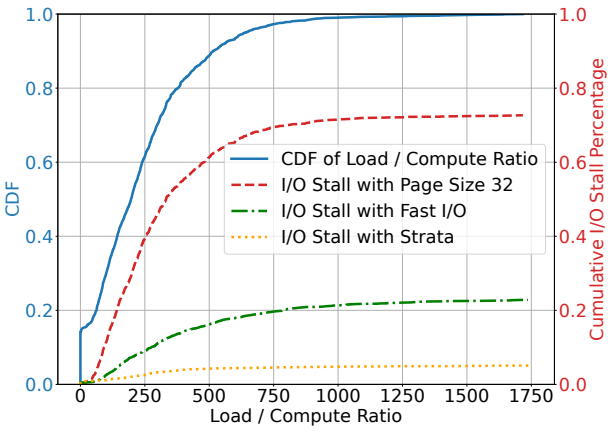

Figure 1: Benchmark profile for Qwen2.5-14B on the LooGLE dataset. The x-axis shows the Load / Compute Ratio (tokens loaded from CPU memory relative to new input tokens) per prefill batch. The right axis displays the I/O stall percentage, representing the amount of prefill execution time attributed to I/O stall. See §5.3 for full benchmark details.

fraction of the available interconnect bandwidth. As we detail in §3.1, this is because current systems adopt PagedAttention [26] to reduce GPU memory fragmentation. Paging, however, fragments KV cache across multiple non-contiguous pages. This yields many small data transfers, sometimes only a few kilobytes, that fail to saturate PCIe bandwidth. Using larger pages could mitigate fragmentation and improve I/O efficiency, but it worsens cache granularity and can reduce cache hit rate, as we demonstrate in §3.1 and §5.3.2.

Second, current schedulers are blind to cache-loading costs and delay hits. Existing systems [26, 36, 53] implicitly assume that the computation needed to prefill new tokens is sufficient to hide the latency of loading historical KV cache from slower memory tiers. However, as context lengths grow, this assumption no longer holds: cache loading time can exceed the compute time needed for prefill, leaving the system loading-bound rather than compute-bound. Figure 1 also highlights this effect. Even with our optimized I/O mechanism presented in §4.2, which removes the overhead of small page transfers (green curve), up to 24% of prefill execution time remains stalled on cache loading. Schedulers that ignore these I/O-bound characteristics generate imbalanced batches, unable to effectively hide cache-loading delays. Moreover, when serving emerging agentic workloads that query same context concurrently, we observe the *delay hit phenomenon* [8], where multiple requests for the same long context arrive while an initial cache miss is still being resolved. This reduces the effective cache hit rate, especially in high-throughput systems, and causes redundant computation of long contexts as we further detail in §3.2 and §5.3.4.

To address these bottlenecks, we propose Strata, a hierarchical context caching framework designed for long context language model serving, without performance degradation in short-context scenarios. Strata employs GPU-assisted data transfer to combat KV cache fragmentation and decouples the GPU's memory layout from that of other memory tiers, improving I/O efficiency across the hierarchy. Strata further reduces long-context overheads through cache-aware request scheduling. It mitigates delay hit, constructs balanced batches that pair sufficient prefill computation to cover I/O latency, and when cache loading stalls are unavoidable, the scheduler inserts useful complementary tasks (e.g., decoding batches) to fully utilize available compute resources. Together, these techniques ensure that scheduling remains efficient even under highly variable latency budgets.

Strata has been integrated into SGLang [53], a widely adopted open-source framework for LLM serving, and has been deployed in production environments at several leading AI companies. Our evaluation on popular long-context benchmarks, across a range of models and hardware platforms, shows that Strata improves throughput by up to 5× over vLLM-LMCache [30], a state-of-the-art open-source hierarchical context caching solution, and by up to 3.75× over NVIDIA's TensorRT-LLM, a highly optimized serving engine, without performance degradation on short-context scenarios.

2 Background

2.1 Long Context LLM Inference

LLM inference operates in two phases: *prefill* and *decode*. During prefill, the model typically processes both (i) new tokens from the user query and (ii) context tokens, drawn from sources such as documents or prior interactions. The intermediate outputs of this step, known as KV caches, are critical for efficiency because they allow subsequent tokens to attend to past tokens without recomputing all previous layers. In the decode phase, the model generates tokens autoregressively, continually reusing and extending the KV cache. Long contexts amplify the cost of both phases. A longer prefix increases prefill latency, and if cached states are evicted or unavailable, recomputing that prefix becomes increasingly expensive. During decode, each generated token reuses and extends the KV cache, whose size grows linearly with sequence length. As a result, for long-context workloads, KV cache memory footprint and data movement can become dominant bottlenecks, making efficient cache reuse, placement, and eviction critical for high-throughput, low-latency serving.

2.2 Memory Management of KV Cache

Inspired by virtual memory, PagedAttention [26] avoids reserving large contiguous blocks for KV caches by using dynamic, page-based allocation. The cache is partitioned into

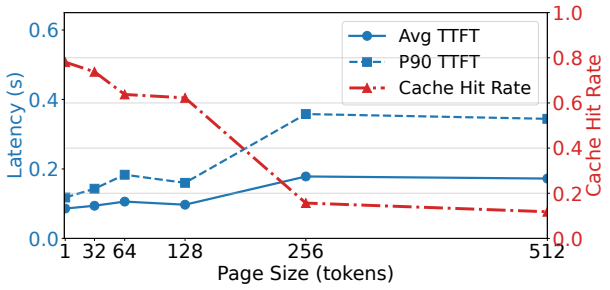

Figure 2: Large page sizes decrease cache hit rate and increase TTFT, benchmarked on H200 for Mistral-24B using the ShareGPT dataset.

small fixed-size pages that preserve logical sequence order but can be placed non-contiguously in memory, improving utilization. Typical page sizes are small — e.g., 32, 16, and 1 tokens in TensorRT-LLM, vLLM, and SGLang — and the KV states of a single token may span from tens of kilobytes to several megabytes. While such fine granularity is manageable for compute kernels, it poses efficiency challenges for data movement across memory tiers, as we will discuss in §3.1.

2.3 Context Caching in LLM Serving

Beyond intra-request reuse, systems exploit *context caching* across requests by identifying common prefixes using structures like prefix trees or hash maps [26, 43], widely adopted by providers such as OpenAI [41] and Google [17]. To extend capacity, caches are stored in slower tiers such as CPU memory [16, 22, 52], distributed memory pools [19, 29, 43], or even disk [14, 21, 30]. Recent systems, e.g., CachedAttention [14], overlap cache loading with computation on a layer-by-layer basis to minimize stalls, while asynchronously backing up newly generated caches to lower tiers.

3 Challenges of Long Context Caching

This paper addresses the challenge of managing large context caches for long-context (i.e., prefill-dominated) workloads. While this is not the only LLM scenario (i.e., short context, long generation, or single-turn workloads exist), long-context workloads constitute an important class of real-world deployments [6, 25, 28]. We next explore the systems challenges that arise in long-context workloads.

3.1 Low Bandwidth Utilization in KV Cache Transfers

The achievable throughput of an I/O subsystem is fundamentally constrained by the relationship described by Little's Law. Let λ be the arrival rate of I/O operations, C be the average number of concurrent I/O operations, and L be the average latency per operation. According to Little's Law, we have $C = \lambda \cdot L$. Let X represent the sustained data throughput (e.g., in GB/s), S be the average data size per I/O operation, the throughput can be described as $X = \lambda \cdot S$. Combining with Little's law we have $X = C \cdot S/L$ describing attainable throughput in a stable state. This equation highlights that maximizing data throughput (X) requires either high concurrency (C), large transfer sizes (S), or low latency (L).

To transfer data between CPU and GPU memory, asynchronous operations like cudaMemcpyAsync are typically used to engage the GPU's Direct Memory Access (DMA) engine [33]. However, the latency (L) in this scenario includes non-negligible CPU-GPU communication overhead and scheduling delays [20]. While concurrency (C) can be increased by launching numerous asynchronous I/O operations, practical limits arise from the available application-level parallelism (e.g., on the CPU) and the queue capacities within the GPU driver (e.g., CUDA driver) and hardware [33, 44]. Consequently, increasing the transfer size (S) often becomes the most practical lever for improving bandwidth utilization. Saturating modern high-bandwidth interconnects underscores this point; for example, achieving 75-80% of theoretical PCIe 5.0 bandwidth necessitates transfer sizes (S) in the megabyte range (i.e., 1-2MB). This principle is not limited to CPU-GPU transfers; achieving high throughput on other media like SSDs or network interfaces often demands even larger transfer sizes [9, 13, 32].

Cost of Large Pages. However, contrary to requirement of transfer efficiency, LLM inference systems favor small granularity. Smaller pages, e.g., in the range of 1-32 tokens, generally lead to better memory utilization [26] and can improve cache hit rate [34], as cache matching is performed on a per-page basis. While increasing the page size (i.e., compacting more tokens into a single continuous page and effectively increasing S) may appear to improve bandwidth utilization based on the formula, it introduces substantial performance penalties for LLM inference. To demonstrate this trade-off, we benchmarked a Mistral-24B model using the popular ShareGPT dataset, varying the KV cache page size from 1 to 512 on the SGLang framework. As shown in Figure 2, increasing the page size leads to a significant drop in the KV cache hit rate. This degradation directly results in a substantial increase in both the average and P90 TTFT, which rise by up to 2× and 2.9×, respectively, at the largest page sizes tested. We also observed similar trends in long context benchmarking scenarios as shown in Figure 10.

This preference for small pages results in very small effective transfer sizes (S) for KV cache operations, leading to severely underutilized I/O bandwidth. As illustrated in Figure 3, transferring KV cache data for 8192 tokens achieves only approximately 22% of the theoretical PCIe 5.0 bandwidth. Page size is set to 32, a value recommended in prior works on hierarchical KV cache [14, 19, 21, 52] and a maximum supported size in vLLM for CUDA GPUs [48]. This

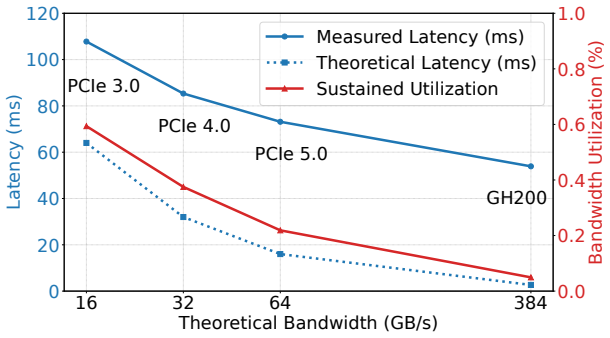

Figure 3: Latency and bandwidth utilization of loading KV caches of 8192 tokens (using page size 32) of Llama-3.1-8B from CPU to GPU on different platforms.

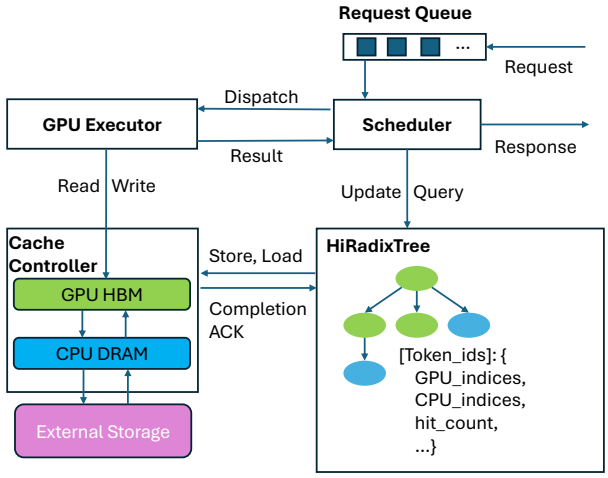

Figure 4: System Architecture of Strata

underutilization is exacerbated on platforms with even higher interconnect bandwidths, falling to as low as 5% on systems like NVIDIA's Grace-Hopper platform that replaces PCIe with NVLink and offers 6× higher peak bandwidth. This fundamental trade-off between transfer efficiency and caching benefit underscores the need for a more effective I/O mechanism that can achieve the best of both worlds.

3.2 Resource Orchestration and Delay Hits

LLM serving engines often treat GPU compute and HBM as first-class resources, since sub-tasks are usually either compute-bound (e.g., dense and attention computation in prefill) or memory-bound (e.g., decoding). With the introduction of hierarchical KV caching, this picture largely remains unchanged. Existing works either regard KV cache loading from CPU to GPU as negligible [14, 52], assuming the latency of loading cache data of layer $N+1$ via PCIe can be effectively hidden by overlapping I/O with the computation of layer N; or else opt for recomputation when the cost is justified [23]. However, when serving requests with long cached contexts but relatively few new tokens to prefill, this assumption breaks down. On one hand, the latency of bulk KV cache transfers can exceed what layer-level computation can hide; on the other hand, recomputation becomes increasingly costly as context length grows, making it an unattractive alternative. Consequently, layer-wise overlapped prefill can degrade into a PCIe bandwidth-bound task. Figure 1 illustrates this bottleneck: even with an I/O mechanism achieving 75% of theoretical PCIe bandwidth, stalls still account for up to 24% of prefill execution time.

Compounding this challenge is the *delay hit phenomenon* [8], previously studied in the networking community. It occurs when multiple requests for the same data object arrive while an initial cache miss is still being resolved, so subsequent requests are effectively treated as cache misses, even though they would have been cache hits had the first request completed. We observe an analogous effect in LLM serving: under high traffic, multiple requests that target the same context (or a prefix of it) may arrive within a short time window, which is especially common in emerging agentic workloads where concurrent attempts often reuse the same context. For example, in the Mooncake agent tool trace [43], 38% of requests share a prefix of at least 6k tokens (excluding the system prompt) with at least one other request arriving within a one second window, making delay hits highly likely in high-throughput serving systems. As illustrated in Figure 7, when such requests are scheduled to execute concurrently (either within the same batch or across data parallel instances), redundant prefill computation occurs. This problem is exacerbated by the asynchronous schedulers widely adopted in modern serving engines [47, 55], which prepare the next batch before the ongoing one completes, extending the cache-miss resolution window to the full execution time of a batch and making delay hits more likely. The impact is especially severe in long-context scenarios, where both recomputation cost and cache-miss resolution time scale unfavorably.

These observations highlight the need to re-think scheduling policies in LLM serving. Schedulers must explicitly treat CPU-GPU bandwidth as a first-class resource, balancing computation and data transfer when batching requests, more carefully overlapping I/O with compute, and mitigating delay hits to avoid redundant work while sustaining throughput.

4 Strata's Design and Implementation

4.1 Overview

Motivated by challenges discussed in §3, we built Strata, a system with two key components. The Strata *Cache Controller* (§4.2) manages the data plane elements throughout the memory hierarchy. It introduces an optimized GPU-CPU data

transfer mechanism and manages KV cache memory layouts to support efficient small page transfers as motivated in §3.1. The Strata *Scheduler* (§4.3) implements the control plane that intelligently schedules requests in a cache resource-aware manner as motivated in §3.2. It references a *HiRadixTree*, which is an extension to SGLang's RadixTree [53], effectively serving as a page table and stores metadata about each KV cache page.

Figure 4 presents the Strata architecture. When a request is submitted, it enters a request waiting queue. During the execution of the ongoing batch, the *Scheduler* continuously estimates available system resources and the resource demands of queued requests, and selects a subset to form the next batch. The *Scheduler* then sends this batch to GPU executor and initiates a KV cache loading request to the *Cache Controller*. During the execution of the prefill batch, the GPU executor synchronizes with the *Cache Controller* to ensure that the KV cache of a certain layer is available before the execution using CUDA events. Once prefill is complete, the prefilled requests are merged into a consolidated decoding batch via continuous batching [51]. Strata uses a prefill-decode (P-D) co-location design, alternating the execution of prefill and decoding batches temporally on the same GPU, and follows SGLang's practice to prioritize the execution of the prefill batch for shorter response time (TTFT) and to form a larger decoding batch for higher throughput. Finally, the *Cache Controller* actively manages the backup and eviction of any KV cache pages to lower memory hierarchies asynchronously.

4.2 Efficient KV Cache I/O

To address the limitations discussed in §3.1, inspired by established practices within the computer architecture community [33,44], Strata leverages *GPU-assisted I/O* to transfer KV cache pages between CPU and GPU memory for low-latency I/O on small, fragmented data. Specifically, instead of invoking standard *cudaMemcpyAsync* API repetitively with small data transfers, a GPU-assisted I/O job operates by launching a CUDA kernel. This kernel spawns thousands of threads. Each thread is responsible for loading a small chunk of data from a source (either GPU global memory or CPU registered pinned memory) into its local register files and then streaming this data to a destination (GPU global memory or registered CPU pinned memory).

GPU-assisted I/O offers several advantages: First, it enables **enhanced concurrency** (*C*): GPUs provide massive, cost-effective parallelism, supporting thousands of concurrent I/O operations compared to typically only tens on CPUs. Second, it is **compatible with small transfers** (efficient *S*): the granularity required for efficient GPU-assisted I/O is only 128 bytes on most architectures [39], which is sufficiently fine for single-page KV caches (kilobytes), eliminating the need to inflate page size for efficiency. Finally, it allows **flexible memory layout**: since light computation in I/O kernels is virtually free, layout transformations between GPU and CPU memory can be performed at negligible cost, enabling flexible and efficient data organization (see §4.2.1 for details).

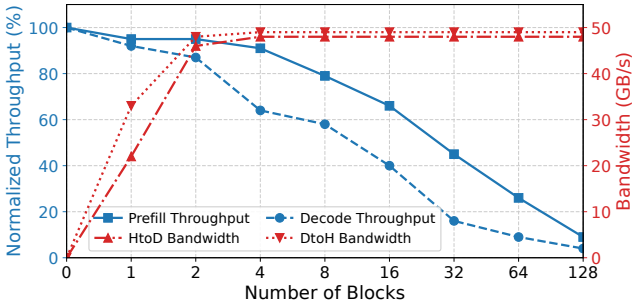

Figure 5: Performance interference vs. resources allocated to the KV-cache I/O kernel. Measurement on concurrently running Strata's I/O kernel with a prefill pass (batch of two requests with 4k input each) and a decode pass (Llama-3.1-8B, batch of 16 requests with 4k input each), respectively.

However, a challenge associated with GPU-assisted I/O, as highlighted in prior work [20], is runtime interference when co-running with other kernels. Without dedicated hardware handling the fine-grained I/O tasks, GPU threads consume valuable resources, such as register files and execution cycles, and can lead to cache pollution. Prior work [31] also demonstrated that GPU hardware schedulers often struggle to effectively manage this resource contention, potentially degrading the performance of both the I/O operations and concurrent computational kernels.

We observe that efficient data transfer does not need to monopolize the entire GPU. Strata employs a strategy of launching a small number of large CUDA blocks to incentivize the GPU's hardware scheduler to confine these I/O kernels to a small subset of Streaming Multiprocessors (SMs), as few as 1. This targeted allocation, when combined with low-level instructions to bypass the cache and thereby mitigate pollution, minimizes interference with concurrent workloads. Moreover, with the ROCm backend [2], these kernel implementations are also compatible with AMD GPUs. To balance resources for overall efficiency, we conducted microbenchmarks co-running I/O kernels with prefill and decoding kernels on an NVIDIA H200 GPU. As shown in Figure 5, using only two CUDA blocks of 1024 threads each, Strata achieves 48 GB/s transfer throughput while incurring less than 5% performance degradation on prefill and 10% on decoding. Based on these results, we select two blocks as the default quota for loading data from CPU to GPU (a critical path operation), and one block for backing up data from GPU to CPU (a non-critical path), where the bandwidth is already sufficient and overhead must be minimized. Our end-to-end evaluation confirms that this configuration sustains high I/O bandwidth while keep-

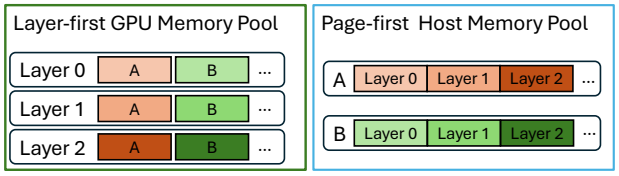

Figure 6: Layer-first vs. Page-first layouts

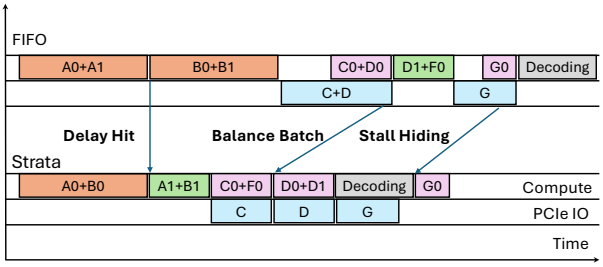

Figure 7: Scheduling Policies in Strata. Orange blocks denote prefill batches that incur a cache miss; green blocks denote cache hits in device memory; purple blocks denote cache hit in host memory; and blue blocks denote data transfer. The one decoding batch is shown in gray. X_n represents the n-th request that uses the context X.

ing overall performance impact under 5%, demonstrating that carefully tuned GPU-assisted I/O can be both efficient and non-intrusive.

4.2.1 Data Management Beyond Host Memory

When external storage is involved, the cache controller opportunistically prefetches data from storage into host memory whenever a cache hit is detected at the storage layer. The prefetch latency is overlapped with the request's queuing delay. Once the scheduler selects the request for execution, the cache controller terminates any in-flight prefetch and uses whatever cache is already available in host or GPU memory. This default *best-effort* policy is motivated by the significantly higher and less predictable latency of the storage layer relative to host-GPU transfers, for which Strata employs a synchronized, layer-wise overlapping scheme. The Strata scheduler can also be configured to hold requests undergoing prefetching until prefetch completion (a *wait-complete* policy) or until a specified timeout (a *timeout* policy), depending on the deployment scenario.

Furthermore, the data transfer inefficiency caused by fragmented memory layout, as motivated in §3.1, also extends to other storage media. In addition to small pages, LLM serving systems also favor a layer-first memory layout in the GPU memory pool (shown in Figure 6), as it aligns with the layer-wise nature of LLM computation. Concretely, the layer-first layout stores all tokens of layer 0 contiguously, then all tokens of layer 1, and so on, so that a layer's attention kernel reads its K/V as one contiguous span. This is ideal for compute but pessimal for transfer: a single logical page (one token's K/V across all layers) is scattered into L non-contiguous fragments, one per layer, each only kilobytes. A transfer-friendly page-first layout instead stores all layers of a page contiguously, yielding large contiguous blocks that saturate the interconnect, but it would force every attention kernel through an extra layer of address indirection. By leveraging GPU-assisted I/O, Strata resolves this conflict by enabling a virtually free, on-the-fly transformation between the compute-friendly and transfer-friendly layouts. To perform the layout transformation, a thread simply applies one additional arithmetic operation to its assigned offset to calculate the correct destination address. This operation has negligible overhead.

As illustrated in Figure 6, this capability decouples the layout requirements across the memory hierarchy: the GPU can maintain its computation-friendly layer-first layout, while other media, such as host memory and external storage, can adopt a page-first layout that maximizes transfer efficiency with larger, contiguous data blocks. In §5.3.5, we demonstrate how this decoupled layout strategy significantly reduces data loading time.

4.3 Cache-Aware Scheduling

As motivated in §3.2, the goal of the scheduler is to maximize caching benefit by avoiding delay hit and loading stalls. The *Scheduler* does so through three stages. First, it identifies requests that are potentially susceptible to delay hits and **defers the execution** to right after the delay hit is resolved. Second, it **formulates a balanced batch** that aims to pair loading (from host memory) with sufficient computation to hide the loading latency. Finally, in the event that batches are still loading-bound, the *Scheduler* **hides I/O stalls** by inserting useful compute inside bubbles. Note while the core scheduler of SGLang is implemented in Python, we augmented it with C++ implementation to minimize the overhead of these scheduling policies.

4.3.1 Deferral on Delay Hit

As discussed in §3.2, delay hits can cause redundant computation in two scenarios: (i) when multiple requests sharing the same cache miss are scheduled into the same batch (Figure 7), and (ii) when the execution of a request is prepared asynchronously without awareness that the corresponding context cache is still being computed. To keep track of potential delay hit, we introduce *transient nodes* in the HiRadixTree. Similar to standard nodes, they use token IDs as traversal keys, but

Algorithm 1 Balanced Batch Formation

```
1:  procedure AddBundleHit(Q, B)
2:      for each r in Q do
3:          if B.is_bundle_hit(r) then
4:              B.add(r); Q ← Q − r
5:  function BatchFormation(Q)
6:      B ← Batch(); D ← []
7:      B.add(Q.pop(0)); AddBundleHit(Q, B)
8:      while |Q| > 0 and ¬B.is_full() do
9:          r ← Q.pop(0)
10:         if B.loading_bound(r) then
11:             D.append(r)
12:         else
13:             B.add(r); AddBundleHit(Q, B)
14:     for each r in D do
15:         if B.is_full() then break
16:         B.add(r)
17:     return B
```

instead of pointing to memory indices, they carry one of two marks: `in-queue`, indicating that a request is referencing a new context, and `in-flight`, indicating that the cache for the corresponding tokens is under computation. When iterating over the request queue, Strata inserts transient nodes marked `in-queue` as needed. If a request matches existing transient nodes, it is deferred to the next scheduling round but placed at the front of the waiting queue to benefit from the soon-to-be-hot cache and minimize its impact on TTFT.

When a request proceeds to execution, its associated transient nodes are marked `in-flight`. Upon completion, the nodes are converted into standard nodes, with indices pointing to the ready context cached in memory. To prevent unnecessary deferrals, Strata uses a configurable threshold: a request is deferred only when the number of token matches on transient nodes exceeds this value. We use a default threshold of 100 matched tokens, which avoids deferring short incidental prefix matches while still capturing long-context delay hits.

4.3.2 Balanced Batch Formation

After removing candidates susceptible to delay hits, the scheduler selects requests to form the next prefill batch. In most LLM serving engines [26, 53], batch formation follows a first in, first out (FIFO) policy by default, where requests are taken in arrival order until the batch is full (either reaching a preset token limit or exhausting GPU memory). To address the loading-bound issue discussed in §3.2, Strata introduces a new batch formation mechanism that balances data loading with sufficient computation. An example is illustrated in Figure 7, a batch containing requests C0 and D0 would require loading both contexts, causing a loading stall. In contrast, forming a different batch (C, F) could get the loading of C overlapped. Another useful case is the batch (D0, D1): since they share the same context, batching them not only balances loading but also reduces GPU memory usage and on-device bandwidth pressure, further improving efficiency. We refer to this case as a *bundle hit*, the counterpart of a *delay hit*.

The procedure is detailed in Algorithm 1. Before each batch is formed, the scheduler obtains the *load* and *compute* requirements of each request using the HiRadixTree. During batch formation, as it iterates through the queue, the scheduler checks whether adding a request would reach the loading-bound limit ('loading_bound' in line 10), defined as the ratio of aggregated load to compute. When this ratio exceeds a threshold, the batch is considered loading-bound. This threshold is hardware- and model-dependent and thus can be profiled separately; in practice, Strata uses a default ratio of 100, corresponding to the point where stalls begin to appear as shown in Figure 1. If the request fits into the batch without making it loading-bound, it will be added into the batch, then the scheduler will iterate through remaining requests to preferentially add requests that bundle-hit with it. Otherwise, the request is moved to a deprioritized list. If the batch is not full till the end of the queue, the scheduler supplements it with deprioritized requests (line 16). To prevent starvation, deprioritized requests retain their original order, and each batch formation always begins with the first request in the queue.

4.3.3 Hide Loading Stalls with Bubble Filling

Even with balanced batching, some batches can still be loading-bound. The final strategy of the scheduler is *bubble filling* that overlaps loading stalls with useful computation. An example is illustrated in Figure 7, when request G0 requires a long context load, the scheduler defers computation of the prepared prefill batch and instead issues a decoding batch to the model executor to run concurrently with the context loading. This strategy complements SGLang's default prefill-first policy (as discussed in §4.1), allowing some flexibilities when choosing between prefill and decoding for improved overall utilization. Although decoding batches are also I/O-bound, they primarily saturate HBM bandwidth, whereas loading tasks saturate PCIe bandwidth. This distinction enables the two operations to overlap with minimal resource contention. It is also possible to insert a prefill batch to fill the bubble, which is more applicable to P-D disaggregated systems [54].

4.4 Cache Controller and Policy

As illustrated in Figure 4, the cache controller oversees data movement between the various memory hierarchies. When a new batch is prepared for execution, the scheduler initiates the loading of the KV cache to the GPU via HiRadixTree. Subsequently, during execution, the GPU executor consults the cache controller to ensure that the KV cache data for spe-

cific layers is available before proceeding to the execution of the subsequent layer. Upon completion of prefill or decoding requests, the scheduler initiates the storage of the KV cache to slower memory tiers, backing up specific KV cache data according to the designated cache write policy.

A single write-once policy is insufficient for hierarchical context caching because different serving workloads impose different trade-offs among write bandwidth, cache capacity, durability, and future reuse. Writing every generated KV page immediately maximizes reuse and persistence, but it can waste host memory and write bandwidth for one-off requests. Writing only at eviction minimizes write traffic, but it can add blocking work to the critical path when GPU memory is under pressure. Strata therefore exposes three write policies that correspond to three deployment regimes. The first, *write-back*, only backs up KV cache tokens when they are on the verge of eviction. This approach is suitable for resource-constrained environments as it minimizes bandwidth and capacity usage, though it can introduce additional runtime blocking. The second policy, *write-through*, initiates a backup each time new KV caches are generated and is well-suited for conversational scenarios where all input and generated content must be persistently stored. The third and default policy is *selective-write-through*. With this approach, a counter is associated with each node in the HiRadixTree and increments with each access to that node. A backup is triggered only if this counter exceeds a configurable threshold. This policy offers the most flexibility: setting the threshold to one makes it equivalent to the write-through policy, while higher values can reduce the memory footprint, particularly for scenarios like single-round question-answering tasks. The default threshold is set to 2 when write bandwidth is abundant, but it can be increased to accommodate tighter resource constraints. For all memory layers, the Least Recently Used (LRU) algorithm serves as the default eviction policy.

5 Evaluation

5.1 Methodology

Testbed. We evaluate Strata and baselines on three platforms. The *H200* platform is a node equipped with 8 NVIDIA H200 GPUs interconnected with NVLink, an Intel Sapphire Rapids CPU, and 1.6TB of DRAM. Each GPU is connected to the CPU via a PCIe 5.0 x16 link, offering up to 64 GB/s of peak bandwidth (unidirectional). The *H20-storage* is a node with 8 NVIDIA H20 GPUs and an Intel P5510 NVMe drive, providing up to 7 GB/s disk read bandwidth. The *GH200* platform is a GH200 Grace Hopper superchip [35] node, which contains one NVIDIA H100 GPU integrated with one NVIDIA Grace 64-core ARM CPU. The *GH200* system is equipped with 464 GB of LPDDR5X DRAM, providing up to 384 GB/s of memory bandwidth (unidirectional) to the CPU.

Baselines. We compare Strata with following state-of-the-art baselines. *vLLM* [26] is a popular open-source serving engine. Additionally, *vLLM-LMCache* enables hierarchical caching on vLLM using the official community extension of LMCache [30]. For our benchmarks, we used vLLM v0.8.5 and LMCache v0.2.1. The LMCache chunk size is set to 256 as default and vLLM page size was set to 32 in line with prior work [14]. *TensorRT-LLM* [36] (TRT-LLM) is an open-source serving library from NVIDIA, specialized for NVIDIA GPUs. Additionally, *TRT-LLM-HiCache* enables hierarchical caching on top of TensorRT-LLM through its automatic CPU memory offloading feature. We used TensorRT-LLM v0.17.0 in our benchmarks, with the page size also set to 32 as default. *SGLang* [53] is an open-source serving engine that delivers comparable performance to vLLM, while offering a more lightweight and customizable architecture. To enable a direct comparison to Strata, we implemented *SGLang-HiCache* which incorporates a state-of-the-art layer-wise KV cache transfer overlapping and hierarchical caching implementation using *cudaMemcpyAsync* transfers, which is in line with prior work including CachedAttention [14], Pensieve [52] and FlashGen [21]. We used SGLang v0.4.5 for all three systems. We set the page size for *SGLang* and Strata to 1 (SGLang's default), and the page size for *SGLang-HiCache* to 32 to be consistent with other hierarchical cache baselines.

Models. We utilize three popular open-source LLMs with long context capabilities, spanning small, medium, and large sizes: Llama-3.1-8B-Instruct [3] (128k context window), Qwen2.5-14B-Instruct-1M [46] (1M context window), and Llama-3.1-70B-Instruct [3] (128k context window). We use a single GPU to serve the 8B and 14B models, and 4 GPUs configured with tensor parallelism for 70B model.

Datasets. We construct workloads from three long context datasets. *LooGLE* [28] features long documents from diverse sources such as arXiv, Wikipedia, and movie/TV scripts. In our benchmarks, we use its Wikipedia portion, which provides both long and short queries paired with the documents. *NarrativeQA* [25] is an influential long-context dataset for testing models' reading comprehension capabilities, featuring even longer context examples than LooGLE. We filtered documents exceeding 128k tokens because of context window limit of the test models, and sampled 50 documents from the remainder. These two datasets mirror classic RAG use cases, in which extensive contexts are repeatedly queried by multiple users over time like question-answering systems over technical manuals [15]. *ReviewMT* [45] is a multi-agent conversation dataset, where agents simulate reviewers to converse

	LooGLE	NarrativeQA	ReviewMT	ShareGPT
avg. in	21613	54797	17708	680.9
avg. out	15.60	13.00	208.3	260.9
# contexts	105	50	100	-
# queries	2410	1461	1092	200869

Table 1: Dataset statistics.

about the quality of technical papers to make final decisions. This represents a typical agentic workflow involving long contexts and relatively longer output compared to other datasets. We also include a dataset to evaluate Strata's performance in short-context scenarios. *ShareGPT* is a popular conversational dataset comprised of a large collection of relatively short conversation histories from thousands of users, and was used in prior hierarchical KV caching studies [14,52]. Table 1 summarizes the characteristics of these datasets.

Since individual query timestamps are not available in these datasets, we simulate query arrivals using a Poisson distribution to benchmark the system using varying request rates, following prior works [21, 52]. For conversational benchmarks (ReviewMT and ShareGPT), we preserve dependencies across conversation rounds. Consistent with the methodology in Pensieve [52], we insert a 60-second "thinking time" between an LLM's response and the user's subsequent query for ShareGPT. For the long-context benchmarks, queries are randomly sampled from the dataset. In §5.3.3, we further examine the performance characteristics under different workload patterns. To avoid benchmark timeouts and unbounded client-side queuing, we cap the maximum number of in-flight requests at 128. Note this is a concurrency cap, not a fixed batch size as the actual prefill batch size is determined by each serving engine's scheduler, token budget, and available GPU memory. GPU memory is allocated according to each serving engine's default policy to ensure fairness and performance. An exception is the ShareGPT dataset, where we restrict GPU memory to approximately 500K tokens to highlight the behavior of hierarchical caching baselines. For caching configurations that utilize CPU memory, we allocate 1 TB of system DRAM as pinned memory (400 GB on GH200 due to platform limits). Disk storage is not used in most benchmarks except in §5.3.5 due to limited support in baseline systems.

5.2 End-to-end Performance Comparison

Strata is designed to improve long-context serving by reducing response latency and increasing overall throughput. Accordingly, we evaluate the system using two primary metrics: average Time To First Token (TTFT) and output token throughput. TTFT captures query response time, a key determinant of user experience, while output token throughput is a widely adopted metric for characterizing LLM serving system performance [1].

5.2.1 How does the performance of Strata compare to state-of-the-art LLM serving systems on long-context workloads?

Figure 8 presents the achieved token throughput and corresponding average TTFT for each system under varying request rates across three models and four datasets. First, we observe that *hierarchical caching is essential for high-performance long-context serving*. Across all three models, non-hierarchical caching solutions perform poorly on LooGLE. Without hierarchical caching, long-context workloads rapidly exhaust GPU memory capacity, leading to frequent cache misses during prefills. This, in turn, triggers repeated recomputation, resulting in low throughput and high latency. By contrast, systems equipped with hierarchical caching achieve substantially higher throughput and lower latency, consistently reaching approximately 95% cache hit rate by leveraging CPU memory.

Second, *Strata delivers substantial improvements over existing hierarchical caching solutions*. For Llama-8B on LooGLE, Strata achieves up to 3.2×, 2.6×, and 1.9× higher throughput at the same TTFT compared to *SGLang-HiCache*, *vLLM-LMCache*, and *TRT-LLM-HiCache*, respectively. Similar gains are observed for Qwen-14B, Strata achieves up to 3.9×, 2.1×, and 1.9× improvements; and Llama-70B, the gains reach 5×, 5×, and 3.75×. A consistent trend is seen on ReviewMT. Although longer decoding reduces the dominance of prefill time, with Llama-8B, Strata outperforms *SGLang-HiCache* by 1.7×, *vLLM-LMCache* by 2.3× and *TRT-LLM-HiCache* by 2.3×. These performance gains stem from Strata 's enhanced I/O efficiency and scheduling mechanisms, as further analyzed in §5.3.1.

5.2.2 How does Strata perform with a warm cache?

NarrativeQA presents much longer average context lengths, resulting in an extensive prefill phase that made non-hierarchical caching solutions impractical. Because this scenario presented the highest amount of memory pressure, we augmented this experiment to better understand steady-state performance characteristics (i.e., after the cache hierarchy has been filled)[1]. In this setup, we first warmed up the CPU memory by pre-computing KV caches for all contexts in the evaluation set and then flushed the KV cache on GPU memory to set the initial state. The second row of Figure 8 reports the throughput-latency curve after restarting the workload post-warmup. We report Strata, *SGLang-HiCache*, and *vLLM-LMCache*, as *TRT-LLM-HiCache* does not support pre-warming. In this setting, Strata achieves up to 2.3×, 2.6× and 2.5× throughput compared with *vLLM-LMCache* on Llama-8B, Qwen-14B and Llama-70B models respectively.

5.2.3 How does Strata perform with short-context?

Strata was explicitly designed for long-context workloads. To understand the performance of Strata on short-context workloads, the final row of Figure 8 shows the average TTFT of the baseline systems, across three models, on the ShareGPT dataset. Note that the underlying SGLang engine exhibits a slight performance disadvantage compared to the base engines

[1] NarrativeQA without pre-warming achieves similar results to the LooGLE workload. We omit results for this scenario due to space.

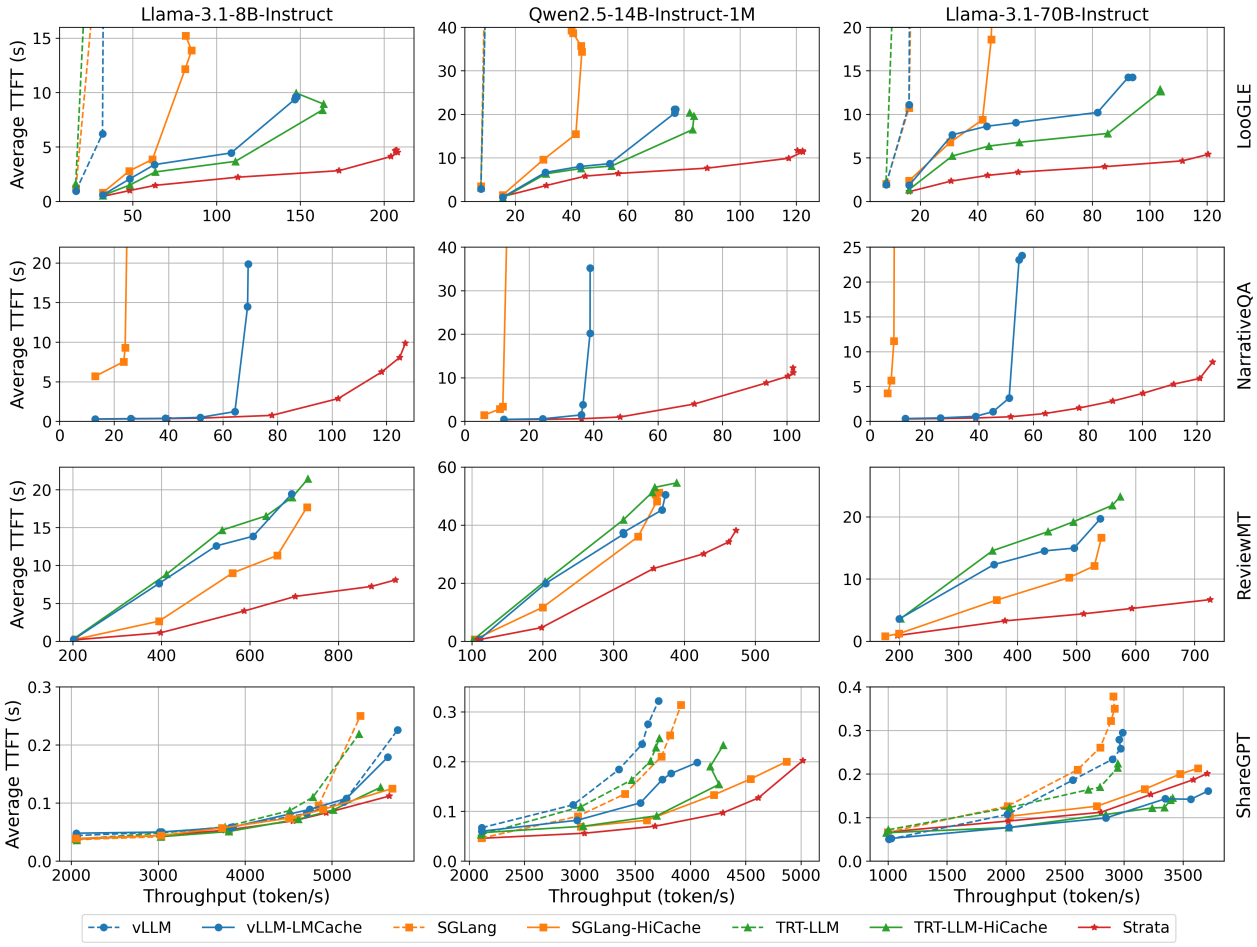

Figure 8: End-to-end benchmark performance comparison on H200.

of vLLM and TRT-LLM on the Llama-8B and -70B models due to kernel differences. Taking this into account, *Strata demonstrates comparable performance to the other state-of-the-art systems on short-context workloads*.

5.3 In-depth Performance Analysis

In this section, we conduct several breakdown analyses to better understand the performance benefits offered by Strata. Unless otherwise specified, all analyses use the LooGLE benchmark with Qwen2.5-14B model on an H200 platform.

5.3.1 How much do efficient I/O and scheduling benefit Strata?

Figure 9 presents the throughput-latency curves of Strata compared to three baselines. On top of *SGLang-HiCache*, we build and evaluate three ablated variants: *Strata-IO*, which incorporates the GPU-assisted I/O mechanism from §4.2, *Strata-Schedule-Only*, which applies the scheduling policy from §4.3, and *Strata-IO-LPM*, which integrates a longest prefix match (LPM) policy [53].

The results show that both the *Strata-scheduling* and *Strata-IO* components significantly improve the baseline hierarchical design, achieving up to 1.8× and 2.3× higher peak throughput, respectively. Each component alleviates the loading stall problem from a different perspective. Under low request rates, *Strata-scheduling* tends to deliver greater gains than *Strata-IO*, since smaller batch sizes generate lighter I/O pressure that can be more effectively mitigated by advanced scheduling. As the request rate increases, however, the I/O subsystem becomes the dominant bottleneck, making the GPU-assisted I/O mechanisms essential for sustaining high throughput.

We further compare *vLLM-LMCache* and *TRT-LLM-HiCache* directly with *Strata-IO*, since all three employ CUDA kernels to accelerate KV-cache I/O. As shown in Figure 9, their performance is comparable at low request rates, but *Strata-IO* maintains higher throughput as the request rate rises, indicating more effective mitigation of interference at scale. We also compare Strata with *Strata-IO-LPM*, which in-

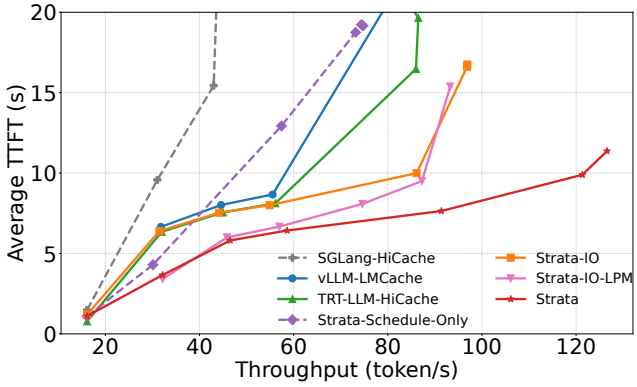

Figure 9: Breakdown of I/O and scheduling of Strata.

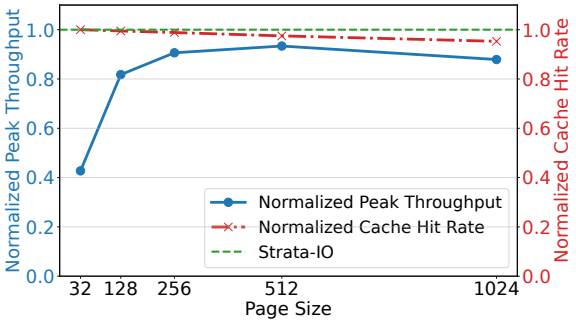

Figure 10: Performance comparison between Strata-IO and SGLang-HiCache with different page sizes.

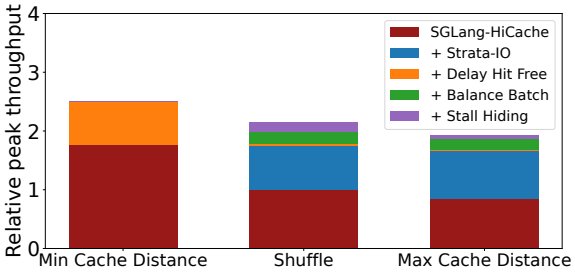

Figure 11: Breakdown of Strata's optimization attributions on different workload patterns.

creases the reuse count of on-device pages, thereby indirectly reducing host-side loading pressure and improving performance under low request rates. However, at higher request rates, it fails to sustain performance gains due to more frequent cache evictions. In contrast, Strata consistently delivers improvements because it explicitly accounts for bandwidth resources in its design.

5.3.2 Can Strata alleviate the burden of choosing a page size?

As discussed in §3.1, page size introduces inherent trade-offs among cache hit rate, I/O efficiency, and overall performance. This makes selecting the optimal page size a practical but non-trivial problem. Strata makes transfer efficiency much less sensitive to page size, reducing the need to choose large pages solely to obtain efficient transfers. To validate this claim, Figure 10 reports the peak throughput of *SGLang-HiCache* across different page sizes, normalized to *Strata-IO*. For *SGLang-HiCache*, increasing the page size initially improves throughput, since larger pages reduce loading stalls. However, beyond a certain threshold, throughput declines as cache hit rate deteriorates. Even at its best-performing setting (page size 512), *SGLang-HiCache* achieves only 93% of *Strata-IO*'s performance, primarily due to a 2.4% lower cache hit rate.

5.3.3 Can Strata adapt to varying cache distances?

Cache distance is an important property of a trace for testing cache system performance. To further augment the cache distance of our workloads, we generate two additional workloads based on the LooGLE dataset. In addition to our original (*shuffle*) workload, we create a *minimum cache distance* workload, where requests sharing the same context are lined up together, and a *maximum cache distance* workload, where queries sharing the same context are evenly distributed in the queue. As shown in Figure 11, we observe that with minimal cache distance, there is no need for hierarchical caching due to the perfect locality. In this scenario, delay hit mitigation benefits the most by improving effective cache hit rate, increasing peak throughput by 42%. However, delay hit mitigation offers no benefit in the max cache distance scenario because the high distance between similar requests naturally reduces the likelihood of the delay hit phenomenon. In contrast, the I/O efficiency mechanisms presented in §4.2 result in an improvement of 76% and 95% for the shuffle and maximum cache distance, respectively, as larger cache distances result in more cache hits to CPU DRAM. On top of that, balance batch further introduces 11% and 12% of the peak throughput improvement, respectively. Stall hiding further contributes 8% and 3% for shuffle and max cache distance, with higher benefit to the shuffle pattern due to higher variance.

5.3.4 What causes delay hit?

Beyond the request patterns discussed in §5.3.3, two system-level factors largely govern the severity of the delay hit effect: cache resolve time and system throughput (and thus the request arrival rate). As shown in Figure 12, longer cache resolve times (driven by prefill and scheduling latency) and higher throughput levels both increase the number of cache misses due to delay hits. A typical cache resolve time for a 1k-token input ranges from hundreds of milliseconds to several seconds, depending on the model and hardware. Note we study this effect using a simulated execution of the Moon-

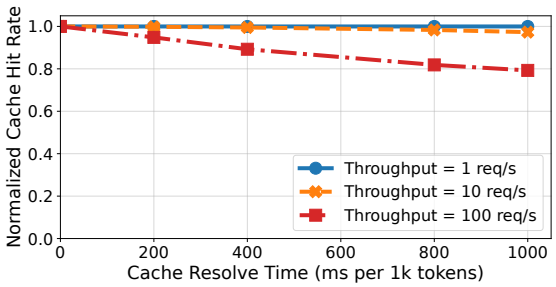

Figure 12: Delay hit impact for the Mooncake Tool-Agent trace under varying cache resolve times and throughputs. Different throughputs are achieved by scaling query timestamps.

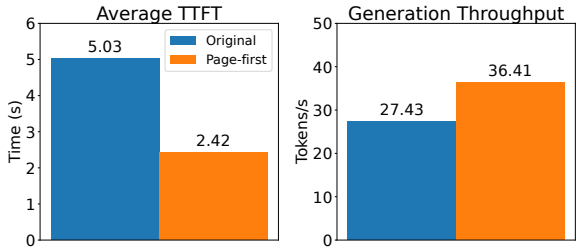

Figure 13: End-to-end performance improvement of the decoupled memory layout for DeepSeek-V3 on 8×H20 GPUs, with page size 32 and request rate 12 req/s.

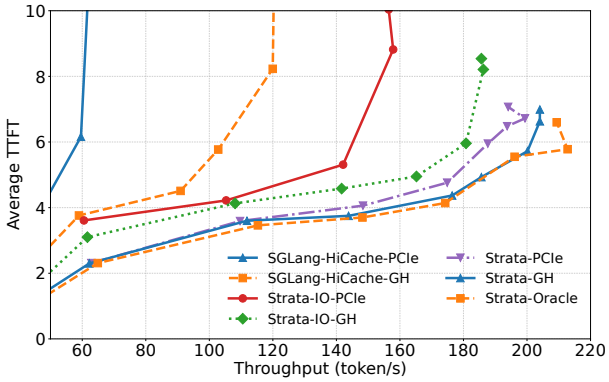

Figure 14: A zoomed-in comparison between benchmarks on PCIe-5.0 and Grace-Hopper platform.

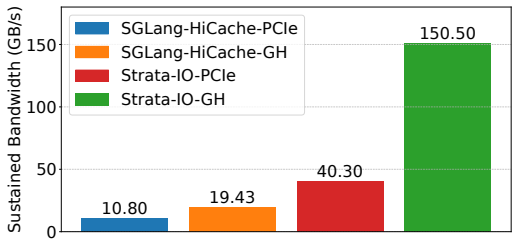

Figure 15: Sustained Bandwidth comparison.

cake trace with an effectively unlimited cache (to eliminate eviction effects), since our testbed cannot sustain sufficiently high throughput.

5.3.5 Does the decoupled memory layout benefit disk caching?

GPU-assisted I/O enables a page-first layout in host memory (and disk) without changing the GPU-resident layout (§4.2.1). Because the disks on the *H200* testbed are bandwidth-limited (<1 GiB/s), we evaluate this effect separately using the DeepSeek-V3 [12] model on the *H20-storage* platform. As shown in Figure 13, at a request rate of 12 req/s, the *page-first* layout improves average TTFT by 2.1× and throughput by 1.3× over an already reasonably large page size.

5.4 Benchmark on GH200 machine

Finally, we explored how Strata aligns with emerging hardware trends that dramatically increase the bandwidth between CPU and GPU. To do so, we benchmarked *SGLang-HiCache*, *Strata-IO* and *Strata* on both our H200 and GH200 platform. We also report a *Strata-Oracle* platform, which simulates the TTFT achieved by a system that had infinite bandwidth between the CPU and GPU.

Figure 14 reports the average TTFT achieved by *SGLang*, *Strata-IO*, and *Strata* across both of these platforms benchmarking Llama-3.1-8B models with LooGLE dataset. Figure 15 reports the averaged sustained bandwidth for the same task. We observe that, in line with our previous evaluation results, standard DMA-managed memory copy is not able to effectively utilize hardware improvement without using larger pages. While the improved bandwidth of GH200 improves latency for the SGLang baseline, only hardware improvements alone cannot outperform even Strata-IO on the H200 platform.

In contrast, using *Strata-IO* increases sustained host-GPU transfer bandwidth from 40 GB/s to 150 GB/s. However, scheduling improvements are still needed to take full advantage of platforms like Grace Hopper. While *Strata-IO-GH* achieves higher throughput with higher bandwidth mitigating the I/O stall, it still does not even outperform *Strata-PCIe*. In summary, Strata's improved I/O transfer mechanisms *with* its bandwidth-aware scheduler can take full advantage of emerging platforms like Grace Hopper, achieving comparable performance to the Oracle setting. These benchmarks reveal that while increased interconnect bandwidth is beneficial, it's often under-utilized by existing software. Ideally, leveraging new hardware capabilities, as demonstrated by *Strata-GH*'s near-oracle performance, could unlock new possibilities. Specifically, this platform shows promise for specialized, cost-effective, and high-performance long-context serving.

6 Discussion

Having demonstrated Strata's advantages, we now discuss its limitations and directions for future work.

I/O Kernel Interference. As analyzed in §4.2, Strata's GPU-assisted I/O trades a small amount of SM contention for high transfer efficiency on small, fragmented pages. CUDA 12.8 recently introduced `cudaMemcpyBatchAsync` [38], which improves transfer efficiency by batching many small copy operations into a single host-driver submission. Because it engages the GPU DMA engine, it does not compete with concurrent computation for SM resources. In the same H200 microbenchmark used for Figure 5, its throughput is lower than our GPU-assisted I/O kernel, 38 GB/s versus 48 GB/s. While this lower throughput could introduce additional stalls on the loading path, it makes the API a good fit for the less critical GPU-to-CPU backup path. Strata can therefore be configured to use the GPU-assisted I/O kernel for CPU-to-GPU loading and the batch-copy API for GPU-to-CPU backup, achieving competitive bandwidth while further reducing kernel interference. Looking forward, we plan to further reduce GPU-assisted kernel overhead and believe these results motivate more versatile on-chip I/O accelerators.

Fairness in Scheduling. Although §4.3.2 introduces a mechanism to prevent starvation, Strata's scheduler prioritizes aggregate I/O and compute efficiency and can still treat requests unevenly, risking Service-level objective (SLO) violations for individual requests. A natural extension is to make batch formation SLO- and fairness-aware when allocating resources. The current policies also focus on hiding the latency of moving data from host DRAM to HBM; an equally promising direction is to create scheduling headroom for hiding the latency of prefetching from slower storage tiers, going beyond Strata's current approach of overlapping prefetches with queuing delay.

Model Coverage. Strata targets hierarchical caching for the dense KV caches produced by standard attention. As hybrid mechanisms such as sparse and linear attention gain adoption, extending the same level of support to these models becomes increasingly important and raises distinct challenges in both memory management and scheduling-policy design.

7 Related Work

Context Caching and Sharing. Prior work has explored several mechanisms for reusing KV caches to avoid redundant computation. SGLang [53] uses a RadixTree to track shared context, while other serving engines such as vLLM [26] and Mooncake [43] employ hashing schemes that generate unique page identifiers from token IDs and prefix page hashes. LMDeploy [10] adopts a hybrid design with coarser-grained tries. Strata builds on SGLang by extending its RadixTree into a HiRadixTree. Beyond exact-prefix reuse, CacheGen [29] and CacheBlend [50] explore approximate KV cache sharing. In contrast, Strata focuses on exact caching and does not affect model accuracy. Marconi [42] adds prefix cache support for hybrid LLMs, which is complementary to Strata and a promising direction for extending our framework to hybrid models.

KV Cache Offloading. Several recent works have explored utilizing secondary memory tiers (e.g., CPU DRAM, SSDs) for KV cache storage, loading them for computation on demand. CachedAttention [14] and Pensieve [52] both adopt a layer-wise strategy to overlap KV cache loading with computation. FlashGen [21] further enhances this pipeline with re-order execution scheduling, which has been implemented in SGLang and used in our baseline settings.

Efficient Host-GPU I/O. Practitioners have long recognized that GPUs can accelerate small data movement between GPU and CPU memory [33, 44]. Strata introduces a GPU-assisted KV-cache transfer mechanism tailored to LLM serving and, to our knowledge, provides the first quantitative analysis of the trade-offs between transfer efficiency, cache hit rate, and interference overhead. GDRCopy [24] and CUDA Unified Memory [37] enable low-latency fine-grained host-GPU data transfer, but their design makes it difficult to sustain the bandwidth required for large KV-cache transfers.

Large-scale KV Cache Disaggregation. Recent works propose building large-scale disaggregated KV cache memory pools and global resource coordinators to achieve caching benefits at a larger scale. Mooncake [43] exploits using resources including CPU, DRAM, SSD and NIC to establish a disaggregated KV Cache. MemServe [19] unifies inter-request and intra-request KV cache optimizations via a global scheduler and an elastic memory pool. Strata can benefit from these designs by integrating with their KV cache transfer engines. However, Strata focuses on memory management and scheduling within single compute instances and does not inherently rely on specialized hardware, such as high-speed networking, to realize its caching benefits.

8 Conclusion

This paper presented Strata, a hierarchical context caching framework that tackles the key bottlenecks of long-context LLM serving. By combining GPU-assisted I/O to mitigate KV cache fragmentation with cache-aware scheduling that balances computation and data transfer, Strata improves utilization across diverse latency regimes. Our evaluation shows that Strata outperforms state-of-the-art systems on long-context benchmarks while preserving strong performance on short-context workloads, establishing Strata as a practical and scalable solution for efficient long-context LLM serving.

Acknowledgments

Abstract

Native sparse attention has emerged as a promising approach for efficient long-context LLM inference without compromising accuracy. While it significantly reduces the attention computation and KV cache access costs, the KV cache size exhibits steeper linear growth with the context length. As a result, GPU HBM capacity becomes the bottleneck, limiting the concurrency of long-context requests and leading to poor hardware utilization and low generation throughput. We introduce ECHO, a serving system designed for native sparse-attention LLMs that employs KV cache offloading to overcome GPU HBM capacity limits. ECHO incorporates a graph-friendly cache manager that enables efficient dynamic KV cache eviction and recall entirely within GPU graphs, minimizing management overhead. Furthermore, by exploiting the numerical predictability of index scores and the sequential processing of queries, ECHO enables lossless intra-query prefetching for decoding and inter-query prefetching for prefill. By applying a fully pipelined fused GPU kernel, ECHO overlaps the recall overhead with indexer computation. Experiments show that ECHO delivers up to 2.1× higher generation throughput than state-of-the-art systems such as SGLang and vLLM under long-context workloads, while maintaining comparable latency under light load.

1 Introduction

Large language models (LLMs) have gained remarkable prominence for their ability to excel across diverse tasks and have been widely deployed in a variety of applications, such as chatbots, agents, and coding copilots [10, 24, 33]. To handle increasingly complex tasks such as multi-turn dialogue, long-horizon planning, and repository-level code understanding, the context windows of LLMs are rapidly expanding to accommodate longer inputs and maintain longer memory. Mainstream LLMs now typically support context windows of 128K tokens [15, 41], and frontier models can reach up to 1 million tokens [11, 57]. As a result, long-context inference has become a critical workload in production LLM serving.

Although extended context windows unlock powerful capabilities, processing long-context requests incurs significant efficiency issues because the cost of self-attention increases quadratically with context length. While KV cache is introduced to avoid recomputation, it does not change the quadratic complexity. Leveraging the inherent sparsity of attention computation, *sparse attention* has been extensively studied and employed to reduce the costs of attention [26, 49]. Typically, sparse attention methods first estimate the attention scores of tokens, prune less critical tokens, and then compute attention only over the top-k tokens with the highest scores.

These methods are training-free, making them simple to deploy. However, they often lead to accuracy degradation, which can impair model performance, particularly on complex tasks. To this end, recent works propose applying sparse attention during pre-training or post-training to mitigate or eliminate accuracy degradation [32, 65, 68]. For example, the recently released DeepSeek-V3.2 incorporates training-time sparse attention, employing a lightweight indexer to identify and select important tokens [13]. It shows comparable or better performance against state-of-the-art full attention models on various complex, long-context tasks [18], demonstrating the promising potential of *native sparse attention models*.

Sparse attention, whether training-free or training-time, significantly reduces the computation cost of long-context processing; however, it does not shrink the KV cache itself, and the memory footprint still grows linearly with context length. Consequently, GPU HBM capacity can be quickly exhausted even with a modest number of concurrent long-context requests. For instance, with DeepSeek-V3.2 deployed on 8 NVIDIA H200 GPUs (141 GB each), a single worker can accommodate only up to 655K tokens, allowing at most six concurrent requests of 100K tokens each. The resulting low request concurrency directly degrades hardware utilization, and the intrinsically lower arithmetic intensity of sparse attention kernels further exacerbates this under-utilization.

To overcome the limitations imposed by GPU HBM ca-

*Corresponding author.

pacity, recent works propose offloading the KV cache to host memory during inference with sparse attention, thereby alleviating GPU memory pressure and enabling higher request concurrency [6, 26]. Only KVs of selected tokens are loaded or *recalled* from the host to GPU memory for sparse attention computation. However, few KV cache offloading systems are designed for realistic serving scenarios. Most existing offloading approaches rely on inefficient cache-management strategies that introduce substantial overhead and are incompatible with graph execution such as CUDA Graphs, thereby limiting their practical applicability.

Moreover, the limited bandwidth of host-GPU interconnects such as PCIe can impose substantial overhead during KV recall operations. Several studies attempt to mitigate this overhead by pre-selecting important tokens and prefetching their KVs, exploiting inter-layer or inter-step similarity [26, 30, 62]. However, such prefetching introduces additional accuracy degradation beyond that inherent to sparse attention, undermining model reliability on complex tasks and limiting adoption in production deployments.

To address these issues, we present ECHO, a serving system for native sparse attention LLMs under long-context workloads through efficient KV cache offloading. Note that ECHO can also serve models with training-free sparse attention. Since these methods inherently incur accuracy degradation, we focus on more challenging native sparse attention LLMs with higher model performance in this work. ECHO improves serving efficiency along two axes. First, ECHO introduces a *graph-friendly cache manager* that eliminates variable-length tensors and updates cache states using fully parallel operations. This design enables all management tasks to execute entirely within the GPU graph, thereby minimizing management overhead. Second, to mitigate recall overhead without compromising accuracy, ECHO exploits the numerical predictability of index scores to break the top-k dependency, enabling *intra-query prefetching* during indexer execution in the decoding phase. For prefill, ECHO leverages the sequential processing of queries to enable *inter-query prefetching*. Both prefetching operations in ECHO are lossless, with guaranteed recall that preserves model accuracy. In addition, ECHO fuses prefetching into the indexer kernels using software pipelining, enabling prefetching to overlap with indexer computation.

In summary, this paper makes the following contributions:

- We identify the GPU memory-capacity limitations inherent in serving native sparse attention LLMs and present ECHO, an efficient long-context serving system with KV cache offloading.
- We design a graph-friendly cache manager that enables the entire decoding path to execute within a single graph, minimizing cache-management overhead.
- We reveal the numerical predictability of index scores, enabling lossless intra-query prefetching during decoding, and exploit the sequential processing of queries to enable lossless inter-query prefetching for prefill.

We implement ECHO atop the state-of-the-art serving framework SGLang [69] and kernel library DeepGEMM [12]. Experimental results show that ECHO delivers up to 2.1× generation throughput improvement over SGLang when serving DeepSeek-V3.2 under long-context workloads, while maintaining comparable latency under light load. Code is available at https://github.com/sjtu-zhao-lab/ECHO.

2 Background and Motivation

2.1 LLM Inference and KV Cache

Transformer LLMs comprise multiple Transformer layers, each with an attention module and a feed-forward network (FFN). In attention, the hidden states $\mathbf{X} \in \mathbb{R}^{L\times D}$ are projected into query, key and value tensors ($\mathbf{Q},\mathbf{K},\mathbf{V} \in \mathbb{R}^{L\times d}$), where L is the context length and D, d are the model and attention dimensions, and the output is $\text{Attn}(\mathbf{Q},\mathbf{K},\mathbf{V}) = \text{softmax}\big(\frac{\mathbf{Q}\mathbf{K}^\top}{\sqrt{d}}\big)\mathbf{V}$. To scale model capacity at low computational cost, modern LLMs augment FFNs with a Mixture-of-Experts (MoE) architecture of sparsely activated expert FFNs [9]. MoE parameters can reach hundreds of billions or even a trillion, imposing substantial GPU memory demands during inference [17, 50].

KV Cache LLMs generate tokens in an *autoregressive* manner, appending each newly produced token to the input sequence to generate the next. Mainstream LLMs adopt a *decoder-only* architecture in which a causal mask is applied to $\mathbf{Q}\mathbf{K}^\top$ during attention computation. Consequently, the $\mathbf{K}$ and $\mathbf{V}$ tensors depend only on preceding tokens and can be cached to avoid redundant computation, a mechanism known as *KV cache*. With KV cache, LLM inference proceeds in two stages: prefill and decoding. The prefill stage processes the entire input sequence, computes the KV cache, and produces the first output token. During decoding, the query vector of the most recently generated token, together with the cached KV tensors from all previous tokens, is used to compute attention for generating subsequent tokens. Prefill efficiency is typically evaluated using time-to-first-token (TTFT) and input-token throughput, whereas decoding performance is assessed using inter-token latency (ITL) and output-token throughput.

Attention Variants The original Transformer utilizes multi-head attention (MHA) with $\mathbf{Q},\mathbf{K},\mathbf{V} \in \mathbb{R}^{H\times L\times d}$, where H is the number of heads [53]. The attention of each head is computed independently, and outputs of all heads are concatenated and projected for later computation. To reduce the memory cost of KV cache and increase the arithmetic density, grouped-query attention (GQA) is adopted by many LLMs [2]. In GQA, $\mathbf{K},\mathbf{V} \in \mathbb{R}^{H_{kv}\times L\times d}$ contain fewer heads

than $\mathbf{Q}$, and a group of $G = \frac{H}{H_{kv}}$ query heads share a single KV head. While multi-query attention (MQA) further improves efficiency by setting $H_{kv} = 1$, it introduces substantial accuracy degradation, which has limited its broader adoption [47]. To strike a better balance between accuracy and efficiency, multi-head latent attention (MLA) employs low-rank compression to KV tensors [16]. Specifically, MLA first down-projects the hidden states to compressed *latent vectors*, i.e., $\mathbf{C} = \mathbf{W}^{DKV}\mathbf{X} \in \mathbb{R}^{L \times d_c}$, and then reconstructs the KV tensors for attention computation by up-projecting the latent vectors, namely $(\mathbf{K}, \mathbf{V}) = (\mathbf{W}^{UK}\mathbf{C}, \mathbf{W}^{UV}\mathbf{C})$. The up-projections can be further absorbed, and only the latent vectors $\mathbf{C}$ need to be cached during inference. Compared to GQA, MLA is both more mathematically expressive and more efficient [34], leading to its adoption in recent models [21, 50].

2.2 Sparse Attention in LLMs

The context windows of LLMs are rapidly expanding to support increasingly complex tasks, reaching 128K and even 1M tokens in state-of-the-art models [11]. To alleviate the quadratic growth of attention computation with context length, a variety of sparse-attention methods have been proposed. These approaches compute attention only over the KV tensors of the selected k tokens, reducing computational cost from $O(L^2)$ to $O(Lk)$.

Training-free Sparse Attention Most sparse attention methods are *training-free*, requiring no training or finetuning of the original models. Early methods select tokens statically, leveraging sliding window or vertical-slash patterns in attention [23, 58]. However, static sparsity typically incurs substantial accuracy degradation. To address this, dynamic methods determine sparsity patterns at inference time based on approximated attention scores (i.e., approximations of $\mathbf{QK}^\top$). For efficient score approximation, Quest [49] compresses each K block into two label vectors and estimates block importance from those labels to select important blocks for attention. Alternatively, InfiniGen [26] identifies critical channels of Q and K and approximates attention scores using only the retained channels. In general, dynamic sparse attention methods follow one of two strategies to reduce approximation cost: compressing along the context dimension or pruning along the channel dimension [6, 31, 60].

Training-time Sparse Attention To eliminate the accuracy degradation associated with training-free sparse attention, recent works explore *training-time* sparse attention. By incorporating sparsity during pre-training or post-training, model parameters are adapted to sparse-attention outputs, allowing the model to preserve its native accuracy at inference time. Sliding window attention (SWA) is one of the simplest forms of training-time sparse attention [22]. Following the block-wise paradigm, MoBA [32], NSA [65], and InfLLM-v2 [68] compress K blocks into label vectors using direct pooling or learnable MLPs.

DeepSeek Sparse Attention (DSA) Building on MLA, DSA implements training-time sparse attention by introducing a lightweight *indexer* [13]. The indexer is an MQA-like module, computing token-importance scores that are used to select the most relevant tokens for sparse MLA. Specifically, given a query token t, the importance, namely *the index score*, of token s is measured by

$$\sum_{h=1}^{H_{\text{index}}} w_{h,t}^I \,\text{ReLU}(q_{h,t}^I, k_s^I), \quad w_{h,t}^I \in \mathbb{R} \text{ and } q_{h,t}^I, k_s^I \in \mathbb{R}^{d_{\text{index}}}$$

where H_{index} is the number of indexer heads, d_{index} is the indexer dimension, $w_{h,t}^I, q_{h,t}^I$ are weights and query vector of indexer head h and token t, while k_s^I is the key vector of token s shared by all indexer heads, respectively. Tokens with the top-k highest importance are selected for sparse MLA computation. To ensure indexer efficiency, H_{index} and d_{index} are set much smaller than their counterparts in MLA. For example, in DeepSeek-V3.2, the indexer uses $H_{\text{index}} = 64$ and $d_{\text{index}} = 128$, whereas MLA employs $H = 128$ and $d_c = 512$. Moreover, DSA applies low-precision FP8 formats for q^I and k^I to further improve indexer efficiency, and the ReLU is also more efficient than the original softmax. To the best of our knowledge, DSA is currently the only training-time sparse attention method that has been validated on large scale models and realistic complex tasks [18], and it has since been adopted by other models such as the GLM-5 series [20].

2.3 KV Cache Offloading

While sparse attention reduces the computational cost of attention and the amount of KV data accessed, the total size of the KV cache still grows linearly with context length. To support extremely long contexts and large batch sizes under limited GPU HBM capacity, recent works propose offloading the KV cache to host DRAM and loading back, i.e., *recall*, only the selected KVs needed for sparse-attention computation [6, 26, 30, 31, 48, 62, 66, 72]. During inference, KV tensors for individual tokens or token blocks are dynamically evicted and recalled, enabling long-context execution within constrained GPU memory budgets. To reduce the substantial recall overhead caused by the limited bandwidth between host DRAM and GPU, InfiniGen [26] and FreeKV [30] propose to pre-select important tokens and prefetch their KVs, leveraging inter-layer and inter-step similarity, respectively.

Beyond dynamic token-level offloading, static request-level KV cache offloading has also been adopted in general LLM serving systems [8, 19, 39, 59, 64]. Unlike token-level schemes, request-level offloading loads the entire KV cache of a prior context into GPU HBM when a request arrives, and no eviction or recall occurs during inference. KVs are evicted only

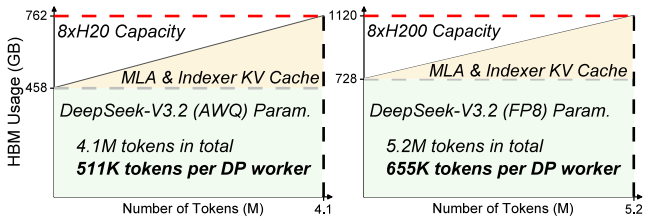

Figure 1: GPU HBM usage of DeepSeek-V3.2 (AWQ) on 8×H20 (96GB) and DeepSeek-V3.2 (FP8) on 8×H200 (141GB). Space for MLA KV cache and indexer K cache increases linearly with the number of tokens.

after the corresponding request completes. These systems focus on improving request-level hit rates to reduce TTFT.

2.4 Motivation and Challenges

Efficiently serving sparse attention models is becoming increasingly important with the emergence of native sparse attention LLMs. However, existing systems struggle to efficiently serve these models under long-context workloads, due to the following limitations and challenges.

Motivation 1: GPU HBM capacity becomes a primary bottleneck for hardware utilization and generation throughput when serving native sparse attention LLMs under long-context workloads. While sparse attention significantly reduces the computation and KV cache access costs, it increases the KV cache size due to storing additional K cache of the indexer, resulting in a steeper linear growth with the context length. Consequently, for long-context requests, GPU HBM capacity constrains the achievable batch size or request concurrency, directly limiting hardware utilization and generation throughput. This bottleneck is further exacerbated by the substantial HBM consumption of MoE parameters and the intrinsic inefficiencies of current sparse attention kernels.

Figure 1 shows the GPU HBM usage of the DeepSeek-V3.2 model as the number of tokens increases. The left plot presents the 4-bit quantized model using AWQ [29] on 8 NVIDIA H20 (96GB) GPUs, and the right plot shows the original FP8 model on 8 NVIDIA H200 (141GB) GPUs. Model parameters are sharded across GPUs using tensor parallelism (TP8). In both configurations, parameters consume more than 60% of the available GPU HBM, leaving room for only ∼4.1M and ∼5.2M tokens, respectively. Although these numbers appear sufficient, the KV cache of MLA cannot be partitioned via tensor parallelism. Instead, data parallelism (DP) is typically used for the MLA module; as a result, each worker can support only ∼511K tokens (AWQ) and ∼655K tokens. In practice, the space for KV cache is even smaller due to runtime overheads such as CUDA graph metadata. For DeepSeek-V3.2 (AWQ) running on 8×H20 GPUs with SGLang configured with TP8 and DP8 for MLA [43], we observe that each DP

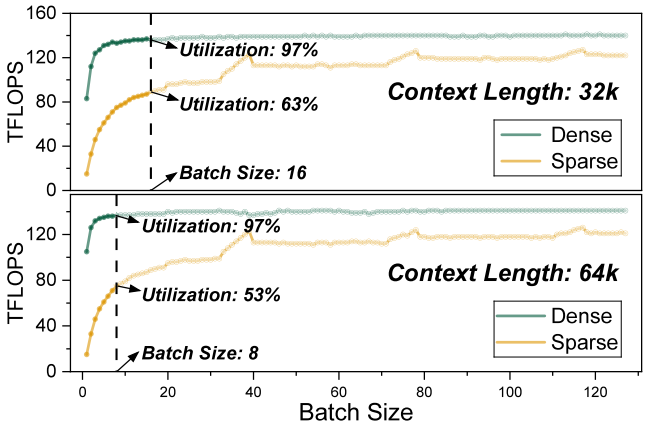

Figure 2: Hardware utilization in TFLOPS of the sparse and dense FlashMLA kernels across different batch sizes.

worker can accommodate at most 380K tokens. This implies that, for requests with ∼100K tokens, each DP worker can serve only 3–4 concurrent requests, severely limiting hardware utilization and generation throughput.

Intrinsic inefficiencies in sparse attention kernels exacerbate the under-utilization problems. Figure 2 shows the hardware utilization (TFLOPS) of sparse and dense FlashMLA [27] decoding kernels on NVIDIA H20, across varying batch sizes and context lengths. Benefiting from high arithmetic density, dense MLA kernels can fully exploit the hardware even at small batch sizes, where a batch size of 8 is adequate for 64K contexts. However, due to non-continuous memory access of the sparse attention kernel, its utilization is much lower than the dense kernel, requiring much larger batch sizes to saturate the hardware. Therefore, the limitation from HBM capacity is more severe for sparse kernels and models. Considering the full DeepSeek-V3.2 (AWQ) model deployed on 8×H20 GPUs, the capacity of 511K tokens can accommodate up to 8 requests of 64K tokens, and the corresponding kernels suffer from under-utilization issues (only 53% utilization), as marked in Figure 2.

As described in Section 2.3, KV cache offloading has been widely studied for long-context inference with limited GPU HBM. However, none of them achieves efficient long-context serving for native sparse attention models in realistic scenarios. We summarize the characteristics of representative KV cache offloading systems in Table 1. First, static request-level offloading such as Strata requires the entire KV cache of requests to be stored in GPU HBM during inference, thus cannot reduce the runtime HBM usage or improve concurrency. While ArkVale, InfiniGen, FreeKV and CLO support dynamic token-level offloading, they are not serving systems and do not support techniques such as continuous batching [63] or multi-GPU inference.

While SparseServe supports serving scenarios with dynamic offloading, its cache management is inefficient and

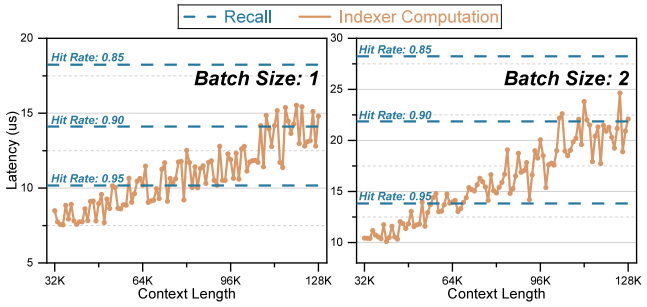

Figure 4: Latency of indexer computation across different context lengths, and latency of recall across different hit rates, profiled using DeepSeek-V3.2 on NVIDIA H20 GPU.

cannot support *graph execution*, which captures execution flow as a deterministic graph and eliminates kernel launch overhead. Graph execution is almost necessary in practical serving frameworks to eliminate significant kernel launch overhead at the decoding stage [54, 55]. The effect of graph execution is even more pronounced for native sparse attention LLMs with more operators and kernels. Figure 3(a) shows the normalized generation throughput for DeepSeek-V3.1 with dense attention and DeepSeek-V3.2 with sparse attention, using SGLang with graph execution (CUDA graph) and without (Eager). As shown, for DeepSeek-V3.1, graph execution improves throughput by 1.2×, while the improvement for DeepSeek-V3.2 is 1.5×.

Furthermore, for dynamic offloading where eviction and recall can happen at each decoding step and model layer, cache management can incur significant overhead, especially at the compute-light decoding stage. Graph execution can also reduce the management overhead, however, it requires the captured graph completely running on GPU, without any CPU control or synchronization. Cache managers and allocators in existing serving systems typically rely on dynamic tensor slicing or concatenation, which cannot be captured by graph execution and can introduce nontrivial overhead. To quantify this cost, we compare the allocation and free latency of the SGLang allocator with the graph-friendly allocator used by ECHO (Section 4), using a KV pool of 300K tokens. As shown in Figure 3(b), one allocation followed by one free takes about 12 μs with the SGLang allocator, whereas the graph-friendly allocator reduces this cost to 6–8 μs, achieving 1.6–1.9× lower latency. Moreover, the SGLang allocator relies on dynamic CPU-side control, which prevents the decoding path from being captured as a graph. Its impact therefore extends beyond the allocator's own management overhead, eliminating the graph execution benefits for end-to-end decoding shown in Figure 3(a). An alternative is piecewise graph execution [55], which runs dynamic operations eagerly while capturing the static computation into graph pieces. However, since eviction and recall occur at every layer in each decoding step, the graph would break at all layers, reintroducing frequent CPU control and kernel launches at the compute-light decoding stage. In contrast, ECHO keeps the entire decoding path within a single full graph, eliminating these per-layer overheads. All existing offloading systems in Table 1 cannot support graph-friendly cache management, incurring significant management and kernel launch overhead.

In summary, *building an efficient, practically usable dynamic KV cache offloading serving system demands graph-friendly cache management.*

Motivation 2: Recall overhead can be substantial, while the indexer computation provides an opportunity for prefetching. Compared with GPU HBM bandwidth, host–GPU interconnect bandwidth is typically one to two orders of magnitude lower. Consequently, KV recall introduces significant overhead and degrades inference efficiency, as all selected tokens' KV tensors must be transferred to the GPU before the subsequent attention computation. To mitigate

this recall overhead, InfiniGen, FreeKV, and CLO propose pre-selection and prefetching of important tokens. However, these approaches rely on inter-layer or inter-step similarity to approximate attention scores, which introduces accuracy degradation on complex tasks due to imperfect prediction.

Prefetching without compromising accuracy appears infeasible due to the sequential dependence among indexer, recall, and attention. However, a key observation that enables breaking this sequential constraint is that indexer computation has complexity $O(L^2)$, whereas recall requires only $O(Lk)$. Specifically for decoding, the indexer must access the K cache and compute index scores for all L preceding tokens, whereas recall requires loading the KV cache for at most k selected tokens, where k is a fixed constant (e.g., 2048) and L grows with context length. In practice, offloading systems maintain a cache for KV of selected tokens on GPU, thus the actual number of recalled tokens is typically less than k.

We present the latency of indexer computation across varying context lengths and the latency of MLA KV recall across varying hit rates during decoding in Figure 4, profiled on NVIDIA H20 GPU which connects with the host via 64GB/s PCIe Gen5. As the context length and hit rate increase, the latency of indexer computation can eventually exceed that of recall, for example, when the context approaches 100K tokens and the hit rate reaches 90%. Recall overhead can be further reduced when using higher-bandwidth interconnects such as NVLink or SXM, which provide 600–900 GB/s of throughput [35]. Because indexer computation and recall contend for distinct hardware resources (GPU compute versus PCIe or other interconnect bandwidth), the recall latency can, in principle, be partially or even fully overlapped through prefetching performed concurrently with indexer computation.

However, similar to other sparse attention methods, DSA selects tokens with top-k highest scores, which can only be determined after computing the index scores for all previous tokens. Consequently, the recall can only be launched after the indexer computation.

To summarize, the second challenge is that *the top-k selection hinders prefetching during indexer computation, leaving PCIe bandwidth idle and preventing the recall latency from being overlapped with indexing*.

To overcome all these challenges, we present ECHO, an efficient LLM serving system with host-side KV cache offloading. To resolve Challenge 1, ECHO incorporates a graph-friendly cache manager that uses tensor-based metadata and parallel in-graph update operations, enabling graph execution while minimizing cache management overhead. To resolve Challenge 2, ECHO introduces lossless intra-query and inter-query prefetching, leveraging numerical predictability of index scores and deeply fused pipelining kernels to enable prefetching and overlap the recall overhead.

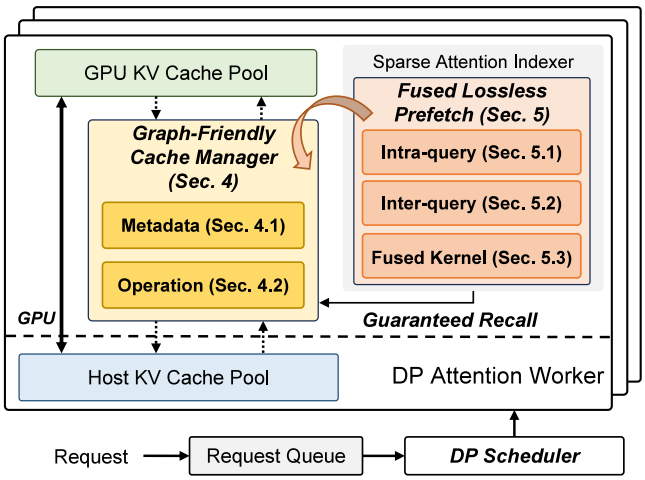

Figure 5: Overview of the ECHO design.

3 Overview of ECHO

The overview of ECHO is presented in Figure 5. As shown, each DP attention worker maintains KV cache pools on GPU and host memory, where the host pool can be much larger than the GPU pool to support more requests and higher concurrency. The DP scheduler routes requests to the selected DP worker. During inference, the K cache of sparse attention indexer is persistently stored in the GPU pool, while the generated MLA KV cache is stored in both the host and GPU pools, where the GPU pool serves as a cache for selected tokens in sparse attention.

The graph-friendly cache manager maintains metadata for the status of the host and GPU pools, which is updated upon recall or eviction. All metadata is on GPU and all update operations can be captured and replayed for graph execution in decoding, executing completely within the GPU graph and minimizing the management overhead. During indexer computation, ECHO prefetches a subset of important tokens, with prefetching fused into the indexer kernel and software-pipelined to hide its overhead. After the indexer computation, a guaranteed recall is launched for the selected tokens that are not yet in the GPU pool. The token eviction priority is then adjusted based on the index scores from the indexer.

Prefill-Decoding (PD) Disaggregation PD disaggregation is a widely applied deployment paradigm [38, 70] that eliminates interference between prefill and decoding, yielding better SLO attainment and optimization flexibility. ECHO is a general system that supports both PD disaggregation and mixed execution. While mixing prefill and decoding requests achieves better throughput in some scenarios [1, 56], we suggest deploying ECHO and other dynamic offloading systems with PD disaggregation for the following reasons. First, for prefill, the number of selected tokens in sparse attention can be substantial, as the selection of each token is independent

and the total selection is the union set of all prefill tokens. In the worst cases, a prefill request accesses KV cache of all previous tokens, which requires a huge number of tokens in the GPU pool and evicts lots of tokens from other requests, significantly degrading the overall throughput. Second, a substantial amount of KV cache needs to be transferred to the host memory during prefill. While ideally the PCIe bandwidths between host-to-GPU and GPU-to-host are independent, we observed that the transfer during prefill interferes with recall, degrading efficiency.

In the PD disaggregation setting, ECHO disables offloading on prefill instances, because prefill has limited concurrency and utilization issues as long as GPU HBM can accommodate a single long-context request (up to 128K tokens for DeepSeek-V3.2). On decoding instances, ECHO stores the KV cache transferred from prefill instances in host memory, and then launches decoding to prefetch and recall KV cache of selected tokens. This ensures that only KV cache selected during decoding is transferred to GPU, avoiding unused KV loads and maximizing HBM utilization.

4 Graph-Friendly Cache Manager

4.1 Management Metadata

Besides common metadata such as block tables in existing systems [25], ECHO maintains additional status metadata of KV cache pools for efficient dynamic eviction and recall. All metadata is stored as integer tensors on GPUs and updated in parallel to minimize overhead. Specifically, the metadata includes the following tensors:

- `GPUTokenFree`: A bitmap indicating whether each slot in the GPU pool is currently free.
- `GPUTokenPriority`: Per-slot eviction priority for the GPU pool. Tokens with lower priorities are evicted first; free slots are initialized with priority -1.
- `GPUIndicesBuffer`: A buffer holding GPU pool indices produced by the allocate and free operations.
- `GPUTokenToHost`: A mapping from each GPU pool slot to its corresponding host pool index, initialized to ∞ to denote an empty slot.
- `HostTokenToGPU`: A mapping from each host pool slot to its corresponding GPU pool index, initialized to ∞ to indicate the token is not currently cached on GPU.

All these metadata tensors are statically pre-allocated and fixed-length because graph execution does not allow dynamically created or variable-length tensors.

In existing systems, the KV cache pool is managed in a *per-model* manner, where KV slots are allocated or freed consistently across all model layers. However, dynamic eviction and recall in sparse attention produce divergent cache states across layers, as each layer selects different tokens. Therefore, ECHO manages the GPU pool *per-layer*, with metadata maintained independently for each layer. The host pool remains per-model, as it is unaffected by dynamic eviction and recall.

Storage Overhead of Metadata Let N_H and N_G denote the number of tokens in the host and GPU pools, respectively. The length of `HostTokenToGPU` is N_H, and the lengths of all other tensors are N_G. `GPUTokenFree` stores boolean elements and other tensors store 32-bit integers. Therefore, the storage cost of all metadata is $4N_H + 13N_G$ bytes. Given $N_H = 2$M and $N_G = 200$K in our setting, the metadata size is about 10MB per layer, totaling 610MB for DeepSeek-V3.2.

4.2 Parallel In-Graph Update Operations

The cache manager updates the status of KV cache pools and metadata using three basic operations: *allocate*, *free*, and *recall*. Compared to the per-model management, which requires only one update per model forward pass, the per-layer management requires updating for each model layer. To minimize management costs, ECHO introduces parallel in-graph update operations. All operations are processed efficiently and entirely in parallel on GPU, and are captured and executed in the graph during decoding, eliminating host interference and minimizing overhead.

Allocate The allocate operation is used to allocate slots from the GPU pool, which is required when (i) accommodating newly-generated KV cache and (ii) preparing slots for tokens to be recalled. It first calls *free* to ensure there are enough free slots. Allocation in existing systems introduces variable-length tensors through dynamic tensor slicing [69], making it incompatible with graph execution. ECHO designs an efficient, parallel allocation operation, addressing this limitation. As shown in Figure 6, the GPU threads read the `GPUTokenFree` in parallel, and threads with free slots launch `atomicAdd` to a global counter. The return value of `atomicAdd` is the old value of the counter, determining which threads should allocate their slots. For the example in Figure 6, slots for thread 1 and thread 5 are allocated. Correspondingly, the metadata tensors are updated by: (i) incrementing the priorities of the newly allocated tokens, and (ii) establishing a mutual mapping between the GPU slots $(1,4)$ and the host slots $(3,4)$. Finally, the indices of the allocated GPU slots are output to a buffer for later use. The allocate operation is fully parallel and processed entirely on the GPU, achieving compatibility with graph execution by avoiding the introduction of variable-length tensors.

Free The *free* operation releases GPU pool slots when the available space is not adequate, providing room for: (i) newly-generated KV cache, and (ii) the KV cache of tokens being

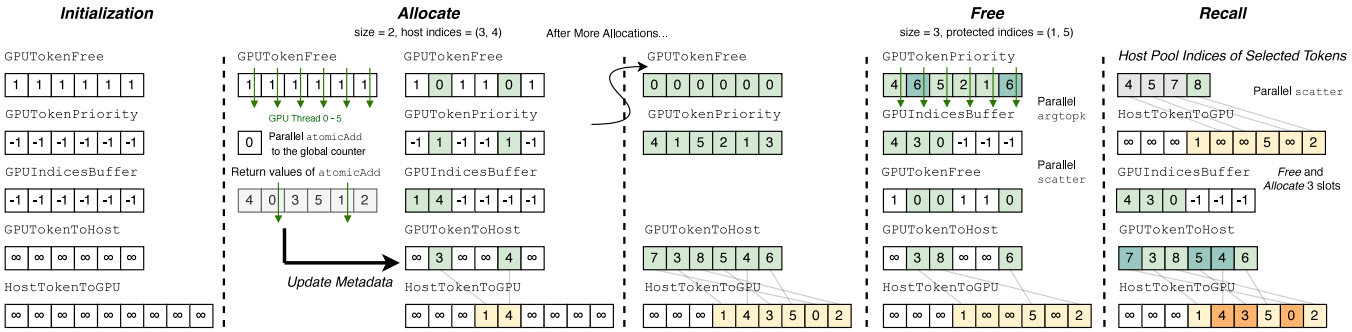

Figure 6: The metadata and update operations in the graph-friendly cache manager of ECHO.

recalled from the host pool. Tokens with the lowest priorities are evicted first, forming an LRU-like eviction policy, and eviction requires only updating the metadata. Notably, there is no need to transfer KV cache to the host pool during eviction, because the KV cache of all tokens has already been backed up to the host pool during generation.

Similar to allocation, *free* in existing systems relies on dynamic tensor concatenation, which is inefficient and not compatible with graph execution. To overcome this limitation, ECHO designs an efficient parallel *free* operation. As shown in Figure 6, it first increments the priorities of *protected* GPU slots to avoid releasing those slots. Specifically, the selected tokens of the sparse indexer are *protected* to prevent them from being evicted. Following the protection phase, a parallel `argtopk` operation is launched to obtain the indices of the GPU slots with the lowest priorities. The result indices are output to the `GPUIndicesBuffer`, thereby avoiding the creation of dynamic variable-length tensors that conflict with graph execution. A parallel `scatter` is then used to update `GPUTokenFree` and `GPUTokenToHost` using the output indices. `HostTokenToGPU` is also updated accordingly, where ∞ indicates that the corresponding token in the host pool is not present in the GPU pool. Tokens in the host pool are only freed upon request completion, which is managed by the per-model block tables.

Recall As shown in Figure 6, the cache manager obtains the host pool indices of the selected tokens from the sparse attention indexer, and uses a parallel `scatter` on `HostTokenToGPU` to identify which tokens are missing from the GPU pool. It then calls *free* and *allocate* to prepare GPU pool slots for the recalled tokens. Using the allocated GPU slot indices in `GPUIndicesBuffer` and the host pool indices of the missing tokens, the cache manager (i) updates `GPUTokenToHost` and `HostTokenToGPU` accordingly, and (ii) transfers the corresponding KV cache from the host pool to the GPU pool. The KV transfer is performed by accessing host memory directly in GPU kernels via unified virtual memory [59,72], which eliminates host-side interference, improves PCIe bandwidth utilization, and preserves graph execution.

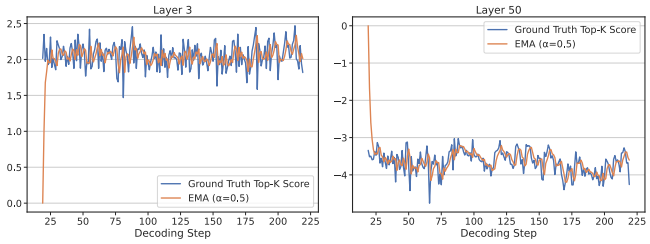

Figure 7: The 2048-th highest index scores in layers 3 and 50 of DeepSeek-V3.2 and prediction using EMA with $\alpha = 0.5$ during decoding.

4.3 Implementation

The implementation of ECHO is based on SGLang [69]. The cache manager utilizes PyTorch tensors [4] to maintain metadata, and the efficient parallel update operations are implemented with custom Triton [52] kernels. While management overhead can be further reduced through specialized CUDA kernels on NVIDIA GPUs, the Triton implementation offers better compatibility, enabling efficient dynamic offloading across a wider range of hardware backends.

5 Fused Lossless Prefetching

5.1 Intra-query Prefetching for Decoding

As discussed in Section 2.4, the top-k selection hinders prefetching during indexer computation. In contrast, top-p selection, which has been well studied in training-free sparse attention, allows a token to be selected as soon as its score exceeds a threshold p [28, 71]. Under a top-p scheme, during indexer computation, any token whose score surpasses p can be recalled immediately, enabling *intra-query prefetching*. Therefore, **prefetching becomes feasible if the top-k selection can be reformulated to top-p selection**.

A key numerical property we identify is that the k-th highest score at the current decoding step exhibits strong predictability from historical indexer scores. In Figure 7, we present the k-th ($k = 2048$) highest score of layers 3 and 50 in DeepSeek-

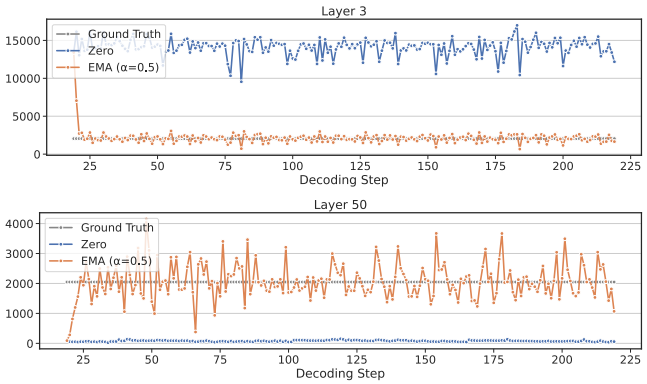

Figure 8: The number of candidate tokens for prefetching in layers 3 and 50 of DeepSeek-V3.2. The blue line uses 0 as the prediction, while the yellow line uses EMA with $\alpha = 0.5$.

V3.2 during decoding, using a 20K-token request from the ShareGPT dataset [42]. We predict the k-th highest score using exponential moving average (EMA). Specifically, let s_t denote the k-th highest score at step t. The k-th highest score at step $t+1$ is predicted with $\hat{s}_{t+1} = \alpha \cdot \hat{s}_t + (1-\alpha) \cdot s_t$, where $\alpha \in (0,1)$ is the smoothing factor. As shown in Figure 7, EMA can predict the k-th highest score of the next step accurately. Therefore, leveraging this prediction, ECHO can prefetch tokens whose scores exceed the predicted threshold during indexer computation, enabling efficient intra-query prefetching without violating top-k semantics.

In Figure 8, we present the number of tokens whose scores are larger than the predicted value, i.e., the candidate tokens for prefetching. As shown, the number of candidate tokens is close to $k = 2048$ at most decoding steps, indicating the effectiveness of our EMA prediction.

At some decoding steps, the number of candidate tokens exceeds 2048 as the predicted threshold may underestimate the true 2048-th highest score. Since prefetching too many tokens can slow down indexer computation, we set an upper bound on the number of prefetched tokens and enforce it using a global counter, as detailed in Section 5.3.

5.2 Inter-query Prefetching for Prefill

Compared to decoding, prefill natively offers the opportunity for *inter-query* prefetching. During prefill, the indexer partitions the input Q into multiple blocks and processes them sequentially. Since prefill sequences are typically long and span many Q blocks, once the scores for Q block i are computed, ECHO can prefetch the selected tokens for Q block i concurrently with the score computation for Q block $i+1$.

However, we find that obtaining the exact top-k for selection during indexer computation can significantly degrade indexer performance. Therefore, **ECHO uses an approximate top-k to obtain a subset of top-k tokens for prefetching**. Specifically, our approximate top-k builds on the radix select

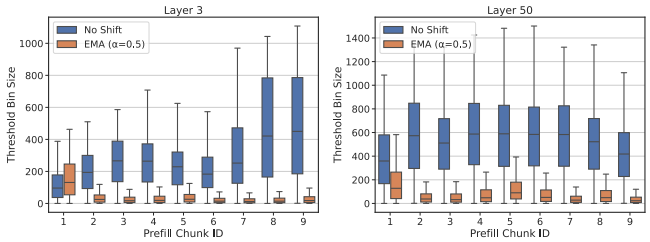

Figure 9: Threshold bin sizes of prefill chunks when computing approximate top-k with and without score shifts, profiled using DeepSeek-V3.2. The boxes and whiskers show the distribution of threshold bin sizes for tokens in the corresponding prefill chunk.

top-k algorithm [46], which constructs histograms of scores and filters higher scores in multiple rounds. Instead of applying all the filter rounds, we only build a coarse histogram and filter *by one round* to get a subset of top-k tokens with highest scores. The scores are mapped to the histogram with 256 bins based on their most significant 8 bits, and tokens within the largest bins are candidates for prefetching. Denote the size of bins as $\mathcal{S}_0, \mathcal{S}_1, ..., \mathcal{S}_{255}$. Selecting the highest j bins implies that $\mathcal{S} = \mathcal{S}_{255-j+1} + ... + \mathcal{S}_{255} \leq k$ and $\mathcal{S}_{255-j} + ... + \mathcal{S}_{255} > k$. The bin $255-j$ is referred to as the *threshold bin*, and its size determines the lower bound of the number of selected tokens, since $\mathcal{S} = \mathcal{S}_{255-j+1} + ... + \mathcal{S}_{255} > k - \mathcal{S}_{255-j}$.

Therefore, to approximate top-k as accurately as possible, we need to minimize the size of the threshold bin. Similar to intra-query prefetching, we use the EMA of the k-th highest score from the ending tokens of the previous prefill chunk to predict the threshold for the current chunk. During histogram construction, scores are shifted by subtracting the predicted k-th highest score to minimize the size of the threshold bin. As shown in Figure 9, shifting scores with the EMA prediction significantly reduces the size of the threshold bin, enhancing the accuracy of the top-k approximation.

5.3 Fused Prefetching Kernels with Pipelining

To hide overhead and benefit from prefetching, ECHO fuses prefetching operations into indexer computation kernels, leveraging *warp specialization* and *software pipelining*.

Warp Specialization Warp specialization is an advanced kernel optimization technique for modern GPUs [5]. Traditionally, GPUs follow the Single-Instruction Multiple-Thread (SIMT) programming model, where all threads within a *warp* execute the same instructions. However, modern GPUs increasingly feature specialized hardware units such as tensor cores and tensor memory accelerators (TMAs), which the SIMT model alone cannot fully exploit. Warp specialization addresses this by assigning distinct roles to different warp groups within a Cooperative Thread Array (CTA) [3]. For ex-

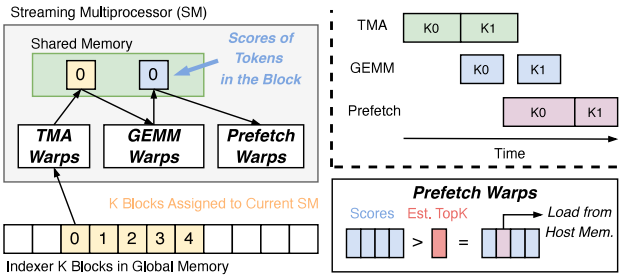

Figure 10: Data flow and timeline of the fused intra-query prefetching kernel for decoding.

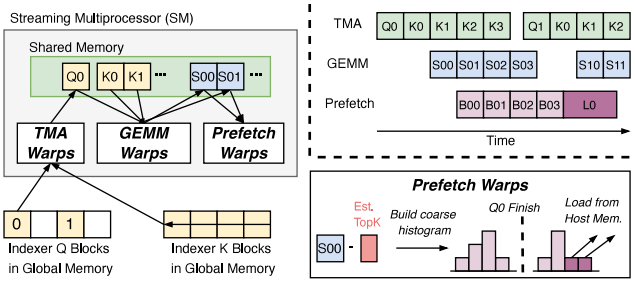

Figure 11: Data flow and timeline of the fused inter-query prefetching kernel for prefill.

ample, some warps load data from global memory via TMA, while others focus on computation with tensor cores.

Software Pipeline To further improve hardware utilization, asynchronous barriers allow the execution of different warp groups to overlap, forming a multi-stage software pipeline [5]. Software pipelining has been widely applied to overlap matrix multiplication with softmax or KV cache loading in attention computation [45, 61].

The fused prefetching kernels in ECHO are built based on the indexer computation kernels from DeepGEMM [12]. Specifically, the original kernel employs a two-stage pipeline, with producer TMA warps loading data from the global memory to shared memory, and consumer GEMM warps computing index scores using data in shared memory.

Figure 10 illustrates the fused intra-query prefetching kernel for decoding. Since the number of query tokens can be small during decoding, the indexer computation is partitioned by splitting the K cache of indexer. Each streaming multiprocessor (SM) computes index scores between a query vector and a part of indexer K cache. The query vector is persistent in shared memory, while the TMA warps iteratively load indexer K blocks from global memory to shared memory. The GEMM warps consume the K blocks, compute index scores and output to the shared memory. The scores are then consumed by the prefetch warps, which compare them with the estimated top-k score and identify tokens that can be prefetched. As shown, the kernel employs a three-stage pipeline of TMA, GEMM and prefetch. To prevent prefetching from blocking indexer computation, we allocate more pipeline stages to prefetching and use a global counter to control the number of prefetched tokens. The maximum number is proportional to context length, because indexer computation time is also proportional to context length.

The fused inter-query prefetching kernel for prefill is illustrated in Figure 11. Different from decoding, the indexer computation for prefill is partitioned by splitting on query. Each SM computes index scores between assigned Q blocks and all the corresponding K blocks. The TMA warps load Q blocks in the outer loop and K blocks in the inner loop, respectively. The GEMM warps output score blocks to shared memory, which are consumed by the prefetch warps. Scores are shifted using the estimated top-k scores as offsets, and scanned to build a histogram. Once computation of the current Q block is finished, the prefetch warps consult the histogram and load tokens with scores above the threshold. Meanwhile, TMA and GEMM warps continue computing scores for the next Q block, forming a software pipeline that overlaps computation and prefetching.

6 Evaluation

6.1 Setup

Testbed All experiments are conducted on a single node equipped with 8 NVIDIA H20 (96GB) GPUs connected to the host via 64GB/s PCIe Gen5. The node features a 224-core Intel Xeon Platinum 8480+ CPU with 1.5TB DRAM.

Baselines and Configurations We compare ECHO with the state-of-the-art LLM serving systems, including vLLM (v0.11.1) and SGLang (v0.5.4), with CUDA 12.9 and PyTorch 2.8. Both ECHO and SGLang are deployed using data parallelism (DP8) for attention and tensor parallelism (TP8) for MoE. vLLM is deployed using TP8 for both attention and MoE because vLLM does not support the DP+TP combination, and using expert parallelism (EP) for MoE incurs substantial GPU HBM costs and fails to launch on our 8×H20 node. We set the size of chunked prefill to 2048 for all the frameworks. CUDA graph during decoding is enabled for all the frameworks. The host KV cache pool in ECHO is set to 1.8M tokens, consuming about 1000GB of host memory.

Workloads Since the original FP8 DeepSeek-V3.2 cannot fit in the HBM of 8×H20, we evaluate using the 4-bit quantized DeepSeek-V3.2-Exp model [40], with the indexer and layers 0, 1, 2 and 60 left unquantized to preserve accuracy. For the long-context workload, we sample a subset of 318 requests with 80K–100K tokens from InfiniteBench [67], amounting

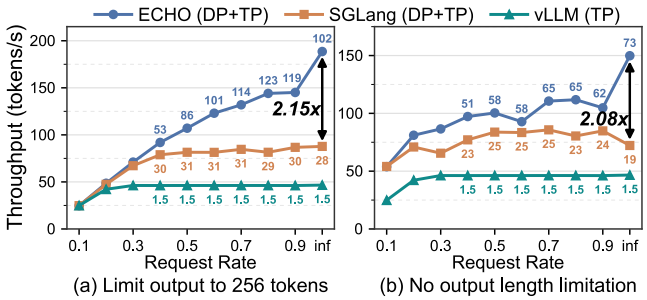

Figure 12: Generation throughput on InfiniteBench under varying request rates on 8×H20, with each system configured to use all available GPU HBM. Annotated numbers denote the effective batch size.

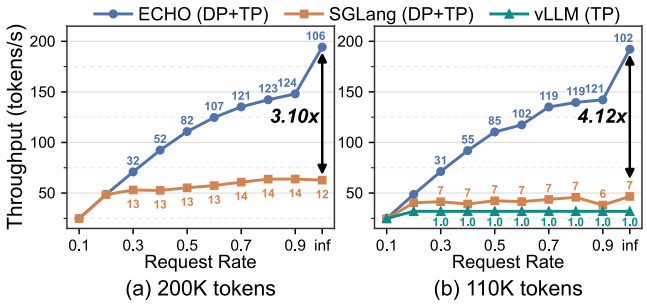

Figure 13: Generation throughput on InfiniteBench under constrained GPU HBM capacity, with output length limited to 256 tokens. Annotated numbers denote effective batch size.

to about 26M input tokens in total. For the short-context workload, we sample requests from the ShareGPT [42] dataset.

6.2 Token Generation Throughput

In this section, we evaluate the token generation throughput in a PD disaggregated setting. The 8×H20 node is launched as a decoding instance, and we pre-compute the KV cache of requests, which can be directly loaded by the decoding instance during inference. SGLang requires a pseudo prefill instance to work properly, incurring some GPU memory overhead.

Maximum Throughput We first evaluate the maximum throughput that can be achieved on the 8×H20 node by allocating all available GPU HBM. We set a fixed output length of 256 tokens for all requests to reduce variance from long-tail generations and ensure that all DP workers are saturated. As shown in Figure 12(a), ECHO achieves comparable generation throughput with SGLang and vLLM at low request rates, and scales more effectively as request rates increase. At `Inf` request rate, where all requests are sent to the serving systems at the same time, ECHO achieves up to 2.15× and 4.1× throughput improvements against SGLang and vLLM, respectively. The throughput improvement achieved by ECHO is

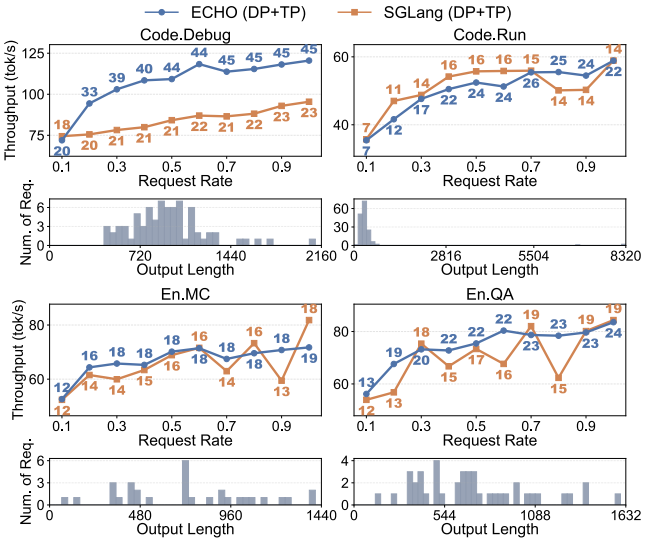

Figure 14: Per-task generation throughput on InfiniteBench without capping output length. The histograms below each task show the corresponding output-length distribution.

enabled by offloading the KV cache to the host pool, which yields larger effective batch sizes, i.e., the average number of active requests processed per decoding step, and higher hardware utilization. On the 8×H20 node, SGLang's 325K-token GPU KV pool supports only 3 to 4 concurrent InfiniteBench requests per GPU, yielding an effective batch size of about 30 across DP workers. vLLM's TP deployment further limits its total KV pool across 8 GPUs to 180K tokens due to duplicated MLA KV cache, reducing its effective batch size to about 1.5. However, vLLM partly offsets this limitation because TP deployment lowers per-step latency, so its throughput does not decrease in proportion to its effective batch size. In contrast, ECHO's host KV cache pool can accommodate 1.8M tokens and sustains much larger effective batch sizes.

Throughput without Output Length Limit Figure 12(b) reports generation throughput without imposing a fixed output-length cap. Compared with Figure 12(a), longer generations improve DP worker utilization at low request rates, increasing the throughput of both ECHO and SGLang. At higher request rates, however, long-tail generations introduce load imbalance across DP workers, leaving some workers idle and reducing the throughput of both systems. In contrast, vLLM uses pure TP and is not affected by DP load imbalance. Moreover, for long-tail requests, end-to-end throughput is dominated by inter-token latency, thus the higher ITL of ECHO narrows its throughput advantage over SGLang.

Throughput with Constrained GPU HBM Usage We further evaluate the generation throughput when the constraints on GPU HBM capacity are more severe, which can arise from

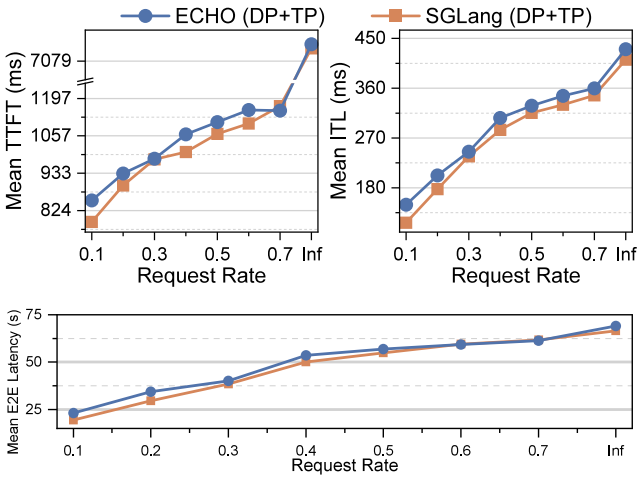

Figure 15: Mean TTFT, ITL, and end-to-end latency of ECHO and SGLang on the ShareGPT dataset.

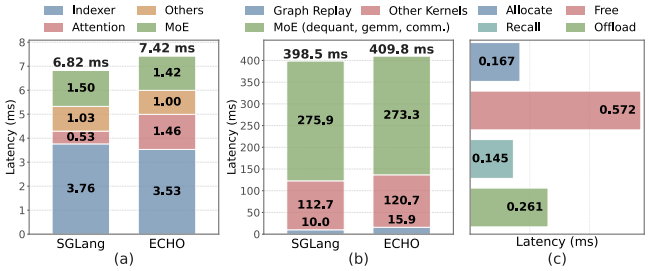

Figure 16: Latency breakdown of ECHO and SGLang. (a) Per-layer prefill latency. (b) All-layer decoding latency, decomposed into graph replay and kernel execution. (c) All-layer offloading overhead of ECHO in one decoding step, including allocate, free, recall, and KV cache offload.

larger MoE parameters. We set a fixed output length of 256 tokens to measure maximum throughput and compare with Figure 12(a). With a 200K-token GPU KV cache pool for both ECHO and SGLang, ECHO's throughput advantage increases to 3.10× at the `Inf` request rate (Figure 13(a)). When the GPU pool is further limited to 110K tokens for all three systems, SGLang and vLLM degrade substantially since their effective batch sizes are bounded by GPU pool size. In contrast, ECHO maintains high throughput by relying on host KV cache pool for a larger effective batch size, achieving up to 4.12× higher throughput than SGLang (Figure 13(b)). ECHO also slightly improves under constrained GPU HBM due to lower management overhead from the smaller GPU pool.

Per-task Throughput of InfiniteBench We further evaluate ECHO on individual InfiniteBench tasks without output length limit. As shown in Figure 14, ECHO improves average output throughput by 27.07% on Code.Debug, 2.83% on En.MC, and 7.11% on En.QA, while slightly underperforming SGLang by 1.74% on Code.Run. The gains are less consistent than in Figure 12 for two reasons. First, the per-task workloads contain relatively few requests (75, 160, 31, and 42, respectively), which limits the available concurrency and prevents them from saturating all DP workers. Second, as shown by the histograms, per-task output lengths are more skewed, causing a few long-tail requests to dominate task runtime and allowing SGLang's lower inter-token latency to offset ECHO's higher effective batch size.

6.3 Inference Latency

In this section, we evaluate inference latency in a mixed PD setting. We randomly sample 100 requests from the ShareGPT [42] dataset as a short-context, light-load workload.

The mean TTFT, ITL, and end-to-end latency of ECHO and SGLang are presented in Figure 15. Overall, ECHO maintains latency close to SGLang while enabling higher long-context throughput. The TTFT changes by at most +7.9% across request rates, mainly due to the overhead of backing up the generated KV cache to host memory during prefill. The ITL overhead is more visible because decoding performs per-layer cache management and KV recall, ranging from +2.7% to +27.8%. This overhead is largest under light load because each decoding step processes fewer concurrent requests, leaving less computation to amortize the fixed cache-management and recall costs; it drops to 2.7–7.7% for request rates of 0.3 and above. As a result, the end-to-end latency overhead is 15.9–19.2% at low request rates of 0.1–0.2, but decreases to at most 7.2% for request rates of 0.3 and above, and remains below 4.6% from 0.5 to `Inf`. The results suggest that although ECHO minimizes the overhead of dynamic KV cache offloading, it still introduces a latency tradeoff and is most beneficial for throughput-oriented long-context serving.

Latency Breakdown Figure 16 presents a detailed latency breakdown of ECHO on the ShareGPT workload under the `Inf` request rate. For prefill, ECHO increases per-layer latency from 6.82 ms to 7.42 ms, an 8.8% increase. The increase mainly appears in the attention component, reflecting the KV cache management and offload overhead introduced by ECHO. For decode, Figure 16(b) reports the all-layer latency, which ECHO increases by 2.8% over SGLang. We decompose the latency into graph replay, MoE and other kernels. MoE accounts for about 70% of the all-layer latency, including dequantization, GEMM, and AllReduce communication. ECHO adds 5.9 ms to graph replay, mainly due to CPU-side launch and metadata overhead. The offloading-specific overhead remains small, as shown in Figure 16(c), where allocation, free, recall, and KV offload take 0.167 ms, 0.572 ms, 0.145 ms, and 0.261 ms across all layers, respectively, totaling 1.15 ms, or only 0.28% of the all-layer decoding latency. Specifically, allocation and free operate on the recalled KV slots, averaging 37

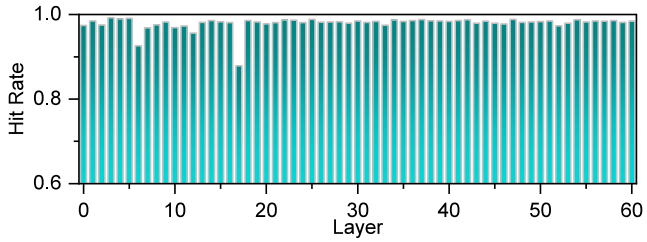

Figure 17: Per-layer GPU pool hit rates of DeepSeek-V3.2 (AWQ) on InfiniteBench, averaged across decoding steps.

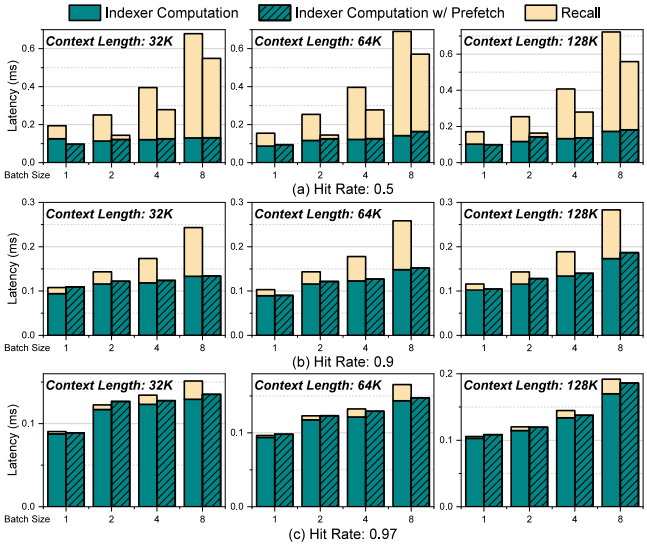

Figure 18: Latency comparison between disabling and enabling intra-query prefetching.

tokens per decoding step, while KV offload writes one newly generated token per active request, averaging 13 tokens per DP worker. These results show that graph-friendly cache management keeps dynamic offloading overhead modest, while high GPU-pool hit rates further reduce recall traffic. The remaining 6.8 ms increase mainly comes from ReduceScatter synchronization across DP workers, due to ECHO's larger concurrency and communication jitter.

6.4 In-Depth Performance Analysis

6.4.1 Hit Rates of the GPU Pool

We collect and dump the hit rates of selected tokens in the GPU pool of each layer when serving the InfiniteBench in Section 6.2, and present the hit rates averaged across decoding steps in Figure 17. As shown, the hit rates for most layers are consistently high, ranging from 0.97 to 0.99. The hit rates of layer 12 and layer 17 are at 0.95 and 0.88, respectively. The high hit rates are consistent with the observation of vertical lines in the attention pattern [23], or similar token selection of adjacent query tokens [30].

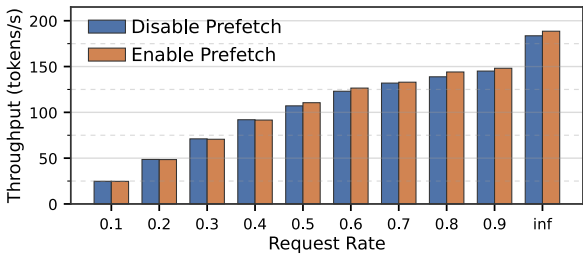

Figure 19: End-to-end generation throughput comparison between disabling and enabling intra-query prefetching.

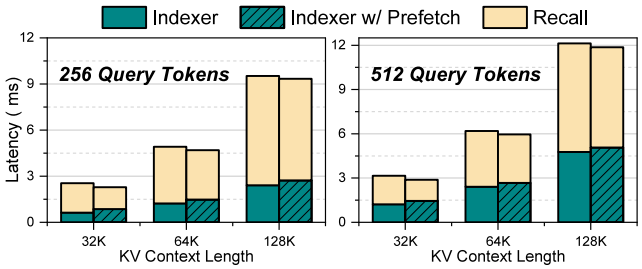

Figure 20: Latency comparison between disabling and enabling inter-query prefetching.

6.4.2 Intra-query Prefetching for Decoding

In Figure 18, we present the latency of indexer computation with and without intra-query prefetching across different context lengths, batch sizes and GPU pool hit rates, along with the latency of their corresponding guaranteed recall. As shown, intra-query prefetching achieves significant total latency reduction for hit rates of 0.5 and 0.9, up to 1.29× and 1.51×, respectively. Specifically, the recall overhead can be almost completely overlapped for hit rate 0.9. The improvements for hit rate 0.97 are modest given that most of selected tokens are already available in the GPU pool and do not require recall.

We further evaluate its end-to-end impact under the same setting as Sec. 6.2. As shown in Figure 19, enabling intra-query prefetching improves generation throughput by up to 4%. This gain is smaller than the microbenchmark improvement since the GPU pool hit rate remains high on InfiniteBench, thus only a small fraction of selected tokens need to be recalled and can benefit from prefetching. In addition, as demonstrated in Figure 16(c), MoE layers account for a large share of end-to-end decoding time, limiting the impact of reducing recall overhead. Using expert parallelism or a more efficient MoE kernel would reduce this bottleneck and make the end-to-end benefit of prefetching more pronounced.

6.4.3 Inter-query Prefetching for Prefill

In Figure 20, we present the latency of indexer computation with and without inter-query prefetching across differ-

ent KV context lengths and batch sizes, using 256 and 512 query tokens, respectively. Compared to decoding, the recall overhead during prefill is much higher because the selection for each query token is independent, resulting in up to *number of query tokens* $\times k$ tokens being selected in total. Consequently, the benefits of prefetching are limited, yielding at most a 1.1$\times$ improvement. We do not include a separate end-to-end throughput ablation for inter-query prefetching, since the PD-disaggregated evaluation in Sec. 6.2 uses precomputed KV cache. Moreover, the microbenchmark suggests that its end-to-end gain would be modest under our conservative assumptions. However, this result underestimates the potential of inter-query prefetching, as our evaluation assumes that the top-k tokens selected by different query tokens are randomly distributed, whereas prior work has observed substantial overlap across query tokens [30]. Exploiting this overlap could reduce redundant recall traffic and further improve inter-query prefetching, which we leave to future work.

7 Discussion

Generalizability to Other Sparse Attention Since DSA is currently the only publicly available native sparse attention validated on large-scale models, ECHO mainly targets DSA and MLA. Nonetheless, the graph-friendly cache manager of ECHO is compatible with both training-time and training-free sparse attention, since it addresses the general system problem of managing dynamic sparsity patterns where selected KV entries must be evicted and recalled during decoding. It is naturally suited to token-wise sparse attention such as DSA, and can also support block-wise sparse attention by changing the metadata granularity and extending the kernels with the KV-head dimension used in GQA-based models. Overall, the cache manager of ECHO should be viewed as a system substrate for dynamic sparse-attention serving rather than a design tied only to DSA, although DSA remains the most compelling target today because of its native model support and strong long-context accuracy. In contrast, intra-query and inter-query prefetching rely on properties of the DSA indexer, including a selection boundary that is numerically predictable across decoding steps and a prefill procedure that exposes a sequence of query blocks whose candidate KV entries can be identified before the exact selection finishes. Other sparse attention mechanisms can benefit from the same prefetching framework when they expose similar early-selection signals, such as threshold-based selection or multi-stage top-k selection. This also suggests an opportunity to co-design training-time or training-free sparse attention with prefetch-friendly selection mechanisms, which we leave to future work.

Throughput-Latency Tradeoff and Practical Deployment As discussed in Section 6.3, offloading introduces latency overhead from cache management and data transfer, making ECHO most attractive for throughput-oriented long-context serving. Recent offloading systems make a throughput-first tradeoff, using dual-batch execution to overlap offload overhead with computation, but may further increase the latency [7]. Although this makes offloading a throughput-first technique today, we believe its additional latency can be substantially narrowed. Specifically, cache-management overhead can be reduced through more dedicated kernel optimizations [44], while transfer overhead will benefit from faster host-GPU interconnects. For example, NVLink-C2C provides 900GB/s on Grace-based systems and is expected to reach 1.8TB/s on Vera-based systems [36]. These trends suggest that offloading can remain practical even for latency-sensitive deployments, while its main advantage today is still in improving throughput under long-context pressure.

Applicability when KV Cache is More Plentiful Although recent models reduce per-token KV-cache cost through quantization and hybrid attention [14,37,51], and newer accelerators provide 200GB or more of HBM, we believe KV-cache capacity will remain an important bottleneck and that offloading will continue to matter. On one hand, long-context inference is becoming increasingly common in agentic workloads, where context lengths of 1M tokens are already entering mainstream use, and the demand for even longer context is likely to continue growing. On the other hand, model parameters, especially MoE parameters, continue to scale toward and beyond the trillion-parameter regime, leaving less HBM available for KV cache under a fixed hardware budget. As a result, improvements in KV cache efficiency and HBM capacity are likely to be offset by simultaneous growth in context length and model size, making efficient offloading and hierarchical KV cache management a persistent system concern.

8 Conclusion

ECHO is a serving system for native sparse attention models under long-context workloads, built around efficient KV cache offloading. ECHO incorporates a graph-friendly cache manager that minimizes management overhead. To reduce recall overhead, ECHO introduces lossless intra-query prefetching based on the numerical predictability of index scores, as well as inter-query prefetching based on the sequential processing of queries. Experimental results demonstrate that ECHO delivers up to 2.1$\times$ generation throughput improvement over the state-of-the-art LLM serving system SGLang on DeepSeek-V3.2 under long-context workloads, breaking the GPU memory capacity bottleneck.

A Artifact Appendix

Abstract

This artifact provides the source code, pre-built environment, scripts, and datasets to reproduce the main results of ECHO, a KV cache offloading system with lossless prefetching for serving native sparse attention LLMs, implemented on top of SGLang. It supports running ECHO and the SGLang baseline on DeepSeek-V3.2 and reproducing the end-to-end throughput, end-to-end latency, fused prefetch kernel, and top-k analysis results reported in the paper.

Scope

The artifact validates the central claims of the paper, namely that ECHO improves generation throughput over the SGLang baseline under long-context workloads, both when all GPU HBM is allocated to the KV cache and under constrained GPU pool sizes, while preserving competitive latency. Specifically, it reproduces: end-to-end generation throughput (Figures 12–13), per-task throughput on InfiniteBench (Figure 14), end-to-end latency on ShareGPT (Figure 15), the fused intra-/inter-query prefetch kernel microbenchmarks (Figures 18–19), and the top-k analysis (Figures 7–9).

Contents

The artifact is distributed in two complementary forms:

- `echo-v0.tar.zst` — a pre-built Docker image with all dependencies (including compiled `sglang` and `DeepGEMM`) and the InfiniteBench test dataset, recommended for reproducing the end-to-end experiments.
- `ECHO.tar.gz` — a lightweight source-only package (`sglang` and `DeepGEMM` not pre-compiled) convenient for browsing the code.

Both forms include the end-to-end experiment scripts, the fused-kernel microbenchmark, and the top-k analysis pipeline (detailed in the experiment workflow below). Two configurations are compared throughout: `no-offload` (the SGLang baseline) and `offload` (ECHO).

Hosting

The artifact is hosted as a Zenodo record at https://zenodo.org/records/20376436, which contains both packages above, this guide, and the integrity checksum for the Docker image.

Requirements

A single server with 8 NVIDIA H20 GPUs (96 GB HBM each), 1.5 TB CPU memory, and GPUs connected to the host via PCIe Gen5. The software environment requires `docker` with GPU support and `zstd`; all dependencies are otherwise bundled in the Docker image. A large local disk (≥400 GB) is needed to store the downloaded DeepSeek-V3.2 (W4 AWQ) model.

Experiment Workflow

The full procedure is summarized below; all commands except setup are run *inside* the container. Each end-to-end script runs the SGLang baseline (`no-offload`) followed by ECHO (`offload`) on the same deployment, sweeping request rates and writing one log per rate to its output directory. By default the scripts sweep ten request rates (0.1–0.9 and `inf`); passing `--request-rates 0.8,0.9,inf` yields a faster run.

1. **Set up the environment.** Load and launch the Docker image, then download the W4 AWQ DeepSeek-V3.2 weights and activate the prepared environment (all later commands run inside the container):

```
zstd -dc echo-v0.tar.zst | docker load
docker run --privileged --gpus=all -it \
  -v /a_large_disk:/data1 --network host \
  --shm-size=128g --name echo-container echo:v0
modelscope download --local_dir \
  /data1/dsv32awq QuantTrio/DeepSeek-V3.2-AWQ
source /workspace/ECHO/.venv/bin/activate
```

2. **End-to-end throughput and latency (Figures 12–15).** From `/workspace/ECHO/sglang`, run the four sweeps below: full-HBM throughput (Figure 12), constrained-pool throughput (Figure 13), per-task throughput (Figure 14), and ShareGPT latency (Figure 15). Results are written under `infini-318/`, `infini-task/`, and `sharegpt-100/`, each split into `no-offload-<MMDD>/` and `offload-<MMDD>/`:

```
cd /workspace/ECHO/sglang
bash e2e_test_pd_infini.sh
bash e2e_test_pd_infini.sh \
  --no-offload-max-total-tokens 200_000 \
  --offload-nsa-dev-cache-size 200_000
bash e2e_test_pd_infini_task.sh
bash e2e_test_mix_sharegpt.sh
```

3. **Fused prefetch kernels (Figures 18–19).** From `/workspace/ECHO/DeepGEMM`, run the kernel microbenchmarks for intra- and inter-query prefetch:

```
cd /workspace/ECHO/DeepGEMM
python test_fuse.py decode_prefetch
python test_fuse.py prefill_prefetch
```

4. **Top-k analysis (Figures 7–9).** Regenerate the analysis figures from the bundled logits tensors; final PDFs appear under `echo/pdfs/`:

```
cd /workspace/ECHO/top-k-figures
pip install -r requirements.txt
./run_pipeline.sh
```

If a server fails to start, inspect the per-phase logs (e.g., `decode.log`, `router.log`) in the working directory, and run `scripts/killall_sglang.sh` to clear any leftover processes between runs.

No Buffer, No Bottleneck: Efficient Zero-Copy KV Cache Offloading for Long-Context LLMs

Shutian Luo Haiying Shen
Department of Computer Science, University of Virginia

Abstract

Long-context large language models (LLMs) store computed attention *key* and *value* (KV) matrices from previous decoding steps to avoid full-sequence recomputation. While this reuse reduces computation, the KV cache grows linearly with sequence length, exerting significant pressure on GPU memory capacity. Existing offloading stores KV blocks in CPU memory but requires extra GPU buffers, wasting GPU memory and doubling CPU–GPU transfers, which creates capacity and bandwidth bottlenecks.

We present DirectKV, to our knowledge, the first zero-copy KV cache offloading system for modern heterogeneous CPU–GPU platforms such as NVIDIA GH200/GB200 with high-bandwidth NVLink-C2C interconnects. By leveraging NVLink-C2C instead of PCIe, DirectKV makes CPU memory a practical extension of GPU KV-cache capacity during long-context inference. DirectKV eliminates the GPU staging buffer (no buffer) by enabling GPU kernels to directly access CPU-resident KV cache, and substantially reduces the CPU–GPU data-movement bottleneck (no bottleneck) through CPU-memory-aware CUDA kernels tailored for heterogeneous CPU–GPU platforms. It further fuses KV generation with attention computation into a single CUDA kernel and employs warp-level pipelining to overlap KV fetching, computation, and write-back, thereby hiding stalls caused by CPU memory access. On GH200, DirectKV reduces CPU–GPU transfer volume by up to 50%, cuts GPU memory usage by 43%, and improves end-to-end performance by up to 1.2× compared to existing solutions.

1 Introduction

Large language models (LLMs) with long-context capabilities underpin applications such as multi-turn dialogue, in-context learning, and long-horizon code generation [18, 35, 50, 51]. To sustain throughput, modern inference engines maintain a *key–value (KV) cache* that stores previously computed *K*/*V* tensors [37]. During attention, each new query Q must attend to all prior K and V entries; caching avoids recomputation and reduces compute cost from quadratic to linear in sequence length. However, this efficiency comes at the expense of memory: KV cache size grows linearly with both sequence length and model dimension. For billion-parameter LLMs with 128K tokens, the cache alone can demand hundreds of gigabytes [28], far exceeding high-bandwidth GPU memory (HBM) capacity.

To address this issue, existing systems explore several CPU offloading strategies. Swap-based approaches [46, 53–55] place KV blocks in CPU memory (or SSD) and use large GPU staging buffers to overlap transfers with computation. Other systems store KV in remote or disaggregated memory and fetch it on demand [39, 42], but still follow a swap-like model in which storage and computation are separated: KV must be staged into GPU memory before attention. Crucially, all of these designs still stage KV cache into GPU memory along the critical path and depend on extra GPU-resident buffers during attention computation, because their attention kernels assume that all operands (including KV) reside in HBM. A third line of work partially offloads attention computation and KV cache to CPUs [27, 34, 41, 57], or moves the entire attention computation onto CPUs to avoid repeated PCIe transfers [31], but in doing so sacrifices the full compute capability of the GPU.

In short, none of these systems strikes the ideal balance of *using CPU memory as low-cost KV storage without additional HBM-resident KV buffers while fully exploiting GPU compute for high-performance attention*. They remain fundamentally limited by the large bandwidth gap between CPU–GPU interconnects (40–60 GB/s over PCIe) and HBM (3–4 TB/s), which leaves GPU compute units underutilized and exacerbates the GPU memory wall [30].

Recent CPU–GPU superchips such as NVIDIA GH200 and GB200 [14, 15] provide up to 900 GB/s bidirectional bandwidth via NVLink-C2C—7× higher than PCIe Gen5 [16]. This creates new opportunities for efficient KV cache offloading. However, existing systems such as Pie [53] still depend on staging buffers in HBM, consuming scarce GPU memory

and preventing full exploitation of this capability.

A more promising direction is *zero-copy*, where GPU kernels directly access CPU-resident KV tensors [2, 4]. Zero-copy eliminates staging buffers and reduces HBM usage, but naive application performs poorly: matrix multiplication kernels are tuned for HBM-resident tensors, so repeatedly fetching operands from CPU memory exposes the bandwidth gap and further lowers GPU L2 hit rate. Our measurements show that naïve zero-copy can be over 20× slower on PCIe and still 2× slower on NVLink-C2C (see § 2.3).

Our key observation is that *shared memory (SMEM)* within each streaming multiprocessor (SM) can be leveraged to make zero-copy practical. Acting as a fast on-chip buffer, SMEM enables flexible tiling strategies that restructure data access in matrix multiplication. By tiling through SMEM, we shift bandwidth pressure from the CPU–GPU interconnect to HBM, fully exploiting NVLink-C2C while maintaining GPU compute efficiency. This makes near-HBM performance achievable without staging buffers, moving closer to the ideal design: *CPU memory for cheap storage, GPU for high-performance computation*.

Building on this insight, we propose DirectKV, to our knowledge the first efficient zero-copy KV cache offloading system for NVIDIA GH200 Superchips. DirectKV targets long-context, latency-sensitive decoding workloads that require large effective batch sizes under tight GPU memory budgets. To relieve GPU memory pressure and fully exploit host DRAM, DirectKV centers on a *CPU-memory-aware tiling strategy* for matrix multiplication that deliberately shifts bandwidth demand from the CPU–GPU interconnect to HBM, using shared memory to stream CPU-resident tensors efficiently and reuse them across tiles. This design allows *zero-copy access to CPU-resident KV* to approach HBM-resident performance without relying on GPU staging buffers.

Beyond optimized tiling, DirectKV integrates two complementary techniques: (i) fine-grained warp-level pipelining that overlaps data transfer with computation, and (ii) kernel fusion of KV projection and attention that keeps *K*/*V* tensors in SMEM rather than round-tripping them through CPU memory. Together, these optimizations eliminate redundant KV transfers, hide interconnect latency, conserve HBM capacity, and deliver high throughput.

We build DirectKV[1] on FlashAttention-3 [44], but fundamentally extend it from GPU-resident execution to heterogeneous CPU–GPU settings on GH200, where interconnect bottlenecks emerge as the key challenge. Compared to prior offloading approaches [34, 46, 53], DirectKV reduces CPU–GPU transfer volume by up to 50%, lowers GPU memory usage by 43%, and improves end-to-end performance by up to 1.2×, all while maintaining full attention accuracy.
In summary, this paper makes the following contributions:

- *A new design for KV cache offloading.* We propose *DirectKV*, to our knowledge the first zero-copy offloading system for NVIDIA superchips. DirectKV eliminates staging buffers (no buffer) and substantially reduces the dominant CPU–GPU data-movement bottleneck (no bottleneck).

- *Kernel–memory co-design.* We identify why naïve zero-copy underperforms—repeated CPU-memory fetches and poor L2 locality—and introduce three optimizations: (i) CPU-memory-aware tiling to shift the bottleneck to HBM, (ii) warp-level pipelining to overlap transfer and compute, and (iii) kernel fusion to eliminate redundant KV refetching.

2 Background and Motivations

2.1 Attention Module in LLM Inference

LLM inference consists of multiple Transformer blocks, each containing an attention mechanism followed by a feed-forward network [28, 50, 51, 56]. The input to a Transformer block is a tensor $X \in R^{N\times D}$, where N is the number of tokens and D is the model dimension. The attention module projects X into three matrices: query (Q), key (K), and value (V), using separate weight matrices W^Q, W^K, and W^V:

$$Q,K,V = XW^Q,\ XW^K,\ XW^V, \quad W^Q,W^K,W^V \in R^{D\times d_k}.$$

For multi-head attention [45], Q, K, and V are reshaped into $R^{H\times N\times d}$, where H is the number of heads and $d = D/H$ is the per-head dimension. A common variant is *grouped-query attention (GQA)* [20], where multiple query heads share the same key and value heads to improve efficiency.

For LLM models that incorporate rotary positional embeddings (e.g., LLaMA [28, 50]), the queries and keys are further augmented with *rotary transformations*:

$$\tilde{Q},\tilde{K} = \mathrm{RoPE}(Q,K),$$

where RoPE applies position-dependent rotations in the query/key space to encode relative positional information. In contrast, other models (e.g., OPT [56]) omit this step and rely on alternative positional encodings.

Finally, for each head, the *scaled dot-product attention* is computed as:

$$\mathrm{Attention}(Q,K,V) = \mathrm{softmax}\left(\frac{QK^\top}{\sqrt{d}}\right)V.$$

LLM inference proceeds in two phases [59]: the prefill phase, where the full input sequence is processed in parallel to initialize the KV cache, and the decode phase, where tokens are generated autoregressively, each new query attending to all cached K/V.

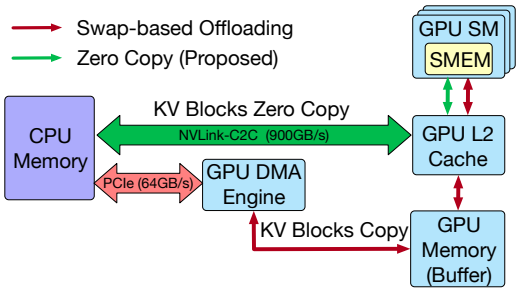

Figure 1: KV cache offloading via swapping and zero copy.

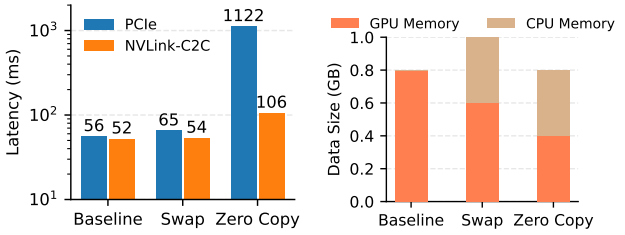

(a) Latency comparison. (b) Memory usage.

Figure 2: Comparison among three mechanisms for matrix multiplication.

2.2 KV Cache Offloading

During autoregressive inference, the KV cache stores K and V tensors from prior decoding steps, reducing attention cost from quadratic to linear in sequence length. Yet the cache grows *linearly* with context length and model dimension, quickly exhausting GPU memory. Existing systems offload KV blocks to CPU memory through HBM staging buffers.

2.2.1 Swap-based KV Cache Offloading

As shown by the red path in Fig. 1, KV blocks are stored in CPU memory and are copied to GPU memory before use via a GPU copy engine [13]. To reduce stalls, systems overlap these transfers with computation. However, PCIe bandwidth (64 GB/s) is far lower than HBM bandwidth (4 TB/s), making data movement a bottleneck. To hide transfer latency, a large GPU buffer is required, wasting valuable GPU memory. Even then, poor prefetch coordination can still cause GPU stalls. Moreover, swap-based designs perform layer-by-layer swap-in and swap-out of KV blocks, doubling interconnect traffic and further constraining scalability.

Swap-based offloading can prevent CUDA Graphs from being replayed unchanged. CUDA Graphs reduce per-token launch overhead by capturing and replaying a fixed sequence of GPU operations. However, swap-based KV offloading introduces explicit `cudaMemcpyAsync` [17] operations for KV swap-in/out, whose addresses vary across decoding steps as different KV blocks are selected. These dynamic transfer addresses can force graph updates or re-capture, reducing the benefits of CUDA Graphs in practical serving systems.

2.2.2 Zero-Copy KV Cache Offloading

As shown by the green path in Fig. 1, zero-copy KV cache offloading [4] allows GPU kernels to directly access CPU-resident KV blocks. This eliminates explicit transfers and HBM staging buffers. Once KV blocks are device-accessible, the attention kernel can fetch them directly and use asynchronous tiled data movement to bring KV tiles into SMEM for computation.

Compared with swap-based offloading, zero-copy is better suited for CUDA Graph execution. Because KV blocks are loaded inside the attention kernel rather than through explicit memory-copy operations, dynamic KV-block selection changes only the kernel inputs or internal address resolution, not the captured graph topology. This allows the graph to be replayed without per-step updates or re-capture.

The effectiveness of zero-copy primarily depends on CPU–GPU bandwidth rather than access latency. KV-cache access in long-context attention is naturally coarse-grained: each SM fetches KV tiles of around 100 KB, aligned with its SMEM capacity, and more than 100 SMs can fetch such tiles concurrently. This creates MB-scale aggregate data movement from CPU memory to the GPU. In this regime, sustained CPU–GPU bandwidth becomes the dominant bottleneck. Recent CPU–GPU platforms such as NVIDIA GH200 make this direction practical with NVLink-C2C, which provides up to 900 GB/s bidirectional bandwidth and allows CPU memory to act as an effective extension of GPU KV-cache capacity.

2.3 Challenges in KV Cache Offloading

Even with NVLink-C2C, a significant *bandwidth gap* remains between the CPU–GPU interconnect (900 GB/s bidirectional) and HBM bandwidth (4 TB/s). In the GEMM case study, repeated operand reuse across the $O(n^3)$ computation amplifies remote-memory traffic. In attention, a similar effect appears when CPU-resident KV tiles are repeatedly fetched across query, head, and batch dimensions.

To illustrate this challenge, we conduct a case study comparing swap-based and zero-copy KV cache offloading using a matrix multiplication benchmark, $C = A \times B$, where A, B, and C are square matrices of size $n \times n$ ($n = 10240$, each 400 MB). We evaluate three configurations: (i) *Baseline*, where both A and B reside entirely in GPU memory; (ii) *Swap*, where a 200 MB GPU buffer is allocated to temporarily store portions of B transferred from CPU memory via PCIe or NVLink-C2C during multiplication; and (iii) *Zero-Copy*, where B resides entirely in CPU memory and is accessed directly by the GPU over PCIe or NVLink-C2C without intermediate buffering. Experiments are conducted on two hardware platforms: an NVIDIA H100 connected to the host via PCIe and an NVIDIA GH200, where an H100 GPU is tightly coupled to a Grace

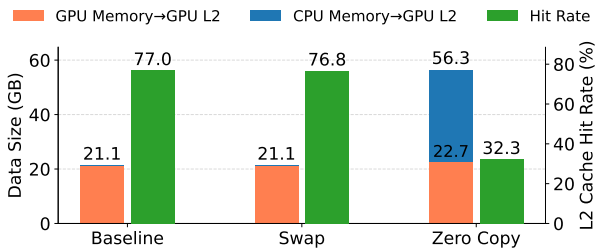

Figure 3: Data fetching and L2 cache hit rate.

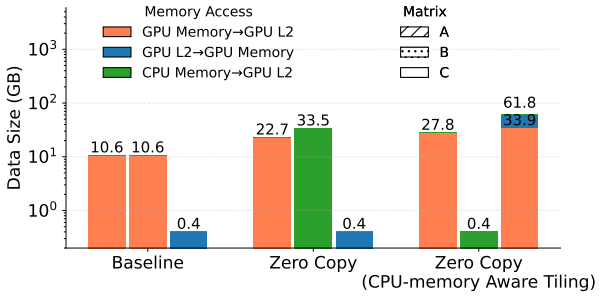

Figure 4: Data movement breakdown across three matrix multiplication strategies.

CPU via NVLink-C2C.

Zero-Copy saves GPU memory but still incurs performance penalties. As shown in Fig. 2(a), the *Swap* configuration adds less than 10% overhead on PCIe and about 5% on NVLink-C2C due to asynchronous data transfer. In contrast, *Zero-Copy* incurs over a 20× slowdown on PCIe (1122 ms vs. 56 ms) and a 2× slowdown on NVLink-C2C (106 ms vs. 52 ms). This penalty arises because *Zero-Copy* repeatedly fetches B from CPU memory throughout the $O(n^3)$ computation, fully exposing the bandwidth gap between CPU–GPU interconnects and HBM. While costly in performance, *Zero-Copy* eliminates the need for a large GPU buffer, reducing memory usage by 50% compared to *Baseline* and by 33% compared to *Swap*, as shown in Fig. 2(b).

Zero-Copy further reduces GPU L2 cache efficiency. To quantify this effect, we measure data traffic and L2 hit rate on GH200 (Fig. 3). *Baseline* and *Swap* perform similarly since both A and B reside in GPU memory, achieving high L2 hit rates (∼77%) and 21.1 GB of HBM-to-L2 traffic—well above the matrix size due to repeated accesses in the $O(n^3)$ computation. In contrast, *Zero-Copy* suffers frequent stalls because CPU–GPU transfers (900 GB/s, 450 GB/s per direction) are much slower than HBM-to-L2 transfers (4 TB/s), increasing CPU-to-GPU traffic to 22.7 GB while reducing the L2 hit rate to 32.3%—a 58% drop compared to *Baseline*/*Swap*. This shows that reduced cache locality, in addition to limited bandwidth, compounds the performance gap of naïve zero-copy offloading.

2.4 Opportunity: Kernel-memory Co-Design

GPU kernels support flexible data access patterns, enabling customized CUDA implementations that can optimize *zero-copy* KV cache access from CPU memory. This flexibility creates opportunities to mitigate the challenges discussed above. In particular, we focus on two key techniques — *tiling* and *warp-level pipelining* — to improve data locality, reduce redundant transfers, and better exploit the available CPU–GPU bandwidth.

2.4.1 Tiling Technology for Asymmetric Bandwidth

To better understand optimization opportunities, we revisit matrix multiplication with a focus on *tiling technology*. Modern GPUs have much smaller cache capacity than global memory but provide high-bandwidth shared memory within each streaming multiprocessor (SM). CUDA kernels can explicitly control shared memory usage, enabling computation to be organized in *tiles*: small submatrices of A and B are fetched from global memory into shared memory, multiplied to produce a partial tile of C, and the partial results are accumulated in shared memory before writing the final output to global memory. This tiling mechanism reduces global memory accesses and provides flexibility to redesign the computation pattern for cases where one input matrix resides in CPU memory.

Figure 4 shows the baseline access pattern. In *Baseline* (both A and B in GPU memory), the bottleneck is fetching A and B from GPU memory to L2 cache, each at 10.6 GB, while writing only 0.4 GB of C back to GPU memory. CUTLASS-based matrix multiplication iterates over tiles of A and B independently to compute each tile of C, with no data dependency between tiles. However, in *Zero-Copy*, where B resides in CPU memory, the asymmetric bandwidth between NVLink-C2C (900 GB/s, 450 GB/s per direction) and HBM (4 TB/s) causes the data fetched from CPU memory to be amplified by repeated accesses, reaching 33.5 GB—over 3× the original tile size—making CPU-to-GPU transfers the bottleneck.

To address this, we develop a *CPU-memory-aware tiling* strategy for matrix multiplication (details in § 5.1). The key idea is to shift bandwidth pressure away from the CPU–GPU interconnect onto on-device HBM. Instead of iterating over tiles of A and B, our optimized kernel iterates over tiles of A and C, while keeping the current B tile resident in SM shared memory. This reduces CPU-to-GPU traffic for B from 33.5 GB to just 0.4 GB, directly attacking the main bottleneck, since HBM bandwidth is roughly an order of magnitude higher than CPU–GPU interconnect bandwidth. The trade-off is that C must now be read from and written to HBM more frequently for accumulation, increasing HBM traffic by about 2× (from 33.5 GB over the CPU–GPU interconnect to 61.8 GB + 33.9 GB in HBM). However, this extra load can be absorbed by HBM's higher bandwidth while substantially relieving the CPU–GPU bottleneck. As shown in Fig. 5, this optimization reduces latency from 106 ms to 54 ms (a 49% performance improvement) and increases the L2 cache hit

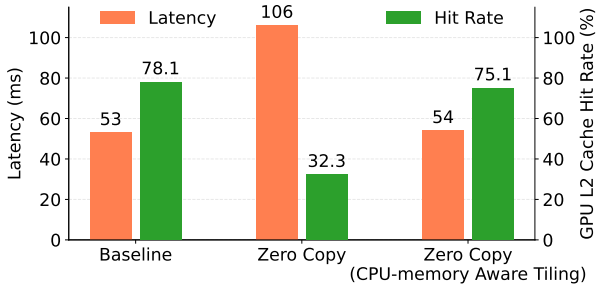

Figure 5: Performance and GPU L2 cache hit rate across three matrix multiplication strategies.

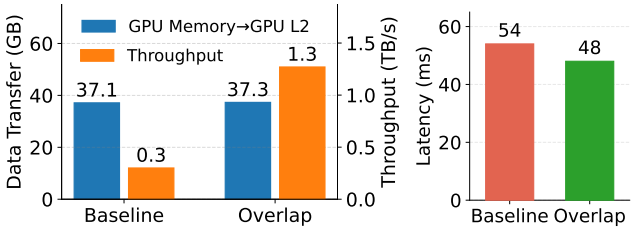

(a) Data fetching & HBM throughput. (b) Performance.

Figure 7: Data fetching and performance under separate kernel vs. fused kernel. Hatched bars (bottom) denote the first kernel.

rate from 32.3% to 75.1%.

Takeaway: By leveraging tiling, we can design a CPU-memory-aware *Zero-Copy* scheme that accommodates asymmetric bandwidth. Iterating over GPU-resident matrices rather than CPU-resident ones shifts bandwidth demand to HBM, fully exploiting its capacity and improving L2 cache efficiency for significantly better performance.

2.4.2 Warp-Level Pipelining for Communication and Computation Overlapping

Modern GPUs such as NVIDIA's Hopper architecture (H100/GH200) support multiple warp groups within a thread block that can execute distinct tasks concurrently. This capability enables *warp-level pipelining*, where different warps overlap communication (data fetching) and computation (matrix multiplication) to hide memory latency (§ 5).

To quantify its impact, we compare matrix multiplication with and without pipeline fetching. In the baseline (no overlap), the kernel fetches one tile at a time, synchronizes all threads, performs computation, and then repeats. In contrast, pipeline fetching allows the SM to prefetch the next tile while simultaneously computing on the current tile. As shown in Fig. 6, both approaches transfer nearly identical data volumes. However, warp-level pipelining sustains 4.3× higher HBM throughput (1.3 TB/s vs. 0.3 TB/s) and reduces latency by 11% (48 ms vs. 54 ms), demonstrating effective communication–computation overlap.

Takeaway: Warp-level pipelining effectively hides memory latency by overlapping data transfer and computation, yielding significantly higher throughput and lower latency without increasing data movement.

2.4.3 Fused Kernel for High Throughput

In conventional implementations, projection and attention score computation are launched as separate CUDA kernels. This separation forces the K and V tensors generated by the projection kernel to be written back to CPU memory (to update the KV cache) and then re-read by the attention kernel — creating redundant CPU–GPU transfers and exacerbating the bandwidth gap between NVLink-C2C (900GB/s aggregate, 450GB/s per direction) and HBM (4 TB/s per direction). This motivates us to *fuse* the projection and attention score computation into a single CUDA kernel to improve the throughput of data transfer (details in § 5.3 and § 5.4).

We evaluate this idea using a simplified case study. Specifically, the first kernel generates K via a matrix multiplication $K = XW_k$ and the second kernel consumes K for another matrix multiplication $P = QK^\top$. Rather than separate it into different kernels, we fuse them into one kernel using two stages. The first stage fetches X and W_k from HBM, generates K in registers, and writes the newly generated K back to CPU memory for KV-cache updates. The second stage immediately consumes K for $QK^\top$ score computation. The tensor X, W_k and Q reside in the SMEM. This design breaks the strict read–write dependency in traditional *Zero-Copy*, minimizes stalls, and increases effective throughput utilization.

As shown in Fig.7(a), the separate-kernel design transfers a similar amount of data as the fused kernel but sustains 15.8% lower HBM throughput due to redundant writes of K back to CPU memory and the subsequent re-fetching in the next kernel. In contrast, the fused kernel eliminates these redundant transfers, achieving 1.9TB/s throughput. This directly translates to performance gains: latency drops from 85ms to 57 ms, a 49% speedup as shown in Fig.7(b), by improving memory locality and bandwidth utilization.

Takeaway: Kernel fusion eliminates redundant memory transfers and improves data locality, further delivering higher throughput and performance.

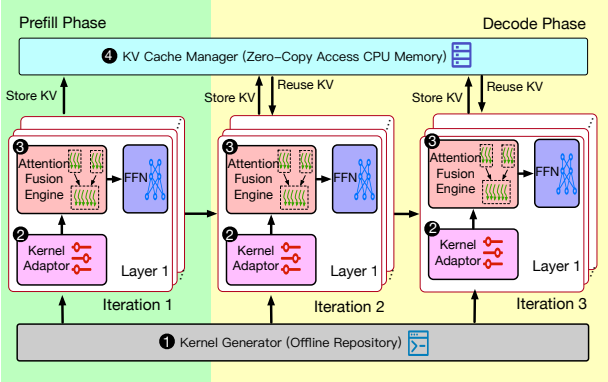

Figure 8: The system architecture of DirectKV.

3 Overview of DirectKV Architecture

This section outlines the overall architecture of DirectKV, a KV cache decoding system for LLM serving by reducing GPU memory pressure and improving runtime efficiency. DirectKV integrates *zero-copy KV cache offloading* with *fused projection-attention kernels*, dynamically adapting to input precision and execution phases (prefill or decode) as shown in Fig. 8. Both phases utilize a shared kernel execution framework that includes the following core components:

The *Kernel Generator* ❶ compiles a rich set of CUDA kernel candidates offline, specialized for different tensor precisions (e.g., FP16, BF16), tiling configurations, and execution modes (prefill vs. decode). It serves as an offline repository, ensuring that optimized kernels are pre-built and ready for runtime dispatch.

The *Kernel Adaptor* ❷ dynamically selects an appropriate CUDA kernel at runtime based on tensor precision (e.g., FP16, BF16), head dimension, and current execution phase (multi-token prefill vs. single-token decode). It allows the system to flexibly dispatch to optimized implementations without manual intervention or recompilation.

The *Attention Fusion Engine* ❸ fuses K/V projection and attention computation into a single CUDA launch to eliminate redundant KV cache transfers. It leverages shared memory within the SM and warp-level programming to overlap KV cache transfer with attention score computation.

The *KV Cache Manager* ❹ stores the key and value tensors in host-pinned memory using zero-copy access. Rather than using explicit cudaMemcpyAsync to move KV tensors between host and device, we utilize pinned memory to allow direct GPU access to host-resident tensors within SM. This design avoids redundant transfers and supports long-sequence inference without increasing GPU memory usage.

4 Kernel Generation and Adaptation

Typically, CUDA requires kernel specialization for input precision and tiling to fully exploit hardware, so multiple kernels must be compiled offline and selected at runtime. Accordingly, DirectKV introduces a *Kernel Generator* to generate candidate kernels offline and *Kernel Adaptor* a runtime component that chooses the most efficient kernel online.

4.1 SMEM Partitioning and Reuse

In DirectKV, SMEM serves as the on-chip buffer for matrix multiplications in the attention module. Its limited capacity is a primary hardware constraint that directly shapes kernel design. To balance projection and attention workloads, the SMEM within each SM is logically divided into two regions:

1. **Projection buffers:** used to store tiles of the input X and projection weights W_k and W_v during KV projection.
2. **Attention buffers:** used to store intermediate K, V, the query Q, and the output O during attention computation.

To alleviate SMEM pressure, DirectKV overlaps the usage of these two regions. Specifically, K reuses the buffer originally allocated for W_k, and V reuses the buffer allocated for W_v. Phase-specific optimizations further reduce demand: in the *decode* phase, O is written directly from registers to HBM (see § 5.3), while in the *prefill* phase, O reuses the buffer allocated for W_v in shared memory (see § 5.4). This partition-and-reuse strategy maximizes SMEM utilization and enables larger tiles under fixed hardware limits.

By default, DirectKV adopts two pipeline stages to overlap computation and communication at the warp level, which doubles the buffering requirement. Since SMEM is carved from the unified L1/SMEM pool (e.g., 256 KB on GH200) [7], we conservatively reserve a fraction α (80% by default) for SMEM and leave the remainder to L1 cache. The SMEM allocation must therefore satisfy:

$$\alpha \cdot P \geq 3 \cdot m \cdot \text{size(T)} \cdot (Dim \cdot N), \tag{1}$$

where P is the total L1/SMEM pool size, the factor 3 accounts for buffering three tensors in projection and attention, m is the number of pipeline stages (2 by default), T is the tensor data type with size(T) denoting its element size in bytes, Dim is the KV head dimension, and N is the tile size.

Given a specific configuration `<T, Dim, N>`, we compute the maximum feasible N that satisfies this constraint. These valid configurations are collected into a candidate set that guides kernel pre-building.

4.2 Offline Kernel Pre-Building

From this candidate set, the *Kernel Generator* pre-compiles fused kernels (details in § 5) using C++ template instantiations. Listing 1 illustrates the prefill kernel; the decode kernel

Listing 1: Offline Kernel Pre-building using C++ Templates.

```
template <typename T, int Dim, int N>
__global__ void prefill_kernel(
    T* X, const T* Wq, const T* Wk,
    const T* Wv, T* Q, T* O, int seq_len);

// Offline instantiations
template __global__ void prefill_kernel<int, 128,
     64>(...);
template __global__ void prefill_kernel<float, 64,
     64>(...);
```

is constructed analogously but specialized for its execution phase. Template syntax allows kernels to be specialized at compile time with respect to `<T, Dim, N>`, ensuring each variant is fully optimized by the compiler while avoiding runtime code generation overhead. This approach also keeps the codebase maintainable, as the same kernel logic can be reused across multiple configurations. All such instantiations are compiled offline into a candidate pool of fused kernels.

4.3 Online Kernel Choosing

At runtime, the *Kernel Adaptor* selects the most suitable kernel for the current phase (*prefill* or *decode*) by matching the requested `<T, Dim, N>` configuration to the closest available instantiation in the candidate pool. This process is lightweight, as it only requires substituting the template parameters with the pre-compiled kernels. As a result, DirectKV can dynamically adapt to workload characteristics while guaranteeing that each kernel execution leverages a carefully tuned, hardware-efficient implementation.

5 Kernel–Memory Co-Design Attention

We design the CUDA kernel to fully exploit *tiling* and *warp-level programming*, adapting the data access pattern to efficiently support zero-copy KV cache offloading. In this section, we detail how these techniques enable a high-performance fused kernel tailored for tightly coupled CPU–GPU superchip architectures.

5.1 CPU-Memory Aware Matrix Multiplication

To exploit HBM bandwidth and relieve pressure on the CPU–GPU interconnect, our key idea is to shift data-fetching overhead from host to device memory. This requires rethinking matrix multiplication access patterns, which conventionally assume all operands reside in GPU memory. Tiling techniques [5, 26] offer a natural solution: by decomposing large matrices into smaller submatrices (tiles) that fit within SMEM, CUDA kernels can flexibly control data movement, maximize reuse and minimize redundant accesses. Building on this, we design a CPU-memory aware tiling strategy that reuses CPU-fetched tiles efficiently while leveraging HBM's bandwidth for repeated accesses.

Algorithm 1: Tiled data-fetching patterns for matrix multiplication (Native vs. CPU-aware).

1 **Procedure** `NativeTiling` $(A \in R^{M\times K}, B \in R^{K\times N}, C \in R^{M\times N})$:
2 Initialize $C_{i,j}$;
3 **for** $k \leftarrow 1$ **to** T_K **do**
4 Load $A_{i,k}$; /* HBM → SMEM */
5 Load $B_{k,j}$; /* HBM → SMEM */
6 $C_{i,j} \leftarrow C_{i,j} + A_{i,k} \times B_{k,j}$; /* reuse stationary C */
7 Store $C_{i,j}$; /* registers/SMEM → HBM */
8 **Procedure** `CpuAwareTiling` $(A \in R^{M\times K}, B \in R^{K\times N}, C \in R^{M\times N})$:
9 Load $B_{k,j}$; /* CPU Memory → SMEM (zero copy) */
10 **for** $i \leftarrow 1$ **to** T_M **do**
11 Load $A_{i,k}$; /* HBM → SMEM */
12 Load $C_{i,j}$; /* HBM → SMEM */
13 $C_{i,j} \leftarrow C_{i,j} + A_{i,k} \times B_{k,j}$; /* reuse stationary B */
14 Store $C_{i,j}$; /* registers/SMEM → HBM */

We use a matrix multiplication kernel $C = A \times B$ to illustrate the distinction between conventional tiling and our CPU-aware tiling as shown in Algorithm 1. The key difference lies in which operand is reused and, consequently, where the bandwidth pressure is concentrated within the memory hierarchy. In *NativeTiling* (Step 1), both A and B tiles are repeatedly fetched from GPU HBM into shared memory, while C remains stationary in registers or SMEM until the final write-back. This design is efficient when all operands reside in GPU memory but requires frequent HBM accesses for both A and B. In particular, each multiplication step reloads B tiles for every (i, j, k) triple, so the data movement on B scales with the $O(n^3)$ computation. In contrast, *CpuAwareTiling* (Step 8) adapts to zero-copy offloading by treating B as stationary: each B tile is fetched once per (k, j) pair and reused across all i, reducing the traffic from $O(n^3)$ to $O(n^2)$. The trade-off is that C must be reloaded and updated from HBM at every step, increasing its traffic cost from $2 \cdot O(n^3)$ in *NativeTiling* to $3 \cdot O(n^3)$ in *CpuAwareTiling*. This design shifts bandwidth demand away from the constrained CPU–GPU interconnect and onto HBM, where the additional overhead can be efficiently absorbed.

This trade-off directly influences the design of attention score computation. Since SMEM is insufficient to hold all tensors, there are two possible iteration strategies: (i) iterate over Q for each (K,V) pair, or (ii) iterate over (K,V) for a given Q. In our design, we adopt the first strategy during the *prefill* phase (§ 5.3), where the KV cache resides in CPU memory and is expensive to reload, making it preferable to iterate over Q stored in HBM. This scheme corresponds to *CpuAwareTiling*. In contrast, during the *decode* phase (§ 5.4), the length of Q is only a single token, so we instead iterate over (K,V) to avoid repeatedly reading intermediate output

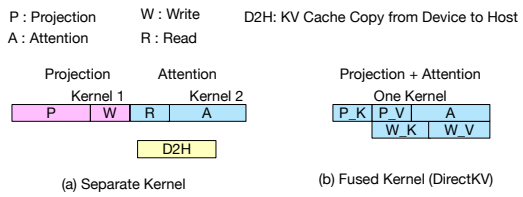

Figure 9: KV Projection and attention fusing.

scores. This scheme corresponds to *NativeTiling*.

5.2 Warp-Level Parallelism for Overlapping

On NVIDIA's Hopper architecture [22], SM threads can be divided into multiple warp groups, with each group independently handling tasks such as computation or communication. To maximize efficiency in the fused kernel, we employ *warp-level pipelining* for both projection and attention: while one set of warps fetches the next tiles from memory, others concurrently compute on the current tiles. This overlap hides memory latency and sustains high throughput, akin to asynchronous data copy in swap-based KV offloading where host–device transfers overlap with computation. On Hopper GPUs, this mechanism is further reinforced by the *Tensor Memory Accelerator (TMA)* [10], a hardware copy engine within each SM that supports asynchronous data movement and frees compute warps to focus on arithmetic.

5.3 Fused Kernel for Prefill Phase

Rather than launching separate kernels for each projection followed by a standalone attention kernel, our fused approach executes the entire sequence in a single pass (Fig. 9). The key insight is that the generated K and V tiles are retained in SMEM and immediately consumed by the subsequent attention computation, eliminating redundant writes to and reads from CPU memory.

Algorithm 2 outlines the design of the fused prefill kernel. The kernel initializes three specialized warp groups—*producer*, *consumer*, and *storer* (Step 3). The producer warps fetch tiles from HBM, the consumer warps perform the computation, and the storer warps handle writing intermediate results (e.g., K/V) back to CPU memory when required. This division enables overlap between data movement and computation.

The projection stage is decomposed into two sub-operations that generate K and V tiles, respectively. For each sub-operation, we employ pipeline parallelism across warp groups. For example, during K tile generation, while consumer warps compute on the current tile (Step 7), producer warps simultaneously prefetch the next tile from HBM (Step 6), thereby overlapping computation with data movement. Once the projection of K and V for a given tile is complete, the storer warps transfer the results to CPU memory, while the consumer warps proceed with attention computation

Algorithm 2: Fused Prefill Kernel

Input: Input embeddings $X \in R^{N\times D}$, projection weights $W_k, W_v \in R^{D\times d}$, query $Q \in R^{S\times d}$, head dimension d, sequence length S, tile sizes B_{kv} and B_q for KV cache and query, respectively.

1 Initialize output tensor $O \in R^{S\times d}$
2 Initialize streaming-softmax state $(\ell=0,\ m=-\infty)$
3 Initialize three Warp Groups including Producer, Consumer and Storer
4 **for** $j \leftarrow 1$ **to** $T_s = \left\lceil \frac{S}{B_{\text{kv}}} \right\rceil$ **do**
  /* KV Projection Stage */
5 **for** $i \leftarrow 1$ **to** $T_d = \left\lceil \frac{D}{d} \right\rceil$ **do**
6 **Producer**: Load X_{ij}, W_i^k from HBM
7 **Consumer**: $K_j = X_{ij} W_i^k + K_j$
8 **if** `use_rope` **then**
9 $K_j \leftarrow RoPE(K_j)$
10 **Storer**: Zero-copy write K_j to CPU Memory
11 **for** $i \leftarrow 1$ **to** $T_d = \left\lceil \frac{D}{d} \right\rceil$ **do**
12 **Producer**: Load X_{ij}, W_i^v from HBM
13 **Consumer**: $V_j = X_{ij} W_i^v + V_j$
14 **Storer**: Zero-copy write V_j to CPU Memory
  /* Attention Stage */
15 **for** $i \leftarrow 1$ **to** $T_s = \left\lceil \frac{S}{B_q} \right\rceil$ **do**
16 **Producer**: Load Q_i, O_i, m_i, ℓ_i from HBM ;
17 **Consumer**:
18 $S_{ij} \leftarrow Q_i K_j^\top$
19 $(m_i, \ell_i, O_i) \leftarrow StreamSoftmax(m, \ell_i, O_i, S_{ij}, V_j)$
20 Write O_i, m_i back to HBM

on previously generated tiles. After generating the K tiles, we optionally apply rotary position embeddings (RoPE) [28, 48] (Step 8). Because RoPE relies only on precomputed sine and cosine functions determined by token positions, each K tile can be transformed independently, enabling efficient parallelization across SMs without inter-tile dependencies.

For attention score computation, we adopt the strategy of iterating over Q (Step 15), which is precomputed before launching the fused attention kernel and resides in HBM. For each (K,V) tile, this design allows SMs to process different tiles independently, thereby maximizing parallelism. A trade-off of this design is that intermediate outputs O_i and auxiliary statistics m_i, ℓ_i must be repeatedly fetched for accumulation and streaming softmax updates [26, 36, 40] (Step 19). These updates are standard in long-sequence attention to ensure numerical stability and are retained without modification. Importantly, the additional HBM traffic introduced by these updates remains modest compared to CPU–GPU transfers, and thus does not become the dominant bottleneck. To avoid write–

read dependencies on O_i across SMs, we assign different attention heads and batches to different SMs. Since the product of the number of heads (e.g., 8) and batch size (e.g., 32) typically exceeds the number of SMs (e.g., 132 on GH200), this scheduling ensures that no two SMs simultaneously operate on the same head–batch pair with different (K,V) tiles. Finally, similar to the projection stage, we employ pipeline parallelism: producer warps prefetch the next Q tiles from HBM (Step 16), while consumer warps concurrently perform computations on the current tiles (Step 18), thereby overlapping data movement with computation.

5.4 Fused Kernel for Decode Phase

In contrast to the prefill phase, where avoiding repeated KV cache fetching from CPU memory dominates the cost, the decode phase reuses the cached K,V heavily while computing projections and attention scores for only a single newly generated query token. To fully utilize parallelism in this setting, we adopt the complementary strategy of iterating over all cached (K,V) given the single query q_t. Since only one token is processed, each (K,V) pair needs to be traversed just once, avoiding additional CPU–GPU memory transfers. Furthermore, this design eliminates redundant reloads of the output attention scores: o_t can be retained in registers and reused across iterations, rather than repeatedly fetched from HBM. This optimization minimizes overhead while preserving high throughput as illustrated in Algorithm 3.

The fused decode kernel requires only two warp groups, *producer* and *consumer*, since only a single newly generated (K,V) pair is written back to CPU memory. In this case, a dedicated storer group is unnecessary, and the consumer warps handle the write-back after completing the new (K,V) projection. Specifically, the producer first fetches the query q_t from HBM (Step 2) to prepare for subsequent iterations. During the attention stage, the producer loads (K,V) tiles from CPU memory into SMEM via zero-copy, while the consumer performs computation over these tiles. Pipeline parallelism is employed to overlap communication and computation: while the producer fetches the next tile (Step 5), the consumer concurrently computes on the current tile (Step 6), thereby sustaining throughput and reducing stalls.

6 Efficient KV Cache Management

The KV cache grows linearly with sequence length and quickly exceeds GPU capacity. To address this, we introduce the *KV Cache Manager*, which offloads KV tensors to CPU memory and enables direct GPU access via zero-copy.

The manager allocates CPU buffers with `cudaHostAlloc` as pinned memory [9], making host memory page-locked and directly accessible to the GPU without staging. Once written, KV tensors remain in pinned buffers and are reused across iterations without recomputation or redundant transfers.

Algorithm 3: Fused Decode Kernel (token-by-token)

Input : New token $x_t \in R^{1\times d_{\text{model}}}$, weights W_k, W_v, head dim d, cached KV length S_{kv}, flags `use_rope`, tile sizes B_{kv} for KV cache.

1 Initialize output tensor o_t
2 Initialize streaming-softmax state $(\ell=0,\ m=-\infty)$
3 **Producer**: Load q_t from HBM
/* Attention over cached KV */
4 **for** $j \leftarrow 1$ **to** $T_s = \left\lceil \frac{S_{kv}}{B_{\text{kv}}} \right\rceil$ **do**
5 **Producer**: zero-copy load cached tiles (K_j, V_j) from CPU memory
6 **Consumer**:
7 $S_j \leftarrow q_t K_j^\top$
8 $(m,\ell,o_t) \leftarrow StreamSoftmax(m,\ell,o_t,S_j,V_j)$
/* Project current token's KV */
9 **for** $i \leftarrow 1$ **to** $T_d = \lceil \frac{D}{d} \rceil$ **do**
10 **Producer**: Load X_i, W_i^k, W_i^v from HBM
11 **Consumer**: $k_t = X_i W_i^k + k_t,\ v_t = X_i W_i^v + v_t$
12 **if** `use_rope` **then**
13 **Consumer**: $k_t \leftarrow RoPE(k_t)$
14 **Consumer**: Append (k_t, v_t) to KV cache in CPU memory
/* Attention with new KV */
15 **Consumer**:
16 $s_t \leftarrow q_t k_t^\top$
17 $(m,\ell,o_t) \leftarrow StreamSoftmax(m,\ell,o_t,s_t,v_t)$
18 Write o_t back to HBM

During *prefill*, the manager stores the initial K,V entries from each layer in CPU memory. During *decode*, the GPU reuses these cached entries directly, while only appending new K,V for the latest token.

Integrated with the Kernel Adaptor and Attention Fusion Engine (Fig. 8), the KV Cache Manager reduces interconnect traffic, relieves GPU memory pressure, and enables scalable long-context generation beyond GPU-only caching.

7 Implementation and Evaluation

7.1 System Implementation

Prototype. We implement *DirectKV* in CUDA 12.4, building on NVIDIA's CUTLASS library for matrix multiplication [12] and extending FlashAttention-3 [44]. The implementation integrates three key techniques: (i) CPU-aware matrix multiplication, (ii) warp-level pipelining, and (iii) kernel fusion of projection and attention. In total, our prototype contributes roughly 5,300 lines of CUDA/C++ code on top of FlashAttention-3, with additional Python bindings to enable integration into PyTorch 2.2. For kernel-level analysis,

we use NVIDIA Nsight Compute to report hardware metrics, including L2 cache hit rate and memory throughput, in order to quantify efficiency gains.

KV cache management. DirectKV includes a lightweight KV cache manager (❹ in Fig. 8) to support direct attention over CPU-resident KV blocks. The manager allocates KV buffers in pinned host memory using `cudaHostAlloc` [9]. Since these buffers are page-locked and GPU-accessible, DirectKV kernels can access CPU-resident KV blocks through device-visible pointers without staging them in GPU memory. Once generated, KV tensors remain in the pinned buffers and are reused across decoding iterations, avoiding recomputation and redundant CPU–GPU transfers.

7.2 Evaluation Setup

Server Configurations. We evaluate DirectKV on an NVIDIA GH200 Grace–Hopper Superchip with a Hopper GPU, 96 GB of HBM3, and LPDDR5X CPU memory [15]. The system runs CUDA 12.4 and PyTorch 2.3, and our custom kernels are implemented using CUTLASS 3.0+ with Hopper support via CuTe. For baseline comparison, we use the H100 (PCIe Gen5) to quantify the benefits of NVLink-C2C (§ 7.4.3), since both GH200 and H100 employ the same H100 GPU architecture.

LLM models. We evaluate Llama-3.1-8B [11] and OPT [56] models with 13B and 30B parameters.

Workloads. Following prior work on LLM serving [37], we evaluate on real-world datasets including ShareGPT [6, 8] (user-shared ChatGPT conversations) and Alpaca [49, 52] (instruction-following data generated by GPT-3.5). Since request timestamps are not provided, we generate arrivals as a Poisson process parameterized by the request rate [37].

Our main experiments use request rates up to 30 req/s and context lengths from 1k to 32K tokens, representing a stable operating region where systems can be compared under reasonable latency. We further add stress-case workloads with higher request rates and longer context lengths to evaluate behavior under saturation and memory pressure. These workloads show when baseline systems run out of GPU memory or experience severe latency degradation from KV-cache movement and staging overheads. We also vary batch size to cover both latency-critical interactive serving and throughput-oriented batch scenarios.

Baseline schemes: We compare DirectKV against three KV cache offloading systems:

- **SGLang** [58] is a high-performance serving framework for large language and multimodal models. We use SGLang as an HBM-resident baseline, where the KV cache is stored in GPU memory.
- **Pie** [53] uses a large GPU staging buffer to swap KV blocks from CPU memory to GPU via NVLink-C2C, overlapping transfers with compute.

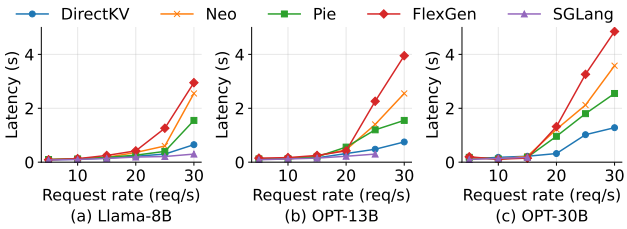

Figure 10: Per-token latency under varying request rate for different models.

- **FlexGen** [46] uses GPU, CPU memory, and disk with a cost-model search and 4-bit compression to reduce memory footprint and enable LLM inference under tight GPU memory constraints.
- **Neo** [34] offloads part of attention computation and KV cache to CPUs, using asymmetric GPU–CPU pipelining and load-aware scheduling to increase throughput.

7.3 End-to-end Performance

7.3.1 Per-token Latency

We evaluate three models under varying request rates, as shown in Fig. 10. SGLang achieves the lowest latency when the model and KV cache fit entirely in GPU memory, as it serves both parameters and KV cache from HBM without offloading overhead. However, this design is constrained by GPU memory capacity: SGLang supports all request rates for Llama-3.1-8B, but runs out of memory at the highest request rate for OPT-13B and beyond low request rates for OPT-30B. DirectKV achieves the lowest latency among offloading-based systems and remains close to SGLang when SGLang is feasible. On Llama-3.1-8B, DirectKV is slightly slower than SGLang but substantially faster than Neo, Pie, and FlexGen, reducing latency at 30 req/s from 1.55–2.95s to 0.75s. For OPT-13B, DirectKV remains competitive with SGLang at moderate loads and continues to support 30 req/s, where SGLang OOMs; at this load, DirectKV achieves 0.75s latency, compared with 1.55–3.95s for other offloading systems. For OPT-30B, SGLang only supports low request rates, while DirectKV scales to 30 req/s and maintains much lower latency than Neo, Pie, and FlexGen under high load.

These results show that SGLang provides the best performance when sufficient HBM is available, whereas DirectKV offers a better performance–capacity tradeoff. By using zero-copy KV offloading, DirectKV avoids staging buffers and redundant CPU–GPU copies, reducing offloading overhead and enabling graceful scaling when GPU-resident systems exceed HBM capacity.

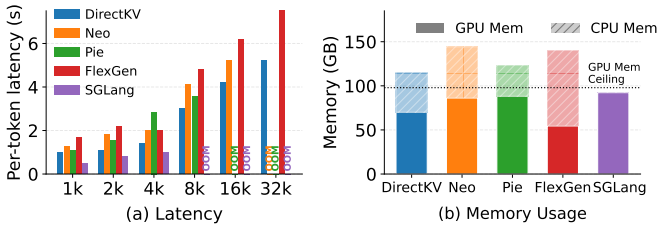

Figure 11: Performance and memory usage under different sequence length.

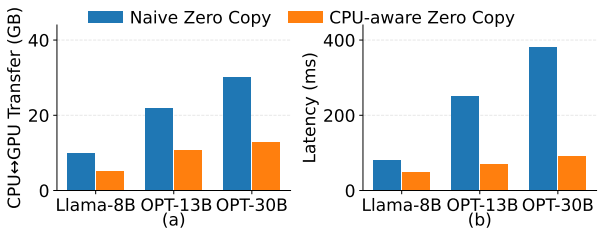

Figure 12: Data fetching and latency per token comparison between naive zero-copy and CPU-aware zero-copy.

7.3.2 Impact of Context Length on Latency

We evaluate per-token latency under different sequence lengths, as shown in Fig. 11(a).DirectKV consistently achieves the lowest latency among systems that support each context length, with a 1.2× average speedup. Its advantage increases as the sequence length grows: at 16k tokens, DirectKV is about 1.3× faster than Neo and Pie and about 1.7× faster than FlexGen. At 32k tokens, DirectKV remains efficient, while Neo, Pie, and SGLang run out of memory and FlexGen incurs much higher latency. SGLang is fast when all data fits in GPU memory, but fails at longer contexts due to GPU memory pressure. FlexGen supports longer contexts but suffers from explicit data movement and multi-tier offloading overhead. By keeping KV cache in CPU memory and directly accessing it through zero-copy execution, DirectKV reduces GPU memory usage while sustaining low latency for long-context serving.

7.3.3 GPU and CPU Memory Savings

We evaluate average GPU and CPU memory usage under varying sequence lengths across different LLM models on GH200, which has 96GB of GPU memory as shown in Fig.11(b). SGLang keeps both model parameters and KV cache in GPU memory, consuming 92GB on average and approaching the GPU memory limit as the sequence length grows. Although Neo, Pie, and FlexGen offload data to CPU memory, they still consume substantial GPU memory due to additional runtime buffers for KV-cache movement, using 86GB, 88GB, and 74 GB, respectively. In contrast, DirectKV uses only 47GB of GPU memory, saving 35GB on average compared with these offloading-based systems, which corresponds to a 43% reduction in GPU memory usage. This saving comes from storing the KV cache in CPU-pinned memory and allowing the attention kernel to directly consume CPU-resident KV blocks. As a result, DirectKV stays well below the 96 GB GPU memory ceiling and avoids SGLang's OOM behavior while achieving lower latency than other offloading-based systems.

7.4 Component-Level Evaluation

7.4.1 Benefits of CPU-Memory-Aware Matrix Multiplication

Naïve zero-copy attention performs matrix multiplications directly on KV blocks fetched from CPU memory, leading to repeated transfers of the same operands and excessive communication overhead. We evaluate our CPU-aware zero-copy mechanism, which reorganizes data access so that each KV block fetched from CPU memory is maximally reused in GPU registers and HBM before eviction. This design shifts the dominant pressure from the CPU-GPU interconnect to the GPU-side memory hierarchy, where HBM bandwidth is much higher and can better absorb the additional traffic. As shown in Fig. 12(a), CPU-aware zero-copy reduces CPU–GPU transfer volume by up to 50% compared with naive zero-copy. This reduction translates into up to 70% lower inference latency across LLaMA-8B, OPT-13B, and OPT-30B, as shown in Fig. 12(b). Overall, CPU-aware zero copy consistently improves end-to-end throughput by reducing communication cost and fully exploiting GPU compute.

7.4.2 Advantage of Fused Kernel

In existing offloading approaches K, and V projections are launched as separate kernels, followed by an attention kernel. This separation forces repeated refetching of KV blocks from CPU memory, inflating interconnect traffic and underutilizing GPU bandwidth. Our fused kernel addresses this inefficiency by combining QKV projection and attention into a single pass. Projected tensors remain in shared memory and are immediately consumed by attention, eliminating redundant global memory accesses. As shown in Fig. 13, the fused design sustains up to 3.5× higher HBM throughput and delivers 2.5–3.0× lower latency across Llama-8B, OPT-13B, and OPT-30B. These results demonstrate that kernel–memory co-design is essential to making zero-copy offloading practical and efficient on heterogeneous CPU–GPU platforms.

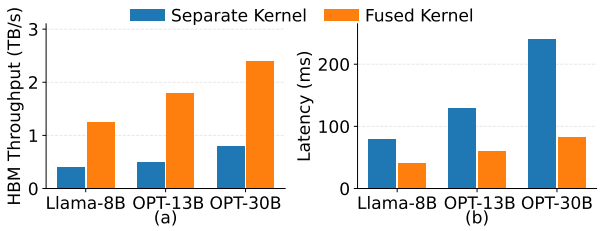

Figure 13: HBM throughput and latency per token comparison between separate kernel and fused kernel.

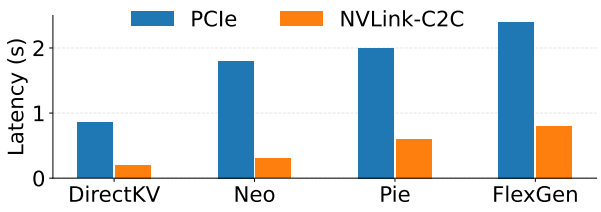

Figure 14: Latency per-token under 512 sequence length when using PCIe and NVLink-C2C.

7.4.3 Impact of High-bandwidth Interconnection

The efficiency of zero-copy offloading is fundamentally limited by the bandwidth of the CPU–GPU interconnect. With PCIe, KV blocks must traverse a lower-bandwidth channel, which can quickly become the system bottleneck and cause GPUs to stall while waiting for data. In contrast, NVLink-C2C provides much higher bandwidth, allowing DirectKV to sustain higher HBM utilization and better overlap communication with computation. Thus, on PCIe, DirectKV should be viewed primarily as a capacity-extension mechanism: it eliminates GPU staging buffers, but its performance advantage remains bounded by CPU–GPU interconnect bandwidth.

As shown in Fig. 14, DirectKV consistently achieves the lowest latency on both interconnects, with the gap especially pronounced under NVLink-C2C. Relative to PCIe, NVLink-C2C reduces attention latency by up to 4.2× and improves throughput stability under long contexts. Competing systems such as Neo, Pie, and FlexGen remain bottlenecked by staging overheads, yielding only modest improvements under NVLink-C2C.

8 Discussion

8.1 Integration with Existing Serving Systems

DirectKV is intended to complement, rather than replace, full-featured LLM serving systems such as vLLM and SGLang. These systems already provide mature mechanisms for continuous batching, prefix reuse, eviction, and hierarchical KV caching [23, 24, 32, 37, 58]. Such mechanisms determine how requests are scheduled, which KV blocks are reused or shared, and when blocks are retained, evicted, or promoted across memory tiers. DirectKV addresses a separate concern: how to execute attention efficiently once the relevant KV blocks reside in CPU memory.

This separation makes DirectKV naturally compatible with existing serving stacks. DirectKV does not change scheduling, batching, or KV-management policies; instead, it provides an efficient execution path for CPU-resident KV blocks. A serving system can integrate DirectKV by extending its KV allocator to support CPU-pinned storage for offloaded blocks, while leaving the scheduler, model execution graph, and frontend API unchanged. Therefore, DirectKV can directly benefit existing KV-cache optimizations that already place KV blocks in CPU memory, including prefix caching, eviction, and hierarchical KV management, by avoiding the copy back to HBM before attention.

8.2 Hardware Applicability

DirectKV is best suited to CPU–GPU platforms with high-bandwidth interconnects, such as NVLink-C2C on GH200/GB200. Its coarse-grained access pattern—∼100 KB KV blocks accessed concurrently by over 100 SMs—creates MB-scale aggregate transfers, making performance primarily limited by sustained CPU–GPU bandwidth rather than individual remote-load latency. Thus, on PCIe-only platforms, DirectKV may still reduce GPU memory usage, but throughput benefits are often limited by interconnect bandwidth.

Importantly, this bandwidth-oriented design does not rely on platform-specific coherence mechanisms. DirectKV uses zero-copy pinned memory rather than GH200's unified page table (UPT). Although UPT provides a coherent CPU–GPU virtual address space, DirectKV does not require coherence because KV blocks are not concurrently updated by the CPU. In our setting, zero-copy achieves comparable NVLink-C2C bandwidth while relying only on standard pinned host memory and device-visible pointers, making DirectKV applicable beyond UPT-specific platforms.

8.3 Scalability and Distributed Serving

DirectKV is primarily a node-local heterogeneous-memory optimization, but it composes with common LLM-serving parallelism strategies and distributed KV layouts. Under tensor parallelism, each GPU maintains its own attention-head shard and CPU-pinned KV pool; under pipeline parallelism, KV pools partition naturally by layer. When KV cache is partitioned across servers, each server can apply DirectKV to its local CPU-resident KV blocks, while the distributed runtime still handles query and partial-output communication. Thus, DirectKV improves per-server KV capacity, but does not eliminate inter-server communication costs.

DirectKV also benefits disaggregated prefill–decode serving because CPU-pinned KV blocks can be transferred via

RDMA without GPU staging. Its main limitations are context-parallel scale-out and host-memory pressure: coordinating remotely owned KV blocks or integrating with a multi-tier KV hierarchy would require additional runtime support, and zero-copy benefits diminish once accesses fall back to pageable or disk-backed tiers. We leave these extensions to future work.

9 Related Work

Efficient LLM Inference. A rich line of work has optimized transformer inference for latency and throughput. Systems such as TensorRT-LLM [3], vLLM [37], and DeepSpeed-Inference [21] accelerate execution through operator fusion, batching, and kernel optimizations. DistServe [59] disaggregates prefill and decode to reduce interference, while TurboTransformers [29] and HuggingFace [1] provide widely adopted runtimes. Sarathi-Serve [19] dynamically allocates prefill/decode resources, ZeRO-Offload [43] shifts optimizer states to CPU memory, PowerInfer [47] exploits activation sparsity, SGLang [58] optimizes multi-turn interaction, and FlashDecoding++ [33] provides low-latency decoding kernels. While effective within GPU memory constraints, none address KV cache offloading across CPU–GPU memory, the focus of DirectKV.

KV Cache Offloading. Many recent systems propose offloading the KV cache from GPU to CPU memory to support longer contexts. FlexGen [46] formulates tensor placement as a linear programming problem across GPU, CPU, and disk, using compression to increase throughput under resource constraints. NEO [34] employs asymmetric GPU–CPU pipelining and load-aware scheduling to balance computation and memory usage, achieving higher throughput under batch-serving settings. Pie [53] adopts a swap-based design, staging KV blocks in large GPU buffers transferred over NVLink-C2C. Infinite-LLM [38] orchestrates all available GPU and CPU memories across the data center to store the KV cache, but applications may experience degraded performance when data resides in CPU or remote memory. FastDecode [31] offloads the entire attention computation onto CPUs to avoid repeated PCIe transfers, but is constrained by limited CPU throughput. HeteGen [57] adopts heterogeneous parallelism with asynchronous overlap to mitigate I/O bottlenecks and reduce inference latency. While effective, these approaches either incur staging overhead, depend on software-level scheduling, or expose applications to unpredictable performance when CPU memory is involved. DirectKV instead eliminates staging buffers through a kernel–memory co-design, making zero-copy practical for attention computation.

GPU Kernels Optimization for Attention. FlashAttention-1 and 2 [25,25] optimize GPU kernel execution by tiling data in HBM, substantially reducing memory traffic and improving throughput. FlashAttention-3 [44] further improves performance on Hopper GPUs with advanced pipelining strategies. FlashInfer [54] targets heterogeneous KV-cache layouts with specialized CUDA kernels, leveraging block-sparse and composable formats to enhance memory efficiency and minimize redundancy. However, all of these optimizations assume that KV caches reside entirely in GPU memory and are not designed for zero-copy access to CPU-resident KV without HBM-resident buffers. When applied naively in a zero-copy setting (i.e., directly pointing K/V to host memory), these kernels suffer severe performance degradation because they do not account for the large bandwidth gap between CPU–GPU interconnects and HBM.

In contrast, DirectKV adapts FlashAttention-3-style kernels to heterogeneous CPU–GPU settings in which KV caches are stored in CPU memory, and mitigates the interconnect bottleneck through a kernel–memory co-design.

10 Conclusion

We proposed DirectKV, an efficient zero-copy KV cache offloading system for heterogeneous CPU–GPU architectures. Naïve zero-copy exacerbates the bandwidth gap between CPU–GPU interconnects and HBM, severely limiting performance. DirectKV addresses this by redesigning matrix multiplication access patterns to shift the bottleneck to HBM, while further improving efficiency through warp-level pipelining that overlaps communication with computation and fused kernels that eliminate redundant KV refetching. Evaluated on NVIDIA GH200, DirectKV reduces GPU memory usage by 43% and improves end-to-end performance by up to 1.2× over state-of-the-art systems.

Simple is Better: Multiplication May Be All You Need for LLM Request Scheduling

Abstract

High-quality LLM request scheduling requires meeting two key objectives: ensuring the routed instance has KV$ to accelerate request execution, and ensuring that the workload is balanced across instances. Achieving both objectives is challenging because pursuing one may compromise the other. Current approaches use various combinators (e.g., linear combinations) to compute a scheduling score that combines indicators for the two objectives. These approaches are complex: they either require significant workload-specific hyperparameter tuning or model-hardware-aware simulator development, yet could still lead to suboptimal performance.

In this paper, we show that using a simple multiplication of two carefully chosen indicators—one KV$-aware (new prefill tokens if routed to an instance) and one load-balancing-aware (current batch size of the instance)—as the scheduling score (LMETRIC[*]) can achieve both objectives simultaneously without any hyperparameter tuning. The key idea is that the simply multiplied score considers both objectives in a manner similar to a linear combination, but the original hyperparameters cancel out during comparison, so no tuning is needed to find the best parameters. The two indicators are chosen based on our analysis of LLM characteristics. Our extensive experiments show that this simple approach can reduce TTFT by 92% and 39%, and TPOT by 24% and 51%, compared to vLLM-v1 and an in-production scheduler on real-world workloads covering chatbots and coding agents. We also derive the mathematical conditions under which multiplication may fail, and find that such conditions are extremely rare in practice and can be detected (and mitigated) beforehand.

LMETRIC has been deployed in production and canary release confirms its effectiveness.

1 Introduction

This paper studies how to efficiently route LLM requests to a cluster of serving instances—the minimal LLM engine deployment unit. Serving LLMs has become a key building block in modern society, and LLM providers typically deploy clusters of instances for serving, where each cluster contains a *global scheduler* that routes incoming requests to the instances it manages [40, 50, 51, 24, 35, 6, 45]. Upon receiving a request, the instance generates result tokens in two phases: The prefill (P) phase generates the first result token, and its serving quality is measured by time-to-first-token (TTFT). The decode (D) phase then generates the remaining tokens in a streaming manner, and its serving quality is measured by time-per-output-token (TPOT).

Providing an effective scheduling policy is crucial for cluster-level LLM serving. This is because, similar to traditional request routing [17, 54, 22], better request placement significantly reduces overall latency (lower TTFT and TPOT) due to factors such as improved load balancing across instances. Low-latency serving is especially critical for current interactive applications such as ChatGPT [37] and copilots [21], as it is essential to meeting user expectations [9, 55, 20]. Moreover, recent agentic workloads consume tokens rapidly through interactive programs [8, 23, 36].

Achieving a good LLM-specific scheduling policy is non-trivial: First, considering only load balancing across instances—which is adopted by a recent state-of-the-art serving system vLLM [45] and traditional request routing—is insufficient. This is because the computation required to process each request differs across instances due to KV$, the intermediate context of the processed tokens (§4.2). Specifically, if an incoming request's (partial) input tokens hit the KV$ cached on an instance, the instance can skip generating the corresponding KV$ for the hit tokens, thereby accelerating the subsequent prefill and decode phases. However, incorporating only KV$-aware indicators into scheduling decisions (e.g., the KV$ hit ratio if routing a request to an instance) is also insufficient, because it biases requests towards instances with KV$ hits and hurts load balancing across instances (§4.3).

To balance the two objectives—KV$-awareness and load balancing—three combination strategies exist.

First, the linear combination strategy (i.e., weighted sum) [29, 35] combines the indicators for each objective—per-instance metrics that score each objective if the request were routed to that instance, e.g., the KV$ hit ratio for KV$-awareness and the current batch size for load balancing—into a single score for scheduling (§4.4). It is a popular choice adopted by current works and one of the world's leading LLM service providers (Alibaba BAILIAN). However, linear combination requires complex workload-specific hyperparameter tuning to achieve both objectives. Moreover, a statically tuned hyperparameter is suboptimal because workloads may change

[*]Our system name LMETRIC stands for **L**arge **M**odel metric, paying homage to Lyapunov's stability theory and Markov's queueing theory.

[†]Most work done when intern at Alibaba Group.

[‡]Jinbo Han and Kaixi Zhang contributed equally and significantly to this work.

[✉]Xingda Wei is the corresponding author (wxdwfc@sjtu.edu.cn).

dynamically (§4.4).

Second, the filter-based strategy first filters out instances that are suspected to suffer from imbalanced workloads, and then selects the instance with the most KV$ hits among the remaining instances [3]. It still requires non-trivial workload-specific tuning to determine the filtering threshold. Worse still, its scheduling is biased towards load balancing and thus cannot fully utilize the KV$ (§4.5).

Finally, the simulation-based strategy [40, 24, 56, 13] first uses a simulator to predict the expected latency of routing a request to each instance, and then takes the latency as the scheduling score. The simulator estimates the latency based on its current indicators, e.g., stored KV$ and request load in progress (queued requests), so the latency score can be viewed as a high-order combination of the KV$ and load-balance indicators to achieve the best of both worlds. However, the effectiveness of the strategy relies heavily on the accuracy of the simulator, which requires complex per-model, per-hardware, and per-deployment development. Otherwise, an inaccurate simulation can lead to poor scheduling performance (§4.6). Even with an accurate simulator, it may still fail to achieve performance comparable to other candidates in certain cases.

In this paper, we show that using the multiplication of one indicator for KV$-awareness and one indicator for load balancing as the scheduling score can effectively combine the two objectives without complex hyperparameter tuning or any simulator. The key idea is to replace the addition operation in a linear combination with multiplication. The resulting score preserves a trend similar to that of a linear combination, and the hyperparameters cancel out during score comparisons among instances, so no tuning is required (§5).

Making this simple method work well in practice requires care. First, we found that careful indicator selection can further improve the method's effectiveness (§5.1). For example, using the number of queued new prefill tokens when routing a request to an instance, considering KV$ hits, as the KV$-aware indicator is better than using the KV$ hit ratio. Second, we mathematically derive the approximate conditions under which multiplication may fail. Based on the formulated conditions, we found that they are extremely rare in practice (§5.2)—occurring under extreme KV$ skewness that compromises load balance. Hence, we further design a two-phase approach to detect and mitigate it. Upon detection, we can fall back to a load-balancing-only policy.

We have compared our method with state-of-the-art systems, including vLLM [45], ai-Dynamo [35], llm-d [24], and the one used in Alibaba BAILIAN [15] on real LLM serving workloads covering chatbots, API calling, and coding agents (§6). On an H20 cluster with up to 16 GPUs, evaluation on popular models covering both dense and MoE architectures confirms the benefits of our approach. LMETRIC has been deployed in production at BAILIAN on hundreds of GPUs, and performance observed from a canary release confirms its effectiveness.

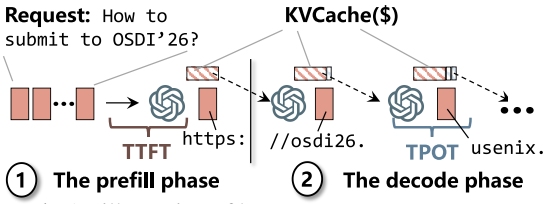

Figure 1: An illustration of how an LLM generates output tokens, and the two performance metrics: time-to-first-token (TTFT) and time-per-output-token (TPOT).

Contributions. This paper makes three contributions:

- The first systematic study of how to efficiently schedule LLM serving requests in a cluster (§4).
- The first multiplicative combination for efficient LLM request scheduling (§5).
- Extensive analysis and evaluation that confirm the effectiveness of the multiplicative approach (§5.1, §5.2, §6).

Our code is open-sourced at https://github.com/blitz-serving/blitz-router, and all our traces can be found at https://github.com/alibaba-edu/qwen-bailian-usagetraces-anon.

Discussion: PD-colocation vs. PD-disaggregation. We focus on PD-colocated serving in this paper, where both prefill and decode requests are served on the same instance. While there also exist deployments where prefill and decode requests are served on different instances (PD-disaggregation) [38, 55, 26], PD-colocated serving is still widely adopted in practice [50] because it is easier to maintain (no instance role management), does not rely on fast networking between instances, and yields better performance under certain conditions [31, 30]. We discuss how our observations and solutions apply to PD-disaggregation in §7.

2 LLM Serving and Scheduling

Serving requests with an LLM (Figure 1). LLMs generate tokens auto-regressively in two steps: ① In the *prefill* phase, the input tokens are fed into the model to produce the first output token. The LLM then enters the *decode* phase (②) to generate subsequent tokens one-by-one, each conditioned on all prior input and generated tokens. To accelerate decode, the *processed context* is materialized as tensors in GPU memory, termed the *key-value cache* (KV$). Consequently, decode computation is far smaller than prefill, since the KV$ for input tokens is already available and not regenerated.

Two key serving-quality metrics are *time-to-first-token (TTFT)* and *time-per-output-token (TPOT)*: TTFT determines the service's responsiveness to user requests, while TPOT affects both subsequent responsiveness and overall request completion time.

Serving instance and KV$ cache (Figure 2). An instance is the minimum unit that serves requests and hosts one complete copy of the LLM's parameters, potentially spanning multiple

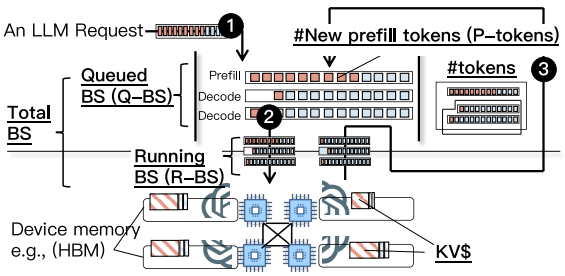

Figure 2: The system view of how an LLM serving instance handles requests and representative direct system **indicators** that can be collected by the global scheduler. The detailed meaning of each indicator will be described at first use. **BS** is the abbreviation for batch size.

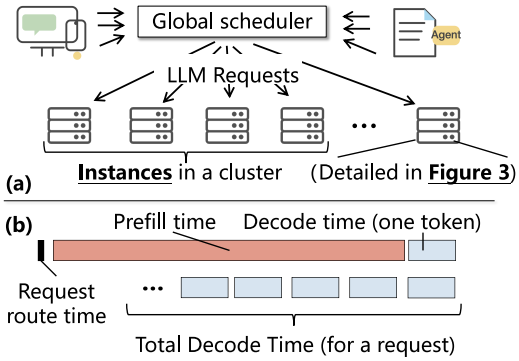

Figure 3: (a) System view of an LLM serving cluster, and (b) Comparison of per-request serving time and routing cost.

GPUs if the model exceeds a single GPU's memory. The serving flow is the same in either case: an incoming request is pushed into a queue (prefill or decode) on the instance (❶). Once the GPU(s) become available, queued requests are batched and executed efficiently with *chunked prefill* [2] (❷). The instance then re-enqueues any request that needs further decoding (❸).

Serving is *stateful*: a request's KV$ is cached in GPU or CPU memory even after generation finishes (KV$ cache [40, 19, 47]). If a future request routed to the instance shares a prefix with a cached KV$, the instance can skip computing the matched prefix tokens, significantly reducing computation cost. In Figure 2, blue tokens skip computation on a KV$ hit.

Request scheduling in a cluster (Figure 3). To handle large request volumes, providers deploy clusters of instances, each with a dedicated *global scheduler* that routes requests to its managed instances, as shown in (a). The scheduler runs a *scheduling policy* to pick a destination instance per request—our focus. Providers may deploy multiple clusters of the same model for reliability and geo-affinity, but inter-cluster routing is out of the scope of this paper.

All existing scheduling policies follow a three-step process: the router first (optionally) *filters* instances, then *scores* the remainder by a preference order, and routes the request to the best-scoring one. Scores derive from per-instance indicators, described in §4.

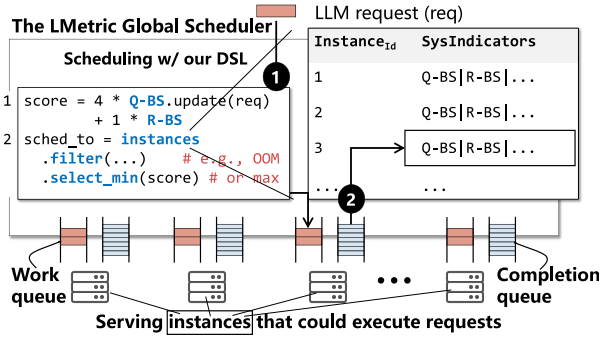

Figure 4: The system architecture of our indicator factory and its programming model for scheduling policies.

3 The Analysis Framework

To analyze different scheduling policies in an apples-to-apples manner, we implement a flexible LLM scheduling analysis framework. Two drivers shape its design. (1) Existing policies are buried in concrete open- and closed-source serving-system implementations, making apples-to-apples comparison hard. For example, AIBrix's [3] Go reimplementation of vLLM's policy runs 6.2 × faster than vLLM's Python version [45] due to a later-confirmed performance bug [46]; our Rust implementation is a further 1.2 × faster than AIBrix on the same policy. (2) Though complex, all existing policies boil down to computing scheduling scores from per-instance indicators. A unified indicator factory thus lets developers implement and explore new policies in a few lines of code (described below).

Indicator factory. Our framework is a standalone inference router written in Rust that works with any LLM serving engine; Rust keeps it efficient and robust. Its core component, shown in Figure 4, is an *indicator factory* that automatically collects and, when needed, computes the indicators each scheduling policy requires. For scalability, the factory piggybacks indicator collection on instance responses: the router maintains a long-lived connection to each engine instance and, on every response, extracts the required indicators from the response header and updates the factory.

Programming model. Our framework provides a simple API to implement different scheduling policies. The API lets developers express scheduling as a function over the factory's symbolic per-instance indicators in a few lines. On top of the score function, we further provide primitives to filter instances and to select the instance with the minimum (or maximum) score. Line 1 of Figure 4 shows the policy adopted by vLLM [45] using our framework: the score is a weighted sum of `Q-BS` (queued batch size—the number of queued requests in an instance's queue) and `R-BS` (the number of running requests within batch). On a new request (line 4), the router retrieves and computes the indicator values from the factory in parallel, derives a score for every instance, and routes the request to the instance with the minimum score.

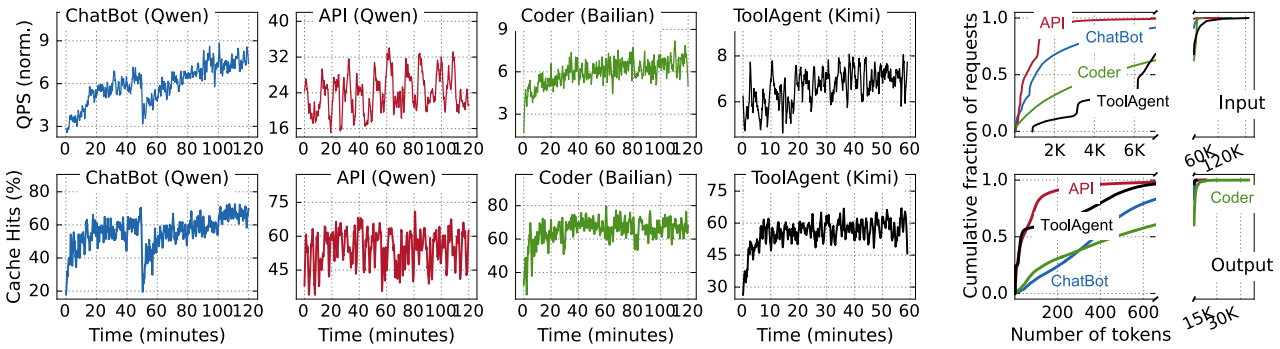

Figure 5: Our studied traces that cover major scenarios in powering LLM services.

4 Characterizing LLM Request Scheduling

4.1 Characterization Methodology

Testbed and instance used. Unless otherwise specified, all experiments run on a testbed with 16 NVIDIA H20 GPUs—hardware similar to that used for hosting LLM services at BAILIAN. Each GPU has 96 GB HBM, sufficient for common models available on the market [50]. The router runs on a high-end CPU server with 160 Intel Xeon cores and 1 TB of DRAM. Our instance runs vLLM-v1 (vLLM) [45]—the state-of-the-art LLM serving engine with the latest optimizations, such as chunked prefill [2] and fast GPU kernels [18].

Models. We chose LLM models representative of different architectures and popular market choices, including dense (Qwen2-7B) and mixture-of-experts (MoE) models (Qwen3-30B) [50].

Workloads. We analyze real-world LLM serving traces, both open-source and collected from BAILIAN, covering common LLM applications: **ChatBot (Qwen)** and **Agent (Qwen)** [11] are open-sourced Alibaba Cloud traces that collect requests from a chatbot service similar to ChatGPT and an LLM API calling agent service [8, 23, 36], respectively. **Coder** collects requests issued by coding agent services to a dedicated cluster in BAILIAN on a single day in November 2025, and **ToolAgent (Kimi)** [34] is another open-sourced trace from Kimi that collects requests from an agent service. All traces except ToolAgent (Kimi) are collected from a single cluster routed by one global router; the source of ToolAgent (Kimi) does not specify whether it is collected the same way.

Our analyzed workloads are representative: they span broad application scenarios, and each selected trace preserves the essential characteristics for evaluating LLM scheduling policies. Specifically, all requests in our traces contain the (hashed) content and request-issuance timestamp, which are critical for evaluating the impact of KV$-aware scheduling on global scheduling (see §4.2). Other popular datasets like AzureLLM-Trace [10] or BurstGPT [49] do not provide such content. Note that with traces containing hashed content, we can still replay them with behavior that exactly matches the original [48]. To facilitate future research, our high-performance trace replayer is open-sourced [12].

Figure 5 visualizes key features of our evaluated traces, including their request arrival rates, input and output token numbers, and the KV$ hit rates assuming an infinite KV$ space. The request arrival rate is normalized due to confidentiality considerations required for the **Coder** trace. Across all traces, over a given serving interval (e.g., 1 hour), the request arrival and KV$ hit rates are relatively stable, with a few short-term fluctuations. Input and output token numbers vary across traces but are typically modest except for a few outliers.

Trace scaling. Since the traces are collected from clusters at different scales than our testbed, we scale them according to our testbed capability similar to prior work [33, 7, 25, 53, 42]. Unless otherwise specified, we scale the average request arrival rate to half of the maximum rate of our testbed obtained via offline profiling. This approximates the serving configurations in BAILIAN because when the arrival rate approaches serving capacity, BAILIAN commonly reroutes requests to another underloaded cluster or simply rejects them in non-critical cases (e.g., ChatApp) [40]. Otherwise, the service-level objectives (SLOs) of many requests cannot be met due to queuing [39]. Our end-to-end analysis in §6 further measures the impact of different request arrival rates on scheduling performance, and shows consistent results.

4.2 Load-balancing Alone is Insufficient for LLM

A starting case: the vLLM policy [45]. Our study starts with the default global scheduling policy adopted by vLLM [45]—a popular open-source LLM serving engine widely used in both industry and academia. Figure 6 (a) shows its scheduling method, which uses the batch size of each instance as the indicator for the routing score. It is a variant of the classic load-balancing-centric join-the-shortest-queue (JSQ) policy with an extension for LLM: at each instance, the batch size includes both the requests running on the instance (R-BS) and those queued in the instance's queue (Q-BS).

Retrofitting vLLM with KV$-awareness (BAILIAN). While JSQ tries to balance the workload across instances, it is unaware of the KV$ state of the incoming requests. This

(a) vLLM

```
req = receive()
## one score per instance
score = 4 * Q-BS + 1 * R-BS
sched_to = instances
           .select_min(score)
req.forward(sched_to)
```

(b) vLLM + KV$-awareness (e.g., Bailian-like)

```
req = receive()
kv_hit = KV$.match(req)
score  = λ * (1-kv_hit) + (1-λ) * norm(BS)
sched_to = instances
           .select_min(score)
req.forward(sched_to)
```

Range [0,1]

Figure 6: (a) The scheduling score of vLLM and (b) adding KV$-awareness to its score for LLM scheduling. Note that the linear combination of two indicators has only one degree of freedom (the weight λ).

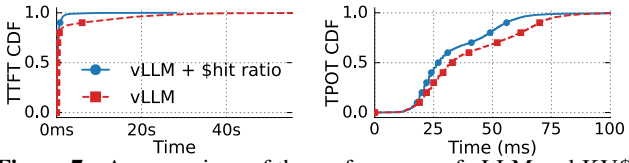

Figure 7: A comparison of the performance of vLLM and KV$-aware scheduling on ChatBot Trace with Qwen3-30B model. Other workloads and models are similar.

matters because routing requests to instances with a higher KV$ hit rate substantially reduces request latency. Figure 6 (b) shows a simple extension of vLLM adopted by BAILIAN and others [35, 6] to make request scheduling KV$-aware: it adds a KV$ indicator to the score function—an estimate of the KV$ hit ratio if the request is routed to that instance. Here, KV is the symbolic value representing the per-instance KV$ hash map. There are two points to note here: (1) the load balance indicator (batch size) needs to be normalized to $[0, 1]$ to match the scale of the hit ratio because otherwise they cannot simply be added together; (2) the analysis in this section assumes the linear combination coefficients (λ) are fixed, and the next section discusses the rationale for setting them.

As shown in Figure 7, adding KV$-awareness to a load-balancing-only policy improves the average TTFT by 84% and the average TPOT by 17%, which is as expected because it increases the KV$ hit ratio as profiled in Figure 8. Interestingly, although the improved KV$ hit ratio—at first glance—is only beneficial to the prefill, we found it also reduces the decode time because it reduces the computation required for each instance, allowing the instance to dedicate more GPU time to the decode phase.

4.3 KV$-awareness vs. Load balancing: The Trade-off

Although adding KV$-awareness is intuitively beneficial (§4.2), realizing this benefit in practice is non-trivial because the KV$ objective may interfere with load balancing. With a linear combination, the priority of each objective is controlled by the weight assigned to each indicator (λ in Figure 6 (b)): a larger weight on the KV$ component prioritizes routing

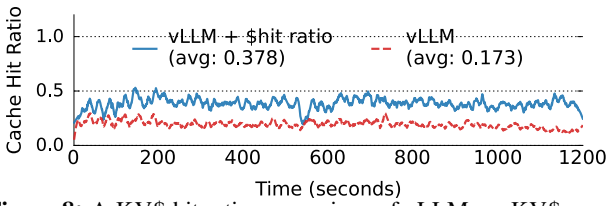

Figure 8: A KV$ hit ratio comparison of vLLM vs. KV$-aware scheduling on ChatBot Trace with Qwen3-30B model. Other workloads and models are similar.

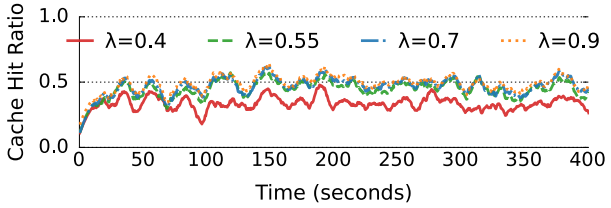

Figure 9: A comparison of the KV$ hit ratio by changing the weight of KV$-awareness in the policy described in Figure 6 (b) on ChatBot Trace with Qwen3-30B model.

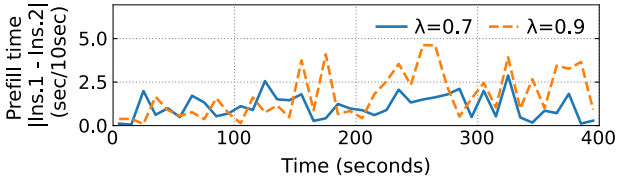

Figure 10: A profile of the workload imbalance between two instances when running with two different weights in a linear combination on the ChatBot Trace using the Qwen3-30B model. The reported metric is the absolute served prefill time in each 10-second window between the two instances (Inst.).

requests to instances with higher hit ratios even when other instances are much less loaded, leading to load imbalance.

Figure 11 illustrates this trade-off, reporting the overall TTFT and TPOT by sweeping weights. We can see that when increasing the weight from 0.4 to 0.9, the TTFT first gradually decreases and then increases, except for the API trace, which is less affected due to its short input length. The increased KV$ hit ratio explains this: as shown in Figure 9, on the ChatBot trace (other traces are similar) the hit ratio rises accordingly with the increased weight.

Despite the increased KV$ hit ratio, there is a knee point in the weight (e.g., 0.7 for ChatBot), beyond which the overall latency starts to increase due to load imbalance across instances. Figure 10 profiles this imbalance, plotting the prefill work assigned to two instances under different weights (0.7 vs. 0.9) over the same 400-second burst period on the ChatBot trace. The prefill time—seconds spent on prefill within each 10-second window—measures the workload per instance: since most tokens are generated during decode, an instance dominated by prefill produces fewer tokens than others. For each setup, we select the two instances (out of 16) with the highest standard deviation of prefill time. We observe that under $\lambda = 0.9$ the average prefill time differs significantly between the two instances (3.57s vs. 2.17s), while $\lambda = 0.7$ yields

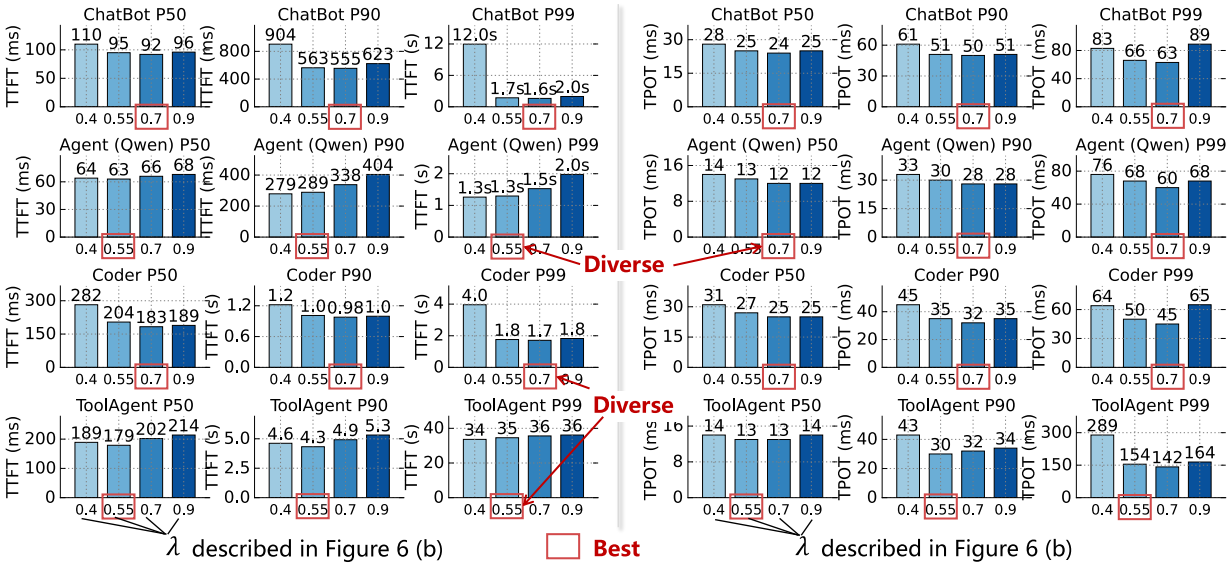

Figure 11: An analysis of how the performance varies with different hyperparameters on four traces with a linear-combination-based method. The model used is Qwen3-30B.

similar values (3.43s vs. 3.40s).

4.4 The Case of Linear Combination

Based on the trade-offs explored previously, using a linear combination to achieve both KV$-awareness and load balancing leads to two issues:

Cons #1. Requires workload-specific hyperparameter tuning. The importance of KV$ and its impact on load imbalance are workload-dependent. For example, Figure 11 presents the tuning results for different traces when running a Qwen3-30B model. We can see that the evaluated optimal weight for each workload varies: in ChatBot the optimal weight is 0.7, while in API it is 0.55, even though both workloads have a similar KV$ access pattern. Note that we cannot afford to sweep all possible configurations, as replaying each trace on the testbed consumes a substantial amount of GPU time. As a result, the linear combination requires workload-specific hyperparameter tuning that is non-trivial in practice due to the diversity of workloads [47].

Cons #2. Sub-optimal performance. During the evaluation in §6, we found that a statically tuned weight cannot always achieve competitive performance compared to other baselines. We hypothesize that this is because the optimal weight may vary over time. Intuitively, if the GPUs are idle, we need to prioritize KV$ hits with a larger KV$ weight. On the other hand, if prioritizing KV$ results in an imbalance, we need to reduce the weight to improve load balancing. However, to the best of our knowledge, all existing work uses a fixed tuned weight for the entire serving duration. While it is possible to design strategies to adaptively tune the weight over time, doing so would add system complexity.

4.5 The Case of Filter-based Combination

Methodology. Figure 13 shows how a typical filter-based combination works for integrating KV$-awareness and load balancing in LLM scheduling systems such as AIBrix [3]. First, the router checks whether the current cluster has an imbalanced load—i.e., the range between the maximum and minimum batch sizes across instances (`BS.max() - BS.min()`) exceeds a threshold (line 3). If so, the router abandons KV$-awareness and simply routes the request to the instance with the smallest batch size for load balancing (lines 4–5). Otherwise, the router uses the KV$ hit ratio as an indicator to route requests to instances (lines 6–9) for KV$-awareness.

Cons #1. Still requires workload-specific hyperparameter tuning. Similar to linear combination, filter-based methods also require hyperparameter tuning because the threshold for determining load imbalance (`Range`) is workload-dependent. As shown in Figure 12, the optimal threshold of a typical filter-based method [3] varies across workloads: for example, in Coder, increasing the threshold from 4 to 16 improves the P50 TTFT and TPOT by 44% and 15%, respectively. On the other hand, for the API trace, 16 is a better choice than 4.

Cons #2. Sub-optimal performance. Besides hyperparameter tuning, filter-based combination is slower than linear combination with properly tuned weights, as shown in Figure 12, because it biases towards load balancing and may forgo the benefits of KV$-awareness. Specifically, when a load imbalance is detected, it completely ignores KV$-awareness, even though routing requests to instances with a higher KV$ hit ratio could still be beneficial if the amount of reduced computation is significant (as it helps reduce the load). With linear combination, this is possible as long as the weight assigned to the KV$ hit ratio is not too small. This is not possible in

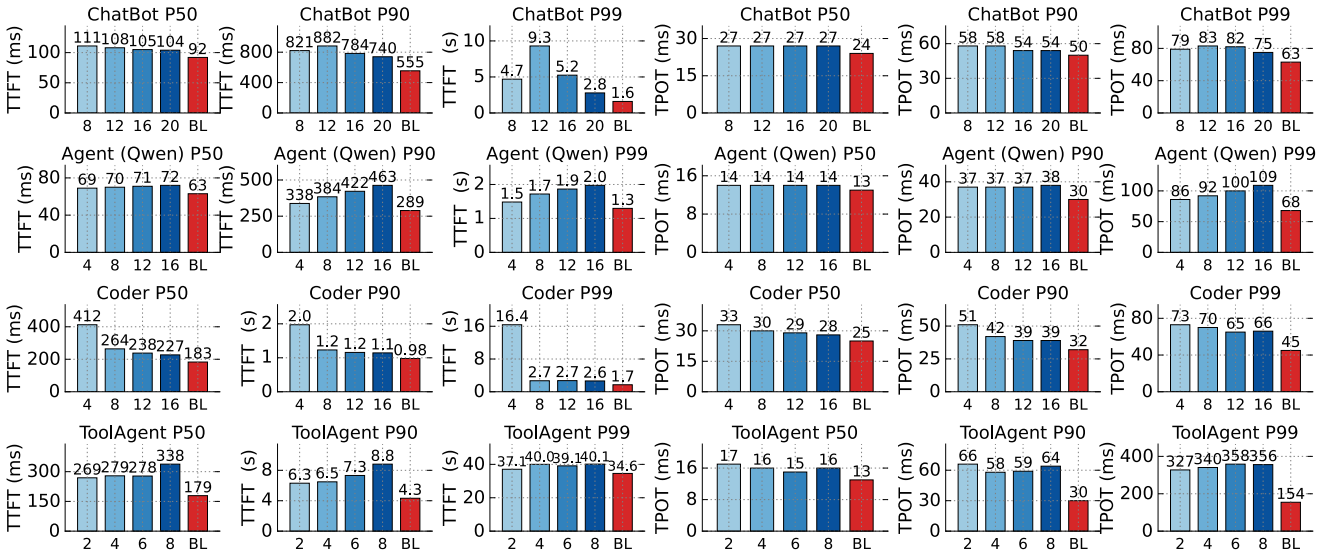

Figure 12: An analysis of how performance varies with different hyperparameters on four traces using a filter-based combination method. **BL** denotes the linear-combination-based method for comparison, tuned with the best hyperparameter. The numbers (2,4,6,8) are the range described in Figure 13. The model used is Qwen3-30B.

```
1  req = receive()                                  Filter-based
2  kv_hit = KV$.match(req)                            method
3  if BS.max()- BS.min() > Range:                (e.g., Aibrix-KV$)
       # Load balance
4      sched_to = instances
                  .select_min(BS)
5  else: # KV$-awareness
6      sched_to = instances
                  .select_max(kv_hit)
                  .select_min(BS)
7  req.forward(sched_to)
```

Figure 13: The pseudocode of filter-based combination of KV$-awareness and load balancing in LLM scheduling, simplified from `prefix-cache` policy of AIBrix [3].

```
1  req = receive()                                  Latency–Based
2  TTFT = Simulator_model.sim(req, BS, KV$, ...)
3  sched_to = instances.select_min(TTFT)
4  req.forward(sched_to)
```

Figure 14: The pseudocode of simulation-based method for combining KV$-awareness and load balancing in LLM scheduling.

filter-based methods.

4.6 The Case of Simulation-based Combination

Methodology. Finally, simulation-based methods [40, 24, 56, 13] use the simulated serving time of routing a request to a specific instance as the routing score. This is based on the observation that the execution of LLM requests is relatively deterministic—each step is a single forward pass—so it can be simulated accurately. Figure 14 shows the pseudocode of a typical simulation-based method [24]: after receiving a request, the router first estimates the TTFT of routing the request to each instance via a simulator (e.g., VIDUR [1]) (line 2), and then routes the request to the instance with the lowest estimated TTFT (lines 3–4). Note that simulation-based methods typically estimate the TTFT instead of the end-to-end latency because the end-to-end latency depends on the number of output tokens, which is unpredictable.

Simulation-based methods can be viewed as a higher-order combination of indicators that achieve KV$-awareness and load balancing. This is because the simulator must use the KV$ state and batch size of each instance as input features to accurately simulate the TTFT. Here, we chose a simulation-based implementation similar to llm-d [24] but with a retrofitted simulator from VIDUR [1]—the state-of-the-art LLM instance simulator. Our retrofitting consists of two parts: (1) we extend the simulator to consider KV$-aware execution by modeling the prefill phase with cache hits, and (2) we re-implement it in Rust and enable parallel simulation to scale the online simulation to multiple instances. Without KV$-awareness, the simulation-based method does not outperform its counterparts in our setting, similar to the observations we made in §4.2. Without Rust, the original Python-based implementation has considerable scheduling latency and would incur substantial online scheduling overhead. We also have several optimizations to scale the simulator to hundreds of instances. We will leave the details to another paper as it is not the focus of this work.

We studied a state-of-the-art method and found that it outperforms the linear-combination-based method in certain traces, as also shown in Figure 14. Despite the improved performance, simulation-based methods still have two issues due to their complexity:

Cons #1. Development complexity due to per-model implementation and per-hardware tuning. The performance of simulation-based methods depends on the accuracy of the simulator, which is non-trivial to achieve in practice because we need to consider both the model architecture and

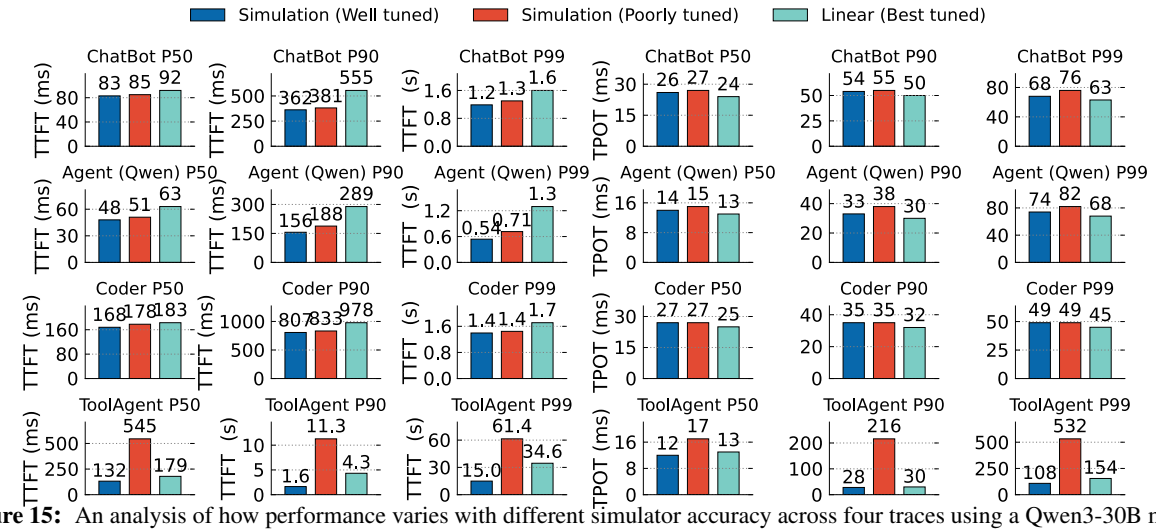

Figure 15: An analysis of how performance varies with different simulator accuracy across four traces using a Qwen3-30B model.

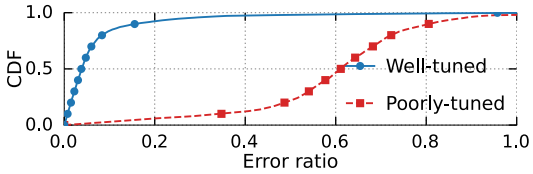

Figure 16: A comparison of a well-tuned simulator vs. a non-tuned one on ChatBot Trace with Qwen3-30B model.

the hardware characteristics. To quantify the impact of simulator accuracy on scheduling performance, Figure 15 presents the performance of using well-tuned vs. non-tuned simulators on four traces when serving a Qwen3-30B model. The poorly tuned simulator is one originally used for another model—Qwen2-7B, while a well-tuned simulator is the one implemented specifically for Qwen3-30B. Figure 16 measures the TTFT deviation when using two simulators to serve a Qwen3-30B model compared with using vLLM. We can see that a well-tuned simulator achieves much higher accuracy than an untuned one. With a more accurate simulator, the TTFT and TPOT tail latency improve by 75.6% and 79.7%, respectively.

While it is possible to develop per-model simulators for high scheduling performance, doing so incurs non-trivial development complexity because the simulations highly depend on the model architecture—which is evolving rapidly with new modules (e.g., linear attention [41] and Engram [14]). Meanwhile, for the same model, the hyperparameters of the simulator need to be tuned according to the hardware characteristics, leading to further engineering efforts.

Cons #2. Still sub-optimal performance. Simulation-based methods still suffer from sub-optimal performance, especially for TPOT. As shown in Figure 15, on the ToolAgent trace, the TPOT tail latency is 71.1% slower than that of the best linear-combination-based method. We hypothesize that this is because mispredictions of the simulator lead to load imbalance. For example, in Figure 16, we can see that even with

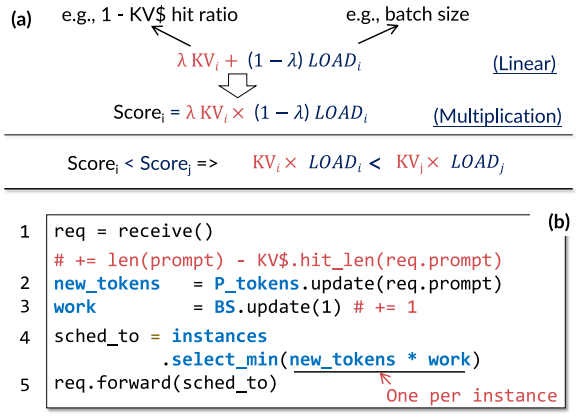

Figure 17: (a) An illustration of how multiplication combines two indicators without the hyperparameters needed in linear combination, and (b) the pseudocode of our scheduling method.

a well-tuned simulator, there are still about 10% of requests with more than 20% prediction error. Such errors mainly come from two sources: request reordering at the vLLM API server, and inaccuracies in latency prediction.

5 Simple Multiplication May Be All You Need

The methodology (Figure 17). Our method is simple: we only need to multiply two carefully chosen indicators to compute the scheduling score, one for KV$-awareness and the other for load balancing, and then route the request to the instance with the minimal score. The basic idea is based on the observation that, if a linear combination of two indicators works, then multiplication can also work, with the benefit of avoiding hyperparameter tuning, as shown in (a). The two indicators—**P-token** (the number of new prefill tokens if the request is routed to an instance, considering KV$ hits) and **BS** (the batch size of the instance)—are chosen based on our analysis in §5.1.

To see why routing to the instance with the minimal (P-

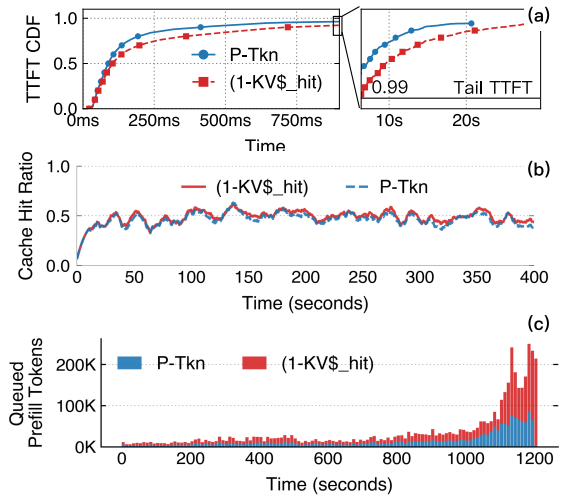

Figure 18: (a) A comparison of using new prefill tokens (**P-token**, shown as "P-Tkn" in the figure) vs. 1-KV$ hit ratio (1-KV$_{hit}$) as the KV$-awareness indicator ($A$) in $A \times BS$ scheduling, (b) the KV$ hit ratio analysis, and (c) the queued prefill tokens analysis. The analysis is done on the Qwen3-30B model with the ChatBot(Qwen) trace. Note that the bottom graph is not a stacked graph; rather, the bars overlap each other.

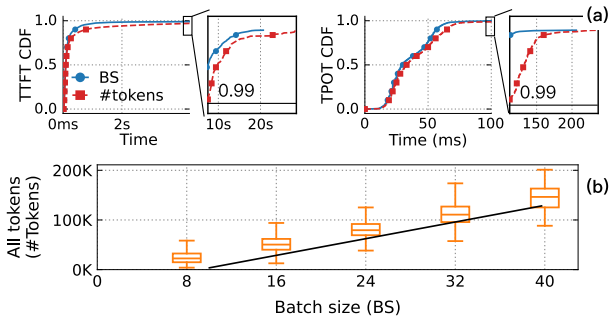

Figure 19: (a) A comparison of using batch size (BS) vs. total tokens (#Tokens) as the load-balancing indicator (B) in P-token $\times B$ scheduling. (b) The profiled relationship between batch size and total tokens. The analysis is done on the Qwen3-30B model with the ChatBot(Qwen) trace.

token $\times$ BS) score considers both objectives well, consider two instances i and j: if routing the request to instance i results in more KV$ hits than routing it to instance j, then instance i will have a lower **P-token** value unless there are many queued prefill requests in instance i (indicating work imbalance). Meanwhile, the **BS** captures the decode workload of each instance, so if instance i has a significantly larger batch size than instance j, the multiplication will likely favor instance j for load balancing.

5.1 The Choice of the Indicators

KV$-awareness indicator (P-token). Besides **P-token**, another natural choice for the KV$-awareness indicator is the **1-KV$ hit ratio**, i.e., the KV$ hit ratio if the request is routed to an instance. It is adopted by works such as Preble [44] and AIGW [6]. Note that we subtract from one because a higher KV$ hit ratio should yield a lower score to align with the new prefill tokens indicator. We do not consider TTFT because it requires a simulator, which is not always applicable.

Our empirical analysis shows that using **P-token** yields better performance than using **1-KV$ hit ratio**. Figure 18 (a) shows that using **P-token** results in a 14.4% lower P50 TTFT and a 42.8% lower P95 TTFT compared to using **1-KV$ hit ratio**. For a fair comparison, we fix the load-balancing indicator to **BS** in both cases. Due to space limitations, we only report the results for one workload here; however, the trend is consistent across all evaluated workloads.

To understand the cause of this difference, Figure 18 further breaks down the KV$ hit ratios of different methods in (b) and the load balancing status in (c). We can see that the two methods achieve similar KV$ hit ratios, so they are equally KV$-aware. The key difference is that using **P-token** achieves better load balancing, as it additionally considers the queued prefill tokens in each instance. As a result, when making scheduling decisions, the router bypasses instances with many queued prefill requests, even if they have a high KV$ hit ratio.

Load-balancing indicator (BS). Besides **BS**, another common choice is the total tokens (**#Tokens**) on each instance, as adopted by works such as ai-Dynamo [35] and AIGW [6]. The rationale is that the total computation cost of a request is proportional to the number of tokens in its context. However, we found that using **BS** yields better performance, as shown in Figure 19 (a), for two reasons. First, workloads can be categorized into prefill and decode loads, where the former is considered in our **P-token** indicator. Thus, we only need an indicator for the decode workload, which is exactly what **BS** captures (note that we have also tried using decode batch size, and the results are similar since the **BS** is dominated by the decode requests). Moreover, **BS** is a better indicator for the (decode) work assigned to an instance because the decode time is more stable across batch sizes. Specifically, a larger batch size leads to a longer decode time, but more decode tokens do not necessarily mean decode is slower when the batch is small, thanks to the KV$ [55]. This is illustrated in Figure 19 (b), where we profile the relationship between batch size and total tokens while serving a ChatBot(Qwen) workload with Qwen3-30B.

5.2 Benign and Failure Cases Analysis of the Multiplicative Scheduling Score

Overview. At a high level, as long as there is no load imbalance, i.e., one instance is overloaded while others are idle, routing requests to instances with high KV$ hit rates (i.e., low **P-token**) is always beneficial. Thus, the multiplication fails when a set of instances is about to be overloaded but their increase in **BS** cannot offset the decrease in **P-token** from high KV$ hit rates, so requests keep being routed there and cause the imbalance. This can happen under extreme KV$

skewness: when some prefixes are repeatedly accessed but only cached on a small set of instances—which we term KV$ *hotspots*. We found that such hotspots are rare in practice—at least not present in any of our evaluated traces. More importantly, as their patterns are clear, we can design a detector to catch them beforehand.

To analyze the failure cases of our multiplication method, we derive the condition under which KV$ hotspots occur and the increased batch size cannot offset the high KV$ hit rate given a workload pattern. For each workload, we first group requests by their KV$ prefixes and partition instances according to their KV$ ownership. Next, for each request class, we analyze the relationship between the workload pattern, the P-token indicator given the KV$ hit rate, and the batch size indicator.

Prelude: request grouping and instance partitioning. First, we partition all requests into a set of classes $\mathcal{C}$, where each $c \in \mathcal{C}$ corresponds to a group of requests that share the same KV$ prefix. In practice, a class roughly matches an application or a user: their requests share the same system prompt and often a similar conversation history [47]. For a fixed class c, we consider an accumulation time window $(t, t+window)$ and denote by x the fraction of all requests arriving at the cluster that belong to class c within this window; the remaining fraction is $\overline{x} = 1 - x$.

For each class c, we partition the cluster into two sets of instances: M and $\overline{M}$. M contains instances whose cache currently holds the prefix of class c, i.e., with KV$ hits, while $\overline{M}$ contains all other instances.

Impact of a request class on batch size. Let QPS be the total query rate of the cluster, and let t be the arrival time of the suspected class-c requests that may lead to imbalance. We denote the average batch size per instance in a balanced state prior to t as BS_0. We also denote the expected batch sizes of instances in M and $\overline{M}$ by BS_t and $\overline{BS}_t$ during the period $(t, t+window)$. We assume the extreme case in which all class-c requests are routed to M due to high KV$ hits, because routing any class-c request to an instance in $\overline{M}$ would cache the prefix there, expand M, and thereby dissipate the hotspot. Under this worst-case assumption, we establish the following approximate expression for the ratio between a potentially overloaded instance's batch size and a non-overloaded one's:

$$\frac{BS_t}{\overline{BS}_t} = \frac{BS_0 + (x \cdot \text{QPS})\,/|M| \cdot t}{BS_0 + (\overline{x} \cdot \text{QPS})\,/|\overline{M}| \cdot t}. \tag{1}$$

The main term $(x \cdot \text{QPS})\,/|M| \cdot t$ corresponds to the number of requests of class c routed to the instances that cache its prefix, while $(\overline{x} \cdot \text{QPS})\,/|\overline{M}| \cdot t$ is the number of all other requests routed to the remaining instances.

Analysis: when multiplication suffices, and is this common? As long as the batch size of the suspected hotspot instances is not larger than that of the others, it is beneficial to route requests to these instances, since doing so can exploit the KV$ hits without incurring load imbalance. This is precisely what our multiplicative method is designed for. The remaining question is whether such cases are common in practice. Fortunately, Equation 1 reveals that the batch-size skewness is governed by two ratios: the class popularity $x/\overline{x}$ and the cache coverage $|M|/|\overline{M}|$. We can therefore empirically analyze the prevalence of such cases by tracking these two ratios at runtime, sampling the request classes with the highest KV$ hits within each one-minute window.

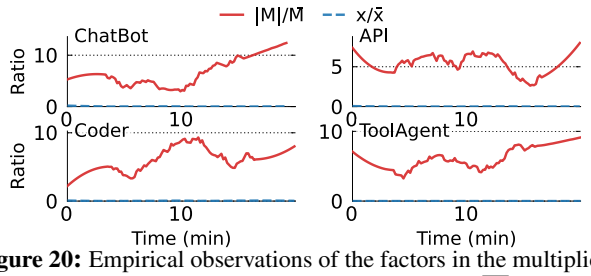

Figure 20: Empirical observations of the factors in the multiplicative score across different traces. If $x/\overline{x} \leq |M|/|\overline{M}|$, no KV$ hotspot can cause load imbalance, so our multiplicative method can effectively balance the load with KV$-awareness.

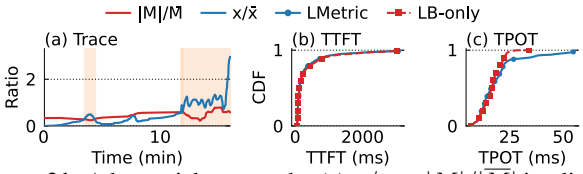

Figure 21: Adversarial case study: (a) $x/\overline{x} > |M|/|\overline{M}|$ implies a hotspot that could cause imbalance under LMETRIC, (b–c) performance comparison with a load-balance-only solution.

Figure 20 shows that for all traces (representative of LLM serving and studied in this work), our multiplication remains in its applicable regime, because the expected batch size of the suspected hotspot instances is not larger than that of the others. Concretely, every sampled class satisfies Equation 2:

$$\frac{x}{\overline{x}} \leq \frac{|M|}{|\overline{M}|} \tag{2}$$

which says the class's relative popularity $(x/\overline{x})$ never exceeds the relative cache coverage it enjoys $(|M|/|\overline{M}|)$; i.e., the prefix is cached on enough instances to absorb its share of the arrivals. This implies that even when every class-c request lands on M, no hit instance accumulates a larger batch size than a non-hit one, i.e., transforming and then substituting Equation 2 into Equation 1, we get $BS_t \leq \overline{BS}_t$.

Analysis: when multiplication fails. Based on the previous analysis, if Equation 2 does not hold, i.e., $x/\overline{x} > |M|/|\overline{M}|$, then a KV$ hotspot can cause load imbalance that breaks our multiplicative method. Though we have not observed such cases in any of our evaluated traces, we used the pattern of KV$ hotspots to examine a subset of the production workloads in BAILIAN and found one, as shown in the orange-shaded windows in Figure 21 (a). The cluster serves a thinking

workload with bursts of long requests sharing a common prefix, visible around minute 11 of the run. In this case, the batch indicator cannot outperform the KV$ indicator, and thus the multiplicative score continuously routes requests to a few instances with high KV$ hits, leading to load imbalance and performance degradation. Figure 21 (b–c) shows that LMETRIC cannot outperform a load-balancing-only solution (i.e., vLLM) during this period.

Retrofit: a two-phase detector for KV$ hotspots. The boundary condition in Equation 2 yields a clear failure-case detector based purely on the workload pattern and KV$ states, which we run alongside each scheduling decision to catch potential hotspots. For each request class, we monitor the two ratios $x/\overline{x}$ and $|M|/|\overline{M}|$ in real time; when Equation 2 is violated, we raise an alarm and intervene by filtering out the suspected instances (M) from the routing targets (e.g., the orange-shaded windows in Figure 21 (a)). To bound the monitoring overhead, we only track requests with the highest KV$ hit rates.

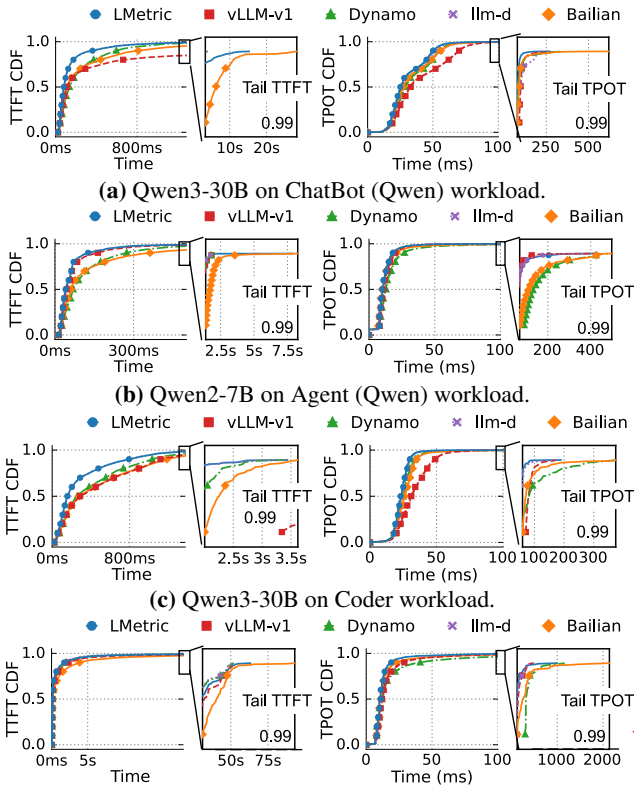
However, Equation 2 is only a necessary (not sufficient) condition for a hotspot, because it was derived under the worst-case assumption that all class-c requests are routed to M. In reality, even when Equation 2 is violated, it may still be beneficial to route requests to the suspected instances with high KV$ hits, as long as we do not route too many. We therefore augment the detector with a second phase: after the first phase raises an alarm, we track each subsequent class request and filter out M from scheduling only when $2|M|$ consecutive requests would receive a smaller multiplicative score on a hotspot instance $m \in M$ than on a non-hotspot one $m' \in \overline{M}$: i.e., P-token$_m \times BS_m \leq$ P-token$_{m'} \times BS_{m'}$.

6 End-to-end Evaluation

6.1 Comparison with Production Schedulers

Baselines. We compare LMETRIC against popular production schedulers and the current scheduler used in BAILIAN. As certain baselines show low router throughput in their default implementations, e.g., vLLM exhibits low processing throughput with its Python-based router [46], we re-implement their policies within our highly optimized Rust router framework described in §3. For an apples-to-apples comparison, we evaluate all policies under our framework, and we have carefully verified that our re-implementations are no slower than their original implementations. The detailed descriptions of the baselines are as follows:

- **BAILIAN** is the production scheduler used in BAILIAN's LLM serving system. It adopts a linear-combination-based approach similar to the one shown in Figure 6 (b). We have carefully tuned its hyperparameters for each workload to achieve the best performance.
- **vLLM [45]** is a widely used LLM serving system that adopts a load-balancing-only design (see Figure 6 (a)).



(a) Qwen3-30B on ChatBot (Qwen) workload.

(b) Qwen2-7B on Agent (Qwen) workload.

(c) Qwen3-30B on Coder workload.

(d) Qwen3-30B on Agent (Kimi) workload.

Figure 22: End-to-end TTFT and TPOT CDFs of LMETRIC and baselines on four workloads.

- **Dynamo [35]** is a popular serving framework released by NVIDIA. It also adopts a linear-combination-based approach but with a different choice of indicators than BAILIAN's. The two indicators chosen are the number of prefill tokens (the same as our P-token) for KV$-awareness and the total tokens in the instance for load balancing. The router routes requests to the instance with the minimal regulated and weighted sum of the two indicators. Similar to BAILIAN, we also tune its hyperparameters for each workload to achieve the best performance.
- **llm-d [24]** adopts a latency-based scheduling policy: it estimates the TTFT and routes requests to the instance with the lowest TTFT using the simulation-based approach described in §4.6.

Overall performance. Figure 22 shows the end-to-end TTFT and TPOT CDFs of LMETRIC and the baselines on four traces. All experiments are conducted on a 16-GPU testbed with 16 instances, and each trace is scaled to half of the maximum load that the testbed can handle. Due to space constraints, we report results for a representative subset: the Qwen3 MoE model on ChatBot, Coder, and Agent workloads, and the Qwen2 model on the Agent (Qwen) workload. We observe consistent performance trends across all model–trace combinations.

LMETRIC outperforms all baselines across all traces. On

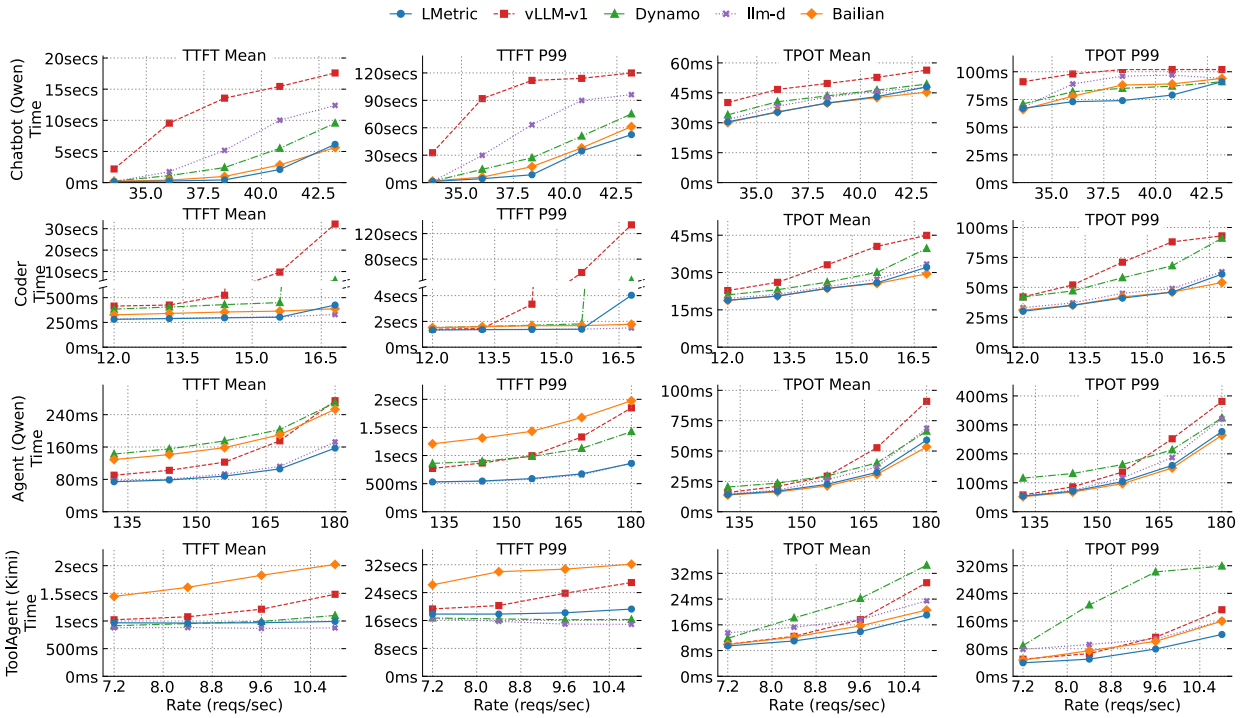


Figure 23: End-to-end performance under different request rates. Except for the second row, which uses a Qwen2-7B model, all other rows use a Qwen3-30B model.

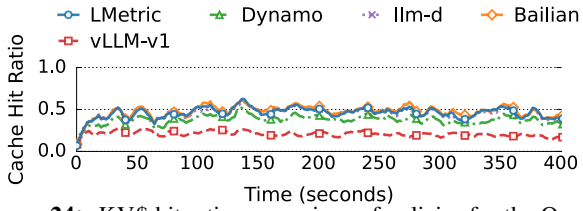

Figure 24: KV$ hit ratio comparison of policies for the Qwen3-30B model on the ChatBot (Qwen) workload.

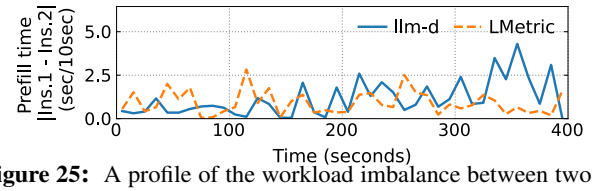

Figure 25: A profile of the workload imbalance between two instances under LMETRIC and llm-d while serving a ChatBot (Qwen) workload with the Qwen3-30B model. The reported metric is the absolute served prefill time in each 10-second window between the two instances (Inst.).

the ChatBot workload, it reduces the mean TTFT by 92% and the mean TPOT by 24% compared to vLLM, and it reduces the P99 TPOT by 13% compared to llm-d—the second-best policy—with a similar TTFT. The improved performance mainly comes from being KV$-aware without sacrificing load balancing. To examine LMETRIC's behavior, Figure 24 plots the KV$ hit ratio for different systems on the ChatBot workload. We can see that LMETRIC consistently achieves a KV$ hit ratio comparable to that of other KV$-aware policies, and its ratio is significantly higher than that of the KV$-unaware policy (vLLM). Meanwhile, Figure 25 further analyzes the imbalance following the approach used in §4.3. For brevity, we compare LMETRIC only with llm-d—the second-best policy on the ChatBot trace. We can see that LMETRIC achieves a better-balanced load than llm-d.

Performance under different request rates. Figure 23 further shows how LMETRIC performs under different request arrival rates. The results are largely consistent with those under a fixed request rate setting: LMETRIC outperforms all baselines across different traces and request rates, except for the ToolAgent trace, where LMETRIC exhibits a slightly higher (10%) mean TTFT than llm-d but achieves a 30% lower TPOT. This may be because a simulation-based approach can better estimate the prefill workload than our simple P-token indicator. Nevertheless, LMETRIC still achieves the lowest TPOT without relying on a complex simulator, as it considers both KV$ management and (decode) load balancing. The performance gap between baselines widens as the request rate increases, because under high load, a more balanced and KV$-aware scheduling strategy can yield higher overall system throughput, leading to faster consumption of queued requests.

6.2 Comparison with Recent Research Schedulers

Baselines. We further compare LMETRIC with two state-of-the-art research schedulers: Preble [44] and PolyServe [56]. As in the previous section, both baselines run in our router framework (§3): (1) Preble's open-source release runs on a different router stack from ours, (2) PolyServe is not

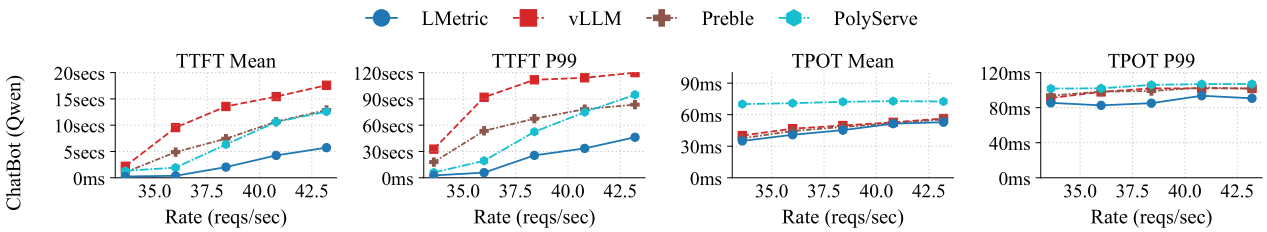

Figure 26: End-to-end performance of LMETRIC alongside two recent research baselines (Preble and PolyServe) under the same setting as Figure 23, with vLLM included as a reference. Model: Qwen3-30B on the ChatBot (Qwen) workload.

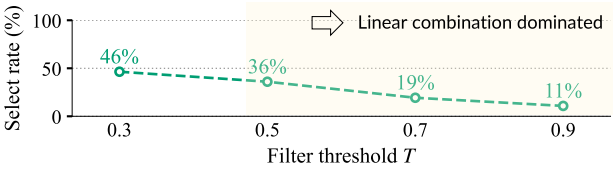

Figure 27: Preble's KV$-aware branch selection rate under different filter thresholds T.

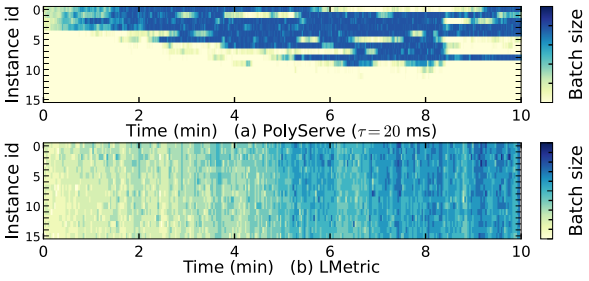

Figure 28: Running batch size across 16 instances over a 10-minute window, under PolyServe and LMETRIC. Workload: ChatBot (Qwen) trace at 18.75 reqs/sec on Qwen3-30B instances.

open-sourced, and re-implementing both in our framework enables an apples-to-apples comparison. We have carefully tuned different implementations and their hyperparameters to achieve the best performance, as detailed in §A.

- **Preble [44]** adopts a hybrid filter-based (§4.5) and linear-combination (§4.4) scheme. It first filters instances with high KV$ hit ratios based on a threshold ($T = 0.5$ tuned in §A.1). If the filter returns any instance, it routes to the one with the highest hit ratio; otherwise, it routes the request to the instance with the highest linear-combined score over KV$ and load indicators.
- **PolyServe [56]** is a simulation-based scheduler (§4.6) that optimizes a different objective from the other baselines and LMETRIC: meet the SLO while creating a load gradient across instances that facilitates auto-scaling. Using the simulator's predicted TTFT and TPOT, PolyServe routes each request to the most loaded instance whose predicted latency still meets the SLO bounds SLO_{TTFT} and SLO_{TPOT}; when no instance is feasible, it falls back to the instance with the lowest predicted TPOT.

Overall performance under different request rates. Figure 26 reports mean and P99 TTFT/TPOT for LMETRIC and the baselines on ChatBot (Qwen) with Qwen3-30B. Other workloads share similar results.

Compared with Preble, LMETRIC reduces mean TTFT by 56% and mean TPOT by 8%, and it reduces P99 TTFT by 45% and P99 TPOT by 16%. Although Preble is faster than vLLM thanks to KV$-awareness, it performs similarly to the linear-combination baselines that LMETRIC outperforms, because it falls back to the linear-combination branch most of the time (see Figure 27). Note that lowering the threshold to reduce the linear-combination branch selection rate does not necessarily improve Preble's performance, as it biases the scheduling towards KV$ and thus sacrifices load balancing.

Compared with PolyServe, LMETRIC achieves lower mean and P99 TTFT and TPOT across all request rates in Figure 26. The gap reflects PolyServe's design objective: instead of balancing load, PolyServe creates a load gradient across instances so that idle ones can be released by auto-scaling. Concentrating load this way raises instance utilization but degrades per-request latency. Figure 28 illustrates this trade-off: PolyServe loads instances 0–8 and leaves 9–15 idle, while LMETRIC spreads the same aggregate workload across all 16 instances.

6.3 In-production Evaluation

Deployment overview and methodology to validate performance improvements. LMETRIC now serves production traffic at BAILIAN as the scheduler for a Qwen3.5-27B cluster, our first full-scale deployment. To measure the impact on service quality, we report the observed performance from a canary release. On one day in May 2026, we split the traffic that previously fed one production cluster across two clusters: 1/3 of the traffic went to a cluster running LMETRIC, and the remaining 2/3 to a cluster running BAILIAN's prior scheduling method. To ensure a fair comparison, we sized the clusters so that each received the same reqs/GPU. The LMETRIC cluster contained several hundred GPUs; the detailed cluster setup is confidential and thus omitted.

Performance. LMETRIC reduces both TTFT and TPOT in production: Figure 29 compares the two clusters using screenshots of BAILIAN's internal performance dashboard. The snapshots show that, compared with BAILIAN's prior scheduler, mean TTFT and mean TPOT drop by 39% and 51% respectively. The results imply that LMETRIC can serve

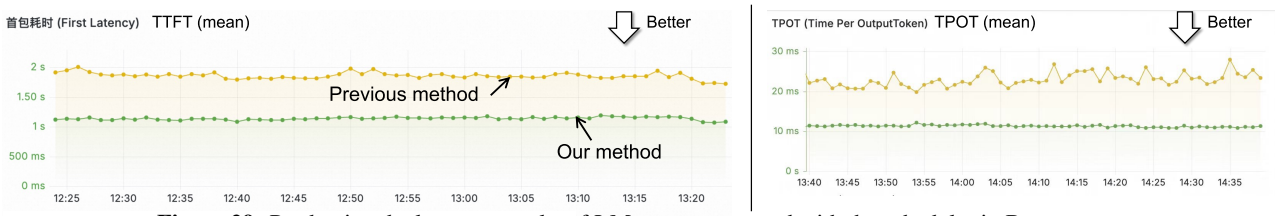

Figure 29: Production deployment results of LMETRIC compared with the scheduler in BAILIAN.

the same workload with fewer GPUs under the same SLO.

7 Discussion

Scheduling under PD-disaggregation. Scheduling under PD-disaggregation is different (and we argue simpler) than our targeted PD-colocation, for two reasons. First, routing decode requests primarily needs to consider load balancing. Existing systems [35, 3, 24, 40] already handle this effectively with simple indicators like batch size [3] or total tokens [35]. Second, routing prefill requests can address KV$-awareness and prefill load balancing with a unified indicator—the number of new prefill tokens after cache hits. Using this indicator as a scheduling score naturally combines both objectives without explicit hyperparameter tuning [3, 35], and we find it effective in our analysis. On the other hand, PD-disaggregation does introduce new scheduling challenges, such as managing prefill and decode clusters with different capacities, which we leave to future work.

Scheduling under heterogeneous deployments. In real-world production, model services are heterogeneous in both models and GPU types, while LMETRIC targets scheduling for a single model under homogeneous GPUs. Nevertheless, LMETRIC still works in this setting because providers, to cope with this complexity, logically partition their deployment into multiple clusters, each serving a single model on a single GPU type. The global scheduler inside each cluster therefore sees a homogeneous pool of instances, where LMETRIC applies.

KVCache sharing. Some serving clusters support KV$ sharing: an instance can fetch the requested KV$ from another instance through RDMA when it does not hold the cache locally [40]. This mechanism reduces the cost of scheduling a request to an instance without KV$, but it does not remove the benefits of KV$-aware scheduling provided by LMETRIC because local KV$ hits are still cheaper than remote KV$ fetches in two ways. First, a local hit avoids a remote transfer on the TTFT path. Second, it avoids keeping the same KV$ on two instances, which saves memory and reduces cache pressure.

8 Related Work

LLM requests global scheduling. LMETRIC continues the line of research on scheduling LLM requests in a cluster [29, 27, 44, 40, 56, 24, 52]. To the best of our knowledge, all these methods target both KV$-awareness and load balancing by combining indicators for each objective through the three approaches discussed in §4. LMETRIC reuses these indicators but combines them with a simple yet efficient multiplication combinator.

LLM requests scheduling within an instance. These works are orthogonal to LMETRIC's global scheduling: they optimize request execution within an instance. Sarathi-Serve [2] introduces chunked prefill, which splits long prefill requests into smaller chunks to reduce stalls for co-located decode requests. VTC [43] adopts token-based admission control to achieve fairness. FairBatching [32] uses a linear-time analytical model to prioritize prefill versus decode tokens and dynamically form batches. A good global scheduler can further improve these local schedulers, e.g., by reducing overloads that are difficult to handle locally.

Optimizing LLM serving. Beyond scheduling, LLM serving systems improve performance by increasing KV$ hit rates [40, 47], adding model-serving elasticity [53, 50], and improving GPU execution efficiency [29, 28, 18, 16], just to name a few. These techniques coexist with scheduling optimizations.

9 Conclusion

We contribute the first multiplicative combinator for high-quality LLM request scheduling, achieving both KV$-awareness and load balancing in a hyperparameter-free manner. Evaluations on real-world workloads covering chatbots and agents confirm the benefits of our approach, and our method has been deployed in production with confirmed effectiveness.

10 Acknowledgment

We sincerely thank the OSDI'26 reviewers for their insightful comments and Neeraja J. Yadwadkar for shepherding our paper. We also thank Jinyu Gu for valuable feedback and for suggesting the classic system term "simple is better" for our paper. A Appendix

A.1 More on Preble

```
1  req = receive()
2  kv_hit = KV$.match(req)
3  if kv_hit > T:
       # KV$-awareness
4      sched_to = instances
                  .select_max(kv_hit)
                  .select_min(P_tokens)
5  else: # Linear fallback
6      sched_to = instances
                  .select_min(∑3min α * P_tokens
                                  + β * BS)
7  req.forward(sched_to)
```

Figure 30: The pseudocode of Preble's method.

Preble method in detail. Preble [44] adopts two of the combination methods we identify in a hybrid form: a KV$-aware filter (§4.5) on top of a linear-combination fallback (§4.4). Figure 30 shows the pseudocode using our scheduling language. After receiving a request, Preble first filters the instances with high KV$ hits—i.e., instances whose cached prefix covers more than a threshold T of the prompt (line 3). Among the instances tied for the highest KV$ hit ratio, it routes the request to the one with the least prefill load (line 4). Otherwise, it uses a linear-combination score over all instances and selects the one with the smallest score (line 6).

More specifically, Preble adopts the following scoring function for the fallback path:

$$\arg\min_i \sum_{r \in W_i} \left(\mathrm{PT}_r + \mathrm{DT}_r\right),$$

a sum of per-request prefill time PT_r and decode time DT_r over recent requests W_i routed to instance i. Preble realizes PT_r by assigning a pre-determined per-token prefill cost to each newly prefilled token of r, and DT_r by assigning a pre-determined per-request decode cost to r itself, both aggregated per instance over a 3-minute sliding window. In its implementation [5], Preble derives these two costs from exact indicators exported by the engine, see below.

$$\arg\min_i \left(\alpha \cdot \sum_{\text{window}} \text{P-token}_i \;+\; \beta \cdot \sum_{\text{window}} \mathrm{BS}_i\right).$$

The fallback score of Preble is therefore a variant of the linear combination analyzed in §4.4.

Setup and tuning. We re-implement Preble inside LMETRIC's router framework for two reasons: (1) to enable an apples-to-apples comparison with our method, and (2) the open-source reference does not sustain our request rate, an issue tracked upstream [4].

We carefully tune the configurations of Preble to ensure a fair comparison. Preble has three knobs to tune[1]: the filter threshold T and the linear-combination coefficients. Tuning the combination space is expensive, so we focus on T and fix the linear-combination coefficients α and β using the profiling method described in Preble's paper. Surprisingly, we find T has little impact on performance (see Figure 31), and Preble's default ($T = 0.5$) is already optimal on our traces. As a result, all experiments in §6.2 use the published default $T = 0.5$.

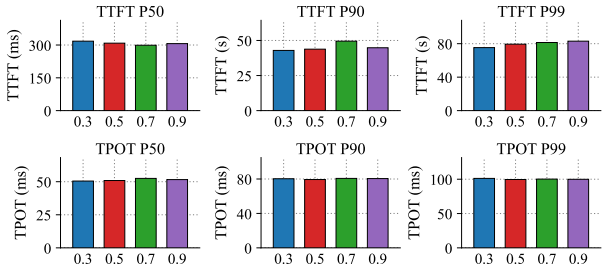

Figure 31: Performance of Preble as the filter threshold T varies on the ChatBot (Qwen) trace; model: Qwen3-30B.

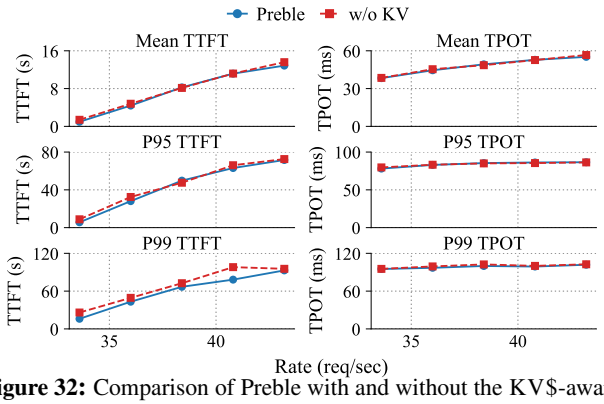

Figure 32: Comparison of Preble with and without the KV$-aware filter.

Comparison of Preble with and without the KV$-aware filter. To characterize how much of Preble's behavior comes from its KV$-aware filter on top of the linear-combination fallback (§4.4), we compare the default ($T = 0.5$) against $T = 1$, which disables the filter and routes purely by the fallback score. Figure 32 reports the comparison on the ChatBot (Qwen) trace with 16 Qwen3-30B instances. We can see that the filter yields a measurable improvement, but the bulk of Preble's performance on this trace is dominated by its linear-combination component, consistent with the T sweep in Figure 31 and our analysis in §6.2 (Figure 27).

A.2 More on PolyServe

PolyServe method in detail. PolyServe [56] is a simulator-based scheduler that optimizes a different objective: meet the SLO while creating a load gradient across instances that facilitates auto-scaling. Figure 33 shows its scheduler in our scheduling language. On each request, PolyServe first calls the simulator of §4.6 to predict per-instance TTFT and TPOT under the new request, conditioned on per-instance batch size

[1] The fallback score actually depends only on the ratio α/β, so the two coefficients carry one degree of freedom. Nevertheless, Preble's implementation exposes α and β as separate parameters, so we tune both to match it.

```
1  req = receive()
2  TTFT,TPOT = Simulator.predict(
                 req, BS, KV$, ...
               )
3  if ∀ instance, TTFT > SLO_TTFT or TPOT > SLO_TPOT:
       # Load-balancing branch
       sched_to = instances.select_min(TPOT)
5  else: # Utilization branch
6      sched_to = instances.filter(
                    TTFT ≤ SLO_TTFT and TPOT ≤ SLO_TPOT
                  ).select_max(TPOT)
7  req.forward(sched_to)
```

Figure 33: The pseudocode of PolyServe's simulation-based filter scheduler.

BS and KV$ footprint (line 2). It then branches on the simulator's output. If any instance meets the SLO bounds SLO_{TTFT} and SLO_{TPOT} (line 5), PolyServe takes the utilization branch: filter to feasible instances and route to the one with the highest predicted TPOT, i.e., the most loaded feasible instance (line 6). Otherwise (line 3), PolyServe falls back to load balancing and routes to the instance with the lowest predicted TPOT (line 4).

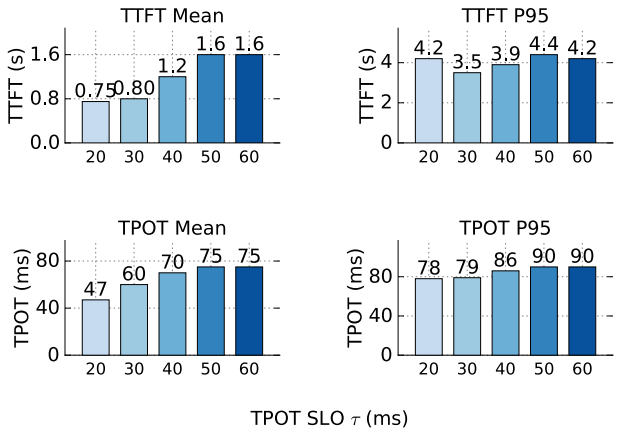

Figure 34: PolyServe end-to-end TTFT and TPOT under different TPOT-SLO thresholds τ on the ChatBot (Qwen) trace at 35.0 reqs/sec on the same 16 Qwen3-30B instances as §6.2.

Setup and tuning. PolyServe's scheduling is parameterized by the SLO bounds SLO_{TTFT} and SLO_{TPOT}, so its performance depends on the configured SLO. Following PolyServe's paper [56], we tune the SLO and adopt the best-performing setting in §6.2. Figure 34 reports the tuning of τ (denoting SLO_{TPOT}) on the ChatBot (Qwen) trace, with SLO_{TTFT} held fixed; we adopt $\tau = 20$ ms. We show only this τ sweep because SLO_{TTFT} had little impact on end-to-end performance on our traces.

Abstract

Inference providers must maintain availability for many LLMs, including low-volume but essential models, making resource efficiency increasingly important as token prices fall. Analysis of production traces reveals a dynamic *bursty-group pattern* in which sets of models become active together and shift over time; existing space- and time-sharing approaches lack principled mechanisms to adapt to this variability, forcing trade-offs between SLO adherence and efficiency. We observe that elastic memory allocation can unify spatial and temporal sharing. Based on this insight, we have developed Prism, a memory-centric LLM co-serving framework that applies *memory ballooning* to reclaim memory across models and support both forms of sharing under a single scheme. Prism's balloon driver, referred to as `kvcached`, has been open-sourced at `https://github.com/ovg-project/kvcached`, and deployed in production environments across 10K+ GPUs.

1 Introduction

Serving LLMs is costly for providers such as Hugging Face and Alibaba Cloud, which must host thousands of base and fine-tuned models, many with low request volumes yet mandatory availability [43, 53, 54]. As token prices fall and models vary widely in size and workload patterns, reducing inference cost while preserving performance has become a central objective. The core challenge, however, is not hardware expense but chronic under-utilization: to satisfy strict SLOs, industry practice often dedicates a *model-parallel GPU group* (*i.e.*, one or more GPUs jointly serving a single model instance), guaranteeing immediate responsiveness but wasting substantial capacity. This strategy is particularly inefficient for models with bursty or sparse traffic, and production analyses show that GPU duty cycles commonly fall below 30% [53, 54].

To improve utilization, prior work has explored various GPU sharing mechanisms at different granularities. Because auto-regressive LLM inference is intrinsically memory-bound, tail latency is governed primarily by memory stalls (*e.g.*, page faults, PCIe migrations). Moreover, compute sharing is already well studied—both via hardware mechanisms such as NVIDIA MIG [29] and vGPU [30], and via software solutions [10, 12, 13, 27, 42, 62]. In contrast, effective memory sharing remains comparatively underexplored. We therefore center this work on advancing effective GPU memory sharing.

The work of memory sharing for LLM serving falls into two categories: space sharing and time sharing. Space sharing (*e.g.*, MuxServe [11]) colocates multiple models on the same GPU to utilize unused memory and compute cycles, which is effective for smaller, low-traffic models that are continuously accessed. Time sharing (*e.g.*, QLM [33] and Aegaeon [53]) swaps models in and out of GPU memory, which is ideal for handling sporadic requests to models as the resources can be freed up when models are idle. While these strategies are effective for specific cases, our analysis of a broad range of production serving traces demonstrates that they fail to adapt to more complex and realistic usage scenarios.

In particular, we have conducted a comprehensive analysis of production traces drawn from major inference providers (*i.e.*, Hyperbolic and Novita AI) as well as independent evaluation platforms (*i.e.*, Chatbot Arena). These traces encompass 11 days to 16 months of traffic across 58 heterogeneous models. Our results indicate that real-world workloads display diverse, rapidly changing patterns that elude any single, fixed sharing mechanism.

Key observations. At the model level, deployed models show a *bursty-group* behavior: when a burst occurs, requests concentrate on a particular subset of models, and that subset shifts over time, similar to an application's dynamically changing working set. This pattern is driven by modern compound AI systems and agentic pipelines, which depend on a central reasoning LLM together with a number of fine-tuned or LoRA models for specialized agent tasks. At the request level, detailed inspection of the traces confirms that requests are extremely *dynamic and volatile* and fluctuate rapidly and unpredictably, limiting the value of existing GPU-sharing tech-

* Corresponding authors.

niques. Space sharing, alone, fails to adapt to longer idle periods; for instance, in the Novita AI trace, where models are idle for over 70% of the time, space sharing creates significant memory fragmentation, leaving 50% of GPU memory occupied but unused. In contrast, time sharing, alone, struggles with rapid workload fluctuations. The significant latency overhead of swapping (*e.g.*, several seconds) causes severe thrashing during traffic bursts, resulting in a spike of requests violating their latency SLOs due to queuing delays.

Maximizing resource utilization while preserving SLO attainment requires integrating both strategies: space sharing for colocating low-traffic models and time sharing for burst handling and idle-resource reclamation. However, mingling these approaches is far from trivial due to the fundamentally different challenges they must address—the flexibility of memory balancing for space sharing vs. the efficiency of model swapping for time sharing. One could attempt to switch spatial and temporal sharing strategies dynamically; yet, co-locating models with conflicting sharing needs creates resource contention. Specifically, a model requiring time-sharing typically relies on preempting resources to maximize burst performance, which directly contradicts the persistent resource availability required by a model colocated through space-sharing. Without a mechanism to fluidly mediate these conflicting operational modes, the system is forced into rigid configurations that cannot adapt to dynamic load changes.

Insight: a memory-centric view to unify space- and time-sharing. Our central observation is that *GPU memory is the unifying bottleneck, and each sharing strategy is concerned with a different portion of that memory*: time-sharing focuses on efficiently swapping in *LLM weights*, whereas space-sharing determines how to scale *KV-cache* capacity among concurrently served models. This perspective parallels *memory ballooning* in virtualization, where a hypervisor dynamically reclaims memory from guest VMs and reallocates it where needed. In the context of LLM co-serving, an analogous "balloon driver" can reclaim memory from idle models to swap in the weights of new models (supporting time-sharing) or from models with low request rates by shrinking their KV-cache reservations (supporting space-sharing). Treating GPU memory as an elastic resource allows the system to fluidly shift between sharing modes and even enable both simultaneously (*i.e.*, apply time-sharing to only a subset of colocated models), ensuring active models obtain the memory required to satisfy their SLOs while maximizing cluster-level efficiency.

Prism. We developed Prism, a new memory-centric GPU sharing system for multi-LLM serving. At its core, Prism implements the concept of memory ballooning for LLMs to enable *demand-aware, cross-model* memory sharing, a capability missing in existing systems but critical for unifying spatial and temporal strategies. Prism ensures that models can promptly expand their memory footprint to meet latency SLOs, while unused memory is efficiently harvested from others to maximize overall cluster utilization. The design of Prism addresses two key challenges.

Challenge 1: How to enable flexible memory ballooning for LLMs? Today's LLM serving engines (*e.g.*, SGLang and vLLM) are designed for single-model serving and adopt *per-model static* memory allocation. While techniques like `PagedAttention` manage memory efficiently within a model, they operate at the application level and cannot harvest memory across model boundaries.

Flexible memory ballooning requires a mechanism to dynamically resize the physical memory footprint of a model at runtime without disrupting its execution. Prism tackles this through a model balloon driver for serving engines (§5). The model balloon driver decouples virtual and physical GPU memory: serving engines reserve a large virtual address space during initialization, but physical memory is allocated and mapped only on demand. This design enables transparent, fine-grained memory redistribution at a 2 MB granularity with millisecond-level overhead, supporting diverse model architectures with zero code change to attention kernels.

Challenge 2: How to place models and schedule requests to maximize SLO attainment? While the balloon driver provides the mechanism for elasticity, maximizing SLO attainment requires intelligent policies to decide *when* and *where* memory should be allocated. Without proper coordination, contention for shared memory can lead to thrashing and performance degradation. Prism solves this through decoupled model placement and request scheduling. First, the fast-changing bursty groups (§3.1) require a placement algorithm that can quickly decide where each model should run. Prism tackles this with a global demand-complementary placement algorithm that minimizes the KV pressure ratio (KVPR), balancing model memory demand with GPU capacity (§6.1). Second, volatile request arrivals and diverse SLO targets require estimating each request's time slack so the memory manager can steer memory toward latency-sensitive tasks. Prism achieves this via a local slack-aware arbitration algorithm, which leverages a GPU-level request queue to prioritize requests based on their slack (§6.2).

Results. We implemented Prism on top of SGLang [64], a widely used LLM serving engine. We evaluated Prism comprehensively with two production traces, and with **58 representative LLMs of varying architectures and sizes, on GPU clusters with up to 32 H100 GPUs.** Our results show that Prism achieves up to 3.3× higher time-to-first-token (TTFT) SLO attainment and 2× higher time-per-output-token (TPOT) SLO attainment given the same number of GPUs. When targeting the same level of SLO attainment, Prism achieves up to over 2× cost reduction or 3.5× more requests compared to the state-of-the-art.

Prism's balloon driver, referred to as `kvcached`, has been open-sourced and actively maintained at https://github.com/ovg-project/kvcached. `kvcached` has been adopted by many industry users to support production work-

Trace name	Service provider	# models	Time span
Hyperbolic	Hyperbolic [19]	24	4 months
Novita	Novita AI [3]	16	1 month
Arena-Battle	Chatbot Arena [9]	129	16 months
Arena-Chat	Chatbot Arena [9]	84	11 days

Table 1: Production trace summary.

loads in clusters of more than 10K GPUs. We report usage analyses from two companies at the end of §7.

2 Background

SLOs of Online LLM Serving. In online LLM serving, unlike offline batch processing, the system must interact with users or downstream applications in real-time. Consequently, providers enforce strict SLOs to guarantee the quality of experience. Two key latency metrics define these objectives. First, *Time-To-First-Token* (TTFT) measures the latency to process the input prompt and generate the first token, which is a crucial metric for interactive applications, such as chatbots. Second, *Time-Per-Output-Token* (TPOT) measures the average inter-token latency during the autoregressive generation, which is essential to ensure that text generation is fluid and matches human reading speeds.

Memory footprint of LLM serving. LLM inference is inherently memory-bound, with GPU memory dominated by model weights and KV cache.

Model weights. LLM weights are massive; for example, a 70B-parameter model requires roughly 140 GB of GPU memory in FP16. Under long-tail workloads [53], idle models waste GPU memory; prior work [13, 53] mitigates this with model eviction and accelerated weight loading.

KV cache and PagedAttention. The KV cache stores intermediate Key (K) and Value (V) tensors for attention layers to avoid redundant computation. Unlike weights, the KV cache is dynamic, growing with sequence length and batch size.

To improve GPU memory efficiency, mainstream LLM serving systems adopt PagedAttention [21], which splits each request's KV cache into fixed-size blocks that can be stored non-contiguously and reused across requests. Frameworks such as SGLang [64] and vLLM [21] implement this design by reserving large PyTorch tensors as a KV block pool and mapping each request's logical blocks to physical offsets in the pool. For each of the L attention layers, a K tensor and a V tensor of shape (B, T, H, D) are allocated, where B is the number of blocks, T is the tokens per block, H is the number of attention heads, and D is the head dimension. The values of L, H, and D vary across model architectures (*e.g.*, Llama-3-8B $(32, 8, 128)$ vs. GPT-OSS-120B $(36, 8, 64)$), resulting in different KV block sizes.

3 Production Trace Analysis

Prior studies have primarily profiled single-model LLM services [48, 50], but the cross-model dynamics that arise in multi-LLM serving remain largely under-examined. As a result, evaluations in recent multi-LLM serving work often rely on synthetic or simplified workloads, such as Poisson/Gamma arrivals [11, 33, 53], temporally rescaled traces from non-LLM domains [13, 14], or dataset-driven replays [39].

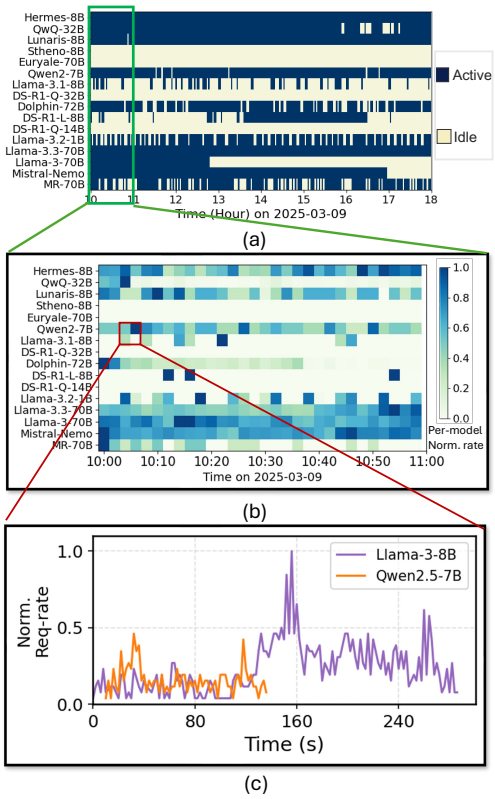

Figure 1: Combined view of model-request dynamics; the x-axes denote time. (a) Variation of concurrently active model groups over a six-hour window (8am–4pm): the y-axis lists all models from the Novita trace; each cell represents a three-minute interval, with dark/-light shading indicating whether the model is active. (b) Zoomed-in view of volatile request patterns from 11am–1pm, showing per-model normalized request rates, where darker colors indicate higher rates. (c) A further zoom-in over a 5-minute window from (b), comparing two models on a shared normalization.

To address these gaps, we conduct a detailed characterization of production workloads from major inference providers (*i.e.*, Hyperbolic and Novita AI) as well as independent evaluation platforms (*i.e.*, Chatbot Arena), explicitly capturing the fine-grained, time-varying dynamics of multi-LLM traffic. The four traces span 24–129 deployed models over weeks to months of traffic, summarized in Table 1. In this section, we utilize the traces from Novita AI as a representati4ve example to illustrate our observations and report cross-trace statistics. We include a detailed CDF analysis in Appendix A.1.

3.1 Model Level: Shifting Bursty Groups

We begin by examining the dynamics of concurrently active models (*i.e.*, those processing at least one request) from the

Novita trace over a six-hour span in Figure 1(a), where a horizontal slice of a model represents its active/idle activities over time, and a vertical slice at a point of time reveals which subset of the models is active at the point. Our analysis reveals two properties that are common for production workloads: *bursty groups* and *heterogeneous access patterns*.

Vertical behavior: bursty groups. Vertically, deployed models demonstrate a *bursty-group* behavior: models receive requests in short, irregular bursts separated by long and variable idle intervals. Because these bursts occur asynchronously across models, only a small subset is active at any moment, and this subset changes rapidly over time. We refer to this transient set as the *bursty group*, analogous to how an application's *working set* changes during its execution—there are common models that appear in almost every group but most models experience sporadic requests and hence appear only in a small number of groups. Across the four traces, 23%–50% of models are active concurrently on average, and the active set changes 54–766 times per hour. Although the total number of deployed LLMs can be large, only the bursty group drives actual demand. Efficient GPU utilization thus requires adapting resources to this shifting model group, rather than allocating resources statically to all models.

Horizontal behavior: Heterogeneous activation patterns. Horizontally, the workload exhibits significant heterogeneity across models in activation patterns. Some models, such as `Llama-3.3-70B`, sustain long stretches of continuous activity, while others (like `Distilled-Deepseek-R1-Qwen-14B(DS-R1-Q-14B)`) activate only in sparse, short-lived instances with only a small group of applications/users using it. This heterogeneity is largely driven by the diverse roles that models play in modern compound AI systems and agentic pipelines. Large general-purpose models (*e.g.*, `Llama-3.3-70B`) often act as central reasoning or planning components and remain active throughout user interactions, leading to sustained request streams. In contrast, smaller distilled models (*e.g.*, `DS-R1-Q-14B`) are typically invoked as auxiliary components—such as for tool use or verification—and are triggered only at specific pipeline stages, resulting in intermittent, bursty activations.

Aggregating requests across many applications and users yields a mixed access pattern in which some models remain persistently active, others appear only sporadically, and even the same model may exhibit different behaviors over time. These differences have direct implications for resource management: long-running models benefit from sustained colocation, whereas short and scattered bursts favor opportunistic execution. Consequently, multi-LLM serving systems must adapt to the heterogeneous activation behavior of each model, rather than assuming uniform access patterns.

Implication: Inefficiency of static partitioning. The existence of shifting *bursty groups* fundamentally challenges any static strategies. Since only a small, changing subset of models drives demand at any given moment, statically partitioning GPU memory across all models (to ensure availability) results in severe resource fragmentation. In the Novita AI trace, for example, models are idle for over 70% of the time on average. Under a static memory-partitioning regime, the memory reserved for these idle models is wasted, preventing active models in the current bursty group from utilizing that capacity to scale up and meet their SLOs.

3.2 Request Level: Dynamic and Volatile

We next zoom in to a shorter period of time to examine the fine-grained dynamics of individual models. Figure 1(b) depicts the request rates for the models over a two-hour window, normalized within each model so that low-volume bursts remain visible alongside high-volume ones.

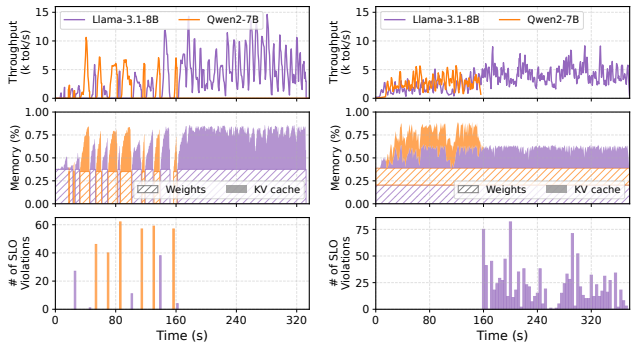
Extreme volatility and pattern shifts. As shown in Figure 1(b), request streams shift patterns frequently. Even models that appear continuously active in coarser views actually exhibit rapid oscillations between low-demand periods and short, intense bursts (*e.g.*, `Qwen2-7B`). Similarly, models that are only sporadically invoked display burst sizes and inter-arrival times that vary significantly over time (*e.g.*, `Llama-3.1-8B`).

Abrupt pattern transitions. Furthermore, these workload patterns often undergo rapid, unforeseen transitions. Figure 1(c) provides a granular, 5-minute zoom-in view of request arrivals for two representative models. This window reveals a stark shift in interaction dynamics: a phase of moderate, interleaved activity—where both models contend for resources simultaneously—abruptly gives way to a concentrated burst from a single model. Such sudden pattern shifts occur without discernible triggers, implying that the system cannot rely on historical stability or long-term pattern recognition; instead, it must possess the agility to react to instantaneous changes. Such transitions are pervasive: across our traces, many models exhibit a request rate coefficient of variation above 1 and 40–100 idle intervals per hour.

Implication: Instability of pure time sharing. The extreme *volatility* and rapid pattern transitions undermine pure time-sharing strategies. As seen in Figure 1(c), request streams frequently transition into phases of interleaved activity where multiple models are active simultaneously. In these scenarios, a time-sharing system relying on swapping must constantly evict and reload weights to serve alternating requests. This leads to model thrashing, where the latency overhead of loading weights dominates execution time, causing immediate SLO violations. This volatility necessitates the stability of space sharing, where working sets remain resident to handle interleaved demand without swapping penalties.

3.3 Applying Existing Approaches

To understand the implications of these abrupt pattern transitions, we ran two representative state-of-the-art strategies,



(a) Pure time sharing. (b) Pure space sharing.

Figure 2: Performance of pure time- (a) and space-sharing (b) for the trace in Figure 1(c). Pure time sharing in (a) causes model switching when both models have requests, while pure space sharing in (b) causes queuing delay during requests spike.

time sharing (QLM [33]) and *space sharing* (static partition [1, 29]), on the trace segment shown in Figure 1(c). Figure 2 illustrates the resulting memory usage and cumulative SLO violations for each approach.

Failure of time sharing. Time sharing manages resources by swapping models in and out of GPU memory. This approach struggles during the initial phase of *interleaved activity*. As both models receive frequent, overlapping requests, the system is forced to repeatedly evict and reload weights to serve alternating inputs. As shown in Figure 2a, this leads to severe *model thrashing*: the GPU spends more time on PCIe transfers and engine re-initialization than on computation. As such, request queues grow rapidly, resulting in a spike of SLO violations even before the workload intensity peaks.

Failure of space sharing. Space sharing avoids swapping by partitioning GPU memory between models. While this provides stability during the interleaved phase, it fails catastrophically when the workload transitions to the burst phase, as shown in Figure 2b. Although one model becomes idle, its model weights remain locked, preventing the active model which is now experiencing a demand surge from utilizing the full GPU capacity. This rigid isolation creates artificial resource scarcity: the active model is starved of KV cache memory while adjacent memory sits idle. The result is a throughput cap that causes significant queuing delays and SLO violations during the burst.

3.4 Takeaway: A Hybrid Approach

Our analysis demonstrates that production multi-LLM workloads exhibit conflicting requirements that no single existing strategy can satisfy:

- **Bursty groups benefit from time-sharing capabilities:** At the model level, the active set shifts over time. Pure space sharing fails here because it rigidly locks memory for idle models, causing fragmentation and preventing active models from scaling. The system must be able to evict idle resources to maximize utilization.
- **Volatile requests benefit from space-sharing capabilities:** At the request level, demand fluctuates rapidly and often interleaves across models. Pure time sharing fails here because swapping causes severe thrashing during these volatile periods. The system must be able to keep active models colocated in memory to provide low-latency access.

Motivation for Prism. These two patterns capture the workload at coarse- and fine-grained levels, respectively. Because they reflect different facets of the same underlying behavior, they cannot be addressed in isolation, necessitating a hybrid approach: the system must fluidly shift between the strategies at runtime. It needs the *elasticity* to act like a time-sharing system when reclaiming memory from the idle models, while simultaneously acting like a space-sharing system to co-serve the models in an active bursty group without causing SLO violations. This calls for a design that manages GPU memory as a dynamic, shared resource rather than static partitions.

4 Overview

Prism is a memory-efficient GPU sharing system for cost-effective multi-LLM serving. Figure 3 shows its system architecture and design overview. Prism receives inference requests at its frontend, which routes them to the corresponding LLMs for processing. To improve cost efficiency, Prism serves LLMs with flexible combinations of space and time sharing. For instance, high-rate models may occupy GPUs exclusively, while multiple low-rate models can be colocated on a single GPU or a model-parallel GPU group. In Prism, a GPU group represents the strict scheduling boundary—a set of GPUs tightly coupled to jointly serve one model instance. Prism's global scheduler treats each of these groups as a distinct, indivisible resource unit. Idle models are temporarily evicted to CPU DRAM and reactivated when new requests arrive. Prism continuously adjusts its sharing strategies based on runtime workload to maximize overall SLO attainment.

Prism achieves this with two key designs for flexible, demand-aware cross-model memory sharing and coordination. First, it introduces a balloon driver, referred to as `kvcached` (§5) that enables flexible and efficient memory sharing between models, forming the foundation for rapid adaptation to workload variations and policy changes. Second, Prism optimizes the overall resource allocation through a memory-centric control plane that uses a combination of (1) load-aware model placement (§6.1) that maximizes memory headroom for GPUs to facilitate ballooning and (2) slack-aware request arbitration that prioritizes requests on each GPU for maximizing SLO attainment (§6.2).

Relation with autoscaling. Prism is orthogonal to and can be seamlessly integrated with autoscaling [4,23,40,59]. Prism focuses on efficiently sharing GPUs between models (replicas)

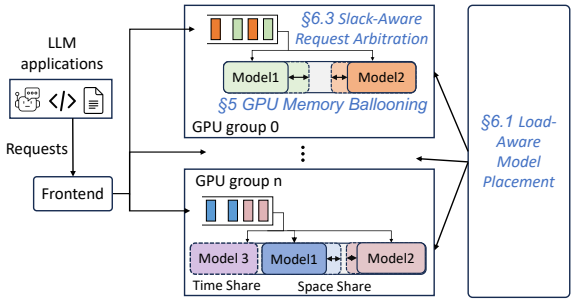


Figure 3: The system architecture and design overview of Prism.

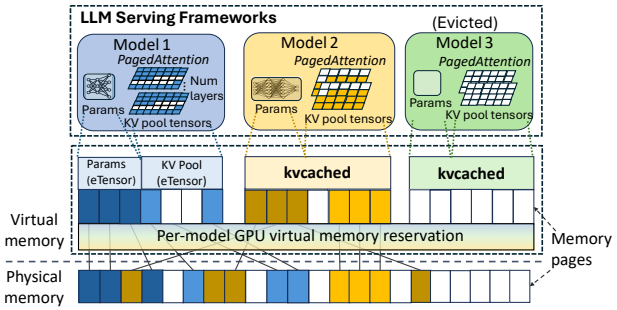

Figure 4: Memory ballooning for effective multi-LLM serving.

while autoscaling automatically scales up/down the number of model replicas.

5 GPU Memory Ballooning for Multi-LLMs

This section describes how Prism enables flexible cross-model memory sharing with our balloon driver, providing a foundation for adapting policies to dynamic workloads.

5.1 Requirements and Challenges

Mainstream LLM serving engines [21, 64] adopt block-based KV token management (*e.g.*, PagedAttention [21]). While this design effectively reduces *request-level* memory fragmentation *within a single* LLM, it requires the application (serving engine) to manage the GPU physical memory directly, by pre-allocating a large portion of GPU memory as the KV block pool. This memory thus remains occupied even when there is no active request, and the KV blocks within the tensor are unused. This prevents the redistribution of unused memory across different LLMs, limiting the ability to support flexible time- and space-sharing among multiple LLMs. This leads to four key requirements for Prism.

R1: Fast memory reallocation between model weights and KV cache. When a model is swapped out, the memory released by its weights should be quickly repurposed by other models as KV cache. Similarly, when an idle model is reactivated upon new requests, the running models must promptly release unused KV cache memory for the new model's weights and KV cache. However, this is hard with statically reserved KV pool tensors, whose physical GPU memory cannot be partially released. A workaround is to copy active token blocks into a smaller tensor and then destroy the old one. However, this not only requires waiting for the slow copy to complete, but also demands enough GPU memory to hold both tensors during the transient period.

R2: KV cache sharing across diverse model architectures. For models colocated on a GPU, their KV cache memory should be flexibly shared; *e.g.*, unused KV cache memory from one LLM can be easily reused by others. However, LLMs often have diverse KV cache layouts, resulting in different tensor shapes, *e.g.*, different head dimensions and number of attention heads. Therefore, simply using a pool of unified KV tensors across models is infeasible: different token sizes lead to misaligned tensor shapes, and different layer counts cause inconsistent numbers of tensors.

R3: Minimal redistribution overhead and memory fragmentation. Since memory redistribution may occur frequently, it must incur low overhead while minimizing fragmentation to improve utilization. This rules out a strawman design that splits the reserved KV pool tensor into multiple smaller segments so that free segments from one model can be reused by another. This is because choosing the segment size is inherently challenging: too many small segments increase second-level indexing overhead, while too few large segments cause severe fragmentation.

R4: Transparent to existing serving frameworks. The new mechanism should remain fully compatible with existing serving frameworks, where the KV block pool is allocated as large tensors, and require no changes to attention kernels. The previously mentioned segment-based method violates this requirement, as it splits the tensor into segments, which necessitates extensive kernel modifications.

Summary. Multi-LLM serving must efficiently cope with heterogeneous memory demands (*e.g.*, different model weights and KV token blocks), each with distinct semantics (*e.g.*, head dimensions and layer counts) and lifecycles. Existing single-LLM systems manage GPU memory entirely at the application level, imposing their own semantics on top of a fixed GPU allocation. This approach works well for a single model, which can efficiently manage its memory in isolation. In multi-LLM settings, however, such isolation becomes a barrier, as memory needs to be shared and reallocated across models dynamically to accommodate bursty group behavior and workload volatility.

5.2 Solution: GPU Memory Ballooning

To meet all the above requirements, our key insight is that memory management should be *pushed down to the GPU runtime level.* At this level, the system can treat all models uniformly, allowing GPU memory to be transparently redistributed across models, while applications manage only the memory allocated to them with their own semantics.

Building on this idea, Prism introduces a *balloon driver*, named `kvcached`, which sits as a shim between inference engines and GPU memory. Open sourced at https://github.com/ovg-project/kvcached, `kvcached` manages the entire GPU physical memory for LLM serving, including both model weights and the KV cache pool. Meanwhile, `kvcached` reserves a large contiguous virtual address space for each engine, which presents it to the engine as if it were dedicated GPU memory. On top of this reserved space, `kvcached` translates application-level semantics (*e.g.*, weights, KV caches, and intermediate buffers) into allocations of physical GPU memory pages. Physical pages are created only on demand and mapped to virtual addresses lazily, allowing memory to expand and shrink as workloads change, as illustrated in Figure 4.

Specifically, `kvcached` meets all the requirements in §5.1 through the following designs.

D1: Unified model weights and KV cache management. `kvcached` achieves fast memory redistribution between model weights and KV cache through unified virtual and physical memory management. Since `kvcached`-managed memory is agnostic to application semantics, both weights and KV cache can be seamlessly reallocated across engines. Moreover, `kvcached` dynamically adjusts physical memory limits: when an evicted model is reactivated, it shrinks the limits of other models on the same GPU, bounding their allocations and immediately freeing space for the new model. The opposite happens when a model is evicted.

D2: Automatic token block mapping. To support models with different layer counts and token sizes, `kvcached` employs an internal KV cache manager to map token blocks onto underlying virtual and physical GPU pages. Prism assigns token blocks to available slots within a virtual page, or allocates a new physical page when necessary. To prevent size conflicts and ensure portability across architectures, the KV cache manager further segregates token blocks from different models onto distinct memory pages.

D3: Overhead and fragmentation optimizations. `kvcached` minimizes memory redistribution overhead and fragmentation through three key optimizations. First, mainstream serving frameworks maintain separate K and V tensors per layer, requiring $2L$ page allocations across all layers each time. To reduce this overhead, `kvcached` reorganizes the memory layout in virtual space, so that all layers' K and V vectors of a token are stored in contiguous virtual space, requiring only one batch allocation for all pages ($2L\times$ speedup). Second, `kvcached` uses a pre-allocation thread to asynchronously prepare a small buffer of GPU pages. Engines draw new pages from this buffer first, while released pages are returned to it and only physically freed if the buffer exceeds its limit or memory must be reclaimed for a new model. Finally, to reduce fragmentation, `kvcached` uses 2MB memory pages, and prioritizes using partially filled pages.

D4: Elastic tensor abstraction. `kvcached` ensures transparency with existing LLM serving frameworks by introducing an *elastic tensor (eTensor)* abstraction, implemented via PyTorch's extension interface to abstract away the details of physical page allocation from the serving engine. Elastic tensors can be used exactly like regular PyTorch tensors, requiring no modifications to attention kernels and remaining fully compatible with CUDA graph optimizations commonly used in LLM serving frameworks.

5.3 Fast Model Loading

Model swapping speed directly impacts the flexibility of GPU sharing. High latency can hinder the timely swapping of models with strict SLOs, limiting policy adaptability. While deactivation is straightforward, *i.e.*, terminating the engine and releasing all memory, reactivation is more complicated, which involves: (1) initializing a new serving engine and reserving a new virtual address space for KV cache pool; and (2) loading the model weights from CPU DRAM. If done naïvely, this process can take tens of seconds—far exceeding the TTFT SLOs of online LLM inference, which are often within a few seconds or less.

Reusable engine pools. The root cause of (1) lies in the tight coupling between the engine and the model it serves. In current systems, an engine shares the same lifecycle as its model—when a model is evicted, its engine is also terminated, along with its virtual address space. As a result, every model activation incurs the full cost of engine initialization.

Prism eliminates this overhead by decoupling the lifecycles of the engines and models. Specifically, it maintains an engine pool on each GPU, where engines are pre-initialized with virtual address space and distributed contexts. Upon model activation, Prism selects an available engine from the pool and starts model loading directly. When a model is evicted, its physical memory is released, but its engine with virtual address space is returned to the engine pool for future reuse. However, an engine cannot directly reuse previously reserved virtual memory space to serve a new model. This is because current inference engines perform index-based token access, which depends on a model-specific memory layout that is incompatible with models of different architectures, *e.g.*, different numbers of layers or token sizes. To address this, Prism introduces a KV cache virtual memory manager to manage the pre-reserved virtual memory spaces in the engine pool. When a new model is loaded, the manager dynamically aligns the reserved virtual space to match the memory layout required by the new model (one-time effort), and then creates a new `kvcached` based on the aligned memory spaces. The `kvcached` can then correctly and efficiently locate the virtual memory page where each token resides during inference.

Parallel model weight loading. The time spent on (2) model weight loading is heavily influenced by the utilization of the CPU–GPU interconnect bandwidth. We found that loading models naïvely via the `cudaMemcpyAsync` API

to a GPU fails to saturate the interconnect bandwidth, even when invoked from multiple threads. This may be due to all `cudaMemcpyAsync` operations targeting the same GPU executing serially, limited by the CUDA driver and hardware. Prism overcomes this bottleneck by chunking model weights into smaller segments, loading them in parallel across multiple GPUs on the same node, and then aggregating them to the target GPU via high-speed NVLink interconnects. This parallelized strategy significantly accelerates model loading. To minimize interference with running workloads on GPUs, Prism partitions model weights at the granularity of individual weight tensors and loads them in a streaming fashion. As a result, each GPU only needs to maintain a small buffer (*e.g.*, 30MB), minimizing possible memory contention.

6 A Memory-Centric Control Plane

The memory ballooning mechanism in §5 provides the elasticity needed to unify spatial and temporal sharing, but leveraging it effectively requires policies that adapt to evolving bursty groups and volatile request patterns. Our goal is to improve memory efficiency and maximize SLO attainment for TTFT and TPOT through coordinated memory sharing. Because TTFT and TPOT can interfere [65], we prioritize TTFT, whose prompt length is known, while noting that the resulting improvements in resource scheduling also benefit TPOT by reducing memory-induced preemptions.

Challenges. Unifying time and space sharing complicates scheduling because decisions must jointly span models, requests, and tokens, all of which shape GPU memory usage and latency. These layers are tightly coupled: model residency sets memory availability, request concurrency determines consumption, and token execution affects both utilization and SLOs. Optimizing any one dimension in isolation—e.g., maximizing colocation or strictly protecting SLOs—can destabilize the others. Consequently, time- and space-sharing choices form a large, interdependent decision space where placement, memory pressure, and request scheduling continually interact in non-trivial ways.

A natural formulation of this problem is a joint optimization over model placement, request scheduling, and memory allocation (*e.g.*, via an ILP), but this quickly becomes intractable. The placement space alone is enormous: with M models and N GPUs, there are N^M possible assignments even before considering migration decisions. Request scheduling is likewise combinatorial, as differing prompt lengths, arrival times, SLOs, output lengths, and engine states yield a factorial explosion in possible execution orders. Moreover, placement and scheduling are tightly coupled—migrating even one model changes which GPUs can serve which requests and how KV caches evolve, thereby altering future scheduling decisions. All of this must be decided online, with the scheduler observing only recent arrivals while lacking knowledge of future bursts, output lengths, or concurrency.

Insight. Our key insight is that *this complexity simplifies when managed through a memory-centric lens*. Models, requests, and tokens influence system behavior primarily through how they consume and contend for GPU memory, while SLO attainment is directly governed by the availability of that memory at execution time. By making memory the central optimization target, we unify multiple interacting objectives, utilization efficiency, latency control, and stability, under a single principle: controlling memory contention. This reduces a multi-metric, multi-level scheduling problem into a tractable design centered on memory management.

Memory contention manifests at multiple scopes: cluster-level model activity drives coarse-grained memory demand, while fine-grained request dynamics determine SLO outcomes. No single control loop can manage both effectively, motivating a memory-centric hierarchical scheduler: a macro, cluster-level plane that shapes memory pressure via model placement, and a micro, GPU-level plane that allocates memory per request to satisfy heterogeneous SLOs. Coordinating these layers enables Prism to maintain high utilization and robust SLO attainment.

6.1 Load-Aware Model Placement

The objective of the global model placement strategy is to place models across GPUs to maximize the headroom available for memory ballooning. If too many models from the same active bursty group are colocated, they will simultaneously demand memory for KV-cache expansion, leading to severe contention and out-of-memory errors.

To prevent this, Prism employs a load-aware placement strategy. Because predicting exact memory usage is difficult due to unknown output lengths of LLM inference requests, we utilize a robust heuristic referred to as the KV Pressure Ratio (KVPR). KVPR quantifies the intensity of memory contention on a GPU by comparing the aggregate urgency of memory demand against the remaining capacity, calculated as $\frac{w_token_rate}{shared_kv}$, where $w_token_rate = \frac{token_rate * token_size}{SLO}$ represents the SLO-weighted token memory usage rate of a model, indicating its memory demand per unit time. By counting both input tokens from newly admitted requests and decode tokens produced by running requests per unit time, $token_rate$ captures the full KV-cache growth rate and helps KVPR accurately reflect GPU memory pressure. We use the TPOT SLO for SLO because autoregressive decoding dominates generation latency and is especially sensitive to KV-cache memory contention. $shared_kv$ is the memory available for the KV cache on a GPU. A high KVPR indicates a high-pressure GPU where memory ballooning is likely to be stifled.

Algorithm 1 realizes our model placement strategy. Prism prioritizes the most aggressive memory consumers by sorting models in descending order of their SLO-weighted token usage rates w_token_rate, ensuring that high-demand workloads are allocated resources first (Lines 1–3). For each model, the scheduler identifies the GPU that minimizes the resulting

KVPR. This step inherently enforces complementarity: by targeting the device with the lowest existing pressure, Prism effectively colocates high-demand models with low-demand ones, thereby maximizing the capacity available for the high-demand model to balloon its memory usage (Lines 5–8). If the selected GPU differs from the model's current GPU, Prism migrates the model accordingly. However, this migration incurs overhead from engine switching and model weight loading. To avoid unnecessary migrations with marginal benefit, Prism compares the KVPR of the best and current GPUs, and proceeds only if the improvement exceeds a threshold τ (Line 8). Finally, Prism assigns the model to its selected GPU and updates the corresponding GPU states (Lines 9–12).

Analysis. This greedy approach approximates the optimal solution by bounding the maximum KVPR across the cluster, ensuring that no single GPU becomes a disproportionate bottleneck that stifles memory sharing. A detailed formal analysis is provided in Appendix A.2. The algorithm also seamlessly supports large models utilizing Tensor Parallelism (TP). By treating each TP partition as a distinct scheduling unit with anti-affinity constraints, Prism ensures they are placed on separate GPUs, thereby aggregating memory capacity across devices to satisfy massive KV demands.

Model eviction and activation. The placement strategy evicts a model if it remains idle and GPU resources become constrained for other models. Prism performs eviction based on an empirical threshold, which can be determined by analyzing the idle interval distribution; a detailed sensitivity analysis is provided in Appendix A.4. When the model receives new requests, Prism immediately reactivates it by placing it on the GPU with the lowest KV pressure ratio, drawing from a pre-warmed engine pool with reusable distributed contexts and buffers to avoid re-initialization, and using parallel weight loading to keep cold-start latency within TTFT budgets (§5.3).

Model migration. Model migration is designed to preserve TTFT during placement changes. Rather than stopping request processing while the destination instance is prepared, Prism keeps the source instance active and continues serving requests until the target is ready. This allows migration latency to be overlapped with ongoing execution, so requests experience only the short switch-over delay. Therefore, Prism's effectiveness does not depend on fast interconnects. Practically, when the source and target GPUs are connected via NVLink, Prism uses NVLink as an optional shortcut for migrating model weights and resident KV caches. In non-NVLink environments, Prism leverages GPUDirect RDMA [31] if available, or falls back to standard eviction and reactivation, which takes at most a few seconds for <70B models.

6.2 Slack-Aware Request Arbitration

While global placement balances demand, memory contention arises locally when resident models process requests concurrently. Under unified sharing, strict isolation causes fragmentation, whereas uncontrolled sharing risks starvation, with urgent requests blocked by long-running ones. Models on the same GPU may compete for KV cache memory, and without coordination a high-rate, relaxed-SLO model can monopolize memory and degrade SLO attainment for stricter workloads.

A naïve approach is to cap each model's memory usage, but choosing appropriate limits is difficult under dynamic workloads and heterogeneous SLOs: conservative caps throttle throughput, while generous ones starve other models. Adapting limits at runtime helps but cannot take effect immediately, since memory must be freed by completing in-flight requests—a process that can take seconds depending on request length and load. This coordination challenge arises because each engine maintains its own queue and greedily schedules requests as memory becomes available.

To resolve this, Prism employs a slack-aware request arbitration strategy. Instead of maintaining separate queues per model, Prism uses a shared per-GPU request queue that arbitrates access to each GPU's physical memory pool to coordinate the memory usage for heterogeneous SLO requests. Our goal is to prioritize requests that are most critical for maximizing SLO attainment. Prism goes beyond simple deadline prioritization by leveraging the exact time slack of each request, which is defined as the buffer between a request's deadline and its required execution time.

With both the deadline (d_r) and execution cost (e_r) known, Prism transforms the scheduling challenge into a classic deadline problem. We adopt the Moore-Hodgson algorithm [25], which minimizes the number of deadline misses. As shown in Algorithm 2, given a set of requests R, Prism first sorts them in ascending order of their prefill completion deadlines (Line

Algorithm 1 Model Placement to Maximize Memory Headroom.

Require: Number of GPUs N, GPU memory capacity C, migration threshold τ, and M models. Each model m_j has: token rate t_j, weight w_j, token size tz_j, current device index g_j, and latency SLO s_j.

Ensure: Assign each model to a GPU to balance the resource demand and remaining memory capacity.

1: Sort models by $\frac{t_j * tz_j}{s_j}$ in descending order. Denote the sorted sequence as $m_1, m_2, \ldots, m_M$.
2: **for** $i = 1$ to N **do**
3: $\quad shared_kv_i \leftarrow C$; $w_token_rate_i \leftarrow 0$
4: **for** $k = 1$ to M **do**
5: $\quad$ /* find the GPU *best_idx* that minimizes KVPR */
6: $\quad best_r,\ best_idx \leftarrow (\min, \text{argmin}) \frac{w_token_rate_i}{shared_kv_i}$
7: $\quad current_r \leftarrow \frac{w_token_rate_{g_k}}{shared_kv_{g_k}}$
8: $\quad best_gpu \leftarrow \begin{cases} best_idx, & \text{if } current_r - best_r > \tau \\ g_k, & \text{otherwise} \end{cases}$
9: $\quad$ Assign model m_k to $best_gpu$
10: $\quad w_token_rate_{best_gpu} \leftarrow w_token_rate_{best_gpu} + \frac{r_k}{s_k}$
11: $\quad shared_kv_{best_gpu} \leftarrow shared_kv_{best_gpu} - w_k$
12: **return** Model-to-GPU placement

Algorithm 2 GPU-Local Request Scheduling

Require: A set of n requests $R = \{r_1, r_2, \ldots, r_n\}$. Each request r_i has: a prompt length p_i, a chunked-prefill speed c_i determined by the model serves it, a TTFT SLO s_i, and an arrival time a_i.

Ensure: A subset of requests $S \subseteq R$ that can be executed in order to maximize TTFT SLO attainment.

1: Sort R in ascending order of deadlines $d_i = a_i + s_i$: $r_1, r_2, \ldots, r_n$ such that $d_1 \leq d_2 \leq \cdots \leq d_n$.
2: Initialize $S \leftarrow \emptyset$, *current_time* $\leftarrow$ Timer.time()
3: **for** $k = 1$ to n **do**
4: Let $r \leftarrow r_k$, $e_r \leftarrow \frac{p_r}{c_r}$
5: Append r to S
6: Update *current_time* $\leftarrow$ *current_time* $+ e_r$.
7: **if** *current_time* $> a_r + s_r$ **then**
8: /* pop the request with longest execution time */
9: Let $r_{\max} \leftarrow \arg\max_{r' \in S} \frac{p_{r'}}{c_{r'}}$
10: Remove $r_{\max}$ from S
11: Update *current_time* $\leftarrow$ *current_time* $- \frac{p_{r_{\max}}}{c_{r_{\max}}}$
12: **return** S

1). Then, for each request in the sorted list, Prism appends it to the schedule list S and checks whether it can finish within its TTFT SLO (Lines 3-7). If the most recently added request cannot meet its deadline, Prism evicts the request in S with the longest execution time (Lines 9–11). It then moves to the next request and continues this process until evaluating all requests. Finally, Prism dispatches the accepted requests in S following their order in the schedule.

Analysis. Prism focuses arbitration on TTFT attainment because it gates when a request can start; once admitted, a request runs through decoding under its TPOT SLO, which is governed by memory headroom rather than queue ordering. Long-running decode requests are preempted only when memory is severely constrained, so a single heavy request cannot stall many newly admitted ones, matching the batch scheduling policies of SGLang and vLLM [21, 64].

Request scheduling ensures optimal TTFT attainment when chunked-prefill has prefill running at each inference step. This is because the prefill time e_r of a request r can be estimated as $e_r = \frac{p_r}{c_r}$, allowing us to compute the prefill completion time of any request r_i in a sequence using $d_{r_i} = a_{r_i} + \sum_{i=1}^{n} \frac{p_{r_i}}{c_{r_i}}$, where n is the number of requests (including r_i) waiting for processing. With this information, we can follow the proof of the original Moore-Hodgson algorithm [8] to prove the optimality of our scheduling algorithm. Our admission control ensures prefill runs at each inference step (so no starvation) by admitting a proper number of requests to each engine and preempting long decoding requests.

7 Evaluation

We implemented a prototype of Prism with ∼10,400 lines of Python and 774 lines of C++ code. As the serving backend, we used SGLang [64], a widely adopted open-source inference engine, and extended it with our elastic memory manager library. The library is built on CUDA VMM APIs [28] and exposes standard KV cache allocation APIs via Python bindings, requiring only 22 lines of changes to integrate with SGLang.

On the frontend, we used a Redis queue [38] to cache incoming requests from all clients. Prism's local scheduler dispatches these requests to the serving engines of corresponding models based on Algorithm 2. For tensor-parallel models, the GPU-local scheduler runs only on the first rank, and the resulting scheduling decisions are broadcast to all other ranks to ensure consistency. Prism's global scheduler operates as a separate Python process, collecting execution metrics from each engine—such as request rates and queue status. It makes scheduling decisions (*e.g.*, model evictions and activations) and communicates them to the engines using ZeroMQ [58].

	Mean E2E (s)	P95 E2E (s)	Req Tput (r/s)	Token Tput (t/s)
MuxServe	7.40	18.85	7.97	3363.53
MuxServe++	5.25	12.09	7.98	3353.09
	Mean TTFT (s)	P95 TTFT (s)	Mean TPOT (ms)	P95 TPOT (ms)
MuxServe	1.47	11.04	21.21	31.95
MuxServe++	0.089	0.320	18.82	33.97

Table 2: Performance comparison of MuxServe and MuxServe++

7.1 Experimental Setup

Testbed. We conducted our experiments on a cluster of four nodes, each equipped with eight NVIDIA H100-80G GPUs interconnected via 600GB/s NVLink. These nodes communicate through a 100Gbps Ethernet network. Each node features two 52-core Intel Xeon Platinum 8480+ CPUs, 1.7 TB of DRAM, and a PCIe Gen5 x16 interface. All nodes run Ubuntu 22.04 with CUDA Toolkit 12.4.

Baselines. We compared Prism against four baselines that share GPUs to serve multi-LLMs: (1) *Static partition (S-Partition)*; (2) *MuxServe++*; (3) *QLM [33]*; and (4) ServerlessLLM [13]. Note that the original MuxServe is built on vLLM and supports only Llama-2 models. We ported it to SGLang and generalized its memory mechanism with our kvcached to support heterogeneous models, referred to as MuxServe++. We evaluated the performance of MuxServe++ and MuxServe using three Llama-3.1-8B models under different request rates over a 10-minute period: 199 requests/min, 262 requests/min, and 22 requests/min. All experiments were conducted under the same and consistent conditions. The results are shown in Table 2. As we can see, MuxServe++ achieves comparable or even better performance.

Note that general GPU-sharing systems target application-agnostic workloads and cannot be directly compared: they focus on single-GPU sharing rather than cluster-level GPU sharing, and are not designed to optimize LLM serving, which requires both TTFT and TPOT adherence (§8).

Traces and models. We used two real-world traces, Hyperbolic [19] and Arena-Chat [9]. For each trace, we sampled a representative set of models, including both popular and

Model size	1B-3B	4B-8B	9B-30B	31B-70B
#LLMs	43	8	3	4

Table 3: Models used in our evaluation.

long-tail models, ensuring their workload characteristics (*e.g.*, popularity distribution and idle patterns) align with the observations in §3. To simulate various scenarios, we scaled the traces by multiplying the number of requests by a factor of N, increasing the load while preserving the original traffic patterns—a common way used in prior work [11, 22]. In total, we evaluated 58 LLMs as detailed in Table 3. The large-scale experiments (§7.4) use all models, while other evaluations (§7.2—§7.3) select subsets tailored to specific goals.

Metrics. Our primary performance metrics are TTFT and TPOT attainment. To establish SLOs for each model, we first ran its workload on dedicated GPUs to measure its P95 TTFT and TPOT latencies. This process produced TTFT SLOs ranging from 0.04s to 0.13s and TPOT SLOs from 5.2ms to 50.9ms. We then scaled these base values by a factor to evaluate system performance under varying latency requirements, following an approach consistent with prior work [11, 22, 36]. We also reported aggregated throughput. To account for model idle periods, throughput considers the actual time (excluding idle time) spent serving them.

7.2 End-to-End Performance

We start with the end-to-end performance of Prism under varying request rates, SLO requirements, and GPU supplies.

SLO attainment vs. request rate. We first evaluated various inference loads by serving eight models on two shared GPUs. As shown in Figure 5 (first row), Prism consistently outperforms all baselines by maintaining a significantly higher TTFT SLO attainment. On the Hyperbolic trace, Prism supports up to 2.3× and 3.5× more requests than MuxServe++ and static partitioning, respectively, while still achieving 99% SLO attainment. On the Arena-Chat trace, it handles over 3× more requests than all baselines. The gains stem from KVPR-driven placement, which keeps per-GPU memory pressure low so active models retain headroom under bursty arrivals. MuxServe++'s TTFT SLO attainment drops quickly with higher request rates because it cannot evict idle models or relocate models across GPUs, leading to memory contention and degraded performance.

QLM time-shares GPUs by packing pending requests into groups and dispatching each group to a GPU under an SLO-aware stochastic policy, swapping models and preempting unfinished requests whenever consecutive groups target different models. The frequent swapping makes QLM's TTFT attainment worse than static partitioning.

ServerlessLLM serves models in a time-sharing manner for serverless workloads: inactive models are unloaded, and newly arriving requests wait until the scheduler reactivates the required model on the server with the fastest startup, selected based on checkpoint locality. Because the full cold-start process still dominates request latency, ServerlessLLM achieves the worst TTFT SLO attainment.

Prism maintains high TPOT attainment through its demand-aware scheduler, which balances workloads to reduce memory contention. Although the scheduler explicitly targets TTFT, TPOT benefits as a side effect: TPOT is degraded mainly by oversized batches and memory-induced preemptions, both of which subside once KVPR-balanced placement caps per-GPU memory contention. QLM achieves lower TPOT because it over-batches under high load, increasing per-iteration latency, while ServerlessLLM performs even worse by allowing unbounded batch sizes that further raise P99 TPOT. Both MuxServe++ and static partitioning experience severe memory contention at high request rates, causing frequent preemptions that substantially degrade TPOT.

SLO attainment vs. SLO requirements. The middle row of Figure 5 shows the attainment across different SLO targets. As SLO scales up, Prism quickly achieves 99% TTFT and TPOT attainment. In contrast, no baseline achieves 99% TTFT attainment even on the largest SLO scale in this experiment, and their attainment rates do not improve significantly as the scale increases. Among the baselines, MuxServe++ achieves the best TTFT performance, reaching 84.79% and 67.22% attainment on the largest SLO scale for the two traces. The gap to Prism is primarily due to their inflexibility to adapt sharing policies dynamically. The TPOT attainment of all systems increases rapidly as the SLO scale grows because TPOT is less sensitive to memory contention. We also observe that the Hyperbolic trace requires higher SLO scales due to more bursty and heavier request patterns.

SLO attainment vs. available GPUs. Finally, we evaluate performance when provisioning more GPUs. We selected 18 models from Table 3, representing a mix of popular and tail models with diverse load variability. To fully test the flexibility of our scheduling strategy, we included models of varying sizes from 1B to 8B, all of which fit within a single 80GB GPU. This setup enables a wide range of model-sharing combinations across GPUs. As shown in Figure 5 (last row), Prism achieves 99% TTFT and TPOT attainment using only four and five GPUs on the two traces, respectively, demonstrating its effectiveness in improving cost-efficiency while maintaining performance. In comparison, all baselines fail to reach 99% TTFT attainment even with eight GPUs, and only a few baselines achieve 99% TPOT attainment when seven or eight GPUs are provisioned.

7.3 Performance Analysis

Next, we provide a detailed performance breakdown to analyze the effectiveness of each design in Prism and how each contributes to its strong end-to-end performance.

Flexible cross-model memory sharing. We first evaluated the benefits of our flexible cross-model memory sharing by comparing with static partition using a simplified two-model trace extracted from Arena-Chat, shown in Figure 6 (first

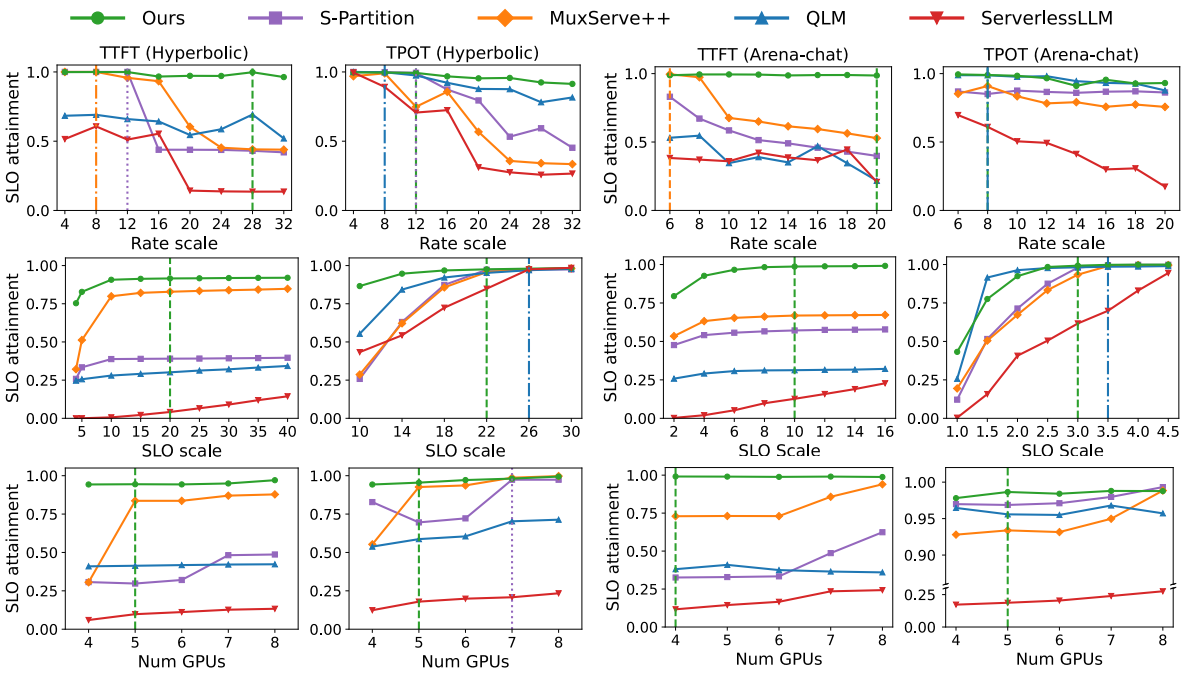

Figure 5: End-to-end performance comparison on SLO attainments under varying scales of rates, SLOs, and numbers of available GPUs. The dotted vertical lines mark where the system reaches 99% TTFT or TPOT attainment.

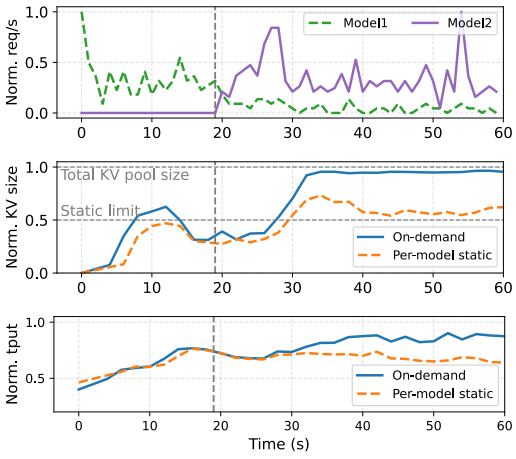

Figure 6: Benefits of cross-model memory coordination. The first figure shows the request rates. The last two figures shows the total KV memory size and the throughout of the two models.

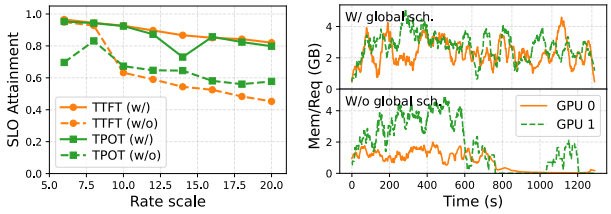
row). We present the normalized total KV cache usage and aggregated throughput for both methods in the last two rows of Figure 6. As we can see, Prism's on-demand memory allocation allows it to use more memory for KV cache, particularly after the 20th second, when Model1 experiences low demand while Model2 faces a surge in request rates. The larger KV cache memory enables Prism to achieve higher throughput, as shown in the last row. In contrast, under static partitioning, even when Model1 underutilizes its memory, Model2 cannot leverage the unused memory due to the static allocation boundary.

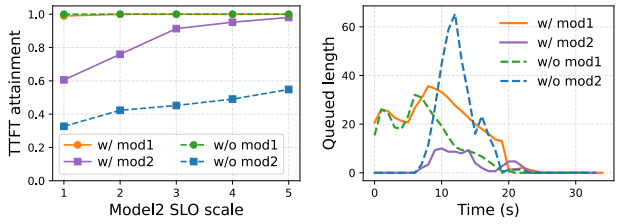


(a) Attainment with rate scales (b) GPU load status

Figure 7: Effectiveness of global model placement scheduling.

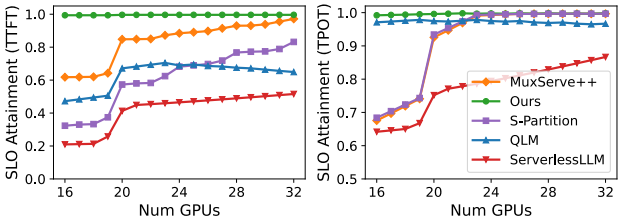
Model placement. Next, we evaluated the benefits of our global scheduler that conducts model placement. In this experiment, we used two GPUs to serve eight models from Arena-Chat. Figure 7a presents the TTFT and TPOT attainment with the global scheduler enabled or disabled. The results show that enabling the global scheduler significantly improves both TTFT and TPOT attainment. To provide further insights, we plot the average KV cache memory available per request as it arrives on each GPU. With the global scheduler enabled, the load is more evenly balanced across the two GPUs, allowing each request to access more KV cache memory on average. In contrast, without the global placement scheduler, the load is imbalanced: GPU1 shows more available memory during the first 600 seconds, while the near-zero availability between the 800th and 1000th seconds indicates that GPU1 is idle while GPU0 is overloaded.

Request arbitration. To evaluate the GPU-local scheduler that prioritizes requests, we use two models: we fix the SLO scale of Model1 to eight and vary the SLO scales of Model2

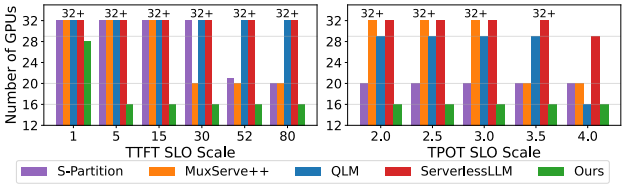


(a) Attainment with SLO scales (b) Queue length with time

Figure 8: Effectiveness of GPU local request scheduling.



(a) SLO attainment with cluster size scaling



(b) Number of GPUs needed for 99% SLO attainments

Figure 9: SLO attainment and cost saving at large scales.

to evaluate the priority-based admission control in the GPU-local scheduling. Figure 8a shows the TTFT attainment as we vary the SLO scale of Model2. Model1 consistently maintains high attainment, and enabling our GPU-local scheduling improves the SLO attainment of Model2 by more than 40%. To dive deeper, we plot the queue length of each model in Figure 8b of one experiment run. From the queue lengths, we clearly observe that when the local scheduler is enabled, the system prioritizes Model2's requests, which are shorter but have stricter SLO requirements.

7.4 Large-Scale Evaluation

Finally, we evaluated how effectively Prism in reducing the cost of multi-LLM serving at scale. We served all 58 models listed in Table 3, following common TP practices for large models: TP=4 for 32B models [46,47] and TP=4 or 8 for 70B models [2, 24], utilizing 32 GPUs in total. We sampled 58 models from the Arena-Chat trace and the Hyperbolic trace.

SLO attainments vs. number of GPUs. Figure 9a shows TTFT and TPOT attainment with an increased number of GPUs. Prism outperforms all baselines, achieving nearly 99% TTFT attainment with just 16 GPUs, while MuxServe++ requires 32 GPUs to reach similar performance, and other methods require even more. As the number of GPUs increases, all baselines improve in TTFT and TPOT attainment

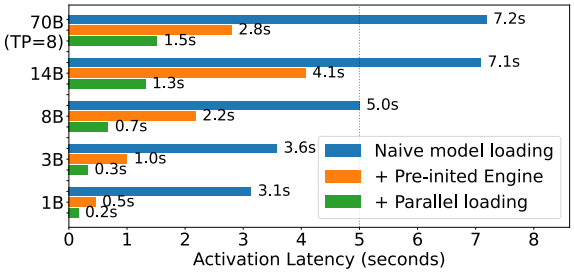


Figure 10: The activation time for models with different sizes. Data is measured on H100 GPUs.

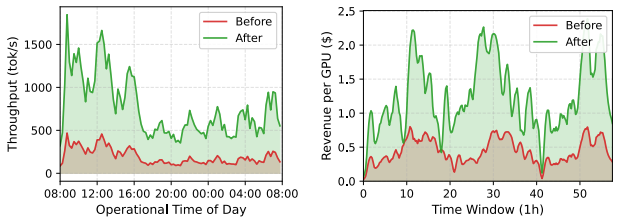

(a) Company A (b) Company B

Figure 11: Production results from two companies, showing (a) throughput and (b) revenue per GPU before and after using Prism.

except QLM. We find this to be related to its suboptimal scheduling algorithm. QLM assigns requests to GPUs without considering which models are already on GPUs; when a queue is empty, it picks the first available GPU, often triggering unnecessary swaps. With more GPUs, this leads to more idle devices and frequent swapping. Its inefficient swapping, which requires engine restart [37], adds significant latency, causing queued requests to miss their SLOs.

Cost saving. Figure 9b shows the number of GPUs required to achieve 99% SLO attainments at different SLO scales. If a system fails to achieve 99% attainment with all 32 GPUs, we denote its GPU requirement as "32+". Prism achieves 99% TTFT SLO attainments with only 16 GPUs when SLO scale is 5 and TPOT SLO scale is 2.0. MuxServe++ needs 20 GPUs to get 99% TTFT SLO attainments with SLO scale $\geq$ 30, while static partition needs even more GPUs or a higher SLO scale. For TPOT, static partition is the best across all baselines, requiring 20 GPUs, while QLM and MuxServe++ need at least 29 GPUs when TPOT SLO scale $\leq$ 3.0.

7.5 System Overhead

Model activation latency. We also measured model activation latency from pageable CPU memory for models ranging from 1B to 70B parameters (see §5.3 for more details). Our optimizations significantly reduce activation latency. Prism loads small models (1B~8B) within 0.7s, a medium-size model (14B) in just 1.3s, and large models (>70B) in 1.5s (Figure 10). These results show that Prism can promptly activate evicted models upon receiving new requests.

Activation and migration frequency. Over a 10-minute window of the eight-models-on-two-GPUs run, Prism issued

2 idle-driven activations and 3 inter-GPU migrations. Migrations stay off the TTFT critical path: weights and in-flight KV state transfer over NVLink within tens of milliseconds (*e.g.*, ∼20 ms for an 8B model) while the source instance keeps serving. Activations complete within 2 s, well inside the multi-second TTFT SLOs typical of online serving.

Elastic memory overhead. We evaluated Prism's elastic memory overhead in the worst case, where the request rates are constant, leaving no opportunities for dynamic sharing. With two colocated Llama-3.2-3B models on an A100-40G GPU, Prism incurs only 3 ms (4 %) TTFT and 4 ms (13 %) TPOT overhead at a high load of 32 req/s and only 2 ms (3.5 %) TTFT and 3 ms (7 %) TPOT overhead at a high load of 28 req/s (see §A.3), compared to static partitioning.

7.6 Production Workloads

As of December 2025, Prism has been deployed in multiple organizations serving LLM workloads. Figure 11 summarizes deployments at a large tech company (Company A) using Prism on an internal GPU cluster, and a commercial LLM inference provider (Company B) serving external customers. To isolate Prism's contribution from workload variation, both deployments use shadow workload replay: the same online request stream is mirrored to two identical clusters, one running Prism and the other not, so that the model mix and traffic patterns are held constant across the two arms.

Figure 11a shows Company A's per-GPU token throughput before and after adopting Prism. Company A serves diverse applications using fine-tuned and off-the-shelf models (3B–70B) on a shared GPU pool. With Prism dynamically adjusting model placement and sharing—without changes to existing inference engines—Company A achieves consistently higher throughput (3.89× on average) over several weeks, with no SLO violations and unchanged tail latency. Figure 11b presents results from Company B, which optimizes revenue per GPU under highly variable traffic, computed as the prefill and decode tokens generated in the window priced at the provider's published per-token rates, normalized by GPU count. Prior to Prism, fragmentation and overprovisioning constrained revenue; after deployment, Prism improves utilization while meeting all SLOs, raising revenue per GPU by 2.86× by converting idle capacity into billable tokens.

8 Related Work

SLO-aware LLM scheduling. Llumnix [45], SLOs-Serve [6], ExeGPT [32], SAGESERVE [20], DistServe [65], and MELL [35] explore SLO-aware scheduling to improve LLM inference performance. However, they primarily focus on request scheduling or resource allocation for single-model serving, while Prism enables dynamic cross-model memory harvesting for efficient multi-model serving.

Memory management in LLM serving. vAttention [34] and vTensor [56] use CUDA virtual memory APIs [28] to decouple physical and virtual memory allocation. However, their purpose is to simplify programming and improve kernel efficiency for single-LLM serving. In addition, they require re-implementing a large portion of the current inference engine stack, while our method preserves compatibility with the widely used PagedAttention [21] mechanism.

GPU sharing techniques. GPU sharing has been extensively studied [5, 7, 11, 13, 16–18, 22, 26, 33, 44, 49, 51–53, 55, 57, 60, 61, 63], but largely at the OS or runtime layer for application-agnostic, single-GPU workloads. Compute-centric designs time-slice between latency-critical and best-effort co-tenants [12, 52] or add preemptive scheduling across heterogeneous accelerators [42], whereas Prism targets memory sharing across uniformly latency-critical LLMs spanning multiple GPUs. The closest memory-centric work, MSched [41], schedules GPU–CPU paging *after* oversubscription, while Prism proactively prevents oversubscription via coordinated placement. Existing multi-LLM solutions remain fragmented: MuxServe [11] supports spatial sharing but pins models to devices even when idle, while Aegaeon [53] performs temporal sharing via prefill–decode disaggregation, requiring weight duplication and struggling with diverse, dynamic access patterns. Prism unifies spatial and temporal sharing through elastic GPU memory management.

9 Conclusion

This paper introduces Prism, a multi-LLM serving system that improves cost efficiency while maximizing SLO attainment via GPU sharing. Prism achieves this by enabling flexible memory ballooning, and employing a two-level scheduling algorithm to make efficient use of GPU memory.

Acknowledgments

We thank the anonymous reviewers for their comments and are particularly grateful to our shepherd Xiaosong Ma for her valuable feedback. We also thank Ion Stoica, Matei Zaharia, Jiangfei Duan, Chenxi Wang, Shi Liu, Zhenting Zhu, and Yicheng Liu for their discussions and insights. A Appendix

A.1 Analysis of All production traces

Overview. To understand the workload of multi-LLM serving, we analyze four production traces in detail. These traces are collected from representative service providers as summarized in Table 1. The first two traces are from Hyperbolic [19] and Novita AI [3], two popular LLM inference service providers. They offer inference APIs for a variety of foundation models and also support user-deployed, fine-tuned models. The last two traces are from Chatbot Arena [9], a widely used open-source platform for LLM evaluation. It compares model responses via human preference voting (Arena-Battle) and also provides interfaces for real-time conversations with various models (Arena-Chat).

Bursty-group behaviors. The bursty groups in the production traces shift rapidly over time, and this behavior can be quantified through model switches. As shown in Figure 12a, we plot the number of model switches per hour for each trace. To compute this metric, we treat a model as active if it has received at least one request in the past two minutes. A model switch is counted whenever the set of active models changes. Across the four traces, Novita exhibits the fewest switches, yet still averages 54 switches per hour, meaning the active set changes almost once per minute. In contrast, Arena-Chat, which contains the largest and most diverse collection of models, experiences an average of 766 switches per hour, reflecting that its active set changes every few seconds.

Unpredictability. The request rate at a given time is also highly unpredictable in our traces. Figure 12b quantifies predictability by measuring, for each model, the Pearson correlation between its request-rate time series on consecutive days. Across all traces, the correlations cluster near zero, showing that a model's traffic at a given time of day provides virtually no information about its traffic at the same time on the next day.

Volatile requests. Figure 13a further shows that models frequently alternate between activity and idleness: many models in the Hyperbolic and Novita traces experience more than 40–100 idle intervals per hour (>10 s each), making static reservations wasteful. Complementing this, Figure 13b reports the coefficient of variation (CV), calculated as the standard deviation divided by the mean (σ/μ), of requests per minute for each model. Both Hyperbolic and Novita traces contain many models with CV > 1. The Chatbot Arena traces have lower request rates, resulting in smaller CVs overall, but many models still exhibit CVs greater than 0.5. Together, the high frequency of idle intervals and the substantial variability captured by CV indicate that all traces exhibit strong, persistent volatility.

A.2 Analysis of Algorithm 1

A.2.1 KVPR Bound Analysis

The global model placement algorithm ensures that the maximum KV pressure ratio (KVPR) across all GPUs is bounded by the maximum KVPR in the optimal placement. We give the following analysis.

Let $KVPR_{OPT}$ be the minimum possible maximum KVPR achievable by any optimal placement. Let $KVPR_{max}$ be the maximum KVPR produced by Algorithm 1. We want to show $KVPR_{max}$ is bounded by $KVPR_{OPT}$.

Bottleneck Analysis: Focus on the GPU, denoted as g_{max}, that achieves the highest KVPR ($KVPR_{max}$) given by Algorithm 1's placement. Let m_k be the *last* model assigned to this GPU g_{max}. Let W_{before} and S_{before} represent the total SLO-weighted request rate and shared KV memory on g_{max} *just before* model m_k was assigned. The final state on this GPU is $KVPR_{max} = (W_{before} + d_k)/(S_{before} - w_k)$, where d_k is the SLO-weighted request rate (r_k/s_k) and w_k is the memory weight of model m_k. Similar to Graham [15], this proof aims to demonstrate that both the state *before* m_k was added and the contribution *of* m_k are bounded relative to $KVPR_{OPT}$. Specifically, it seeks to establish two conceptual bounds:

- **Bound 1 (Related to state before m_k):** The KVPR on g_{max} just before m_k's assignment, $\frac{W_{before}}{S_{before}}$, was the minimum among all GPUs at that moment due to the algorithm's greedy choice. This minimum KVPR is typically related to the average "pressure" across the system, which, in turn, is argued to be no larger than the optimal maximum pressure. This suggests the inequality: $W_{before}/S_{before} \leq KVPR_{OPT}$
- **Bound 2 (Related to model m_k):** The "pressure" exerted by the critical model m_k must be handled by the optimal

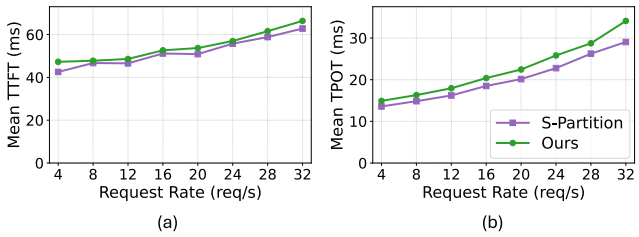

Figure 14: Mean latency comparison.

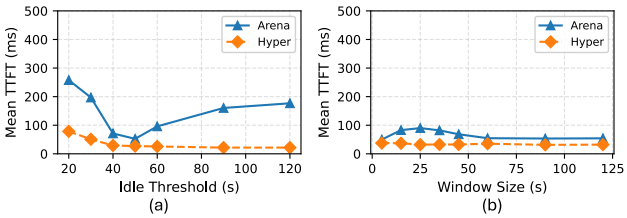

Figure 15: Sensitivity to hyperparameters.

solution. A fundamental lower bound on the optimal solution is the maximum pressure any single model would exert if placed alone on an otherwise empty GPU, *i.e.*, $KVPR_{OPT} \geq d_k/(C - w_k)$.

The final step involves integrating these insights to bound $KVPR_{max} = \frac{W_{before}+d_k}{S_{before}-w_k}$. Following Graham's proof [15], we substitute these into the numerator and get $KVPR_{max} \leq KVPR_{OPT} \cdot (1 + \frac{C}{S_{gmax}-w_k})$.

A.2.2 TP Support

The model placement algorithm in Algorithm 1 seamlessly integrates models utilizing Tensor Parallelism (TP). We conceptualize a TP model requiring tp_size GPUs as being composed of tp_size distinct parts. For scheduling purposes, we create tp_size entries in the sorted model list for such a model, assigning each entry $\frac{1}{tp_size}$ of the original weight and request rate. A beneficial property emerges from this decomposition: since these entries have identical $\frac{r_k}{s_k}$ values, they remain adjacent after sorting. This adjacency increases the likelihood that, as the algorithm iterates, these parts are initially assigned to different GPUs due to rising KVPRs. To ensure the distribution, if assigning a TP part to the GPU with the minimum KVPR would result in collocating it with another part of the same original model, we instead assign it to the GPU exhibiting the second-lowest KVPR. Through this decomposition strategy and modified assignment rule, our algorithm effectively considers and manages the placement of TP models alongside single-GPU models.

A.3 Elastic Memory Overhead

To stress-test the worst case, we evaluate the system under a constant request rate without idle periods, eliminating opportunities for memory coordination through either time- or space-sharing. In this setting, static partitioning provides the strongest baseline, as it divides memory according to the steady request rate. Figure 14 presents a comparison between our system and static partitioning when serving two Llama-3.2-3B models on a single A100-40G GPU. In this experiment, the global scheduler does not alter placements and the GPU-local scheduler does not reorder requests, since all requests have equal priority. The only additional cost arises from the elastic memory manager, which dynamically maps and unmaps pages, unlike static partitioning that relies on pre-allocation. With optimizations such as buffer preallocation and contiguous layouts, this overhead remains modest: mean TTFT and TPOT increase by only 3–5% as request rates scale, demonstrating the efficiency of our system even under worst-case conditions.

A.4 Sensitivity Analysis

We analyze the sensitivity of Prism to two key hyperparameters: the model eviction idle threshold and the load monitoring window size with Hyperbolic and Chatbot Arena traces. The results are shown in Figure 15.

Idle Eviction Threshold. Figure 15(a) reports the mean TTFT as we vary the idle threshold, which dictates how long a model must remain inactive before being evicted. The results reveal a clear convex trade-off. When the threshold is too short (*e.g.*, < 40 s), the system becomes overly aggressive, evicting models during short inter-arrival gaps. This leads to instability and thrashing, where the system must frequently pay the high penalty of model reactivation for subsequent requests, thereby inflating TTFT. Conversely, when the threshold is too long (*e.g.*, $>$ 80s), idle models hoard GPU memory that could otherwise be harvested. This resource locking prevents the scheduler from placing new active models or expanding the KV cache for concurrent requests, resulting in resource starvation and increased queuing delays. Empirically, a threshold of approximately 45 seconds achieves the optimal balance between minimizing reactivation overhead and maximizing resource reclamation.

Load Monitoring Window Size. Figure 15(b) examines the impact of the sliding window size used to calculate the moving average of token rates for the KVPR. This parameter controls the sensitivity of the placement algorithm: a small window makes the scheduler sensitive to transient bursts, while a large window focuses on long-term trends. The results demonstrate that Prism is generally robust to variations in window size. We observe that a window size of approximately 60 seconds provides a stable estimation of memory pressure, effectively smoothing out short-term noise while remaining responsive enough to shift resources during sustained workload changes.

Break on Through to the Other Side: Pooling Memory Elastically with RAMRYDER

Yanbo Zhou[†], Erci Xu[‡*], Dongjoo Seo[§], Adam Manzanares[§], Steven Swanson[†]
[†]*UC San Diego* [‡]*Shanghai Jiao Tong University* [§]*Samsung Semiconductor*

Abstract

Cloud vendors offer diverse infrastructure services by flexibly allocating resources, such as compute, storage, and networking, across virtual machines. However, memory allocation is still less flexible: the vendors allocate memory capacity in a fixed ratio to virtual CPUs and provide no mechanism for allocating memory bandwidth. Recent data show that this can lead to underutilization of both capacity and bandwidth when an application's demands diverge or change over time. To address these challenges, we propose RAMRYDER, a software-defined elastic memory system for cloud virtual machines that allows the system to allocate memory bandwidth and capacity (mostly) independently. RAMRYDER controls the mapping between memory pages in the guest OS and the underlying memory channels, providing performance isolation between virtual machines and allowing dynamic changes to bandwidth and capacity allocation. RAMRYDER improves average capacity and bandwidth utilization by 28.6% and 43.2%, respectively, across the cluster while delivering performance comparable to the best case with exclusive access.

1 Introduction

Cloud service providers provide low-cost and flexible compute resources by supporting the flexible allocation of resources across virtual machines (VMs). Although existing virtualization mechanisms allow for flexible allocation of CPU [7, 9, 81], disk [13, 30, 31], and networking [14, 29] resources, cloud vendors often provide CPU and memory resources in fixed ratios. This can lead to underutilized memory resources in the cloud. Indeed, recent reports show that up to 45% of memory capacity is untouched for half of the VMs in Azure's data center [70].

Previous studies have addressed this problem by allowing more flexible allocation of memory capacity [70] or enabling memory capacity harvesting [40, 70, 85], but large cluster traces show that memory bandwidth is even more severely underutilized, leaving substantial bandwidth stranded in cloud data centers. We find that 90% of servers exhibit average bandwidth utilization below 44.5%. Even peak bandwidth utilization stays below 82.2% for 90% of servers.

The underlying causes of these problems are *spatial over-provisioning* and *temporal over-provisioning*. First, spatial over-provisioning arises because users with strict performance requirements often want exclusive hardware access to avoid bandwidth contention and meet performance quality of service (QoS) targets. A typical practice in multi-tenant cloud environments is to subscribe to at least half of a physical server (i.e., one CPU socket), which guarantees exclusive access to hardware resources [22] and thus avoids performance interference from co-located VMs. Second, temporal over-provisioning arises because users appear to over-provision memory capacity, but in practice they are reserving memory bandwidth to sustain the applications' peak loads as the memory resource is allocated at VM creation and remains fixed throughout the VM lifespan.

Furthermore, the underutilized bandwidth is not necessarily correlated with underutilized capacity. Rather, they exhibit different spatial and temporal patterns. Ideally, cloud providers could allocate memory capacity and bandwidth independently to match the varying demands of co-located VMs, thereby improving overall memory utilization. However, existing approaches, including memory harvesting [40, 85, 104], memory disaggregation via RDMA [2, 8, 25, 44, 45, 62, 66, 68, 86, 90, 95, 105] or CXL [3, 24, 41, 42, 46, 50, 51, 70, 114, 117, 120], only focus on memory capacity utilization and do not alleviate either spatial or temporal over-provisioning for memory bandwidth. Moreover, although CPU vendors have introduced hardware throttling mechanisms [20, 54] by inserting delays between the L2 and the last-level cache (LLC), previous studies [37, 84, 97, 110, 115, 118] show that these techniques cannot precisely allocate memory bandwidth or mitigate interference.

To address the challenges of memory management, we propose RAMRYDER, a software-defined elastic memory system for cloud VMs. RAMRYDER comprises three key techniques. First, RAMRYDER enables bandwidth allocation by assigning memory channels[1] to VMs and taking control of the mapping between memory pages in the guest OS and underlying memory channels. This also provides robust performance isolation between VMs on different channels. Second, RAMRYDER enables the system to allocate memory bandwidth and capacity (mostly) independently from CXL devices. To achieve this, RAMRYDER controls the number of CXL channels mapped to the VM's physical memory and how pages are interleaved

*Corresponding author: Erci Xu (jostep90@gmail.com).

[1] In this paper, a DIMM channel denotes a DDR channel attached to the CPU and populated with DIMMs, while a CXL channel denotes a DDR channel inside a CXL memory device. We use memory channel as a generic term for both DIMM and CXL channels.

across DIMM and CXL channels. Finally, RAMRYDER allows dynamic changes to bandwidth and capacity allocation by adjusting channel allocation and page-to-channel mapping at runtime.

RAMRYDER[2] runs on unmodified commodity servers by exposing memory channels to software via BIOS/UEFI reconfiguration and memory region detection, and implementing a user-space resource manager for channel management, a hypervisor for channel virtualization, and a guest kernel for channel abstraction and page-to-channel allocation policies.

We evaluate RAMRYDER on an AMD EPYC Zen 5 server with DDR5 DIMMs and CXL 2.0 memory devices. The results show that RAMRYDER enables VMs to achieve bandwidth and latency close to those of exclusive hardware access, and reduces the tail latency impact of a noisy neighbor by up to 42.2% on shared hardware. Moreover, RAMRYDER improves average capacity and bandwidth utilization by up to 28.6% and 43.2%, respectively, across the cluster.

The rest of the paper is organized as follows. §2 introduces relevant technologies. §3 analyzes memory bandwidth underutilization and the limitations of existing approaches. §4 and §5 present the design and implementation of RAMRYDER, respectively. §6 evaluates RAMRYDER. §7 discusses RAMRYDER's limitations and target scenarios, §8 surveys related work, and §9 concludes the paper.

2 Background

RAMRYDER targets memory systems for cloud VMs and relies on microarchitectural details of the memory subsystem. This section provides background on relevant technologies.

2.1 Memory Provisioning in the Cloud

Cloud vendors offer elastic infrastructure services (e.g., compute [7,9,81], storage [13,15,31,80], and networking [14,29]), but per-instance memory allocation remains static throughout the instance's lifetime. To accommodate diverse user requirements, cloud vendors design several types of physical servers with different memory-to-CPU ratios as instance types [10, 16, 17] and split each server into several units as instance sizes. For example, AWS defines its compute-optimized instances [10] with a 2:1 memory-to-vCPU ratio (i.e., 2 GB of memory per vCPU), its general-purpose instances [16] with a 4:1 ratio, and its memory-optimized instances [17] with an 8:1 ratio. The largest memory-optimized instance provides 192 vCPUs and 1536 GB of memory [12] while the smallest one provides 1 vCPU and 8 GB of memory. Tenants must select one of the instance types and then an instance size based on estimates of the workloads.

2.2 Memory Organization Inside the Server

A server's memory consists of several hardware components, and DRAM mapping determines how physical memory is mapped to them. This subsection briefly introduces the memory subsystem and DRAM mapping relevant to RAMRYDER.

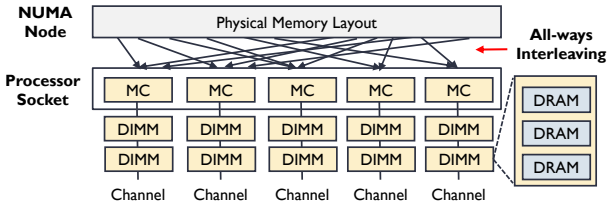

Figure 1: Server memory subsystem (§2.2). *Memory controllers (MCs) and channels are integrated into each processor socket. The physical memory of a NUMA node is interleaved across all channels of the socket, leading memory accesses to share and compete for the aggregate channel bandwidth.*

The server memory subsystem consists of memory controllers, memory channels, DIMMs, and DRAM. As shown in Figure 1, memory controllers and memory channels are integrated into the processor socket, and the DIMMs are installed in slots connected to each channel. From the OS perspective, the DIMMs attached to a processor socket appear as the physical memory of a distinct NUMA node.

DRAM mapping defines how physical memory addresses are mapped to underlying hardware components, determining how much parallelism across memory channels is utilized when accessing a given sequence of pages and consequently affecting memory bandwidth. Unlike virtual-to-physical address mapping, which is controlled by the OS via page tables and can change at runtime, DRAM mapping is set by hardware registers at boot time through BIOS/UEFI settings [19,28,48] and remains fixed after boot. Modern servers interleave sequential physical addresses across all memory channels in a socket (i.e., all-ways interleaving shown in Figure 1) at cache-line granularity (i.e., 64 B [75]) or larger (e.g., 256 B to 4 KB [19,28,48]) to maximize memory bandwidth.

2.3 Memory Expansion Beyond the Server

CXL [34] enables DRAM expansion over PCIe. DRAM on CXL is also subject to DRAM mapping, but with additional complexity. CXL devices contain internal DDR channels [102] and are exposed as physical memory in CPU-less zNUMA [70] nodes in servers. CXL devices can be interleaved at granularities from 256 B to 16 KB [59,96]. Each CXL component (e.g., a root port or CXL device) includes Host-managed Device Memory (HDM) registers that define the interleaving granularity [59,96] and can be configured via BIOS/UEFI and CXL configuration tools [32].

3 Motivation

Memory bandwidth in data centers is severely underutilized, and this underutilization is orthogonal to the well-documented underutilization of memory capacity. Bandwidth underutilization has several causes, yet existing techniques for managing capacity or throttling bandwidth do not address the problem.

[2]The source code of RAMRYDER is publicly available at https://github.com/ramryder-project/ramryder

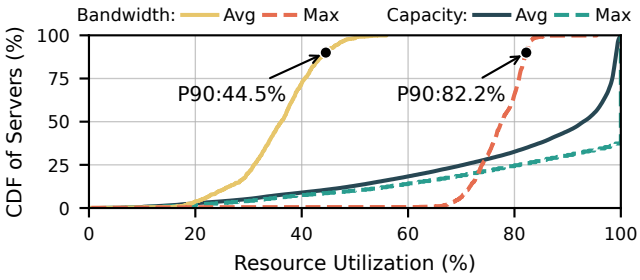

Figure 2: Resource utilization across servers in the cloud (§3.1). *Memory bandwidth is more severely underutilized than memory capacity: 90% of servers in the cloud use no more than 44.5% of available bandwidth on average and no more than 82.2% at peak.*

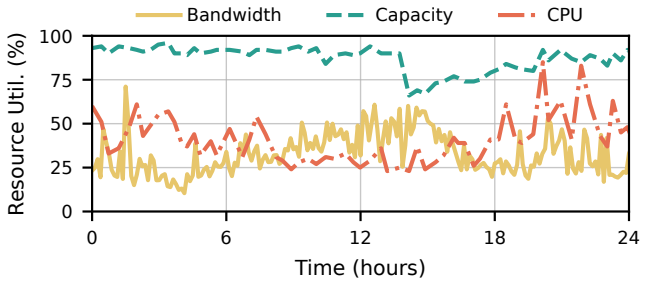

Figure 3: Resource utilization of a single server over one day (§3.1). *A closer look at individual servers reveals decoupled resource utilization trends: memory capacity, memory bandwidth, and CPU utilization can vary over time and in different ways.*

3.1 Bandwidth is Underutilized yet Understudied

Memory bandwidth is more severely underutilized than memory capacity yet remains understudied. To quantify this underutilization, we analyze cluster traces[3] from a major cloud vendor [6] and summarize the following two key observations.

Severely stranded bandwidth. Memory bandwidth underutilization leaves substantial bandwidth stranded in cloud data centers (Figure 2): 90% of servers exhibit average bandwidth utilization below 44.5%; even peak bandwidth utilization stays below 82.2% for 90% of servers. In contrast, 55.4% of servers exhibit both average and maximum capacity utilization above 90%, although 18.3% of servers still have average capacity utilization below 60%. Therefore, optimizing memory resource efficiency should consider both memory capacity and bandwidth.

Decoupled resource utilization. Memory capacity and bandwidth utilization vary over time and in different ways (Figure 3): memory capacity and bandwidth utilization on a physical server are not correlated with each other or with CPU utilization. Therefore, independently managing memory capacity and bandwidth can potentially consolidate complementary workloads and improve overall memory resource efficiency.

3.2 Root Causes of Underutilization

Memory resource underutilization can be attributed to both spatial and temporal over-provisioning.

Spatial over-provisioning. Users with strict performance QoS often want exclusive access to dedicated hardware resources. A typical practice in multi-tenant cloud environments is over-provisioning, such as subscribing to at least half of a physical server (i.e., one CPU socket). This guarantees exclusive access to hardware resources [22], including the LLC and the memory channels described in §2.2, and thus avoids performance interference from co-located VMs. However, this approach achieves isolation by purchasing extra memory and CPU capacity, which is inefficient for both customers and vendors.

Consider a dual-socket server with 96 cores, 384 GB memory capacity, and 600 GB/s memory bandwidth per socket. User A runs a latency-sensitive service (e.g., Redis [89], Memcached [79]) that requires 48 cores, 256 GB capacity, and 50 GB/s bandwidth, while user B runs a bandwidth-intensive job (e.g., STREAM [78], graph processing [23]) requiring 48 cores, 96 GB capacity, and 500 GB/s bandwidth. In principle, these complementary workloads could consolidate on a single socket without over-provisioning. In practice, however, meeting latency targets and bandwidth guarantees forces user A to occupy an entire socket, while user B must take the other full socket to secure sufficient bandwidth.

Temporal over-provisioning. The memory resource is allocated at VM creation and remains fixed throughout the VM lifespan. This forces users to provision memory resources to accommodate the applications' peak loads, resulting in underutilization at off-peak times. In this case, users appear to over-provision memory capacity, but in practice they are reserving memory bandwidth to sustain the applications' peak loads. As shown in Figure 3, despite the high demand for capacity, its utilization remained below 80% for four consecutive hours during the day due to over-provisioning for peak load. Across the full trace dataset (§3.1), more than 30% of servers show long periods (over one hour) of off-peak capacity usage and over 90% of servers show long periods of off-peak bandwidth usage.

3.3 The Limitations of Existing Approaches

Modern systems provide a rich array of memory management features in hardware and software, but none of them effectively addresses the bandwidth utilization problem. This subsection discusses existing approaches and their limitations.

Memory pooling. Prior work utilizes CXL to pool memory resources to improve memory utilization [3, 24, 41, 42, 46, 50, 51, 70, 114, 117, 120]. However, these approaches mainly manage memory capacity rather than bandwidth, and thus do not eliminate spatial over-provisioning for performance QoS or temporal over-provisioning for peak loads.

[3] The traces span thousands of physical nodes running diverse public-cloud workloads, including latency-sensitive services (e.g., e-commerce) and bandwidth-intensive jobs (e.g., MapReduce, Spark, and ML training).

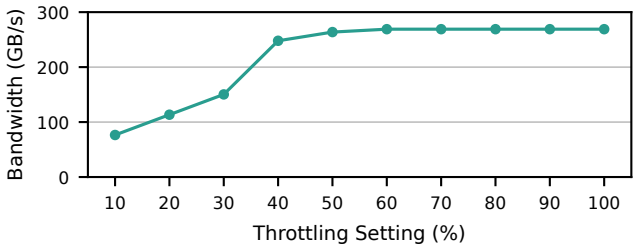

Figure 4: Memory bandwidth with different hardware throttling settings (§3.3). *Hardware throttling cannot precisely or linearly control memory bandwidth. It provides noticeable bandwidth control only at very low throttling settings, where the injected delay is long.*

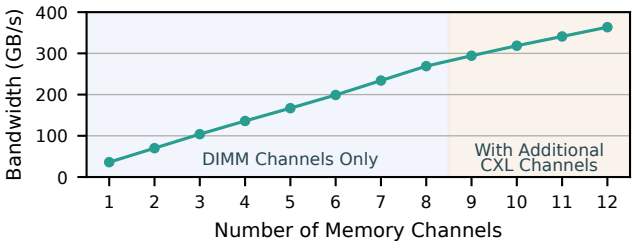

Figure 5: Memory bandwidth with different memory channel configurations (§4). *Bandwidth scales nearly linearly with available DIMM channels. CXL channels provide additional bandwidth and follow the same scaling trend.*

Hardware throttling. CPU vendors provide hardware throttling mechanisms to allocate memory bandwidth and reduce interference among co-located VMs (e.g., Intel MBA [54], AMD QoS [20]). These techniques insert delays between the L2 cache and the LLC to throttle bandwidth usage. However, delay-based throttling cannot provide precise bandwidth control (see Figure 4) and thus fails to effectively mitigate interference caused by co-located VMs (see more experimental results in §6.1 and §6.2). Previous studies have also reported this limitation [37, 84, 97, 110, 115, 118]. Furthermore, inserting extra delays wastes CPU cycles by stalling cores [39].

Software throttling. To control and isolate memory bandwidth, several software-based throttling mechanisms have been proposed. Canvas [105] isolates memory bandwidth by scheduling network packets. Spirit [67] controls memory bandwidth by limiting network transmission. However, these techniques target RDMA-based remote memory and cannot control memory bandwidth for cache-coherent memory (i.e., DIMMs and CXL devices) because, after pages are mapped, memory accesses are issued by the CPU via load/store instructions without software involvement on the access path.

Indirect approaches. Since there is no direct bandwidth allocation mechanism [26], several indirect approaches have been proposed, including limiting the number of cores [39, 74, 115], reducing core frequency [52, 84], and restricting LLC ways [26, 83]. However, these techniques are impractical in cloud environments, as they compromise other key VM metrics (e.g., CPU cores and frequency) in exchange for memory bandwidth control or are only effective for LLC-sensitive applications with LLC-related controls [26, 83].

4 RAMRYDER

RAMRYDER is a software-defined elastic memory system for cloud VMs, providing flexible capacity and bandwidth allocation with robust performance isolation. Its key insight is to manage memory at channel granularity, motivated by two observations. First, bandwidth scales with available memory channels, including both DIMM and CXL channels (Figure 5). Second, congestion stems from channel sharing caused by hardware-controlled interleaving. Therefore, RAMRYDER

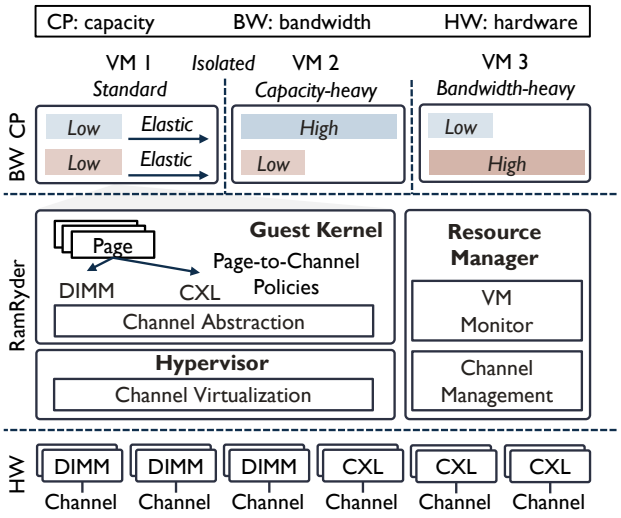

Figure 6: Overview of system architecture (§4). *RamRyder enables memory channel allocation in software to achieve elastic capacity and bandwidth allocation with performance isolation. The runtime includes a user-space resource manager for channel management, a hypervisor for channel virtualization, and a guest kernel for channel abstraction and page-to-channel allocation policies.*

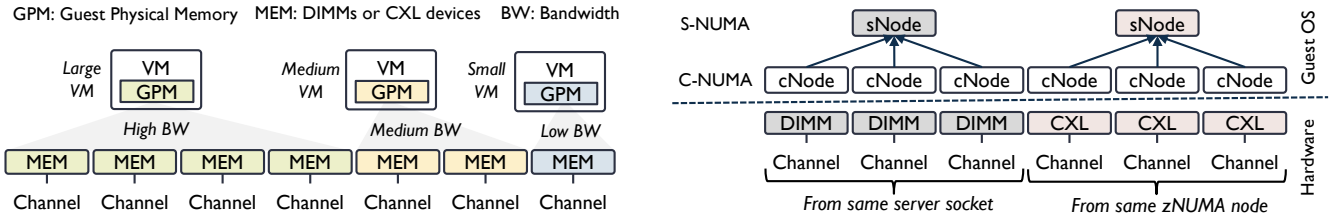
takes the role of hardware and directly manages channel allocation and page-to-channel mapping in software.

Goals. To address the challenges of memory resource efficiency in cloud data centers (§3), RAMRYDER targets three goals: **Goal 1:** enable bandwidth allocation and performance isolation on commodity servers without hardware modifications; **Goal 2:** extend capacity and bandwidth independently; and **Goal 3:** adjust capacity and bandwidth dynamically.

Architecture. RAMRYDER manages memory channels and the devices attached to each channel in software (Figure 6). It statically allocates DIMMs to provide guaranteed capacity and bandwidth, and uses CXL devices to provide elastic best-effort capacity and bandwidth that VMs can independently subscribe to and dynamically scale on demand. The RAMRYDER runtime consists of a resource manager in the host user space, a hypervisor, and a modified guest kernel. The resource manager is responsible for per-channel capacity



(**a**) Channel Allocation

(**b**) Channel Abstraction

Figure 7: Overview of memory channel allocation and abstraction (§4.1). *To allocate memory channels to VMs, the hypervisor maps the VM's guest physical memory to memory devices on the target channels (**a**). Memory on each channel is then exposed as a C-NUMA node (i.e., cNode) in the guest OS, and multiple cNodes are organized as an S-NUMA node (i.e., sNode) by the guest OS (**b**).*

management and channel allocation, the hypervisor enables channel virtualization, and the guest kernel provides channel abstraction and page-to-channel allocation policies in the OS.

Key techniques. To achieve Goal 1, RAMRYDER allocates memory bandwidth by allocating memory channels and controls how pages in the guest OS map to underlying channels. This also provides robust performance isolation since VMs on different DIMM channels are unlikely to interfere with each other (§4.1). To realize Goal 2, RAMRYDER introduces a channel selection policy that determines how many channels to allocate based on bandwidth and capacity demands, and a cross-tier page allocation policy that interleaves pages across DIMM and CXL channels to use additional CXL bandwidth (§4.2). Finally, to achieve Goal 3, RAMRYDER introduces a channel hot-plug/unplug mechanism to allocate and reclaim bandwidth at runtime. It also leverages lazy migration to redistribute previously allocated pages, allowing these pages to utilize the bandwidth of newly attached channels (§4.3).

4.1 Enabling Bandwidth Allocation and Isolation

To achieve bandwidth allocation and performance isolation, RAMRYDER needs to control how memory pages in a VM map to underlying memory channels. This requires four steps. First, RAMRYDER enables channel allocation in software to override hardware-controlled channel interleaving. Next, RAMRYDER isolates LLCs across VMs to avoid cache-level contention that reduces the benefits of channel allocation. Then, RAMRYDER introduces a channel abstraction in the guest OS to expose this hardware component while remaining compatible with existing kernel mechanisms. Finally, RAMRYDER introduces a new page allocation policy to fully utilize the allocated channels within each VM.

Channel allocation. To realize memory channel allocation for VMs, RAMRYDER overrides the hardware-controlled interleaving (§2.2) by directly managing the memory devices attached to each channel, including DIMMs and CXL devices. To allocate channels to a VM, the RAMRYDER hypervisor maps the VM's guest physical memory to the memory devices attached to the target channels (Figure 7(a)). §5.1 explains how RAMRYDER identifies the DIMMs and CXL devices attached to each channel on commodity servers via BIOS/UEFI.

For locally attached DIMMs, RAMRYDER allocates channels in proportion to the VM's memory capacity. For example, a VM that subscribes to 40% of the memory capacity receives 40% of the dedicated channels, which provide 40% of the available bandwidth. Moreover, using this channel allocation mechanism, RAMRYDER can independently allocate additional capacity and bandwidth from CXL devices (§4.2).

LLC isolation. Channel allocation alone cannot achieve full performance isolation since the LLC can introduce cache-level contention across VMs. Therefore, RAMRYDER further isolates LLCs across VMs by pinning each VM's vCPUs on separate chiplets [38], each containing one core complex (CCX) with its own LLC [21].

Channel abstraction. After channels are allocated to a VM, the guest OS needs to recognize the new hardware component while remaining compatible with existing kernel mechanisms. RAMRYDER abstracts memory channels as C-NUMA (i.e., Channel-NUMA) nodes and uses S-NUMA (i.e., Server-NUMA) nodes to preserve the original server-level NUMA topology (e.g., server sockets and zNUMA nodes for CXL [70]). This channel abstraction allows the guest kernel to leverage existing NUMA primitives for page-to-channel allocation while preserving server-level NUMA optimizations.

Specifically, the RAMRYDER hypervisor virtualizes the guest physical memory mapped to each memory channel as a distinct C-NUMA node (cNode) and exposes its physical topology (e.g., socket/zNUMA and channel) to the RAMRYDER guest kernel via the ACPI table [58], which describes hardware topology. The guest kernel then detects the topology of each cNode and constructs S-NUMA nodes (sNodes) by grouping cNodes from the same socket/zNUMA domain (Figure 7(b)). The kernel also maintains a mapping between sNodes and cNodes and only exposes sNodes to users.

Page allocation policy. To better utilize allocated channels within a VM, the guest OS needs to decide how to allocate memory pages across those channels. The RAMRYDER guest kernel uses a channel-interleaving policy to maximize performance. Specifically, when allocating memory pages for applications, the RAMRYDER guest kernel performs page allo-

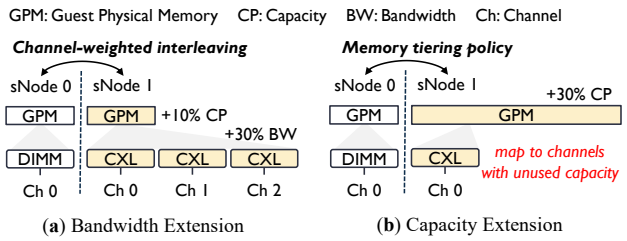


Figure 8: Example of bandwidth and capacity extensions (§4.2). *For bandwidth extension (**a**), RamRyder maps guest memory across multiple CXL channels and leverages a channel-weighted interleaving policy to utilize additional CXL bandwidth. For capacity extension (**b**), RamRyder maps guest memory to channels with unused capacity and leverages a tiering policy to utilize CXL capacity.*

cation in two steps and applies a different policy at each step. It first selects an sNode based on the server-level NUMA-aware policy and then chooses a cNode within that sNode by interleaving pages equally across all cNodes. This channel interleaving allows applications to utilize all available memory channels in parallel within an sNode and achieves performance comparable to hardware-controlled interleaving, which operates at granularities ranging from cache-line size to page size [19, 28, 48, 75].

4.2 Extending Capacity and Bandwidth

RAMRYDER uses CXL devices to provide additional memory capacity and bandwidth. To extend these resources independently, RAMRYDER first uses a channel selection policy to determine how many channels to allocate based on capacity and bandwidth demands. Then, because CXL memory appears as a separate memory tier (i.e., a remote S-NUMA node in the guest OS), RAMRYDER introduces channel-weighted interleaving as a cross-tier page allocation policy for utilizing additional CXL bandwidth.

Channel selection. Given a certain amount of guest physical memory (GPM), RAMRYDER can control the available bandwidth by selecting the number of channels the memory will span. RAMRYDER maps GPM across multiple CXL channels when a VM requires additional bandwidth but only limited capacity (Figure 8(a)). In contrast, RAMRYDER maps GPM to fewer CXL channels when a VM needs additional capacity without proportional bandwidth demand (Figure 8(b)).

With this mapping, capacity and bandwidth utilization within a single CXL channel may become imbalanced. To mitigate this imbalance without sacrificing performance QoS, RAMRYDER pairs VMs with complementary memory demands and co-locates them on the same CXL channels. For instance, if one VM consumes an additional 10% capacity and 60% bandwidth (i.e., occupying 60% of the CXL channels), RAMRYDER allocates the remaining 50% capacity on those channels to another VM that requires less than 50% of CXL capacity with little additional bandwidth demand.

Channel-weighted interleaving. After allocating CXL memory and exposing it as a separate tier, the RAMRYDER guest kernel applies a traditional memory tiering policy [77], which migrates hot pages to DIMMs and keeps cold pages in CXL devices, to utilize additional CXL capacity and introduces channel-weighted interleaving as a cross-tier page allocation policy for utilizing additional CXL bandwidth (Figure 8).

The channel-weighted interleaving policy maximizes bandwidth across tiers by using a weighted ratio between S-NUMA nodes (sNodes) based on each sNode's maximum bandwidth. The maximum bandwidth of a sNode is determined by its number of channels and the bandwidth provided per channel.

For example, consider a VM with three DIMM channels in sNode-0 and one CXL channel in sNode-1, where each DIMM channel provides 36 GB/s and each CXL channel provides 27 GB/s of bandwidth. The guest kernel applies an 8:3 weighted ratio between sNode-0 and sNode-1 (derived from 36×3 and 27×1) by allocating 8 pages from sNode-0 followed by 3 pages from sNode-1, and so forth. Within each sNode, the guest kernel retains channel interleaving equally across its C-NUMA nodes, as described in §4.1.

4.3 Adjusting Capacity and Bandwidth at Runtime

To dynamically adjust memory capacity and bandwidth at runtime, RAMRYDER uses different mechanisms for the two resources. For capacity, RAMRYDER reuses existing Linux memory statistics and the hot-plug/unplug mechanism in the guest OS. For bandwidth, RAMRYDER monitors VM bandwidth usage and introduces a channel hot-plug/unplug mechanism, along with page redistribution, to adjust VM bandwidth.

Capacity monitoring and allocation. RAMRYDER monitors each VM's memory usage by reading Linux's statistics in `meminfo` via a domain socket and hot-plugs memory chunks from CXL devices into the guest when usage exceeds a high threshold (e.g., 80%) or hot-unplugs them when usage falls below a low threshold (e.g., 40%) for consecutive seconds.

Bandwidth monitoring. RAMRYDER leverages processor performance counters to monitor VM bandwidth usage and detect bandwidth bottlenecks and waste for bandwidth adjustment. Every second, RAMRYDER measures the aggregate bandwidth across all cores assigned to each VM. When a VM's bandwidth consumption exceeds the high threshold (e.g., 80%), the RAMRYDER resource manager allocates additional bandwidth (i.e., CXL channels) to the VM. Conversely, if bandwidth consumption stays below the low threshold (e.g., 40%) for consecutive seconds, the RAMRYDER resource manager reclaims bandwidth from that VM.

Channel hot-plug/unplug. To dynamically adjust memory bandwidth without altering capacity, RAMRYDER needs to change the channels allocated to the VM at runtime. To enable this capability, RAMRYDER introduces a channel hot-plug/unplug mechanism. This requires four steps. First, RAMRYDER allocates extra guest physical memory mapped to an

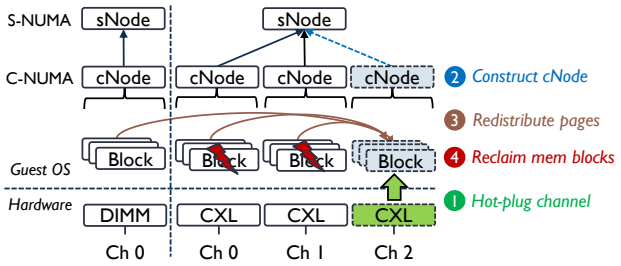

Figure 9: Workflow of adaptive bandwidth adjustment (§4.3). *Adjusting bandwidth at runtime first adds memory channels, then constructs new C-NUMA nodes (cNodes), redistributes pages across cNodes, and finally reclaims memory blocks to retain the same capacity. These four steps are color-coded, with matching icons and text labels indicating the corresponding operations.*

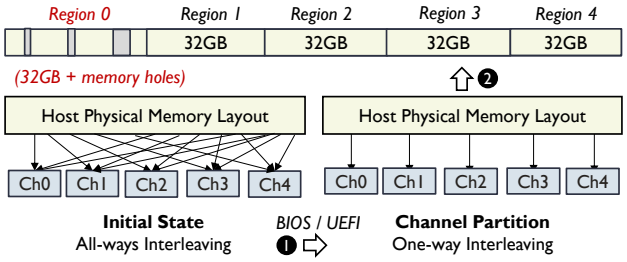

Figure 10: Process of memory topology provisioning (§5.1). *RamRyder gains software control over per-channel memory by first partitioning memory channels via BIOS/UEFI and then detecting per-channel regions from the memory layout. These regions are then reserved as DAX devices for software management.*

additional CXL channel. If the VM previously had a total capacity X across N channels, the new channel is mapped to a new guest physical memory region of size $X/(N+1)$. Next, the RamRyder hypervisor hot-plugs the additional guest physical memory into the guest OS (1, Figure 9). The RamRyder guest kernel then constructs a cNode and adds it to an existing sNode (2, Figure 9), or creates a new one if no sNode exists. Then, RamRyder reclaims the same amount of capacity $X/(N+1)$ from the VM's previously allocated channels by hot-unplugging memory from existing cNodes under the same sNode (4, Figure 9). Since the target reclaim size is $X/(N+1)$ and the VM previously spanned N channels, each cNode should return $X/(N+1)/N$ capacity to keep capacity balanced across all cNodes under a sNode. Through these steps, the VM gains additional bandwidth while maintaining the same total memory capacity.

Note that this procedure enables the VM to immediately utilize additional bandwidth if the workload is allocation-intensive. However, if pages are already allocated on previous channels, RamRyder performs page redistribution (3, Figure 9) between step 2 and 4 above to balance pages evenly across channels. We explain this redistribution process in detail below. Similarly, during channel hot-unplug, RamRyder applies the same procedure in reverse to reclaim bandwidth when the workload demand decreases, including page redistribution across fewer channels when necessary.

Page redistribution. To utilize the newly attached channels, RamRyder redistributes existing pages so that their page-to-channel placement is realigned with the original channel-weighted interleaving (§4.2) and page allocation (§4.1) policies. This redistribution is performed by triggering page faults followed by lazy migration. After hot-plugging new channels, the RamRyder guest kernel scans the page table entries of mapped pages and clears their present bits, which triggers page faults when these pages are subsequently accessed by applications. Upon a page fault, RamRyder recalculates the target sNode and its corresponding cNode, and marks misplaced pages for migration to the new cNode.

5 Implementation

RamRyder is implemented on unmodified commodity servers with a memory topology provisioning toolchain and runtime software. The toolchain reconfigures servers to expose the underlying memory topology required to run RamRyder, while the runtime software implements RamRyder's key components as an end-to-end system.

5.1 Memory Topology Provisioning

To realize RamRyder on commodity servers, we need to gain control over raw memory devices, including DIMMs and CXL devices, under each memory channel in software. To achieve this, we implement a memory topology provisioning toolchain that involves the following operations.

Partitioning memory channels. Since the physical address space is interleaved across all DIMM channels by default, the first step to gain control over the DIMMs under each channel is to partition DIMM channels. We partition DIMM channels primarily by disabling channel interleaving via BIOS/UEFI during system boot (1, Figure 10). After partitioning DIMM channels, the physical address space is linearly mapped to underlying channels (see channel partition in Figure 10).

Detecting memory regions. The second step is to detect each DIMM channel's memory region. As the physical address space is linearly mapped to underlying channels after partitioning, we calculate each DIMM channel's memory region based on the capacity of the DIMMs populated in that channel (2, Figure 10). In practice, the host OS may reserve holes in the memory layout [60]. RamRyder adjusts its address calculations by adding offsets to skip these holes when determining each channel's region (see region 0 in Figure 10).

Reserving memory regions. The final step is to reserve memory under each DIMM channel in user space. We keep 10 GB for the host OS to ensure it has sufficient memory to operate and reserve the remaining region under each channel as a separate DAX device using the `memmap` kernel parameter.

CXL device reservation. For CXL devices, current PCIe Gen 5 CXL devices have one DDR5 channel internally [102].

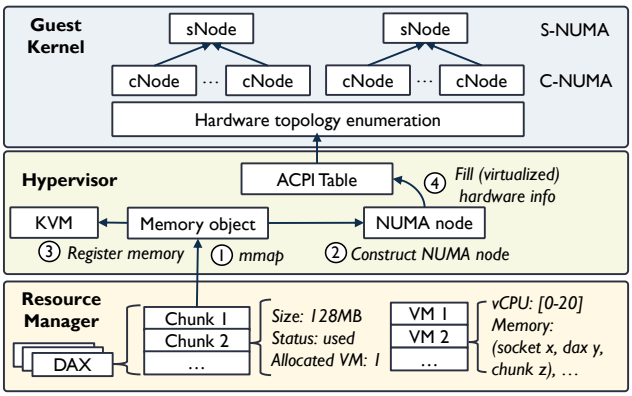

Figure 11: Implementation details. (§5.2). *The RamRyder runtime consists of a user-space resource manager, a hypervisor, and a guest kernel. The resource manager splits per-channel DAX devices into chunks; the hypervisor virtualizes allocated chunks from the same device as a NUMA node and exposes the hardware topology via the ACPI table; and the guest kernel constructs cNodes and sNodes from the exposed hardware topology.*

Therefore, we only need to reserve the whole CXL device, which represents DRAM under one CXL channel. We reserve each CXL device as a separate DAX device in user space via BIOS/UEFI and the CXL configuration tool [32].

5.2 Runtime Software

RAMRYDER's runtime (Figure 11) consists of a resource manager (RM) built from scratch, a hypervisor built on top of QEMU, and an extended guest kernel based on Linux.

Resource manager. The RAMRYDER RM is a user-space daemon that manages memory and monitors VMs. The RM splits each DAX device into 128 MB chunks as the minimal allocation units for VMs, aligned with the kernel's hot-plug block size. Each chunk is uniquely identified by `(socket_id, dax_id, chunk_id)`. The RM also exposes an RPC interface over domain sockets for QEMU to request memory during VM boot. In addition, it uses Linux `perf_event` APIs [61] to collect per-core performance counters and aggregate them into per-VM bandwidth utilization, and interacts with the QEMU Guest Agent [35] to obtain per-VM capacity usage.

Hypervisor. The RAMRYDER hypervisor is QEMU with four major modifications. First, it organizes memory chunks from different DAX devices (i.e., memory channels) into distinct NUMA nodes and exposes the physical topology (i.e., socket and DAX indices) to the guest kernel via reserved domains in the ACPI table [58]. Second, it extends the QEMU Guest Agent to support memory-usage queries used by the RM. Third, it integrates an RPC client that allows QEMU to request memory from the RM during VM launch. Finally, it adds support for attaching and detaching channels at runtime.

Guest kernel. The RAMRYDER guest kernel extends Linux with four major modifications. First, it extends the memory probing process to retrieve physical topology information of C-NUMA nodes from the ACPI table during system boot. Second, it implements the S-NUMA and C-NUMA abstractions within the existing NUMA framework and establishes metadata mappings between them. Third, it implements a new page-mapping policy in the memory-policy layer to maximize performance under these abstractions. Finally, it extends the kernel's memory hot-plug/unplug mechanism to construct new S-NUMA and C-NUMA nodes and trigger page redistribution upon C-NUMA hot-plug/unplug events.

6 Evaluation

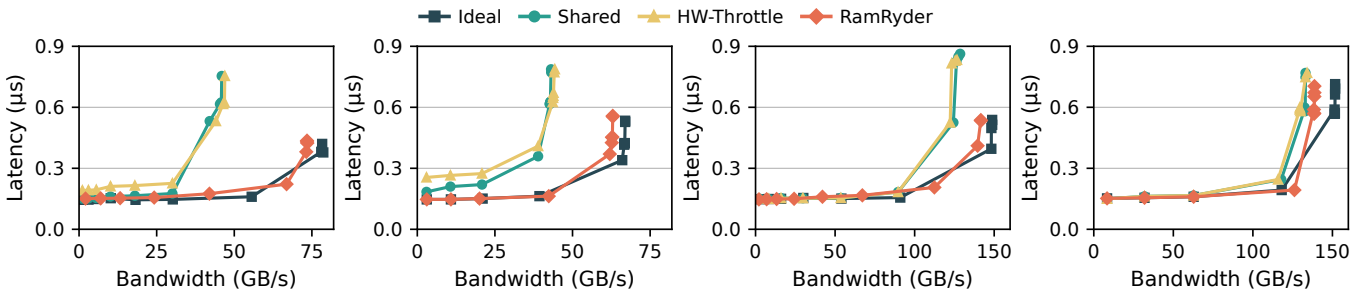
Our evaluation aims to answer the following questions:

- What benefits does RAMRYDER provide for VMs in terms of performance and isolation (§6.1)?
- Can RAMRYDER provide additional memory capacity or bandwidth while maintaining QoS for applications with asymmetric memory demands (§6.2)?
- Can RAMRYDER improve memory utilization across both capacity and bandwidth in cloud data centers (§6.3)?
- What overheads does RAMRYDER introduce, and how sensitive is RAMRYDER to highly dynamic workloads (§6.4)?

Testbed. Our server has an AMD EPYC Zen 5 processor with 128 logical cores (SMT enabled) and 12 DDR5 DIMM channels per socket. The cores are organized into 8 CPU dies, each with a 32 MB L3 cache and 16 logical cores. To match cloud compute-optimized instances (i.e., high compute with minimal memory), we use 8 DIMM channels in one socket, each populated with a 32 GB DDR5 DIMM. We create four VMs (details below), each using the same vCPU-to-memory ratio as AWS and Alibaba compute-optimized instances [5, 11]. The server also includes four 256 GB Samsung CXL 2.0 memory devices and runs Debian with Linux 6.15.

VM setup. We create four VMs to model multiple tenants. VM 1 and VM 2 each have 16 vCPUs and 32 GB of memory, while VM 3 and VM 4 each have 48 vCPUs and 96 GB of memory, following AWS and Alibaba compute-optimized instances [5, 11]. Each VM's vCPUs are pinned to logical cores on separate core complexes (CCXs) [21], giving each VM dedicated LLCs. For RAMRYDER, we initially allocate one DIMM channel each to VM 1 and VM 2 and three DIMM channels each to VM 3 and VM 4, keeping memory bandwidth allocation proportional to capacity and CPU cores.

Compared approaches. We compare RAMRYDER against three approaches: *Ideal*, where VMs have exclusive access to hardware resources without co-located VMs; *Shared*, the default configuration where multiple VMs co-locate on a server; and *HW-Throttle*, which throttles memory bandwidth on top of *Shared* to mitigate co-located VM interference using Intel MBA [54] and AMD QoS [20]. For *HW-Throttle*, bandwidth is throttled in proportion to allocated capacity and CPU cores (e.g., a VM allocated 60% of the capacity and CPU cores is throttled to 60% of the maximum bandwidth).



(a) VM 1 (16 vCPUs): Read (b) VM 2 (16 vCPUs): 3:1 R/W (c) VM 3 (48 vCPUs): Read (d) VM 4 (48 vCPUs): 3:1 R/W

Figure 12: Latency and bandwidth under co-located VMs (§6.1). *VMs with fewer vCPUs (VM 1 and VM 2) are more vulnerable to interference from co-located VMs with more vCPUs (VM 3 and VM 4). RamRyder mitigates contention and delivers performance close to the ideal baseline with exclusive hardware access.*

6.1 Microbenchmarks

RAMRYDER guarantees performance QoS in multi-tenant environments through bandwidth allocation and performance isolation, without dedicated hardware resources. This subsection uses microbenchmarks to quantify this benefit.

Configuration. We use Intel MLC [53] to generate memory-intensive workloads, with read-only traffic on VM 1 (16 vCPUs) and VM 3 (48 vCPUs), and a 3:1 read/write mix on VM 2 (16 vCPUs) and VM 4 (48 vCPUs). Each VM runs the benchmark on all available cores with a 100 MB buffer and a 64 B stride per core, ensuring the working set exceeds the CPU cache and accesses come from main memory. We run all VMs concurrently and measure memory bandwidth and average memory access latency.

Reads. Under read-only workloads (Figure 12(a) and (c)), both *Shared* and *HW-Throttle* suffer noticeable performance degradation, while RAMRYDER mitigates contention and delivers performance close to *Ideal*. In *Shared*, VM 1 experiences the most severe slowdowns: its memory access latency increases by up to 78.5%, and its maximum bandwidth drops by up to 41.2% compared to *Ideal*. This degradation arises because all VMs share the same memory channels, and VMs with more CPU cores can contend for more bandwidth, resulting in greater interference to VMs with fewer cores.

HW-Throttle, however, fails to mitigate contention and instead increases latency for the small VM with fewer cores (see the small gap between the green and yellow lines under 25 GB/s bandwidth in Figure 12(a)). This occurs because inserting extra delays cannot precisely control bandwidth and further wastes CPU cycles by stalling cores [39]. This observation aligns with prior work showing that *HW-Throttle* is ineffective for high-bandwidth workloads and only effective for low-bandwidth workloads when throttled to very low levels by inserting many delays [37, 84, 97, 115].

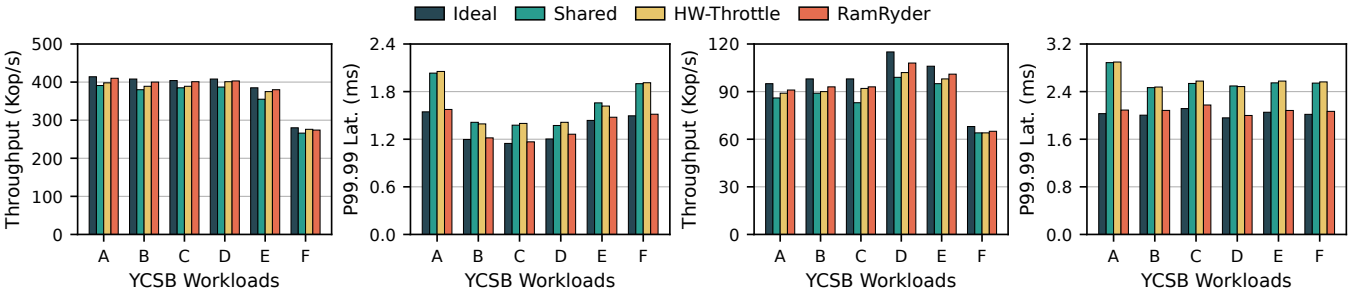
In RAMRYDER, VMs achieve bandwidth close to *Ideal* through channel allocation and isolation, which precisely control bandwidth and physically isolate VMs to avoid contention. For latency, VM 1 differs from *Ideal* by less than 5%, and its latency is up to 42.7% lower than that in *Shared*. A small gap to *Ideal* still exists because the VM in *Ideal* can use more available channels at the same bandwidth level, enabling greater parallelism and thus lower latency. Although RAMRYDER limits the number of channels, it effectively mitigates contention from co-located VMs through physical isolation.

Mixed reads/writes. Under mixed workloads (Figure 12(b) and (d)), the overall trends remain consistent with those under read-only workloads. However, VM 2 shows about 15.3% lower bandwidth than under read-only workloads for both *Ideal* and RAMRYDER. In addition, VM 4 experiences less impact under both *Shared* and *Ideal* than under read-only workloads. These differences arise from the varying capabilities of memory channels to handle reads versus writes. §6.4 analyzes the scalability of memory channels under different read/write ratios in detail.

6.2 Application Benchmarks

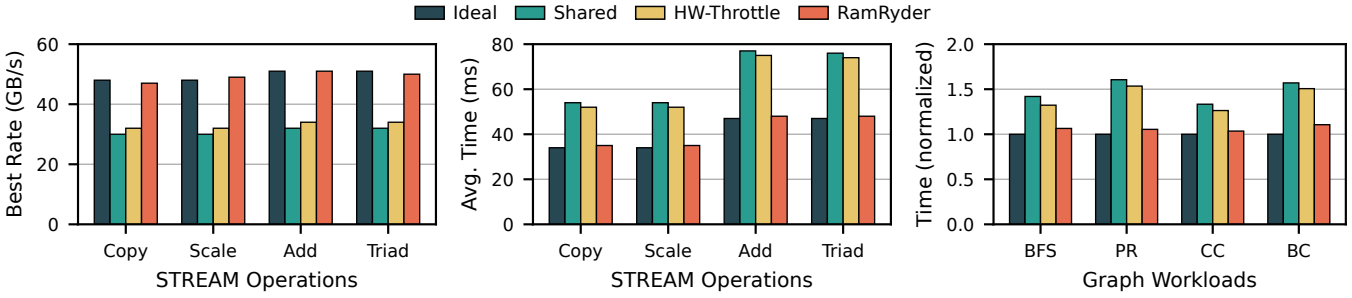
RAMRYDER enables independent memory capacity and bandwidth extension with CXL devices while maintaining performance QoS, without subscribing to extra memory resources (i.e., paying for additional capacity to obtain more bandwidth, or for additional bandwidth to get more capacity). This subsection uses application benchmarks to quantify this benefit.

Configuration. We evaluate two scenarios: (1) mixed workloads where capacity-demanding and latency-sensitive applications co-locate with bandwidth-intensive applications, and (2) all bandwidth-intensive applications. In the mixed scenario, we allocate an additional 100 GB of CXL memory to each of VM 1 and VM 2 and run Memcached and Redis with YCSB [33], respectively. In the bandwidth-only scenario, we allocate 10 GB of CXL memory and map it to one CXL channel for each of VM 1 and VM 2 and run STREAM and graph processing, respectively. Because VMs with fewer CPU cores are more susceptible to interference (§6.1), we allocate one CXL channel with 10 GB of CXL memory to each of VM 3 and VM 4 and generate peak mixed read/write traffic with Intel MLC to stress-test both scenarios. For *Ideal*, *Shared*, and *HW-Throttle*, we apply the existing Linux kernel



(a) Throughput of Memcached (b) Tail Latency of Memcached (c) Throughput of Redis (d) Tail Latency of Redis

Figure 13: Performance of Memcached and Redis under YCSB workloads with co-located VMs (§6.2). *RamRyder mitigates channel contention through channel isolation and thus achieves throughput and tail latency close to the Ideal baseline, while Shared and HW-Throttle suffer higher latency and lower throughput due to channel contention.*



(a) Throughput of STREAM (b) Execution Time of STREAM (c) Execution Time of Graph Processing

Figure 14: Performance of STREAM and graph-processing workloads with co-located VMs (§6.2). *RamRyder mitigates channel contention through channel isolation and thus achieves throughput and execution time close to the Ideal baseline, while Shared and HW-Throttle suffer lower throughput and higher execution time due to channel contention.*

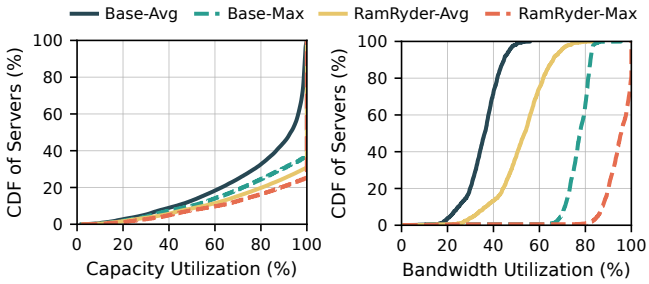
tiering [77] policy to utilize CXL memory for all four VMs.

Memcached. We populate 60 million key-value pairs (16 B keys and 1 KB values), and each YCSB workload issues 30 million operations. In terms of throughput (Figure 13(a)), all approaches achieve similar performance across YCSB workloads because memory bandwidth utilization remains low during execution, so throughput is not significantly affected by co-located VMs. However, both *Shared* and *HW-Throttle* exhibit higher tail latency (Figure 13(b)), particularly under YCSB-A (31.4% higher) and YCSB-F (27.2% higher). We observe that most memory accesses are served from local DIMMs, while CXL memory only stores cold pages with low access frequency. Therefore, the latency degradation primarily stems from contention on DIMM channels. In contrast, RAMRYDER mitigates contention from the bandwidth-intensive workloads and achieves latency close to *Ideal* by allocating exclusive DIMM channels to each VM.

Redis. We use the same configuration as in the Memcached experiment (60 million key-value pairs and 30 million YCSB operations per workload). The throughput (Figure 13(c)) and latency (Figure 13(d)) trends are similar to those seen in the Memcached results. We further observe that both *Ideal* and RAMRYDER achieve slightly higher throughput than *Shared* and *HW-Throttle*, particularly under YCSB-D (RAMRYDER improves throughput by 9% and *Ideal* by 16.2%). For latency, *Shared* and *HW-Throttle* incur up to 42.7% higher latency in the worst case (YCSB-A), while RAMRYDER remains within a 5% latency increase relative to *Ideal*.

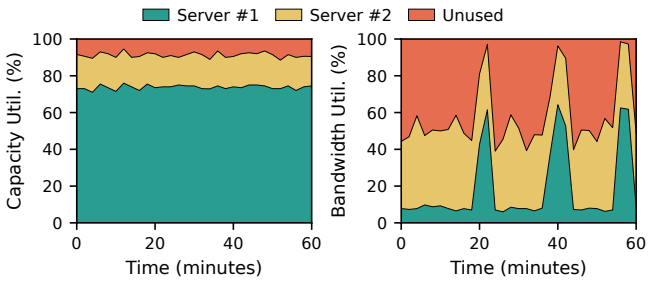
STREAM. We configure each STREAM workload (Copy, Scale, Add, and Triad) with an array size of 50 million elements to ensure that the working set far exceeds the LLC capacity, forcing most accesses to be served from main memory. In *Shared*, throughput (Figure 14(a)) is 37.3% lower and execution time (Figure 14(b)) is 58.8% higher compared to *Ideal* due to contention from co-located VMs. In *HW-Throttle*, both throughput and execution time remain similar to *Shared* (only about a 7% improvement for both metrics). By contrast, RAMRYDER achieves performance comparable to *Ideal*, with both throughput and execution time within 5% across all STREAM workloads, by allocating exclusive DIMM and CXL channels to the bandwidth-intensive VMs, thereby mitigating contention.

Graph processing. We generate graphs with 67 million nodes and 1.3 billion undirected edges and run four workloads: Breadth-First Search (BFS), PageRank (PR), Connected Components (CC), and Betweenness Centrality (BC).



(a) Utilization of Capacity (b) Utilization of Bandwidth

Figure 15: Cluster-level resource utilization before and after co-locating compatible workloads from cloud traces (§6.3). *RamRyder improves both capacity and bandwidth utilization by co-locating workloads with complementary demands within hardware limits.*



(a) Utilization of Capacity (b) Utilization of Bandwidth

Figure 16: Server-level resource utilization when replaying cloud workloads from a matched server pair (§6.3). *The two servers have complementary demands, allowing RamRyder to improve utilization while meeting both capacity and bandwidth demands.*

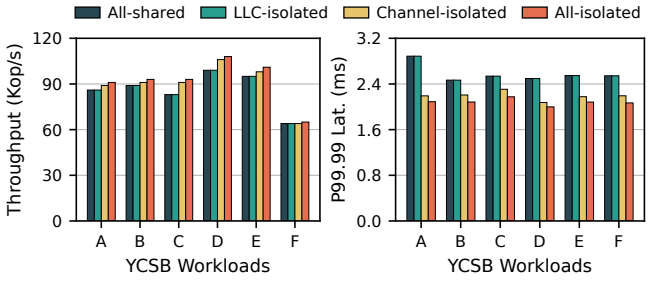
Because these workloads report only execution time and exhibit large differences in absolute runtime, we normalize all results to *Ideal* (Figure 14(c)). In *Shared*, execution time is 41.4% higher than *Ideal* due to contention from co-located bandwidth-intensive VMs. In *HW-Throttle*, execution time improves slightly but still shows a substantial gap compared to *Ideal*. By contrast, RAMRYDER reduces execution time by 25.2% relative to *Shared* and remains within 5% of *Ideal*. These benefits arise from RAMRYDER's channel allocation and isolation, which eliminate contention and ensure QoS.

6.3 Cloud Workloads

RAMRYDER improves both capacity and bandwidth utilization in cloud data centers by consolidating complementary workloads on the same server while guaranteeing performance QoS. This subsection quantifies these benefits at both the cluster and server levels by emulating cloud workloads using the cluster traces [6] described in §3.

Cluster-level utilization. We analyze the memory traces to identify server pairs whose combined capacity and bandwidth usage at each timestamp remains within hardware limits (i.e., under 100%), and then calculate the resulting cluster-level utilization. At the cluster level, RAMRYDER improves average and maximum capacity utilization at P30 by 28.6% and 22.1% (Figure 15(a)), and average and maximum bandwidth utilization at P90 by 43.2% and 26.1% (Figure 15(b)).

Server-level utilization. We replay the memory requests of selected server pairs using a custom workload generator that reproduces their timestamped capacity and bandwidth usage, and run these workloads on the previously configured VM 3 and VM 4. As shown in Figure 16, server 1 requires high capacity (over 70%) with low bandwidth (averaging 10.1%) and occasional bursts, whereas server 2 uses low capacity (below 20%) but high bandwidth (averaging 38.4%). RAMRYDER accommodates these complementary demands and dynamically allocates memory bandwidth when workload demands change, improving utilization while meeting each workload's requirements.



(a) Throughput (b) Tail Latency

Figure 17: Attribution of performance isolation with Redis under YCSB workloads (§6.4). *Channel isolation contributes more to reducing interference than LLC isolation, and combining both isolation mechanisms achieves the best performance.*

6.4 Overhead and Sensitivity Analysis

RAMRYDER achieves its performance and utilization benefits with limited overhead. This subsection quantifies the overhead of RAMRYDER's internal mechanisms and its sensitivity to highly dynamic workloads.

Attribution of performance isolation. We conduct an ablation study to quantify the contributions of LLC and channel isolation, using the same VM configurations and workloads as in §6.2. We compare the all-shared, LLC-isolated, channel-isolated, and all-isolated setups, using Redis on VM 2 as a representative workload. As shown in Figure 17, channel sharing causes more severe interference than LLC sharing. Therefore, LLC isolation alone provides limited benefit. Channel isolation achieves much stronger isolation, although it still leaves residual LLC contention. With both LLC and channel isolation enabled, RAMRYDER achieves the best performance.

Scalability of memory channels. To evaluate scalability, we launch a VM with 128 vCPUs and initially one DIMM channel. We use Intel MLC to measure peak bandwidth under different read/write ratios while incrementally adding DIMM and then CXL channels. As shown in Figure 18, bandwidth scales linearly with the number of DIMM channels for both

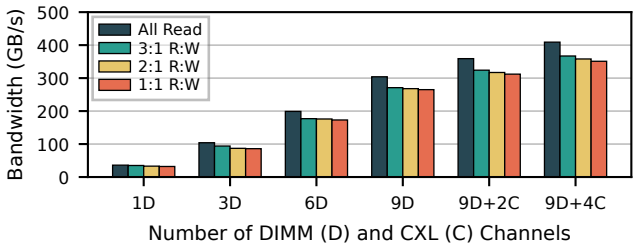


Figure 18: Scalability of software-defined memory channels (§6.4). *Memory bandwidth scales nearly linearly with DIMM channels under both read-only and mixed workloads; additional CXL channels further increase bandwidth.*

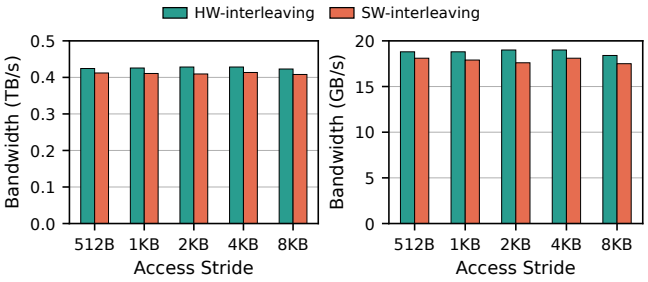

(a) Bandwidth with 128 threads (b) Bandwidth with 1 thread

Figure 19: Overhead of software-defined interleaving under different access strides (§6.4). *Software-defined interleaving delivers bandwidth close to hardware-controlled interleaving with low overhead across both 128-thread and single-thread workloads.*

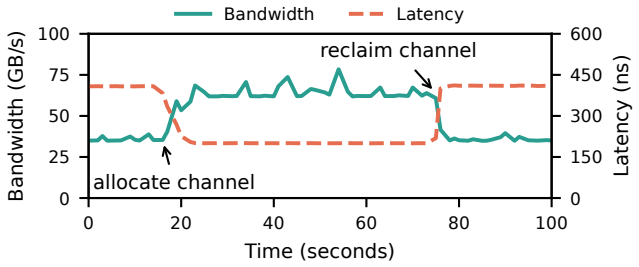

Figure 20: Bandwidth and latency during dynamic channel allocation and reclamation (§6.4). *Since channel changes require page redistribution, RamRyder leverages lazy migration to redistribute pages, avoiding large latency spikes despite the migration delay.*

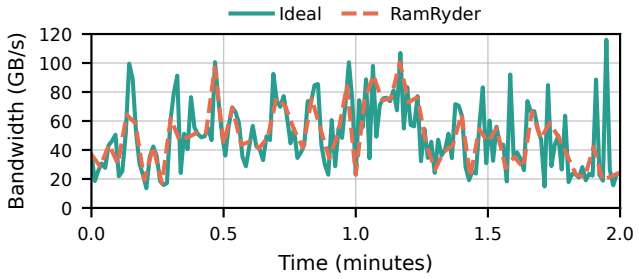

Figure 21: Bandwidth adjustment under highly dynamic workloads (§6.4). *RamRyder adapts to sustained bandwidth changes and approaches the over-provisioned ideal baseline, while transient bursts may be missed due to monitoring granularity and page-redistribution delays.*

read-only and mixed workloads. When CXL channels are added, the scaling slope decreases slightly because CXL channels provide lower bandwidth than DIMM channels.

Overhead of software-defined interleaving. To quantify this overhead, we launch a VM with 128 vCPUs and all DIMM channels, then use STREAM to measure peak bandwidth with multiple threads and a single thread under different stride sizes. With 128 threads, RAMRYDER achieves peak bandwidth comparable to hardware interleaving, with an average overhead of 3.6% and a maximum of 4.4% across stride sizes (Figure 19(a)). With a single thread, RAMRYDER introduces a higher average overhead of 5.1%, with a more visible gap at intermediate stride sizes, especially the 2 KB stride, where overhead reaches 7.4% (Figure 19(b)). This is likely because hardware interleaving benefits from finer interleaving granularity, which better exploits row buffer locality.

Overhead of dynamic bandwidth allocation. Dynamic bandwidth allocation involves channel hot-plug/unplug and page redistribution. Channel hot-plug/unplug takes only a few microseconds and is negligible; redistribution dominates the cost and depends on the number of allocated pages and migration rate. To measure this overhead, we run a read-only workload on a VM with one DIMM channel using Intel MLC, then attach a CXL channel, and later reclaim it (Figure 20). The workload uses 10 GB of memory and initially reaches 38 GB/s. After adding a CXL channel, bandwidth rises to 68 GB/s over 2.2 seconds, corresponding to a 1.82 GB/s migration rate while migrating about 40% of pages. Reclaiming the channel completes in 1.1 seconds because RAMRYDER performs lazy migration on allocation but immediate migration on reclamation. In both operations, latency remains smooth without noticeable spikes, indicating that redistribution incurs low overhead despite lasting a few seconds.

Sensitivity to highly dynamic demand. We evaluate RAMRYDER with a highly dynamic workload and compare it with an ideal baseline that over-provisions all channels. We observe two expected differences from this over-provisioned baseline (Figure 21). First, RAMRYDER may miss extremely short bursts and cannot provide instantaneous bandwidth for such transient spikes. Second, for other bandwidth changes, RAMRYDER takes time to increase bandwidth and therefore slightly lags behind the ideal baseline. These gaps come from two sources. First, RAMRYDER needs at least 1 second to collect performance-counter information, so very short bursts can finish before the next decision point. Second, increasing bandwidth requires page redistribution, so newly attached channels contribute bandwidth gradually rather than immediately. Overall, RAMRYDER transitions smoothly and catches up to sustained demand increases, making it more suitable for VMs with gradually increasing bandwidth demand.

7 Discussion

Our prototype and evaluation focus on the feasibility of elastic capacity and bandwidth allocation by managing memory channels in software. While the results are encouraging, we acknowledge several limitations. This section discusses approaches to address them and describes target scenarios.

Guest kernel modifications. RAMRYDER requires guest kernel modifications, which complicates deployment in the cloud. This design, however, could enable finer-grained isolation: the guest kernel can isolate memory channels across co-located jobs within a VM, while these jobs remain opaque to the host. We therefore expect memory channel abstractions to become a standard OS interface for both guest and host kernels, eliminating the need for guest kernel modifications.

Reserving bandwidth beforehand. RAMRYDER initially allocates DIMM channels based on each VM's memory bandwidth demand estimated from its proportion of allocated vCPUs, following the same policy used for local storage in the cloud [4, 18]. If this estimate deviates significantly from the VM's actual demand, RAMRYDER can also reallocate DIMM channels dynamically to avoid bandwidth shortages and resource waste.

Efficiency of dynamic bandwidth allocation. RAMRYDER requires several seconds to redistribute pages after channels are hot-plugged. This dynamic bandwidth allocation capability is suitable for VMs with gradually increasing bandwidth demand. For future optimization, RAMRYDER could leverage learning-based policies to predict bandwidth demand and trigger channel hot-plugging and page redistribution in advance.

Channel sharing for small VMs. Modern processors support up to 12 DIMM channels per socket, but this granularity remains too coarse for small VMs whose demand is below a full channel. Thus, RAMRYDER can place multiple small VMs on the same channel while isolating them from large VMs with many vCPUs, a major source of interference (§6.1). This also fits hardware throttling, which is effective mainly when the bandwidth limit is set very low [84, 115], making it a potential mechanism to control small VMs sharing a channel.

Granularity of CXL channels. The CXL memory devices in our testbed use a single DDR5 channel; thus, the entire device can be reserved as DAX to represent one channel. Future PCIe 6.0/7.0 CXL devices will require multiple DDR channels for higher bandwidth [102], but their internal interleaving policies remain unclear. Ideally, vendors should expose these policies as configurable options, allowing the OS to control the mapping from physical memory to internal DDR channels.

Applicability to multi-host CXL memory pools. RAMRYDER is currently designed and implemented for a single host server, but can be extended to a CXL memory pool shared by multiple hosts. In such scenarios, one host can act as the master node running the RAMRYDER resource manager, while others communicate with it via the RAMRYDER RPC interface (§5.2) to request memory capacity and bandwidth.

8 Related Work

Memory interference optimization. Prior work reduces memory interference via architectural techniques such as LLC partitioning [43, 57, 76, 87, 91, 92] and channel partitioning [73, 82, 116], which require hardware changes. System-level approaches include Canvas [105] for far-memory isolation and DRAM mapping aliases [47] for OS-guided partitioning or interleaving. RAMRYDER is inspired by both architectural and system-level designs to physically isolate channels across VMs to reduce interference.

Memory bandwidth allocation. Existing bandwidth allocation relies on indirect controls, including throttling between L2 and LLC [37, 55, 110, 115], CPU-level mechanisms [52, 84, 115], LLC partitioning with throttling [26, 83, 118], and CPU scheduling [39, 74]. These techniques are indirect, often workload-specific, and may compromise other metrics. RAMRYDER allocates bandwidth directly by allocating channels.

Memory bandwidth extension with CXL. Recent work explores using CXL devices to extend memory bandwidth. Many studies quantify the bandwidth benefits of CXL and examine page interleaving across memory tiers [27, 56, 71, 93, 100, 101, 106, 107]. Other efforts leverage CXL bandwidth for databases [49], PCIe device pooling [120], and LLM inference [63, 111, 113]. RAMRYDER extends this direction by enabling independent bandwidth allocation on CXL devices.

Memory capacity extension with CXL. CXL-based capacity extension spans memory tiering within a single server [1, 36, 64, 65, 69, 72, 77, 88, 94, 98, 99, 103, 108, 109, 112, 119] and memory disaggregation across multiple servers via CXL switches [3, 24, 41, 42, 46, 50, 51, 70, 114, 117]. RAMRYDER focuses on the single-server setting and can further extend to switch-based multi-host settings.

9 Conclusion

Memory bandwidth is severely underutilized in cloud data centers due to spatial and temporal memory over-provisioning, which stems from inflexible memory allocation and the lack of bandwidth allocation and performance isolation. This paper proposes RAMRYDER, a software-defined elastic memory system for cloud VMs. RAMRYDER takes the role of hardware and directly manages memory channel allocation and mapping in software to allocate bandwidth and capacity independently. This also enables performance isolation and allows resource allocation to change dynamically at runtime. RAMRYDER therefore improves both memory capacity and bandwidth utilization while guaranteeing performance QoS.

Acknowledgments

We thank our shepherd and the OSDI'26 anonymous reviewers for their insightful feedback, and Fan Ni for early discussions and suggestions. This work was supported in part by ACE, one of the seven centers in JUMP 2.0, a Semiconductor Research Corporation (SRC) program sponsored by DARPA.

Abstract

Compute Express Link (CXL) DRAM has emerged as a promising solution to address the capacity constraints of conventional systems using DDR DRAM. By decoupling memory expansion from the DDR interface generation imposed by the host CPU's memory controller, CXL DRAM allows cost-effective scaling of system memory capacity. However, as memory capacity grows, memory management metadata can become too large to fit entirely in DDR DRAM, necessitating that part or all of it to be placed in CXL DRAM. Moreover, since the OS views CXL DRAM as a CPU-less remote node, the host CPU manages metadata in CXL DRAM, thereby increasing metadata management latency. We find that this overhead significantly reduces memory reclamation efficiency and causes considerable increases in the tail latency of latency-sensitive applications. In this work, we investigate the performance impact of metadata placement in CXL DRAM and propose MAC, a near-memory processing (NMP) solution that accelerates memory-intensive components of metadata management directly within CXL DRAM to improve memory reclamation efficiency. Compared to conventional OS-based memory reclamation, MAC reduces application tail latency by up to 98%.

1 Introduction

CXL DRAM has emerged as a promising solution to address the memory capacity limitations of applications whose datasets exceed available memory, such as large-scale analytics and database workloads [58, 7, 61]. The CXL interface enables significantly larger memory capacity with fewer platform-level constraints compared to traditional DDR DIMMs. Although CXL DRAM has approximately 2.4× higher access latency than DDR DRAM [34, 80], it offers substantial scalability benefits. Servers can overcome the traditional 'memory capacity wall' and provision memory at a lower cost. Furthermore, by equipping servers with CXL DRAM, memory provisioning costs for the servers can be reduced by more than half compared to DDR DRAM-based systems with equivalent total capacity—for example, in configurations where the DDR-to-CXL DRAM ratio is 1:4 [9, 60, 59, 18].

However, such servers introduce new challenges in memory management. The operating system (OS) maintains a page descriptor [49] for each physical memory frame to keep track of the state of each page (where a "page" refers to a logical unit that is mapped to a physical frame in virtual memory systems), including metrics such as the recency of access and the reference count. The OS also uses the Xarray data structure [52] to index file-backed pages in the page cache [84]. The size of these metadata structures scales proportionally as a function of total system memory and file sizes, and may become too large to fit entirely in DDR DRAM of a server, which provides low latency but limited capacity under cost constraints. For example, in a server with a DDR DRAM to CXL DRAM capacity ratio of 1:4, the total size of memory management metadata can reach up to 24% of the DDR DRAM capacity. If the ratio increases to 1:8, this capacity overhead can approach 40%.

When these metadata structures spill over into slow CXL DRAM due to insufficient space in DDR DRAM, we uncover a deterioration in the rate of memory reclamation, which degrades application performance. Specifically, modern operating systems rely on a background memory reclaimer (*e.g.*, kswapd [38] in Linux) to free pages under memory pressure. However, when the background memory reclaimer has to access metadata in slow CXL DRAM, it cannot free pages quickly enough. This forces user applications to trigger a foreground memory reclaimer. Because the foreground memory reclaimer lies on the critical path of application I/O [68, 54, 82, 83], its accesses to slow CXL DRAM significantly increase the tail latency of applications.

To observe the impact on foreground reclamation on application tail latency, we conducted experiments where the latency of metadata access—specifically for Xarray and page descriptors—was modulated during both background and foreground memory reclamation. When metadata access latency increased by approximately 2.4×, we observed that the 99.99th-percentile (p99.99) tail latencies increased by about 2.7×, primarily due to a 6.5× increase in the number of direct reclamation events on the critical path of application

execution. These findings suggest that placing metadata in high-latency CXL DRAM can severely deteriorate application responsiveness—especially for latency-sensitive workloads that demand tail latency guarantees within just a few milliseconds (*e.g.*, 1–10 ms at p99.99 [75, 31, 78, 1, 90]).

To address these challenges, we propose MAC (Memory Reclamation Acceleration for CXL), a near-memory processing (NMP)-based memory reclamation acceleration solution designed for systems deploying large-capacity CXL DRAM in this paper. Specifically, we make the following key contributions.

Contribution-1: Uncovering the capacity and performance bottlenecks of kernel metadata in CXL memory systems. We uncover that metadata structures—such as page descriptors and Xarray nodes—can impose significant overhead on both memory capacity and application performance. We further show that their simple and repetitive access patterns make them well-suited for offloading to near-memory processing units within modern CXL devices in big-data systems.

Contribution-2: Co-designing OS and hardware for memory reclamation acceleration. MAC accelerates memory reclamation by offloading two main operations in the page reclaim path to an NMP accelerator within CXL DRAM: the traversal of victim page descriptors and Xarray walk. To enable efficient access, metadata is placed directly in CXL DRAM, which shares the same physical address space as the host CPU. MAC leverages the Linux kernel's direct address mapping mechanism [44] to allow the NMP accelerator to access metadata without the need for host CPU's involvement or additional address mapping tables, enabling fast metadata traversal. Furthermore, MAC places a host-accessible shared buffer inside the CXL DRAM region, enabling low-latency communication between the host CPU and the accelerator, thereby minimizing data transfer overhead.

For each offloading request, the CPU first compiles a batch of operations and writes the arguments to the shared memory buffer. The CPU then issues a MMIO [36] write to the NMP, upon which the NMP will fetch the arguments asynchronously with CXL.cache requests. Upon receiving the input arguments, the NMP processes the batch with multiple operation units. Each operation unit fetches the data with CXL.cache link, processes it with its internal state machine, and repeats until reaching the result. Finally, the NMP writes the returned data to the shared buffer and signal the CPU for completion.

Contribution-3: Prototyping MAC with a commercial CXL device for a demonstration. MAC was prototyped with an Intel Agilex 7 I-series FPGA [24] to accelerate requests offloaded from the host CPU. Since current commodity hardware does not support the FPGA-initiated fast cache invalidation feature (BIsnp[1]), which is needed for fast coherency between FPGA-modified data and the host CPU cache, we replace the BIsnp feature with a CXL.cache operation that performs coherent write to CXL memory. In this mode, memory requests are always sent to the host CPU's root complex for coherence processing and perform any cache invalidation if necessary. We anticipate that performance will remain similar once BIsnp is supported in future generations of CPUs.

[1] In the host-biased mode [5] supported by the current commodity

2 Background

2.1 CXL DRAM

Compute Express Link (CXL) [8] is a cache-coherent interconnect protocol built upon the PCI Express (PCIe) interface. CXL-attached memory, such as DDR DRAM, operates over this interface and leverages the physical and electrical characteristics of PCIe. Recent high-capacity, high-bandwidth CXL DRAM modules typically occupy a full PCIe ×16 slot and can support large memory capacities—for example, up to 4 TiB per device [77, 10, 76].

To communicate with such memory devices, the host CPU must support the CXL protocol stack [70]. Modern server-class processors, such as Intel 6th-generation Xeon Scalable Processor [25], provide native support for CXL 2.0 and allocate a portion of their PCIe lanes accordingly. For instance, a single-socket server offers up to 64 CXL lanes out of 136 total PCIe lanes, supporting data transfer rates up to 32 GT/s per lane [23].

One notable advantage of CXL DRAM modules is that they decouple memory technologies from the host CPU's integrated memory controller [80, 4, 72, 29]. Since the DRAM interface is internal to the CXL device itself, the memory type (*e.g.*, DDR4, DDR5) is no longer constrained by what the CPU natively supports. This abstraction enables greater flexibility in memory configurations and allows vendors to integrate cost-effective or higher-density DRAM technologies regardless of CPU generations.

Consequently, systems can provision larger memory pools at lower cost by relying more heavily on CXL DRAM, rather than expanding DDR DRAM through conventional DIMM slots. Due to these advantages, hyperscalers can reduce server memory costs by more than 50%, when using CXL DRAM based on recycled DIMMs from retired servers, compared to DIMM-only configurations for the same memory capacity [9, 60, 59, 18].

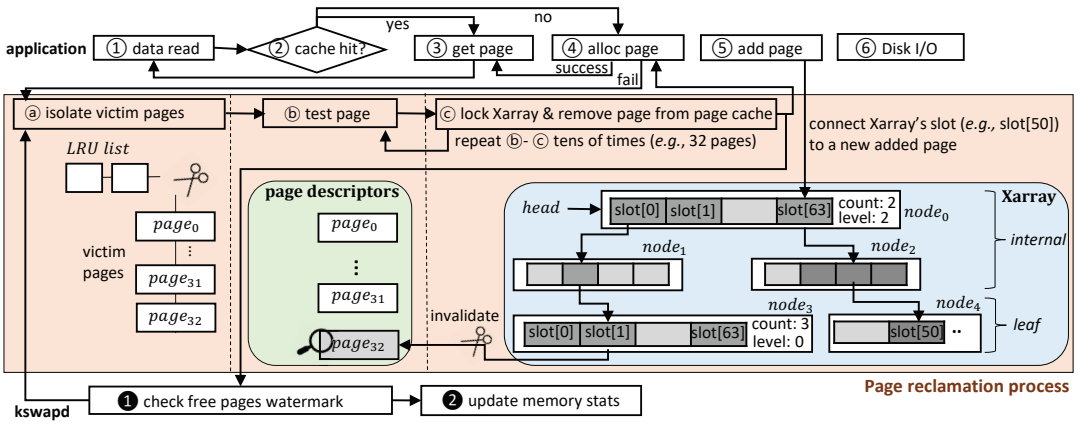

Figure 1: Page reclamation and metadata access.

2.2 Linux Memory Management

Modern Linux manages physical memory by dividing it into fixed-size page frames, typically 4 KiB in size. In Linux, the page cache subsystem associates each page frame with a corresponding 64-byte page descriptor [49], which maintains metadata such as access frequency, mapping information, and file-related properties. These descriptors are used by the Linux kernel to track page status during accesses and evictions. The total memory footprint of page descriptors is 1.6% of the system's physical memory, assuming 4 KiB pages and a 64-byte descriptor size, and must reside in system memory to ensure fast lookup and updates.

When an application performs file I/O operations with offset within a given file, the accessed file data are loaded into memory, and the kernel instantiates page descriptors for each 4 KB chunk of that file. To efficiently locate a page descriptor within the page cache using a file offset, Linux employs the Xarray data structure [52] as an index. Each file is associated with its own Xarray, and each Xarray node is 584 bytes, containing up to 64 entries that point to page descriptors. As the size of the file-backed memory working set grows, and as system memory scales up, the aggregate size of the Xarray nodes increases accordingly. These metadata structures are heavily accessed during memory reclamation.

When the host CPU runs data-intensive workloads, high memory demands can increase memory pressure. This causes the number of free pages to drop below the high-watermark threshold, prompting the Linux kernel to initiate page reclamation and free memory. To manage this process, the kernel spawns a kernel thread (kswapd) per NUMA node [48], with each thread bound to a dedicated CPU core to perform background reclamation. However, in scenarios where applications perform I/O operations across tens of CPU cores, the rate of memory allocation can outpace that of memory reclamation. Once free pages drop below the low-watermark threshold during execution of an application, the CPU core suspends its application process to carry out page reclamation, which is known as foreground reclamation [47].

Figure 1 illustrates how each type of metadata is accessed under both background and foreground reclamation scenarios. For example, when an application attempts to read file data (①), the kernel first checks whether the corresponding data page resides in the page cache (②). If the page exists (cache hit), it is returned directly to the application (③); otherwise (cache miss), a free page is allocated (④). If the system's free page count exceeds the low watermark, the newly allocated page is inserted into the page cache (⑤), and disk I/O is performed to fetch the data (⑥). Conversely, when the allocation step (④) observes the free page count below the low watermark, memory reclamation runs in the application thread context (foreground reclamation). First, candidate pages are isolated from the system's page list (*e.g.*, LRU list) (ⓐ). Next, each page descriptor is inspected to evaluate its eviction suitability—verifying attributes such as validity, clean/dirty state, recency of access, reference count status, and other relevant flags (ⓑ). The kernel then traverses the Xarray structure down to the leaf node to remove the corresponding page index within the file from the page cache (ⓒ)—for example, invalidating the pointer in slot[1] of $node_3$, as shown in the Figure 1. To invalidate the pointer, the kernel stores a special shadow value [57] into the Xarray slot[1]. This action invalidates the original pointer and means that the corresponding page is no longer present in the page cache. In a single reclamation cycle (ⓐ-ⓒ), this process is repeated tens to hundreds of times depending on memory pressure.

In contrast, background reclamation is handled by the kernel thread kswapd, which is triggered under memory pressure. This thread executes a loop: as long as the free page count remains below the high watermark (❶), it repeat-

FPGA, when the FPGA needs to modify the data in its attached CXL DRAM, it must send the memory request to the host CPU's root complex for coherence processing, relying on the host CPU to access the CXL DRAM. This involvement of the host CPU leads to sub-optimal performance.

edly performs the reclamation process (ⓐ-ⓒ) and maintains memory state (*e.g.*, managing LRU lists and free/used page statistics) (❷).

3 Impact of Deploying Large-Capacity CXL DRAM

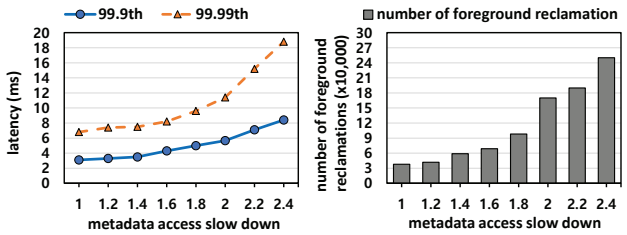
In this section, we examine the impact of deploying large-capacity CXL DRAM on system performance, focusing on the capacity and performance overheads of managing kernel metadata. We show that metadata placement in CXL DRAM can significantly affect both memory utilization and the efficiency of memory reclamation.

3.1 Overhead of Managing Metadata in CXL-Enabled Memory Systems

Capacity overhead. In large-memory systems, the metadata for memory management can occupy a substantial portion of the physical memory, making it expensive to keep entirely within the host DDR DRAM. Consider a workload accessing a single 1.8 TiB file on a system with 120 GiB memory. Accessing the entire file requires indexing up to 483 million pages (1.8 TiB / 4 KiB), which, given 64 entries per Xarray node, corresponds to a maximum of 7.5 million leaf nodes and an Xarray footprint of approximately 4.1 GiB (= 7.5 millions × 584 B), assuming sufficient memory to hold the entire Xarray. Furthermore, because each file maintains its own Xarray comprising both internal and leaf nodes, the total Xarray footprint grows with the number of files. Similarly, the page descriptor consumes around 2 GiB of memory space (= 120 GiB / 4 KiB × 64 B per descriptor).

For example, in our evaluation using the YCSB RocksDB [71] read-intensive workload [88] with a 1.8 TiB database and 120 GiB system memory comprised of 24 GiB DDR DRAM and real 96 GiB CXL DRAM, the Xarray metadata footprint reached 3.7 GiB. In total, metadata, including 2 GiB for page descriptors and 3.7 GiB for Xarray nodes, consumed approximately 5.7 GiB of system memory. Similarly, under a PostgreSQL [65] TPC-B workload [64] with a 1 TiB dataset, the Xarray metadata was 3.3 GiB and page descriptors accounted for 2 GiB, collectively occupying around 5.3 GiB of the 120 GiB memory.

The problem is, in environments where the capacity of DDR DRAM is relatively smaller than the CXL DRAM, such metadata is too large to be fully stored within CXL DRAM. If CXL DRAM capacity is four times that of the DDR DRAM capacity, the total size of metadata can consume 24% of the DDR DRAM capacity (= 2 GiB + 3.7 GiB) / (120 GiB / 5). As the proportion of CXL DRAM increases, the relative share of metadata within DDR DRAM also grows. For instance, if CXL DRAM is eight times larger than DDR DRAM, metadata alone can occupy approximately 40% of DDR DRAM capacity.



(a) (b)

Figure 2: Impact of metadata access slowdown on application performance: (a) tail latency of application and (b) foreground reclamation frequency when running RocksDB with YCSB, 10M Read Ops with 100 threads, 1.8 TiB DB, 120 GiB DDR DRAM, and 32 CPU cores.

To avoid excessive consumption of DDR DRAM by page descriptors when installing memory devices like CXL DRAM, recent Linux kernels support placing these descriptors on the device itself [42]. Additionally, when allocating Xarray nodes, the kernel employs a fallback mechanism [43]: if no DDR DRAM is available, the allocation automatically shifts to CXL DRAM, preventing contention with application data in DDR DRAM and potential Out-Of-Memory (OOM) events.

Performance cost. Placing metadata in CXL DRAM, nevertheless, can adversely impacts the performance of latency-sensitive applications. The page reclamation process traverses the Xarray and page descriptors repeatedly to remove tens or even hundreds of pages depending on the degree of memory pressure (as shown in the ⓑ-ⓒ of the Figure 1). Each time, the host CPU must access metadata residing in CXL DRAM, incurring the extra latency associated with remote memory accesses.

When the efficiency of metadata access by the Linux kernel's background memory reclaimer (kswapd) is reduced due to slow remote memory accesses, the memory reclamation rate declines. This, in turn, forces applications to perform foreground reclamation directly, which can increase application's tail latency considerably. To observe the effect of metadata access latency on application tail latency, we intentionally introduced delays in accessing metadata structures (specifically, the Xarray and page descriptors) during background reclamation. As shown in Figure 2(a), when metadata access latency increases by 2.4×, the 99.9th and 99.99th-percentile (p99.9 and p99.99) latencies increase by approximately 2.6× and 2.8×, respectively. The underlying reason, as shown in the Figure 2(b), is that the frequency of foreground reclamation, which lies on the critical path of the application I/O, increases by 6.5×. This demonstrates that placing memory metadata in CXL DRAM can substantially degrade application performance. Considering that latency-

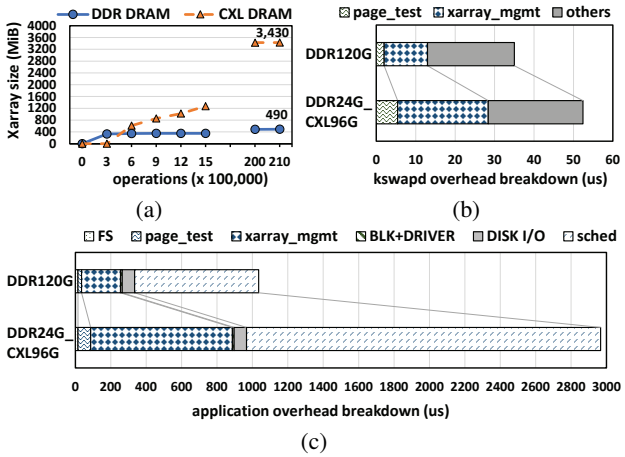


Figure 3: Impact of Xarray management on (a) per-node memory capacity, (b) kswapd performance, and (c) application performance overheads in a system equipped with large capacity CXL DRAM.

sensitive hyperscale applications often require p99.99 read latencies within just a few milliseconds [75, 31, 78, 1, 90], the observed slowdown can pose a significant challenge.

To verify the occurrence of metadata placement in CXL DRAM and the resulting tail-latency effects, we evaluated YCSB workload on RocksDB under realistic application conditions. As shown in Figure 3(a), at the start of execution (up to 400 thousand operations), the kernel allocates Xarray nodes in DDR DRAM to enable fast metadata access. However, as the free pages in DDR DRAM runs out, Xarray nodes begin to compete with application data for the free pages, causing them to spill over into CXL DRAM. During the later stages of execution, most Xarray nodes end up residing in CXL DRAM. This makes kswapd access remote memory while traversing the Xarray, the effect of which is shown in Figure 3(b). As a result, the Xarray access latency significantly increases. Furthermore, because page descriptors are also placed in CXL DRAM, page test time increases by 2.2×. Overall, these effects reduce kswapd 's page reclamation efficiency by 42%. This, in turn, triggers foreground reclamation, which causes the application to experience frequent tail latency spikes, as depicted in Figure 2(a).

Figure 3(c) presents a breakdown of I/O overhead for application threads experiencing foreground reclamation. In systems using both DDR DRAM and CXL DRAM, page descriptor traversal overhead (page_test in Figure 3(c)) during direct reclamation is 3.6× higher than in all-DDR systems, and Xarray traversal overhead (xarray_mgmt in Figure 3(c)) is 3.9× higher. These differences exceed the 2.4× higher access latency of CXL DRAM compared to DDR DRAM, indicating a deeper inefficiency in page reclamation. One main reason is that I/O operations often request data sizes larger than the 4 KiB page, which requires allocating multiple pages. Each page allocation (④ in the Figure 1) triggers a foreground reclamation if free pages are unavailable, substantially increasing I/O latency. Furthermore, these reclamation events consume the CPU core for long periods, allowing other threads to preempt the offending core via scheduling [56, 50], which causes additional long latency spikes (sched in Figure 3(c)). As a result, Figure 3(c) shows that systems with CXL DRAM exhibit 2.8× more extreme latency spikes compared to those using DDR DRAM alone.

3.2 Suitability of Offloading Kernel Metadata Management to CXL DRAM

The kernel's page reclamation process involves simple yet repetitive operations. First, as shown in ⓑ of Figure 1, during page descriptor traversal, the kernel iteratively evaluates each victim page descriptor's flag bits (*e.g.*, valid, referenced, active, clean bits) using basic bitmask operations to determine whether pages are eligible for reclamation. Likewise, during Xarray traversal—as shown in ⓒ of Figure 1—the kernel descends from the Xarray head to a leaf node and replaces the pointer to the page descriptor in the target slot with a specific long integer "shadow [57]" value. This descent process uses simple arithmetic: based on the page offset in the file, the kernel selects the target slot (slot[0] of the $node_0$ in the Figure 1) in the current node's slot array and computes the next node's virtual address via pointer subtraction and shift. Overall, these operations are composed of basic bitmask checks, arithmetic, and shift operations. These operations are repeated for each batch multiple pages (at least 32), which constitutes the minimum unit of a single kernel's page reclamation cycle.

Moreover, both page descriptors and Xarray structures reside within the kernel's direct-mapped virtual address space [44]. Consequently, translating a kernel virtual address to its corresponding physical address requires no page table walk and can be accomplished using a simple arithmetic operation (*e.g.*, via the ___pa() [39] macro). This lightweight translation enables an in-DRAM accelerator attached to CXL DRAM to efficiently access and process metadata without additional mapping logic. Since a single instance of kswapd handles each memory node (both DDR DRAM and CXL DRAM) reclamation, the compute resources provided by modern CXL DRAM controllers (*e.g.*, 16-core Arm processors [73]) are sufficient to effectively manage these tasks.

Additionally, for pages that require extra work beyond the Xarray walk, we can significantly reduce page-reclamation time by letting the host CPU process those tasks in parallel. For instance, file-backed pages mapped via mmap must be unmapped from user PTEs before reclaim; the kernel performs this via reverse mapping (rmap [37]). Since rmap unmapping is control-flow–heavy and can proceed in parallel with the Xarray walk, the host CPU can execute it concurrently with the CXL DRAM-side walk to improve overall reclamation efficiency.

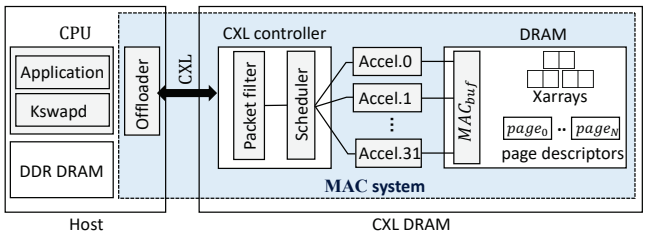

Figure 4: An overview of MAC system.

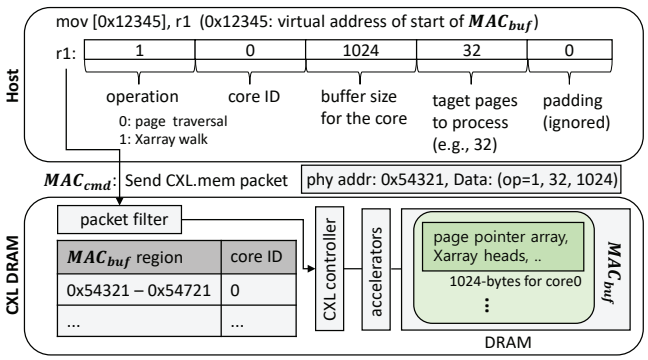

Figure 5: NMP launch process in the MAC system (the virtual address 0x12345 of $\texttt{MAC}_{\text{buf}}$ corresponds to the physical address 0x54321 and is translated by the host.).

4 Design

4.1 Overview

To ensure stable performance for latency-sensitive applications through efficient and swift memory reclamation, we propose Metadata Acceleration in CXL DRAM (MAC). By offloading metadata processing during page reclamation into CXL DRAM, MAC enables rapid memory recovery and effectively eliminates frequent, long tail-latency events.

As shown in the Figure 4, the MAC system enables both applications and the kswapd —the primary triggers of page reclamation—to offload metadata processing (page descriptor traversal and Xarray walks) to CXL DRAM. Accelerators in CXL DRAM then perform near-data processing (NMP) to manage metadata efficiently. The offloading workflow consists of two stages: (1) metadata information (including target page descriptors and head pointers of the Xarrays) is delivered to CXL DRAM, and (2) the accelerators traverse the metadata in parallel and execute the necessary operations. In the MAC system, both page descriptors and Xarray metadata are intentionally allocated to the capacity-rich, low-contention CXL DRAM rather than the more limited DDR DRAM. This placement enables the accelerators to access metadata within CXL DRAM at high speed and with low contention, greatly enhancing metadata-processing efficiency. This design aligns with recent kernel mechanisms [42] that enable metadata placement directly into CXL DRAM, reducing DDR DRAM pressure.

4.2 Metadata Acceleration Launch in CXL DRAM

To offload metadata access operations in page reclamation (traversing page descriptors to identify reclaimable pages and traversing Xarray to remove pages from the page cache), each task must support NMP launch capability. The host must deliver metadata information such as pointer addresses to target page descriptors and Xarray structures. This delivery must be lightweight and efficient.

One could modify the CXL.mem protocol to encode this data directly, but doing so would require hardware modifications to commodity CPU processors—an impractical approach in general-purpose environments [17, 69]. Instead, we introduce a memory-mapped [17] based command mechanism ($\texttt{MAC}_{\text{cmd}}$) and a shared buffer ($\texttt{MAC}_{\text{buf}}$) for communication.

First, private memory in the CXL DRAM ($\texttt{MAC}_{\text{buf}}$ in the Figure 5) is reserved to deliver NMP information. The $\texttt{MAC}_{\text{buf}}$ contains the information required by the accelerators to perform NMP operations within CXL DRAM. The information includes head addresses of Xarray structures to be walked, file page indices targeted for removal from the Xarray, shadow values to be stored in the Xarray, and arrays of addresses to page descriptors. As shown in Figure 5, $\texttt{MAC}_{\text{buf}}$ allocates a dedicated work buffer per host CPU core at system boot.

Second, each host core issues $\texttt{MAC}_{\text{cmd}}$ —a memory-mapped command using the standard CXL.mem protocol—to initiate NMP. As shown in Figure 5, we pre-register the work-buffer address ranges of each host core ($\texttt{MAC}_{\text{buf}}$ regions) in a packet filter. Whenever NMP is needed, the host core writes its $\texttt{MAC}_{\text{cmd}}$ to CXL DRAM. The $\texttt{MAC}_{\text{cmd}}$ is not a new CXL protocol—it is simply a standard memory write operation using the existing CXL.mem request. The packet filter recognizes the memory writes within the registered address range as NMP commands, parses the command, and triggers metadata processing with the accelerator. The $\texttt{MAC}_{\text{cmd}}$ encodes the type of operation (whether traversal of page descriptors or the Xarrays), the requesting host core's ID, and the size of the $\texttt{MAC}_{\text{buf}}$ containing data required for the NMP. Although multiple processes (*e.g.*, application threads, kswapds) may be scheduled per CPU core on the host, Linux disables core preemption during page reclamation. As a result, the process that initiates the NMP remains bound to a single core until reclamation completes. Consequently, allocating one $\texttt{MAC}_{\text{buf}}$ per core (rather than per process) is sufficient to support all concurrent reclamation activities.

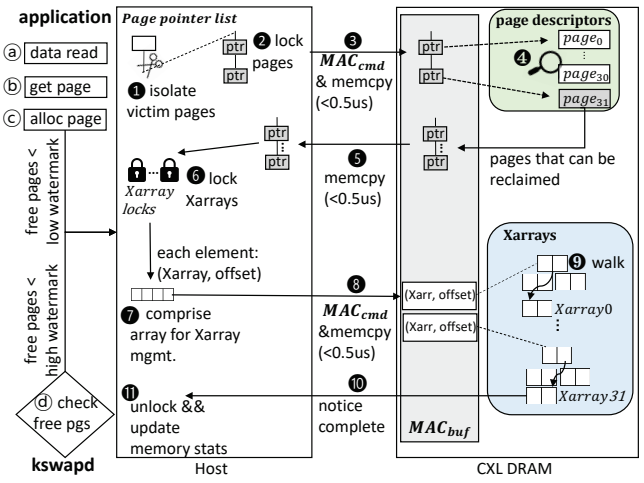

Figure 6: An operational overview of MAC.

4.3 Metadata Acceleration (MAC) in Action

When page reclamation occurs on the host—whether triggered by foreground or background activity—our design leverages near-data processing (NMP) in CXL DRAM to accelerate the process. Figure 6 illustrates the communication and acceleration between the host CPU and CXL DRAM under each reclamation scenario.

Background reclamation acceleration . Each memory node (*e.g.*, host node and CXL DRAM node) runs a dedicated kswapd thread that continuously monitors system free memory and triggers page reclamation when free space drops below the high-watermark (ⓓ in Figure 6). At this point, kswapd first isolates a subset of candidate page pointers (*e.g.*, 32 entries) from a page-pointer list (such as the LRU list) (❶). Next, kswapd acquires locks on these pages (❷), collects their physical addresses into an array, delivers it into the CXL DRAM buffer $\texttt{MAC}_{\text{buf}}$, and issues a $\texttt{MAC}_{\text{cmd}}$ (❸). Accelerators within CXL DRAM then access each page descriptor via the supplied addresses and inspect their flags across all pages (❹). During this inspection, pages are classified into reclaimable (clean file pages) and non-reclaimable (*e.g.*, dirty, invalid, active, or recently referenced). Once the acceleration completes, the host CPU retrieves the results into host memory via memcpy (❺). It then proceeds to evict the reclaimable pages from the page cache by first holding locks on the relevant Xarray structures (❻). The CPU constructs an array of pairs containing each Xarray 's head pointer and the target page index (❼), delivers these into $\texttt{MAC}_{\text{buf}}$, and issues another $\texttt{MAC}_{\text{cmd}}$ (❽). The accelerator uses this information to traverse each Xarray and invalidate the specified pages, repeating the process for the entire set of pages to be removed (❾). Finally, once all invalidations have been performed, the host CPU releases all Xarray locks and updates memory and Xarray statistics (❿-⓫).

Foreground reclamation acceleration . Foreground reclamation is triggered during an application's I/O when free pages drops below the low-watermark. As illustrated in Figure 6, during I/O an application thread may allocate new pages from the kernel (ⓐ–ⓒ). If the number of free pages falls below the low-watermark, the page reclamation routine (❶–⓫) is repeatedly invoked in the kernel. Moreover, when an application allocates multiple pages—such as for I/O units larger than 4 KiB—the page reclamation routine (❶–⓫) may be invoked repeatedly for each individual page allocation attempt (ⓒ).

4.4 Metadata Synchronization between Host and CXL DRAM

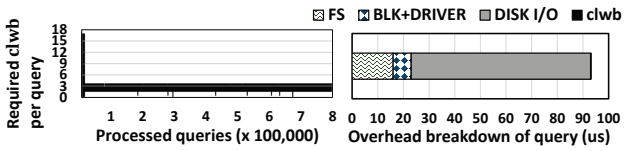
Xarray updates on page insertions and evictions modify internal nodes, requiring synchronization between the host CPU cache and CXL DRAM. For example, when a new page is inserted (⑤ in Figure 1), the node data in the Xarray is updated to point to the newly inserted page (*e.g.*, slot[50] of $node_4$ in Figure 1). To ensure accelerators in CXL DRAM observe up-to-date Xarray content, the host issues clwb to write back the modified cacheline, which costs about 30 ns in our experiments[2]. In contrast, when a page is evicted from the page cache (ⓒ in Figure 1) by the CXL DRAM, the pointer to that page must be invalidated (*e.g.*, slot[1] of $node_3$ in Figure 1). This requires invalidating the corresponding cacheline in the host CPU cache. Starting with CXL 3.x, the memory device supports an invalidate protocol (BIsnp [6]) that allows the device to trigger cacheline invalidation directly, and this is expected to incur a latency of around 500 ns[3]

Accordingly, we integrated a delay model into the MAC system, which enforces that either a clwb instruction or the BIsnp protocol is invoked after the Xarray is updated by the host CPU, in order to guarantee data consistency between the host CPU and CXL DRAM.

However, if such synchronization occurs too frequently, it may degrade application performance. To assess this, we measured clwb/BIsnp rates in practice by counting Xarray-node modifications during insertions and evictions while running RocksDB with YCSB. First, we measured the number of clwb instructions issued per query and the corresponding overhead. As shown in Figure 7(a), the number of clwb operations is high during the early phase of the workload due to the creation of Xarray structures, as almost internal and leaf nodes are allocated at this stage. Over time, however, the number stabilizes to about 1–3 clwb instructions per query. This corresponds to the insertion of 1-3 pages fetched from SSD due to cache misses, each of which requires updating

[2]Because newly inserted pages are excluded from reclamation—and are therefore untouched during Xarray walks in CXL DRAM—we use asynchronous clwb rather than a synchronous clwb

[3]Since no commodity device-biased CXL product provides cache coherency today, we estimated BIsnp overhead using host-biased mode: on our Intel Agilex 7 FPGA, a single host–device coherence handshake measured about 500 ns.



(a) (b)

Figure 7: clwb overhead breakdown: (a) clwb operations required on cache-misses during application execution and (b) application performance when writeback cachelines.

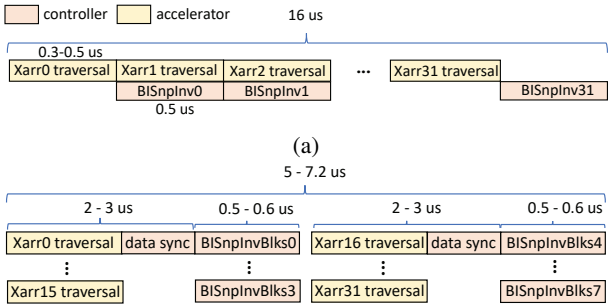


Figure 8: Cooperative parallel page reclamation within the CXL DRAM: (a) overlapping BIsnp and Xarray walk and (b) parallel Xarray walk and bulk invalidation.

the slot array in a leaf node of the Xarray. The overhead of these operations is relatively small: as shown in Figure 7(b), two Xarray operations incur 60 ns (2 × 30 ns) on average, accounting for only 0.06% of the overall query lifetime.

Second, in the case of page deletions, each reclaimed page requires a single cacheline back invalidation. Since pages are reclaimed in batches of 32, the accelerators in CXL DRAM perform 32 Xarray walks via NMP, which takes approximately 12.8 (0.4 us × 32) us on average as shown in Figure 8(a). If BIsnp operations are performed serially after each Xarray walk, they introduce an additional overhead of 16 us (0.5 us × 32), which is longer than the Xarray walks. We address this BIsnp-induced overhead using the techniques described in the following section 4.5.

On the other hand, for page-descriptor traversal, the small subset of descriptors that participate in reclamation (*e.g.*, 32 pages) are not modified by the CXL DRAM; thus no back-invalidation is required. Furthermore, clwb is required only at step ❸ in Figure 6. Issuing clwb in batches (*e.g.*, for 32 pages) pipelines the writebacks asynchronously, and because victim pages are unlikely to have been recently accessed—and thus rarely reside in the CPU cache—the overhead is negligible.

4.5 Cooperative Parallel Page Reclamation

Parallel processing within CXL DRAM . Unlike the read-only descriptor traversal, when offloading Xarray walk, the kernel must write a "shadow" value into the leaf slot of the Xarray (*e.g.*, slot[1] of $node_3$ in Figure 1). This write requires maintaining coherence between host CPU caches and CXL DRAM. Since one shadow is stored per Xarray walk, on average, a single host CPU cacheline must be invalidated via Back Invalidation Snoop message (BIsnp [6]). If BIsnp messages are sent serially for each Xarray walk, their overhead can decrease page reclamation efficiency. To hide this BIsnp overhead, we parallelize the process: as shown in Figure 8(a), the CXL DRAM accelerator and controller perform Xarray walk and the back-invalidation (BIsnpInv in the Figure 8(a)) concurrently.

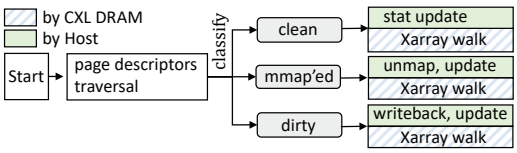

Figure 9: Cooperative page reclamation between Host CPU and CXL DRAM.

Moreover, by exploiting accelerator parallelism, we further reduce total Xarray walk time. Because no structural changes (node allocation or deallocation in the Xarray) occur during the walk, we can process multiple traversals in parallel—up to the number of accelerators or ARM cores, as in Figure 8(b). After batching the Xarray walks, the device issues BIsnp invalidations; these transactions can be pipelined, allowing multiple invalidations to be in flight and overlapping the 500 ns coherence-handshake latency. In addition, CXL 3.x provides block invalidation (BIsnpInvBlks) that covers up to four consecutive cache lines per message, reducing the number of protocol messages by up to 4×. However, when multiple accelerators execute tasks in parallel, the controller must track each accelerator's completion status, because accelerators finish at different times and there are atomically updated shared variables for each accelerator (*e.g.*, the number of accelerators completed). To enable this, shared variables are maintained between the controller and the accelerators to monitor task progress and ensure synchronization. The overhead of this execution and data synchronization introduces an additional delay of approximately 1 us; consequently, as shown in Figure 8(b), executing 16 Xarray walks takes about 2–3 us. As a result, as shown in Figure 8(b), parallelism enables a further 55% reduction in Xarray walk overhead.

Cooperation between host and CXL DRAM . When the host CPU offloads Xarray walks to CXL DRAM, it must hold the corresponding Xarray locks (as illustrated in ❻ of Figure 6) and prohibit CPU preemption until the offloaded operation completes to prevent deadlocks on the held Xarray locks. We exploit this idle interval by parallelizing reclamation: CXL DRAM performs metadata traversals while the host executes the remaining steps.

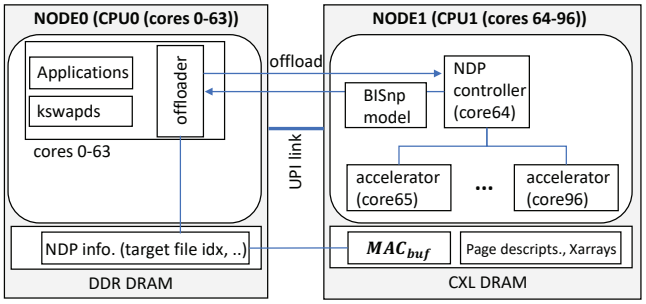

Figure 10: MAC emulation environment.

Table 1: Emulation system configurations.

Component	Specification
OS	Ubuntu 24.04.1 LTS (Linux kernel v6.14)
Storage	Enterprise NVMe SSD 8 TiB and 4 TiB
CPU	Intel Xeon 6710E (2 CPU sockets, each with 64 cores and 96 MiB LLC per CPU)
Socket 0 Socket 1	2 × 32 GiB DDR5-6400 (2, 4, or 8) × 32 GiB DDR5-6400
Local / remote memory access	118 ns / 270 ns

As shown in Figure 9, once page descriptors have been traversed, pages are classified as clean, dirty, or mapped. Clean pages can be immediately removed from the page cache, whereas mapped pages must first be unmapped from page tables before eviction. Dirty pages require a writeback operation before they can be reclaimed. Because writeback incurs costly I/O (via the block layer and device drivers), the kernel prioritizes reclaiming clean pages [81, 2, 50]; nevertheless, under write-excessive workloads (*e.g.*, almost of the pages are dirty), dirty pages can still be reclaimed. To maximize parallelism and hide unmap/writeback costs, we employ a classification-based scheme: while CXL DRAM walks the Xarray, the host CPU concurrently either unmaps mapped pages or initiates writeback for dirty pages, and updates memory and Xarray statistics, as shown in Figure 9.

5 Evaluation

5.1 Setup

We evaluate the effectiveness of our MAC system through two complementary implementations. First, we built a software-based emulation using a dual-NUMA-node server to model CXL-attached NMP behavior. Second, we developed a hardware prototype on FPGA to demonstrate performance gains from accelerations. Our evaluation focuses on comparing tail-latency and analysis, with real-world datacenter workloads.

Emulated MAC **system.** We integrate MAC into Linux kernel 6.14; configuration parameters are in Table 1. As shown in Figure 10, the application and kswapd execute on NODE0 (64 cores), whereas NODE1 emulates a CXL device with 33 cores (one controller and 32 accelerators). To enable metadata processing within CXL DRAM, we allocate NODE1's page-descriptor array via memory hotplug [45] and place Xarray-related slabs on NODE1 using NUMA-controlled allocation [11]. As shown in Figure 10, an offloader lets the application or kswapd on NODE0 send NMP information to NODE1 via memcpy. We implement a BIsnp model to emulate protocol behavior and delay for coherence during metadata updates. Finally, to minimize cache effects in the emulation environment, we maintained the LLC cache size of NODE0 at 96 MiB and restricted the LLC cache size of NODE1 to the minimum allocatable unit of 8 MiB using Intel Cache Allocation Technology (Intel CAT) [26].

Evaluated systems. The evaluated systems are as follows:

- Baseline: Our baseline is the patched Linux 6.14 kernel that optimizes reclaim cycles and reduces tail latency [74]. Xarray nodes are preferentially allocated in CPU-local DDR DRAM, and fall back to CXL DRAM under memory pressure; page descriptors are split by node—NODE0 in NODE0 DRAM, NODE1 in NODE1 DRAM. This placement is a practical approach that efficiently leverages metadata locality and capacity in CXL DRAM systems.

- Baseline-P: Unlike the Baseline, we modified the kernel to pin metadata in CPU-local DDR DRAM by allocating metadata in DDR DRAM even when free space is scarce. Specifically, we implement kernel support for dynamic allocation of Xarray nodes by introducing a flag (GFP_THISNODE) that enforces allocation on the DDR DRAM node when allocating metadata [46]. However, attempting to allocate metadata under extreme memory pressure (*i.e.*, out-of-memory conditions) may lead to abnormal application termination [33]. To mitigate this issue, when an OOM condition is imminent, metadata allocation is redirected to CXL DRAM [51].

- MAC-S: MAC-S (corresponding to Figure 8(a)) accelerates metadata management using a single controller and four accelerators. The controller schedules offloaded requests (*e.g.*, 32 Xarray walks); two accelerators serve two background kswapds and two serve foreground reclamations. Page descriptors for DDR DRAM are allocated in DDR DRAM and traversed by the host CPU. Page descriptors for CXL DRAM and all Xarrays reside in CXL DRAM, with their traversal offloaded to a accelerator.

- MAC-P: MAC-P (corresponding to Figure 8(b)) accelerates metadata management by exploiting the maximum available parallelism of CXL DRAM-resident accelerators, using one controller and thirty-two accelerators. Offloaded tasks run in parallel; after each batch, the controller aggregates results and applies a modeled BIsnpInvBlks delay computed by the BIsnp delay model.

Hardware prototype for MAC system. We prototype MAC on FPGA to quantify the reduction in page descriptor traversal and Xarray-walk time from hardware offload versus host-only traversal in CXL DRAM. At initialization, the host allocates a host buffer and passes its physical address to the accelerator; this buffer carries inputs for Xarray walk and page-descriptor traversal, and later the results. Offloading proceeds as follows: (1) the host writes inputs and triggers the accelerator via an MMIO write; (2) the accelerator fetches inputs with CXL.cache reads and distributes them to per-operation units whose state machines mirror the software logic; (3) the units issue device-biased memory requests that do not require updates[4], but the final Xarray update is performed via a host-biased write, thereby keeping the update coherent with the CPU cache; (4) and the host is notified upon completion. To preserve correctness, when the host updates the Xarray, it flushes the modified cache lines to the device so the accelerator does not operate on stale data.

5.2 Workloads

We conducted evaluations across a diverse set of database workloads using systems that are widely adopted in practice:

- **RocksDB with YCSB workloads:** We deployed RocksDB [71] alongside YCSB [88] to evaluate behaviors under both read-intensive and write-intensive workloads. For this purpose, we generated two RocksDB databases (2.5 TiB and 2.0 TiB).
- **PostgreSQL with OLTP workload:** Using PostgreSQL [65]—an open-source, object-relational database management system—we evaluated transaction workload with the OLTP benchmark [64]. We created a 2.0 TiB database for the evaluation.
- **Neo4j with LDBC SNB workloads:** We evaluate Neo4j [15], a graph database, using the LDBC SNB benchmark tool [16]. We use two types of queries: Interactive Short (IS) workload and Interactive Complex (IC) workload [12]. To this end, we import a 1 TiB dataset (SF: 1,000) [14] into the database.
- **LMDB with GET workload:** We evaluate LMDB [55], a database that performs file I/O using mmap [41], with the ioarena [27] benchmark. We created a 1.7 TiB database.

5.3 Results

All reported results are collected after a warm-up phase, during which both DDR DRAM and CXL DRAM are fully populated. Logs used for CDF and box-plot analysis are flushed to a separate SSD to avoid interfering with application performance.

RocksDB with YCSB workloads. We first evaluate a YCSB read-only workload on a 2.5 TiB RocksDB database. To assess the impact of metadata spillover into CXL DRAM on page-reclamation efficiency, we vary the DDR:CXL capacity ratio by fixing host memory at 64 GiB and setting CXL to 64/128/256 GiB (1:1/1:2/1:4); for each configuration, the thread count is tuned to highest throughput. Figure 11 presents the latency distribution in the form of a CDF. Across all ratios, MAC-S and MAC-P exhibit lower tail latencies than Baseline. For example, at a DDR DRAM to CXL DRAM ratio of 1:2, MAC-S reduces the p99.99 latency by 97% compared to Baseline, while MAC-P achieves a 98% reduction. These improvements are closely tied to the page reclamation rate.

Table 2: Xarray distribution across DDR DRAM and CXL DRAM under Baseline at the end of the benchmark.

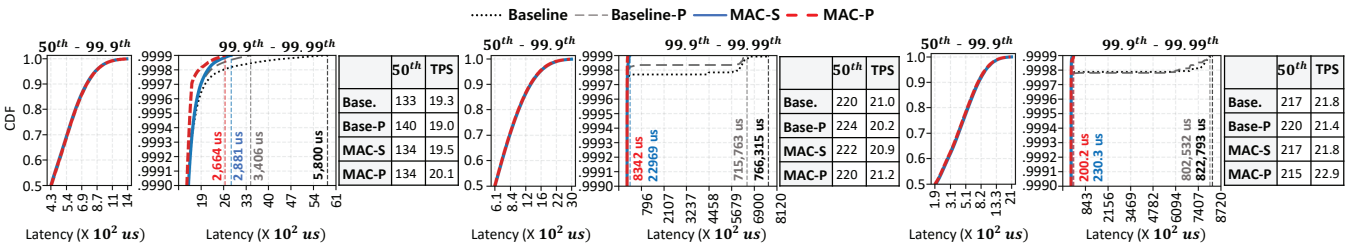
DDR-CXL Configuration	DDR	CXL	Total
64G-64G	2,047 MiB	2,378 MiB	4,425 MiB
64G-128G	2,030 MiB	3,451 MiB	5,481 MiB
64G-256G	2,101 MiB	4,420 MiB	6,521 MiB

Table 2 shows Baseline suffers substantial Xarray spillover to CXL (*e.g.*, 68% at 1:4), throttling kswapd. In contrast, MAC-S and MAC-P place metadata in CXL DRAM and accelerate its management via NMP, thereby maximizing the efficiency of kswapd. For example, compared to Baseline, MAC-S and MAC-P reduce Xarray walk overhead by 25% and 80%, respectively, and reduce page descriptor traversal overhead by 58%. As a result, the MAC-P increases free-page generation by 36%, despite incurring BIsnp (sync.) and host–device communication (comm.) overheads, as shown in Figure 12(b). Consequently, as shown in Figure 12(a), MAC-P reduces foreground reclamations by 66% at 1:2 compared to Baseline.

Compared to Baseline-P, both MAC-S and MAC-P also exhibit lower tail latency distributions. As shown in Figure 11(a), MAC-S and MAC-P reduce the p99.99 latency by 15% and 22%, respectively, relative to Baseline-P. In Baseline-P, most metadata resides in DDR DRAM, which reduces page reclamation overhead by 22% compared to Baseline, as shown in Figure 12(b). Despite this benefit, Baseline-P still suffers from latency spikes due to the high overhead of slab memory management [40].

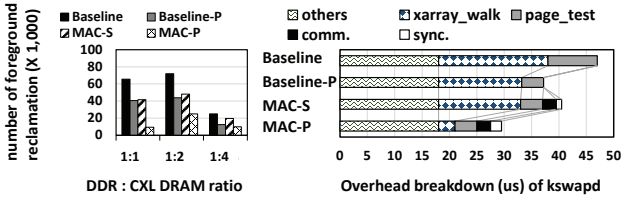
When an application fetches data from SSD into memory, Xarray nodes are dynamically allocated from pages in slab memory pools [40], where each NUMA node (DDR DRAM or CXL DRAM) maintains its own pool. However, under Baseline-P, which allocates Xarray only on DDR DRAM, severe memory pressure significantly increases the overhead of managing the DDR DRAM node's slab memory pool for metadata allocation. Specifically, application data and kernel metadata contend heavily for DDR DRAM space, as metadata allocations are restricted to the DDR DRAM despite the presence of separate slab pools in CXL DRAM. We observed that while slab allocation latency [46] ranges from 2–4 μs in Baseline, MAC-S, and MAC-P, it increases to 10–600 μs in Baseline-P.

[4] We issue device-biased reads to bypass the CXL home agent's coherence checks, thereby accelerating each read.



(a) (b) (c)

Figure 11: Latency CDFs and TPS (×1,000) across memory configurations for the RocksDB read-only workload: (a) DDR:CXL = 1:1 (90 threads), (b) DDR:CXL = 1:2 (200 threads), and (c) DDR:CXL = 1:4 (250 threads).



(a) (b)

Figure 12: kswapd reclamation overhead and resulting foreground reclamations: (a) foreground reclamation frequency and (b) kswapd for CXL DRAM overhead breakdown when running RocksDB with YCSB read-only workload under DDR:CXL = 1:2 configuration.

Consequently, as shown in Figure 11, the increased slab allocation cost and resulting contention on shared resources cause Baseline-P to exhibit tail latencies comparable to Baseline.

In addition to the slab management overhead, the preferential allocation of large metadata to DDR DRAM forces application data to be allocated and served from CXL DRAM, thereby degrading application throughput. We observe that Baseline-P achieves lower TPS (transactions per second) than the other schemes. For example, as shown in Figure 11(c), Baseline-P delivers 6% lower TPS than MAC-P, which experiences the least memory pressure on DDR DRAM and achieves higher utilization of application data in DDR DRAM.

We next evaluate a YCSB workload with a 5:5 read-to-update (read-modify-write) ratio on a 2.0 TiB RocksDB database. Updates trigger memory-intensive compactions; when compactions stall, the tail latency of writes and reads increases sharply [86]. As shown in Figure 13, across all memory configurations our MAC system delivers stable performance. For example, for read operations, as shown in Figure 13(a), MAC-P reduces the p99.9 latency by 24% and the p99.99 latency by an average of 27% compared to Baseline. For update operations, as shown in Figure 13(d), MAC-P reduces p99.99 latency by 52% compared to Baseline and by 48% compared to Baseline-P. Notably, by alleviating DDR DRAM memory pressure caused by large metadata, MAC-P improves throughput by 10% over Baseline and 17% over Baseline-P. This result suggests that, for update workloads, higher utilization of fast DDR DRAM by application data leads to improved throughput.

PostgreSQL with OLTP. We evaluate an OLTP workload (SELECT-only) on a 2.0 TiB PostgreSQL database using pgbench [64]. We configure PostgreSQL 's internal buffer (shared_buffers [66]) to 25% of system memory following PostgreSQL 's guidance [66], and for each memory setting, we increase the thread count to achieve the highest queries-per-second. As shown in Figure 14, our MAC-S and MAC-P deliver stable performance across all memory configurations compared to Baseline. For example, in a configuration with a DDR DRAM to CXL DRAM ratio of 1:2, MAC-P reduces the number of queries that experience foreground reclamation by 88% (Figure 14(e)), which in turn lowers the p99.99 latency by 92% (Figure 14(b)) and maintains stable latency during execution.

Moreover, as shown in Figure 14(d), MAC-S and MAC-P improve TPS by up to 5% across all memory configurations over Baseline and Baseline-P by more efficiently utilizing DDR DRAM.

Neo4j with LDBC SNB workloads. Graph processing in Neo4j can incur significant disk I/O under memory pressure when the dataset exceeds available memory, which in turn triggers frequent memory reclamation. We first evaluate our system using an IS workload that concurrently executes seven Interactive Short Queries (IS) [12], which exhibit OLTP characteristics. As shown in Figure 15(a), both MAC-S and MAC-P achieve lower tail latencies across all queries by enabling more efficient page reclamation under memory pressure. For example, for SQ6, MAC-P reduces p99.9 latency by 21% and p99.99 latency by 82% compared to Baseline, and further reduces p99.9 and p99.99 latencies by 11% and 24%, respectively, compared to Baseline-P.

Moreover, MAC-S and MAC-P achieve shorter overall benchmark runtimes than Baseline-P. As shown in Figure 15(b), they reduce the total runtime by 7% compared to Baseline-P, driven by faster metadata allocation as well as higher application data fetch and processing within DDR

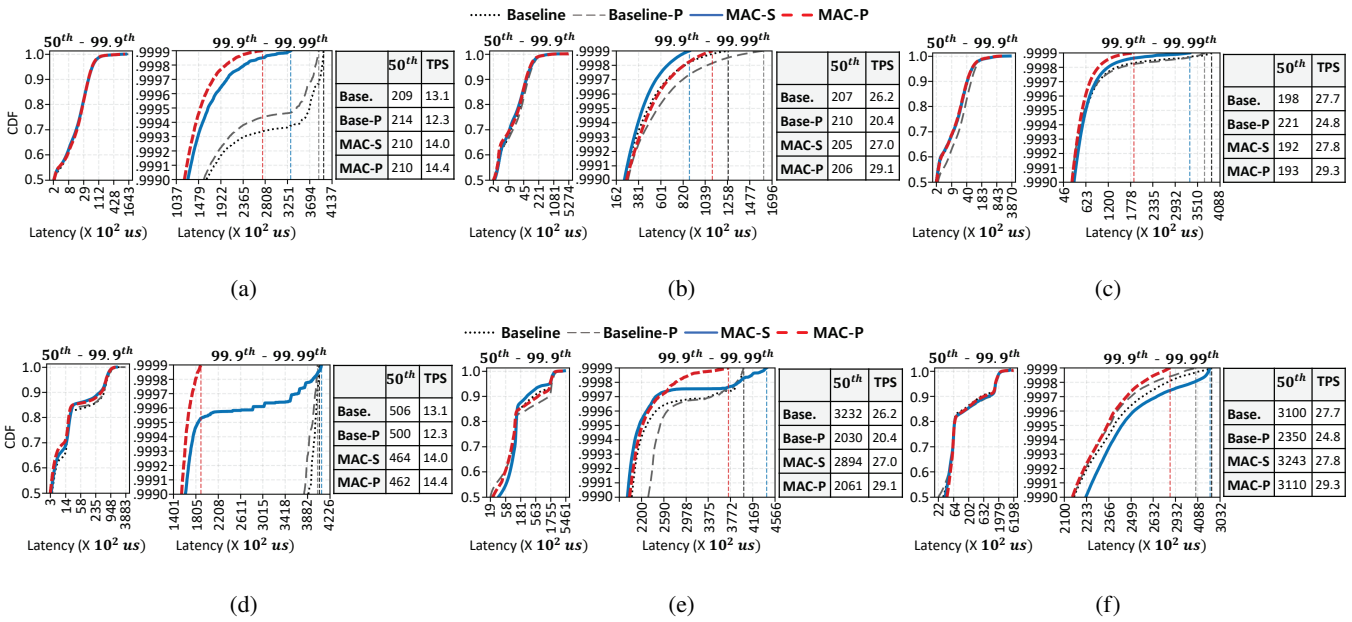


Figure 13: Latency CDFs and TPS (×1,000) across memory configurations for the RocksDB 50/50 read–update workload: (a) DDR:CXL = 1:1 (READ, 100 threads), (b) DDR:CXL = 1:2 (READ, 230 threads), (c) DDR:CXL = 1:4 (READ, 250 threads), (d) DDR:CXL = 1:1 (UPDATE, 100 threads), (e) DDR:CXL = 1:2 (UPDATE, 230 threads), and (f) DDR:CXL = 1:4 (UPDATE, 250 threads).

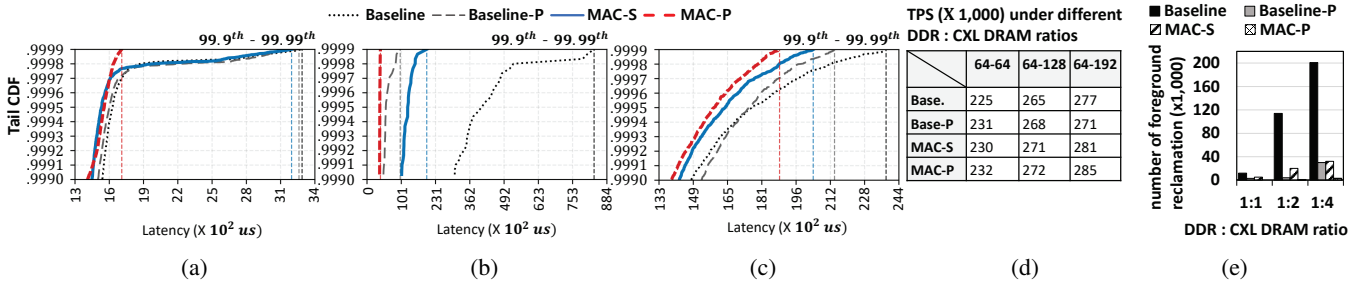

Figure 14: Latency CDFs, TPS, and foreground reclamation frequency across memory configurations for the OLTP workload with PostgreSQL: (a) DDR:CXL = 1:1 (100 threads), (b) DDR:CXL = 1:2 (160 threads), (c) DDR:CXL = 1:4 (250 threads), (d) TPS comparisons, and (e) foreground reclamation frequency.

DRAM.

Next, we evaluate our system using a hybrid workload that concurrently executes seven Interactive Short (IS) queries and eleven Interactive Complex (IC) queries [12] which exhibit OLAP characteristics. As shown in Figure 16(a), our system achieves lower p99.9 and p99.99 tail latencies for most queries. However, for some long-running, computation-bound queries (e.g., CQ1 and CQ2), the improvement is smaller. Nevertheless, in terms of overall runtime, both MAC-S and MAC-P still outperform Baseline-P, achieving an 11% reduction in total runtime, as shown in Figure 16(b).

LMDB with GET operations. We evaluate the GET workload on a 1.7 TiB LMDB database using ioarena [27]. Since LMDB [55] accesses the database via mmap [41], we assessed how the cooperative page reclamation scheme in Fig-

ure 9 affects performance. As shown in Figure 17(a), MAC-S and MAC-P reduce p99.9 latency by 62% and 35% on average over Baseline and Baseline-P, respectively, while maintaining stable performance.

This performance improvement stems from the fact that our MAC processes the unmapping of reclaimed mmap'ed pages from the process page table in parallel with the Xarray walk, as shown in Figure 9. As a result, as shown in Figure 17(b), in MAC-S and MAC-P the unmap operation is overlapped with the Xarray walk time, reducing page reclamation time by 26% and 42%, respectively, compared to Baseline. Compared to Baseline-P, MAC-S and MAC-P reduce reclamation time by 10% and 31%, respectively.

Results with a prototype system.

To validate the fidelity of our emulation results, we measured the end-to-end latency of kswapd 's page reclamation on real FPGA hardware. To do so, we synthesized the Linux kernel's Xarray walk function [53] and page-descriptor traversal logic [50] into an FPGA RTL design. We perform our FPGA evaluation on a server described in Table 3.

Table 3: Prototype system configurations.

Component	Specification
OS	Ubuntu 24.04.1 LTS (Linux kernel v6.11)
DDR DRAM size	128 GiB
CPU	Intel Xeon 6538Y+ (2 CPU sockets, each with 32 cores and 60 MiB LLC per CPU) [22]
Socket 0 & 1	2 × 64 GiB DDR5-4800
CXL device On-board DRAM	Intel Agilex 7 I-series FPGA [24] 2 x 8 GiB DDR4-2666
FPGA utilization	ALM: 233k(26%), Registers: 480k(26%), M20K: 2123(16%) [20, 19]

We benchmark the overhead of the page-reclamation process invoked by kswapd, using synthetic page descriptors and Xarray structures representative of file-sizes and tree depths observed in RocksDB and PostgreSQL (e.g., Xarray depth of 3 levels).

As shown in Figure 18, our MAC technique reduces the Xarray-walk overhead by 82% and the page descriptor traversal overhead by 48% by enabling pipelined and parallel execution of accelerators within CXL DRAM. While offloading work to CXL DRAM introduces additional costs—the time for the host CPU to transfer required information and trigger MMIO operations (comm. in Figure 18), and the overhead of notifying the host CPU of completion via polling and returning the computed values, along with cache-coherency overhead (sync. in Figure 18)—MAC still decreases the end-to-end runtime of kswapd page reclamation by 30%. This improvement is comparable to the performance of MAC-P in Figure 12(b), validating the results of the emulated architecture.

6 Related Work

We organize related work into two areas: (1) metadata overhead reduction and (2) near-memory processing (NMP).

Metadata management. Several studies [33, 13, 68, 63, 35, 87, 67] have improved system and application performance by reducing the overheads of kernel metadata management. For example, Radiant [33] tackles the performance degradation caused by long address translation when page tables spill over to high-latency non-volatile main memories [21] by migrating page tables. Hermit [68] mitigates tail-latency issues caused by remote memory accesses during application-page swapping in RDMA-connected clusters using multiple swap threads, but focuses on in-memory applications and does not consider the overheads of metadata structures. In contrast, our MAC system is distinguished in that there has been no prior characterization of the size or performance overhead of existing kernels' memory management metadata in large-capacity, CPU-less CXL DRAM environments.

NMP with CXL DRAM. Many works [79, 28, 32, 62, 85, 89, 30] have improved application performance by leveraging CXL DRAM–based near-memory processing (NMP) to overcome performance bottlenecks. For example, [85] accelerates query processing with in-memory column scans and B^+-tree operations, while [79] performs NMP-based memory profiling on CXL DRAM to reduce the host-CPU burden, improving both migration accuracy and performance. In contrast, our MAC system offloads Linux's page-reclamation path to CXL DRAM, showcasing a complementary NMP use case that targets OS-level memory-management overheads.

7 Discussion

While vendors typically consider DDR DRAM to CXL DRAM ratios ranging from 1:1 to 1:4, future systems may employ more aggressive configurations such as 1:8. As shown in Figure 19(d), under a 1:8 ratio, metadata occupies approximately 20 GiB, corresponding to 31% of DDR DRAM capacity. Consequently, Baseline and Baseline-P, which place metadata in DDR DRAM, experience 5-30% higher 50th-90th percentile latencies than MAC-S and MAC-P due to increased contention for scarce DDR DRAM, as shown in Figure 19(c). These results show that, as CXL DRAM capacity scales, preserving DDR DRAM for application data becomes increasingly important for latency-sensitive workloads [3].

Although we focus on CXL memory expanders, the same considerations apply to future CXL 3.0 memory-pooling systems [34] with multiple CXL DRAM devices. In this case, nodes belonging to the same Xarray should preferably reside in the same CXL DRAM device and migrate together when reassigned. Moreover, applications spanning multiple CXL DRAM devices could exploit device-level parallelism for metadata processing.

8 Conclusion

We have presented MAC, a near-memory processing approach that co-designs the OS and a CXL-resident accelerator to offload the dominant metadata operations in the memory reclaim path—Xarray [52] walks and page-descriptor [49] traversals. To our knowledge, this is the first paper to address the capacity and performance costs of kernel metadata in CXL DRAM systems from a sustainability perspective and to resolve them via NMP-based reclamation offloading. Compared to a modern Linux kernel–based system equipped with CXL DRAM, MAC reduces the p99.99 latency by up to 98%, thereby ensuring sustained, stable application performance.

Abstract

Modern datacenter servers increasingly deploy heterogeneous, multi-tier memory hierarchies. For these new architectures, OSes depend on measurements of memory usage to make intelligent placement and control decisions. However, existing hardware and software mechanisms for tracking memory usage on these systems require difficult tradeoffs between coverage, timeliness, granularity, flexibility, and overhead.

We present NEMO, a nimble and expressive hardware memory telemetry engine for server memory controllers (MCs) that gives OS subsystems policy-specific views of memory behavior. NEMO enables flexible telemetry rules that filter memory operations, map accesses to counters, and apply simple updates to per-counter state. We prototype NEMO on an FPGA-based CXL-attached memory expander. Evaluating three diverse use cases, we show that NEMO provides higher-fidelity signals at substantially lower CPU overhead across a range of state-of-the-art memory management systems: it speeds up HeMem's reaction to hot-set changes by 5×, accelerates THP splitting in MEMTIS by 10.4×, and detects noisy neighbors in Linux with 350× lower overhead. These telemetry improvements yield up to 1.7× higher throughput and 23% lower latency across key-value stores and databases.

1 Introduction

Modern datacenter server memory hierarchies have become increasingly complex with cache-coherent multi-socket DRAM, accelerator unified virtual memory [19], and Compute Express Link (CXL)-attached memory expanders [23, 43, 56] that may themselves implement internal tiering [71], compression [15], and pooling [39, 72]. A cache miss or uncached streamed memory operation can experience very different latency and bandwidth depending on where and how it is served [62]. At the same time, memory has become an expensive server component requiring careful management, accounting for 40-50% of server costs [43, 57].

To use these various types of memory effectively, OSes and runtimes need to actively manage and control the placement and use of memory [17, 35, 36, 43, 48, 63, 64, 67, 71, 73]. CXL is now deployed in major cloud platforms [23], where multi-tenancy demands flexible and evolving memory policies: some tenants require hot-set tracking, others need to identify sparsely accessed regions inside huge pages, and operators must attribute bandwidth to catch noisy neighbors. Early operational experience confirms that the lack of efficient CXL runtime telemetry limits the ability of cloud providers to attribute slowdowns to individual tenants and mitigate interference [7]. Small changes in placement or migration decisions can produce large shifts in application performance and interference between co-located tenants [36, 62, 64, 67]. Finally, memory management must incur low overhead to leave more resources available to end users [49, 60].

Existing mechanisms for gathering memory usage information pose awkward tradeoffs to the OS developer. Page-level access bit tracking is flexible, but can be expensive when tracking usage across large memories and multiple memory tiers [48]. Hardware cache miss sampling can reduce overheads, but comes at the cost of reduced precision [2, 68]. Hardware counters on CPUs and memory controllers typically aggregate events at the level of channels, banks, or sockets, revealing overall pressure but not which virtual pages, objects, or tenants are responsible [46, 53]. In response, recent CXL/OCP specifications [15] and research systems [55, 73] have proposed fixed-function hotness tracking and bandwidth statistics, but these provide only rigid, design-time semantics that cannot adapt as datacenter policies and memory hierarchies evolve (§2.2).

This paper proposes NEMO, a hardware-software co-designed memory telemetry engine that addresses these problems. On the hardware side, NEMO is a lightweight extension to memory controllers (MCs): each MC is augmented with a small, off-data-path telemetry pipeline and a modest SRAM budget for telemetry state. NEMO pipelines let the OS define telemetry rules that filter relevant memory operations, map access sites via a small MC-resident table to telemetry state, and apply simple update operations to per-counter state. On the software side, NEMO exposes an OS-facing programming model and Linux driver that gives the OS flexi-

*Equal contribution.
†Work done at Microsoft.

ble, policy-driven control over what telemetry to track, while preserving high fidelity and full coverage. OS kernel subsystems can install and evolve their own sets of rules via a common controller-side engine. The controller executes these rules on each memory operation to maintain policy-specific state over OS-chosen granularities and aggregates (e.g., page ranges, tenants, or allocation sites), as opposed to predefined aggregates offered by fixed-function hardware counters.

Designing NEMO raises three concrete challenges. First, MCs see requests at very high rates, forcing us to represent rich policies within a small, carefully managed SRAM state budget. Second, for flexibility, NEMO must support observations at multiple software-defined spatial granularities concurrently. Third, the OS must configure and read out NEMO state efficiently, without turning the memory controller into a new CPU bottleneck. We will show how NEMO's match-update pipeline, translation scheme, and driver interface address these constraints while preserving full coverage.

We prototype NEMO in FPGA on a CXL-attached memory expander development kit [3] and integrate it with existing OS memory management mechanisms, anchoring our design in the CXL Type-3 deployment model that cloud providers are already rolling out today [23]. The prototype monitors every CXL memory operation and exports compact aggregates to the kernel, enabling near-real-time views of hot sets and sparse access patterns. An implementation in server integrated memory controllers (IMCs) would further reduce overheads by providing fast-tier coverage. Recent Xeon processors, for example, already support delivering memory responses to additional consumers without affecting cache performance (e.g., Direct2Core [26]).

NEMO sits at a practical vantage point in the memory hierarchy. MCs already host QoS and monitoring features, making them a natural place to host a small, flexible telemetry engine. In contrast, cache-centric designs such as täkō [51] require intrusive changes to core microarchitecture, making them hard to deploy in existing processors, while in-DIMM approaches offer only very limited logic and vendor-specific control paths, making rich telemetry difficult. Because the NEMO pipeline runs alongside, rather than on, the memory datapath, it does not add latency to cache hits or DRAM/CXL accesses; it only observes request metadata and maintains aggregates in local SRAM. Compared to existing telemetry approaches, this hardware offload raises fidelity and reduces CPU overhead, allowing the OS to reason about complex, multi-tier memory hierarchies using precise, up-to-date signals within a tight compute and SRAM budget.

We make four contributions:

1. We characterize the challenges of memory observability in heterogeneous, multi-tier server memory systems and study the tension between fidelity, flexibility, and resource constraints (§2).
2. We present NEMO, a lightweight MC-resident memory telemetry engine that exposes filtering, translation, and aggregation abstractions, enabling OS subsystems to install telemetry rules that express a wide range of policies within realistic compute and SRAM budgets (§3).
3. We build a working NEMO prototype[1] on a CXL-attached FPGA memory expander development kit and integrate it with existing OS memory management mechanisms in Linux, HeMem [48], and MEMTIS [36] (§4).
4. We evaluate NEMO on three diverse use-cases, showing that NEMO improves policy effectiveness and CPU efficiency over existing telemetry mechanisms (§5). Across these cases, NEMO-based policies improve tail latency, throughput, and isolation compared to state-of-the-art baselines that rely on sampled PMU data or coarse per-core counters, while consuming a modest fraction of the CPU cycles used by host-only telemetry. In particular, the NEMO telemetry information provides 2-10× faster identification of hot (§5.1) and skewed (§5.2) pages than alternative approaches with similar CPU overhead, and provides bandwidth tracking within 0.1% of ground truth with ~350× lower overhead (§5.3), resulting in up to 1.7× throughput improvement with a 23% latency reduction across FlexKVS [31], FASTER KV [14], and Silo [59].

2 Background

We characterize memory observability into five dimensions that directly affect OS policy performance in the datacenter environment:

1. *Coverage*: the fraction of memory accesses that are directly observed.
2. *Timeliness*: the delay between a change in memory-access behavior and when telemetry reflects that change.
3. *Granularity*: the smallest unit to which memory accesses can be attributed (e.g., cache line, page, region, or tenant).
4. *Flexibility*: the degree to which the OS can define which accesses are tracked and how they are aggregated.
5. *Overhead*: the system resources consumed to collect, process, and export telemetry.

We use these dimensions to survey existing memory telemetry mechanisms. Software techniques provide flexibility but achieve limited coverage and timeliness at high CPU cost (§2.1), while hardware offloads offer efficient, high-coverage signals only at coarse granularities and with fixed semantics chosen before tape-out (§2.2). Prior to NEMO, no existing mechanism simultaneously delivers on all five.

2.1 Software Telemetry: Flexible but Costly

Many memory management policies must infer access behavior indirectly using software-based aggregation built on hardware signals. These approaches provide flexibility, but

[1] NEMO is open source at https://github.com/vic-lsh/nemo.

incur high CPU overhead while achieving limited coverage and timeliness.

One of the simplest techniques is *soft page faults*: the OS deliberately unmaps pages (or marks them read-only) and infers access patterns from the resulting faults [1,5,8,33,43,61]. This mechanism can, in principle, capture every access. However, fault handling has high CPU overhead in practice, and so systems can only apply it to a small subset of memory [43], limiting coverage. Granularity is also limited to hardware-defined page sizes.

To reduce overhead, systems often rely on *page-table scanning*. The OS periodically walks page tables and inspects accessed and dirty bits to collect per-page read and write activity [1,17,29,42,67]. This eliminates the direct cost of faults but introduces two limitations. First, it sacrifices timeliness: accesses are only observed at each scan interval. For example, production systems limit the scan frequency to every 30 seconds [17]. Second, it lacks coverage and granularity: each page yields only one bit of information per interval, providing no notion of access intensity within the interval or at a granularity other than the page. Increasing scan frequency improves timeliness and coverage, but quickly drives CPU overhead to impractical levels [39,48,71]. CPU overhead can be decreased by mapping at a coarser page granularity, but this decreases fidelity.

A third approach combines hardware sampling with software aggregation. For example, Intel Processor Event-Based Sampling (PEBS) [27] supports sampling cache misses and lets the OS reconstruct access patterns from the sampled access locations [17, 36, 48]. This improves granularity but reintroduces a tradeoff between coverage and timeliness on one hand, and CPU overhead on the other. This occurs in two ways: 1) A higher sampling rate improves coverage but increases CPU cost for sample processing. 2) A higher sample collection frequency improves timeliness but also increases CPU cost due to increased interrupt rates. Prior work [73] shows that sampling 10% of all cache misses leads to an application slowdown of more than 50%. In practice, systems sample at a much lower rate to limit CPU overhead [17, 48]. Being Performance Monitoring Unit (PMU)-based, PEBS also misses important DRAM traffic (cf. §2.2). Finally, PEBS does not support profiling VM guests from the host [66], making it non-viable for public cloud operators.

Across all three techniques, the same pattern emerges: flexibility is achieved via software processing. However, fidelity is limited by how much CPU overhead the system is willing to tolerate, forcing the OS to trade coverage, timeliness, and granularity against overhead. As a result, even state-of-the-art profilers that carefully manage sampling and multiplexing still pay non-trivial CPU overheads and cannot run continuously at high rates without perturbing the workload [37].

2.2 Hardware Offloads: Efficient but Rigid

Modern CPUs and memory controllers (MCs) expose hardware counters such as Intel's Memory Bandwidth Monitoring (MBM) [46] and integrated MC statistics [27]. These provide low-overhead, timely, and high-coverage telemetry, but only at the coarse granularities and semantics chosen by hardware designers. For example, Intel's PMU tracks per-core LLC misses and socket-level MC DRAM activity, missing important traffic such as prefetches, non-temporal accesses, or the ability to attribute memory activity to a core or process. Intel's MBM hardware counters can attribute memory bandwidth to processes, but they have known accuracy issues [53] and does not offer options such as filtering reads or writes. Research approaches [55, 73] go further by tracking hot pages or cache lines in hardware, but they fix telemetry configuration, granularity, and coverage (e.g., top-5 hot pages and cache lines [55]) at hardware design time. As a result, hardware telemetry performs well for the specific use cases that it was built for, but sacrifices flexibility. When policy needs to evolve, the OS is forced to fall back to software aggregation.

3 NEMO: Nimble and Expressive

NEMO is a hardware-software co-designed memory telemetry engine that gives the OS a flexible, high-fidelity view of server memory traffic at the memory controller. On the hardware side, NEMO is a modest change: each MC is augmented with a small, off-data-path processing pipeline, coupled with a small SRAM state array, to enable tracking memory operations without adding latency. On the software side, the OS programs these pipelines via a narrow interface and retrieves pre-aggregated state, keeping CPU overhead low. NEMO's goal is to provide high coverage, timely updates, fine-grained attribution, and OS-defined metrics, while incurring low CPU and MC overhead. We now describe the constraints this setting imposes and the abstractions NEMO provides to remain both expressive and practical.

Challenge: enabling flexibility with full coverage. Full coverage limits per-request computation: telemetry processing must keep up with controller bandwidth, ruling out designs with unbounded or data-dependent processing latency. It also restricts where telemetry state can reside: updates cannot add memory traffic or interfere with application access, yet every request may modify state. Storing telemetry in DRAM would require two extra accesses per update and severely reduce bandwidth, so all telemetry must fit within a small SRAM near the controller, requiring careful allocation across granularities and regions to support diverse OS needs. Lastly, modern servers interleave physical memory across MCs at fine granularity; to maintain full coverage, NEMO must track telemetries across MCs and provide OS-level aggregation. As a result, NEMO must create nimble abstractions that sat-

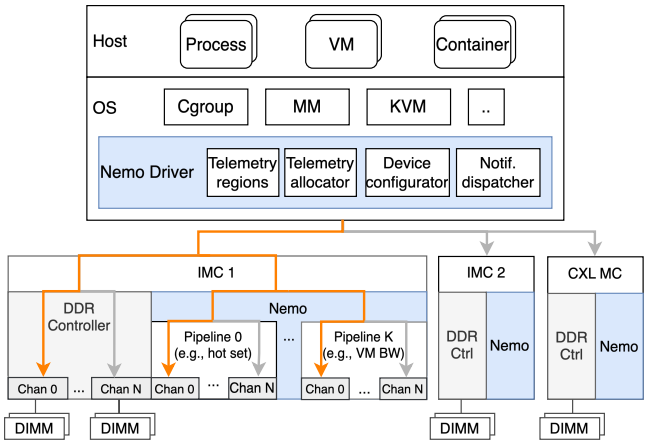

Figure 1: NEMO augments each MC with a programmable telemetry engine. Each memory request is broadcast to all NEMO pipelines (monitoring only), while the memory operation itself is routed to a single channel (one possible route shown in orange). The NEMO driver orchestrates NEMO instances to track telemetries requested by OS subsystems.

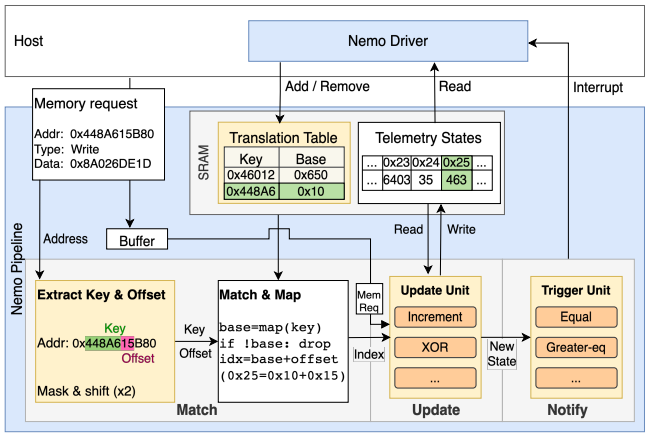

Figure 2: NEMO pipeline and host interactions. Each pipeline implements a fixed match-update-notify structure; highlighted tiles are configured per telemetry.

isfy line-rate, SRAM, and aggregation constraints while still supporting diverse telemetry use cases.

System overview. Figure 1 shows NEMO's architecture. Each memory controller is augmented with a small telemetry engine and exposes it to the OS through a driver. Each engine contains a number of telemetry pipelines, each of which can be configured for a different telemetry. As memory requests arrive, NEMO taps their headers off the data path and feeds them to all telemetry pipelines simultaneously, while the original requests are routed to DRAM. Each NEMO pipeline is capable of snooping all memory channels on the MC. The OS specifies and reads back specific telemetries via the NEMO driver. The driver programs per-controller pipelines, manages telemetry state in SRAM, and returns aggregated views to OS subsystems. For important signals, the OS installs predicates that let NEMO raise interrupts. Memory management policies then act on these high-fidelity signals.

Running example. Consider a telemetry that tracks accesses to selected 2 MiB pages (hugepages). The OS asks NEMO to maintain one counter per tracked page. When a memory request for a tracked page reaches the memory controller, NEMO increments that page's counter. The OS periodically reads these counters to estimate page hotness. This is the simplest use of NEMO's pipeline. The same structure also supports different filters, granularities, update operations, and notification predicates.

3.1 NEMO Telemetry Pipeline

To maintain full coverage with predictable latency, NEMO leverages OS-configurable fixed-function pipelines inside each memory controller. As shown in Figure 2, NEMO telemetry pipelines follow a match-update-notify structure, inspired by the reconfigurable match table architecture [11] used in programmable network switches and interface cards. Each pipeline applies this structure to all memory channels. To carry out this work, each pipeline owns (1) a *translation table* that maps each incoming memory request via its physical address to a telemetry state index and (2) a set of *telemetry states* that hold its per-channel telemetry counters. First, a pipeline matches all or part of the physical memory address to produce an index into the telemetry state. If there is a match, the pipeline's update stage updates the selected telemetry state using a configured operator and, optionally, any part of the memory request as operand. Finally, the pipeline's notify stage may optionally trigger an interrupt to notify the host of notable state updates, using a comparison operator. For page hotness tracking, the match stage maps the request to the specific counter for its 2 MiB page, and the update stage increments that counter. The OS periodically reads the counter array for placement decisions.

NEMO restricts per-request telemetry updates to associative and commutative operations. This is for scalability within and across controllers. Commodity servers often need multiple MC instances (e.g., one or more per socket or SNC partition [24], as well as CXL memory controllers behind the PCIe root complex). Physical memory access is interleaved across controllers at fine granularity for performance. Within one MC, a telemetry may itself be implemented using multiple NEMO pipelines, and each channel within a pipeline owns some telemetry state SRAM banks. Associative and commutative updates let each NEMO instance combine concurrent updates locally and let the OS merge per-MC states in any order to reconstruct a global view. Each pipeline stage is replicated per memory channel in order to maintain full bandwidth within a pipeline.

We now describe each telemetry pipeline stage and the host interface for reading telemetry state.

Match stage. The match stage maps each memory request to the corresponding telemetry state index. The main design challenge is that the mapping must be flexible enough to support OS-defined granularities and semantics, yet simple enough to compute at line rate.

To address this challenge, NEMO adopts a mask-shift-add design that uses simple, fixed-latency arithmetic and a compact translation table to support flexible aggregations (e.g., from cache line to multi-GiB regions, from per-page to per-tenant). At a high level, the match stage matches a request to a telemetry state index, identifying the state to update in the next stage. For page-hotness tracking, NEMO derives a key from the request's physical address by masking and shifting away the offset within a 2 MiB page. The key indexes the translation table, which returns the counter index for that page. If the key is missing or invalid, NEMO drops the request.

The translation table is itself stored in banked SRAM and gives flexibility in indexing the telemetry state SRAM. In general, NEMO derives the key using two OS-specified parameters: (1) a bitmask that selects the relevant address range, and (2) a right shift that sets the primary region size. These two parameters let keys identify *primary regions* (e.g., a 2 MiB or 4 GiB region), which must have power-of-two sizes and be aligned to their size boundaries.

Keys index the translation table, which returns the *base indices*. Keys may map one-to-one to states (e.g., one counter per page) or many-to-one (e.g., all pages in a tenant share a telemetry state).

For simple telemetries such as per-page hotness, the base index is the final state index. For telemetries that subdivide a primary region, the translation table's output—the base index—is added to an *offset* to produce the final state index. With offsets, a memory request matches on a sub-region within the request's primary region. The OS supplies a secondary mask and right shift that determine sub-region size. NEMO takes the designated masked bits of the physical address, shifts them, and obtains the sub-region offset, which is added to the base index to get the final state index. When no subdivision is needed, the OS sets the secondary mask to zero. Figure 2's Match Stage illustrates the full base-index-plus-offset arithmetic. This simple arithmetic lets the OS trade spatial fidelity for coverage: the same SRAM budget can either track a small region at fine granularity or maintain coarse-grained counters over large regions.

Lastly, different pipelines can filter and translate at different granularities. Pipelines can be configured to drop reads or writes, giving more flexibility to the OS.

Update stage. The update stage takes the telemetry state index and the memory request as input and performs a read-modify-write on the state selected by the match stage, using the update operator chosen for the telemetry (Table 1). The hotness telemetry uses addition: each request adds one to the selected counter. Operators use request fields as operands.

To store telemetry states while maintaining the bandwidth requirements of a memory controller, NEMO leverages banked SRAM. Each channel in each pipeline can be configured by the OS to exclusively own some number of banks. This ensures that bank conflicts never arise and avoids SRAM stranding. SRAM accesses do not stall the NEMO pipeline. Instead, we use value forwarding to protect against data hazards when updating the same SRAM telemetry state consecutively (cf. §4).

Telemetry state access. Each controller advertises a *telemetry region*: a physically contiguous range whose contents are backed by MC SRAM. The NEMO driver reserves these regions in the OS kernel so they are never used as anonymous memory, and knows to use this region to read telemetry states.

On a memory load from the telemetry region, the controller bypasses DRAM and the telemetry pipeline and instead returns the telemetry state from SRAM. To support efficient state resetting, NEMO allows the driver to configure an optional reset operation (any update operator in Table 1 or reset-to-constant) that is executed immediately after returning the telemetry data. Reset-on-read makes each OS poll return per-page access counts for the latest placement interval.

Notify stage. Polling is sufficient for many policies, including page-hotness tracking. For urgent signals, the notify stage allows each pipeline to specify a simple predicate on updated state (e.g., comparison against a threshold). After an update, the notify logic evaluates the predicate and raises an interrupt if it holds. Each controller only sees its slice of traffic, but fine-grained interleaving makes per-controller patterns similar; alerts thus act as hints that the OS should re-check telemetries across controllers.

3.2 NEMO Control Plane

The NEMO driver is the control plane for all interactions with NEMO controllers. It installs telemetries, allocates telemetry state, manages translation entries, exposes telemetry regions, and dispatches notifications.

Telemetry installation. To install a telemetry, NEMO exposes a constrained per-request programming model. Each NEMO *telemetry* is installed by specifying:

1. *Memory request filter*: R/W type and address range;
2. *Translation rule*: maps addresses to telemetry states;
3. A *telemetry update operation* on the selected state;
4. *Notify predicate*: optional notification trigger;
5. *Telemetry read side-effect*: optional state reset.

When an OS service submits a telemetry specification to the NEMO driver, the driver first validates the telemetry, then allocates available pipelines on each relevant MC.

Category	Config	Options
Match	Filter	Request type (R/W/All)
	Base index	Bit mask & shift
	Offset	Bit mask & shift
Update	Update op	One of: +, -, >>, <<, XOR; specify operand.
Notify	Predicate	One of: ==, >=, >, <, <=; specify operand.
Read telemetry	Side effect	One of the update ops, or reset to a configured value.

Table 1: Configuration options in NEMO telemetry rules.

Telemetry state allocation and translation. The NEMO driver uses a slab allocator to allocate the appropriate number of pipelines and telemetry state banks, and then programs the translation table to map physical memory ranges to allocated telemetry state indices. For any allocated state, the OS can dynamically update which regions map to it by adding or removing translation entries. This is helpful for aligning the translation table with OS telemetry semantics (e.g., mapping only a process's pages to telemetry states). The driver validates translation entries by only mapping addresses within the physical memory range that a controller serves. It also tracks how a telemetry's states are allocated across multiple controllers to ensure correct aggregation on telemetry reads.

Reading telemetry. At boot, the NEMO driver discovers each controller's telemetry region, maps it, and removes it from general use. The driver exposes an API to aggregate a telemetry's states across controllers, applying the optionally configured read-side effect. For most metrics, OS services may simply periodically read telemetry state from controllers (polling).

When reading telemetry, the driver reconstructs a global view by reducing per-MC states using the update operator's natural combine rule (e.g., sum per-MC values for addition, XOR for bitwise-XOR, and multiplication for right bit-shifts). Because all update operators are associative and commutative, the driver can compute a logical telemetry state by folding per-MC states.

Notification dispatch. OS services can also install predicates that let NEMO raise interrupts. When a NEMO controller raises an interrupt, it tags the corresponding pipeline. The driver resolves this to a telemetry and invokes its registered callback, delivering alerts to the OS subsystem.

3.3 Putting It Together

We now extend the hotness example with offsets, producing a concrete telemetry for access skew within selected hugepages.

Tracking within-page skew. To measure access skew within selected 2 MiB hugepages, NEMO maintains one counter per 4 KiB basepage. A hugepage-splitting policy can use these counters to find pages whose accesses concentrate in only a few basepages.

```
1  nemo_telemetry_t t = nemo_register_telemetry((nemo_spec_t)
2  {
3    .filter      = {.type=R|W},
4    .translation = {
5      // Track hugepages across all physical memory
6      .primary   = {.mask=NEMO_ALL_MEM, .shift=HP_SHIFT},
7      // Offset: basepage number within the hugepage
8      .sub       = {.mask=HP_BP_MASK,   .shift=BP_SHIFT},
9    },
10   .update      = {.op=NEMO_OP_ADD,    .operand=1},
11   .notify      = {.op=NEMO_OP_NOOP},
12   .read_effect = {.op=NEMO_OP_RESET, .value=0},
13 });
14
15 // Set translation table to track new hugepages
16 void reprogram(uint64_t hp_paddr[], int npages) {
17   for (int i = 0; i < npages; i++)
18     nemo_set_translation(t,
19         /*key=*/        hp_paddr[i] >> HP_SHIFT,
20         /*region_idx=*/ i);
21 }
```

Listing 1: NEMO telemetry for basepage skewness within selected hugepages. The primary region is a 2 MiB hugepage; the sub-region is a 4 KiB basepage.

Listing 1 shows this telemetry. Lines 2–13 install the static telemetry rule `t`: match both reads and writes, compute a hugepage key from the physical address, compute a basepage offset within that hugepage, increment the selected counter, and reset counters on read. Resetting on read makes each poll return basepage access counts for only the last interval.

The OS then chooses which hugepages to track by calling `reprogram()`, which installs a translation entry for `t` per tracked hugepage with `nemo_set_translation(t, key, region_idx)` (lines 15–21). The *key* is the hugepage frame number (`paddr >> HP_SHIFT`), and the *region index* assigns this hugepage a distinct base index in the telemetry state array; the driver picks base indices so different hugepages' 512-counter ranges do not overlap. As before, the basepage number within the hugepage forms the offset that NEMO adds to the base index to select the final per-basepage counter.

Listing 1 is one point in NEMO's configuration space. Translation entries are dynamic: the OS can reprogram any entry to time-multiplex its slots across more regions than fit in SRAM. The per-basepage skewness telemetry in §5.2 uses this to track skewness across all of memory. Translation can be one-to-many, as in this example, where one hugepage maps to 512 basepage counters. Translation can also be many-to-one: the per-tenant bandwidth telemetry in §5.3 maps all of a tenant's pages to a single state. Other telemetries vary request filters, state update operations, read-side effects, and notification predicates within the same match-update-notify structure.

What NEMO can and cannot express. NEMO's per-request semantics—an associative and commutative single-step update to one memory location, optionally followed by a fixed-cycle predicate—cover the broad class of memory observability tasks that aggregate per-access events into per-region or per-tenant counters, including all three use cases in §5. NEMO does not support telemetries that need multiple arithmetic steps or multiple locations per request, unless they can be done by different pipelines operating independently and later combined. For example, computing the variance of a region's access counts must maintain both a running sum and a running sum of squares of the differences from the running sum. Likewise, exact top-K tracking depends on history beyond a single SRAM-resident counter. §6.3 discusses extensions that lift these restrictions.

Summary. NEMO simultaneously provides high coverage, low overhead, flexibility, granularity, and timeliness for memory telemetry. Its off–data-path pipeline and SRAM-resident state avoid perturbing MC latency or bandwidth, while the fixed-function pipeline sustains full coverage at line rate with predictable latency. The pipeline's configurable stages offer flexibility, and the translation table supports use-case-specific aggregations at OS-defined granularities. Finally, the driver's memory-mapped telemetry region and optional alerts offer low-overhead state retrieval and timely reactions. Together, these mechanisms give the OS a flexible, high-fidelity telemetry mechanism that fits within the throughput and resource constraints of modern memory controllers.

4 Implementation

NEMO is prototyped on an Altera Agilex 7 FPGA I-Series Development Kit with CXL 2.0 Type-3 support in hard IP [3]. The FPGA is connected to our host machine via PCIe 5.0 x16, and has 16GiB of onboard DDR4 DRAM. It features 913k logic modules (ALMs), 3.7M ALM registers, and 13k M20K SRAM blocks, summing to 32MiB of usable SRAM blocks. Our design consists of the CXL IP, a DDR4 memory controller, and our NEMO logic, running at 400 MHz with resource usage described in Table 2. The host machine runs an Intel Xeon Gold 6430 CPU, with 32 physical cores and 64 hyperthreads. It contains 2MiB of L2 cache per core and 60MiB of shared LLC cache, and 256GiB DDR5 memory. The CXL-attached DRAM is substantially slower than host DRAM. Using Intel MLC [28], we measure host DRAM at 114.1 ns load-to-use latency and 114.9 GiB/s bandwidth, while the CXL DRAM exhibits 380.3 ns latency and 16.4 GiB/s bandwidth, i.e., roughly 3.3× higher latency and 7× lower bandwidth.

NEMO pipeline. Our FPGA has 2 memory channels corresponding to the parity of a cache line address. Thus, each pipeline must support the match-update protocol on two channels in parallel. Since each channel can issue one read or one write on each FPGA cycle, maintaining an initiation interval of 1 on each channel is crucial to achieving full coverage.

	Full Bitstream	NEMO
Logic Utilization	17%	4.8%
Logic Registers	9.3%	1.7%
M20Ks (SRAM)	14%	4.4%

Table 2: FPGA resource utilization. Full Bitstream refers to the utilization of the entire design, including CXL and DRAM controller logic, whereas NEMO refers to the NEMO logic overhead.

Match stage. The translation table is implemented as a dual-port SRAM, with one port used to read and one used to modify the table. The translation table is currently replicated across each channel, though a true dual-port design could eliminate this extra duplicate. The translation table key is extracted from the memory operation's address via a configurable subtraction and shift sequence. As a prefilter, we also implement range bounds before key lookup. Once the telemetry state base is retrieved, an offset computed from the address is added to get the final telemetry state index.

Update stage. Each channel in the pipeline features its own telemetry state SRAM, implemented via the M20K block RAM primitives on our board. In order to maintain coverage and keep up with memory controller bandwidth, it is crucial that we implement read-modify-write hazard protection without stalling the pipeline. The SRAM primitives offered on the board provide 1-cycle latency reads and writes, meaning that a 1-cycle update operation can use data forwarding as a hazard solution. All of our update operations fit this 1-cycle latency requirement, so forwarding is sufficient to avoid data hazards. If a future update operation takes more than 1 cycle to compute, we can double the clock speed and halve the initiation interval to ensure full line-rate. If that is not an option, we could further split the N existing channels into $N \times M$ virtual channels using a round robin load balancing strategy per physical channel, allowing an initiation interval of M cycles to perform update operations at the cost of M times the SRAM.

Notify stage. Notifications are not currently implemented, but are simulated by polling counters every 1 ms on a core until a counter threshold is met.

Telemetry State Access. We modify the provided memory controller instantiation to advertise a 32GiB address range instead of its 16GiB DDR capacity. The prototype intercepts requests to the upper half of the address space for telemetry state retrieval. The driver is responsible for ensuring that this address range is only used by the driver to read telemetry.

To extract telemetry, NEMO interposes on memory requests and intercepts those that belong to the state retrieval address range. Since we expose telemetry as a standard memory region rather than an MMIO region, the driver must be careful to invalidate old cached telemetry information. However, we chose this as it improves performance over MMIO, giving us prefetchable, 512 bits/cycle/channel of telemetry output, matching DRAM throughput. Our implementation does not yet fully pipeline telemetry state access.

To configure each pipeline, each pipeline exposes control registers to the host via MMIO, allowing the NEMO device driver to configure all aspects of its functionality. This operates at 64 bit/cycle data width. We chose MMIO because these operations are typically not performance-critical and simplify the implementation by not having to intercept writes.

Resource budget. Each pipeline carries an 8,192-entry translation table (~14 KiB at 14 bits/entry) for the match stage and a per-channel $8{,}192 \times 64$-bit state array (128 KiB across the FPGA's 2 channels) for the update stage, totaling ~150 KiB. Across the full bitstream, NEMO uses 4.4% of the FPGA's M20K SRAM and 4.8% of its logic (cf. Table 2); the largest deployment we evaluate, MEMTIS-NEMO (§5.2), uses 8 such pipelines for ~1.2 MiB of telemetry SRAM. The headroom can support larger tables, deeper state, or more pipelines.

5 Evaluation

We evaluate NEMO by integrating it into three OS responsibilities that rely on memory telemetry: detecting application hot-set changes for tiering (§5.1), identifying transparent hugepage (THP) split candidates (§5.2), and detecting and throttling memory-bandwidth noisy neighbors (§5.3). Compared to state-of-the-art systems in each setting, NEMO delivers ~5× faster adaptation to hot set changes, accelerates THP splitting by 10.4×, and detects noisy neighbors in Linux with 350× lower overhead. These improvements yield up to 1.7× higher throughput and 23% lower latency across key-value stores and databases—core building blocks in modern clouds that are often deployed as large, memory-resident services that are both latency and cost-sensitive. Their access patterns stress exactly the phenomena our mechanisms target, making them representative workloads to evaluate.

For each use case, we describe a NEMO telemetry, the OS integration, and measure the resulting improvements in performance, reaction time, and CPU overhead compared to state-of-the-art telemetry approaches. Together, these results show that NEMO's match-update-notify pipelines with OS-controlled translation can address diverse memory telemetry challenges across a wide range of memory management systems and applications.

```
nemo_telemetry_t t = nemo_register_telemetry((nemo_spec_t)
{
  .filter      = {.type=R|W},
  .translation = {
    .primary   = {.mask=NEMO_ALL_MEM, .shift=HP_SHIFT},
    // no sub-region: one counter per hugepage
  },
  .update      = {.op=NEMO_OP_ADD,   .operand=1},
  .notify      = {.op=NEMO_OP_NOOP},
  .read_effect = {.op=NEMO_OP_RESET, .value=0},
});

// Map each tracked hugepage to its own counter slot
for (i = 0; i < n_hp; i++)
  nemo_set_translation(t,
      /*key=*/        hp_paddr[i] >> HP_SHIFT,
      /*region_idx=*/ i);
```

Listing 2: NEMO telemetry for per-hugepage hot-set tracking. One counter per tracked hugepage; no sub-region offset.

5.1 Hot Set Phase Change Recovery

Detecting application hot set changes is crucial for application performance in tiered, memory-capacity-constrained environments. Existing systems rely on sampled memory telemetry, forcing a tradeoff between sample rate and CPU overhead; in contrast, NEMO captures a complete view of memory accesses, reacts to hot set changes 5× faster, and improves application throughput by up to 1.69×, all while maintaining similar CPU overhead.

NEMO integration. We integrate NEMO telemetry into HeMem [48], a userspace memory tiering system. HeMem uses Intel Processor Event-Based Sampling (PEBS) to track page hotness by sampling LLC misses at a 0.02% rate. Each second, HeMem processes new samples by locating the corresponding page struct and incrementing its access counter, before migrating hot data to the fast tier and cold data to the slow tier.

With NEMO, HeMem sets up NEMO to update a per-hugepage counter on *every* LLC miss. This is shown in Listing 2. The counter is reset on read so each poll returns counts for the last interval. HeMem then scans the telemetry array to update each page struct's access counter by the NEMO-reported count.

Evaluation setup. We compare HeMem with NEMO telemetry (HeMem-NEMO) against HeMem with PEBS (HeMem-PEBS). As discussed in §4, NEMO only observes the slow memory tier, so both setups still use PEBS to sample the fast tier. To make hotness scores comparable across tiers, we scale NEMO access counts by the PEBS sampling rate and otherwise leave HeMem's tiering policy unchanged.

We first evaluate HeMem-NEMO and HeMem-PEBS using FlexKVS [31], an in-memory key-value store. We run FlexKVS with 6 threads, 32B keys, 1024B values, and 1:2 fast:slow memory ratio (24 GiB total); 20% set of keys form a hot set which are accessed 90% of the time. To stress time-

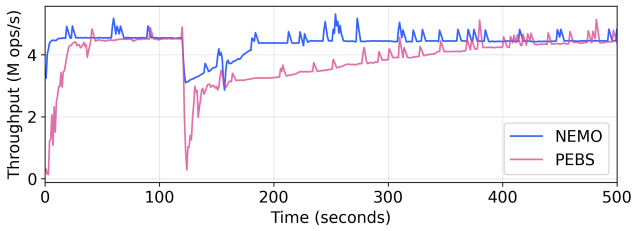

Figure 3: FlexKVS timeline with hot set phase change, featuring HeMem's default PEBS sample rate of 0.02%. NEMO is able to recover to steady state 5× faster than PEBS.

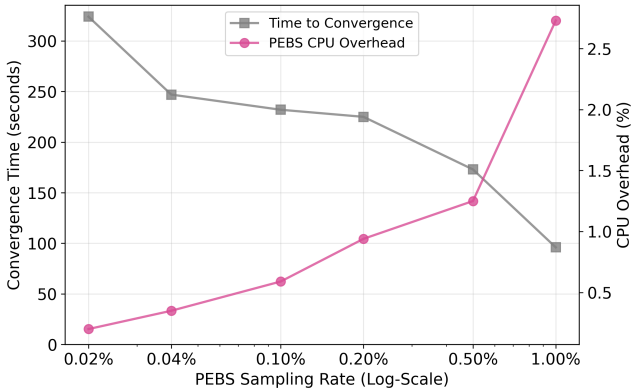

Figure 4: Hot set migration time and CPU overhead with different PEBS sampling rates in HeMem. NEMO takes 67 seconds to converge with 0.89% CPU overhead.

liness of hot-set detection, we engineer a complete hot-set shift: the initially hot keys become cold and a disjoint set of keys become hot. Since FlexKVS's working set spans both fast and slow memory tiers, HeMem migrates pages between tiers based on its hotness estimates. We track FlexKVS performance over time and compare how quickly each variant converges after the hot-set shift.

We then study object-size sensitivity using FASTER KV [14], a concurrent key-value store and cache used in Azure Durable Functions [12]. We choose the number of items and value size so that each experiment fills both fast and slow memory: total memory used (keys, values, metadata) is 30 GiB with a 1:1 fast:slow ratio. FASTER KV runs with 16 client threads, each pinned to its own core, issuing operations according to YCSB workload B [16] (95% reads, 5% writes). We measure aggregate throughput over 5 minutes, reporting the median per-second throughput after a 5-minute warmup. Keys follow a Zipf distribution tuned to approximate an 80/20 rule (80% of accesses target the hottest 20% of keys), mimicking production KV stores [6].

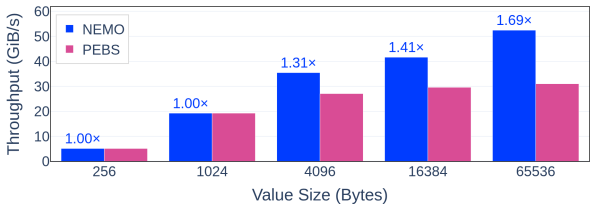

Figure 5: FASTER KV throughput across various value sizes. HeMem-NEMO identifies the hot set with larger value sizes, which PEBS is unable to do because of the prefetcher. There is no hot set with smaller value sizes.

5.1.1 Results

Hot set churn. Figure 3 shows FlexKVS throughput when the entire hot set shifts two minutes into the run. HeMem-NEMO recovers within 67 s, bounded by HeMem's migration bandwidth. HeMem-PEBS takes 324 s at HeMem's default 0.02% sampling rate. With PEBS, time to convergence depends strongly on the sampling rate (Figure 4): low rates reduce CPU cost but delay detecting the new hot set, while high rates improve timeliness at the expense of substantial sampling overhead. Raising the sampling rate beyond 1% is not feasible because it degrades application performance, as shown by prior work [73]. Due to this tradeoff, the gap between HeMem-NEMO and HeMem-PEBS cannot be closed, even in the limit. NEMO eliminates the tradeoff by offloading observation to the memory controller, providing full-fidelity hotness signals at 0.89% CPU overhead.

Value size sensitivity. Figure 5 shows FASTER KV throughput as we vary value size. For small values, HeMem-NEMO and HeMem-PEBS perform similarly: many objects fit in each huge page, so accesses are effectively uniform at page granularity and there is little page-level hot-set signal to exploit. As value sizes grow, HeMem-NEMO performance improves while HeMem-PEBS stagnates. Accesses to larger values become increasingly prefetch-friendly. These prefetches generate DRAM traffic but do not produce PEBS samples [27]. PEBS misses several types of traffic, including prefetches and non-temporal accesses; in contrast, NEMO captures all memory traffic.

With larger values with NEMO, a few hot values dominate each page. NEMO's per-hugepage counters accurately capture this skew, allowing HeMem-NEMO to keep the working set in the fast tier. Overall, NEMO enables higher throughput for skewed, large-value workloads without tuning sample rates or incurring higher CPU overhead.

5.2 THP Page Split Candidate Selection

We next evaluate NEMO on a tiering system that supports transparent huge page splitting. Linux transparent huge

page system (THP) [58] automatically coalesces base pages into 2 MiB huge pages to reduce TLB pressure and page-management overheads. However, THP can cause *hugepage bloat* [35,36,38]: workloads that touch only a few base pages within each hugepage still pin the entire 2 MiB in the fast tier. In tiered memory, where fast-tier capacity is scarce, splitting a *skewed* hugepage, whose accesses are concentrated on a small subset of base pages, allows hot base pages to remain in the fast tier while demoting cold base pages to the slow tier, freeing space for other hot data. We evaluate the benefits of using NEMO to reduce hugepage bloat in a tiered memory system: NEMO finds 2× more page-split candidates with up to 10.4× reduction in detection time, with up to 1.13× better application performance.

NEMO integration. We integrate NEMO into MEMTIS [36], a memory tiering system that modifies Linux v5.15 to support hugepage splitting. Our integration uses the telemetry described in Section 3.3 to simultaneously track hugepage access counts and skewness. Instead of processing PEBS samples, MEMTIS-NEMO reads hugepage access counters directly from NEMO and applies its original policy: MEMTIS ranks pages by access count and classifies the highest-ranking pages that fit in the fast tier as hot. In our prototype, NEMO sees only CXL-attached memory, so we retain MEMTIS's original PEBS-based mechanism for the local DRAM tier.

Because NEMO's SRAM capacity limits the number of basepage counters, we time-multiplex skewness tracking across hugepages. Our telemetry instantiates eight NEMO pipelines: one tracks hugepage access counts and seven each track 16 hugepages at basepage granularity, allowing skewness tracking for 112 hugepages simultaneously. MEMTIS-NEMO extends MEMTIS's mechanism of grouping hot and cold pages with Linux's active/inactive LRU lists. Every 500ms, MEMTIS-NEMO reuses MEMTIS's PEBS sampling thread to program NEMO to track the next 112 hugepages from one of the two lists, using `reprogram()` from Listing 1. Scanning the inactive list is necessary because a hugepage that looks cold overall can still contain hot basepages; consecutive scans alternate between the active and inactive lists. The basepage counters then feed MEMTIS's skewness score. A full sweep takes $(|\text{active}| + |\text{inactive}|)/112 \times 500\,\text{ms}$; §6.1 analyzes how this time-multiplexing approach scales with memory size.

Evaluation setup. To stress fast-tier memory efficiency, we vary the fast-to-slow memory capacity ratio from 1:2 to 1:8. As the fast tier becomes more constrained, the penalty of not splitting skewed hugepages increases, since promoting an unsplit skewed hugepage consumes a disproportionately large share of fast-tier capacity. Our question is whether MEMTIS-NEMO's benefit grows as the fast tier shrinks, because NEMO can identify skewed pages to split more accurately and quickly.

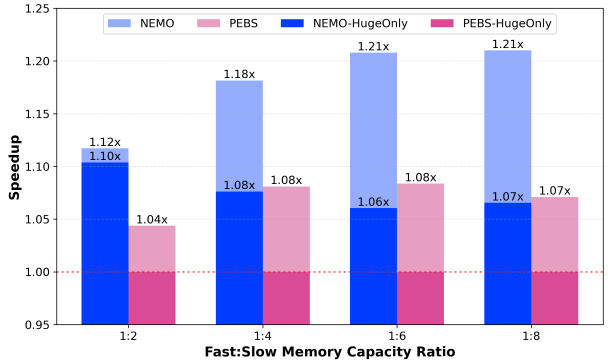
Our prototype can only observe telemetry over CXL memory, so memory allocated to the fast tier and never migrated would not be visible to NEMO. To give NEMO an opportunity to collect telemetry on all pages, we cap the application's memory usage at 16 GiB (the CXL capacity in our prototype) and modify MEMTIS-NEMO to allocate from CXL first and pin memory on CXL for 180 seconds. This is a conservative setup for MEMTIS-NEMO: MEMTIS-PEBS allocates from the fast tier by default and begins migrating immediately, giving it a 180-second head start. Our experiment uses Silo [59], an in-memory database engine. Following prior work [36], we run the YCSB-C workload [16] with a Zipfian distribution, 90M keys, and key and value sizes of 64 B and 100 B, respectively. We confirm that Linux THP allocates over 99% of Silo's memory on huge pages. We run Silo for 1,500 seconds on 20 CPU cores and report performance after a 500-second warmup period, allowing application performance to stabilize after migration and page splitting.

5.2.1 Results

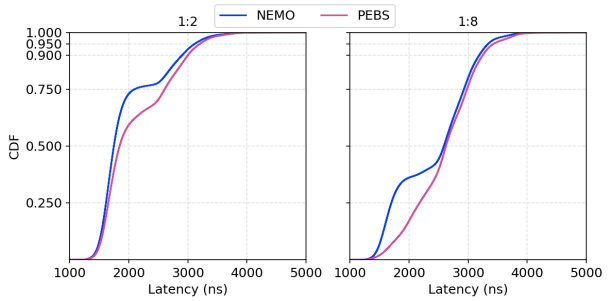
Silo performance. Figure 6a shows Silo's throughput speedup when using MEMTIS-NEMO. We also report the performance with page-splitting disabled (labeled NEMO-HugeOnly) to isolate the benefits of NEMO's skewness telemetry from the benefits of its hugepage access count telemetry. The figure is normalized to MEMTIS-PEBS with page-splitting disabled (i.e., only uses transparent hugepages).

When fast tier memory is abundant (1:2), NEMO shows little benefit in page splitting, because NEMO's high fidelity telemetry already identifies better page promotion candidates than PEBS due to the lack of sampling. The gap between NEMO and NEMO-HugeOnly widens as fast tier memory becomes smaller (1:4 to 1:8), showing that NEMO's page splitting telemetry helps MEMTIS use fast tier memory more efficiently by splitting and promoting hot basepages. MEMTIS-NEMO outperforms the PEBS-based baseline across all fast-to-slow memory ratios, with larger performance improvements as fast tier memory becomes more constrained. This is because NEMO identifies more than 2× the number of skewed pages than PEBS, allowing MEMTIS to pack more hot basepages into the fast tier. At the 1:8 memory ratio, Silo on MEMTIS-NEMO outperforms Silo on MEMTIS-PEBS by 13%.

Figure 6b shows that Silo benefits from better page placement decisions in MEMTIS-NEMO. As fast tier capacity becomes smaller (1:2 vs. 1:8), both MEMTIS-PEBS and MEMTIS-NEMO see higher latencies due to more accesses to slow tier memory. However, because NEMO identifies pages to split more effectively, MEMTIS can use the fast tier more efficiently by packing more hot basepages into the fast tier. This lowers Silo's latency across all percentiles compared to the PEBS baseline.



(a)



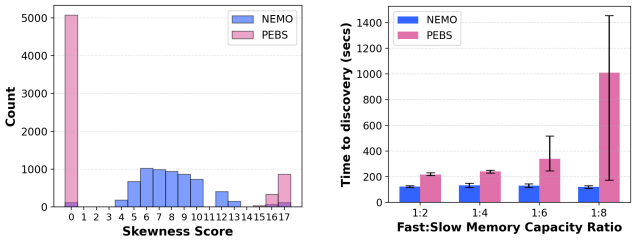
(b)

Figure 6: Silo performance under MEMTIS-NEMO and MEMTIS-PEBS across fast:slow memory ratios (1:2 to 1:8). Top: throughput speedup normalized to MEMTIS-PEBS without page splitting; NEMO-HugeOnly and PEBS-HugeOnly disable page splitting. Bottom: Silo latency CDF under 1:2 and 1:8 ratios.

Accuracy of page-split telemetry. Why is MEMTIS-NEMO's page-split telemetry more effective than MEMTIS-PEBS's sampling-based approach? MEMTIS ranks a huge page's skewness using a score computed from its base-page access counts: the more uneven the accesses, the higher the skewness score; if none of a huge page's base pages are hot, its skewness score is 0.

Figure 7a shows the distribution of skewness scores for all huge pages in Silo under the 1:8 fast-to-slow ratio, measured after each system reaches steady state. The distribution derived from PEBS is bimodal: most huge pages appear non-skewed (score = 0), while about 18% appear highly skewed (score $\geq$ 16). In contrast, NEMO yields a smoother distribution with far fewer zero-score pages and a broad spread of non-zero skewness values.

The PEBS distribution is distorted by sampling and cooling. MEMTIS periodically "cools" access counts by aging out old samples so that pages that no longer receive samples become cold, a standard technique in sample-based systems [36, 48]. Short cooling intervals improve responsiveness but give cold pages too few samples per interval, causing most hugepages



(a) (b)

Figure 7: Left: distribution of per-hugepage skewness scores under 1:8 memory ratio. Right: median time to identify 95% of page-split candidates over 5 runs; error bars show min/max.

to collapse to a zero skewness score; longer intervals allow counts to accumulate but hurt responsiveness to changes in access patterns, degrading application performance.

NEMO avoids this cooling trade-off. Since NEMO captures every cache miss to a tracked huge page, the policy can compute skewness directly from the per-basepage counts collected over a brief window (500 ms in our setup). The resulting telemetry reflects current access patterns without needing to age out stale observations. With NEMO, on this workload, skewness values span a wide range. NEMO enables MEMTIS to distinguish moderately from highly skewed pages and select splits more precisely.

Timeliness of finding page-split candidates. We now compare how quickly MEMTIS-PEBS and MEMTIS-NEMO discover split candidates. Using the same setup as the end-to-end experiment, Figure 7b reports the median time to identify 95% of all page-split candidates over five runs. We see that MEMTIS-NEMO's detection time is essentially independent of fast-tier size, because the number of candidates it can examine per unit time is tied to total physical memory, not to how much resides in the fast tier. In contrast, PEBS slows down and becomes more variable as the fast tier shrinks (e.g., 1:6 and 1:8 ratios). PEBS can quickly detect the most skewed hugepages (within roughly 250 seconds) but requires many more samples to classify moderately skewed pages. MEMTIS's dynamic PEBS sample rate adjustment, aimed at maintaining CPU overhead below 3%, produces large variance observed in sample rates for moderately hot pages in the 1:8 configuration. In contrast, since NEMO counts every access to tracked pages, it can compute accurate skewness for all candidates within about 150 seconds, yielding up to 10.4$\times$ detection speedup from PEBS.

CPU overhead. MEMTIS-NEMO incurs 3% overhead across all fast-to-slow memory ratios: 1.67% from NEMO processing and the rest from hot-tier PEBS sample gathering. MEMTIS-PEBS incurs 2.89% overhead.

```

  for (j = 0; j < tenant[i].n_hp; j++)
    nemo_set_translation(t,
        /*key=*/        tenant[i].hp_paddr[j] >> HP_SHIFT,
        /*region_idx=*/ i);
```

Listing 3: NEMO telemetry for per-tenant bandwidth estimation. Many hugepages map to one tenant state. The notify predicate triggers when the threshold is exceeded.

5.3 Noisy Neighbor Detection

We also evaluate NEMO on its ability to accurately detect noisy neighbor applications. We show that NEMO detects noisy neighbors with two orders of magnitude lower CPU overhead compared to the state-of-the-art.

Memory performance isolation remains challenging in virtualized environments. Tenants expect stable memory latency and bandwidth, but operators cannot observe VM-internal behavior. As a result, a background task such as garbage collection can temporarily saturate DRAM bandwidth and violate the SLOs of a colocated latency-sensitive service [18]. Achieving isolation first requires detecting when a tenant consumes excessive memory bandwidth—a *noisy neighbor*. Timely detection is crucial: any delay directly delays mitigation and exposes other tenants to performance loss. Existing approaches built on hardware performance counters suffer from imprecise measurements, limited programmability, and high CPU overhead (§2.2). In contrast, NEMO can be programmed to attribute exact DRAM throughput to each tenant, enabling precise and timely noisy-neighbor detection [54].

NEMO uses the translation table to map all huge pages of a tenant to a single telemetry state. On each memory access, hardware increments this state, yielding a per-tenant count of DRAM accesses. The OS polls each counter every Δt milliseconds to compute bandwidth. When a tenant allocates or frees huge pages, the OS updates the translation table to preserve correct attribution. The administrator chooses Δt based on isolation needs; it can range from milliseconds to minutes. Finally, the OS installs a notification condition that raises an interrupt when a tenant's counter exceeds its bandwidth allocation. Listing 3 shows the telemetry: many-to-one translation maps every hugepage of a tenant to that tenant's state, the update operator sums accesses, and a $\geq$ predicate raises an interrupt on bandwidth-cap violation.

NEMO integration. We integrate NEMO with Linux cgroups to throttle noisy neighbors in software. A userspace QoS controller, modeled after node-level Kubernetes agents [34], monitors each tenant's NEMO bandwidth counter and adjusts its cgroup CPU quota to enforce a per-tenant bandwidth cap. We use cgroups as the actuation mechanism because they are ubiquitous in modern OSes and cloud platforms; we avoid Intel Memory Bandwidth Allocation (MBA) [22], whose throttling behavior is inaccurate in our measurements and prior work [53, 65]. The controller implements a simple feedback loop: every epoch it reads per-tenant counters, maintains an exponentially weighted moving average of bandwidth, and proportionally increases or decreases CPU quota based on the gap to the target bandwidth, using a learning rate to dampen adjustments, similar to prior regulators [18, 65, 70]. To reduce detection latency and CPU overhead, it also relies on NEMO notifications to react immediately when a tenant exceeds its allocation. Our prototype currently tracks bandwidth only for CXL-attached memory, so we restrict allocations to CXL. Finally, we use emulated NEMO notifications as detailed in §4.

Evaluation setup. As a baseline, we use Intel Memory Bandwidth Monitoring (MBM) counters via the PQoS library [30]; PMU-based schemes are less suitable due to inaccuracy and limited virtualization support (§2.1). In both cases, a userspace controller periodically polls per-tenant bandwidth counters and adjusts Linux cgroup CPU quotas to enforce a per-tenant bandwidth cap, varying the polling interval to explore the tradeoff between CPU overhead and reaction time. Our workload consists of a latency-sensitive victim, FlexKVS [31], and a single-core synthetic noisy neighbor that uses non-temporal stores to saturate memory bandwidth. The noisy neighbor alternates every 0.5 s between high-bandwidth execution and sleep, and is configured with a target cap of 1 GiB/s (~5% of our prototype's peak bandwidth).

5.3.1 Results

Bandwidth telemetry accuracy. We first run the noisy neighbor in isolation and compare bandwidth reported by MBM and NEMO against an application-level estimate. We approximate the application's true DRAM bandwidth by summing its non-temporal (NT) store volume. Across three 30-second runs, both NEMO and MBM closely match this NT-derived ground truth, with reported bandwidths within 0.1%.

Noisy neighbor throttling efficacy. Next, we co-locate the victim and noisy neighbor, throttling the noisy neighbor using either NEMO or MBM telemetry, and compare against two baselines: the victim alone and the victim with an unthrottled noisy neighbor. Figure 8 shows the resulting FlexKVS latency CDFs. With an unthrottled noisy neighbor, FlexKVS p99 latency increases by ~22%. With throttling based on NEMO

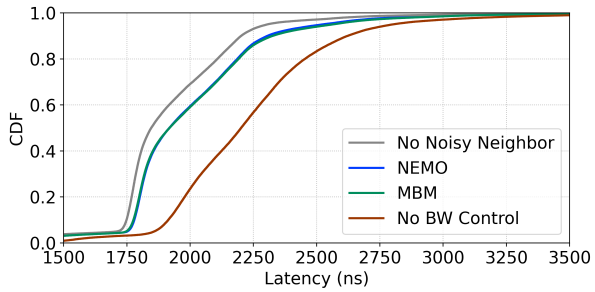

Figure 8: FlexKVS latency CDF using different telemetries for noisy neighbor detection and throttling. NEMO and MBM show equivalent detection capabilities when MBM uses a 1000Hz polling frequency (consuming 30%+ CPU overhead).

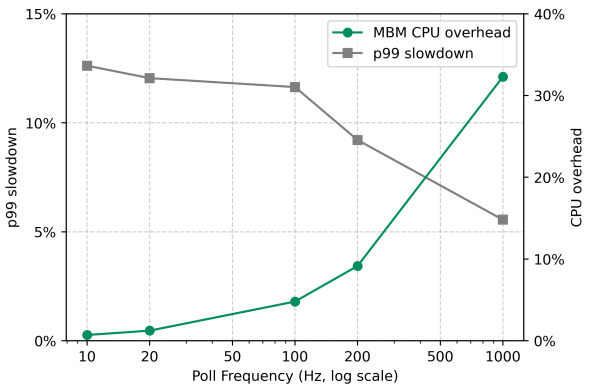

Figure 9: MBM p99 slowdown and CPU overhead vs. polling frequency.

and MBM, the p99 increase shrinks to 5.2% and 5.5%, respectively. In both cases, efficacy is ultimately limited by cgroups' actuation latency (~10 ms).

CPU overhead. Polling more frequently improves reaction time but increases overhead, so for MBM we vary the polling interval from 1 ms to 100 ms. Figure 9 shows the trade-off. At a 100 ms polling interval, MBM consumes only 0.7% of a core but reacts slowly, leading to a 13% increase in p99 latency. At a 1 ms interval, MBM reduces the p99 increase to 5.5% but raises CPU overhead to 32%. In contrast, NEMO achieves similar throttling effectiveness with only 0.09% CPU overhead. NEMO's notification mechanism triggers immediate reaction when a tenant exceeds its bandwidth allocation; the controller clears NEMO counters at a 50 ms interval in our setup.

6 Discussion

The preceding sections show that MC-resident telemetry can provide OS policies with timely, low-overhead memory signals. We now discuss three implications of the design: telemetry scalability with SRAM-backed state, the threat model under bare-metal and virtualized deployments, and how chained pipelines can extend NEMO to support more use cases.

6.1 Telemetry Scalability

The granularity of NEMO telemetries scales with on-chip SRAM, depending on the number of translation table entries and the amount of telemetry state. Many use cases rely primarily on one or the other resource, balancing SRAM utilization. Coarse telemetries (per-tenant bandwidth, §5.3) use many translation entries mapping into few states. Fine-grained telemetries (per-basepage skewness, §5.2) use fewer translation entries but many states per region.

Telemetry time multiplexing. When regions of interest exceed the resident SRAM budget, the OS can time-multiplex telemetries by reprogramming translation table entries between scans. Below we compute the *sweep time* T_{sweep}, the time to visit every telemetry region once under uniform coverage (the worst case; in practice, skewed access patterns and hot-region prioritization yield shorter effective sweeps). With P pipelines, S states of width W at G-byte granularity, and scan period τ, sweeping an M-byte region takes

$$T_{\text{sweep}} = \frac{M \times \tau}{P \times S \times G}.$$

Substituting $|\text{SRAM}| \approx P \times S \times W$ to utilize all available SRAM, this becomes

$$T_{\text{sweep}} = \frac{M \times \tau \times W}{|\text{SRAM}| \times G}.$$

Scaling implications. The formula has two scaling implications. First, the DRAM (M) to SRAM ($|\text{SRAM}|$) ratio sets the area-vs-timeliness trade-off. Second, counter width W is a knob orthogonal to coverage. At a fixed SRAM budget, halving W doubles the number of states and proportionally halves T_{sweep}. In our MEMTIS-NEMO prototype ($P=7$, $S=8{,}192$, $G=4$ KiB, $\tau=500$ ms), 1.4 MiB of telemetry SRAM covers 16 GiB DRAM at $T_{\text{sweep}} \approx 37$ s. At constant ratio, a 1 TiB tier needs ~90 MiB, on the same order as on-die SRAM for datacenter SoCs [4, 25]. Unlike CPU caches, NEMO uses SRAM in less area-constrained sites like the uncore (for IMCs) or controller ASICs (for CXL MCs). The prototype's $W=8$ B is conservative for our 500 ms scan; 1–4 B counters would shrink either the SRAM or T_{sweep} by 2–8×. Better encoding lowers the bit width W required per counter; for example, a saturating overflow bit for very hot data is sufficient to distinguish very hot counters, with remaining bits spent discriminating among warm and less-warm counters.

6.2 Security

NEMO's trusted computing base consists of the MC hardware and the NEMO driver in the OS or hypervisor kernel. We assume that telemetries are configured by a privileged operator. The NEMO driver validates each translation entry against the MC's physical address ranges, reusing the kernel's page-ownership checks to decide which pages each telemetry covers. In a virtualized setting, a paravirtualized interface lets a guest OS request telemetries over its memory. The hypervisor validates each request against the guest's allocated ranges and never exposes another guest's pages.

The hardware path adds no observable timing channel. Under both bare-metal and virtualization, the MC observes only request metadata (address and R/W type) for OS-registered pages, and the match-update pipeline runs with fixed overhead off the data path, so memory access latency is independent of NEMO's state. Side channels outside the MC (cache and DRAM timing) are unaffected.

6.3 Supporting Complex Telemetries

NEMO's pipeline performs one bounded update per request, keeping hardware simple and at line rate but ruling out telemetries needing cross-state reads or multi-step computation. A natural extension chains pipelines so one's output feeds the next (analogous to multi-stage match-action in RMT [11] switches) to express richer telemetries while preserving fixed-cycle stages. For example, approximate frequency sketches such as count-min [69] help when per-region tracking exceeds the SRAM budget: each chained pipeline holds one of the sketch's k counter arrays, and in its match stage a single-cycle hash (e.g., multiply-shift) projects each address onto that array, a small extension to the existing mask-shift key derivation. Querying a region's frequency hashes its address k times and takes the minimum across arrays. Each chained pipeline retains bounded per-request work at line rate.

7 Related Work

Hardware memory telemetry. Recent works have explored gathering telemetry directly from the memory controller [40, 47, 50, 52, 55, 73], employing different techniques (e.g., count-min sketches [55, 73] or Majority Element Algorithm [47]) for different use cases (e.g., tiered memory [55,73], disaggregated memory [40]) and memory technologies (e.g., 3D-stacked [40, 55]). While these designs demonstrate the value of in-memory telemetry, they lack flexibility because the telemetry is fixed at hardware design time. In contrast, NEMO enables the OS to define and install custom telemetry to MCs, achieving both flexibility and coverage.

OS-inferred memory telemetry. The OS can infer memory access patterns from hardware-generated signals, such as page access tracking via soft page faults [1, 5, 8, 33, 43, 61], page table scanning [1,17,29,42,67] or sampling-based approaches using PMUs [17, 36, 48]. These approaches provide flexibility but necessarily are limited because of high CPU overhead. NEMO offers an alternative by allowing the OS to install use-case-specific telemetries to memory controllers, achieving flexibility and high coverage with low CPU overhead.

Memory programmability. Prior works have explored introducing programmability to memory controllers. These works can alter the memory request (address or data), the request schedule, or DDR commands to improve application performance [9, 13], energy efficiency [9], fault tolerance, QoS [41], or for prototype exploration [21]. Beyond the memory controller, täkō [51] proposes a polymorphic cache hierarchy that executes software callbacks to transform data or alter traversal paths. Relative to these proposals, NEMO is simpler. It performs passive monitoring off the MC data path, making it lightweight and deployable.

Line-rate programmability. For network protocol stacks, the Reconfigurable Match-Action Table (RMT) architecture [11] and the P4 programming model [10] enable line-rate configurable dataplane actions. Operators often use these for telemetry [20, 32, 44, 45]. Inspired by these works, NEMO occupies a distinct design point: HW/SW codesign to provide high-fidelity telemetry on MCs for diverse OS use cases.

8 Conclusion

Server memory hierarchies demand high-fidelity, low-overhead telemetry, but existing techniques are often heavyweight, coarse, noisy, or fixed-function. NEMO addresses this gap by augmenting memory controllers with a small, flexible, off-data-path match-update-notify pipeline and per-controller SRAM state. Together with an OS-facing programming model and driver, OS kernel subsystems can define what to track and at which granularity. Using our CXL-based FPGA prototype, we show that this model improves the efficiency, accuracy, and responsiveness of tiering, huge-page splitting, and noisy-neighbor detection, outperforming state-of-the-art baselines within practical compute and SRAM budgets.

Abstract

Hardware and OS mechanisms for memory tiering are widely deployed, yet datacenters still overprovision DRAM. The root cause is *hotness fragmentation*: allocators place objects by size rather than access pattern, so hot and cold objects become interleaved within the same pages. A single hot object marks its page as active, trapping surrounding cold data in expensive DRAM. Our analysis of Google datacenter workloads shows that up to 97% of the bytes in active pages are cold and unreclaimable. We propose *address-space engineering*: dynamically reorganizing virtual memory so that hot objects cluster into uniformly hot pages and cold objects into uniformly cold pages. We present *OBASE*, a compiler-runtime system for unmanaged languages that serves as an object-aware *frontend* for page-aware OS *backends*. *OBASE* tracks accesses via lightweight pointer instrumentation and migrates objects at runtime using a lock-free protocol that is safe under concurrency. By reorganizing the address space, *OBASE* enables unmodified backends (kswapd, TMO, TPP, Memtis) to tier memory effectively. Across ten concurrent data structures, six backends, and production traces from Meta and Twitter, *OBASE* improves page utilization by 2–4× and reduces memory footprint by up to 70%, with only 2–5% overhead.

1 Introduction

Memory capacity, especially DRAM, has become the dominant cost driver in modern data centers, often accounting for 50% of server capital expenses [1, 49, 59]. Memory tiering promises a solution: by placing cold, less accessed data in cheaper, slower tiers—such as compressed memory, SSDs, or CXL-attached disaggregated memory [3, 4, 6, 11, 42, 43]—one could significantly reduce the expensive DRAM capacity required, thereby lowering costs [29, 44, 49, 56, 60, 62].

In principle, this approach shows great promise, primarily because in hyperscale workloads, only a small volume of memory is hot; the vast majority remains cold and un-accessed for extended periods. As shown in Figure 1, across six different Google workloads [13], only 1.7%–21.3% of bytes are accessed during the trace duration. Indeed, four of the six workloads access less than 3% of bytes, suggesting that we could reclaim 80% to 98% of DRAM for secondary tiers with minimal impact on application performance.

*Work done at Google

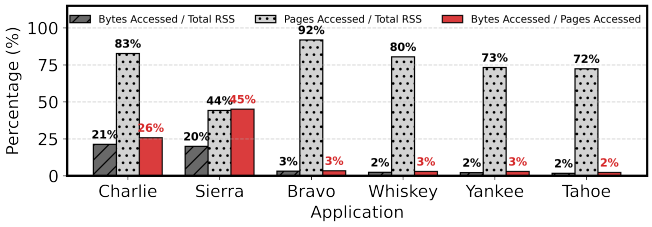

Figure 1. The granularity gap in memory access of Google workloads. Dark Grey: The percentage of total memory *bytes* actually accessed. Light Grey: The percentage of total memory *pages* accessed. Red: The page utilization (calculated as Bytes Accessed / Pages Accessed, see §2.2 for more details).

In practice, however, realizable gains often fall short of this potential. Google reported offloading only 20% of infrequently accessed data to a compressed memory tier [43], while Meta achieved similarly modest savings of 20–32% [62].

The crux of this gap lies in a mismatch between how applications organize data and how the OS manages memory: applications access data at *object* granularity, which varies in size, while the OS manages memory at fixed-size *page* granularity (4KB, 2MB, or 1GB) [20]. Modern allocators place objects on pages with no regard for how these objects will be accessed in the future, often placing frequently accessed objects and rarely touched objects intermingled on the same page. As a result, a few hot bytes (e.g., a single object) would make a whole page active from the OS's perspective, trapping the whole page in expensive DRAM. One can clearly see this phenomenon in Figure 1, where even though only 3.2% of *bytes* are accessed in a workload Bravo, 91.8% of the *pages* are accessed, making them unfit candidates for reclamation. Similar trends can be observed across all six workloads. We term this phenomenon **hotness fragmentation** and identify it as the root cause of inefficient tiering at hyperscalers. We quantify this fragmentation using the *page utilization* metric.

To combat hotness fragmentation, we introduce **address space engineering**, which *dynamically* reorganizes objects within the address space so that objects with similar access intensities are grouped together. By segregating hot and cold objects, address space engineering promises to close the gap between theoretical and realizable memory savings. It creates a memory layout with uniformly cold pages (or hot) that are significantly more amenable to tiering.

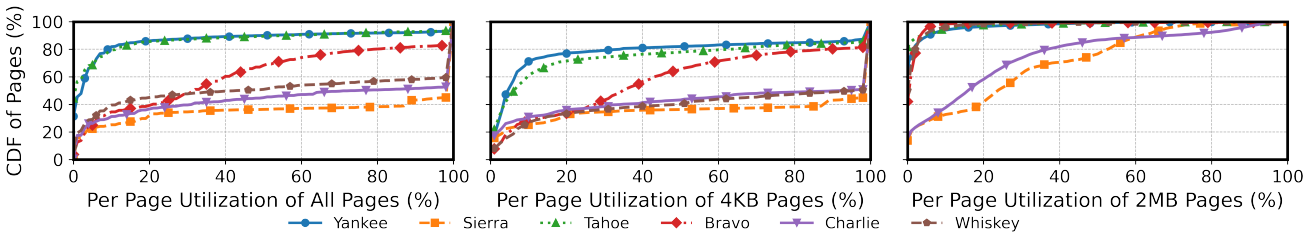

Figure 2. Low Per-Page Utilization in Google Data Center Workloads. CDFs of page utilization for six applications, shown for all pages combined (left) and separately for 4KB pages (center) and 2MB pages (right).

Crucially, by focusing on the address space *layout*, we decouple memory tiering into two orthogonal concerns, allowing independent innovation within each: the *layout* (frontend) problem, which organizes objects to yield high-quality page candidates for reclamation; and the *reclamation* (backend) problem, which focuses on migration policies and mechanisms across different tiers. This separation allows us to reuse existing page-based tiering infrastructures—both swap-based [43, 62] and byte-addressable [44, 49, 56]—and leverage future improvements in reclamation mechanisms. It also ensures that our layout optimization techniques remain applicable to future, currently non-existent memory tiers (e.g., CXL 3.0 fabrics or NVM). Further, it significantly lowers the adoption barrier for hyperscalers: rather than requiring changes to their existing tiering backends, address space engineering provides a superior memory layout that makes existing backends work more effectively.

In this paper, we present ***O*bject-*B*ased *A*ddress-*S*pace *E*ngineering (*OBASE*)**, a compiler-runtime system that engineers the address space for *unmanaged* languages like C/C++. *OBASE* acts as an intelligent *frontend* for memory organization: it manages pointer-based data structures, transparently profiles object access using lightweight instrumentation to determine access intensity, and employs a novel lock-free protocol to migrate objects safely, clustering hot and cold objects together. As a result, *OBASE* prepares the memory layout for any OS *backend*, enabling them to work more effectively. *OBASE* preserves a familiar programming model: developers annotate which pointer fields may relocate, and the compiler routes their accesses through guides. This does require giving up two assumptions (stable object addresses and pointer arithmetic over managed objects) and applies to pointer-based structures rather than arbitrary code; we make this boundary explicit in §7.

We evaluate *OBASE* with ten concurrent pointer-based data structures and six state-of-the-art reclamation and tiering backends [17, 44, 49, 60, 62]. Using key-value store workloads (YCSB) and production traces (Meta, Twitter), we demonstrate that *OBASE* improves page utilization (by 2–4×) and achieves higher memory savings (up to 70%) at the same performance overhead, or conversely, achieves equivalent savings with negligible performance impact. For tiered-memory configurations, *OBASE* achieves the same throughput with half the DRAM capacity.

2 Case for Dynamic Object Reorganization

In this section, we show that hotness fragmentation is both severe and unavoidable under static object placement. We introduce a metric to quantify fragmentation, analyze data center traces from Google [13], and demonstrate that object hotness changes continuously over time. Finally, we explain why unmanaged languages make dynamic reorganization especially challenging, motivating the design of *OBASE*.

2.1 Page Utilization: A Metric

The OS marks a page as "active" if it receives at least one access during a time window T. We define *per-page utilization* as the fraction of a touched page's capacity that is actually accessed. Let $P(T)$ be the set of touched pages during T, and let $U(p,T)$ be the number of unique bytes accessed within page p during T. We then define the aggregate *page utilization* as:

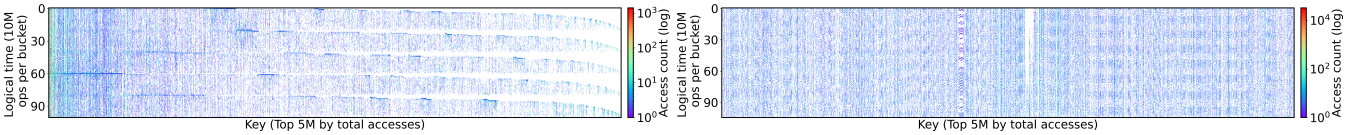
$$\text{Page Utilization}(T) = \frac{\sum_{p \in P(T)} U(p,T)}{\sum_{p \in P(T)} \text{Size}(p)}$$

Low utilization means a page appears hot to the OS even when most of its bytes are cold. Previous work [21] demonstrated low page utilization for open-source databases (e.g., Redis, MongoDB) where 75–90% of accessed pages utilized less than 15% of their capacity for YCSB workloads.

2.2 Fragmentation in Data Center Workloads

To understand hotness fragmentation across a broader range of applications, we analyze memory access traces from six data center workloads at Google [13], collected using DynamoRIO [12]. We process each unique access, annotate pages as 4KB or 2MB using `/proc/self/smaps`, and count unique 64B cache lines touched per page. Based on instruction counts, core counts, and typical warehouse-scale CPU characteristics [41], we estimate the traces capture up to ~30s of steady-state execution.

Figure 2 shows the cumulative distribution of per-page utilization for all workloads, ordered as: (a) aggregated across both 4KiB and 2MiB page sizes, (b) 4KB pages only, and (c) 2MB pages only.



(a) Meta KV Trace. White horizontal bands indicate coordinated quiet periods where access drops across many keys. These bands reveal phased workload behavior.

(b) Twitter Trace. A sparse, scattered pattern indicates sporadic hotness. A few keys on the far left remain consistently hot, but the majority exhibit bursty access with long idle gaps.

Figure 3. Temporal Evolution of Key Hotness. Heatmaps showing access frequency (log scale) for the top 5M keys over logical time buckets (10M operations each). If hotness were static, we would observe continuous vertical bands on the left side of each plot. Instead, we see shifting phases (Meta) and intermittent bursts (Twitter), demonstrating that the hot working set evolves continuously.

Aggregated view. Aggregated across both page sizes, all six workloads show populations of poorly-utilized pages. Yankee and Tahoe are the most fragmented: median utilization is around 3%, meaning half of their touched pages waste over 95% of capacity on cold data. Bravo follows with a median near 35%. The remaining workloads have higher overall utilization but still carry long left tails: roughly 25–30% of pages in Sierra, Charlie, and Whiskey use less than 20% of their capacity. Page-based reclamation cannot distinguish these poorly-utilized pages from well-utilized ones without object-level information.

4KB pages. Fragmentation is visible even at the smallest page size: for Tahoe and Yankee ~80% of pages fall below 20% utilization, for Bravo 60% fall below 40%, and Charlie, Whiskey, and Sierra have 35–40% of pages below 40%. Hotness fragmentation is thus inherent to access patterns, not merely an artifact of huge pages.

2MB pages. Fragmentation worsens dramatically for huge pages. Tahoe, Bravo, and Yankee are extreme: 85–90% of their huge pages utilize under 10% of their 2MB capacity, and even Sierra has 40% below 20%. Each such page, consuming 512× a base page, holds over 1.8MB of cold data alongside a few accessed cache lines.

Finding 1: *Active pages are mostly cold: 70–90% of bytes in pages the OS considers hot receive no accesses.*

2.3 Object Hotness Changes Over Time

One potential solution for hotness fragmentation is to segregate hot and cold objects at allocation time, using static hints or profiling [40]. This strategy assumes that hotness is both identifiable at allocation time and relatively stable afterward.

First, identifying hotness at allocation time is challenging because the same code path allocates objects with vastly different lifecycles. For example, in Redis and Memcached, a single `SET` handler allocates memory for all incoming records, yet one record might be a session token accessed every millisecond, while another is a user profile never touched again. Static analysis cannot distinguish these cases at allocation time. Second, this approach assumes that object hotness is relatively stable: objects identified as hot when allocated will remain hot throughout their lifetimes.

We show that these assumptions do not hold. We analyze object-level traces from Meta [22] and Twitter [65], which record operations in logical time (10M operations per bucket). Figure 3 visualizes access intensity for the top 5 million keys (ranked by total accesses) over 100 such buckets. If hotness were static, the most popular keys (left) would exhibit continuous vertical bands. Instead, both traces show significant churn: bursts of activity followed by long idle gaps.

Meta: Phased hotness. The Meta workload shows coordinated phases where many keys become inactive at once, visible as white horizontal bands. Even keys that are repeatedly accessed overall alternate between active bursts and extended dormancy. A page packed with currently-hot objects eventually becomes a page dominated by cold objects as access patterns shift.

Twitter: Sporadic hotness. The Twitter workload shows a sparse pattern. A small slice of keys remains consistently hot, but the majority exhibit brief access bursts separated by long idle gaps, even among the top 5 million keys.

To quantify churn, we measure reuse-distance variability (75th to 25th percentile of number of operations between accesses to the same key). For mid-sized objects (64B–4KB), representing 94% of Meta keys and 98.2% of Twitter keys, 75% of keys have a reuse spread exceeding 5×, and 65% exceed 30×. Thus, access gaps for the majority of keys fluctuate by more than an order of magnitude.

Finding 2: *Hotness is transient; object hotness is neither knowable at allocation time nor stable over time. As a result, one-time placement cannot prevent hotness fragmentation, and dynamic object migration based on changing hotness is required.*

2.4 Object Mobility in Unmanaged Languages

Moving objects dynamically presents varying degrees of difficulty depending on the language runtime. Managed runtimes, such as the JVM and Go, can relocate objects during garbage collection by updating references atomically, making mobility relatively straightforward. In unmanaged languages like C++, however, programs assume that an object's address is stable [23], rendering dynamic object migration significantly

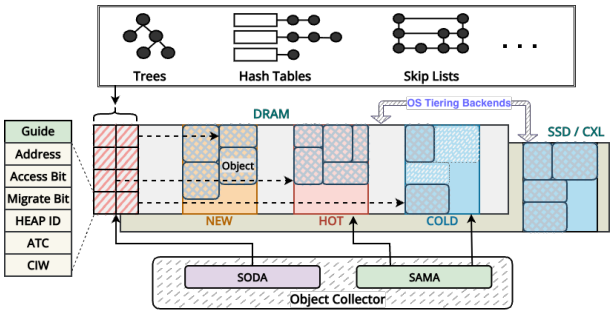


Figure 4. *OBASE* Overview. *OBASE* acts as a frontend that organizes the virtual address space into hot and cold regions. The Object Collector monitors access via Guides and SODA, migrates objects using SAMA, and presents a re-organized address space to the OS backend.

more challenging. Thus, the challenge is not merely to reorganize the layout dynamically, but to do so without breaking program correctness under aliasing and concurrency.

n this paper, we demonstrate how to enable object mobility in *unmanaged* languages specifically because of this challenge. We show that address-space engineering is achievable in C++, where stable addresses are the default assumption, by routing accesses through an indirection rather than preserving the address itself; techniques proven in this setting generalize naturally to managed runtimes.

To make the problem tractable in an unmanaged context, we focus on **pointer-based data structures**, where elements are accessed indirectly through pointers. These structures are ubiquitous in memory-intensive applications (Table 2). Rather than attempting to intercept arbitrary raw-pointer dereferences, which is intractable in C++, we route accesses to relocatable objects through an explicit indirection object (a *guide*, §3.2) that the application uses in place of a raw pointer. When an object moves, the system redirects the guide to its new location transparently. This mechanism must operate safely in highly concurrent environments, without resorting to coarse-grained locks or stop-the-world pauses that would negate the performance benefits of an improved memory layout.

In § 3, we show how *OBASE* provides this transparency and concurrency within the C++ execution model, enabling dynamic reorganization.

3 *Object-Based Address-Space Engineering*

Our goal is to engineer an application's address space so that page-based backends can efficiently reclaim or tier memory. *OBASE* achieves this by reshaping object placement: cluster hot objects into dense regions to increase page utilization, and segregate cold objects into separate regions to expose large pools of reclaimable memory.

OBASE operates in environments where the operating system manages memory in page-sized units and may migrate pages across tiers [20, 42, 43, 58]. The design does not assume a particular tiering policy or memory hierarchy; it only assumes that backends observe per-page activity. By presenting backends with regions that are uniformly hot or cold, *OBASE* allows existing mechanisms—from traditional page reclaim (kswapd, zswap) to tiering engines (such as TMO, TPP, Memtis, and HeMem)—to make better decisions without becoming object-aware [43, 44, 49, 56, 62].

Achieving object-level placement with page-level backends poses four challenges: **(C1) object mobility**—C++ ties object identity to its address, so relocation must be transparent and safe under aliasing; **(C2) low-overhead tracking**—hotness classification must run in the common path without degrading performance; **(C3) dynamic adaptation**—hotness shifts continuously (§2.3), so the layout must evolve; and **(C4) safe concurrent migration**—objects must move without global pauses even while threads hold pointers to them.

3.1 System Overview

OBASE's design rests on separating the *layout* problem (organizing objects so pages contain uniformly hot or cold data) from the *tiering* problem (deciding which pages to evict and where to put them). We call systems addressing the layout problem *frontends* and those addressing reclamation *backends*: existing tiering systems like Kswapd, TPP, Memtis, and TMO are backends that assume the layout is given. *OBASE* is a frontend that takes responsibility for layout so any backend can operate on uniformly hot or cold pages.

The following subsections describe how *OBASE* enables object mobility (§3.2), tracks accesses efficiently (§3.3), organizes the address space (§3.4), and migrates objects safely under concurrency (§3.5).

Figure 4 illustrates the architecture. *OBASE* runs in a continuous control loop. All dereferences of managed objects pass through a lightweight *guide* abstraction, which records whether an object was accessed recently. A background *Object Collector (OC)*, periodically processes this metadata to classify objects by access activity and decide whether they should reside in the NEW, HOT, or COLD heaps. Based on this classification, the OC reorganizes the address space by migrating objects between heaps using a safe, lock-free protocol based on *Active Thread Counts (ATC)*. Finally, *OBASE* exposes these organized regions to the OS through a *Spatially-Aware Memory Allocator (SAMA)*, which lays out each heap as a contiguous virtual range, enabling coarse-grained OS hints. This control loop ensures that the virtual address space continuously adapts to the application's shifting working set while presenting page-based backends with clear hot and cold targets.

3.2 Object Mobility in Unmanaged Languages

OBASE decouples an object's logical identity from its location using a lightweight *guide* abstraction. A guide carries the current location of the object as well as additional metadata needed by *OBASE*. Developers interact with objects by using guides rather than raw pointers. When a guide is dereferenced, *OBASE* resolves it to the object's current address and

records that the object was accessed (described in §3.3). The indirection layer is the mechanism that makes later relocation transparent; code that previously operated on pointers continues to operate on guides.

Developers choose which pointers can participate in relocation by marking them with annotations (e.g., the pointers to keys and values in hash-table buckets or the record pointers in B+ trees). In practice this annotation is small: for the ten data structures in our evaluation (Table 2), each managed type carries one to three relocatable pointer fields (typically the structure's authoritative child) while container algorithms and client code are untouched. Guides are enforced through three compiler passes (detailed in §4.7). A type-level pass identifies annotated pointers and rewrites their dereferences to invoke the guide. An instrumentation pass injects hooks at access sites so *OBASE* can observe uses without modifying application logic. A validation pass ensures that managed objects are not used in unsupported ways (e.g., pointer arithmetic over nodes or assumptions about physical contiguity). These passes allow developers to adopt *OBASE* incrementally, starting with the portions of a codebase where object residency matters most.

The division of labor is deliberately narrow: the *developer* marks a small set of pointer fields and guarantees that no unannotated raw pointer aliases a managed object; the *compiler* performs everything else: rewriting declarations and dereferences, and inserting the tracking hooks. An annotated guide carries unique ownership of its object, analogous to `std::unique_ptr`: *OBASE* updates that single guide when relocating, and does not track hidden aliases, so structures that share a node through multiple pointers (e.g., graphs, doubly-linked lists) are out of scope. The validation pass rejects pointer arithmetic and physical contiguity assumptions over managed objects rather than silently miscompiling them. A raw pointer obtained from a guide dereference (e.g., held in a register) remains valid for the duration of the enclosing public operation, because that operation keeps the object's active-thread count above zero and thereby vetoes any concurrent migration (§3.5); callers must not cache such pointers beyond the operation.

Two further programming-model restrictions keep these invariants intact under concurrent migration. First, the `Guide<T>` type appears only inside the data structure's implementation, where Pass 2 rewrites the developer-marked pointer fields (§4.7); it does not appear in calling code. Second, guides do not cross the data structure's public boundary as parameters or return values; they are held as internal fields, and callers interact through primitive-typed APIs (e.g., `HashMap::get(int idx)` in Figure 7). Together these ensure that every guide dereference is reachable from a public-method entry whose TAG participates in the migration protocol.

3.3 Low-Overhead Access Tracking

To classify objects by temperature, *OBASE* must observe which objects are accessed over time, but tracking must be cheap enough to run continuously. Existing mechanisms fall short at both ends of the spectrum. Hardware page table access bits operate at page granularity and cannot distinguish a few hot cache lines from megabytes of cold data on the same page [8, 43]. Software profilers such as DynamoRIO and LLVM's memory profiling provide fine-grained information but impose prohibitive overheads for always-on deployment [12, 14]. Hardware sampling via PEBS offers lower overhead but provides statistical coverage rather than precise per-object tracking [7].

Instead, *OBASE* embeds access tracking directly into guide pointer dereferences, yielding object-level information without significant overhead. A guide overloads the dereference operator so that each access records that the underlying object was used. Modern 64-bit architectures reserve high-order address bits in canonical user-space pointers, so *OBASE* stores a small amount of per-object metadata in these unused bits [16]. Inline metadata avoids external side tables and ensures that recording access is part of normal pointer use.

Metadata is updated on every dereference using a single atomic read–modify–write (RMW): an `accessed` bit is set if it has not already been set, thereby skipping subsequent updates to avoid unnecessary cache-coherence traffic for frequently touched objects. This design keeps the common path small, and the resulting per-access cost is comparable to a cache hit. The metadata also holds state used by the runtime to classify objects or coordinate relocation, without requiring separate allocations or indirection.

To let the runtime observe all managed objects without walking application-specific pointer graphs, *OBASE* maintains a Sparse Object Data Activity (SODA) bitmap (§4.3) over the process heap. SODA records which virtual regions contain managed objects and enables the Object Collector (OC) to discover objects by scanning these regions rather than interpreting container internals.

3.4 Dynamically Engineering the Layout

The access signals from §3.3 feed into a layout policy that continuously reorganizes the virtual address space. OBASE groups objects by observed temperature so that page-based backends see large, uniform regions rather than interleaved hot and cold data. Three logical temperature heaps capture this temperature: NEW holds freshly allocated objects whose access pattern is not yet clear, HOT holds the current working set, and COLD holds objects inactive for multiple scan periods. Each heap occupies a dedicated virtual address range, so an object's address directly encodes its temperature.

Objects move between heaps as access intensity changes (Figure 5): inactive HOT objects are demoted to COLD, and COLD objects that become active again are promoted back.

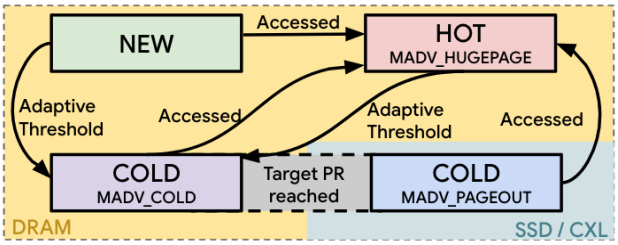

Figure 5. Object Migration State Diagram. Objects transition between heaps based on access intensity. The Object Collector promotes accessed objects to HOT and demotes inactive objects to COLD, allowing SAMA to apply different `madvise` policies to each region if required.

This continuous reclassification tracks the workload's evolving working set rather than its allocation history.

To realize these logical heaps in the virtual address space, *OBASE* employs a Spatially-Aware Memory Allocator (SAMA) that reserves a contiguous virtual address range for each heap and sub-allocates objects within that range. Contiguity is a deliberate design choice that allows coarse-grained OS hints to be applied to whole heaps rather than individual pages, exposing large pools of cold memory to page-based tiering systems. The Object Collector (OC) periodically scans SODA to classify each managed object. Objects touched since the last scan are candidates for promotion; objects that remain untouched accumulate evidence of coldness.

Reacting to a single inactive window would make classification sensitive to transient bursts. *OBASE* therefore tracks a per-object Consecutive Inactive Window(CIW) counter: each scan window without an access increments CIW; any access resets it to zero. Objects whose CIW exceeds a cold threshold become eligible for demotion to COLD; objects in COLD that are accessed rejoin HOT. This hysteresis ensures that only sustained inactivity triggers migration to COLD.

The cold threshold C_t governs how long an object must remain inactive before migration. Too aggressive and COLD objects are frequently re-accessed; too conservative and reclaimable memory lingers in HOT. *OBASE* adapts C_t using a promotion-rate target. We define the promotion rate (PR) as the fraction of the working set drawn from COLD heap in each scan window:

$$PR = \frac{\text{unique COLD pages accessed}}{\text{working set size}} \times \frac{60}{\text{scan interval (s)}}$$

Crucially, *OBASE* measures COLD-heap accesses regardless of where those pages physically reside—it cannot determine which tier a page occupies and does not attempt to. If the observed rate exceeds a target, C_t increases by one window; if below, C_t decreases. This additive adjustment converges to a workload-specific regime. The goal is not to minimize COLD-heap accesses, but to ensure that pages classified as COLD are *safe targets* for any backend policy. §4 details initialization and tuning.

By design, *OBASE* is decoupled from any specific backend. The base system reorganizes the address space but issues no reclamation hints. This separation is intentional: the value of address-space-engineering lies in making pages uniformly hot or cold, which improves the precision of any page-based mechanism. Backends such as kswapd, TMO, TPP, and Memtis observe per-page activity through their existing interfaces (PTE-A bits, PEBS samples, or PSI signals) and naturally make better decisions when COLD pages contain only cold objects.

Optionally, *OBASE* can issue proactive hints to accelerate reclamation. In this hinted mode, once the promotion rate stabilizes below the target, *OBASE* marks COLD pages with `MADV_COLD` or `MADV_PAGEOUT` to signal that they are safe to reclaim. Similarly, SAMA may request huge pages for HOT (`MADV_HUGEPAGE`) to selectively improve TLB coverage over dense hot data. These hints are strictly advisory and complement rather than replace backend policies.

3.5 Safe Concurrent Migration

Reorganizing the address space requires relocating objects while application threads may hold pointers to them. In managed languages, garbage collectors solve this problem using load barriers or stop-the-world pauses. C++ offers neither: there is no runtime to intercept pointer loads, and production systems cannot tolerate pauses. OBASE must therefore migrate objects without blocking threads, while guaranteeing that every dereference sees a valid location. As described in §3.2, all dereferences pass through guides, so relocation reduces to atomically updating a single pointer-sized word. Callers never follow stale pointers and do not need explicit synchronization.

Lightweight Scoping. An object can be migrated only when no thread is actively using it. Classic approaches—stop-the-world pauses or per-access load barriers—are unsuitable for C++ systems code [30, 50, 63]. Instead,*OBASE* introduces a per-object *Active Thread Count* (ATC) that tracks how many public data structure operations have observed a guide during a migration window. The ATC captures the notion of active use: if a thread begins an operation that may dereference an object, ATC is incremented once for that scope; when the operation completes, the ATC is decremented. Migration is permitted only when the ATC reaches zero, indicating that no thread is currently executing an operation that could read or modify the object.

The ATC must be updated efficiently. Rather than incrementing the ATC on every pointer dereference—which would impose unacceptable overhead—*OBASE* scopes tracking to public API boundaries. When a thread enters a data-structure operation (e.g., get, insert), it registers with a Thread-local Active scope guard (TAG); when the operation completes, the guard decrements the ATC for all objects touched. This design reflects how C++ programmers reason about pointer validity: pointers are valid for the duration of the operation that

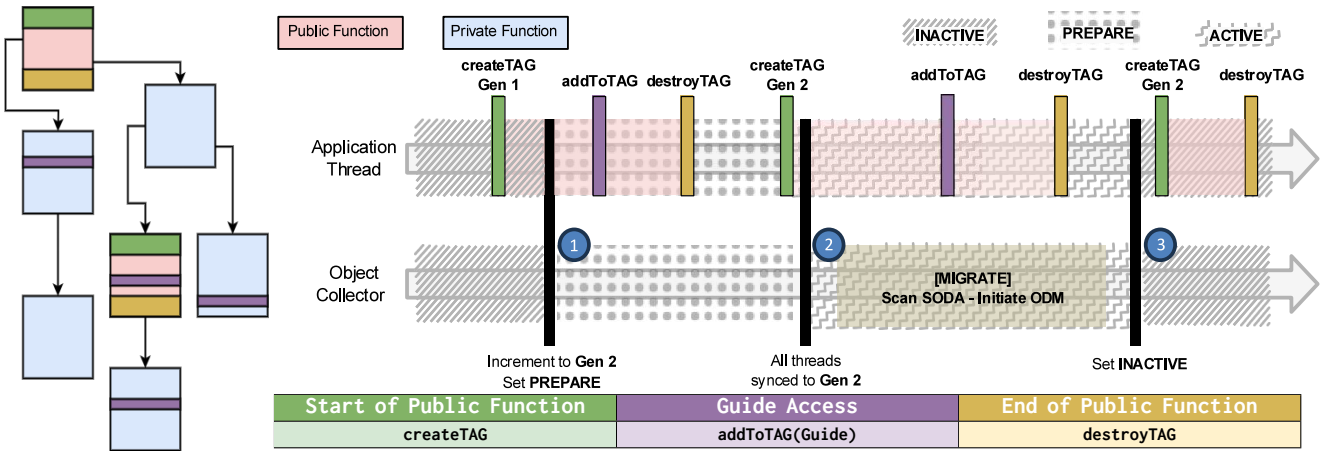

Figure 6. Application Thread Execution Flow And Interaction With OC The left side shows the instrumented call graph, code is inserted in three scenarios as shown. Public functions create and destroy Thread-local Active scope Guards (TAGs), maintaining nesting levels and registering the thread in the Thread Activity Index (TAI). Guides increment active reference counts only if added to the TAG. Reference counts are decremented only when the outermost public function exits. Active Thread Count (ATC) is enabled only during `PREPARE` and `ACTIVE` states.

obtained them, not indefinitely. Compiler instrumentation (detailed in §4.2) inserts the necessary hooks automatically.

Active Windows via Epochs. Always-on ATC tracking would impose overhead even when no migration is in progress. *OBASE* therefore activates ATC only during periodic migration epochs. Outside these windows, guide dereferences record only access activity (§3.3) with no ATC overhead. When the OC initiates migration, it coordinates an epoch transition that ensures all active threads enable ATC tracking before any object is moved. This epoch-based activation confines the synchronization cost to brief, infrequent windows.

Optimistic Migration. Given ATC=0, *OBASE* moves objects using an optimistic protocol inspired by optimistic concurrency control. The Object Collector copies the object to its target heap, then attempts to atomically swing the guide to the new address. If any thread accesses the object during the copy, the commit fails and the move is abandoned—the object remains in place, and the thread sees valid data. This optimistic approach has two key properties: (1) threads never block on migration, and (2) concurrent access safely vetoes relocation rather than observing inconsistent state. §4.5 details the CAS-based protocol.

Safety and Non-Blocking Progress. Safety follows from a single invariant: the guide is updated atomically, and migration aborts on any conflicting access. No thread can ever follow a stale pointer. Progress is non-blocking: application threads never wait on the collector, and the collector performs bounded work per object before committing or abandoning. Frequently accessed objects naturally resist migration (their ATC rarely reaches zero), while cold objects eventually move. The result is an address space that reshapes continuously without stop-the-world pauses, while preserving familiar pointer semantics.

4 Implementation

This section details *OBASE*'s concrete realization.* We cover the guide metadata encoding (§4.1), scope-guard data structures (§4.2), SODA bitmap layout (§4.3), controller parameters (§4.4), the epoch-based migration protocol (§4.5), kernel reclamation optimizations (§4.6), and the compiler passes that automate guide management (§4.7).

4.1 Guide Metadata Encoding and Heap Allocation

Each guide uses the 48 bits required for canonical x86-64 user-space addresses and repurposes the upper 16 bits for metadata: 7 bits encode ATC (supporting up to 128 concurrent threads per object), 5 bits track CIW (up to 32 windows, or 60+ minutes at the default 120s interval), 2 bits identify the current heap (NEW, HOT, COLD), and 2 bits store the access and migration-lock flags. As 128-bit addressing becomes more prevalent [5], implementations can expand these fields without changing the guide abstraction. We implement the three heaps using a Spatially-Aware Memory Allocator (SAMA) built on jemalloc's extent management. SAMA reserves large `mmap` regions for each heap and allocates objects within them, returning unused extents to the OS as objects migrate or are freed.

4.2 Efficient Scope Guard Tracking

Figure 6 illustrates the instrumented call graph. The compiler inserts three hooks: `createTAG` (green) at public API entry, `addToTAG(guide)` (purple) at each guide dereference, and `destroyTAG` (yellow) at public API exit. Public functions may

OBASE is open-sourced at https://github.com/WiscADSL/obase

call private helpers that also dereference guides; the TAG tracks all such accesses but only decrements the ATC when the *outermost* public function returns. This nesting-aware design ensures that the ATC remains positive throughout the entire operation, even when internal helpers are inlined or called multiple times.

We implement TAGs using a `BaseDeltaPtrSet` that exploits pointer locality: it encodes pointers as a base address plus 32-bit deltas, grouping up to 16 nearby pointers within two cache lines. Insertion is O(1) when the pointer falls within an existing group; otherwise a new group is created in O(log G) time, where G is the number of groups. Since pointers within a single operation cluster tightly (e.g., keys and values in the same bucket, nodes along a tree path), most insertions hit existing groups. Across the ten data structures in our evaluation, the median number of unique guides per operation ranges from 3 (hash tables) to 12 (B+Tree traversals), keeping per-operation TAG overhead under 100 ns.

4.3 SODA Bitmap Structure and Object Discovery

The Sparse Object Data Activity (SODA) bitmap uses a two-level structure to cover the heap address space without allocating storage for empty regions. SODA divides the address space into coarse-grained blocks; each block contains 64-bit words where individual bits indicate guide presence at fixed-size slots. Blocks are allocated lazily and reclaimed when empty. Because SODA tracks guide pointers rather than object addresses, it remains valid across relocations; the guide's address does not change when the object moves. Memory overhead is one bit per potential guide slot plus block-level bookkeeping. The OC scans SODA at a configurable interval (120 s by default), chosen to align with cold-memory detection thresholds in warehouse-scale tiering systems [29, 43].

4.4 Cold Threshold Controller

OBASE initializes C_t to three scan windows; at the default 120 s interval, this is approximately six minutes of inactivity before demotion, consistent with the five-minute rule for tiered storage [19, 32, 33]. The target promotion rate of 1% is based on budgets used in production compressed-memory and CXL tiering deployments [29, 43]. C_t is bounded between 1 and 32 windows. After each scan window, an additive-increase/additive-decrease (AIAD) loop (Algorithm 1) compares the observed promotion rate PR_{actual} (§3.4) against the target and adjusts C_t accordingly, so the threshold settles into a workload-specific regime without large swings.

4.5 Epoch Protocol and Optimistic Migration

As shown in Figure 6 the OC coordinates migration through three states (`INACTIVE`, `PREPARE`, and `ACTIVE`) using a global epoch counter and a Thread Activity Index (TAI) - a per-thread slot that lets the OC verify, without blocking threads, that every active thread has observed the new epoch before migration begins.

Algorithm 1 Cold-Threshold Controller (per scan window)

$$PR_{actual} \leftarrow \frac{\text{unique COLD pages accessed}}{\text{working-set size}} \times \frac{60}{\text{scanInterval}}$$

if $PR_{actual} > PR_{target}$ **then** ▷ demotions revisited too often
  $C_t \leftarrow \min(C_t + 1, 32)$ ▷ demote more conservatively
else if $PR_{actual} < PR_{target}$ **then** ▷ slack in the budget
  $C_t \leftarrow \max(C_t - 1, 1)$ ▷ reclaim more aggressively
end if

Time	Actor	Action	ATC	Lock	Outcome
(a) Concurrent dereference aborts migration:					
t_0	OC	read guide	0	0	eligible
t_1	OC	CAS: set lock	0	1	copying begins
t_2	Thread	dereference	1	0	lock cleared
t_3	OC	CAS: commit	*mismatch*		**aborted**
(b) No interference, migration succeeds:					
t_0	OC	read guide	0	0	eligible
t_1	OC	CAS: set lock	0	1	copying begins
t_2	OC	CAS: commit	0	0	**success**

Table 1. Race between migration and concurrent access. (a) A dereference at t_2 modifies the guide, causing the OC's commit CAS to fail. (b) When no thread intervenes, both CAS operations succeed and the object moves.

Epoch Transitions. In the `INACTIVE` state, the ATC updates are disabled; dereferences only set access bits. When the OC initiates migration, it increments the epoch counter and enters `PREPARE` state 1. Threads entering public methods record the current epoch in the TAI (a small array indexed by thread-ID hash); exits clear their slot. The OC repeatedly scans the TAI; once every non-empty slot reflects the new epoch 2, all active threads have enabled ATC tracking, and the OC enters the `ACTIVE` state . After migration completes, the OC returns to `INACTIVE` state 3. Crucially, threads never block; they simply record epoch participation, while the OC performs convergence checks.

Optimistic Data Migration. Within `ACTIVE` states, the OC migrates objects using an Optimistic Data Migration (ODM) protocol (Algorithm 2), similar in spirit to Optimistic Concurrency Control (OCC), where a job is performed first and verified later, essentially acting as a weak transaction. For a candidate with ATC=0 and migration-lock clear, the OC: (1) atomically sets the migration-lock bit on the guide slot; (2) allocates space in the target heap via SAMA and copies the object; (3) constructs a new guide (new address, heap ID, reset CIW, cleared lock) and publishes it with a single commit CAS, the same atomic both installs the new address and releases the lock. If the commit CAS fails, a concurrent dereference has changed the guide and the migration is abandoned (the OC explicitly clears the lock it set; see Algorithm 2).

Race Resolution. Table 1 illustrates a race between migration and access. Every dereference performs an atomic

Algorithm 2 Optimistic Data Migration (ODM)

```
1:  procedure MigrateObject(ptr, targetHeap)                    ▷
    ptr: address of guide slot
2:      guide ← AtomicLoad(ptr)                                 ▷ Load object guide
3:      if RefCount(guide) > 0 then
4:          return false                                        ▷ Object in use
5:      end if
6:      srcAddr ← ExtractAddr(guide)
7:      srcHeap ← ExtractHeapType(guide)                        ▷ Get current heap type
8:      SetMigrationLock(ptr)                                   ▷ CAS; mark as migrating
9:      size ← GetSize(srcAddr)
10:     dstAddr ← samalloc(size,targetHeap)
11:     if dstAddr = null then
12:         ClearMigrationLock(ptr)
13:         return false                                        ▷ Allocation failed
14:     end if
15:     Copy(dstAddr,srcAddr,size)                              ▷ Copy data
16:     newGuide ← CreateGuide(guide,dstAddr,targetHeap)        ▷
    Inherits lock from guide metadata
17:     ClearMigrationLock(newGuide)                            ▷
    Local clear of inherited lock; commit via CAS below
18:     success ← AtomicCAS(ptr,guide,newGuide)
19:     if success then
20:         Free(srcAddr,srcHeap)                               ▷ Release old memory
21:         return true
22:     else
23:         Free(dstAddr,targetHeap)                            ▷ Rollback
24:         ClearMigrationLock(ptr)                             ▷ CAS; release lock we set
25:         return false                                        ▷ Migration failed, guide changed
26:     end if
27: end procedure
```

CAS that sets the access bit and *clears* the migration-lock bit. If a thread accesses object x while the OC is copying it (t_2), the guide changes, the commit CAS fails (t_3), and x remains at its original address. The thread always sees valid data; concurrent access supersedes migration.

4.6 Kernel Page Reclamation Optimization

When objects migrate to the COLD heap and the Object Collector issues `MADV_PAGEOUT`, Linux's page reclamation path becomes the bottleneck for efficient memory tiering. The default path in `shrink_folio_list()` processes each page individually: it clears the page table entry (PTE), issues a TLB flush or shootdown that triggers an inter-processor interrupt (IPI) to every core, and submits the page to the block I/O layer. This fine-grained approach creates substantial overhead when reclaiming large regions, as the cumulative cost of per-page TLB invalidations and IPIs degrades performance even for threads accessing unrelated hot data.

We modify `shrink_folio_list()` to batch these operations: it aggregates pages (up to a full PMD spanning 512 base pages), clearing each PTE and marking it for pageout, but defers TLB invalidation until a complete batch is prepared, then issues one flush over the entire range and submits all pages together for I/O. By amortizing TLB shootdowns and I/O submissions, this reduces IPIs by more than 99% when demoting 10 GiB of memory versus the unmodified kernel. Beyond local tiering, batched invalidation also addresses a scalability bottleneck in RDMA-based far-memory systems [35, 48, 57], where per-page shootdowns cause IPI storms whose latencies grow super-linearly with thread count; aggregating across hundreds of pages lets the reclamation path scale for both CXL and RDMA backends.

```
1  void HashMap::get(int idx) {
2      createTAG();                    // public entry
3      Guide<char>& v = buckets[idx]; // HashMap member
4      addToTAG(&v);                   // before deref
5      if (*v > 37) { destroyTAG(); return; }
6      addToTAG(&v);  *v = 42;
7      addToTAG(&v);
8      std::cout << "Value: " << *v << std::endl;
9      destroyTAG();                   // public exit
10 }
```

Figure 7. Compiler transformation. The developer marks one pointer field of `HashMap`; the pass rewrites its type from `char*` to `Guide<char>`, brackets the public method with `createTAG`/`destroyTAG`, and inserts `addToTAG` before each guide dereference. The `buckets` array is unmarked and stays in memory, so indexing itneeds no guard; only the guide dereference (`*v`) does. Callers invoke `HashMap::get` with a primitive key (no `Guide` crosses the public-method boundary), so caller code neither holds nor dereferences a `Guide`. ATC increments inside `addToTAG` only when the TAG state is not `INACTIVE`.

4.7 Compiler Passes for Guide Management

OBASE uses three complementary compiler passes, implemented on Clang and LLVM, to convert raw pointers to guides and insert the TAG/ATC instrumentation, confining developer effort to marking which pointer fields are managed. **Visibility extraction.** A Clang frontend pass ensures TAGs are created only at public boundaries by using a `RecursiveASTVisitor` to find public methods that serve as data-structure entry points (e.g., `get`, `set`, `delete`) and records their visibility for later stages. **Pointer-to-guide conversion.** A second Clang pass uses the rewriter to convert the developer-listed pointer declarations and usages into guides, giving precise control over which objects *OBASE* manages. **IR instrumentation.** The third pass runs on the LLVM IR. A fixed-point analysis first identifies the set of functions that directly use guides (via conversions, destructor calls, operator overloads, or assignments), propagates this set through the call graph to find functions that touch guides indirectly, and combines it with the visibility data from Pass 1 to classify each function. It then inserts `createTAG`/`destroyTAG` at the entry and exit of public functions that touch guides, and `addToTAG` before each guide dereference in all transformed functions (public and private). This restricts TAG creation to public boundaries while still tracking every access throughout the call stack (Figure 7).

Structure	Concurrency Control	Used In
HashTable Harris [36]	Lock-free algorithm	NGINX
HashTable Pugh [54]	Fine-grained r/w lock	Redis, Memcached
HashTable Java CHM [15]	Segmented bucket locks	Linux kernel, HAProxy
SkipList Coarse	Global lock	LevelDB/RocksDB
SkipList Fraser [31]	Lock-free algorithm	Redis Sorted Sets
SkipList Herlihy [37]	Optimistic fine-grained	Cassandra, CockroachDB
B+Tree Coarse	Global lock	SAP HANA
B+Tree OCC	OCC w/ epoch reclaim	VoltDB index
MassTree [47]	OCC + RCU	MICA, Silo
Adaptive Radix Tree [45]	Fine-grained r/w lock	DuckDB, PostgreSQL

Table 2. Concurrent data structures evaluated with *OBASE*. These structures span lock-free, fine-grained, and coarse-grained concurrency mechanisms, demonstrating *OBASE*'s compatibility with diverse synchronization approaches.

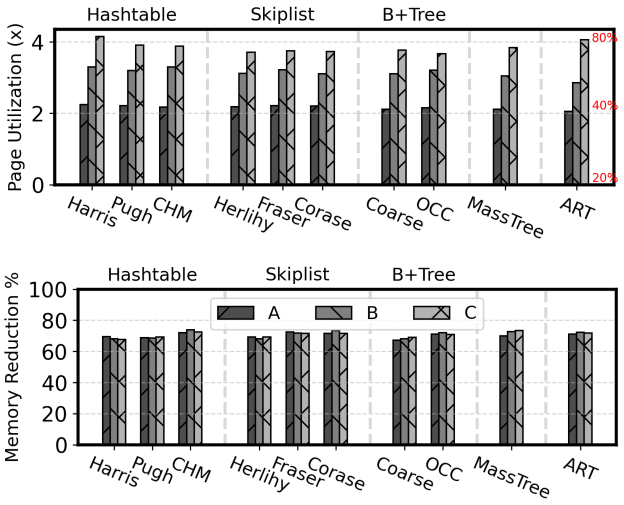

Figure 8. *OBASE* effectiveness (YCSB, 10M keys). Top: Page utilization improvement relative to the baseline allocator; *OBASE* increases utilization by 2–4× across workloads and data structures. Bottom: RSS reduction after *OBASE* pages out the COLD heap (via Kswapd). Memory footprint shrinks by 65–72%.

5 Evaluation

We evaluate *OBASE* along four dimensions:

E1: Effectiveness. Does *OBASE* reduce hotness fragmentation and memory footprint across different data structures and workloads? (§5.2)

E2: Backend synergy. How much does *OBASE* improve the effectiveness of existing page-based reclamation and tiering backends? (§5.3)

E3: Overhead and scalability. What runtime overheads do tracking and migration introduce, and how do they scale with thread count? (§5.4)

E4: Dynamic behavior. How does *OBASE* adapt to changing hotsets in long-running, real-world workloads? (§5.5)

5.1 Experimental Setup

All experiments run on an Intel Xeon Gold 5218 (16 cores, SMT disabled) server configured in `performance` governor mode with Ubuntu 22.04 and Linux kernel 6.12. The memory subsystem comprises two tiers: a fast tier of 2×16 GB DDR4 DRAM modules at 2400 MHz, and a slow tier of 4×128 GB Intel Optane DC Persistent Memory 100 modules at 2666 MHz. All six memory devices occupy distinct channels to avoid interface. We configure Optane PMEM in `Memory Mode` and expose it as a separate NUMA node, creating a two-tier hierarchy representative of emerging CXL-attached memory deployments [46, 49]. The Optane tier provides approximately 2.5× higher access latency than local DRAM [64], consistent with first-generation CXL memory characteristics [58]. For reclamation experiments requiring swap, we use a 512 GB Intel P4800X Optane SSD.

CrestDB testbed. We implemented CrestDB, a concurrent in-memory key-value store, to evaluate *OBASE* across diverse data structures and concurrency mechanisms. CrestDB integrates ten high-performance data structures spanning the concurrency-control spectrum (Table 2), from lock-free algorithms to global locks. Many structures are borrowed from ASCYLIB [34], which provides production grade implementations. This diversity demonstrates that *OBASE*'s compiler instrumentation and migration protocol are compatible with a wide range of synchronization approaches without structure-specific modifications. All data structures maintain guide pointers to key and value objects; CrestDB deep-copies inserted data, ensuring *OBASE* manages the authoritative copy rather than application-held aliases. Unless otherwise noted, CrestDB runs with six server threads and six client threads.

Workloads. We use the YCSB benchmark suite with Zipfian-distributed keys to model skewed access patterns typical of production workloads. To evaluate real-world adaptivity, we replay production traces from Meta (CacheLib [22], DBbench [24]) and Twitter (Cluster 7, Cluster 23) [65].

Controller parameters. Unless otherwise noted, the Object Collector scans every 120 s, targets a 1% promotion rate, and adjusts C_t by ±1 window per scan within $1 \le C_t \le 32$ (§3.4); the conservative 1% target follows production compressed-memory deployments [43, 62]. The optimal rate is hardware-dependent (faster tiers tolerate higher cold-access fractions), and hardware-aware tuning is future work. §5.5 examines C_t dynamics over time.

5.2 Effective Address-Space-Engineering (E1)

We first evaluate whether *OBASE* achieves its core objective: reducing hotness fragmentation and converting unreclaimable cold data into reclaimable pages. We run CrestDB with all ten data structures under YCSB workloads A, B, and C with Zipfian keys. We load 10M keys with 30-byte keys and 1024-byte values, creating a 13 GiB dataset. Unless stated otherwise, all results in this section are measured after *OBASE* has converged (promotion rate below the 1% target).

Page utilization. Figure 8(a) reports page utilization before and after *OBASE* reorganizes objects into NEW, HOT,

and COLD heaps. Initially, the data structures exhibit 18–20% utilization when measured over 120 s windows: most pages contain only a handful of accessed cache lines, reflecting the hotness fragmentation observed in production traces (§2).

After three scan intervals, the Object Collector classifies objects based on guide access bits and migrates them into HOT or COLD heaps. Compared to the baseline, *OBASE* improves page utilization by 2× for workload A (50% writes), approximately 3× for workload B (5% writes), and up to 4× for the read-only workload C. Across data structures, absolute utilization after convergence ranges from roughly 40% (workload A) to 80% (workload C).

The variation across workloads reflects how the NEW and HOT heaps interact. Workload C has no updates: once objects are classified as hot, they remain in the HOT heap and no new objects are allocated there. Nearly all accessed bytes end up densely packed in a small number of HOT pages, and utilization approaches 80%. In workload B, occasional updates allocate fresh values in NEW, so the working set splits between NEW and HOT and overall utilization stabilizes around 60–70%. Workload A performs frequent updates, continuously injecting new objects into NEW. Utilization still roughly doubles, but cannot reach read-only levels because a larger fraction of hot objects reside in NEW during their initial epochs.

The consistency of the improvement across ten structurally different data structures shows that *OBASE*'s benefits derive from object-temperature clustering rather than data-structure-specific layout optimizations.

Memory footprint. Higher page utilization translates directly into reclaimable cold memory. Once the promotion rate falls below the 1% target—typically after 3–4 scan intervals (6–8 minutes) for YCSB—*OBASE* proactively issues `madvise(MADV_PAGEOUT)` on the COLD heap. Figure 8(b) shows the resulting RSS reduction relative to a baseline without reclamation.

Across all data structures and workloads, *OBASE* reduces RSS by 65–72%. For workload B with 10M keys, the baseline uses 12.4 GiB; after *OBASE* converges and pages out COLD, RSS drops to 3.5–4.0 GiB. Because COLD pages contain almost exclusively inactive objects, proactive paging does not cause swap-in storms or noticeable throughput degradation (we quantify overheads in §5.4).

Takeaway #1: *OBASE improves page utilization across all data structures as it tracks object hotness without the semantic knowledge of each structure. This enables uniform hotness fragmentation reduction across diverse concurrency mechanisms.*

5.3 Backend Synergy (E2)

The memory savings demonstrated in §5.2 are valuable only if OS tiering backends can exploit them without degrading performance. We now show that *OBASE* enables existing reclamation and tiering systems to achieve aggressive memory savings while preserving throughput.

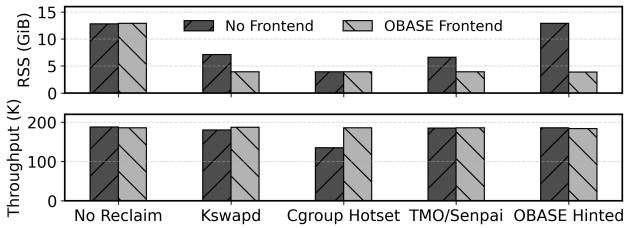

Figure 9. *OBASE* with reclamation backends (YCSB-C, MassTree). Top: RSS after convergence. Bottom: throughput. Without *OBASE*, backends face a trade-off between memory savings and performance. With *OBASE* (hatched bars), all backends achieve near-optimal memory savings with minimal throughput loss.

5.3.1 Paging-based Reclamation Backends. We run CrestDB with MassTree under YCSB-C in a memory-constrained configuration: the workload has a 13 GiB footprint but an active working set of approximately 4 GiB. We compare four reclamation strategies, each with and without *OBASE* as a frontend:

- **Kswapd:** Linux's background reclaimer, triggered by memory pressure from a co-located process.
- **Cgroup:** Memory limit set to working-set size (4 GiB), forcing aggressive reclamation.
- **TMO:** Meta's PSI-based proactive reclaimer [62].
- ***OBASE* Hinted:** Proactive `MADV_PAGEOUT` on the COLD heap after convergence.

Throughout the evaluation, *OBASE* denotes the frontend alone, address-space reorganization with proactive paging disabled, so combinations like *OBASE*+TMO isolate the benefit of reorganization from any hinting. *OBASE* Hinted additionally issues `MADV_PAGEOUT` on the COLD heap.

Figure 9 reveals a fundamental trade-off that *OBASE* resolves. **Without *OBASE***, backends must choose between memory efficiency and performance. Kswapd reduces RSS from 13 GiB to 7 GiB (1.8×) with no throughput loss, but leaves 3 GiB of cold data trapped in mixed-temperature pages due to its page level view through PTE scans. Cgroup reaches 4 GiB (3.2×), but throughput collapses by 38% as the kernel inevitably evicts hot objects. TMO achieves a 6.5 GiB RSS (2×) with no throughput loss, but cannot reclaim further because PSI signals page-level pressure regardless of object-level coldness.

With *OBASE*, all backends reach 4 GiB RSS—matching the most aggressive policy—with no throughput degradation. Kswapd now reclaims COLD pages preferentially. Cgroup no longer thrashes because evicted pages contain genuinely cold objects. TMO's PSI probes no longer encounter mixed-temperature pages that resist reclamation. *OBASE* Hinted achieves the same result proactively, without relying on any backend policy.

Takeaway #2: *OBASE achieves aggressive reclamation while preserving application performance.*

5.3.2 Tiering Backends. To demonstrate the memory tiering benefits of reduced hotness fragmentation, we evaluate

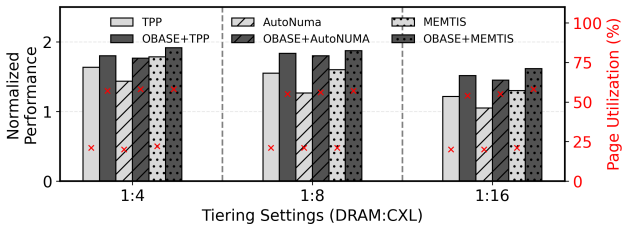

Figure 10. *OBASE* with tiering backends (YCSB-B, MassTree, 50M keys). Throughput normalized to CXL-only baseline (higher is better). Without *OBASE*, performance degrades as DRAM shrinks because the hot set cannot fit. With *OBASE*, the hot set compacts, enabling stable performance even at 1:16.

OBASE with three page based migration systems: TPP [49], AutoNUMA [60], and Memtis [44].

Setup. We load CrestDB (MassTree) with 50M keys (30-byte keys, 1024-byte values), a 67 GiB dataset. We vary the DRAM:CXL ratio across three configurations: 1:4 (14.8 GiB DRAM), 1:8 (7.4 GiB DRAM), and 1:16 (3.9 GiB DRAM), with the remaining capacity on Optane PMEM. As in [44], performance is normalized to a baseline where all data resides on the slow tier; values above 1.0× indicate speedup from effective DRAM use.

The hot-set mismatch. Without *OBASE*, the working set spans 16.3 GiB of pages at 21% utilization— slightly larger than the 1:4 DRAM budget of 14.8 GiB. No configuration can keep all accessed data in DRAM. With *OBASE*, the same logical working set compacts to 6.33 GiB at 57% utilization, fitting comfortably at 1:4 and 1:8 ratios.

TPP. TPP uses hysteresis-based promotion and proactive demotion to manage DRAM headroom. Figure 10 shows TPP achieves 1.65× speedup at 1:4, degrading to 1.25× at 1:16 as the DRAM budget shrinks below the fragmented hot set. With *OBASE*, TPP reaches 1.85× at 1:4 and retains 1.45× at 1:16—a 16% improvement at the most constrained ratio.

AutoNUMA. AutoNUMA promotes any accessed remote page immediately, without hysteresis, causing thrashing when the hot set exceeds DRAM capacity. Without *OBASE*, AutoNUMA underperforms TPP by 15–20%, achieving only 1.05× at 1:16—barely better than CXL-only. With *OBASE*, AutoNUMA matches TPP-alone performance: at 1:8, *OBASE*+AutoNUMA (1.6×) exceeds TPP alone (1.55×). When pages are uniformly hot or cold, even naive promotion decisions become correct.

Memtis. Memtis uses hardware sampling (PEBS) to identify hot pages, achieving the best baseline results: 1.8× at 1:4 and 1.55× at 1:16. With *OBASE*, Memtis improves to 1.95× and 1.7×, respectively. The gains are smaller (3–10% vs. 12–29% for TPP/AutoNUMA) because Memtis already captures much of the page-level signal—but even the most sophisticated page-level policy benefits from object-level reorganization.

Because *OBASE* reduces the effective hot set by 2.5×, ratio **1:X** performs comparably to baseline at **1:(X/2)**. For example, *OBASE* + TPP at 1:16 reaches 1.45×, within ~6% of TPP alone at 1:8 (1.55×). For operators, this means the same performance with half the DRAM, or double the effective capacity of existing tiered deployments.

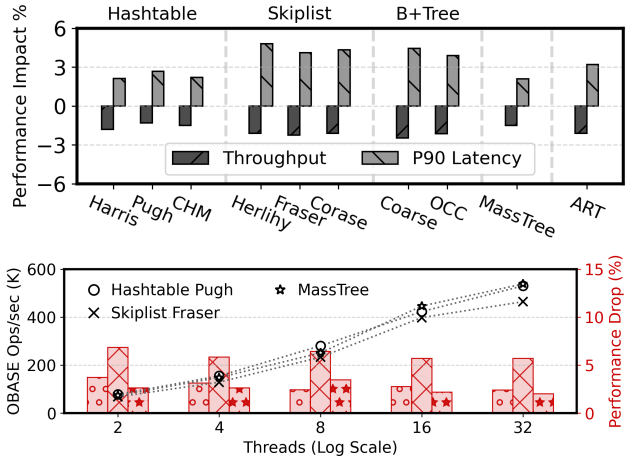

Figure 11. *OBASE* overhead and scalability (YCSB, 10M keys). Top: Throughput and p90 latency overhead across data structures. Overhead ranges from 1.5–5% depending on structure. Bottom: Scalability from 2 to 32 threads. Bars show absolute throughput; markers show overhead relative to baseline. Overhead remains bounded at 1–8% with no upward trend.

Takeaway #3: *OBASE compacts the hot set so it fits in smaller DRAM budgets, making page-based tiering backends effective.*

5.4 Overhead and Scalability (E3)

Given the memory savings and backend improvements demonstrated above, we now quantify *OBASE*'s runtime costs.

5.4.1 Steady-State Overhead. Figure 11(a) reports throughput and p90 latency overhead when no reclamation or tiering backend is active, normalized to an uninstrumented baseline.

On average, *OBASE* reduces throughput by 2.5% and increases p90 latency by 5%. Hash tables see the smallest impact (1.5–3% throughput drop), while skiplists, B+Trees, and ART experience 3–5% overhead. This variation correlates with the number of guides touched per operation: hash table lookups dereference few nodes, whereas tree traversals visit more nodes and incur proportionally more tracking overhead.

The overhead has two main sources: (1) a tagged-pointer read-modify-write on each guide dereference (4–5 ns, comparable to an L1 cache hit), and (2) TAG/ATC bookkeeping during `ACTIVE` migration epochs. The Object Collector runs in a dedicated thread and consumes less than 1% of CPU time.

5.4.2 Thread Scalability. A natural concern is whether *OBASE*'s atomic operations become contention bottlenecks at higher thread counts. We measure scalability by varying CrestDB server threads from 2 to 32 on three representative data structures spanning different synchronization mechanisms: Hashtable Pugh (fine-grained locking), Skiplist Fraser (lock-free), and MassTree (OCC with epoch reclamation).

Figure 11(b) shows that throughput scales and overhead remains bounded at 1–8% regardless of thread count. Critically, overhead does not increase with concurrency: all three data structures exhibit similar overheads at 2 and 32 threads.

This scalability follows from *OBASE*'s design: guide metadata updates target per-object state (no cross-thread contention), the test-and-set optimization skips redundant writes for hot objects, TAGs are thread-local, and ATC increments occur only during brief `ACTIVE` epochs. The 2–5% overhead is measured against a DRAM-only baseline with no memory pressure—an idealized scenario that production systems rarely enjoy. In the tiered-memory environments where *OBASE* is designed to operate, the comparison reverses: as §5.3 showed, backends *without OBASE* suffer 10–38% throughput loss from poor page-selection decisions, while backends *with OBASE* match DRAM-only performance.

Takeaway #4: *OBASE imposes 1.5–5% overhead across data structures and stays within 8% from 2 to 32 threads, a modest cost relative to the backend improvements in §5.2–5.3.*

5.5 Real World Traces

Synthetic workloads exercise controlled forms of skew, but production systems exhibit substantially more complex behavior: shifting hotsets, mixed read/write/delete ratios, and locality patterns that evolve over hours. We therefore evaluate *OBASE* on four real-world traces to assess whether its fragmentation-reduction benefits generalize beyond YCSB and whether the feedback controller adapts stably to long-term changes in access patterns.

We evaluate four traces that span a range of access patterns:

- **Meta CacheLib** [22]: Read-heavy (83% GET) with gradually shifting popular keys.
- **DBench Mixgraph** [24]: Models Meta's ZippyDB with key-range locality across 30 prefixes. Read-heavy (85% GET, 14% PUT, 1% SEEK).
- **Twitter Cluster 7** [65]: High skew (α=1.07) with small, concentrated working set of reads and writes.
- **Twitter Cluster 23** [65]: Write-heavy (31% SET, 30% INCR) with low skew (α=0.274) and deletes.

These traces cover the spectrum from highly skewed (Cluster 7) to nearly uniform (Cluster 23), and from read-dominated (CacheLib) to write-heavy (Cluster 23). We replay each trace on CrestDB with ART and measure memory reduction and page utilization improvement.

Page utilization (E1). Page utilization improves by 1.8–3.4× across traces. Cluster 23 shows the highest gain (3.4×) because its low skew disperses accesses across many keys, yielding very low baseline utilization. Cluster 7's high skew naturally concentrates accesses, so the baseline is already reasonable and the relative improvement is smaller (1.8×).

Memory reduction (E1, E2 & E4). Figure 12 shows that *OBASE* Hinted reduces RSS by 36–58% compared to no reclamation. Cluster 7 achieves the largest reduction (58%) because its high skew concentrates the working set into fewer hot objects; DBench shows the smallest (36%) because key-range locality spreads accesses more uniformly. Adding *OBASE* to TMO provides 15–30% additional savings relative to TMO-alone, demonstrating that *OBASE* and TMO are complementary: TMO identifies reclaimable pages, while *OBASE* ensures those pages contain uniformly cold data.

Figure 12. Production trace results. Memory reduction (left axis): *OBASE* Hinted vs. no-reclaim, and *OBASE*+TMO vs. TMO-alone. Page utilization improvement (right axis, hatched) from address-space reorganization.

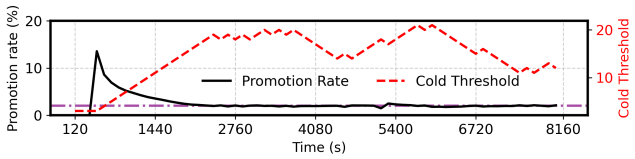

Figure 13. Cold threshold adaptation (Meta CacheLib). Promotion rate (black) and cold threshold C_t (red) over time. The controller automatically adjusts C_t to maintain the 1% target (purple).

Adaptive cold threshold (E4). Figure 13 demonstrates *OBASE*'s ability to adapt to workload dynamics over 2.3 hours of the Meta CacheLib trace. At startup, the initial C_t=3 causes premature demotions, spiking the promotion rate to 14%. The controller increments C_t each scan interval; within 25 minutes, C_t reaches 18 and the promotion rate drops below the 1% target. A high promotion rate during convergence *does not indicate degraded performance*: COLD-heap pages remain in DRAM until a backend explicitly pages them out, and the promotion rate reflects workload behavior rather than backend decisions (§3.4).

Around t=5400 s, a workload shift causes a brief spike, as previously cold keys become active; the controller raises C_t and the system re-converges as the new hotset stabilizes. Throughout the trace, C_t varies between 10–20 windows while maintaining the promotion rate near the target, demonstrating that *OBASE* tracks workload evolution.

Takeaway #5: *OBASE delivers consistent memory savings across real world workloads with diverse characteristics and dynamically adapts to shifting access patterns.*

6 Related Work

Object-Level Management. AIFM [57] and MIRA [35] manage memory at object granularity for disaggregated far memory, bypassing OS page management for specialized user-space runtimes; AIFM builds on Shenango's green threads and kernel-bypass networking, with explicit `DerefScope` guards around far-memory accesses. *OBASE* is complementary: it

acts as a *frontend* that reorganizes the address space for unmodified OS *backends*, optimizing *what* to tier rather than the latency of remote access, so we do not compare directly. The `DerefScope` contrast is instructive: it guards each individual far-memory dereference so the runtime can fault the object in, whereas *OBASE*'s TAG/ATC scopes bracket a whole public operation as a quiescence check that permits migration only when no thread is active, closer to epoch-based reclamation than to per-access load barriers.

Other systems indirect through pointers for different ends. Midas [55] harvests idle memory for application-managed *soft state*, dropping recomputable data under pressure, while Atlas [26] accelerates far-memory applications with a hybrid paging/runtime data plane; both optimize access to *remote* memory, whereas *OBASE* reorganizes *local* resident objects by observed access intensity so page-based backends see uniformly hot or cold pages. Alaska [61] uses handle-based indirection for heap compaction but does not track object hotness or organize memory by access intensity. ObjecTier [53] proposes a non-invasive object-consolidation framework with the same high-level vision as *OBASE*, motivated by simulations and they defer implementation to future work.

Allocation-Time Placement. Static placement approaches [27, 28, 40, 51, 66] make decisions at allocation time based on hints or profiling. However, object hotness is neither knowable at allocation nor stable over time(§2). *OBASE* tracks access patterns at runtime, enabling runtime migration.

Page-Level Tiering. TPP [49], Memtis [44], HawkEye [52], and TMO [62] all operate at page granularity. Even efforts to shrink the tiering granularity (e.g., Memtis's dynamic 4KB classification [44]) are bounded by the page floor, since subpage objects of differing hotness still share a 4KB page (§2). *OBASE* works below this floor by reorganizing at object granularity, and is designed to improve these backends.

Garbage Collection and Object Relocation. GCs have long relocated objects to improve locality: generational collectors cluster recent allocations, profile-guided reordering [39] groups hot objects during copying, and the Bookmarking Collector [38] avoids paging during collection. *OBASE* differs in relocation safety: where ZGC [63] and Shenandoah [30] use load barriers to redirect accesses while threads hold stale pointers, *OBASE* adopts a *quiescence-based* approach inspired by epoch-based reclamation [25, 31] and RCU [50], relocating only when an object's active-thread count reaches zero and aborting on any concurrent access via CAS failure. It also differs in purpose: GCs relocate to reclaim memory or improve cache locality, whereas *OBASE* relocates to improve *page utilization* so that tiering mechanisms see uniform pages.

7 Limitations and Applicability

OBASE targets a specific class of code, pointer-based concurrent data structures in unmanaged languages, rather than aiming for universal applicability. Its requirements bound where it applies, which we make explicit so users can judge fit.

- **No pointer stability.** Relocation invalidates raw pointers cached across operations (e.g., addresses retained by Abseil maps or STL iterators). Callers must re-resolve through the guide, as pointer-unstable containers already require [10].
- **Single ownership.** A guide asserts exclusive ownership like `std::unique_ptr`, and migration updates only that guide. Multiple guides aliasing one object (shared graph or doubly-linked nodes) are unsupported. CrestDB enforces this by deep-copying on insert.
- **No pointer arithmetic.** Guides do not support `+`/`[]` across object boundaries, so contiguous arrays, matrices, and packed columnar data are not supported in *OBASE*; a validation pass rejects such uses.
- **Language support.** The design relies on dereference-operator overloading, which is not supported by Go or Java.
- **Annotation.** Developers mark a small set of pointer fields, so adoption is not fully transparent; the compiler handles the rest (§4.7).
- **Hardware composability.** The guide encoding reuses high-order address bits, which can contend with Intel LAM [2], ARM TBI [9], or HWASAN [18] if those features claim the same bits; wider addressing [5] relaxes this.

We target unmanaged languages, as most latency-sensitive datacenter code is C++ or Rust; the mechanisms generalize to managed runtimes.

8 Conclusion

OBASE shows that memory tiering improves when applications cooperate with the OS rather than bypass it. By reorganizing virtual address space so that page boundaries align with object temperature, *OBASE* makes existing backends more effective without modifying them. The approach has limitations: it requires developer annotation of relocatable pointers and applies only to pointer-based structures. However, the principle of address-space engineering extends beyond tiering. The same techniques could improve generational garbage collection (grouping by access intensity rather than age), reduce false sharing of pages across NUMA nodes (separating objects by access pattern), and strengthen isolation (grouping by trust level). An application's address-space layout is itself a channel to the OS [20]: by grouping objects of similar temperature, *OBASE* turns layout into an object-level signal that unmodified page-based tiering can act on, with no new interface between the two.

Abstract

The traditional memory management problem maximizes application performance when constrained by a fixed-size memory. Today's data centers face a different problem: their goal is to maximize the number of jobs on a server without violating performance Service Level Objectives (SLOs). Since a key constraint for placing additional jobs is memory, data center systems proactively reclaim memory from running jobs to create space for new jobs. This difference fundamentally flips the optimization problem that memory management policies need to address.

Designing practical policies requires a set of tools: 1) an optimal policy that provides a bound on what any policy can achieve, 2) metrics to compare policies, and 3) efficient techniques for evaluating potential policies. However, we find that foundational tools from the traditional setting, such as the optimal policy OPT, Miss Ratio Curves (MRCs), and efficient ways to generate MRCs, do not apply in this new setting. The data center setting demands a new set of tools.

We present the Memory Designer's Kit, *MDK*, a framework for designing and evaluating data center memory management policies. *MDK* includes an offline provably optimal policy; *Memory Performance Curves (MPCs)*, which show how memory savings vary when constrained by performance; and an efficient technique that is up to 208× faster than simulation for producing MPCs. We demonstrate *MDK*'s utility by developing three data center policies that improve average memory savings by up to 10% relative to a state-of-the-art policy.

1 Introduction

Memory management, especially policies for effective eviction of pages from caches, has long been a cornerstone of operating systems [4, 8, 9, 15, 19, 32, 33, 35, 47, 48]. These policies focus on managing the memory of a single computer (node) and can be framed as an optimization problem with the goal of maximizing application performance while constrained by the node's limited memory capacity. Page replacement policies, such as LRU, evict pages in reaction to memory pressure (i.e., when the memory is full and new pages need to be allocated). In this setting, application performance is tracked using a *performance proxy*, the cache miss rate, which is defined as the ratio of the number of cache misses to the total number of memory accesses, measured over the application's lifetime. Replacement policies minimize the miss ratio under the assumption that doing so will maximize application performance.

Optimizing memory usage in *data centers* has become increasingly important, due to the high cost of DRAM [14, 21, 34, 38, 45, 63]. In a data center, each server operates as part of a cluster, and jobs can be placed on or migrated between servers. The goal is to run as many jobs as possible on each server, while satisfying application performance targets [5, 6]. Maximizing server utilization allows data center operators to reduce their total cost of ownership (TCO). Data center operators deploy *reclamation policies* that proactively evict cold pages from memory before facing memory pressure, in order to reduce DRAM usage and make space for scheduling additional jobs. Evicted pages are either demoted to a cheaper byte-addressable memory tier over CXL [1], or swapped to disks [66] or to compressed memory [37].

Like traditional reactive *replacement policies*, proactive data center *reclamation policies* track performance using performance proxies; the main differences are how the proxies are measured and the choice of specific metrics. A replacement policy measures the overall miss ratio across an application's lifetime, whereas a reclamation policy measures a performance proxy in discrete time windows. This windowed approach is better aligned with data center application performance SLOs, which are enforced in a statistical manner over time intervals. Reclamation performance proxy metrics are defined at the OS level to provide consistency across the diverse set of data center workloads. Some modern examples of performance proxy metrics used for reclamation include Google's *promotion rate*, defined as the ratio of faulting pages to the number of unique pages accessed within a time interval [37], and Meta's *Pressure Stall Information (PSI)*, defined as the percentage of compute potential that is unproductive

over a time window due to resource stalls [66].

These differences in the data center environment create a new optimization problem that flips the traditional goal and constraint: the *goal* is to maximize memory savings whenever an application can relinquish memory to allow more jobs to be run, and the *constraint* is to maintain target performance proxies over all time windows to comply with application SLOs. We focus on maximizing average memory savings, subject to a target promotion rate; we discuss the broader problem space in §2.

Designing a new policy requires several tools, as shown in Figure 1. Traditional replacement policy development benefits from an established set of tools, developed over decades. The optimal policy OPT [47] is used to understand policy performance headroom, the best any policy can perform. Policies are compared using Miss Ratio Curves (MRCs) [47], which plot the miss ratio as a function of cache size. Numerous algorithms have been developed to efficiently generate MRCs (*e.g.,* [47,57,64]) based on the inclusion property [47], which makes it possible to calculate miss ratios for multiple cache sizes in a single iteration over a trace. Unfortunately, these well-established tools for evaluating replacement policies do not apply to the data center reclamation problem. As we demonstrate in §2, OPT [47], the well-known optimal policy that minimizes miss ratio, violates time-window performance proxy targets, making it non-optimal for the data center reclamation problem. Further, since the data center reclamation problem formulation flips the optimization goal and constraint, and uses a diverse set of metrics [6,37,62,66] other than the miss ratio, MRCs and their generation techniques are not applicable.

We present the **Memory Designer's Kit**, ***MDK***, an offline framework for designing new data center reclamation policies. *MDK* consists of four components: 1) the **Memory Performance Curve (MPC)**: the data center equivalent of conventional MRCs, which plots a memory optimization goal (*e.g.,* average memory savings) as a function of a performance proxy (*e.g.,* promotion rate). 2) the **Optimal Performance Proxy (OPP) policy**: an offline, provably optimal policy for maximizing average memory savings subject to a performance proxy, the promotion rate constraint. It can be generalized to maximizing average memory savings subject to any performance constraint that is computable on a trace of accesses. 3) **theoretical properties**: properties that relate a reclamation policy's performance proxy and memory savings as a function of different policy settings. Analogous to the inclusion property in the traditional setting, these properties, *eviction decisions* and *eviction times*, make it possible to efficiently calculate MPCs. 4) an **efficient MPC generation framework**: a method that lets us efficiently generate MPCs for multiple performance proxy values in a single pass. *MDK*'s MPC generation is linear in time complexity, 12.5× to 208× faster than our simulator depending on the number of page access events in a trace.

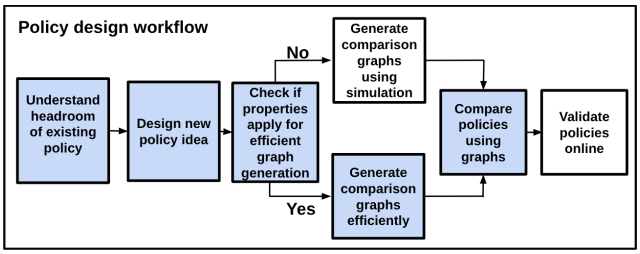

Figure 1: Typical workflow for designing new replacement and reclamation policies. *MDK* contributions are required for multiple reclamation policy development steps (blue squares).

We demonstrate how *MDK* can be used to analyze and develop policies for the data center reclamation problem. First, we examine the age-based reclamation policy (AGE, an approximation of the working set policy [17]) used in g-swap [37] and evaluate its effectiveness in the data center setting. We compare it to *MDK*'s optimal policy, OPP, using MPCs and show that a significant gap exists between the two, indicating substantial room for improvement.

Second, we use *MDK* to develop three policies. Two are history-based heuristics: the single-parameter **P**rior **A**ge with **W**ait (PAW) and the two-parameter **P**rior **A**ge and **C**urrent **E**lapsed (PACE). The third is a learned policy that imitates OPP. Our heuristic policies reclaim a page as soon as it's accessed rather than waiting for the page to cool off (as done in AGE). Using *MDK*, we analyze the performance of these policies, compared to AGE, on offline traces. PAW, PACE, and AGE have tunable parameters dependent on trace characteristics. We measure their maximum potential performance achieved by tuning their parameters using complete evaluation trace information. PAW generates slightly better average memory savings than AGE at lower promotion rates for workloads that exhibit repeating access patterns (four out of eight benchmarks). We validate PAW's performance by implementing it on Linux and confirm that PAW achieves 4% higher memory savings than AGE for a graph processing workload without any performance loss. However, for workloads without any repeating patterns, AGE performs significantly better. Given a representative trace, our second policy PACE performs as well as AGE for any workload by design, and improves performance by 10% for a subset of workloads. Evaluating policy tuning in *MDK* with training and testing phases, or tuning the policies online, are valuable topics of future research.

MDK is generalizable beyond the problem we study in this paper. We selected two metrics out of a set of many possible metrics used in data centers [20,39,66,75]. *MDK* is designed to support different memory saving targets and performance proxies, and we describe the additional work required to apply *MDK* to an even broader context. The rest of the paper is organized as follows: First, we discuss the requirements for data center memory reclamation and motivate the new problem formulation (§2). Then we introduce *MDK*, a toolkit for evaluating policies under the new problem formulation (§3)

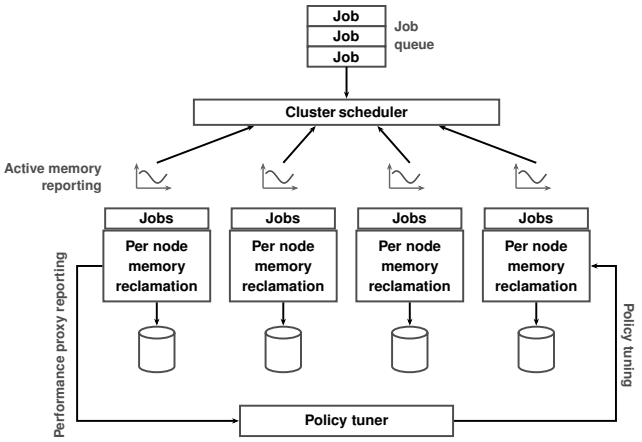

Figure 2: Data center system architecture. Reclamation policies run on individual nodes and proactively reclaim application memory and swap it to disk or compressed memory.

and discuss our implementation (§4). We outline our evaluation methodology and demonstrate the design workflow for developing new policies using *MDK* (§5). Finally, we review related work (§6) and conclude (§7).

2 Data center memory reclamation

We begin by describing the architecture of existing data center reclamation systems, the selection of memory savings targets, and performance constraint metrics in existing systems. We then identify the requirements and intuition for what constitutes a good metric. Finally, we motivate why designing new reclamation policies demands new tools, illustrating this with specific metrics. Because the space of reasonable metrics is vast, we focus our discussion on the metrics used throughout the rest of the paper, mentioning others as areas for further research.

2.1 Data center reclamation architecture

Data center operators use memory reclamation policies to reduce applications' memory usage, so they can run more jobs on servers, thus maximizing server utilization and minimizing TCO [37, 39, 66]. Figure 2 shows a typical data center architecture, which includes a complex ecosystem of feedback loops that operate across multiple timescales and influence the design of memory reclamation. Cluster schedulers manage and place jobs on nodes [62] and periodically track resource usage to predict future demands and place new jobs [6, 54].

Memory reclamation policies, operating on individual nodes, decide *when* to reclaim pages, *which pages* to reclaim, and *how many* to reclaim. They proactively free up DRAM by moving cold application data to slower and cheaper storage, such as compressed memory [37], and SSDs [66]. Recent systems [20, 39, 43, 75] also use byte-addressable CXL [1] memory pools to store cold data.

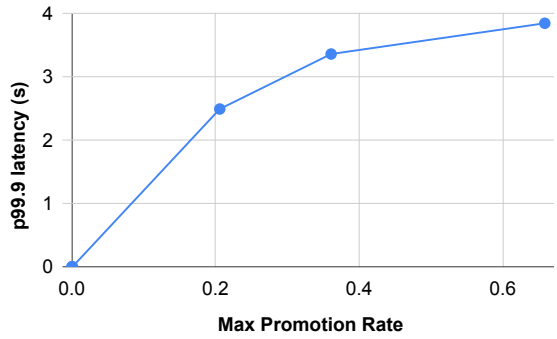

Figure 3: Promotion rate versus tail latency for Cassandra running YCSB. Promotion rate increases as tail latency across windows increases.

Reclamation policies use a *proactive operating mode* in which they reclaim memory alongside application execution, using a *tuner* that determines how many pages to reclaim. The tuner determines the number of pages to reclaim based on the observed performance degradation of the application. It measures performance degradation in discrete time windows over seconds or minutes, which allows the system to maximize memory savings while satisfying application SLOs. Applications evaluate their SLOs (e.g., query rate or tail latency) over discrete periods, not over their entire execution; therefore, satisfying application SLOs requires that a system promptly measure, report, and respond to degradation. For instance, TMO's Senpai [66] measures the performance for ten-second windows, while g-swap [37] measures two-minute windows. If performance suffers, the system reclaims memory less aggressively; if performance is acceptable, it reclaims memory more aggressively.

A policy's *control parameter* determines if a page should be reclaimed. For example, g-swap [37] uses page age, reclaiming every page that is unused after a time T, while TMO uses a page's position in LRU ordering to determine which pages to reclaim.

Although the reclamation system design dictates the overall optimization problem, system designers must still decide meaningful ways to measure performance degradation and memory savings.

2.2 SLO-aligned performance proxy metrics

Systems track application performance degradation using *performance proxies* that the operating system (not the application) can easily evaluate. This is analogous to what systems have historically done, i.e., identify the page to evict by minimizing the number of page faults. In either setting, a performance proxy should: 1) be easy for the OS to monitor (despite hardware heterogeneity), 2) be meaningful for the diverse application mix hosted in the data center, and 3) correlate with application performance metrics commonly used in data centers.

Traditional performance proxy metrics such as cache miss rate and page fault rate are not a good match for data centers. Cache miss rate (defined as total misses divided by total accesses) cannot be accurately measured in the data center. Miss rate can be computed in the OS as the number of page faults divided by the number of page accesses, which requires observing every page access, but typical OS telemetry doesn't provide exact counts of repeated accesses to pages already in memory. Page fault rate (the total number of page faults normalized by time) is used by earlier work [15, 55], since it can be easily measured by the OS. However, as shown by TMO [66], page fault rate isn't a good data center metric: it doesn't account for hardware heterogeneity, and it fails to account for the total number of application memory accesses in a time interval.

Because traditional proxies lack applicability, reclamation system designers have developed their own. g-swap [37] uses the *promotion rate per time window*, which Google's deployment defines as the number of non-compulsory page faults normalized by the number of unique pages accessed in that window [37]. g-swap monitors this metric every two minutes and ensures it does not exceed a threshold [37]. This metric proves especially effective if page faults have a relatively uniform cost; we found that it tracks application performance well. Figure 3 illustrates that as Cassandra's (described in §5) tail latency increases, it also leads to a higher promotion rate. Additionally, checking page table entry (PTE) access bits reliably measures the number of unique pages accessed across different hardware platforms without introducing CPU caching or security concerns.

TMO uses *Pressure Stall Information* (PSI) [66]. PSI measures the time tasks spend waiting for page faults, thus measuring the impact of each page fault. Page faults have different performance costs on hardware with different performance characteristics (e.g., compressed memory or SSD); promotion rate might not capture this difference. PSI addresses this memory tier heterogeneity and provides a more direct indication of performance degradation due to memory contention; however, because PSI is a function of system load, it is harder to use in offline settings over memory access traces.

Recent byte-addressable systems use still other proxies [20, 46] such as *Secondary Tier Access Ratio* (STAR). STAR calculates the total accesses directed to a secondary tier (e.g., CXL memory) relative to the total number of accesses. STAR is a good match for byte-addressable memory because data can be accessed directly without promotion. Ultimately, the system architecture and hardware heterogeneity determine the proxy choice.

2.3 Memory savings optimization targets

Optimizing for a *memory savings target* should enable running more jobs on a node, which decouples memory reclamation and cluster scheduling. Higher level feedback loops guide the design of the memory savings target: a cluster scheduler can leverage memory savings only if those savings last long enough to allow newly scheduled applications to amortize the overhead of job placement. For example, Google data centers use a threshold of at least five minutes [54].

In addition to increasing overall efficiency, optimization targets might encode other goals such as minimizing page migration traffic between memory tiers. For example, if a page is reclaimed and migrated to a slower memory tier and then accessed again a short time later, it produces unnecessary page migrations, which harm application performance.

An effective metric must therefore lead to meaningful savings that increase utilization, while satisfying other goals such as keeping page migration activity low. TMO and g-swap maximize the average memory savings of an application over time. Another metric worth exploring is *tail memory usage*, which measures the $95^{th}\%ile$ (or higher) memory usage of a node (i.e., machine memory capacity minus memory savings) and can serve as an effective indicator of future peak memory usage [6], which is helpful for capacity planning [12].

2.4 The data center reclamation problem

The data center reclamation problem space offers many possible optimization problems, defined by the choice of memory savings metric and performance proxy. Having determined the desirable characteristics of these metrics, we focus on one specific problem formulation to understand how to design reclamation policies and to demonstrate the use of *MDK*.

We adopt average memory savings as the memory savings target, as is currently done in several existing systems [37, 66]. We adopt g-swap's promotion rate per time window as the performance proxy. We choose promotion rate because it's easier to compute on offline traces than PSI, making it a practical choice for understanding how to design reclamation policies.

The specific problem we explore is: **maximize average memory savings subject to the constraint that the promotion rate (measured every time window T_{proxy}) does not exceed a specified threshold (the target promotion rate)**. Here, T_{proxy} defines the time scale for monitoring and reacting to performance violations.

2.5 The need for a new design toolkit

Unfortunately, foundational tools designed for replacement policy design workflow shown in Figure 1, don't translate directly to the reclamation problem.

First, policies deemed optimal for the traditional problem are suboptimal for data center reclamation. Consider Mattson's OPT [47], the optimal policy for minimizing miss ratio for a cache of a fixed size M, and VMIN [50], the optimal policy for minimizing miss ratio in a variably-sized cache of average size M. OPT evicts the resident page that will be

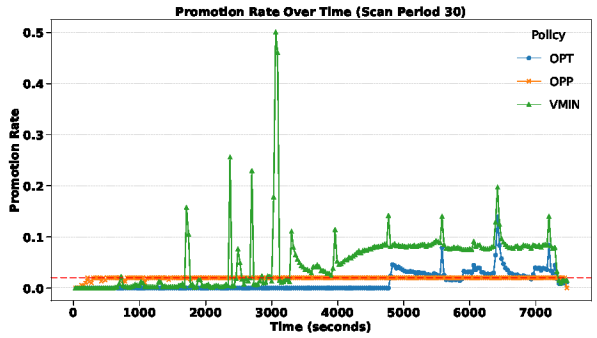

Figure 4: Promotion rate over time for a Cassandra server running YCSB with 50% read and 50% update operations. The red line depicts the target promotion rate. Both OPT and VMIN violate the target promotion rate.

accessed farthest into the future. VMIN proactively reclaims a page immediately after access, if its next access is greater than a given preset parameter T_F. Figure 4 shows how the promotion rate varies over time for a Cassandra workload (described in §5), with the target promotion rate set to 2% (shown as a horizontal red line). We see that both OPT and VMIN violate the target promotion rate when measured over discrete time intervals, while Optimal Performance Proxy (OPP, the optimal policy we define in §3.2) satisfies this constraint throughout.

Mattson's MRC construction algorithm [47] allows researchers to compare policies in the traditional setting. It relies on a theoretical property called the *the inclusion property* that states that a cache of size $C_1 > C_2$, implies C_1 always contains all elements contained in C_2. Therefore, if a memory access causes a miss in C_1, it also causes a miss in C_2. Researchers define the largest cache size that experiences a miss as the critical capacity C_t; caches larger than C_t will not experience the miss. Mattson's algorithm uses this insight to compute the critical cache capacity for each access in a trace. This allows the algorithm to compute Miss Ratio Curves (MRCs) in log-linear time complexity. This approach falls short for reclamation policies, because they do not use the same control parameters, *i.e.,* cache size C. Additionally, the memory size used by the application is implicit for replacement policies, but not for reclamation policies, where it changes as we reclaim memory over time, requiring us to compute the memory size alongside the performance proxy. Clearly, new approaches are needed for developing practical reclamation policies.

3 *MDK*: a toolkit for the new problem

We present the **Memory Designer's Kit** (*MDK*), the data center memory reclamation analog to the policy development tools and techniques used for traditional cache replacement. *MDK* consists of four components: 1) the *Memory Performance Curve (MPC)* (§3.1): the data center equivalent of conventional MRCs to illustrate policy tradeoffs. 2) the *Optimal Performance Proxy (OPP) policy* (§3.2): an offline, provably optimal policy for maximizing average memory savings subject to a promotion rate constraint. 3) *theoretical properties* (§3.3): properties that relate a reclamation policy's promotion rate and memory savings as a function of different policy settings. 4) an *efficient MPC generation framework* (§ 3.4): a method that leverages the theoretical properties to efficiently generate MPCs for multiple performance proxy values in a single pass. We also discuss *MDK*'s generality (§3.5).

3.1 Memory Performance Curves (MPCs)

Memory Performance Curves (MPCs), shown in Figure 7 and Figure 8, plot how the average memory savings (on the y-axis) changes as a function of the target promotion rate (on the x-axis). Since both metrics are dependent values driven by the policy control parameter, R_t, (described in §3.3), their relationship is not surjective, meaning that the achievable memory savings do not map to the entire spectrum of performance values. We present MPCs as scatter plots because drawing lines between points would falsely imply that these intermediate performance proxy values can be achieved when, in fact, they cannot. Just like MRCs, MPCs help us understand how to trade performance for memory savings under a given policy and answer questions such as: if we can tolerate a certain level of performance degradation (e.g., a 2% promotion rate instead of 1%), what additional memory savings can we achieve? MPCs also provide a consistent way to compare the performance of different policies: under the same performance constraint (e.g., a 1% target promotion rate), which policy achieves greater memory savings? §5 demonstrates using MPCs for these purposes.

3.2 Optimal Performance Proxy (OPP) policy

A provably optimal policy is an important tool for developing practical policies for a given problem, even if it requires future knowledge and is impractical to implement. It allows system designers to compare policies to the optimal to determine how much performance might be gained by designing a better practical policy. It often inspires more practical policies; for example, S3FIFO [2] used OPT to conclude that, at smaller cache sizes, most objects are accessed only once. For learning-based policies, it also serves as ground truth for training [29, 40, 42, 44, 52, 56, 58–60, 65, 68, 71, 76].

We present an optimal policy for the data center reclamation problem. We begin by illustrating the intuition behind an optimal policy for this setting (§3.2.1) and then formally present the Optimal Performance Proxy (OPP) policy and discuss key insights (§3.2.2).

T	Pages accessed	Pages cached			Pages evicted		
		OPT	VMIN	OPP	OPT	VMIN	OPP
1	a,b,c	a,b,c	a,b,c	a,b,c		a,b	a,c
2	d,e,f	d,e,f	c,d,e,f	b,d,e,f	a,b,c	e	e
3	d	d,e,f	c,d,f	b,d,f		d	d
4	c,f	c,e,f	c,f	b,c,f	d	c,f	c,f
5	a,b	a,b,c	a,b	a,b			

Table 1: Non-optimality of OPT and VMIN. Both OPT (cache size 3) and VMIN (forward reuse distance 3) evict pages that violate future promotion rates. Page promotions for previously accessed pages, i.e., *page faults*, appear in red. A violation of the target promotion rate occurs in a period where the ratio of page faults to accesses is greater than 50%.

3.2.1 Non-optimality: an example

To understand the key requirements of an optimal policy for data center reclamation, it's helpful to first examine why traditional optimal replacement policies such as OPT and VMIN fail. Table 1 provides an example: for a given access trace, it shows accessed, cached, and evicted[1] pages for OPT, VMIN, and OPP and highlights (in red) violations of the target promotion rate (set at 50%). A violation occurs in a time period when the promotion rate (the number of page faults for previously accessed pages relative to the total number of pages accessed) is greater than the target.

All three policies begin by caching a, b, and c. During time $T2$, OPT for a cache of size 3 evicts a, b, and c, to make room for d, e, and f. No eviction happens during $T3$ as the only accessed page (d) is already cached. During $T4$, OPT evicts d, which will never be accessed again, to accommodate c. Finally, during $T5$, accesses to both a and b produce cache misses, leading to a promotion rate of 100%, which exceeds the 50% target and constitutes a violation.

VMIN with a forward reuse distance of 3 (i.e., pages not accessed during the next 3 windows should be reclaimed) has the same initial cache state as OPT. However, at the end of $T1$, VMIN retains c, which is used again in $T4$ for a reuse distance of only 2, but evicts a and b proactively, because they are not used again until $T5$ for a reuse distance of 3. VMIN's cache state at the end of $T2$ contains four pages, as VMIN does not impose a fixed cache size. During $T3$, VMIN retains c and f, but evicts e as it will never be accessed again. During $T4$, only d is evicted, because it is never accessed again. However, during $T5$, accesses to both a and b cause misses, resulting in a 100% promotion rate, violating the constraint.

As we can see, both OPT and VMIN perform reclamation without considering *the future promotion rate*. They may be optimal in terms of the *total* promotions, but not the *rate in time windows*. As a result, they may cause promotions to be clustered in a single time window rather than spread out, which may violate SLOs.

Key insight: An optimal policy whose goal is to maintain a target promotion *rate* should treat *the number of promotion events relative to the number of unique elements accessed in a given time window* as a constraint during reclamation.

[1]We use the terms *reclamation* and *eviction* interchangeably, but prefer *eviction* when contrasting with prior work.

3.2.2 Optimal Performance Proxy (OPP) policy

OPP is a two-pass algorithm that takes a trace of page-level accesses and produces a set of page reclamation decisions for each time window, defined by a parameter *window_size*. During the first pass, it determines the set of pages accessed in each time window. During the second pass, at the end of each window, OPP reclaims all pages, p, that will not generate a page fault that violates the target promotion rate in the future window in which they are accessed.

More formally, given a trace of accesses A at times T to a set of all uniformly-sized pages P, $A \subseteq T \times P$, where each access is represented as a tuple $\langle t, p \rangle$ with $t \in T$ and $p \in P$. Given $W = \{1, 2, \ldots, N_w\}$ a set of measurement windows, each of a uniform time duration D, OPP maintains $U = \{U_w \mid w \in W\}$, the count of (unique) pages accessed in each window w, calculated during the first pass of the trace, and $F = \{F_w \mid w \in W\}$, a set of F_w, the running count of promotions (page faults) in each window w. $\forall \langle t, p \rangle \in A$, OPP will reclaim p, accessed at time t with known future access t_b in window B, where the window index B is computed as t_b/D, as long as the promotion rate generated by p's next access will not exceed the target promotion rate (i.e., $F_B/U_B \leq$ target promotion rate). If p is reclaimed, then the number of future promotions (F_B), is incremented.

Let us now return to the example in Table 1. Starting with the same initial state as VMIN and OPT, OPP reclaims a at the end of interval $T1$, but not b (unlike VMIN, which reclaims both), as both a and b are accessed during $T5$, and reclaiming them both will violate the target promotion rate of 50%. For the same reason, OPP avoids reclaiming b in future intervals, but OPP reclaims c at $T1$ as c's next access in $T4$ does not violate the target promotion rate.

Key insight: *OPP reclaims page as soon as possible, such that the future accesses of reclaimed pages are spread across time windows instead of clustered together. This approach allows it to meet the performance constraint for promotion rate while maximizing average memory savings.* We present the proof of OPP's optimality in Appendix C.

3.3 *MDK* theoretical properties

We next explore the properties of reclamation policies, with the goal of identifying properties analogous to the inclusion property in the traditional setting that, when present, will enable efficient MPC production.

Consider policies with one control parameter, R_t. The tuple $\langle e, T \rangle$ is an *eviction tuple* indicating that page e is evicted at time T. Let $S_{R_t} = (\langle e_1, T_1 \rangle, \langle e_2, T_2 \rangle, \ldots \langle e_n, T_n \rangle)$ be the sequence of all eviction tuples for a given policy

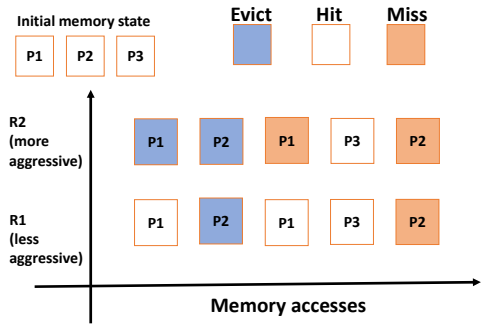

Figure 5: Decisions of a hypothetical reclamation policy that follows both *eviction decisions* and *eviction times* properties. Blue blocks depict a page reclamation after that page is accessed. The more aggressive control parameter, R2, always evicts everything that R1 evicts, at the same time.

configured with parameter R_t. The eviction sequence $E_{R_t} = (e_1, e_2, \ldots, e_n)$ is an ordered sequence of *evictions* extracted from S_{R_t} without timestamps.

Definition 1: A policy configured with parameter R_2 is *more aggressive* than R_1 if $|E_{R2}| \geq |E_{R1}|$, i.e., a policy with a larger number of evictions is more aggressive.

Definition 2: The *critical parameter,* R_C is the least aggressive parameter that causes an eviction, i.e., if R_C is the critical parameter for an eviction e, then e is an element of E_{R_C}, and for all configurations R_x: $e \in E_{R_x} \iff |E_{R_x}| \geq |E_{R_C}|$
This is analogous to the inclusion property's critical capacity, where R_C is a critical parameter if it is the least aggressive parameter for which an eviction happens.

Property: ***Eviction decisions***. *If* $|E_{R2}| \geq |E_{R1}|$ *then* $E_{R1} \preceq E_{R2}$, *i.e.,* E_{R1} is a subsequence of E_{R2}.

The *eviction decision* property states that if parameter R_2 is more aggressive than parameter R_1 for a policy, then every eviction made with R_1 is also made with R_2. Figure 5 illustrates this for a hypothetical policy where R2, which is more aggressive than R1, evicts every page evicted by R1. Note that this property applies to E_{R_t} and not S_{R_t}, which means that it does not impose a restriction that caches contain the same elements at all times T, only that their eviction sequences are ordered subsequences.

Property: ***Eviction times***. *If* $|S_{R2}| \geq |S_{R1}|$ *then* $S_{R1} \preceq S_{R2}$.

The *eviction times* property states that if a policy can be configured with two parameters R_2 and R_1, and R_2 is more aggressive than R_1, then every eviction tuple with R_1 also occurs with R_2, i.e., *evictions happen at the same time*. The policy in Figure 5 illustrates this: for both control parameters R1 and R2, P2 is evicted at the same time. The *eviction times* property can be satisfied only if *eviction decisions* is satisfied.

These properties enable efficient MPC generation. If a policy follows both the properties, then, for any given page fault, we need to track only promotion and savings caused by this fault for the critical parameter, as values for all more aggressive parameters must experience this fault and can be computed using the critical parameters' value.

We can prove that VMIN adheres to the *eviction decisions* and *eviction times* properties. VMIN takes a reuse distance T_F as input. If an element's next-access distance exceeds T_F (determined using future access knowledge), it is reclaimed immediately after access. If a reuse distance parameter T_F induces a page fault for a memory access, all reuse distance parameters smaller than T_F must also induce page faults, as the next-access distance must exceed them as well. Further, since a page is reclaimed immediately after being accessed, all parameters that cause a page to be reclaimed, must do so at the same time. Thus, VMIN follows both properties. We omit proofs for other policies implemented in *MDK*, but they can be derived by construction.

3.4 Efficient MPC generation

The *MDK* MPC generation framework provides the building blocks to efficiently construct MPCs for various reclamation policies that adhere to the *MDK* properties. Efficient MPC generation is important, as simulating policies can take a long time.

```
def generate_mpc(A):
    savings    = [0] * GetParamSpaceSize()
    promotions = [0] * GetParamSpaceSize()

    for t, p in A:
        R_C = GetCriticalParam(t, p)
        promotions[R_C] += 1
        access_savings = GetMemorySavings(t, p)
        savings[R_C] += access_savings

    cumulative_promotions = 0
    cumulative_savings    = 0

    # Iterate through parameters sorted by their aggression
        level order
    param_order = GetParamAggressionOrder()
    for R_t in param_order:
        cumulative_promotions += promotions[R_t]
        cumulative_savings    += AccumulateSavings(savings[
            R_t])

        print(R_t, cumulative_promotions, cumulative_savings
            )
```

Listing 1: Efficient MPC generation template. Users need to manually implement five policy-specific functions.

3.4.1 Understanding the MPC template

Listing 1 presents a high-level approach for constructing MPCs for policies that operate with a single control parameter. It takes as input a trace of page accesses and their access times and requires that the user provide five policy-specific functions. We first explain the core ideas of the approach and

```
GetCriticalParam(page_id, curr_time) {
  return (curr_time - prev_time[page_id])
}
```

```
GetMemorySavings(page_id, curr_time) {
  return (curr_time - prev_time[page_id] ) * page_sz
}
```

```
AccumulateSavings(savings) {
  return savings
}
```

Figure 6: Policy specific function examples for MPC generation of the VMIN policy. *GetCriticalParam* computes the critical parameter, which is the least aggressive future reuse distance for which a page access causes a page fault. *GetMemorySavings* returns the time-multiplied savings associated with each page, assuming it was migrated back into DRAM for the current access. *AccumulateSavings* iteratively computes the memory savings associated with all control parameters of a policy.

then discuss how to use this implementation by detailing the policy-specific functions required for VMIN [50].

The generator leverages the fact that all memory accesses cause a page fault under a sufficiently aggressive control parameter setting. For each access, we compute the critical parameter R_C (line 6), the least aggressive setting where that access causes a page fault. In traditional systems, this is the largest cache size for a miss: any cache size smaller than this critical size will also experience a miss if the policy follows the inclusion property. Similarly, in our context, any parameter that is more aggressive than R_C will also experience a given page fault if the policy follows the *eviction decisions* property. Computing R_C depends on the policy and the control parameter: g-swap uses page age threshold, VMIN uses future reuse distance, etc. Thus, we implement a policy-specific *GetCriticalParam* function.

Page faults create memory savings for the time a page is removed from memory. The key idea for efficient memory-saving computation of all parameters is that the generator tracks savings from reclaiming page P only for the critical parameter R_C (line 9). If the policy follows the *eviction times* property, more aggressive settings will save the same amount, because they will *reclaim the page at the same time as* R_C. We easily calculate savings: if a page is reclaimed at T_1 and faulted in at T_2 (for the current access), the saving is $(T_2 - T_1) \times page_size$. The policy-specific function *GetMemorySavings* determines T_1, as different policies reclaim pages at different times. For example, g-swap reclaims once a duration of age has elapsed since the page was last accessed, while VMIN reclaims immediately after a page is accessed.

The algorithm's last step builds the full MPC. It recursively calculates promotion rate and average memory savings for all possible policy parameters. For the sake of exposition, we simplify promotion rate calculation here, but our algorithm computes it per time window. First, we determine the order of parameter iteration from least aggressive to most aggressive. The order of aggressiveness is also policy specific, e.g., largest age to smallest for g-swap, smallest to largest promotion rate for OPP. Assuming policies follow *eviction decisions*, we cumulatively add page faults to more aggressive settings (line 17) to get the promotion rate for all parameters. *AccumulateSavings* recursively computes average memory savings. For policies following *eviction times*, we add savings from less aggressive parameters to more aggressive ones. This generates the entire MPC.

3.4.2 Using the generator with policy specific functions

We used *MDK* to implement several policies; we include the policy-specific functions for these policies in Appendix A. Here we illustrate how to use *MDK*'s MPC generator using VMIN [50] in Figure 6. Recall that VMIN reclaims any page whose next access occurs more than than T_F time period in the future.

GetParamSpace and *GetParamAggressionOrder* (omitted from Figure 6) define the template's invariant for building the MPC from least to most aggressive parameters. The least aggressive parameter for VMIN is the largest reuse distance in a trace, and the most aggressive value is 1, so we order these parameters from high to low.

GetCriticalParam takes the page ID and access time of the page access and calculates the critical parameter R_C. For VMIN, R_C is simply the current page's reuse distance, i.e., the largest possible T_F setting for which this page would have been reclaimed by the policy when the page was previously accessed. Because VMIN reclaims on access, the currently accessed page would cause a page fault only if VMIN immediately reclaimed this page after its last access. Suppose the current time is T_2 and the previous time the page was accessed was T_1. At T_1, the policy finds the next access, which occurs at T_2, and reclaims the page for any $T_F < (T_2 - T_1)$, with R_C being $T_2 - T_1$. In the generator, we can directly compute R_C at T_2 by looking at the last time the page was accessed. Therefore, we do not need to maintain future data. As shown in Figure 6, we compute this by subtracting the last access time from the current one, T_C. Because VMIN follows *eviction decisions*, any $T_F < T_C$ will also experience this page fault, and the template counts faults for all $T < T_C$ to construct the MPC.

GetMemorySavings takes the same input as *GetCriticalParam* and calculates the memory saved by a reclamation, when a promotion happens. The value will be determined by the time between when a page is reclaimed and the time of its next access. In VMIN, pages are reclaimed immediately after access, so the savings are the number of windows between a page's reclaimed access and its next access.

AccumulateSavings adds up memory savings for all settings as the MPC is constructed. For policies such as VMIN that follow *eviction times*, we simply add the savings of less aggressive settings to more aggressive ones as we go through the settings in the template, as shown in Figure 6. If a policy does not follow *eviction times* (e.g., the AGE policy), this

function lets designers create custom recursive calculations.

3.5 Generality of *MDK*

We present *MDK* in the context of one specific problem, characterized by the metrics *average memory savings* and *promotion rate*. However, as discussed in §2, there is a large problem space for data center memory reclamation, with different choices of memory savings targets and SLO-aligned performance proxies. The tools provided by *MDK* generalize well to this broader problem space, enabling researchers to explore beyond the specific problem presented here: (1) An MPC, by definition, accommodates any memory-saving metric and performance proxy, making it applicable to any problem in the space. (2) The optimal policy will vary by problem formulation; however, the development of OPP provides key insights into designing optimal policies for other problems: the performance constraint should always be treated as a first-class consideration, regardless of which proxy defines the constraint. (3) The *eviction decisions* and *eviction times* properties allow us to categorize policies with one control parameter, R_t, based on whether they satisfy these properties, regardless of the specific problem they address. (4) The MPC generation template works with any single parameter policy that satisfies the *eviction decisions* property, regardless of the specific problem formulation. With the PACE generator (Appendix B), we demonstrate that it is possible to apply our properties to two-parameter policies as well; generalizing them to multiple parameters is future work. (5) We focus on metrics that can be computed using page access traces. Runtime metrics such as PSI require an analytical model that can approximate PSI values offline; developing and incorporating such a model in *MDK* is future work.

4 Implementation

MDK consists of a collection of C++ tools and libraries to simulate data-center memory reclamation policies and generate MPCs efficiently.

Trace collection and format: We collect page access traces on Linux using a kernel thread similar to *kstaled* from g-swap [37]. Applications run with all their data in DRAM and hugepages disabled, and the kernel thread periodically (every 30 seconds in our experiments) walks the page table, writes a trace record for each page accessed, and clears the access bits. The trace record contains the page ID and an access period counter value. The performance metric that we use in the paper, promotion rate, is evaluated on a per-application basis as described in g-swap; we focus on collecting per-application traces instead of traces for applications competing against each other. This periodic algorithm does not capture multiple accesses to a page in the same period. This omission is problematic for frequency-focused policies or performance metrics. However promotion rate is resilient to this omission as long as a page is not faulted multiple times within a time window (which is unlikely).

Policy simulation: Simulation provides ground truth for evaluating the accuracy of MPCs generated using *MDK*, but existing simulators do not implement variable-sized-memory policies, so we implemented our own, similar to libcachesim [72]. Our simulation framework takes as input the traces described in the previous section and simulates both fixed- and variable-sized-memory eviction algorithms. At the end of each time period, the simulator selects pages to reclaim according to the policy.

We simulate eight different policies: two fixed-sized-memory policies (LRU and OPT) and six variable-sized-memory policies (VMIN, AGE, PAW, PACE, L-OPP, and OPP). LRU was faithfully implemented based on prior work, and OPT follows the algorithm described by Mattson et al. [47]. VMIN was implemented as described by Prieve et al. [50], and our AGE policy follows the description from Lagar-Cavilla et al. [37]. Finally, we implemented new policies PAW, PACE, and L-OPP that are described in §5.4. We implemented OPP as described in §3.2.2.

Efficient MPC construction: Our MPC construction library takes as input a trace and a policy and outputs a collection of performance proxy, memory saving pairs that together express an MPC. We implemented MPC generators for AGE, OPP, VMIN, PAW, and PACE as case studies. Single-parameter policies were implemented in *MDK* in fewer than 87 lines of code. All single-parameter policies follow the *eviction decisions property*, and all but the AGE policy follow the *eviction times property*. Policies that follow the *eviction times* property can use the same AccumulateSavings function. However, the GetCriticalParam and GetMemorySavings functions require policy-specific data structures and computation, such as the one described for VMIN in §3.4.2. The framework supports only integer control parameters, so we currently generate only integer promotion rates for OPP. For PACE, our new two-parameter policy (§5.4), we implemented a specialized MPC generator described in Appendix B.

5 Evaluation

We evaluate the individual components of *MDK* and demonstrate *MDK*'s use in Figure 1's policy design workflow. To evaluate *MDK*'s components, we compare the accuracy and speed of its MPC generation relative to simulation and compare its OPP policy to VMIN. To illustrate *MDK*'s use in designing new policies, we show how it can be used to understand the headroom of existing policies, inspire the creation of new policy ideas, and efficiently generate MPCs to compare policy alternatives.

Table 2: Workloads used to evaluate *MDK*. Execution time (in seconds) for *MDK*'s MPC generator and simulation for the OPP policy, which is the slowest. *MDK* generates the plot for all parameters; for simulation, we conduct separate simulations for 10 control parameters to populate the MPC.

System	Workload	Memory	Trace duration	*MDK* (s)	Simulation (s)	Speedup
Cassandra	YCSB	17.48G	120 minutes	88.4	9752	110×
Memcached	Twitter KV	15.06G	120 minutes	432.4	24165	55×
GraphX PageRank	PageRank on Twitter dataset	10.2G	28 minutes	36.8	2253	61×
NGINX Media streaming	Video serving	820M	11 minutes	0.4	5	12.5×
TaoBench	Caching	160G	45 minutes	583.2	48240	82×
DjangoBench	Web serving	1.56G	51 minutes	6.7	160	24×
FeedSim	Object aggregation/ranking	56G	22.5 minutes	52.9	11050	208×
MediaWiki	Web serving	3.9G	15.5 minutes	8.2	260	32×

5.1 Methodology

We evaluate *MDK* using page access traces generated from eight workloads in the CloudSuite [49] and DCPerf [61] benchmark suites, as listed in Table 2. All workloads were configured with the default parameters specified in the CloudSuite Docker images and DCPerf documentation. We collected all our page traces and ran our end-to-end case study on Linux kernel version 5.10 on a machine with an Intel Xeon CPU E5-2696 with 256 GB of RAM. We used a 64-core AMD EPYC 7B13 machine with 128GB of RAM for benchmarking *MDK*'s simulator and MPC generator.

5.2 *MDK* MPC generation

We evaluate the accuracy and speedup of *MDK*'s MPC generation relative to that of simulation for the workloads in Table 2.

MPC generation accuracy: *MDK* includes MPC generation algorithms for policies enabled by our theoretical properties. To validate the accuracy of *MDK*'s MPC generation, we compare *MDK* MPCs to MPCs created via simulation. We confirm that the simulator and MPC produce similar average memory savings and promotion rates for all policies. For one-parameter policies, we compared ten different parameter settings, and for the two-parameter policy PACE, we compared 15 different parameter settings. The mean absolute errors of all MPCs are within 1% of the simulation (due to rounding inconsistencies).

MPC generation time: Our goal in pursuing fast MPC generation is to enable rapid evaluation of new policies and/or parameter settings for those policies, rather than relying on simulation or in-kernel implementations. Table 2 shows the runtime for generating MPCs using *MDK* versus simulation for the OPP policy, the slowest policy in both the *MDK* framework and our simulator. OPP MPC construction takes twice the time of both VMIN and AGE, as OPP needs to process the trace twice, first to gather the number of pages accessed in each window and second to compute reclamation decisions. The time that we report for simulation is for simulating ten different parameter settings, run sequentially. The simulation time is dependent on the number of page access events in each trace. Memcached and TaoBench have the highest number of page access events, leading to the slowest simulation time. *MDK*'s MPC generation algorithms outperform simulation by 12.5× to 208×. *MDK*'s MPC generation is faster due to the linear time complexity of the MPC generation algorithms compared to the quadratic time complexity of simulation. The simulation time can be reduced by running simulations in parallel; however, the simulator would still be limited by its time complexity.

5.3 Comparing optimal policies

Figure 4 shows the promotion rate over time for Cassandra. Recall that VMIN and OPT violate the promotion rate. OPP maintains a target promotion rate for the duration of the entire workload, due to it considering both the accesses per time interval and the reclamations. Although VMIN and OPT maximize system throughput and can lead to better average memory savings when the performance proxy is measured over the entire execution of a program [18], they make suboptimal decisions that lead to promotion rate violations in time windows, likely leading to application SLO violations.

5.4 Using *MDK*

We show how we use the policy development workflow (Figure 1) for new policies. First, we use *MDK* to understand AGE's performance compared to OPP. Then, leveraging insights from OPP, we describe how we design two heuristic policies and a learned policy. We then describe the generation of their MPCs and discuss our policies' performance compared to AGE. Finally, we validate one of our heuristic policies on Linux.

5.4.1 Understanding headroom:

Figure 7 shows the average memory savings as a function of the promotion rate for our workloads. We expect that memory savings should increase as the promotion rate constraint increases (i.e., policy becomes more aggressive). MPCs tell us what parameters of a policy perform best under an operating

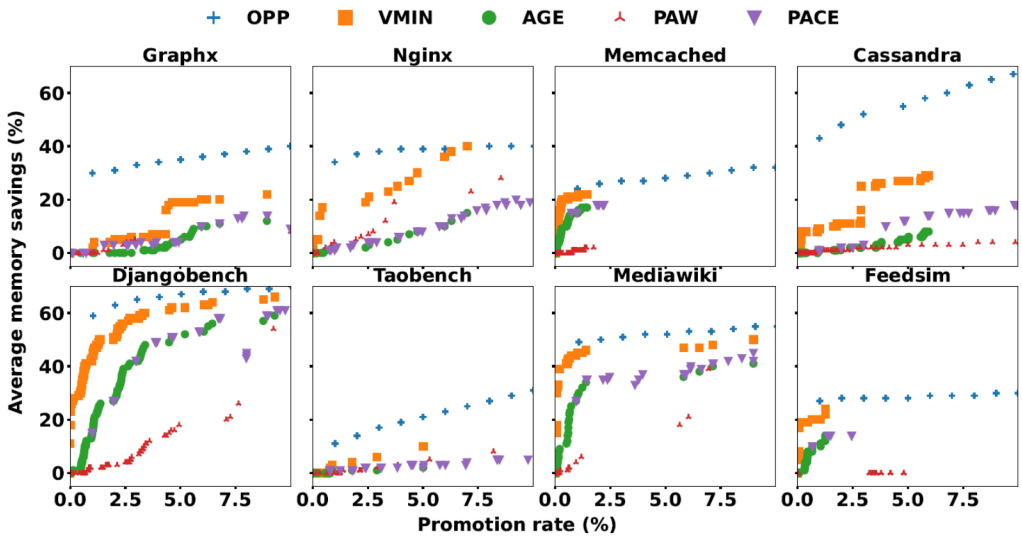

Figure 7: MPC for various policies supported by *MDK*. We show results only at lower, more practical, promotion rates. OPP and VMIN are offline optimal policies, while AGE is a practical one. PriorAgeWithWait (PAW) is a new practical heuristic policy that we introduced. As expected, OPP always has the best average memory savings for any promotion rate. PAW can perform better than AGE for workloads with predictable access pattern, while AGE performs better than PAW for unpredictable workloads. PACE, a new two-parameter policy that combines PAW and AGE, always performs as well as AGE and has the potential to outperform AGE for workloads such as Cassandra.

regime. We use our MPC results to answer questions about operating regimes, *i.e.,* "what is the best memory saving that can be achieved under a certain promotion rate?". Although not directly visible in our MPCs, the generation algorithm also helps answer "what is the control parameter setting that we should use to achieve a certain promotion rate?" as shown in Listing 1 (line 20). Our MPCs show that for multiple applications, tuning practical policies cannot achieve certain operating regimes. This can be observed in Memcached, where policies do not have any parameters that lead to a promotion rate higher than 2.5%. Collections of vertical points (often called "cliffs" for MRCs) are desirable, as they represent an increase in memory savings for a small increase in promotion rate (e.g., the AGE and VMIN policies for Memcached and MediaWiki). In other words, these vertical patterns indicate that slightly more aggressive policies improve average memory savings nearly "for free". In contrast, horizontal plateaus are undesirable: they represent cases in which increasing the promotion rate constraint does not increase memory savings, as can be observed in the case of Mediawiki. In all cases, the MPCs quantify the policy operating range by showing how a given promotion rate impacts average memory savings, enabling the selection of a reasonable target promotion rate. MPCs also provide insights about what promotion rate must be tolerated to achieve a desired average memory savings.

We compare the performance of the optimal policies, comparing OPP to VMIN. We omit OPT from discussion, because it is a fixed-sized memory policy that VMIN consistently outperforms. Understanding the performance of the optimal policy for a given setting is important, as it provides an upper bound on what can be achieved by a practical implementation. As expected, OPP (blue plus) consistently has the highest average memory savings. Varying the promotion rate constraint for workloads such as Cassandra and TaoBench can lead to better average memory savings, as indicated by the slope of the MPC. For Cassandra, OPP achieves 40% average memory savings under a 1% promotion rate, while VMIN cannot achieve the same savings even under a 10% promotion rate. For workloads such as FeedSim and MediaWiki, the average memory savings for OPP is relatively flat, indicating that it is not possible to increase savings via more aggressive reclamation (i.e., by tolerating further performance degradation). This provides insight into the performance ceiling for each workload, given different promotion rates.

Now that we understand optimal performance, we examine the performance of AGE policy that approximates Google's g-swap [37] (green circles in Figure 7) compared to OPP. AGE is a simple policy that reclaims a page if a certain time period has elapsed since its last access, and it hasn't been accessed since. This mandated waiting period prevents unnecessary reclamations, but it also prevents AGE from reclaiming pages quickly, foregoing savings. As a result, compared to OPP, the AGE policy does significantly worse. This suggests that there is ample headroom to develop a better policy. For many workloads (such as Memcached and DjangoBench), the best memory savings that the AGE policy achieves under different operating regimes scale similarly to VMIN; this is expected, since page fault characteristics are theoretically identical for

these policies [18], while savings are not. Further, the AGE policy is often conservative, as shown in the GraphX workload; the AGE policy never exceeds ∼10% average memory savings, even on the most aggressive settings, as it waits for a minimum number of time windows before reclaiming pages, making it impossible to reap the full potential savings.

5.4.2 Designing and evaluating new policies

We use the insights revealed in Figure 7 to propose policies that bridge the gap between AGE and OPP. The steps for designing a policy shown in Figure 1 are: coming up with a new policy idea, generating its MPC, which entails understanding whether *MDK* properties apply, and if they do, implementing their MPC generators in *MDK*, and comparing the new policies' performance to AGE. We describe the steps per policy for three new policies.

Prior Age with Wait (PAW)

Design: First, we develop a simple heuristic policy that reclaims pages after access, similar to OPP, by using historical reuse distances. This policy, **P**rior **A**ge with **W**ait (PAW), reclaims a page if its prior age, the distance between a page's last two accesses, is greater than a threshold P, and at least one minute has elapsed since its last access. Waiting one minute addresses potential issues for frequently used pages: if a page is recently accessed, it is likely to be accessed again, so the policy waits briefly before reclaiming it to increase confidence in the reclamation.

Generating MPC: PAW follows the *eviction decisions* and *eviction times* properties, so we implemented its generator in *MDK*. Writing the policy-specific functions took fewer than 65 LOC. For the *GetCriticalParam* function, we reused the AGE policy's implementation, as the only difference is looking at the current reuse distance versus the previous one. The other two memory functions are identical to VMIN's, as both policies follow the *eviction times* property.

Comparing performance to AGE: Figure 7 illustrates the MPC for comparing AGE with PAW. PAW outperforms AGE on workloads with predictable access patterns: it saves up to 10% more memory than AGE on GraphX, NGINX, and TaoBench. However, for workloads such as Memcached and FeedSim, where past behavior is not a good indicator of future accesses, AGE's conservative approach is better. As our results clearly show, for certain workloads where reuse distances are not a good indication for reclaiming a page, AGE outperforms PAW significantly.

Prior Age and Current Elapsed (PACE)

```
def PACE(page, P, A):
    alpha = get_prior_age(page)     # Last reuse distance
    beta  = get_current_age(page)   # Time elapsed since last
    active reference
    evict = False
    if alpha > P:
        evict = True
    if beta > A:
        evict = True
    return Evict
```

Listing 2: The PACE two parameter policy. PACE evicts pages immediately if their reuse distance is greater than a control parameter P. If the reuse distance is small, then PACE waits until time A has elapsed, similar to AGE. to reclaim a page.

Design: The **P**rior **A**ge and **C**urrent **E**lapsed (PACE), detailed in Listing 2, is a simple two-parameter policy that combines the aggressiveness of PAW with the conservative nature of AGE. PACE directly addresses the shortcomings of PAW for workloads where reuse distances are not enough to make good decisions. For each page, PACE checks if its reuse distance, *i.e.,* the difference between its prior two accesses, is greater than a prior age threshold P; if so, it evicts the page immediately. Unlike PAW, PACE does not wait for one minute before reclaiming a page. If the reuse distance is not greater than P, then PACE waits a time period A after a page's last access before reclaiming it. PACE has two control parameters, P and A. Tuning P allows PACE to evict pages immediately upon access, similar to PAW, and for pages where P is not a good indication for eviction, PACE reclaims a page after it is not accessed for A time intervals, similar to g-swap's current AGE policy.

It is trivial to see that under the correct (P,A) setting PACE must always perform as well as, if not better than AGE. If P is set to infinity, no page would ever satisfy the prior age condition; therefore PACE can always fall back to AGE. The challenging part is determining the best parameter combination for a given application. Simulating all parameters for PACE is prohibitively expensive due to many possible (P,A) values; our traces have more than 10,000 unique (P,A) combinations. Additionally, there is no intuition that allows us to guess good (P,A) combinations.

Generating MPC: We present a novel specialized algorithm for efficiently generating the MPC for the PACE policy, rooted in our theoretical properties. Although we cannot compare the aggressiveness of two arbitrary parameter combinations (P_1,A_1) and (P_2,A_2), because these parameter combinations don't follow the *eviction decisions* and *eviction times* properties, P and A individually follow these properties, implying that both $E_{(P+1,A)}$ and $E_{(P,A+1)}$ would be subsequences of $E_{(P,A)}$. This fact allows us to generate the MPC for PACE efficiently using the dynamic programming solution to the suffix sum problem. We describe the algorithm that we

implemented in about 300 loc, in detail in Appendix B.

Comparing performance to AGE: In Figure 7, we report the top three performing configurations for PACE for each 1% promotion rate increments, such as 1-2%, 2-3%. The results show the maximum potential benefit (an upper bound) when the optimal parameters are chosen on the same trace used for evaluation. As expected, PACE's best configurations always perform as well as AGE's best configurations. For most workloads, PACE obtains modest memory savings improvement of 1-4% across different promotion rates. For workloads such as Cassandra and GraphX, PACE 's best configurations outperform AGE by 8-10%; PACE increases savings by evicting pages earlier. Since AGE, PAW, and PACE have parameters dependent on application characteristics, a tuner would need to observe application characteristics online and then set *P* or *A* parameters for all three policies. Note that with more tunable parameters, the results are more susceptible to overfitting when using the exact same trace for tuning and evaluation; tuning without a priori trace knowledge for unseen traces is left for future work.

Learned OPP (L-OPP)

Design: OPP demonstrates significant headroom over AGE, however it requires future information. Inspired by prior work on learned policies in the traditional problem [29, 42, 59], we investigate whether a learned policy that imitates OPP, *L-OPP*, can improve upon AGE without needing future information. Our intent is to illustrate that OPP can be used more directly to derive a new policy, rather than to create the perfect learned policy. We frame page reclamation as a binary classification problem: given a page access and its re-access history, the model predicts whether to reclaim the page. We train a gradient boosted tree model for this task, using the open-source YDF library [24] with default hyperparameters. To build the training dataset, we first use periodic page table access bit scans to collect page access traces for the DCPerf benchmarks [61]. Then, we use our simulator to run OPP on these traces with a target promotion rate of 2% and log every reclaim/not reclaim decision along with the historical reuse distances of each page. Our goal is that L-OPP will achieve the same promotion rate. We then train a separate model for each workload on the first 80% of the dataset, using six past reuse distances for each page as features. We use the last 20% of the dataset for validation. The final L-OPP policy uses AGE to reclaim first-use pages (i.e., those that have no reuse features); for all other pages, it queries the trained model at the end of the time interval in which they have been accessed.

Generating MPCs: We implement L-OPP in our simulator, because it does not obey the *eviction decisions* and *eviction times* properties, because it doesn't have any tunable parameters. We incorporate the C++ implementation [24] of L-OPP as a new policy in our simulator to generate MPCs. For simulator testing, we use a completely different trace than the one used for training; we collect this trace by running access bit scans on a second execution of the same workload.

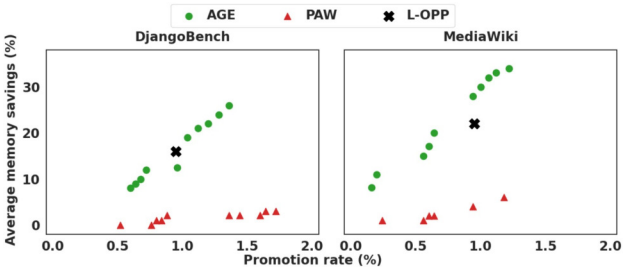

Figure 8: MPC for AGE and our learned policy, L-OPP.

Comparing policies to L-OPP: Figure 8 compares AGE, PAW, and L-OPP for the DCPerf benchmarks. L-OPP has better average memory savings than PAW for both workloads and is modestly better than AGE for DjangoBench. L-OPP is conservative and the number of per-window reclamations it makes are small, so we need to have longer workloads such as DjangoBench to accumulate savings over time to show benefit. (Similar observations have been reported for conservative non-learned policies [66].) L-OPP maintains a 1% promotion rate constraint, demonstrating that the learned policy maintains the promotion rate for which it was trained. For TaoBench and FeedSim (results omitted), L-OPP's low offline precision results in a high promotion rate, showcasing that high precision models are important to meet the promotion rate constraint. Although these initial results suggest the need for feature engineering and training at different target promotion rates to improve L-OPP's performance (a topic for future work), L-OPP demonstrates OPP's utility for policy creation, in addition to headroom analysis.

5.4.3 Validating policy end-to-end in Linux:

We evaluate *MDK*'s findings by implementing PAW and AGE in Linux. Both policies reclaim pages every 30 seconds: AGE reclaims pages that are unused for 10 minutes, and PAW reclaims pages with reuse distance greater than 2.5 minutes. We use an SSD as the swap backend and turn off hugepages. Table 3 shows the average memory consumption and swap usage of both policies for running the Page Rank benchmark on GraphX. We choose parameter settings to operate under a 4% promotion rate threshold based on our offline MPC results.

As predicted by our MPC, PAW saved 4% more memory without compromising performance. The savings are as expected, because AGE is cautious and reclaims late, while PAW reclaims pages shortly after access, increasing the average memory savings as shown in our results. The promotion rate of both policies was around 1.5%, significantly lower than the 4% threshold we expected. For promotion rate to match

the simulation and our framework, policies need to observe page accesses at similar times. However, both policies ran faster than our offline trace, and the promotion rate is directly dependent on the runtime of the application. The fact that the policies run in less time than our original trace shifts the windows in which reclamations occur, changing the observed promotion rate. There are several avenues of future work to explore to analyze and mitigate this effect: (1) Implementing *MDK* MPC generators in a self-tuning system similar to Senpai [66], would allow for accurate estimation of promotion rate while applications are running, (2) Running an analytical analysis that develops confidence bounds of the offline MPC results for online use.

Table 3: Policy Comparison on Linux for GraphX. We measure the mean and standard deviation of memory and swap usage.

Policy	Swap (GB)	Memory Usage (GB)	Time taken (mins)
PAW	0.59 ± 0.75	9.11 ± 0.84	16.9
AGE	0.23 ± 0.29	9.52 ± 0.27	17.1

6 Related work

MDK builds upon concepts from prior work on optimal algorithms, variable-sized cache policies, approaches for generating MRCs, and memory reclamation metrics.

Optimality: Several prior works focus on optimal policies for fixed-sized memories for uniform object sizes [8, 47], non-uniform object sizes [10], variable-sized memories [50], and for non-uniform memory access cost [30]. These policies do not consider performance constraints that the data center context requires. Optimal policies have been adapted to various domains including databases [13, 31, 69], cache-oblivious algorithms [22], tiered memory systems [73], and confidential applications [36]. These prior works on fixed-sized memories could be extended to the data center formulation.

Several works use optimal algorithms to train ML models [29, 40, 42, 44, 52, 56, 58–60, 65, 68, 71, 76]. We explore training a learned policy L-OPP using OPP, that demonstrates OPP's utility for policy creation.

Variable-sized policies: Working set [17] provided a theory to model applications by their memory behavior. Replacement policies inspired by this model optimize for miss ratio without a fixed-sized memory constraint [18] and generate better average memory savings than OPT while using statistical future knowledge [41]. These works are complementary to our work. Prior work explored adapting cache size based on performance metrics [3, 25], and modern application frameworks also exploit variable-sized allocation by forcing applications to shrink their internal cache footprints under pressure [23, 51]; our work focuses on variable-sized policies instead of adapting the size.

Miss ratio curves: *MDK* extends the work of Mattson et al. [47] and later work on MRC construction for algorithms other than LRU [7, 18], by introducing new theoretical properties that apply to a larger set of policies. Additional related work uses approximation to speed up Mattson's approach, including Shards [64], KOSMO [57], AET [28], and Counter Stacks [67]. *MDK* produces exact MPCs, and we leave approximate concepts for *MDK* algorithms as future work. Several systems use online MRC generation to guide cache size allocation (e.g., Memshare [11] and OSCA [74]) and tune policies (e.g., Cliffhanger [16, 27, 77]). We leave using *MDK* MPCs to tune data center systems for future work.

Memory reclamation metrics: Prior work used metrics other than miss ratio, such as fault rate [15, 55], pressure stall information (PSI) [66], promotion rate failures [70], frequency of access [53], amortized offcore latency [43], and throughput [26]. *MDK* is designed to be extensible in order to accommodate a diverse set of metrics.

7 Conclusion

Data center memory reclamation has a goal of maximizing memory savings to allow more jobs to be scheduled on servers, while maintaining application performance targets. This formulation leads to a different optimization problem than the traditional one, and the tools required to address this problem are lacking. We introduced *MDK*, an offline framework for data center policy exploration that includes a new optimal policy OPP, MPCs to evaluate policy performance, theoretical properties, and efficient algorithms to construct MPCs. Using *MDK*, we show that existing policies leave ample room for improvement. We develop new practical and learned policies by leveraging OPP insights and evaluate these policies using *MDK*, demonstrating *MDK*'s utility and the potential to improve upon existing policies. Ultimately, we hope researchers will use *MDK* to develop better memory reclamation policies for the data center problem.

A MPC constructors for OPP and AGE policies

We discuss the MPC constructors for AGE and OPP for exposition.

MPC construction for AGE

AGE policy only adheres to the eviction decisions *and not the* eviction times *property.*

The AGE policy accepts a parameter R_A representing the threshold age of a page. Any page not used for R_A time intervals is reclaimed. This policy follows the eviction times property as any age that is less than R_A (i.e. more aggressive) would also reclaim the same page, thus incurring the same fault. However, this policy doesn't follow the eviction times property, as the more aggressive age would reclaim the page earlier than a less aggressive one. The page would reach that age sooner, which means that the eviction times property can't be satisfied. The critical parameter R_c computation (shown in Table 4 for AGE eviction policy is similar to VMIN's. The key difference lies in the parameter: AGE policy waits R_A time intervals for eviction, making the critical parameter one less than the reuse distance. However, it's memory savings function differs significantly from that of VMIN's. The memory savings is always the size of the element because the critical parameter (the age) of AGE is always 1 less than the reuse distance. For example, if an element is accessed at times 10 and 20, the critical age parameter would be 9, and the page would be evicted at time 19 for one time unit by the critical parameter. When accumulating memory savings, the less aggressive parameter's savings must be adjusted to account for the earlier evictions (as the *eviction times* property is violated). This adjustment involves adding the difference between the two age parameters (assumed to be 1 here) multiplied by the number of pages evicted by the less aggressive parameter, as these pages would have been evicted one time unit earlier by the more aggressive policy.

MPC construction for OPP

OPP adheres to the eviction decisions and the eviction times property.

The OPP policy that we presented follows both the theoretical properties we introduced. OPP accepts a target promotion rate, to maintain in each time window. It evicts elements as soon as they are accessed similar to VMIN adhering to the *eviction times* property. An aggressive target promotion rate will always evict the pages from the less aggressive promotion rate first. For example, all the evictions under a target promotion rate of 1% would also happen under a target promotion rate of 2% as all the pages that cause page faults under 1% setting would also be included in the 2% setting.

In the case of OPP, the size of the integer parameter space is 100, the max possible target promotion rate assuming integer promotion rates. Floating promotion rates can be configured using the *GetParamSpace* and *GetParamAggressionOrder* functions. The parameter traversal order is increasing as the least aggressive parameter (target promotion rate) is 1% and the most aggressive is 100%. This is the opposite case of VMIN and the AGE policy.

OPP MPC construction requires additional data structures. It requires maintaining the future accesses for a given page and the number of pages accessed in all windows. We construct this by first pre-processing the trace in linear time and computing the number of unique pages accessed in each time window and maintaining a per-page vector of windows in which it is accessed. Once the trace is pre-processed, the template computes the MPC. OPP's *GetCriticalParameter* function first updates the promotion rate that the page's *next* access will cause, by computing the expected number of future faults divided by the total accesses in the future period. The reason to do that is identifying the promotion rate associated with a memory access by looking at the past is not feasible efficiently, so we must update future promotion rates before the access occurs. The critical promotion rate R_C then is simply read from the same data structure that was written on the page's previous access.

OPP's memory savings is the same as VMIN as it follows the *eviction times* property, this simplifies it's memory savings computation.

B MPC construction for PACE

Listing 3 details the MPC constructor for the PACE policy. Our algorithm takes as input a page access trace, and outputs the memory savings and promotion rate associated with every (P,A) combination. The core logic relies on using suffix sum for computing the MPC. The algorithm first computes $\text{Raw}_{(p,a)}$, counting the number of pages with exact reuse distance p and elapsed age a. We then compute a Co-Age threshold matrix, denoted as $C_{(p,a)}$, that counts pages that would be evicted for reuse distance greater than P **and** elapsed time greater than A as $C_{(p,a)} = \text{Raw}_{(p,a)} + C_{(p+1,a)} + C_{(p,a+1)} - C_{(p+1,a+1)}$. This counts instances where pages meet or exceed thresholds p and a simultaneously; a summation of the pages that exactly have a reuse distance and elapsed time of P and A and all the pages that satisfy less aggressive parameters, *i.e.,*$(P+1,A)$ and $(P,A+1)$, subtracting the evictions due to $(P+1,A+1)$, the intersection of the two settings to avoid double counting the same evictions. The correctness of this recursion lies in the fact that P and A follow *eviction decisions* and *eviction times* individually, allowing us to use the well-known dynamic programming solution to the suffix sum problem for solving this recursion efficiently.

PACE evicts pages if they satisfy the reuse distance P **or** the current idle limit A. We use the Co-Age threshold matrix

Table 4: Policy details for *MDK* MPC generator that allows for easy implementation of MPC algorithms

Policies (LOC)	**GetParamSpace**	**GetParamAggressionOrder**	**GetCriticalParam (page_id, time)**	**GetMemorySavings (page_id, time)**	**AccumulateSavings (savings)**
LRU (53)	max_cache_size	$\{c \in N \mid \text{max_c} \geq c \geq 1\}$	return stack.index_of(page_id)	N/A	N/A
VMIN (40)	max_distance	$\{d \in N \mid \text{max_d} \geq d \geq 1\}$	return time - prev_access[page_id]	return (time - prev_access[page_id]) $\times$*Page_size*	return savings
AGE (52)	max_distance	$\{d \in N \mid \text{max_d} \geq d \geq 1\}$	return (time - prev_access[page_id]) - 5 min	return Page_size	return savings + Page_size $\times$(*npages_reclaimed*)
OPP (87)	100	$\{r \in N \mid 1 \leq r \leq 100\}$	curr_PR = saved_PR[page_id] j = next_access(page_id) F(j)++ saved_PR[page_id] = F(j)/W(j) return curr_PR	return (time - prev_access[page_id]) $\times$*Page_size*	return savings
PriorAgeWithWait (PAW) (62)	max_distance	$\{d \in N \mid \text{max_d} \geq d \geq 1\}$	interval = prev_access[page_id] - prev_reaccess[page_id] return interval < 1 min ? 0 : interval	return (time - prev_access[page_id]) $\times$*Page_size*	return savings

C to compute the final promotion rate, $Promotion_rate_{(P,A)}$ as $Promotion_rate_{(P,A)} = C_{(P,1)} + C_{(0,A)} - C_{(P,A)}$. Here, $C_{(P,1)}$ computes promotions arising due to pages that have a reuse distance greater than P and are going to elapse at least one time interval after their eviction, *i.e.,* their age would be at least 1 on reaccess. $C_{(0,A)}$ captures age-based promotions due to pages that would have an elapsed time greater than A. Finally, subtracting the intersection $C_{(P,A)}$ corrects the overlapping promotions that both conditions would satisfy.

The memory savings $Savings_{(P,A)}$ computation uses the same logic as the promotion rate. However, it requires an adjustment. Pages would be evicted at different times based on the condition they satisfy. Suppose a page with reuse distance $\alpha = T_2 - T_1$ accessed at time T_1, with next access at T_2. When the page is refaulted at T_2, we need to evaluate the savings generated. If $\alpha > P$, then the page is removed from memory immediately at T_1, and the savings generated by this eviction would be $(T_2 - T_1) \times page_size$. If $\alpha < P$, then the page has to stay idle for a time period A before it is evicted; in this case, the savings generated would be $(T_2 - T_1 - A) \times page_size$. The savings need to be adjusted for this waiting period. To handle this, along with $Raw_{(p,a)}$, we also compute $Gap_{(p,a)}$, which computes the maximum time a page stays out of memory for every two accesses to it; in our example, it is $(T_2 - T_1) \times page_size$. The Co-Age Threshold matrix for memory savings is computed as $C_sv_{(p,a)} = \text{Gap}_{(p,a)} + C_sv_{(p+1,a)} + C_sv_{(p,a+1)} - C_sv_{(p+1,a+1)}$. For the final savings, we subtract the adjustment required to accurately count the savings for the AGE policy using, $Savings_{(P,A)} = C_sv_{(P,1)} + C_sv_{(0,A)} - C_sv_{(P,A)} - (num_pages_age \times A)$, we achieve this by keeping track of the number of pages evicted due to the AGE condition in our algorithm.

C Proof of Optimality for OPP

We first focus on a trace collected by reading accessed bits similar to existing data center systems, where all accesses within a time window W_n are assumed to have occurred at the exact same time, $t_{start}(W_n)$, the start time of the window. The kernel can only observe accesses to pages by reading the access bit at regular time intervals, only allowing it to assign that time interval as the time of access when the tracing happens.

We prove the optimality of the OPP algorithm by contradiction using a "first difference" argument. An optimal schedule maximizes total memory savings while adhering to all constraints.

Definition of Memory Saving: Let the saving from a single eviction of page p at time t_{evict} be defined as:

$$s(p, t_{\text{evict}}) = \left\{ t_{\text{next}}(p) - t_{\text{evict}} \right\}$$

where $t_{\text{next}}(p)$ is the time of the next access to page p. The

```

total memory saving for a schedule S is the sum over all its evictions assuming uniform page size:

$$\text{Saving}(S) = \sum_{(p,t_{\text{evict}})\in S} s(p,t_{\text{evict}})$$

Let S_{OPP} be the schedule from the OPP algorithm. Assume there exists a hypothetical optimal schedule S_{opt} with $\text{Saving}(S_{\text{opt}}) > \text{Saving}(S_{\text{OPP}})$. This implies the schedules must differ.

Let's consider the first access event in the trace, (P,t_p), where the decisions of the two schedules diverge as both schedules cannot be identical if $\text{Saving}(S_{\text{opt}}) > \text{Saving}(S_{\text{OPP}})$. Both schedules were identical for all accesses prior to t_p, their internal states (e.g., fault counts for future windows) are identical at this point. One theoretical way for them to differ is if S_{opt} evicts P at t_p, but S_{OPP} does not. However, this is impossible. If S_{opt} evicts P, the eviction must be valid, i.e., the fault slot in the future window W_n is available and this eviction doesn't violate the promotion rate. Because the states are identical, the eviction would also be valid for S_{OPP}. The OPP algorithm is maximally greedy by definition: it **always** performs an eviction if it is valid. Therefore, S_{OPP} would also have evicted P, which contradicts our premise that the schedules differ.

Thus, the first point of divergence can only be the other way around:

$$(P,t_p) \in S_{\text{OPP}} \quad \text{and} \quad (P,t_p) \notin S_{\text{opt}}$$

For OPP to evict P, the eviction must be valid, contributing a saving of $s(P,t_p) > 0$. Let the next access to P be in window W_n, which means this eviction consumes one fault from W_n's budget.

Now, consider why S_{opt} would not evict P. There are two possibilities for how S_{opt} uses the fault budget in window W_n:

Case A: S_{opt} never uses the fault slot in W_n that P's eviction would have taken. In this case, S_{opt} simply forgoes the savings $s(P,t_p)$ by not reclaiming this page. We could construct a new schedule $S' = S_{\text{opt}} \cup \{(P,t_p)\}$. This schedule is valid because the required fault slot in W_n was available in S_{opt}. The savings of this new schedule would be $\text{Saving}(S') = \text{Saving}(S_{\text{opt}}) + s(P,t_p)$, which is strictly greater than the savings of S_{opt}. This contradicts the assumption that S_{opt} is optimal.

Case B: S_{opt} uses the same fault slot in W_n for another page, Q. For S_{opt} to use the fault slot on a different page, it must evict a page Q at some time t_q, where Q's next access is also in window W_n. Since we are at the **first** point of difference at time t_p, it must be that $t_p \le t_q$. Let's construct a new schedule S' from S_{opt} by swapping the decision for Q with the decision for P:

$$S' = (S_{\text{opt}} \setminus \{(Q,t_q)\}) \cup \{(P,t_p)\}$$

This new schedule S' is valid. It uses the same fault slot in W_n that S_{opt} used, just for a different page.

$$\text{Saving}(S') = \text{Saving}(S_{\text{opt}}) - s(Q,t_q) + s(P,t_p)$$

The saving for each eviction is $s(p,t_{\text{evict}}) = t_{\text{next}}(p) - t_{\text{evict}}$. Under our assumption, both P and Q are re-accessed at the exact same time, so $t_{\text{next}}(P) = t_{\text{next}}(Q) = t_{start}(W_n)$.

Therefore, the difference in savings becomes:

$$s(P,t_p) - s(Q,t_q) = (t_{start}(W_n) - t_p) - (t_{start}(W_n) - t_q) = t_q - t_p$$

Since we established that $t_p \le t_q$, it follows that $t_q - t_p \ge 0$. Thus, $\text{Saving}(S') \ge \text{Saving}(S_{\text{opt}})$. We have transformed S_{opt} into a schedule that agrees with OPP's first decision without decreasing the total savings. By repeating this argument for all points of difference, we can show that $\text{Saving}(S_{\text{OPP}}) \ge \text{Saving}(S_{\text{opt}})$, which contradicts our initial assumption. Therefore, under this setting, OPP is optimal.

D Investigating OPP optimality for traces with exact timestamps

Now, we relax the assumption and allow accesses to be spread within a window given a trace with exact time stamps for each memory access. The below counter-example demonstrates that OPP is not optimal in this case.

Parameters:

- Window Size (W): 100 time units. ($W_1 : [1,100], W_2 : [101,200]$)
- Target Promotion Rate (ρ_{target}): 0.5 (50%)
- Durable Threshold (T_{durable}): 50

Access Trace (T):

$$T = [(A, t = 10), (B, t = 20), (A, t = 110), (B, t = 190)]$$

There are two accesses in W_2, so its fault budget is $0.5 \times 2 = 1$.

OPP's Sub-Optimal Schedule:

1. At $t = 10$, OPP considers evicting page A. The next access is at $t = 110$. The eviction is valid ($110 - 10 = 100 \geq T_{\text{durable}}$) and a fault slot is available in W_2. OPP evicts A and uses the only fault slot for W_2. The saving is $110 - 10 = 100$.

2. At $t = 20$, OPP considers evicting page B. While the eviction is valid ($190 - 20 = 170 \geq T_{\text{durable}}$), the fault budget for W_2 is now full. OPP cannot evict B.

The total saving for the OPP schedule is **100**.

Optimal schedule for exact trace: An optimal algorithm would compare the potential savings. Evicting A yields a saving of 100, while evicting B yields a saving of 170. Knowing it only has one fault slot, the optimal schedule would forgo evicting A to save the slot for the more profitable eviction of B. The total saving would be **170**.

Since $170 > 100$, OPP is not optimal for this scenario.

Proof of Bounded Gap for OPP schedule

We prove that the total gap between the savings of ideal S_{opt} for this scenario and S_{OPP} is bounded.

Let $E_n(S)$ be the set of pages evicted by schedule S that fault in window W_n, and let F_n be the fault budget for that window. The number of such evictions is bounded, so $|E_n(S)| \leq F_n$. Because OPP is maximally greedy, it will always make at least as many valid evictions for a given window as any other valid schedule. Thus, $|E_n(S_{\text{OPP}})| \geq |E_n(S_{\text{opt}})|$. Let $m_n = |E_n(S_{\text{OPP}})|$ and $k_n = |E_n(S_{\text{opt}})|$, where $m_n \geq k_n$.

The total savings gap is the sum of the gaps from each fault window:

$$\text{Gap}_{\text{total}} = \text{Saving}(S_{\text{opt}}) - \text{Saving}(S_{\text{OPP}}) =$$

$$\sum_{n=1}^{N_{\text{windows}}} \left(\sum_{Q_i \in E_n(S_{\text{opt}})} s(Q_i) - \sum_{P_j \in E_n(S_{\text{OPP}})} s(P_j) \right)$$

Let's analyze the gap for a single window n. Since $m_n \geq k_n$ and all savings $s(P_j)$ are non-negative, we can find an upper bound by dropping the extra $m_n - k_n$ terms from OPR's savings:

$$\text{Gap}_n \leq \sum_{i=1}^{k_n} s(Q_i) - \sum_{j=1}^{k_n} s(P_j)$$

where $\{P_j\}$ represents the first k_n pages chosen by OPP for window n (i.e., those with the earliest access times).

$$\text{Gap}_n \leq \left(\sum_{i=1}^{k_n} t_{\text{next}}(Q_i) - \sum_{j=1}^{k_n} t_{\text{next}}(P_j) \right) +$$

$$\left(\sum_{j=1}^{k_n} t_{\text{evict}}(P_j) - \sum_{i=1}^{k_n} t_{\text{evict}}(Q_i) \right)$$

Now we bound the two parenthesized terms.

1. Bounding the t_{evict} term: The set $\{P_j\}$ contains the k_n valid evictions with the earliest possible eviction times. The set $\{Q_i\}$ is another set of k_n valid evictions. By definition, the sum of the earliest eviction times must be less than or equal to the sum for any other set of the same size. Therefore, $\sum t_{\text{evict}}(P_j) \leq \sum t_{\text{evict}}(Q_i)$, which implies the second term is non-positive and can be dropped for an upper bound:

$$\text{Gap}_n \leq \sum_{i=1}^{k_n} t_{\text{next}}(Q_i) - \sum_{j=1}^{k_n} t_{\text{next}}(P_j)$$

2. Bounding the t_{next} term: For any page X in these sets, $t_{\text{next}}(X)$ must fall within window W_n. Let $t_{start}(W_n)$ be the start time of this window. We can establish firm bounds: $t_{start}(W_n) \leq t_{\text{next}}(X) < t_{start}(W_n) + W$. To maximize the gap, we maximize the sum for Q_i and minimize the sum for P_j:

$$\sum t_{\text{next}}(Q_i) < \sum_{i=1}^{k_n} (t_{start}(W_n) + W) = k_n \cdot (t_{start}(W_n) + W)$$

$$\sum t_{\text{next}}(P_j) \geq \sum_{j=1}^{k_n} t_{start}(W_n) = k_n \cdot t_{start}(W_n)$$

Substituting these into our inequality for Gap_n:

$$\text{Gap}_n < k_n \cdot (t_{start}(W_n) + W) - k_n \cdot t_{start}(W_n) = k_n \cdot W$$

Since $k_n = |E_n(S_{\text{opt}})| \leq F_n$, we can conclude that $\text{Gap}_n < F_n \cdot W$. The gap for a single window is strictly bounded by its fault budget multiplied by the window size.

3. Bounding the Total Gap: The total gap is the sum of the per-window gaps. Let $F_{\text{total}} = \sum F_n$ be the sum of all fault budgets over the entire trace.

$$\text{Gap}_{\text{total}} = \sum_{n=1}^{N_{\text{windows}}} \text{Gap}_n <$$

$$\sum_{n=1}^{N_{\text{windows}}} (F_n \cdot W) = W \cdot \sum_{n=1}^{N_{\text{windows}}} F_n = F_{\text{total}} \cdot W$$

Thus, the total savings gap is strictly bounded by the total fault budget multiplied by the window size. This proves the algorithm is near-optimal.

USEC: A User-Requirement-Driven Mandatory Access Control Framework for Operating Systems (Operational Systems)

Abstract

Fine-grained access control over kernel resources is essential for containing compromised applications and protecting modern operating systems. However, mainstream mandatory access control (MAC) mechanisms such as SELinux are notoriously hard to configure, incur non-trivial performance overhead, and often break compatibility. In practice, many enterprise Linux deployments disable SELinux by default due to its complexity, configuration burden, and compatibility issues.

In this paper, we present `USEC`, a new kernel access-control framework co-designed with security vendors to make strong MAC practical at scale. `USEC` introduces: (1) simpler configuration via resource-centric policy templates and semantic resource classes; (2) a demand-driven enforcement path with decision caching that reduces kernel overhead; and (3) binary-compatible LSM interfaces for process lifecycle, file I/O, and socket events that coexist with existing modules for compatibility. We implement `USEC` as a Linux security extension and evaluate it in terms of configuration simplicity, runtime overhead, and compatibility. Under the same security requirements,`USEC` policies contain up to 10× fewer lines of policy code than SELinux, while reducing runtime overhead by 3.4%–17.1% relative to SELinux across representative server and desktop workloads. `USEC` has been adopted by over 210 security vendors, including QiAnXin, 360, and NSFOCUS. As of early 2025, it has been deployed on more than 8,000,000 enterprise endpoints in production. These results demonstrate that `USEC` can provide strong, configurable kernel protection that is both efficient and widely deployable.

1 Introduction

Operating systems rely on the kernel to mediate all accesses from user processes to kernel-managed resources such as files, devices, IPC endpoints, and network sockets. Fine-grained control of these kernel resources is crucial for containing compromised applications and enforcing least privilege in practice. Modern Linux therefore uses kernel security frameworks [22] and mandatory access control (MAC) policies to decide, on each system call, whether an operation should be allowed, denied, or audited.

However, mainstream kernel MAC frameworks such as SELinux [12] are notoriously hard to deploy in practice. For example, several Oracle enterprise products either explicitly do not support SELinux or fail when it is enabled [8, 9]: the Oracle HSM client and Oracle Database documentation note that 'Security-Enhanced Linux (SELinux) is not supported on Oracle Automatic Storage Management Cluster File System (Oracle ACFS) file systems' [7].

Generally, existing MAC frameworks are hard to use due to three major limitations: **First, policy configuration is complex:** administrators must write and maintain thousands of low-level rules tied to kernel resources and operations, making policies difficult to understand, audit, and evolve as software stacks change. **Second, the overhead is relatively high:** fine-grained checks on frequent file, IPC, and socket operations introduce non-trivial runtime cost, so operators often disable strict policies on latency-sensitive or high-throughput workloads. **Third, compatibility is fragile:** strict MAC policies frequently break legacy or proprietary applications, and diagnosing such failures is painful, which discourages enabling these mechanisms by default in production systems. However, addressing these three limitations remains difficult for the following reasons.

The first challenge lies in designing a practical configuration mechanism for MAC policies, as resource types and application behaviors are complex and continuously evolving. Existing frameworks such as SELinux expose a very low-level policy interface: administrators must assign security labels to subjects and objects and then express access control in terms of type pairs and operations. In realistic deployments, this quickly leads to thousands of types and rules spread across multiple policy modules, making it hard to understand the global effect of a change, to review policies, or to evolve them as the software stack changes.

The second challenge is to reduce MAC enforcement over-

*Fuchen Ma and Yuanliang Chen are the corresponding authors.

head without weakening control over the resources that actually need protection. Current frameworks such as SELinux install a large number of hooks along system-call and kernel-subsystem paths (files, processes, IPC, networking) and invoke the MAC engine on almost every access. For example, prior work [26] reports about an 87% slowdown on Linux v5.3 under a much more MAC-intensive setting. However, because policies are written under the assumption that all these hooks are present, selectively removing or coalescing checks without creating security blind spots is extremely difficult, forcing operators to choose between strong but expensive enforcement and weaker ad-hoc configurations.

The third challenge is how to enforce vendor-specific MAC policies without breaking the installation and execution of current applications. Current MAC frameworks, such as SELinux, typically control access at the file path and label type levels. Distributions and products therefore ship default policies that restrict writes to many system directories; however, real-world applications often need to create or modify files in various locations during installation and updates. In practice, it is very hard to decide in advance which resources must be strictly protected and which can remain flexible across vendors, so minor errors in MAC policy design can easily lead to compatibility issues for end users.

In this paper, we present `USEC`, a new MAC framework for Linux that addresses these three challenges. (1) To simplify configuration, `USEC` designs a resource-centric policy abstraction. Instead of requiring administrators to enumerate domain–type pairs and maintain thousands of allow rules, `USEC` anchors every policy rule directly at the resource being protected, and expresses which principals may read, write, or execute it. For example, on UOS V25, the deployed USEC policy uses only 11 policy modules and a 949 KB policy file, whereas the corresponding SELinux policy contains 320 modules and a 2.1 MB policy file. USEC also reduces the number of `file_contexts` rules from 5,428 to 1,577 and the number of `homedirs` rules from 408 to 65. (2) To reduce enforcement overhead, `USEC` adopts demand-driven security enforcement: vendors declare only the few security-critical capabilities they need, and `USEC` enables hooks only along those paths, letting other operations bypass the MAC engine. (3) To improve compatibility, `USEC` adds a small set of binary-compatible LSM hooks for process lifetime, file I/O auditing, and socket events, providing the necessary observability while coexisting with existing kernel security modules.

To evaluate whether `USEC` can achieve these goals, we implement it as a Linux security extension and compare it against SELinux and other MAC frameworks under multiple server and desktop operating-system workloads. Under equivalent security requirements, `USEC` policies contain up to 10× fewer rules than other frameworks, while consistently incurring lower runtime overhead than SELinux across all three evaluated benchmarks. To further evaluate its real-world effectiveness, we build a UAPP ecosystem [20] to collaborate with more than 210 security vendors such as QiAnXin and 360, and promote `USEC` among them. By early 2025, it has been deployed on more than 8,000,000 enterprise endpoints [19], including financial institutions and critical-infrastructure clients in the energy and transportation sectors.

Overall, this paper makes the following contributions:

- We design the `USEC` MAC framework with a resource-centric policy model, demand-driven security enforcement, and compatibility security interface.These techniques ensure secure access to explicitly protected kernel resources while supporting highly available, online policy updates.
- We implement `USEC` as a Linux security extension, and more than 210 security vendors adopt it. By early 2025, we have deployed over 8,000,000 endpoints with `USEC`.
- We evaluate `USEC` against SELinux and other frameworks. Under equivalent security requirements, `USEC` policies contain 10× fewer lines of policy code than SELinux and consistently incur lower (3.4%–17.1%) runtime overhead.

2 Background

2.1 Mandatory Access Control

Mandatory Access Control (MAC) is a security mechanism that operates within the operating system and enforces access to system resources [2, 10, 23]. In MAC, both subjects (e.g., processes or threads) and objects (e.g., files, ports, memory segments) are assigned security attributes or labels, and access requests are evaluated by comparing these labels against a centrally defined policy. The principal workflow typically involves: (1) labeling of subjects and objects, (2) a policy that defines permitted interactions based on labels, (3) runtime enforcement where each access request is checked against the policy, and (4) auditing or logging of access decisions for verification and compliance. Because the control is not at the user side, MAC systems offer isolation and can reduce the risk of misuse by users or compromised processes.

On Linux, MAC is typically implemented through the Linux Security Modules (LSM) framework [22]. The kernel exposes security hooks for system calls, file operations, and inter-process communication. And MAC modules such as SELinux [12] and AppArmor [1] register callbacks on these hooks to consult their policies before an operation proceeds.

2.2 How MAC Works in Practice

In a general MAC implementation, as shown in Figure 1, a user-space program issues a system call such as `open()` or `connect()` to access some resource. The call enters the kernel, which first resolves the concrete object being accessed (e.g., kernel file). Before the kernel actually accesses the target object, the MAC logic runs. In detail, the kernel exposes security hooks at critical points, and MAC modules register

callbacks on them. When a hook is invoked, the MAC subsystem looks up the security labels of the calling process and the target object. These labels describe which application or domain a process belongs to, or how sensitive or trusted a file is. The MAC policy engine then determines whether the requested operation is permitted for this label and action combination. Because these checks run inside the kernel's trusted MAC layer, user-space code cannot bypass them. If the policy allows, the system call proceeds to the resources; if it denies, the kernel aborts the call and returns an error.

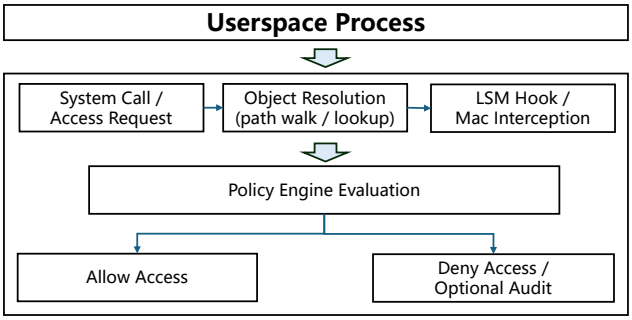

Figure 1: Basic runtime workflow of MAC enforcement

3 Motivating Examples

3.1 MAC Configuration in Practice

Consider a security vendor that wants to ship an endpoint protection agent for Linux servers. The vendor's policy goal is like: (1) only the agent process may read and write files under `/opt/agent/data/`, (2) system administrators may install or upgrade the agent binary, but cannot tamper with its runtime data, and (3) a separate audit operator may only read logs under `/var/log/agent/`. In addition, the customer requires a three-way separation of duties among the system administrator, security administrator, and audit administrator.

Expressing this policy in SELinux quickly becomes nontrivial. The vendor must first introduce several new types (e.g., `agent_t`, `agent_exec_t`, `agent_data_t`, `agent_log_t`) and attributes, add corresponding `file_context` rules so that different installation paths on different distributions are labeled correctly, and then write `allow` rules that tie these types to existing domain types such as `sshd_t`, `init_t`, and distribution-specific admin domains. To enforce separation of duties, the policy must also define SELinux users and roles (`sysadmin_u`, `secadmin_u`, `audit_u`), map Unix accounts to these users, and encode role-specific constraints over the `_u` field using low-level `constraint` statements that govern who is allowed to change which labels on which objects.

In a realistic deployment, this configuration is hard to get right and even harder to maintain. Small changes to the underlying Linux distribution (e.g., moving the agent's data directory, renaming an admin domain, or adding a new log location) may require coordinated edits across multiple SELinux modules and constraint blocks. A missing or overly restrictive rule leads to silent denials that are difficult for non-experts to diagnose; an overly permissive rule weakens the intended separation of duties and may only be discovered during an audit. As a result, vendors either ship large, complex policy modules that few customers are willing to enable, or avoid using SELinux's full model and fall back to ad-hoc scripts and DAC-based conventions.

Requirements: To be usable in real deployments, a MAC mechanism should expose a configuration model that matches how administrators and vendors reason about security, rather than forcing them to work directly with low-level kernel types and constraints. Concretely, policies should be expressed in terms of applications, roles, and a small number of explicitly protected resource groups (e.g., "agent data," "logs," "keys"), rather than thousands of distribution-specific label types. The mechanism should provide built-in templates for common patterns (such as three-way separation of duties between system, security, and audit administrators), allow policies to be updated incrementally without editing multiple interdependent modules, and offer automated checks or tooling to catch conflicts and missing rules before deployment. Such a configuration model would let vendors and operators describe high-level intent concisely, while the MAC framework is responsible for translating that intent into concrete enforcement on the target kernel.

3.2 Overhead under MAC Enforcement

The overhead of MAC enforcement is a significant concern, particularly in high-performance computing environments. A primary example of this is the performance degradation caused by SELinux. While offering robust security, SELinux achieves this by instrumenting the kernel with a large number of hooks at various points in the system call path.

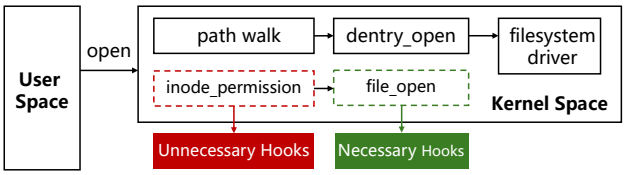

Figure 2: Illustration of how SELinux hooks along a simple file-open path.

For instance, as shown in Figure 2, even a simple file-open request must pass through several MAC check points after the `open()` syscall enters the kernel and before the filesystem is actually accessed. In a simple "allow-all" or coarse-grained policy, only the final decision point (green box) is effectively needed, while the earlier checks (red boxes) never change the outcome but are still executed on every call. Zhang et al. [26] show that on Linux 5.3, merely enabling such hooks

can increase the latency of `open()` by up to 87% compared to a DAC-only kernel, meaning that much of the overhead comes from traversing generic MAC hooks without any corresponding security benefit.

Requirements: This highlights a critical requirement for a practical MAC framework: the ability to enforce security policies with minimal overhead. A suitable design should derive, from the declared protection scope, the precise kernel paths on which hooks are actually required. By retaining mediation only on those capability-relevant paths, it becomes possible to significantly reduce performance overhead without weakening protection for the resources explicitly placed under MAC control. Such an approach avoids burdening the system with unnecessary security checks, thereby improving performance while preserving strong protection where it is needed.

3.3 MAC-Induced Compatibility Failures

Beyond configuration complexity and runtime overhead, a third motivation comes from frequent compatibility failures when MAC is enabled in real systems. In practice, many enterprise applications assume DAC-style permissions and break once SELinux starts enforcing path- and type-based policies: installers fail to create or modify files under protected directories, backup or security suites lose access to devices, and camera or container services refuse to start until SELinux is disabled or put into permissive mode [3, 4, 25].

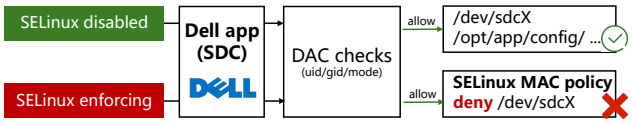

Figure 3: Illustration of a Dell application SDC failed to load correctly with SELinux enabled.

A concrete example comes from Dell's Storage Data Collector (SDC) software [4]. As shown in Figure 3, when SELinux is configured in enforcing mode, SDC fails to start and certain management operations cannot be performed, even though all traditional UNIX permissions are correctly set. The root cause is that SELinux's type-based policies block SDC from accessing specific device files and system directories that the application assumes are usable during startup and runtime. From the administrator's perspective, the system passes DAC checks but the MAC layer silently denies these accesses, causing the service to fail until SELinux is switched to permissive mode or disabled entirely. This illustrates how, once MAC enforcement is tied to fine-grained path and type rules, it becomes easy for a seemingly reasonable policy to break legitimate software. It's hard to predict which applications will stop working when SELinux is turned on.

Requirements: To avoid breaking legitimate software, a practical MAC mechanism should provide strong protection only where it is explicitly needed, while remaining non-intrusive elsewhere. Concretely, enforcement on a given resource should be *opt-in*: critical files, devices, and sockets that require protection are explicitly bound to MAC policies, while other resources fall back to DAC or audit-only behavior rather than being silently blocked. The MAC layer should also support a learning or shadow-enforcement mode that observes real deployments, reports would-be denials, and lets vendors refine their policies before switching to strict enforcement. This is particularly important in practical deployments, where vendors often need to harden only a small set of high-value resources, yet cannot afford widespread disruption to installation, update, or normal execution paths elsewhere in the system. Such a compatibility-aware design allows operators to protect the resources they explicitly care about, while keeping the rest of the software stack largely unaffected.

4 USEC Design

4.1 Threat Model and Protection Scope

`USEC` follows an *explicit protection model*: rather than mediating all kernel objects, it enforces strong protection only for resources covered by the declared capability set.

Formally, let O denote the set of kernel objects visible to the system, such as files, devices, IPC endpoints, and sockets, and let $\mathcal{C}$ denote the set of capabilities declared by the deployment. Each capability $c \in \mathcal{C}$ corresponds to a protected resource set $O_c \subseteq O$ and a set of security-sensitive operations $\mathcal{A}_c$ that may affect those resources. `USEC` guarantees that accesses to $\bigcup_{c\in\mathcal{C}} O_c$ through operations in $\bigcup_{c\in\mathcal{C}} \mathcal{A}_c$ are mediated by the retained hook set derived from $\mathcal{C}$.

We consider an attacker who can execute unprivileged or application-level code and invoke normal kernel interfaces, including file operations, IPC, device access, and networking paths, in an attempt to access, modify, disable, or indirectly reach protected resources. We assume kernel integrity, correct operation of the LSM framework, and trustworthiness of the small management TCB, including `usecd`, `dbus-daemon`, `udevd`, and the audit infrastructure. Accordingly, `USEC` is designed to stop unauthorized accesses to declared critical resources, but it does not attempt to automatically infer missing security-critical resources; ensuring that all relevant resources are included in $\mathcal{C}$ remains a deployment responsibility.

This scope is important for interpreting `USEC`'s guarantees. The goal is not complete mediation over all kernel objects, but a closed protection boundary for explicitly declared high-value resources. For protected file objects, `USEC` enforces protection on kernel object state rather than user-visible names whenever possible. As a result, alias-based or indirect accesses, such as hard links, symbolic links, rename, or file-descriptor passing, are mediated through capability-relevant hooks rather than trusted merely because they use different names. More broadly, the resource-centric design reduces

the attack surface of policy configuration and common proxy paths by directly protecting the resources and management interfaces that matter, while leaving undeclared resources outside the strong-protection scope.

4.2 Resource-Centric Policy Model

Traditional kernel MAC frameworks such as SELinux [12] and AppArmor [1] are fundamentally *process/domain-centric*: administrators typically start from process domains (subject types) and enumerate which object types they may access. This model works well for system-wide hardening, but it is a poor fit for security vendors who typically care about protecting a small set of high-value resources against 'everyone else'. Expressing such intent with process-centric rules often means touching many domains and types, and it is difficult to ensure that all untrusted processes are covered.

To address these issues, `USEC` adopts a *resource-centric* configuration model. Instead of starting from processes and asking "what may this process access?", we start from resources and ask "who may touch this particular resource, and how?". For example, to secure files, each rule is anchored at a file path and lists which users or applications may read, write, or execute that file. `USEC` extends this idea from files to other kernel resources: a policy rule is always attached to a *resource descriptor* (e.g., a file path prefix, a device node, a mount point, or a socket endpoint), and specifies the set of principals and operations that are allowed on that resource. Principals are represented by `USEC`'s identity bitmap, so that a rule can simply say "allow processes with bits `AGENT` or `SECADMIN` to write this resource", while all other processes are implicitly denied.

Concretely, the overall design of the resource-centric policy model in `USEC` is shown in Figure 4. Each JSON entry is anchored at a specific resource and records its metadata, resource-specific attributes (`attrs`), and the set of operations that a policy may grant on this resource. These JSON policies are then compiled into an identity-bitmap layout and a compact rule table, which the kernel enforces through LSM hooks. For each access, `USEC` builds a resource descriptor and looks it up in the rule table. Only if a matching rule exists does `USEC` perform the bitmap and operation checks.

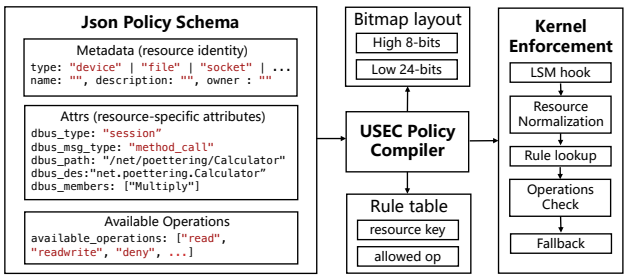

Figure 4: Overall design of resource-centric config policy.

A key property of this design is that `USEC` performs *matching only on resources that have been explicitly declared as protected*. At enforcement time, LSM hooks extract a canonical descriptor for the accessed resource (e.g., the absolute file path, device identifier, or socket tuple) and look it up in the `USEC` rule tables. If there is at least one matching rule, `USEC` applies the corresponding bitmap and operation checks to decide allow or deny. If there is no matching rule, the resource is treated as unprotected by `USEC` and the access decision falls back to the underlying DAC (and optional audit), with no additional policy lookup. In other words, resources that vendors never mention in JSON incur effectively zero `USEC` overhead and are not accidentally constrained by `USEC` policies.

This resource-centric, demand-driven design has two practical benefits. First, it aligns configuration with how vendors and administrators naturally think: they only need to write rules for the relatively small set of sensitive resources they care about, rather than modifying many process domains or global type lattices. Second, it ensures that enabling `USEC` does not impose a blanket policy cost on the entire system: only accesses that touch protected resources pay the price of policy matching, while all other accesses remain as cheap and compatible as in a DAC-only system. The next subsection describes how these declared resource-oriented rules are translated into the capability set that drives retained-hook resolution and selective enforcement in the kernel. At compile time, the declared resource-oriented rules are translated into the capability set that drives retained-hook resolution and selective enforcement.

4.3 Demand-Driven MAC Enforcement

A central design goal in `USEC` is to decouple mandatory access control (MAC) enforcement from the conventional assumption that all kernel objects and all control paths must always be mediated. Traditional MAC systems such as SELinux rely on broad, always-on mediation: they install a dense set of hooks across file-system, process, IPC, and networking paths, and route relevant accesses into a common policy engine. While this design provides broad coverage, it also incurs unnecessary cost in the deployments we target, where many accesses unrelated to the declared protection goal still pay MAC dispatch, cache lookup, and synchronization overhead.

Formally, given a declared capability set $\mathcal{C}$, `USEC` does not attempt to mediate all kernel objects in O. Instead, it enforces protection only for the protected resource sets $\{O_c\}_{c\in\mathcal{C}}$ and operation sets $\{\mathcal{A}_c\}_{c\in\mathcal{C}}$ induced by the active capabilities. Intuitively, O_c captures *what* must be protected, while $\mathcal{A}_c$ captures *how* those resources may be accessed or modified. `USEC` then derives a retained hook set that mediates accesses to $\bigcup_{c\in\mathcal{C}} O_c$ through $\bigcup_{c\in\mathcal{C}} \mathcal{A}_c$, while bypassing hooks that are irrelevant to the declared capability set. Figure 5 shows the basic enforcement pipeline.

Capability-to-Hook Resolution: Given the active capability set $\mathcal{C}$, `USEC` resolves each capability $c \in \mathcal{C}$ through

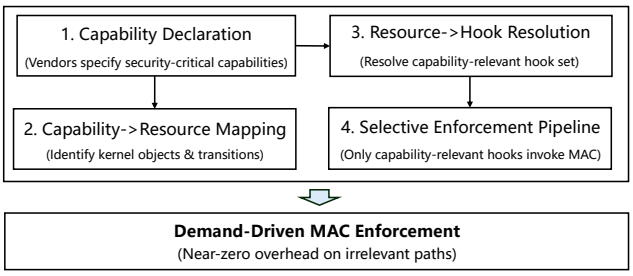

Figure 5: The Basic Pipeline of USEC's MAC Enforcement.

a compiler-driven translation pipeline rather than by manually selecting hooks. Concretely, policies are written in a compact JSON format and compiled into (i) TE permissions for the policy engine and (ii) a hook set for selective enforcement. For each declared capability, the policy compiler queries a capability dictionary that maps the capability to its corresponding TE permissions and dependent mediation hooks. For example, `FILE_READ` expands to permissions such as `read`, `open`, and `getattr`, and to hooks such as `file_open`, `inode_permission`, `mmap_file`, `file_read`, and `file_close`; similarly, `SOCK_CONNECT` maps to `socket_connect`, and `PROC_FORK` maps to `task_create`. Thus, USEC resolves a high-level capability into both the policy semantics and the concrete kernel mediation points required to enforce it.

After expanding all capabilities, USEC computes the retained-hook set by taking the union of the hook sets associated with all declared capabilities. This union is materialized as a compact global bitmap, where each bit corresponds to one hook in the target kernel's hook inventory. At runtime, only hooks whose bits are set are allowed to enter the policy path; all other hooks return immediately. This bitmap-based formulation makes the enforcement boundary explicit: hook pruning is not an ad hoc optimization, but the direct result of capability expansion and hook aggregation. A hook can be elided only if it does not belong to the hook set required by any declared capability.

The mapping is kernel-aware rather than universal. The same high-level capability may be realized through different mediation points depending on the kernel version and enabled subsystems. USEC therefore maintains a per-kernel hook inventory and checks version compatibility between the compiler and the kernel before materializing the bitmap. If the exported kernel hook version does not match the compiler's expected version, policy compilation is rejected rather than silently using a stale mapping. In this way, correctness comes from capability-dictionary expansion, kernel-specific hook binding, and version matching, while representative workloads are used only to validate deployment coverage and identify redundant hot-path hooks after the required enforcement surface has already been established.

Selective Enforcement Pipeline: At runtime, USEC replaces the monolithic always-on MAC path with a selective enforcement pipeline. Each installed hook first performs a constant-time membership test against the retained-hook bitmap. If the hook is not enabled for the active capability set, it returns immediately without entering the MAC engine. Otherwise, USEC invokes `check_usec_perm()`, which consults the permission cache and policy database to complete normal policy evaluation. Thus, USEC preserves the familiar hook-based mediation structure, but avoids dispatching irrelevant accesses into the policy engine.

Table 1: An example of capability-to-hook resolution in USEC.

Capability	Protected Operations	Retained Hooks
File-write-related integrity protection	write, mmap write, metadata update, link/rename	`file_open`, `file_permission`, `mmap_file`, `inode_setattr`, `inode_link`, `inode_rename`

This design differs from SELinux's uniform enforcement model, where a broad hook set remains active regardless of whether a deployment actually protects the corresponding resources. In USEC, enforcement cost scales with the declared protection scope. A deployment that only protects sensitive files and process attributes need not pay for mediation on unrelated network or device paths, while a deployment that enables socket or device control retains precisely those hooks.

Table 1 illustrates a concrete capability-to-hook resolution example. Consider a deployment that protects the integrity of sensitive files through file-write-related capabilities. During compilation, USEC expands the declared file capabilities into the operations that may modify file contents or metadata, or otherwise change the authority over the same object, including direct writes, memory-mapped writes, metadata updates, and link/rename operations. It then resolves these operations to the concrete hooks that mediate them on the target kernel. For example, `file_open` and `file_permission` cover ordinary write paths, `mmap_file` covers memory-mapped access, `inode_setattr` covers metadata changes, and `inode_link` and `inode_rename` cover aliasing-related updates. Hooks outside these paths, such as `task_kill` or `socket_sendmsg`, are not retained because they do not affect the declared file-integrity capability. This example illustrates that the retained-hook set is derived from capability expansion rather than manually selected, and that enforcement remains closed over the relevant access paths without paying the system-wide cost of full mediation.

Operational Benefits: Demand-driven enforcement provides three practical benefits. First, the enforcement surface grows with the declared security intent rather than with the full kernel mediation surface. Second, it gives operators a principled way to avoid the system-wide cost of full mediation without manually disabling checks in an ad hoc manner. Third, it supports heterogeneous deployments: when the pro-

tected capability set changes, when USEC is ported to a new kernel family, or when new capabilities are introduced, USEC simply re-instantiates the capability-to-hook mapping and recomputes the retained-hook bitmap for the target environment. This makes USEC particularly suitable for production deployments where usability and performance matter as much as access-control strength.

4.4 Compatibility-Oriented Security Interface

Beyond configuration complexity and runtime overhead, a key goal of USEC is to avoid the compatibility problems that often appear when SELinux is enabled in real deployments. Therefore, USEC needs to meet two compatibility requirements. First, enforcement is resource centric and opt in, with a permissive mode that lets operators validate policies without triggering SELinux style breakage. Second, the implementation is fully stackable with SELinux and other LSMs, keeping policy and state separate so that enabling USEC does not interfere with existing MAC modules.

Preventing Hook-Level Incompatibility with SELinux. In conventional deployments, SELinux and other in-kernel security modules are wired directly into LSM hook sites. Once these hooks are compiled in, third-party security logic can only be added by patching and rebuilding the kernel, and any mismatch in hook prototypes or call order may cause subtle breakage. In practice, enabling SELinux often changes which hooks run and in what order, so applications that relied on a particular hook behavior or on a vendor kernel patch may start to fail as soon as SELinux is turned on.

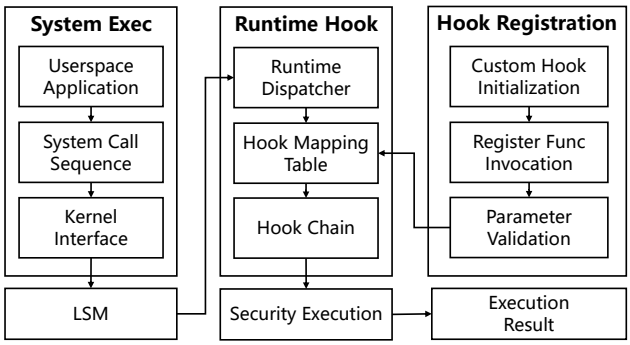

Figure 6: Workflow of USEC's Security Interface.

As shown in Figure 6, USEC inserts a security interface between normal system execution and vendor code. Once a userspace application issues a system call, which traverses the kernel interface and reaches the LSM hook. Instead of invoking third-party modules directly, the LSM hands control to USEC's runtime dispatcher, which consults a hook mapping table and, if a matching entry exists, runs the corresponding hook chain to produce a security decision. When no mapping exists, the dispatcher returns immediately and the LSM continues with its default behavior, so enabling USEC does not alter how SELinux or other in-kernel modules see the call. Also, to maintain the mapping table, vendors initialize their custom hooks and call a registration function in USEC, which validates the argument list, return type, and function pointer against the original LSM prototype before inserting any entry into the mapping table. Hooks that fail validation are rejected and never affect runtime execution.

Compatibility with SELinux and other MACs. Beyond improving compatibility for individual applications, USEC is designed to run alongside existing MAC modules, such as SELinux. At the LSM level, USEC follows the upstream stacking model and uses the standard blob-based security domains for tasks, inodes, and files. It tracks its own state in `struct usec_state`, which points to an independent usec_policy, upolicydb, usec_uavc, and usidtab. This mirrors SELinux's separation of `selinux_state`, policydb, selinux_avc, and sidtab, but all data structures and permission-checking routines (e.g., `check_usec_perm()`) operate on USEC's own state. Loading or updating USEC policies therefore does not affect SELinux's policy database or AVC cache, and the reverse is also true.

SELinux	USEC
`struct selinux_state`	`struct usec_state`
`struct selinux_avc`	`struct usec_uavc`
`struct policydb`	`struct upolicydb`
`struct selinux_policy`	`struct usec_policy`
`struct sidtab`	`struct usidtab`
`struct av_decision`	`struct uav_decision`
`selinux_avc_init()`	`usec_avc_init()`
`avc_has_perm_noaudit()`	`check_usec_perm_noaudit()`
`avc_has_perm()`	`check_usec_perm()`

Table 2: USEC's policy/AVC layer mirrors SELinux with a separate set of data structures and interfaces.

Table 2 summarizes this mapping relations between SELinux and USEC at the policy and AVC layer. Each SELinux structure or interface that manages policy state, SIDs, and cached decisions has a corresponding USEC structure that serves the same role but is kept separate in memory, which makes coexistence possible without entangling internal state.

For hooks that are already fully stackable under the blobs mechanism, USEC simply registers as another LSM, where other MACs, including SELinux in enforcing mode, run as usual. For legacy mount-related hooks that still share fields such as `fs_context.security`, USEC avoids conflicts by not storing its options in that field; instead, it records its mount security options in a private in-kernel list keyed by the caller's task, and applies them when the mount completes. This allows USEC to coexist with SELinux even on mount paths.

Finally, USEC reuses the SELinux policy model and on-disk format while keeping its runtime policy state separate. Its policy layer ports the relevant SELinux code into renamed structures (for example `upolicydb` and `usidtab`) and trims features that fall outside USEC's narrower scope. Labels follow

SELinux conventions as well, which means systems that already deploy SELinux can introduce USEC without changing the on-disk labeling scheme, and the same extended attributes remain meaningful to both modules. Taken together, these choices let operators incrementally deploy USEC on top of existing SELinux configurations, using USEC's opt-in rules and permissive mode to harden selected resources while preserving compatibility with existing SELinux policies.

5 Implementation

USEC is implemented as a Linux security extension that integrates with the LSM framework and provides a lightweight, capability-driven access control path. It consists of five core components. (1) User space provides policy management via usecd and libusec, which generate and load capability policies. (2) usecfs is a kernel interface that transfers policies and configuration data into the kernel at runtime. (3) LSM hooks serve as mediation points for kernel operations such as file access, process control, and socket communication. (4) UAVC (USEC-specific AVC Access Vector Cache) caches recent authorization decisions to avoid repeated policy lookups on hot paths. (5) the policy engine evaluates access requests against capability policies stored in the kernel.

Enforcement Path. At runtime, each LSM hook first checks whether it belongs to the retained hook set derived from the active capabilities. If not, it returns immediately through the bypass path. Otherwise, the request is forwarded to the UAVC cache; on a cache miss, the policy engine evaluates the request and updates the cache. This design preserves the standard hook-based mediation model while avoiding unnecessary policy invocations on irrelevant paths.

Integration with Linux. USEC is implemented as a loadable LSM module and is compatible with LSM stacking. It reuses existing kernel security infrastructure, including security blobs for labeling and hook dispatch mechanisms, and does not require intrusive changes to core kernel subsystems. Policies are loaded dynamically from user space via usecfs, allowing deployment without modifying application binaries.

Automation vs. Manual Effort. Most of USEC's operation is automated. Policy loading, hook dispatch, cache lookup, and enforcement are handled entirely within the system. The only manual component is the maintenance of capability-to-hook bindings for different kernel versions and configurations. This process is lightweight and localized, as it updates only the mappings required for affected capabilities rather than the entire enforcement pipeline.

Implementation Size. USEC adds 19,223 lines of kernel code, including 18,765 lines of new implementation and 458 lines of conditionally compiled code under #ifdef CONFIG_SECURITY_USEC. The user-space components add 63,189 lines of code in total, including 37,787 lines in permission-manager, 5,333 lines in usecpolicy, 17,524 lines in libusec, and 2,545 lines in libsemanage. Overall, USEC consists of 82,412 lines of new code across kernel and user space.

6 Evaluation

6.1 Policy Complexity Reduction

In this section, we present a comparative case study demonstrating how USEC reduces the complexity of expressing access control policies compared to existing Linux MAC systems. We use two representative scenarios: 1) camera device permission control and 2) ATSPI/DBus interface management, to evaluate expressiveness, extensibility, and maintainability.

6.1.1 Camera Access Control

To experimentally evaluate policy complexity, we compare how SELinux, AppArmor, and USEC implement the same task: restricting third-party applications from accessing the system camera device. Although the enforcement goal is identical, the mechanisms differ fundamentally, resulting in different policy sizes and maintenance costs.

```
attribute deepin_app_domain;
attribute uos_controlled_resource_type;
attribute uos_camera_resource_type;

allow deepin_app_domain { file_type -
       uos_controlled_resource_type }:
       chr_file all_chr_file_perms;

interface(`uos_camera_resource_type_set',`
       typeattribute $1 uos_camera_resource_type;')

tunable_policy(`allow_app_access_camera',`
       allow app_t uos_camera_resource_type:chr_file {
       getattr ioctl map open read };')
```

Figure 7: SELinux attribute and allow-rule construction

In SELinux, the camera device ultimately corresponds to the kernel label v4l_device_t. However, SELinux cannot directly express the concept of a 'camera resource'. Instead, the policy writer must distribute this concept across multiple policy subsystems. In our reproduced configuration, three new attributes (deepin_app_domain, uos_controlled_resource_type, and uos_camera_resource_type) must be created before any access control rule can be written. Additional attributes such as deepin_app_private_file_type are required because SELinux decomposes resources into file-system classes and type categories rather than treating them as logical entities. Once these attributes exist, access control is implemented procedurally. A representative fragment from our SELinux experiment is shown in Figure 7.

To complete the policy, the camera device label v4l_device_t must be registered inside the kernel module, and this interface must be exposed to third-party modules

through a dedicated `.if` file. These fragments occupy multiple files (`uos_perm_control.te`, `uos_perm_control.if`, `devices.te`). Even the minimal working configuration exceeds **300 lines** of SELinux policy code. AppArmor is simpler than SELinux in this case because it can constrain access using pathname-oriented rules rather than type attributes and inter-module bindings. However, it still does not directly capture the higher-level notion of a protected "camera resource" and remains tied to concrete device nodes and profile rules.

In `USEC`, we repeat the same experiment using the resource-centric model. Instead of decomposing the concept of a camera across multiple subsystems, `USEC` treats the camera as a first-class resource described declaratively in a single JSON object as shown in Figure 8.

```
{  "name": "camera",
   "type": "object",
   "subtype": "device",
   "attrs": { "devtype": "camera" },
   "available_operations": ["read",
   "readwrite", "deny"],
   "version": "1.0"
}
```

(a) USEC resource definition for a camera

```
{  "policies": [{
   "subject" : { "name":"com.example.app" },
   "objects": [{
       "object": "camera",
       "operations": ["read"]
   }]
 }]
}
```

(b) USEC policy granting read access

Figure 8: USEC's configuration for camera resource control.

These two JSON documents, together fewer than 20 lines, capture the entire access control logic. No attribute propagation, no macro definition, no kernel-module modification, and no policy recompilation are required. The fundamental reason for this reduction is that `USEC` is *resource-centric*. A resource is expressed directly at the level developers reason about (e.g., 'camera device'), while SELinux requires mapping this concept into filesystem classes, device types, type attributes, Boolean tunables, and module interfaces, and AppArmor still relies on concrete pathname-based profile rules. As a result, although all three systems can enforce the same high-level restriction, the SELinux implementation spans hundreds of lines across several policy modules, AppArmor remains bound to low-level device naming, whereas the `USEC` configuration is fully contained in a small declarative specification. This experiment demonstrates that `USEC` achieves the same enforcement outcomes at a fraction of the configuration complexity, providing better maintainability and extensibility.

6.1.2 ATSPI/DBus Interface Control

To further evaluate expressiveness and policy complexity, we study a second scenario involving the AT-SPI accessibility framework. AT-SPI exposes dozens of DBus interfaces such as `EditableText`, `Action`, `Component`, and `DeviceEventController`, each containing numerous methods including both read-oriented queries (e.g., `GetExtents`, `CopyText`) and security-sensitive write operations (e.g., `InsertText`, `GenerateKeyboardEvent`).

```
attribute uos_controlled_resource_type;
attribute uos_atspi_write_type;

# associate a DBus interface with a custom controlled type
typeattribute atspi_EditText_t uos_atspi_write_type;

# allow or deny DBus method calls via dbus class rules
allow app_t uos_atspi_write_type:dbus { send_msg };
```

Figure 9: SELinux-style DBus mediation for AT-SPI methods

In SELinux, implementing such control is challenging because SELinux has no direct notion of 'DBus interface' or 'DBus method'. Instead, DBus mediation must be reconstructed indirectly through a combination of types, attributes, and allow rules governing the `dbus` class. Each method to be restricted must ultimately be represented through the DBus message type, the object path, the interface string, and possibly custom DBus type attributes. This causes the semantics of a single AT-SPI interface to be fragmented across multiple policy constructs that must be coordinated manually. The figure 9 below shows a representative SELinux fragment.

```
{ "name": "ATSPI-WRITE",
  "type": "object",
  "subtype": "dbus",
  "attrs": {
    "bus_type": "accessibility",
    "dbus_msg_type": "method_call",
    "dbus_interface": "org.a11y.atspi.EditableText",
    "dbus_members": ["InsertText", "CutText", "DeleteText"],
    "operations": ["read", "readwrite", "deny"]
  }
}
```

(a) USEC definition of AT-SPI write interfaces

```
{ "policies": [{
  "subject": { "name": "dbus-send" },
  "objects": [{
    "object": "ATSPI-WRITE",
    "operations": ["read"]
  }]
}]}
```

(b) USEC granting read-only AT-SPI access

Figure 10: USEC's configuration for AT-SPI interface control.

Extending this pattern to dozens of AT-SPI methods requires repeating the same steps: creating new types or attributes, binding them to the correct interface strings, and ensuring that the correct DBus object paths are labeled. The resulting policy spans multiple files and hundreds of lines. Again, this complexity arises not from the difficulty of the se-

curity requirement, but from SELinux's type-centric architecture: DBus interfaces must be decomposed and re-assembled manually using low-level primitives. AppArmor is also limited here: although it is lighter-weight than SELinux, it does not naturally express method-level DBus semantics as first-class policy objects, and fine-grained interface control still requires indirect, string-oriented rule construction.

In contrast, `USEC` models DBus interfaces directly as first-class resources. A single JSON object describes the bus type, message type, interface name, member list, and allowed operations. The semantics remain intact without any intermediate type constructions. The JSON fragment in Figure 10 defines all write-oriented AT-SPI methods as a controlled object.

The experiment demonstrates that `USEC` enforces fine-grained method-level control over DBus interfaces without requiring SELinux-style decomposition into types, attributes, macros, or inter-module bindings, and without AppArmor-style indirect string-oriented policy construction. In scenarios like AT-SPI, where interfaces evolve frequently and clients dynamically issue method calls, `USEC`'s configuration provides better simplicity and maintainability.

6.2 Evaluation on Overhead

To evaluate the runtime overhead introduced by `USEC`'s MAC enforcement, we use UnixBench 5.1.3 [18] as a general-purpose system benchmark, and further supplement it with two workloads that exercise security-relevant kernel paths more directly: Filebench, a filesystem-intensive benchmark suite, and Nginx, a network-facing web-server workload. Compared with UnixBench, these two workloads stress the VFS, inode, file-permission, socket, and IPC paths that are central to MAC enforcement, and therefore provide a more meaningful view of MAC overhead in practice. The experiment environment is a HONOR NBLK-WAX9X notebook with an AMD Ryzen 7 3700U processor (4 cores / 8 logical processors). The operating system is UOS Desktop 20 Professional, running Linux kernel version 4.19.0-amd64-desktop, and the main memory is 16GB DDR4. The storage device is a 512 GB Toshiba KXG60ZNV512G SSD. All experiments are repeated 10 times, and the tables report the average, standard deviation, and volatility.

We evaluate four different tools: (1) SELinux, representing a traditional full-coverage MAC framework where all LSM hooks remain active; (2) USEC, our lightweight capability-driven MAC module; (3) AppArmor, another widely deployed MAC system with pathname-based mediation; and (4) LSM Disabled, where all security modules are removed, serving as the zero-overhead baseline. To ensure a fair comparison, we configure USEC, SELinux, and AppArmor to enforce same protection goals for each evaluated workload. In particular, for a given benchmark, all MAC systems are configured to protect the same class of resources and to mediate the same high-level operations required by the workload; the only difference is how each system realizes that protection internally. USEC uses its capability-driven policy model and retained-hook bitmap, whereas SELinux and AppArmor use their native policy mechanisms. The LSM-disabled baseline removes MAC enforcement entirely and therefore differs only in that no access-control checks are performed.

UnixBench as a general-purpose baseline. We retain UnixBench as a broad system benchmark, but use it only as a general-purpose reference rather than the main evidence for MAC overhead. As shown in Table 3, based on 10 runs, SELinux lowers the average System Benchmarks Index Score from 3,993.15 in the LSM-disabled baseline to 3,681.53, corresponding to a 7.80% slowdown, while USEC and AppArmor incur 2.96% and 3.21% overhead, respectively. This result is expected because several UnixBench components are CPU-bound and exercise few MAC-relevant kernel paths, making them relatively insensitive to mediation overhead.

UnixBench reveals that CPU-bound components such as Dhrystone and Whetstone show only minor variation across configurations, indicating that these workloads spend most of their time in user mode and trigger relatively few MAC-relevant kernel checks. By contrast, filesystem- and IPC-related components show a clearer separation, where SELinux imposes higher overhead than the lighter-weight configurations. This suggests that broad system benchmarks are useful for establishing a baseline, but they can understate the cost of always-on MAC mediation because not all subtests heavily exercise security-sensitive kernel paths.

Filebench: filesystem-intensive overhead. We next evaluate filesystem-intensive workloads using Filebench. These workloads repeatedly exercise file creation, open, read/write, metadata update, namespace traversal, and fsync operations, all of which frequently traverse the hooks targeted by MAC enforcement. Table 4 reports the results on five representative Filebench workloads.

Overall, USEC remains closer to the LSM-disabled baseline than SELinux across the evaluated Filebench workloads. On *webserver*, USEC achieves 88,908.51 ops/s, compared with 91,029.30 ops/s in the baseline, while SELinux achieves 84,359.23 ops/s. On *fileserver*, USEC reaches 56,510.22 ops/s, again closer to the baseline (58,267.98 ops/s) than SELinux (53,391.44 ops/s). On the fsync-intensive *varmail* workload, USEC achieves 27,000.82 ops/s, which is also closer to the baseline (27,643.02 ops/s) than either SELinux (24,334.93 ops/s) or AppArmor (25,715.50 ops/s). These results indicate that USEC generally reduces the performance cost of MAC mediation on common filesystem-intensive paths, even though these operations frequently traverse security-relevant hooks in the VFS and inode layers. At the same time, the Filebench results also show that filesystem-intensive workloads can be affected by factors beyond the MAC mechanism itself. For example, on *random write* and *single stream read*, the relative ordering of USEC and AppArmor is less uniform than on the other workloads, and the LSM-disabled baseline is

Table 3: Selected UnixBench results comparing SELinux, USEC, AppArmor, and the LSM-disabled baseline. Each configuration was run for 10 trials. For each metric, we report the average, standard deviation, and volatility (volatility = standard deviation / average). Higher throughput or composite index values indicate better performance. The bottom row shows the relative performance degradation compared to the LSM-disabled configuration.

Test Item	SELinux			USEC			AppArmor			LSM Disabled		
	Avg.	Stdev.	Volatility	Avg.	Stdev.	Volatility	Avg.	Stdev.	Volatility	Avg.	Stdev.	Volatility

System Call Overhead	5,975,768.33	5,950.58	0.10%	6,224,448.09	52,963.26	0.85%	6,271,104.63	327,866.08	5.23%	6,341,157.01	10,767.52	0.17%
Process Creation	39,528.68	143.65	0.36%	40,275.54	158.28	0.39%	40,349.44	170.82	0.42%	40,360.75	110.25	0.27%
Shell Scripts	2,871.43	11.97	0.42%	2,980.05	13.95	0.47%	2,926.74	114.94	3.93%	3,004.96	15.09	0.50%
System Benchmarks Index Score	3,681.53	4.45	0.12%	3,875.07	200.36	5.17%	3,864.81	66.14	1.71%	3,993.15	164.12	4.11%
Performance Degradation vs Baseline (LSM Disabled)	7.80%			2.96%			3.21%			0%		

not always far above the MAC configurations. This suggests that filesystem-internal behavior, caching, synchronization, and I/O scheduling effects can have a substantial influence on throughput in these workloads. When aggregating the five Filebench workloads, SELinux incurs a 10.86% performance degradation relative to the LSM-disabled baseline, whereas USEC incurs 6.87%, and AppArmor incurs 9.51%. Overall, these results show that `USEC` substantially narrows the performance gap compared with a traditional full-coverage MAC design on filesystem-intensive workloads.

Nginx: network-facing overhead. We further evaluate a web-server workload using Nginx. This benchmark stresses socket creation, connection handling, request processing, and message transmission, which together exercise the socket-, file-, and IPC-related paths often involved in MAC checks for server applications. As shown in Table 5, USEC achieves 92,185.08 req/s on average, corresponding to 95.68% of the LSM-disabled baseline and incurring only 4.32% throughput overhead. In contrast, SELinux achieves 84,748.05 req/s, corresponding to 87.96% of the baseline, while AppArmor achieves 81,774.77 req/s, corresponding to 84.87% of the baseline and incurring 15.13% throughput overhead.

The larger gap observed here, compared with UnixBench, suggests that realistic server workloads are much more effective at exposing the runtime cost of MAC enforcement because they repeatedly trigger socket-, file-, and IPC-related checks along the request-processing path. The latency results show a similar trend. USEC remains relatively close to the baseline in both median and tail latency, with a P50 latency of 3.569 ms and a P99 latency of 12.140 ms, whereas SELinux increases P50 latency to 3.710 ms and P99 latency to 12.990 ms. AppArmor shows the largest throughput loss and also exhibits higher latency than USEC across the key percentiles, with a P75 latency of 8.333 ms, a P90 latency of 9.526 ms, and a P99 latency of 12.120 ms. This means that the benefit of lightweight mediation is not limited to average throughput, but also extends to request latency behavior, which is particularly important for interactive services. In other words, USEC not only preserves near-baseline throughput, but also avoids the more visible latency inflation observed under heavier mediation mechanisms.he pronounced long-tail latency inflation observed under heavier mediation mechanisms.

Overall, the evaluation shows that traditional full-coverage MAC enforcement incurs limited slowdown on broad CPU-oriented benchmarks, but can introduce more visible overhead once workloads repeatedly traverse filesystem and network paths that are central to MAC enforcement. In contrast, `USEC` remains consistently closer to the LSM-disabled baseline across both Filebench and Nginx, while substantially outperforming SELinux and showing more stable behavior than AppArmor under high-concurrency web serving.

This also clarifies the apparent gap between the 87% slowdown cited in our motivation and the smaller overheads observed in our own evaluation. The 87% number comes from prior work [26], which evaluates SELinux under a much more MAC-intensive setting on Linux v5.3, and should therefore be interpreted as a workload-specific stress-case result rather than a general statement about SELinux overhead in most environment scenarios. Our experiment results show the same qualitative trend across workloads: SELinux incurs only a 7.8% slowdown on the broad, CPU-heavy UnixBench suite, but this grows to 12.04% on the more security-sensitive Nginx workload reported above, where MAC-relevant kernel paths are exercised much more frequently. At the same time, even Nginx remains a realistic service workload rather than an extreme stress case, since substantial execution time is still spent in ordinary request processing and protocol handling outside MAC-dominated paths. In this sense, the 87% result reflects a specific upper-end MAC-intensive scenario, whereas our Filebench and Nginx results capture more representative practical deployments.

6.3 Evaluation on Compatibility

To evaluate compatibility, we focus on two scenarios. First, we consider applications that fail to deploy under SELinux, and show that `USEC` can protect selected resources without breaking them. Second, we start from an existing SELinux policy known to work in production and demonstrate that `USEC` can remain compatible with such policy. We also discuss AppArmor where relevant: although it is often less intrusive than SELinux, it does not provide the same migration path

Table 4: Filebench results comparing SELinux, USEC, AppArmor, and the LSM-disabled baseline. Each configuration was run for 10 trials. For each metric, we report the average, standard deviation, and volatility (volatility = standard deviation / average). Higher throughput values indicate better performance. The bottom row shows the relative performance degradation compared to the LSM-disabled baseline.

Test Item	SELinux			USEC			AppArmor			LSM Disabled

from existing SELinux policies nor the same resource-centric abstraction used by `USEC`.

Case 1: Mitigating SELinux-induced failure. Many applications are built assuming pure DAC semantics [11, 14]. When SELinux's path- and type-based rules are enabled without a well-tuned policy, installers may fail to update their own files, and services may lose access to devices or D-Bus endpoints. AppArmor is often more permissive in practice because it relies on pathname-oriented profiles and may therefore avoid some SELinux-specific deployment failures. However, this does not eliminate the underlying policy-engineering burden when administrators still need to align application identifiers, resources, and interface permissions. In this case, `USEC` uses templates and D-Bus-based configuration to derive SELinux-compatible rules from a compact app identifier, protecting private files and D-Bus interfaces while avoiding failures common with hand-written SELinux policies.

```
1  policy_template_t g_policy_template[MAX_ID_TYPE] = {
2      [APPID_TYPE] = {
3      .policy_template = "type deepin_app_@n_t;\n"
4          "deepin app domain_set(deepin_app_@n_t)\n"
5          "domain unkillable(deepin_app_@n_t)\n"
6          "type deepin_app_@n_file_t;\n"
7          "deepin_app_private_file_type_set(deepin_app_@n_file_t)\n"
8          "allow deepin_app_@n_t deepin_app_@n_file_t:dir
9          _file_class_set ~{ relabelfrom relabelto };\n"
10         "deepin_access_all_sensitive_resource(deepin_app_@n)\n\n",

12     },
13 }
```

Figure 11: A template that turns an app identifier into a SELinux-compatible policy fragment.

As shown in Figure 11, we first declare the global template table and select the `APPID_TYPE` entry(lines 1–2), and encode the SELinux rules with the placeholder `@n` (lines 3–10). Instead of manually writing all rules for every program, the administrator only supplies an app identifier (e.g., the D-Bus name) over `USEC`'s management D-Bus; the policy generator substitutes `@n` with that identifier, emits SELinux-compatible rules, and loads them into `upolicydb` and `usidtab`. For the `net.poettering.Calculator` test service, we bind its identifier to the `APPID_TYPE` template and describe the calculator object and subjects (`d-feet`, `busctl`, `dbus-send`) in JSON, choosing operations such as `readwrite` or `deny`. This keeps the enforcement semantics aligned with SELinux while removing most manual policy editing that previously caused SELinux-induced application failures. Compared with AppArmor, the benefit is different: rather than relying on simpler pathname matching alone, `USEC` allows the administrator to start from a compact resource-oriented description while still preserving SELinux-compatible policy semantics.

Case 2: Matching SELinux protection and compatibility. To evaluate whether `USEC` can reuse existing SELinux policies without losing protection or compatibility, we install the upstream SELinux default policy and load a subset of its rules into `USEC`. This case is primarily a comparison against SELinux, since AppArmor does not share SELinux's policy representation, label model, or binary policy format, and therefore does not offer an analogous policy-migration path.

In detail, we migrate a SELinux policy into `USEC`'s policy engine, as shown in Figure 12. First, we place `USEC` in permissive mode via the system security manager (`DisableSecurity`), so that policy changes do not disrupt running applications (lines 1-6). Next, we copy the compiled SELinux policy `usec_test.pp` from

```
# Put USEC in permissive mode during migration
$ busctl call \
org.deepin.PermissionManager \
/org/deepin/PermissionManager/PolicyManager \
org.deepin.PermissionManager.PolicyManager \
DisableSecurity

# Copy the SELinux policy fragment into USEC 's policy set
$ cp /etc/selinux/targeted/policy/usec_test.pp \
/etc/usec/policy/usec_test.pp

# Load policy into USEC
$ usec-policy-load /etc/usec/policy/usec_test.pp

# Re-enable USEC enforcement via the system security manager
$ busctl call \
org.deepin.PermissionManager \
/org/deepin/PermissionManager/PolicyManager \
org.deepin.PermissionManager.PolicyManager \
EnableSecurity
```

Figure 12: Migrating a SELinux policy fragment into USEC.

/etc/selinux/targeted/policy/ into USEC's policy directory under /etc/usec/policy/, and load it with usec-policy-load (lines 8-13). At load time, USEC parses the SELinux binary policy and populates its own upolicydb, usidtab, and usec_uavc, which mirror SELinux's policydb, sidtab, and AVC but live in a separate usec_state. Finally, we re-enable enforcement with the EnableSecurity call, so subsequent accesses are checked by USEC (lines 15-20).

USEC reuses the SELinux policy format and label syntax, so policy fills upolicydb and usidtab with the same rules and security identifiers that SELinux has, while on-disk labels stay unchanged. At the same time, this state lives in usec_state and is wired to LSM hooks through the blobs mechanism, so USEC runs alongside SELinux without sharing internal data. For objects covered by the imported policy, both modules see the same subject–object pairs and reach the same allow or deny result; for other objects, USEC returns early, and the request is handled by DAC and any SELinux rules. In practice, loading a SELinux policy into USEC preserves SELinux-level protection on protected resources and does not introduce extra denials when the two MACs are stacked. This compatibility is complementary to AppArmor: AppArmor provides lightweight confinement, but does not support direct reuse of existing SELinux policies as USEC does.

7 Lessons Learned

Lesson 1: Hook retention must be instantiated for the target kernel and software stack. Although USEC's policy model is conceptually portable, practical hook pruning is not a one-time universal mapping. Our initial prototype assumed that a single generic capability-to-hook mapping would be sufficient across deployments. In practice, this assumption proved too coarse. The same high-level capability may be realized through different mediation points depending on the kernel version, enabled subsystems, and userspace software stack. As a result, a retained hook set that is correct and efficient on one product may be suboptimal, or even require additional bindings, on another.

This led us to treat capability-to-hook resolution as a compiler-driven, kernel-aware construction step. In USEC, a declared policy is first translated into capabilities, each capability is then expanded through a capability dictionary into TE permissions and dependent hooks, and the final retained-hook set is materialized as a compact bitmap for the target kernel. This means that hook retention is derived systematically from the declared security intent rather than from ad hoc profiling or manual pruning. To keep this process sound across environments, the compiler and the kernel must also agree on the hook inventory; when the exported hook version changes, the mapping must be re-instantiated rather than silently reused. Representative workloads still matter, but for narrower purposes than we initially expected. First, they validate that the retained set covers the control paths exercised in the intended deployment. Second, they help identify redundant mediation points on hot paths once the required capability coverage has already been established. In other words, profiling improves performance, but it does not determine which security-relevant transitions may remain unchecked.

This distinction proved important in deployment. On some desktop builds, the dominant retained hooks were concentrated in file-system paths such as file_open and inode_permission. On appliance-style systems with heavier network or device activity, a larger fraction of the retained cost came from socket- and device-related hooks. The lesson is not that USEC should keep only "hot" hooks; rather, it must first retain all hooks required by the declared capabilities on the target kernel, and only then optimize away redundant mediation points that unnecessarily burden hot paths.

Lesson 2: Deployability depends on how small the enforcement surface can be made in practice. Although USEC is motivated by strong access-control semantics, our industrial deployments repeatedly showed that deployability depends at least as much on efficiency as on policy expressiveness. System integrators rarely reject a security mechanism because they disagree with its protection goal; they reject it because the runtime cost is visible on latency-critical paths or because the operational workflow becomes too complex.

This was especially evident during early rollouts. Even after replacing SELinux-style broad mediation with capability-driven selective enforcement, the initial retained-hook set was not always performance-optimal for deployed products. Real workloads exposed concentration points that were only weakly reflected in synthetic testing. On desktop systems, reducing redundant checks on frequent file-system paths improved responsiveness. On appliance-style systems, the main costs often shifted to networking and device paths, where a retained set that worked well elsewhere could still introduce noticeable latency under sustained packet or I/O activity. These experiences reinforced a practical rule: correctness

must be established first through capability expansion and kernel-aware binding, but deployability depends on how aggressively the implementation removes unnecessary enforcement from the paths that dominate real workloads. More broadly, this experience shaped USEC's overall design philosophy. A deployable MAC mechanism should not optimize for theoretical generality alone. Instead, it should expose a narrow and understandable security intent, compile that intent into a compact retained-hook set for the target kernel and software stack, and then tune the resulting enforcement surface against representative workloads for the product line. For us, the combination of explicit capability scope, kernel-aware capability-to-hook resolution, bitmap-based selective enforcement, and workload-guided refinement was essential to making USEC acceptable in production.

8 Related Work

8.1 MAC on Operating Systems

Mandatory Access Control has been widely adopted in operating systems, especially via the Linux Security Modules (LSM) framework. Among popular implementations, SELinux [12] offers a rich MAC model with type enforcement, role-based access control, and optionally multilevel security. It labels both subjects and objects and enforces kernel-level decisions, providing strong isolation and expressive policies, but it is also burdened by substantial runtime overhead and policy-management complexity. In contrast, AppArmor [1] uses pathname-based profiles rather than full label+type enforcement, making configuration and deployment simpler, but its expressiveness and isolation guarantees are weaker. Smack [17] is tailored for simplicity and embedded/IoT use cases: trading off many of SELinux's advanced features in favor of reduced complexity and overhead, yet empirical studies indicate that in default settings Smack (and similar lightweight systems) may not prevent attacks as effectively as SELinux. Finally, TOMOYO [16] uses an invocation-history domain model and pathname-based policies, while Yama [5] adds supplementary MAC-like restrictions, both reduce overhead and administrative burden but at the cost of weaker isolation.

USEC fits into a familiar trade-off between expressiveness, overhead, and usability. SELinux offers rich policies at higher complexity and runtime cost, while AppArmor, Smack, and TOMOYO favor simpler, lower-overhead configurations with weaker guarantees. Prior work shows SELinux can block all tested attack stages in embedded firmware, where these lighter systems fail under default settings. USEC builds on this lineage, targeting the low-overhead corner while preserving mandatory enforcement.

8.2 MAC in Cloud/Virtualised Systems

Early work on MAC in virtualised environments focuses on enforcing isolation at the hypervisor or VM level. sHype [13] extends the Xen hypervisor (and later the IBM POWER hypervisor) with a MAC architecture that controls VM–VM and VM–resource interactions using configurable policies such as simple type enforcement and Chinese Wall, with an emphasis on low overhead and strong VM isolation. Xen Security Modules (XSM) [24] provide a general MAC framework inside Xen; its FLASK module [15] brings SELinux-style fine-grained MAC to domains, event channels, and I/O resources, implementing flexible policies over hypercalls and hypervisor objects. Building on these foundations, Win et al. [21] combine hypervisor-level MAC with virtual machine introspection, enforcing STE/CWE-style policies on resource accesses in cloud environments. Shamon [6] generalises sHype into a shared reference monitor that uses TPM-based attestation and security VMs to enforce distributed MAC policies across coalitions of VMs and hosts.

USEC targets a different point in the stack by running inside the guest kernel and protecting in-guest files, devices, and sockets. Like sHype and XSM/FLASK, it is label-based, but enforcement is resource-centric and opt-in, so only named resources trigger MAC checks, and others follow DAC and any in-guest MAC, such as SELinux. Unlike Shamon and VMI-based schemes that use separate security VMs, USEC keeps enforcement local and offers a permissive shadow mode to refine policies before enabling strict enforcement.

9 Conclusion

In this work, we presented USEC, a practical mandatory access control framework co-designed with security vendors to make strong kernel protection both usable and deployable at scale. By introducing a resource-centric policy abstraction, USEC lets administrators express high-level intent directly over the small set of security-critical resources they care about. USEC further reduces runtime costs through demand-driven enforcement, and improves compatibility by preserving DAC semantics for all resources not explicitly opted into protection. USEC can provide SELinux-level protection with significantly fewer rules, substantially lower overhead, and far fewer compatibility issues across real server and desktop workloads. USEC has already been adopted by over 210 commercial security vendors and deployed on over 8,000,000 endpoints, showing that strong, configurable kernel MAC enforcement can be both efficient and practical in modern Linux systems.

Abstract

We present Mohabi—a modern Firefox browser with a securely sandboxed JavaScript engine. Mohabi leverages software-based fault isolation (SFI) to ensure JavaScript engine bugs cannot affect the rest of the browser. To achieve this, we disaggregated the JavaScript engine (SpiderMonkey) from the rest of the browser, and developed techniques that leverage the type system and automatic code generation to make this complex transformation—that spans numerous data structures and deeply intertwined control flow across tens of thousands of functions—safe and tractable with reasonable engineering effort.

We then sandboxed SpiderMonkey using an optimized SFI toolchain we developed to meet the unique challenges of JavaScript engines, such as efficient support for large memory footprints. Mohabi only incurs modest overheads on common benchmarks—24.82% on JetStream and 24.43% on Speedometer. Mohabi is the most ambitious case study in retrofitting in-process sandboxing in a large system to date, and our x86-64 SFI toolchain is the fastest to date, imposing overheads between 5.9%–6.6% in SPEC 2017.

1 Introduction

Modern JavaScript engines are a seemingly inexhaustible source of critical memory-safety vulnerabilities [73]. In the past decade, these have become a major vector for in-the-wild attacks on browsers [58,90,130]. This problem is fundamental to the design of modern JavaScript engines, and there are several reasons for this.

First, production JavaScript engines like SpiderMonkey, V8 and JavaScriptCore rely on an intricate system of code generation and execution engines including interpreters, just-in-time compilers, and profile-based code optimizers. JavaScript engines dynamically juggle these different engines to achieve an optimal balance of startup latency and efficiency. This makes them incredibly complex (§2).

Next, their inputs—JavaScript, WebAssembly, and various Web APIs—are quite complex; as a result, the compiler and optimization stages have a very large attack surface. Further, this attack surface is not static, and continues to change and grow as Web standards evolve.

The final and perhaps most damning element that makes this situation intractable is that memory safety bugs in JavaScript engines are often not directly in the compilers or interpreters, but rather in runtime-generated code. For example, while JavaScript requires all array accesses to be bounds checked, JavaScript JITs produce code without these bounds checks when range analysis proves they can be safely elided. However, bugs in the range analysis [18, 19, 40] result in memory-unsafe code that can perform out-of-bounds array accesses. Consequently, our most powerful tool for preventing memory safety bugs—language-level type systems, e.g., in Rust—cannot address this problem.

Operating system and browser vendors have tacitly acknowledged that this is not a solvable problem in the near term, and introduced new modes that enhance security by disabling the JIT. In 2022 Apple introduced Lockdown Mode—an optional feature across their mobile, desktop, and wearable platforms—that disables the JIT in Safari [27]. Microsoft introduced Enhanced Security Mode [98] that similarly disables the JIT, and Android recently announced Advanced Protection Mode that "disables the JavaScript optimizer" [25].

This solution comes at a high cost. For example, in SpiderMonkey, JITs offer a 3.5×–7× speedup [52] for JavaScript. Even worse, disabling JITs doesn't offer a complete solution. For example, 5 of the 12 exploits in Chrome's JavaScript engine in 2025 would not be prevented by disabling the JIT [62], while a recent study found 23 remote-code execution vulnerabilities in the interpreter used in Edge's enhanced-security mode [135]. Browsers need a better solution.

Our solution. To address this challenge, we present Mohabi[1], the first sound sandbox relying on software-based fault isolation (SFI [134]) applied to JavaScript (JS) engines in a modern web browser.

[1] Mohabi stands for Monkey Habitat—a pleasant, but secure enclosure for the SpiderMonkey JavaScript engine used by the Firefox browser.

Mohabi sandboxes SpiderMonkey JS engine instances in the Mozilla Firefox browser. Thus, even if the JS engine is compromised, it is confined, and cannot arbitrarily corrupt memory in the rest of the browser or invoke disallowed system calls to escalate privileges.

In contrast, prior academic work [26, 106, 107] on JIT sandboxing (§9) has only sandboxed standalone JS engines in isolation, while industry-developed sandboxes (e.g., V8's Ubercage [70] and Safari's JITCage [37]) have so far been unsound and frequently bypassed (§7.4).

To build Mohabi, we have developed two new capabilities. First, we needed tools to allow disaggregating SpiderMonkey from Firefox, i.e., to separate out the JS engine, and then securely and efficiently re-enable control and data flow with minimal engineering effort. Second, we needed an SFI toolchain that could meet the challenges of sandboxing SpiderMonkey in production with low overhead—something that no existing SFI toolchain could do.

To enable disaggregation, we developed a set of C++ types and tools that allow us to securely express common patterns for sharing and control flow. For example, split-allocation types (§4.2) enable us to shard an object across separated (sandboxed and unsandboxed) allocators—based on what needs to be shared, and what needs to remain isolated. We also observed that modern browsers rely heavily on automatic code generation [5,15,17,39] and wrapper types [63,100,104] to integrate components together; we hook into and modify these tools to simplify disaggregation. Without these tricks, disaggregating SpiderMonkey would be a massive engineering effort—the JS engine itself supports well over 2,000 API calls, with an order of magnitude more call sites into the engine scattered over Firefox's considerable codebase. Once disaggregated, we needed a way to efficiently sandbox SpiderMonkey instances in memory—as the high memory and context switch costs of process sandboxing would have been a non-starter.

To address this challenge of scalable SFI, we developed MH-LFI. MH-LFI's key differentiating features are (1) its efficient support for large sandboxes—sandboxes with memory pools greater than 4 GiB, and (2) its safe handling of JIT-compiled code. The former is a necessity for modern browser features like ArrayBuffers and WebAssembly instances[2], while the latter is needed for all modern JS engines. MH-LFI works by rewriting assembly files to insert SFI-style guard checks into binaries, and is (mostly) independent from the choice of C/C++ compilers used to compile the browser—only a small amount of MH-LFI is implemented with compiler changes.

MH-LFI provides a separate validator to check that all sandboxed code has been correctly instrumented. This allows us to ensure that SFI instrumentation added by the JIT and AOT compilers is correct, removing the compilers from the trusted computing base (TCB). We also found that the validator was essential to catching edge cases of missing SFI checks that would otherwise have been overlooked (§6.3).

Mohabi's performance & security. We evaluate Mohabi on Speedometer [11]—the industry-standard full browser benchmark that tests both JavaScript and overall browser performance—and observe overheads of 24.43%. We break down the individual sources of overheads in §7.1. We also evaluate Mohabi on a pure JavaScript benchmark (JetStream [9]) to compare to prior work that sandboxed standalone JS engines [26,106,107]—and observe an overhead of 24.82%. We compare MH-LFI to Native Client (NaCl)—the SFI toolchain used in prior work sandboxing JS engines [26] and show how MH-LFI outperforms NaCl in §7.2. All modified AOT and JIT compilers pass all tests in the LLVM and SpiderMonkey codebases respectively, and based on our analysis, MH-LFI is the fastest x86-64 SFI toolchain to date.

In §7.3, we analyze how Mohabi defends against commonly used JS engine exploitation techniques and highlight some JS engine bugs that Mohabi would have mitigated—specifically, recent bugs reported by Anthropic's Mythos LLM [81] several months *after* Mohabi was developed. Additionally, we contrast Mohabi with Ubercage (V8's partial JavaScript sandbox) to highlight the differences between the two systems in §7.4. We analyze a subset of prior Ubercage sandbox bypasses and show how Mohabi prevents them.

Artifacts. All source code, prototypes, and benchmarks from this paper are available at `https://github.com/UT-Security/jitsbx-root`.

2 Why JavaScript Engine Security is Hard

Modern JavaScript (JS) engines have an extremely high bar for performance—they must begin executing code instantly to avoid introducing latency during page loads, while also efficiently executing modern websites that can be as complex as full-fledged desktop applications using JIT compilation.

To achieve this, they rely on a range of complex JITs and interpreters. This complexity has led to numerous vulnerabilities [69]. SpiderMonkey—the JS engine in Firefox that we sandbox in Mohabi—consists of 9 different code execution-engines [101]. JavaScript alone consists of a C++ bytecode interpreter, an optimized interpreter, along with non-optimizing and optimizing JIT compilers. These compilers are organized as tiers—at each tier the compiler takes longer to start executing, but applies more optimizations for greater efficiency. Additionally, there are interpreters and JITs for WebAssembly (Wasm) and regular expressions [83]. Other JS engines such as V8 (Chrome) and JavaScriptCore (Safari) use similar tiered architectures, although their internals differ.

[2]While WebAssembly code is already sandboxed [80], browsers' implementations are very buggy as they (1) reuse compiler infrastructure from their buggy JS engines, and (2) execute WebAssembly code that is very intertwined with JavaScript. We thus treat WebAssembly as effectively unsandboxed.

JS engines use these different *tiers* by dynamically changing compilation strategies at runtime, switching execution tiers based on how often a piece of code is executed. SpiderMonkey supports this with the help of *on-stack replacement*, allowing code to *tier-up* in the middle of execution—switching from being interpreted to executed as JITted code.

SpiderMonkey also supports switching from executing a JITted version of JavaScript code to interpreting it, through *bailouts*. This is necessary because the optimizing tiers employ *speculative optimization* [113], meaning that they optimize code based on type information collected during runtime—which is required for dynamically typed languages like JavaScript. This information is used along with other optimizations to specialize code, for instance, by eliding security checks (e.g., array bounds checks), if they are deemed redundant. The specialized code includes checks to ensure that assumptions hold on inputs to functions; if inputs are found to not be of the expected types, the result is a *bailout* from optimized tiers to the interpreter.

This complex architecture means that bugs in any of the above components—e.g., the JavaScript interpreters [69], the JavaScript compilers [20, 40, 66], the WebAssembly runtime [108]—result in vulnerabilities affecting the entire JS engine [76] and browser. These vulnerabilities are a common part of real-world exploit chains [58, 90] where JavaScript engine vulnerabilities are used to obtain initial code execution in the browser's renderer. This is then chained with privilege escalation vulnerabilities to take over a victim's machine.

Browsers have historically resorted to process-based isolation to address security concerns. The multi-process architecture [35] separated the browser into a privileged parent process and content processes. Site isolation [102, 119] extended this further by ensuring that tabs belonging to different top-level sites never share a content process. However, applying the same approach here—separating the JS engine—is a non-starter. The JS engine is tightly coupled with the DOM engine, event loop, and other browser subsystems, with extremely frequent interactions. Introducing an additional process boundary would require IPC for each of these interactions, resulting in prohibitive overhead.

In this paper, we present Mohabi—a sound, in-process sandbox for JS engines that can address this problem.

3 Mohabi: Securing the JavaScript Engine

Mohabi secures the JS engine by placing it in a sandbox implemented using software-based fault isolation (SFI). SFI works by isolating all memory (code and data) used by the JS engine in a dedicated portion of the process' address space called the *sandbox memory*, and restricting all memory-access and control-flow operations to this memory. Consequently, memory corruption resulting from JS engine bugs is restricted to sandbox memory and cannot affect the rest of the browser.

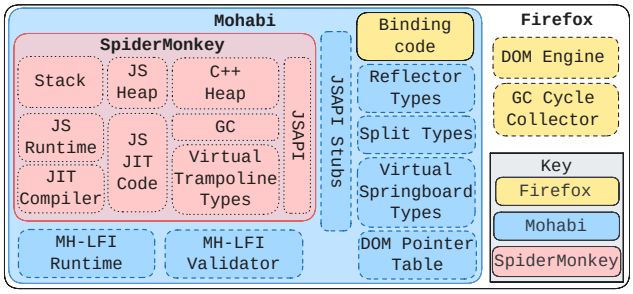

Figure 1: **Mohabi's design.** *Mohabi disaggregates SpiderMonkey from Firefox and places it in a high-performance MH-LFI sandbox. Disaggregation and secure interactions are mediated by custom types such as Reflector types. System-calls are checked by MH-LFI's runtime and code pages are checked by MH-LFI's validator to preserve security.*

Mohabi relies on our new SFI toolchain, MH-LFI (§5), that scales to a JS engine's unique requirements. MH-LFI is implemented in two parts: (1) an external rewriter that modifies the binaries produced by C/C++ compilers to ensure they follow SFI rules, and (2) a modified JIT compilation pipeline to ensure that all JITted code produced follows SFI rules. To exclude these compilers from Mohabi's TCB, MH-LFI comes with a binary validator that checks that all executable code pages within the sandbox comply with SFI rules.

Mohabi's design (Figure 1) is based on several observations about modern browsers that allow JS engine sandboxing without significant performance or engineering costs.

Browsers employ site isolation. Browsers implement site isolation [102, 119] to ensure different top-level sites are rendered in separate processes. This model ensures that a site's process does not contain any secrets about other sites visited by the browser. Consequently, Mohabi sandboxes JS engines in the site's process using write-only sandboxing—it does not restrict any reads of data. This is sufficient to prevent a compromised JS engine from escalating privileges.

Browser JITs share a compiler backend. The various JIT compilers used by JS engines produce native code through a shared architecture-specific emission backend [8, 12, 14]. Additionally, these backends tend to be stable over long periods of time; e.g., SpiderMonkey's backend last received a major update 10 years ago [2]. Mohabi uses this shared backend as a choke point for enforcing SFI—enabling instrumentation regardless of the specific JIT optimizations or the IRs used.

Browsers auto-generate glue code. All browsers auto-generate the glue code layer [1, 5, 17] between the JS engine and DOM—the primary browser component that interacts with the JS engine. Mohabi augments this code generation as a location to include safety checks on data output by the JS engine APIs—a necessary step to prevent confused deputy attacks on the DOM engine by a compromised JS engine.

Mohabi leverages these insights along with the new MH-

LFI SFI tool to sandbox the SpiderMonkey engine used by the Firefox browser. We note that Mohabi's design is general and can be applied to any modern browser.

4 Disaggregating SpiderMonkey from Firefox

The first step in Mohabi is to separate or "disaggregate" SpiderMonkey's code from Firefox code as sandboxing restrictions should only be applied to the former. This involves disaggregating control flow and data structures.

We *disaggregate control flow* by first isolating control flow, and then explicitly permitting safe control flow from SpiderMonkey to Firefox, e.g., for functions that are explicitly passed to the JS engine as callbacks. This is challenging as control flow can get arbitrarily nested. We then *disaggregate data structures* between Firefox and SpiderMonkey by placing only data that must be shared in the sandbox's memory.

Fortunately, we found this task was tractable across the large and complex Firefox codebase due to the presence of a handful of repeated patterns in how control flow and data sharing occur. We developed tools to handle these patterns, and thus enable safe and sometimes automated disaggregation.

These tools include split-allocation types (§4.2), which enable selective sharing of object fields across trust boundaries, as well as Reflector (§4.3), Virtual Trampoline, and Virtual Springboard types (§4.5), which enable safe and structured control flow between browser and sandbox. Additionally, we developed a stub library generator to wrap the SpiderMonkey interface (§4.4), which exposes 2,250 unique functions, and is used at an order of magnitude more call sites across Firefox.

We next explain our process of disaggregating SpiderMonkey, i.e., separating it from the browser and then safely reintegrating it back into the browser using the above tools.

4.1 Breaking out the JavaScript Engine

Firefox uses SpiderMonkey by directly linking it with browser code. We began by modifying the browser build process to compile SpiderMonkey separately using our Ahead-of-Time MH-LFI SFI toolchain (§5). Additionally, since SpiderMonkey's JITs compile code within the sandbox, we modify them to produce code conforming to our SFI scheme (§6).

To ensure SpiderMonkey does not share any data structures or symbols with the rest of Firefox, it is compiled as a standalone binary with its own private libc. This library must be explicitly loaded and assigned a memory region it can use—the sandbox memory. We refer to the produced library as the sandboxed SpiderMonkey instance—having all its control flow and stores restricted to a sandbox memory region.

Next, we modify each Firefox process that uses the JS engine to create a per-process sandbox instance. These processes include: the browser's UI (managed using JavaScript), each Content Process (handles JavaScript from the web), and the Proxy Auto-Config Process (configures the browser's proxy settings using JavaScript). When a sandboxed SpiderMonkey instance is loaded, our SFI validator (see §5.4) confirms that it is sandboxed correctly, then instantiates the sandbox instance. All threads spawned by the process (e.g., Web Workers in the Content Process) use the same sandbox instance, but receive their own per-thread sandbox context for stack, thread-local storage and registers.

```
template <typename T>
struct Rooted {
  Rooted<T>** stack; // pointer to stack top
  Rooted<T>* prev; // previous root in stack
  T ptr; // pointer to GC'd JS object

  explicit Rooted(RootingContext* cx) : ptr(...) {
      ...
    this->prev = ...; // point to prev root
    *this->stack = this;
  }
  ~Rooted() { ... }
};
```

Figure 2: **The Rooted<T> Type.** *One of the types used for JS object references in the browser that need to be registered with the GC. We implement this in Mohabi as a split-allocation type, with select fields moved into the sandbox.*

4.2 Safe Garbage Collector Support

SpiderMonkey provides a moving garbage collector (GC) that moves JavaScript (JS) object allocations to optimize tracing and reduce fragmentation on the heap. Moving a JS object requires the GC to update all references to the object to the new location; this includes any references from Firefox code.

SpiderMonkey tracks such references by requiring Firefox to use custom types like `Rooted<T>` in Figure 2 to declare references to JS objects. On construction, `Rooted<T>` automatically adds itself as a node in a LIFO linked-list of GC roots. SpiderMonkey uses this LIFO linked-list to trace the active roots when a GC is triggered.

However, disaggregating SpiderMonkey means that the GC can no longer directly update such references to JS objects that come from Firefox code. To restore functionality, we must allow the GC to modify `Rooted` references when object migration or heap compaction occurs. Concretely, this means that the GC should be permitted to modify the `ptr` field from Figure 2, but not other fields in the object such as the LIFO link-list. To allow secure updates to the `ptr` field, we introduced split-allocation types.

Split-allocation types. These types split a single logical object across two locations. Some fields are stored in sandbox memory, to enable updates by sandboxed code—other fields are allocated outside of the sandbox—to protect their integrity. This separation and management of multiple allocations for different fields is hidden from the user of the type.

A split version of `Rooted<T>` is one use of split-allocation

```
1  // this is called when 'window.location' is modified
2  static bool
3  set_location(JSContext* cx_, JS::Handle<JSObject*> obj,
4               ... , JSJitSetterCallArgs args) {
5    BindingCallContext cx(cx_, "Window.location setter");
6    ...
7    JS::Rooted<JSObject*> targetObj(cx, &v.toObject());
8    return JS_SetProperty(cx, targetObj, "href", args[0]);
9  }
10 // defines set_location as a JSObject property setter
11 static const JSJitInfo location_setterinfo = {
12   { set_location }, ... ,JSJitInfo::Setter, ...};
13 static const JSPropertySpec sUnforgeableAttributes_spec[]
14   = { JSPropertySpec::nativeAccessors(
15           "location", JSPROP_ENUMERATE | JSPROP_PERMANENT,
16           ..., &location_setterinfo), ...};
```

Figure 3: **The DOM-JS Engine binding layer.** *All production browsers use automatic code generation to create a binding layer between the JS engine and the DOM. Here the code shows a setter function on the* `window` *DOM reflector object.*

types. Other GC types such as `Heap<T>`—which captures long-term references from Firefox's heap to SpiderMonkey objects—were also migrated to split-allocation types. Overall, these types were applied to thousands of sites in the browser.

4.3 Supporting Firefox's DOM reflectors

The Document Object Model (DOM) specification and associated web platform specifications [3, 6] list APIs that JS engines can use to interact with the browser. Beyond HTML manipulation, these APIs support Web Workers (background threads), Web Storage (key/value storage), and Geolocation. These APIs are exposed to the JS runtime with the help of DOM reflectors, which are projections of DOM functionality as JS objects.

For example, the `window` object in Figure 3 is a DOM reflector that has several attributes—one of which is `location`. When executing JS code that sets the `window.location` property, SpiderMonkey invokes the `set_location` function at line 3. This function forwards the write to the `window` object's `href` property (line 8), requiring a nested invocation to the JS engine at the `JS_SetProperty` call.

However, disaggregation would mean that such callbacks cannot directly be invoked by SpiderMonkey, as the code is outside the sandbox memory (in Firefox's code). Mohabi instead requires SpiderMonkey to register all such callback functions as legitimate callback targets via a provided API. When registered functions are invoked as callbacks, Mohabi permits this control-flow securely through a trusted routine called a trampoline (described in §4.4).

We modify Firefox to explicitly register each callback function with the sandbox runtime at the time of creating a DOM reflector object. An instance of this is when defining the setter function (line 12) for the `location` property (line 15) before wrapping the browser's `window` object in a DOM reflector.

To apply this modification automatically across multiple data types, we introduced sandboxed reflector types.

Sandboxed reflector types. These types build on the observation that all browsers use API specifications written in WebIDL (an interface definition language) to auto-generate binding code [1, 5, 17, 39] to set up DOM reflector types. We modify this code generator to be sandbox-aware. For each DOM reflector type that it previously generated, we instead generate a sandboxed reflector type. When the first reflector object instance corresponding to a sandboxed reflector type is created, the browser functions exposed to JS are automatically registered as callbacks with the sandbox.

We needed a systematic solution to this because this approach applies not just to the `Window` reflector type but for the over 1,075 other reflector types automatically generated from WebIDL. These reflector types could potentially register up to 15,700 callbacks—if JavaScript code causes an instance of every single DOM reflector type to be created at least once.

4.4 Safe JS Engine Calls from the Browser

The browser can make function calls into the JS engine, for example, to modify the properties of a DOM reflector object as discussed in §4.3. These functions are exposed to Firefox through SpiderMonkey's library interface (the *JSAPI*). By building and linking SpiderMonkey separately from the browser, we have blocked direct calls into this code. We now focus on securely permitting these function calls.

Mohabi requires that all control-flow transfers from Firefox into the sandboxed JS engine use a piece of trusted code called the springboard. Springboards perform a safe context-switch on the way into the sandbox—they are responsible for switching stacks, saving callee-saved registers and setting the contents of reserved registers used by the SFI scheme (§5.1). Trampolines do the inverse for control-flow transfers in the other direction, when SpiderMonkey code returns to the browser, for example, through a callback registered with the sandbox runtime (§4.3).

To automatically re-allow safe JSAPI calls in Firefox via springboards, we build a stub-library generator.

Stub-Library Generator. The generated stub-library helps us account for the now dynamic location of the sandbox instance being invoked. This is done with the help of (1) an indirect-jump table with an entry for the resolved sandbox address of each JSAPI symbol and (2) a unique springboard routine corresponding to each JSAPI symbol.

Linking the browser to the SpiderMonkey stub-library statically resolves all JSAPI symbol references to a springboard. When the MH-LFI runtime instantiates the SpiderMonkey sandbox instance, it populates the indirect-jump table in the stub-library, allowing calls from Firefox to the JS engine.

The support provided by our automatically generated stub library is essential as the JSAPI exposes over 2,250 functions and Firefox contains an order of magnitude more unique

references to them, making explicit modification at each call site in the code impractical.

4.5 Interactions with the Browser Event Queue

JavaScript provides support for programming with asynchronous tasks using Promise objects. For example, the Fetch API, which is the modern JS interface to make HTTP requests, returns a Promise object. The `Promise.then` method allows a user to specify continuation code, which is scheduled for execution once the fetch request completes.

```
const promise = fetch("https://example.org/products.json");
promise.then((response) => ..., (error) => ...);
```

Support for scheduling these asynchronous jobs is provided by the browser rather than the JS engine. Concretely, the browser provides a `JobQueue` object (shown below), allowing SpiderMonkey to schedule jobs on the browser's job queue:

```
class JobQueue {
  // Enqueue a resolution job for promise
  virtual bool enqueuePromiseJob(JSContext* cx,
    JS::HandleObject promise, JS::HandleObject job,
    ...) = 0;
  ...
};
```

However, this is a problem when separating SpiderMonkey from Firefox. As this abstract class is implemented within the browser, the virtual functions are located outside the sandbox and must be explicitly registered as allowed callbacks (similar to the DOM reflectors in §4.3) to be callable by the JS engine. However, since vtable entries are automatically populated by the C++ compiler, there is no easy way to do this.

To address this, we introduce virtual trampoline and virtual springboard types, which help mediate dynamic dispatch across the sandbox boundary in both directions.

Virtual Trampoline Types. These are types within the sandbox that inherit from another underlying type, then override its virtual method implementations to redirect the call through a function pointer table instead. The user of a virtual trampoline type is expected to initialize the function pointer table with valid callback functions (§4.3).

Virtual Springboard Types. These are types outside the sandbox that help transfer control-flow into the sandbox. They expose the same interface as the underlying sandbox type, and act as wrappers. Each virtual method implementation forwards the call through a corresponding function exposed by the sandbox; this performs the actual virtual dispatch on the underlying instance within the sandbox.

In addition to job scheduling for Promises, we use virtual trampoline and springboard types in SpiderMonkey's implementation of JavaScript Proxy Objects, External DOM Strings and GC tracing, among others. In total, we expose these types for around 20 classes in the JSAPI.

```
1  // Binding code before tainting
2  bool get_width(..., JS::Handle<JSObject*> obj,
3           void* void_self, ...) {
4    ...
5    auto* self = static_cast<mozilla::dom::ImageData*>
6                                (void_self); }
7
8  // Binding code after tainting
9  bool get_width(..., JS::Handle<JSObject*> obj,
10   MC::OpaquePointer<void*> void_self, ...) {
11   ...
12   auto* self = MC::dom::DOMPointerTable::sanitize
13             <mozilla::dom::ImageData*>(void_self); }
```

Figure 4: **Adding Sanitization Checks to the Boundary.** *Firefox's binding code auto-generation is modified to insert sanitization checks before using the DOM pointer retrieved from the sandbox. This example shows the generated binding code for returning the width of an image.*

4.6 Type Safety at the Binding Layer

Secure disaggregation requires sanitizing any data received by Firefox that comes from SpiderMonkey. This is needed to prevent the sandboxed code from compromising Firefox via confused-deputy attacks [45, 82, 104]. We illustrate this using DOM reflectors as an example.

When DOM reflectors are passed to JavaScript, a pointer to the underlying C++ DOM object that it reflects is stored within it. When JS engines invoke a permitted DOM reflector callback (§4.3), this pointer is extracted and used to call methods on the underlying DOM object. However, this pointer could have been corrupted by compromised JS code to induce memory-safety errors in Firefox when the reflector is used.

To address this, we introduce pointer tables.

DOM Pointer Table. This is a table where each entry stores a valid DOM pointer, along with the type of the object. To make sure DOM code remains safe, we augment binding code generation to sanitize the incoming pointer, by making sure it exists within the table and is of the right type. Figure 4 illustrates one such example—the code at line 5 unsafely uses the pointer, whereas the augmented code at line 12 sanitizes the pointer before using it. To support this, we modify DOM reflector initialization to add an entry to the pointer table. As multiple reflector objects may point to the same underlying DOM object, each table entry also maintains a reference count, which is decremented on DOM reflector finalization.

While this case study serves as an example of how we can automate boundary checks, a more complete handling of boundary checks requires more work, and is discussed in §8.

5 Sandboxing SpiderMonkey Code

We now discuss how Mohabi can sandbox a disaggregated SpiderMonkey engine from Firefox using software-based fault isolation (SFI) [134]. SFI modifies compilers to insert guards

prior to all memory accesses and control-flow instructions to restrict them to the sandbox memory; additionally, all system calls are rewritten to function calls on a trusted runtime that blocks calls which may compromise the sandbox [47].

In order to scale to a production system like SpiderMonkey, an SFI toolchain must satisfy the following requirements:

- **No artificial memory limits.** Almost all SFI toolchains [53, 80,97,105,123,139] impose a limit of 4 GiB on the sandbox memory for efficient sandboxing. This is entirely impractical for browser features like ArrayBuffers, WebAssembly, etc. The rare SFI toolchains that don't impose this limit today (e.g., Wasm-64 toolchains [121]) lose efficiency and have impractically high performance overheads [126].
- **Support concurrent JIT code generation.** The SFI runtime must allow safe additions, removals, and modifications to sandbox code—even under concurrent execution by multiple threads[3]. This is necessary to support sandboxing of the JIT compilers used by JS engines.
- **Support binary validation.** While the JIT compiler itself is sandboxed, safely running code produced by it requires the SFI scheme to support binary validation [134]—to ensure that all SFI checks are present in the generated code. Binary validation has the added benefit of moving a buggy AOT SFI compiler [89, 99] out of the TCB.
- **Use the native ABI.** SFI tools such as NaCl [140] and Wasm [80] use sandbox-relative pointers (offsets) rather than native pointers—requiring translation between these representations at the sandbox boundary. While improving a sandbox's memory footprint [124], this significantly complicates retrofitting [104].
- **No reliance on hardware extensions.** While allowing efficient sandboxing [133, 137], browser users have a variety of different hardware and operating systems [4], without consistent support for such features.
- **No compiler "hard forks".** SFI compilers are often implemented as bespoke forks of GCC/clang [54, 123, 140]. This imposes a long-term maintenance burden and often means SFI tools are stuck as forks of outdated compiler versions.

We designed MH-LFI (building on the LFI [139] SFI compiler) to meet all these requirements—requirements that no existing SFI toolchain satisfies. MH-LFI's SFI scheme and supporting runtime are described in §5.1 and §5.2.

Even beyond these requirements, large applications like SpiderMonkey contain code patterns that add slowdowns not observed in standard benchmarks where SFI tools are tested. We describe several new optimizations that we needed to develop to address this in §5.3. Finally, we describe how MH-LFI can meet the above requirements when implemented as a simple assembly rewriter operating on the output of compilers (§5.4)—allowing Firefox to continue to support multiple compiler toolchains and frequently upgrade versions.

[3] Support for concurrent execution and generation/modification of code is needed as browsers' JS engines support threads via Web Workers.

Original code	Sandboxed equivalent (a "macroinstruction")

`addq %rdi, (%rax)`	`movq %rax, %r11`
	`andq %r15, %r11`
	`addq %rdi, (%r14, %r11)`

`movq %rdi, (%rax)`	`pext %r15, %rax, %r11` `movq %rdi, (%r14, %r11)`

`jmpq *%rdi`	`andq %r15, %rdi`
	`andq $0xfffffffffffffffe0, %rdi`
	`addq %r14, %rdi`
	`jmpq *%rdi`

Table 1: **Rewrites needed to conform to MH-LFI's data access and control-flow policies.** *Instructions on the left are rewritten into a* `macroinstruction`*—a collection of instructions that must all reside within the same bundle (to guarantee their execution as a unit). Note that the* `movq` *example preserves flags by using* `pext` *rather than* `and`*.*

MH-LFI allows us to sandbox SpiderMonkey's ahead-of-time code written in C/C++. We defer the discussion of adapting MH-LFI's scheme to SpiderMonkey's JITs to §6.

5.1 MH-LFI's SFI Scheme

MH-LFI's rewriter enforces a sandboxing scheme reminiscent of prior SFI tools (e.g., Native Client's x86-64 implementation [123]), but designed for sandboxes with large memory pools and augmented with additional optimizations (§5.3).

MH-LFI assumes that sandbox memories are contiguous, have a size that is a power of two, and are also aligned to the same power of 2. Within the sandbox memory, all pages are either non-writable for code or non-executable for data (enforced via `mmap` protections), with additional special handling for JITs (§6.2) which require writable *and* executable pages.

Like prior classic SFI schemes, MH-LFI comes with a binary validator that analyzes executable machine code to determine whether such code is guaranteed to maintain the sandbox's security guarantees. We now describe these requirements along with the associated rewrites that must be applied to compiler output to allow it to pass this validator.

MH-LFI's rewriter applies three security policies: the *data access policy*, which ensures that all memory writes are restricted to the sandbox region; the *control-flow policy*, which ensures that all control flow stays within the sandbox region (except to specific entry points in host code); and the *system-call policy*, which ensures that system-call instructions are rewritten to function calls in the trusted runtime. The rewriter uses three reserved registers—`r14` (sandbox base), `r15` (sandbox mask) and `r11` (scratch)—to enforce these policies, as illustrated by the examples in Table 1.

Data access policy. Memory writes are prefixed with guard instructions that (1) Compute the original effective destination address into the `scratch` register; (2) Mask out the top bits of the `scratch` register to restrict the address to a specified size—256 GiB for Mohabi; and (3) Add the 64-bit sandbox

base address to produce the final address that is used for the write. As Mohabi's sandbox memory is an aligned, contiguous allocation of 256 GiB (§5.2), this transformation guarantees that memory writes to the stack or heap are within the sandbox memory. MH-LFI optionally allows memory reads to be restricted in the same way, but this is unnecessary for Mohabi when site isolation [102, 119] is present.

Stack operations that operate directly on the stack pointer register, `%rsp` (e.g., push, pop, etc.) are handled by ensuring that the `%rsp` register always points to sandbox memory—for performance, this is enforced any time `%rsp` is updated [134] (rather than prior to each stack operation). As Mohabi's sandbox memory is surrounded by guard regions (§5.2)—unmapped memory pages—sequences of stack push/pops will fault if they go past the ends of sandbox memory.

Control-flow policy. To enforce that control transfers remain within the sandbox region, we use a similar mask sequence before indirect jumps. However, we must additionally enforce that indirect jumps do not target the middle of another instruction, as this may execute alternate instruction streams. To prevent this, we use bundling [97].

Bundling requires that individual instructions and macroinstructions (e.g., the sandbox-equivalent transformation of instructions shown in the second column of Table 1)—be contained within a single 32-byte bundle. If a (macro) instruction spans a bundle boundary, the rewriter injects padding using no-op (`NOP`) instructions to move the instruction into the next bundle. The rewriter ensures that the control-flow mask zeroes the bottom 5 bits of the control-flow targets prior to jumps—forcing all jumps to land on the start of bundles.

Return instructions (`ret`) are transformed to a `pop-mask-jump` sequence so that we can mask the address in a register—directly masking this on the stack would allow a concurrent thread to modify a return address after it has been guarded.

System-call policy. Allowing arbitrary system calls can allow sandboxed code to effectively break out of the sandbox [47]. Thus, similar to prior work, system calls are rewritten into function calls to a trusted runtime (§5.2) which checks if the system call can be safely permitted [84, 88, 122].

5.2 MH-LFI Runtime

MH-LFI also provides a runtime for Firefox to safely interact with the sandboxed SpiderMonkey instance. Such runtimes are a standard part of sandboxing toolchains [16, 84, 88, 96, 122, 123, 139, 140], so we only offer a brief description here. The MH-LFI runtime offers the following features.

The runtime provides binary (ELF) loaders and sandbox memory initialization routines that allocate a contiguous memory space, copy the binary code into this space, and initialize a new stack for the sandboxed code in order to support code execution in a sandboxed context.

The runtime provides *springboards* and *trampolines*—assembly routines that allow safe transitions into and out of sandboxed code. These routines switch the location of the program stack (sandboxed code requires stacks inside the sandbox memory), enforce caller/callee-save register expectations to preserve security [91], and set reserved registers (e.g., `r14` sandbox base) to expected values prior to transferring control-flow. MH-LFI's springboards and trampolines are standard and resemble those used in prior SFI tools [123, 140].

Finally, the runtime interposes on all system calls made by sandboxed code (with help from the rewriter (§5.1)), and permits only system calls that don't compromise the sandbox. These include the system calls used to manage executable code pages (§6.2)—to allow safe addition, removal and modification of JIT-compiled code within the sandbox.

5.3 Optimizing MH-LFI

In addition to implementing known SFI optimizations [105], we implemented several novel optimizations in MH-LFI. The first optimization is implemented in an LLVM pass, while the other two are implemented directly in the rewriter.

Prefix Padding. Bundles require inserting `NOP` instructions to prevent instructions from crossing bundle boundaries. Such `NOP`s may increase frontend stalls in the CPU pipeline. As a remedy, we replace `NOP`s by distributing their padding length across other non-`NOP` instructions within the bundle using x86 instruction prefixes [10]. We do this by adding one or more `cs` segment prefixes to instructions that immediately precede a `NOP` within the same bundle, limiting the total number of prefixes to 5, to avoid CPU decoding overheads.

Thread Local Storage (TLS) Operations. On Linux, TLS is supported using the `FS` segment base register. In the context of SFI, since the `FS` segment register is already used by the host, sandbox code must access TLS in a different way. Our original implementation of MH-LFI followed prior work, locating TLS using a call to the sandbox runtime—while reasonably performant for most domains, we found that this was extremely slow for browsers. We optimized these TLS operations by leveraging the observation from [105]—to make use of the unused `GS` segment register on x86-64.

Flags Preserving Masking. MH-LFI uses bitwise `and` instructions to ensure that memory accesses remain in the sandbox memory. However, the x86-64 `and` instruction modifies the processor flags; in cases where this is an issue for subsequent instructions, we use the `pext` instruction instead, which does not modify the flags. Since `pext` is slow compared to `and`, we only use it when the assembly rewriter determines that the flags must be preserved across the memory access.

5.4 Implementing MH-LFI

MH-LFI is implemented on top of LFI [139] and is a standalone assembly rewriter operating on the output of (mostly) standard clang/LLVM compilation with specific flags and a minor patch to clang/LLVM to support optimizations.

The rewriter. The rewriter consumes object files output by compilers and transforms the GNU assembly into the bundled macroinstructions described previously. These new object files can then be linked and used as normal. The rewriter relies on minor changes to the compiler that we discuss next.

Compiler patch. Since Firefox uses clang/LLVM as its compiler by default, we focus on this toolchain (although our approach also works with GCC). MH-LFI relies on three minor changes to the compiler, which we expose under a new compiler target (target triple `x86_64_mohabi-linux-musl`). First, MH-LFI's scheme utilizes guard instructions that require a `scratch` register for intermediate computations, a `base` register and a `mask` register (§5.1). Since we have to transform code after register allocation, we instruct the compiler to leave these registers unused during compilation. Second, we enable the use of instruction alignment directives—an off-by-default feature supported by LLVM—to align instructions into bundles. Third, we add an LLVM backend pass that optimizes assembly for our SFI scheme (§5.3). These changes account for only ≈ 600 lines in clang/LLVM. As a proof point of easy maintenance, we began the project in LLVM 19, but shifted to LLVM 22 partway, with less than 3 days of work.

Validating the SpiderMonkey binary. Similar to other SFI toolchains such as Native Client (NaCl) [140], MH-LFI includes a binary validator to ensure that all code within sandboxed binaries follows the control-flow and data-access policies specified in §5.1. Our validator, however, supports a large-sandbox model and uses a modern decoder (Fadec [55]) to enhance performance (making it faster than NaCl's validator (Table 3)). The verifier is written as a C program that checks all requirements of the SFI scheme, similar to prior work [89, 99, 140].

6 Sandboxing the JIT

SpiderMonkey uses a complex hierarchy of JIT compilers to speed up execution (§2). We need to modify these JITs so that the generated code is securely sandboxed. Concretely, this takes two steps: (1) modifying JIT compilers to generate MH-LFI-compliant code, and (2) using new secure APIs to manage modification of code pages—a unique challenge for JITs as this is very performance-sensitive code. We discuss this next followed by examples of easy-to-miss edge cases.

6.1 Modifying JIT Compilers

SpiderMonkey uses an abstraction layer called MacroAssembler (MASM) for all dynamically generated code. All of its JIT compilers emit code as sequences of MASM operations, each of which gets lowered to native code by an architecture-specific backend. We modify MASM's x86-64 backend to enforce MH-LFI's data access and control-flow SFI policies.

Implementing the SFI scheme. Like we did for AOT code, we reserve registers `r14` and `r15` for SFI by marking them as unallocatable in the MASM register allocator. We modify MASM operations that perform memory-access or indirect control-flow to emit the appropriate masked macroinstructions, and modify MASM's x86-64 instruction assembler to insert `NOP`s to prevent (macro) instructions from crossing bundle boundaries. Finally, we identify all valid indirect targets in the code emitted by each of the JIT compilers and ensure that they are bundle aligned. A difference compared to the AOT case is that we don't reserve `r11` since SpiderMonkey's JITs used this as an internal scratch register; we opted instead to share the scratch register (for JIT and SFI) to reduce the register pressure on this code.

Disentangling JIT-compiled Code and Data. As an optimization, JITs emit data such as floating point constants and relocation tables—used to trace and update references to garbage collected data in the JIT-compiled code—in executable memory. Unfortunately, this results in JIT-compiled code containing code-gadgets (random constants that are interpreted as instructions) that violate the SFI scheme. To prevent this, we modify MASM to emit constants in 32-byte bundles where constants are placed in bytes 1 to 31, and byte 0 is fixed as the byte for an x86 `HLT` instruction, meaning any attempt to jump here would fault. Where possible, we also used a more direct approach of moving data outside code sections.

6.2 Managing JIT Code Pages

The sandboxed JIT compiler must update executable code pages to both add new JIT code and modify existing JIT code (for instance, to perform bailouts (§2)). However, this is a major performance challenge for an SFI tool, because the safe way to update code pages in a multi-threaded environment is a prohibitively slow three-step process: (1) the code page must be made read-write and the JIT compiler modifies the part of the code page it wants, (2) the code page must be made read-only and the validator must check the *entire* code page as any part of the previously writable page could have been tampered with by a concurrent thread, and (3) the code page must be made read-exec after the validator has finished. Any deviation from this recipe would introduce opportunities for a malicious concurrent thread to execute unvalidated code or tamper with code page contents to remove SFI checks.

Our solution: Dual Mapping. To avoid the overheads of having to reverify entire code pages any time code is updated, Mohabi uses an alternate approach called Dual Mapping. Here, MH-LFI's runtime uses its system-call interposition (§5.2) to support writing to sandboxed code pages in two steps: First, when an executable page is made writable, the runtime creates a shadow virtual page with read-write permissions to the same underlying physical page outside the sandbox. Second, MH-LFI offers a trusted-runtime call to safely and efficiently perform updates to this shadow mapping. This trusted call

takes the following steps: (1) it makes the code page mapped in the sandbox read-only, (2) it updates the externally mapped writable page with the new code and validates *only the new code*, (3) it restores the code page in the sandbox to executable. This approach is much faster as it reduces page permission updates from 3 to 2, and requires only validating new code. The latter optimization makes a huge difference in practice—safe code updates went from doubling our overheads to adding negligible overheads in our evaluations. While dual-mapping with multiple processes was explored by prior work [128] and prior production browsers [56], we see that MH-LFI's in-process isolation makes this much more practical.

6.3 Why Validating SFI Code Matters

Using a binary validator, beyond being necessary for secure JIT compilation, also helped uncover cases of missed SFI checks in the JIT in early prototypes. We discuss this below.

Case study 1: Zero-padding code pages. Wasm and JavaScript JIT compilers do not always fill the entirety of allocated executable memory with code. The unused space at the end of an allocation is filled with the byte `0x00`, which decodes to the `addb %al,(%rax)` instruction, violating the memory isolation properties of MH-LFI. Upon discovery, we modified the trusted-runtime call used to manage JIT code pages (§6.2) to instead pad inserted code with the `0xcc` byte—a safe interrupt instruction on x86.

Case study 2: Missing Indirect Jump Masks. We modified MASM to mask the target of all indirect jumps. However, in certain instances, the JIT compiler directly uses the low-level assembler to emit indirect jump instructions, which are unmasked and therefore insecure. The validator found these errors, allowing us to fix this.

Case study 3: Clobbering of Reserved Registers. The Wasm compiler generates code that may trigger traps as a form of error handling. To support recovery from the trap, Wasm saves any register it uses when the trap occurs and restores it upon resuming. However, since Wasm code is not trusted, it should not be permitted to restore reserved registers like the sandbox base `r14`. The validator flagged these errors, and we made changes to ensure that these registers were never modified.

7 Evaluation

In this section, we evaluate Mohabi's performance and security. Mohabi's performance is evaluated on a machine with an Intel Raptor Lake i9-13900K, 32 GiB RAM, Ubuntu 24.04 on Linux 6.14.0. For browser and JS benchmarks, we use Firefox ESR-115 (with and without Mohabi) pinned to two isolated CPU cores whose frequency is fixed at 2.2 GHz with hyper-threading disabled. SPEC benchmarks run isolated on one CPU core fixed at 2.2 GHz with hyper-threading disabled.

Benchmark	Firefox	Mohabi
JetStream 2.2	86.27 ± 0.71	64.86 ± 1.10 (24.82%)
Speedometer 3.1	6.81 ± 0.06	5.14 ± 0.03 (24.43%)

Table 2: **Comparison of Firefox and Mohabi scores on the JetStream 2.2 and Speedometer 3.1 benchmarks.** *Results characterize the median score across 15 runs of vanilla Firefox and Firefox with Mohabi on each benchmark. For both benchmarks, a higher score is better.*

7.1 Performance of Mohabi

We evaluated Mohabi on the industry-standard browser benchmark, Speedometer 3.1 [11]. Speedometer measures end-to-end browser performance using simulated user interactions with web applications—modeling real-world web use.

While our focus is on full-browser performance, prior academic work [26, 106, 107] only sandboxed standalone JS engines and thus relied on JavaScript and Wasm benchmark suites like JetStream 2.2 [9]. We also evaluate this to enable a more direct comparison with prior work.

Finally, we isolate the cost of each element of the sandbox: memory masks, instruction bundling, forward-edge control-flow checks, backward-edge control-flow checks, system call mediation, trampolines and springboards. As a reference point, we also show the browser performance when disabling the JIT—to estimate overheads of the hardened no-JIT modes as used in Edge, Safari, and Chrome.

Results. Mohabi's Speedometer and JetStream results are shown in Table 2. We see total overheads of 24.43% and 24.82% respectively. While not negligible, these are extremely modest compared to partial security wins of disabling the JIT altogether. Mohabi also imposed no noticeable slowdown in routine use on sites like YouTube and Reddit.

While a full apples-to-apples comparison with prior work is impossible as JS engines and benchmark suites differ and continually evolve, we nevertheless look at the rough trends (Figure 8). Compared to prior work, Mohabi is not as expensive as previous attempts at a fully sandboxed JavaScript engine, e.g., NaClJIT [26], but more expensive than unsound SFI mitigations used by production browsers like Ubercage [70].

We show the performance overheads of the individual components of Mohabi in Figure 5. Broadly, backward-edge control-flow checks are the dominant source of overhead. Other costs are smaller, but they still add up. However, as noted by prior work [26], the costs of the individual components do not add up linearly, as each component has an impact on others when enabled together.

7.2 Performance of MH-LFI

To evaluate MH-LFI, we compare its performance with the Native Client (NaCl) SFI toolchain [123]. We chose this for two reasons. First, this was the toolchain used by Na-

Fwd-CFI	Bwd-CFI	Bundles	Store-Masks	Syscalls	Mohabi	No-JIT
6%	13%	5%	6%	3%	24%	53%

Figure 5: **Mohabi decrease in Speedometer score by SFI component.** *We observe that each security check from SFI adds some overheads, with the largest overheads coming from backward-edge control-flow protections. For reference, we also show the overheads of disabling JS JITs.*

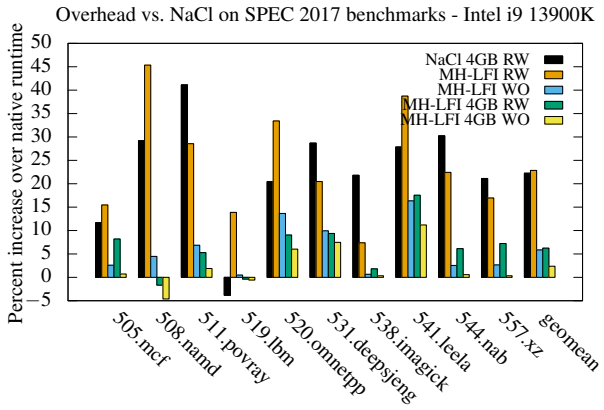

Figure 6: **SFI overheads on SPEC 2017 benchmarks that are compatible with NaCl.** *We observe that MH-LFI* 4 GiB *outperforms NaCl (6.6% vs. 22.3%) on the compatible sandbox configuration.*

ClJIT [26]—the closest prior work to this paper. Second, despite newer standards for sandboxing such as WebAssembly [80], prior work has shown that these toolchains incur significant overheads [87, 104] (in part, because they use a simple platform-agnostic intermediate representation). NaCl still remains the fastest x86-64 SFI baseline available today.

To ensure a fair comparison, we run MH-LFI both as used by Firefox, but also in a configuration that matches NaCl—a 4 GiB sandbox that guards read and write operations. NaCl does not support larger sandboxes and no longer supports write-only sandboxes. Since MH-LFI and NaCl are built on different baseline compiler versions (clang 22 and clang 3.7.0 respectively), we measure overheads normalized with respect to their own baseline clang versions for fairness and report these on the subset of SPEC 2017 that NaCl supports.

Beyond this, we report the benefit of Mohabi's optimizations (§5.3), the speed of Mohabi's validator, and overheads of Mohabi on the full SPEC 2017 benchmark in the Appendix.

Results. Figure 6 shows overheads on SPEC 2017. Comparing 4 GiB sandboxes, we see that MH-LFI imposes 6.6% overhead vs NaCl's 22.3%. For a large-memory, write-only sandboxing as we use in Mohabi, we see 5.9% overhead. The Appendix shows that Mohabi optimizations were able to speed up Mohabi by 6%–8% (Figure 9) and Mohabi's validator outperforms NaCl's validator (Table 3).

7.3 Security Analysis of Mohabi

Ideally, the security of systems like Mohabi can only be evaluated with extended production use. As a basic assessment, we discuss how Mohabi blocks common JS engine exploit techniques, give examples of mitigatable JS engine bugs discovered after its implementation, and finally discuss its TCB.

Common JS attack techniques. We discuss how Mohabi blocks common JS attack techniques used in exploits—both in-the-wild and in competitions like Pwn2Own.

Code pointer hijacking: Exploits can corrupt control flow by attacking code-pointers on the forward edge [115] or the backward edge [48]. MH-LFI's CFI scheme ensures that jump and return targets remain within the sandboxed region, and that they are bundle-aligned, as described in §5.1. MH-LFI is also not vulnerable to control-flow bending [43]-style attacks, as it does not rely on a fine-grained CFI to provide guarantees.

Overwriting Executable Memory: Some exploits take advantage of the fact that not all browsers implement *Write Xor Execute* for JIT executable memory [41, 69]. Mohabi prevents this by construction with the dual-mapping scheme (§6.2).

JIT spray attacks: Exploits may try to fill code pages with shellcode/gadgets by either leveraging existing JITted code or by crafting code that uses floating point constants that encode gadgets [115, 120]. The MH-LFI validator prevents such attacks by making sure that JITted code cannot contain gadgets that bypass SFI guarantees.

Corruption through concurrent threads: Exploits may leverage the presence of JS engine threads (in the form of Web Workers [7]), to use one thread to overwrite code in the JIT compilation buffer of another thread [77, 78]. MH-LFI prevents this by ensuring that the runtime always checks compiled code using the binary validator before it is copied into an executable page. TOCTOU issues with validation are prevented through the dual mapping scheme (§6.2).

Unsafe syscalls: Exploits may invoke syscalls as part of a privilege escalation [42, 49, 129]. The MH-LFI runtime prevents this as it intercepts all syscalls from within the sandbox, and allows only a safe subset of syscalls with checked parameters.

Evaluating new JS bugs. In April 2026 (after Mohabi's prototype was complete), Firefox shipped their largest batch of security fixes in monthly updates [65], to fix bugs discovered through Anthropic's Mythos LLM including several bugs in the SpiderMonkey JS engine [81]. We examined a few of these bugs and saw cases of memory corruption in the JIT compiler [21], GC [24], inline caches [22], and the JS runtime [23]. Mohabi would mitigate all these bugs by confining the memory corruption to within the sandbox's memory. Attacks leveraging these bugs would only be possible via confused-deputy attacks on missing boundary checks (consistent with the threat model of Mohabi).

TCB. The unsandboxed SpiderMonkey engine contains ≈ 784,000 lines of code (≈ 50% from the JIT compiler and

Wasm runtime)—all of which are a part of its TCB; further, any JITted code emitted at runtime is also part of the TCB. In contrast, Mohabi has a relatively small TCB consisting of the MH-LFI runtime, MH-LFI validator and data sanitizers at the sandbox boundary. The MH-LFI runtime is implemented in 6,200 lines of C. The MH-LFI validator relies on the Fadec [55] x86 decoder which uses a 1,894 line x86-64 instruction encoding lookup table generated at build time and 1,276 lines of C. The validator itself consists of 991 lines of C. SFI runtimes and validators have been shown to be formally verifiable by prior work [88, 89, 99], and could enable further TCB reduction. Our data sanitization layer only implements a limited set of boundary checks at this time and does not cover the full JSAPI interface; it currently consists of 650 lines of C++ definitions for various wrapper types and 80 lines of C++ to maintain the DOM reflector table.

7.4 Comparison with Ubercage

We contrast Mohabi with Ubercage. Although Ubercage is only a partial sandbox, it is still the most significant deployment of SFI techniques for JS engines currently in use.

Ubercage Design. Ubercage takes a fundamentally different approach to sandboxing vs. Mohabi. Rather than choosing a sandbox boundary and performing disaggregation all at once, it is building one incrementally and at a different layer than Mohabi—between the JS heap (and by extension, the Wasm heap), and the rest of the JS engine. While this has greatly simplified its deployment as performance overhead is very low ($\approx$ 1% [71]), its security guarantees are weaker.

Ubercage works by requiring JITted code to include SFI-style masks to restrict memory operations to a 1 TiB sandbox[4], using a code-pointer table to restrict forward-edge control flow to safe locations, and an external-pointer table to secure access to sensitive data outside the sandbox. Any AOT-compiled JS runtime code relies on a type system to prevent confused deputy attacks, with different types used to access sandboxed pointers, code-pointer tables, and external-pointer tables. However, Ubercage being a partial SFI scheme, does not protect data on the stack (including return addresses), and does not employ a binary validator, which is critical given the size of its TCB as discussed below. Ubercage treats the JS engine's AOT code (the GC, the JIT compiler, etc.), as well as JIT-compiled code, as trusted and within its TCB.

Ubercage has proposals to address some of this—a binary validator [75] (similar to Mohabi's) that ensures JIT-compiled code can never violate sandboxing guarantees, and prototypes for hardware-based isolation schemes (for hardware that supports it) to eliminate sandbox bypasses [72]. Like Mohabi, Ubercage must also apply sanitization checks to data originating from the sandbox; for Ubercage, this is any data from the JS heap. Importantly, given the size and complexity of Ubercage's chosen boundary, we believe that it is much more challenging to manually secure in comparison to the boundary chosen by Mohabi (which can leverage the auto-generated nature of DOM-JS glue code §4.3).

Ubercage Bypasses. Ubercage's phased rollout over multiple years has resulted in over 150 bugs to date [13], originating from both rigorous testing [34, 74] and real-world attacks [92]. While the number of such bugs has trended down as development progressed and bug-bounty programs helped identify missed checks, bugs still arise as a direct consequence of Ubercage's current design and choice of complex sandbox boundary. We highlight some of these bugs[5] in Figure 7 according to the JS engine component that was targeted, and contrast this with how such bugs would be mitigated by Mohabi. We analyze a few of these in detail below.

Case study 1: Bug 350292240 [93]. This is a vulnerability in Wasm function signature validation, caused by attackers being able to corrupt type metadata located in the sandbox. Wasm type signatures rely on runtime type checks to guarantee correctness, but these checks operate on sandboxed data, making them vulnerable to corruption. Unlike Mohabi, Ubercage considers the JIT compiler trusted, meaning that it must validate data coming from the untrusted JS heap. Ubercage misses a sanitization check here, allowing an attacker to generate buggy JIT code that accesses memory outside the sandbox.

Case study 2: Bug 338381304 [109]. This bug displays how attackers can corrupt the number of expected parameters in a JS function's stack frame, resulting in a miscomputation of stack size, and subsequent improper stack access. The bug is a result of Ubercage storing a trusted field for parameter count on the sandboxed heap, and not sanitizing it on use. This field is referenced when attempting to de-optimize a JIT-compiled function, to read the number of stack parameters it uses. When this value is corrupted, the stack frame is shrunk by the wrong size, and subsequent accesses use unintended values, causing type confusion. In contrast, Mohabi's design means that the entire C++ runtime is untrusted, ensuring that such mistakes are constrained to within the sandbox.

Case study 3: Bug 462217236 [116]. This bug describes how attackers can induce a use-after-free in the host as V8's GC relies on in-sandbox data to determine liveness of an object outside the sandbox. Specifically, the trusted JS runtime creates an object called a dispatch entry as part of the trusted stack-unwinding support for (`asm.js`) exceptions. In some execution paths, the only strong reference to the dispatch entry is from an object inside the sandbox. If the untrusted JS code uses in-sandbox memory corruption to remove the reference to this dispatch entry, the dispatch entry can get cleaned up by the GC. In this scenario, any subsequent exceptions thrown by JS code would be handled by the trusted runtime and use

[4] In practice, Ubercage uses a nested 4 GiB sandbox within a 1 TiB region for JavaScript objects, but this does not change its security guarantees.

[5] Note that we deliberately exclude bugs that emerged due to Ubercage's phased rollout over multiple years (i.e., bugs targeting unimplemented parts of Ubercage), and focus on bugs that arose due to Ubercage's design.

	Ubercage	Mohabi
JIT Compiler	Ubercage places V8's JIT compilers outside the sandbox, and the JITs are trusted to generate correctly sandboxed code. Multiple bugs were caused by the JIT missing masks for stores [92, 94] or missing sanitization checks on input coming from the sandbox [93].	Mohabi sandboxes SpiderMonkey's JIT compilers and any code generated/modified by JITs is checked by the binary validator prior to receiving executable page permissions (§6.3).
JS Runtime	Ubercage places V8's JS interpreter and runtime outside the sandbox. Multiple bugs [95, 109, 131, 132] have been found in these components due to missing sanitization checks on input coming from the sandbox.	Mohabi sandboxes SpiderMonkey's C++ runtime, checks it using the binary validator during sandbox instantiation (§5.4).
Garbage Collector (GC)	Ubercage places V8 GC outside the Ubercage sandbox boundary. Multiple use-after-free (UAF) vulnerabilities [116–118] were caused by the GC relying on untrusted sandbox data to determine liveness, resulting in premature memory reclamation.	Mohabi places SpiderMonkey's GC primarily inside the Mohabi sandbox. However, a portion of the GC responsible for reclaiming cyclic references [31] across the JS engine and DOM is outside the sandbox boundary. Mohabi utilizes split-allocation types (§4.2) to harden these interactions; sanitizing all data flow across this boundary is left for future work.
JS-DOM Boundary	Ubercage's sandbox boundary is fundamentally internal to the JS engine, and does not expose a security surface to the DOM, *assuming* the internal sandbox boundary does not have bugs.	Mohabi's design places the sandbox boundary outside the JS engine, allowing it to use the auto-generated glue layer between the DOM and JS engine to insert sanitization checks as shown in the example with DOM reflectors (§4.3). Mohabi's hypothesis is that this is a more securable and maintainable boundary for a JS engine sandbox, given the smaller attack surface.

Figure 7: **Comparison of the Ubercage and Mohabi sandbox boundaries.** *Ubercage's sandbox contains only the JavaScript heap-data memory region leaving the V8 JIT compilers, JavaScript runtime, and GC as trusted code outside the sandbox. In contrast, Mohabi places the entire SpiderMonkey engine in the sandbox. To guarantee security, both Ubercage and Mohabi must sanitize untrusted data crossing their respective sandbox boundaries. However, Mohabi presents a smaller attack surface, which we illustrate using examples of past Ubercage sandbox bypasses at the boundary of each component.*

the stale dispatch entry pointer from the stack. This UaF can result in an attacker obtaining control over the stack pointer.

8 Discussion and Future Work

Securing the JS Engine boundary. An important next step for Mohabi is to build a system that can check that all required boundary security checks have been added. While Mohabi illustrates how to secure this boundary with case studies such as the DOM reflector objects (§4.3), building and guaranteeing full coverage remains an open challenge. This is because the boundary between the browser and JS engine was not originally engineered with JS engine isolation in mind—it exposes low-level interfaces and makes pervasive use of shared data structures that are implicitly trusted by the browser. While we believe this next step is tractable (e.g., by automatically generating sanitizations in the glue layer), redesigning this boundary to be narrower can greatly simplify this task.

Taking Mohabi beyond x86-64. We focus on x86-64 in this paper as it dominates Firefox deployments on desktop devices [4]. However, RISC architectures such as ARM64 and RISC-V have gained usage on other platforms. Prior work [139] has shown that RISC ISAs lend themselves to efficient SFI schemes due to the availability of more general purpose registers and a fixed-length instruction encoding. However, as in the case of x86-64, prior SFI tools have mostly targeted 4 GiB sandboxes for ahead-of-time compiled code.

Optimizing SFI with Hardware Features. Modern CPUs provide hardware extensions [28, 29, 85, 86] for control-flow integrity and memory isolation that can be used by SFI schemes to reduce overheads [44, 133]. However, limited hardware availability and inconsistent operating system support make it impractical to rely entirely on these features alone. Systems that use JIT compilation, such as JS engines, can—in principle—partially overcome this by dynamically using the available hardware support for just-in-time code, while relying on software enforcement for ahead-of-time code.

9 Related Work

Prior work [26, 57, 70, 106, 107] has tried to secure JS engines with SFI. We analyze these attempts on two aspects: (1) *Full browser support*—does the design handle the complexities of integration with JS engines in production browsers? (2) *SFI completeness*—is the SFI scheme sound and does it come with a binary validator to minimize the TCB? We summarize our findings in Figure 8 and give more details in Figure 10 in the Appendix.

Broadly, academic work has made good progress on adapting sandboxing tools for JS engines; however, these cannot be applied to production browsers as they do not address the challenges discussed in §1. Industry efforts, in contrast, have optimized overhead by selectively applying some SFI techniques; however, being partial schemes, they are frequently bypassed. Thus, the challenge of a full sandbox for JS engines in a production-scale browser has not been tackled yet.

NaClJIT. NaClJIT [26] first demonstrated sandboxing JS engines by sandboxing the V8 engine. They compiled V8's runtime code using the Native Client (NaCl) SFI compiler [123, 140] and modified the V8 JavaScript JIT to only emit code that followed NaCl's SFI rules, along with an SFI validator to ensure that no checks were missing. While NaClJIT demonstrated the changes needed in SFI compilers to support sandboxing JIT engines, they found that their approach had high overheads of 51%–60% due to (1) the added

	NaClJIT [26]	RockJIT [106]	Ubercage [70]	JITCage [37]	Mohabi
Full browser support	No (Shell/JS engine)	No (Shell/JS engine)	Yes	Yes	Yes
Completeness of SFI scheme (with validator)	Yes	Yes	Partial guarantees (ad-hoc checks, bytecode validator, future binary validator [75])	No	Yes
Performance overhead[a]	51% (V8 bench, Sunspider)	14% (Octane2)	1% (JetStream, Speedometer)	Not reported	24.82% (JetStream), 24.43% (Speedometer)

[a]Different browsers, versions, benchmarks (Sunspider, JetStream, V8) used. This column is included only so readers can get a rough idea.

Figure 8: **Prior efforts to sandbox JavaScript engines.** *Academic efforts have focused on sandboxing JavaScript engines in shells/standalone JavaScript engines. Efforts from the industry, in production browsers, have focused on partial security mitigations. Mohabi, to our knowledge, is the first effort that overcomes all of these downsides.*

SFI runtime checks, (2) the longer compilation times of JITs that enforce SFI, and (3) time needed to run the SFI validator.

RockJIT. RockJIT [106] enforced a different security invariant—fine-grained control-flow integrity in the V8 JS engine. However, their approach required ensuring *memory write*s from the JS engine did not corrupt the data structures maintaining valid CFI targets. They also included a binary validator for this. The resulting system only imposed a 14% overhead on JavaScript engine performance. However, RockJIT (like NaClJIT) operated on the pre-2015 (i.e., single JIT), standalone V8 JS engine rather than in a browser, and thus did not have to address support for complex tiering or disaggregation. It also imposed a 4 GiB memory limit, making it inapplicable to present-day browsers.

Ubercage. In 2021, Chrome implemented partial SFI-style restrictions in Chrome's V8 JavaScript engine in the Ubercage [70] project. It represents the largest use of these techniques in a production JS engine today. We contrast Mohabi and Ubercage in detail in §7.4. Ubercage continues to evolve, and includes plans to leverage hardware support [64] (e.g., Intel MPK) to provide more robust security (as guaranteed by Mohabi using SFI) and incorporate a binary validator to check correctness [75] (similar to Mohabi). However, it is not clear that this incremental approach to adopting SFI will ultimately result in sandboxes that cannot be bypassed (§7.4).

JITCage. Safari's JavaScriptCore (JSC) employs a few SFI-style restrictions to stop specific attacks that leverage type confusions [69]. For example, attackers try to forge fake pointers to ArrayBuffers in JavaScript as it allows them to access large regions of memory. JSC combats this by placing some sensitive objects like ArrayBuffers in dedicated memory regions called Gigacages [57], with guarded memory accesses to these regions. JSC also relies on hardware features like SPRR [110, 125] to enforce *Write Xor Execute* protections, and Pointer Authentication Codes (PAC) [30] and recently Memory Tagging [114] for best-effort [36, 68] control-flow and memory-safety protections. However, these mitigations are partial, not directly attempting to constrain the effects of vulnerabilities. Attackers have been able to show that Safari's protections are all bypassable [90, 130] in multiple real-world exploit chains. [37, 38] offer more details on these mitigations.

Other hardening approaches. Formal verification has been used to prove the correctness of specific JS JIT optimizations [40, 127], or used to build (simpler) verified JS JITs [32, 33, 79, 103]—however more work is needed to scale these techniques to production browsers. NoJITSu [107] separates data types in JS engines into a handful of pools for which write-permissions can be selectively enabled as needed (leveraging Intel MPK for efficiency). Similar to Gigacage, V8 uses the hardened PartitionAlloc [46] to isolate sensitive objects such as ArrayBuffers [61]. JSC also previously used a best-effort [67, 136] StructureID randomization to prevent attackers from being able to forge fake objects in the heap. JS engines have historically used *Write Xor Execute* memory for some code-overwrite protections [50]; however, browsers have started to remove these for performance [51] and are opting to instead use hardware features such as SPRR and MPK where available [59, 60, 111]. JS engines may also implement constant blinding [112] to mitigate JIT spray attacks.

10 Conclusion

Browser vendors today are scrambling to fix the firehose of bugs found in JavaScript engines including those recently found by LLMs like Anthropic's Mythos. What's clear from this chaos is that modern JavaScript engines are notoriously complex systems that, while fast, are a seemingly inexhaustible source of memory-safety vulnerabilities. This is not fundamental though: Mohabi shows that browsers can isolate JavaScript engines using in-process sandboxing with modest performance overhead to eliminate the large JavaScript engine security surface that browsers are exposed to today.

Acknowledgments. We thank the reviewers for their insightful feedback, Samuel Groß for feedback on the Ubercage section of this work. Appendix

We include some additional performance and security evaluations beyond what is in the paper below.

We report the speed of Mohabi's validator in Table 3, the benefit of Mohabi's optimizations and overheads of Mohabi on the full SPEC 2017 benchmark in Figure 9—the body of the paper only reports performance on the NaCl supported subset of benchmarks (§7.2).

Results. Broadly, we see that Mohabi's validator outperforms NaCl's validator. While this is in part due to careful optimizations we included, we attribute this speedup primarily because we rely on a modern high-performance x86-64 decoder [55]. We also see that Mohabi optimizations were able to speed up Mohabi by 6%–8%.

Benchmark	MH-LFI 4 GiB	MH-LFI Large	NaCl
deepsjeng_r	126.70	100.70	82.77
imagick_r	148.61	119.08	95.08
lbm_r	118.93	98.32	79.26
leela_r	147.03	122.81	86.07
mcf_r	112.05	90.50	72.78
nab_r	123.70	98.93	83.29
namd_r	154.33	127.79	89.38
omnetpp_r	167.81	145.00	101.57
parest_r	161.15	130.44	95.50
povray_r	157.40	133.75	83.07
xz_r	126.37	106.35	78.10
Average	140.37	115.79	86.08

Table 3: Validator throughput comparison (MiB/s)

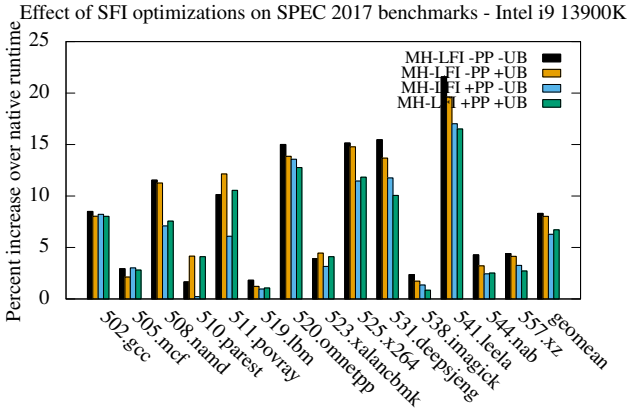

Figure 9: Breakdown of benefits from SFI optimizations. PP is prefix padding and UB is unaligned branches. Unaligned branches are primarily a binary size optimization as they have little-to-no positive effect for runtime performance.

We also provide a more detailed comparison of prior work and existing industry efforts to secure JS engines using SFI-style techniques in Figure 10.

	NaClJIT [26]	RockJIT [106]	NoJITsu [107]	Ubercage [70]	JITCage (Gigacage + PAC + SPRR) [37]	Mohabi
Isolates	pre-2015 V8 JS engine	pre-2015 V8 JS engine	SpiderMonkey JIT-compiled code	V8 JS engine	JSC JS engine	SpiderMonkey JS engine
Runs in full browser	N (Shell/JS engine)	N (Shell/JS engine)	N (Shell/JS engine)	Y	Y	Y

Abstract

Tracing memory objects (*who* accessed[1] *what* object and *when*) is often important for understanding the runtime behavior of modern software. This type of rich per-access metadata can aid in debugging, tracing, forensics and other tasks. Collecting this information is non-trivial since it will be either be incomplete or requires heavy instrumentation and/or hardware support and likely adds significant runtime overheads (*e.g.,* Intel Pin or Valgrind slow programs down by $10-100x$).

We present `Ichnaea`[2], a purpose-built, precise and complete framework based on memory protection keys (MPK) that delivers context-rich object events at *very low cost* to the application. `Ichnaea` is dormant until one of the objects of interest (ObjOfInterest) is read or written to — at which point it logs any access attempts and changes to the ObjOfInterest along with rich context information ("*who is attempting access?*", "*what changes, if any, are being applied?*") before returning control to the application. In general `Ichnaea` reduces the tracing overheads by $10-60x$ when compared to the widely used framework Intel Pin , while still capturing *precise*, per-access information needed to diagnose memory vulnerabilities, performance hot-spots and subtle concurrency errors.

1 Introduction

> "*Every move you make, every bond you break, every step you take, I'll be watching you.*"
> — Police, Every Breath You Take (1983).

Modern software written in low-level languages (*e.g.,* C/C++) continues to grow in both size and complexity while relying on manual memory management, exposing raw pointers and permitting (unrestricted) indirect control flow. For instance, `nginx` [41], a widely deployed web server application written in C now exceeds 160 KLoC[3]. As codebases expand, maintenance becomes increasingly difficult, particularly when reasoning about subtle control-flow anomalies and memory-safety violations that stem from unintended or rogue *object accesses* [1]. Often control flow is not expressed explicitly but is data-driven — function pointers, callback tables and state-carrying objects determine which code runs next (*e.g.,* `nginx`, `postgresql` [44], *etc.*). For example `ngx_http_request_t` is a central, state-carrying object that guides request control-flow across nginx's event-driven phase pipeline. Tracing *accesses* to such objects can be quite challenging as they are hard to find due to the large number of *control and data-flow indirections*. These issues are especially exacerbated in multi-threaded codebases where in order to understand parallel object access patterns, one is either forced to serialize applications [28] or deal with incomplete information [15]. It is difficult to make headway in any of the above without tracing critical data or control flow objects with high degrees of indirection — all of which requires the ability to track *pointers*, including *function pointers* and *who (*`function`, `thread_id`, `user_id` *) is reading from/writing to them* and *when*.

Hence, there is a need for more *precise tracing* of object accesses (*e.g.,* reads/writes) in memory. Existing approaches for object tracing fall into two broad classes: *(a)* static and *(b)* dynamic analysis. Static techniques, *e.g.,* symbolic execution [6, 23] or compile-time instrumentation [10] struggle in practice, especially for large codebases. Symbolic execution suffers from path explosion (*e.g.,* [24, 25]), while precise compile-time instrumentation [38] struggles with undecidable problems like the difficulty in statically locating all access sites, especially under pointer aliasing and indirect control flow (see section 2.1.1). Figure 1 depicts a simple program where memory accesses can either be missed or over-approximated by a static analyzer — the object, `GLOBAL`, is accessed via complex control flows (function pointers based on user input) and data indirection (pointer to dynamically allocated object, passed as function argument). Such patterns

[1] Read or write
[2] "Ichnaea" is the Greek Goddess of tracing and tracking
[3] Measured using *cloc* [2] on `nginx` [35] commit 6ed1188.

```
int GLOBAL; % ObjectOfInterest

typedef void (*func_ptr)(struct ctrl);
func_ptr funcArr[] = { &foo, &bar, ... };

int main(int argc, char **argv) {
    struct ctrl A { int * reference , ... };
    A.reference = &GLOBAL;
    int idx = atoi(argv[1]);
    funcArr[idx](A);
}
```

```
void foo(struct ctrl prm) {
    printf("%d\n", *(prm.reference));
    ...
}

void bar(struct ctrl prm) {
    *(prm.reference) = 10;
    ...
}
```

Figure 1: An example of object access through indirect control flow manipulation. Such access are hard to find statically *e.g.,* knowing that the object `GLOBAL` is written to by the function `bar()`

are common in software, often leading to subtle memory-safety violations, *e.g.,* CVE-2021-23017 [1], where a single out-of-bounds write in the request resolver (triggered through intricate pointer arithmetic) corrupted a heap object and enabled denial-of-service (DOS) and remote code-execution (RCE) attacks. Such off-by-one errors, especially when memory (*e.g.,* object reference) is shared across multiple components in a multi-threaded program, remain pervasive and are notoriously difficult to detect using conventional debugging or static analysis techniques.

Dynamic techniques can avoid many of these issues since the information about the actual object/function is available at access time. These methods often introduce high overheads as they usually involve tracking almost *all loads/stores* using *(i)* compile-time instrumentation [19] or *(ii)* runtime instrumentation (*e.g.,* Pin [30], DynamoRIO [8]) — all of which slow down execution by 10–100×, making them unsuitable for long-running applications, test-suites, benchmarks or even for fuzzing-type methods [39]. Tracking accesses via the backing memory (*e.g.,* hardware debug registers [18] or virtual-memory mechanisms [28]) reduces overheads but is fundamentally constrained as such techniques either support only a small number of objects or suffer from false sharing [45], causing missed accesses in multi-threaded environments (see section 2) thus making the approach *lossy*.

Hence, current dynamic approaches are either prohibitively slow or fundamentally lossy, making them unsuitable in practice. More importantly, none provide **precise** (tracing singular objects instead of blocks of memory or all loads/stores), **complete**[4] (tracing accesses from application, external libraries and the kernel) and **lossless** (logging all accesses without misses) tracing of memory objects in one package. We found no tool that meets all the above requirements in one package.

We present `Ichnaea`, a tracing framework that uses the virtual-memory mechanism along with Memory Protection Keys [43] (MPKs) for *precise*, *lossless* and *complete* memory object tracing of programs written in low-level, manually managed languages such as C/C++ using compile-time annotations. While using compile-time annotations might reduce the scope of use since most binaries don't contain enough debug information to be used in order to generate high quality traces, we believe that such annotations are a reasonable requirement since most analyses that require precise tracing also require source code. `Ichnaea` works by first disabling access to the page that holds our 'Object of Interest' (ObjOfInterest) using virtual page protection. This means that any access to the object triggers a page fault. A pagefault handler routine is then used to *(i)* first allow the access *(ii)* log the "access context" and *(iii)* lock the object back again so that future accesses can still be caught — hence "tracing" the object. With traditional `mprotect` based page protection (*e.g.,* used by `Dthreads` [28]), changing the page access permissions is too slow (2µs+) and global (*for all threads*) leading to significant slowdowns and false sharing problems. In `Ichnaea` we use MPKs, to change the access permission of pages, which is very fast (50ns) and local to the thread (see section 2.2). This enables us to *precisely* and *efficiently* track when an object is accessed (*i.e.,* read from or written to) even in multi-threaded programs while completely alleviating the aforementioned sources of loss. `Ichnaea` *significantly reduces tracing overheads* — for instance, $10-60x$ reduction in overheads for SPECInt [40] workloads compared with SoTA tools like Intel Pin (see section 5.3). We can also *attribute accesses to their origins* and even provide *accurate timestamp information* — that can then be examined offline for further forensic analyses and debugging of complex (multi-threaded) programs .

Hence, our main contributions are:

1. **A *precise* and *lossless* object-tracing model** [Section 2.1]. We identify fundamental sources of loss in practical dynamic analysis techniques — *viz.,* coarse access-control granularity, global page permissions, syscall windows, atomic writes and false sharing. We then formalize requirements for complete object-level read/write tracing in both, single and multi-threaded C/C++ programs.
2. **`Ichnaea`: A new MPK-based tracing framework** [Section 3]. To the best of our knowledge, `Ichnaea` is the first object-tracing system to use Memory Protection

[4] we claim to be complete in userspace, not kernel. See Section 6, *para* 2.

Keys to provide efficient *per-thread* access control. This design eliminates all of the aforementioned dominant sources of trace losses, making it possible to analyze object accesses patterns in complex (multi-threaded) programs.

3. **Low overhead pagefault handling** [section 5.6.2]. We developed a low-overhead pagefault handling path (section 4.1) where we show that lightweight `pkey_set` operations *reduce pagefault handler overheads* by as much as 25*x* compared to traditional `mprotect`-based methods (see section 2.1.3)! This allows for more efficient accesses and improved precision while logging traces.

Our practical and deployable object-tracing framework[5] (section 3.2) integrates seamlessly with C/C++ programs, with *minimal* and *non-invasive* annotations to the source and supports real-world, multi-threaded workloads.

`Ichnaea` enables analyses that were previously impractical such as debugging rogue object accesses [1] in large codebases, recovering precise object-access patterns in multi-threaded systems [28], performing post-incident forensics and understanding accesses to security-critical objects to devise finer-grained access-control policies for compartmentalization [26]. Prior approaches either incur prohibitive slowdowns (slowing down test suites, benchmarks and fuzzers to a crawl) or produce incomplete traces, leading to inaccurate or misleading analyses. `Ichnaea` is a perfect tool for tracing a sizable number of objects with minimal slowdown, tracing all objects however comes with caveats (see section 6).

We next discuss some relevant background material.

2 Background

2.1 Tracing Memory Objects

There are two broad ways to trace objects in memory (hereby referred to as ObjOfInterest): static analysis [10] and dynamic analysis [7].

2.1.1 Static analysis

Static analysis does not produce complete or sound [29] traces as doing so would require precise symbolic executions [6, 23] which is impractical for most codebases since it suffers from problems like *path explosion* [24]. Compile-time nondeterminism further exacerbates this limitation since it is impossible to predict some aspects of the execution *(e.g., user input)* resulting in over-approximated results. Another idea is to statically find all sites where ObjOfInterests are modified and inject instrumentation that logs the accesses dynamically (a mix of static and dynamic analysis). However, for any given ObjOfInterest (heap-allocated or global) it is generally *undecidable* to identify *all* potential access sites, particularly in the presence of indirect memory references, pointer arithmetic, aliasing and data-dependent control flow. An example of this is shown in Figure 1 where the object `GLOBAL` is modified by a chain of indirections. There are pruning based approaches [47] that can reduce the number of instrumented `loads` and `stores` by removing paths guaranteed to not touch an ObjOfInterest. However, for complex programs *e.g.,* `nginx` this is impractical as the various control flow indirections lead to an over-approximation of accesses sites — resulting in no reduction in the amount of instrumentation anyway. Further, static analysis-based instrumentation necessitates *compiling every library statically into the program* which might be impractical when library source code is either hard to instrument (*e.g., libc*) or unavailable. As a result, there is a high likelihood that static analyses will miss many read/write operations.

2.1.2 Dynamic analysis

Dynamic analysis solves many of the above problems by *instrumenting* all *load and store* instructions in the program at runtime, so that no access goes untraced. Dynamic analysis *requires significant instrumentation* (usually a call to a trampoline function when ObjOfInterest is accessed) that can be either at *compile-time* [19, 38], *runtime* (*e.g.,* Dynamic Binary Instrumentation tools like Intel Pin [30], DynamoRIO [8] and others [34]) or by *binary rewriting* [11]. Accesses from kernel or dynamically loaded libraries are still not covered as that'd require kernel or dynamic library instrumentation which is often impractical due to the complexity of the kernel and dynamic loaders. However, dynamic analysis suffers from following problems:

Performance Impact: The issue with tracking loads and stores is that the instrumentation cannot be precisely injected at all object access sites since finding all such locations is know to be undecidable. Thus, instrumentation based dynamic techniques pay the penalty of instrumenting most loads and stores, slowing down the program by as much as *50-100x*. Some tools claim to have better performance (*e.g.,* 2x in case of ASAN [38]), but these claims are for simpler tasks (*e.g.,* bounds checking) instead of *precise* and *complete object tracing*. This slowdown makes it impractical to exercise long running test-suites, benchmarks, fuzzing, *etc.* that are crucial for simulating runtime behavior of big complex programs.

Limited Coverage: Some of the dynamic analysis techniques (that use compile-time and binary-rewriting [33] methods) do not cover accesses in *shared libraries* unless they're baked in with the original program. Sources for shared libraries are not always available or easily instrumentable, reducing trace quality. Furthermore, these tools do not *trace kernel reads*[6]*/writes* for an object.

General tools: most of the tools mentioned above are general-purpose tracing tools and do not specialize in precise tracing of memory objects, thus needing some further work to adapt them as such.

[5] Open-sourced at https://ichnaeatracer.github.io/

[6] `Ichnaea` does not claim to completely trace kernel reads, see section 6

2.1.3 Tracing Backing Memory — Dynamic Analysis

A better way (again via dynamic analysis methods) is to *trace writes to the backing memory*, either by using hardware debug registers [17] or virtual memory [31] protection. Hardware debug registers are limited in number and size (usually 4 in x86 with a max capacity of few bytes) making them impractical for tracing big, or a multitude of objects. The idea behind using virtual memory protection-based tracing is that the access permissions of the memory page that is backing an ObjOfInterest can be modified to disallow reads/writes. Any thread attempting to access the object would run into a pagefault (segfault). The pagefault handler can be customized to let the access proceed — by temporarily unlocking the page using `mprotect` [31], *i.e.,* making it read/write (R/W) — and logging the access. This means that once access to a object (the backing page) has been restricted (via the `mprotect` call), no active instrumentation is needed to trace the objects. Thus the *program pays virtually no cost as long as the object isn't accessed*. This is a more efficient approach than watching every load and store since there's virtually no overhead for user-space tracing until an ObjOfInterest is accessed. In contrast, monitoring every load/store adds constant overhead even when the loads and stores are not made to ObjOfInterests.

Tools like Dthreads [28] and others [3, 20–22] use this technique to trace memory accesses though none match our purpose exactly which is to precisely trace objects in memory with rich metadata. However, in the context of precise and complete tracing of memory objects, this technique suffers from various challenges:

1. **Interrupt Handler Overhead:** when a restricted access is attempted, the CPU calls the kernel pagefault handler that then calls a custom handler — a costly ordeal taking up to 2.2µs (see stage 1 in Table 5) for each attempted access. Next, the custom handler must *(a)* unlock, *(b)* emulate the faulting instruction, *(c)* log the access and *(d)* lock the page back. This unlock-relock cycle requires two `mprotect` calls (2µs each, 4µs total; see appendix A.2), making it the primary bottleneck. Further, tracing of reads becomes quite expensive as programs naturally tend to read more than write, adding significant performance impacts to objects that reside on the same page as an ObjOfInterest. Naively isolating all ObjOfInterests on their own dedicated pages can solve this issue but, it significantly increases memory usage.

2. **Trace Losses:** one of the biggest problems faced by pagefault based tracing is the issue of losses in multi-threaded systems. The reasons being the coarse granularity of virtual memory protection (access control can only be applied on page sized blocks) and the fact that traditional page permissions apply across *all* threads and not just one. Trace losses can happen due to any of the following cases in multi-threaded systems:

   Syscall Losses: to cover kernel writes to traced objects (not reads, see section 6), the least non-invasive idea (*i.e.,* without modifying the kernel) is to wrap all *libc* covered syscalls (*e.g.,* `read(), readv()`) with a wrapper using the LD_PRELOAD mechanism [14]. The wrapper's job is to *unlock and lock all/one traced objects* before and after a syscall, which is extremely expensive. More importantly, *either one or all traced objects are unlocked during this time* and *any* thread can simply write to any traced objects without causing a pagefault *i.e.,* without being traced. This could potentially result in *significant trace losses* since syscalls can take an arbitrary amount of time (up to a few milliseconds) while memory accesses generally take less than 100 nanoseconds. This means that in a multi-threaded program with frequent trace object accesses, the possible lower bound for losses could be *hundreds of missed traces per syscall*.
   False Sharing Loss: in cases where multiple objects share the same backing page *e.g.,* a traced object sharing a page either with another traced or un-traced object. One thread could unlock the whole page (for a brief window) to access one object, while also leaving other objects on the same page unintentionally unlocked. Writes to these objects will be lost during this window.
   Atomic objects: since atomic objects don't need locks, two threads can try to access an object at the same time. This means that while one thread has temporarily enabled access to a traced atomic object (unlocked the object), another thread could access the same object without triggering the pagefault. This is because the time window for handing the pagefault in the first thread (the object is unlocked during a part of this window) can be very large (see *R/W window* in Table 5) in comparison to how long it takes to do complete atomic write.

3. **False Sharing:** since virtual memory protection works at page granularity, if any other objects (that aren't being traced) share the same page with a traced object then they will also trigger a pagefault. These faults can be filtered out by the pagefault handler (by checking the exact faulting address). However, a pagefault and its handling is expensive (see stages 1,2 in Table 5) and must now include, the cost of two additional expensive, `mprotect` calls. Hence, incurring too many pagefaults will *significantly reduce performance*. This can be solved by allocating a dedicated page for every object. However, as mentioned earlier the memory overhead of doing this may become impractical.

2.2 Memory Protection Keys

Memory Protection Keys (MPKs) [36] extend the traditional virtual-memory model by *decoupling access rights from page-table entries*. One or more pages can be tagged with a key of which there are 16 in total. The reason for

multiple keys is to have a larger number of distinct access control domains. A domain could be a secure crypto library which needs its own key to isolate it's pages from other parts the code and similarly other libraries and modules can have their own keys to isolate their data and stack thus improving security by memory isolation. Page table entries only know which key is associated with each page. Each processor core maintains a local register that specifies the access permissions for pages tagged with any of the 16 keys. A thread can therefore revoke access (*e.g.,* remove write access to all pages tagged with key *k*) without modifying page tables or triggering TLB flushes — overheads unavoidable with classic page-protection mechanisms. By default, all pages are associated with key 0 and all threads have access to pages tagged with key 0 but these can be changed during runtime to provide isolation. MPKs enable fast, user-level domain switching and fine-grained intra-process isolation. For our system, this prevents cross-thread interference since granting access in one thread does not affect others, thereby avoiding false-sharing-induced trace losses. MPKs are supported on both Intel [36] and ARM architectures [5] and are used for memory isolation, *e.g.,* page table hardening [9].

3 Design

To solve the challenges mentioned in Section 2, we introduce `Ichnaea`, a tracing framework designed for **precise**, **lossless** and **complete** memory object tracing for programs written in low-level manually managed languages *viz.,* C/C++. `Ichnaea` works by using Memory Protection Keys [43] (MPKs) that provide `mprotect`-like access control without requiring page table changes, needing only a CPU-local register rewrite to switch protection domains. This enables per-thread access control completely *alleviating all losses* (see section 2.1.3) while *halving interrupt handling cost*, leading to significant reduction in tracing overheads. Further, traced global objects can be put in a dedicated section by simply adding a macro (see appendix A.1) before its initialization. This ensures that other global ObjOfInterests do not trigger unnecessary segfaults. Heap objects can be isolated efficiently (section 4.5). `Ichnaea` is realized as a shared library, `libichnaea.so`, that is loaded into the target process (at load time) to trace ObjOfInterests. This design alleviates the need of linking the program with our library or adding special compiler passes, both of which require modifying complex build systems. `Ichnaea` exposes a simple API call and some helper macros (see appendix A.12) that can be added to the program just by adding a header file. This file contains a *weak reference* to our API call — thus, it does not require any build-system changes or additional linking steps.

3.1 Design Principles

We believe a tracing mechanism must follow these principles:

1. Low startup overhead: startup overhead is important as many benchmarks launch repeated short-lived instances and fuzzers could execute thousands of runs per second. Even a few extra milliseconds per launch can balloon into hours over the life of a campaign.

2. Minimal cost until ObjOfInterest is accessed: most executions may never access the objects we care about (ObjOfInterests). The tracer must remain effectively dormant until a monitored object is accessed.

3. Low implementation complexity: a smaller code base is easier to audit, maintain and port. Avoiding heavyweight features such as a JIT compiler or kernel modules not just reduces the chance of side effects but also startup overheads.

4. Ease of use: users should be able to trace objects with minimal API call. Simple usage patterns encourage adoption.

5. Rich contextual information: when an access to an ObjOfInterest occurs, the tracer must record more than just the address and value from each running thread — it should also capture the instruction pointer, thread ID, stack trace, data and an accurate timestamp. This context turns raw events into helpful debugging data.

3.2 System Overview

Figure 2 illustrates the overall workflow of `Ichnaea`. The framework is divided into three stages:

1. **Compile-time:** `Ichnaea` employs lightweight compile-time annotations to register ObjOfInterests. Developers *explicitly* identify objects by invoking our API call:

   ```
   ichnaea_register_obj(addr,size,name,type);
   ```

   This call records the address, size and type information of the object to be tracked during runtime. We also add special compiler directives (line #2, Listing A.12) so that stores to these objects are not optimized away by the compiler. Once annotated, the workload is compiled without *any modification to its build system*. Wrong annotations (*e.g.,* object size) may result in incorrect traces but *all the correctly annotated objects will be traced without any loss*.

2. **Runtime:** The call to register an ObjOfInterest constructs metadata tables that create a map of registered ObjOfInterests, their address and backing pages. Next, it disables read/write (or both) access to the object's backing page. Future calls to register other objects (at any point in time) do the exact same steps. Since access to the backing pages of ObjOfInterests is disabled, any future attempt by the program (or its child processes or external libraries) to access any of the pages belonging to ObjOfInterests triggers a segmentation fault (`SIGSEGV`) *i.e.,* the segfault happens at the moment when the page access is initiated. A *custom signal handler* within `libichnaea.so` intercepts this fault and performs the following actions:

   - checks if faulting address is a registered ObjOfInterest (sets flag `isTraced`),

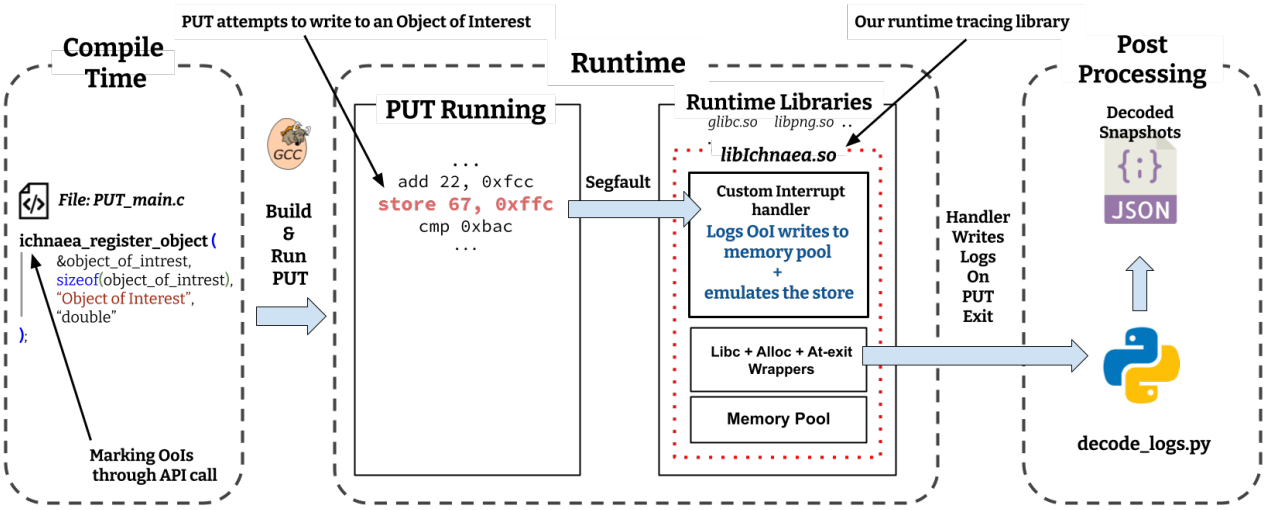

Figure 2: System Overview of `Ichnaea`. The dashed lines represent the tracing phase. The red dotted line box contains all the components that form `Ichnaea`'s runtime library

- enables access to the underlying page
- emulates the instruction that tried to access the ObjOfInterest (so that the program runs correctly)
- `iff (isTraced)`:
  - it logs the attempted memory access with metadata (*i.e.,* execution stack, thread id) to a dedicated trace buffer
- resets the pkey to disable access again
- returns so the program can proceed normally

This selective interception strategy ensures that only accesses to designated objects incur overheads, while *all other program execution proceeds without interruption*. Hence, `Ichnaea` remains *toggled off* until an ObjOfInterest is accessed. To trace accesses made by syscalls, we wrap all `libc` syscalls. These wrappers inspect the syscall arguments to find if an ObjOfInterest is being accessed. If so, they log the access after the syscall finishes. These wrappers remain inactive till the first call to register an object is made (see Section section 4.3 for more details.)

3. **Post-processing:** upon program termination, event logs stored in trace buffer are serialized into a standardized `JSON` format. This structured representation aids downstream analysis, enabling *(i)* investigation of fine-grained access patterns, *(ii)* correlation of memory activity with program phases and *(iii)* integrating traces into profiling or visualization pipelines with minimal effort. For each traced object, `Ichnaea` provides data *e.g.,* the accessor's call stack, process_id, thread_id, access type (R/W), timestamp and hash *etc.* See Appendix A.4 for more details.

4 Implementation

The `Ichnaea` prototype was implemented using less than two thousand lines of C code and *required no kernel modifications.* We have open-sourced our implementation online[7].

4.1 Segfault driven tracing

Figure 3 shows sequence of operations in `Ichnaea`. The framework uses *pagefaults* (also known as *segfaults*) to *trace object access*. A segmentation fault is an interrupt raised by the memory management unit (MMU) when a program accesses a page without the right permissions that are set at runtime. At any point during runtime (ideally at the start of program, *e.g.,* `main()`), one or more ObjOfInterests (heap or static allocations) are "registered" for tracing. The registration API then invokes `pkey_mprotect` syscall to tag the backing virtual pages that hold those objects with a `pkey`. This `pkey` is assigned by the kernel and we use it to tag all pages that are to be traced. The current running thread then disables access to any pages that are tagged with our `pkey`. Hence, any subsequent access (the first box in Fig 3) to these pages triggers a segfault (`SIGSEGV`) — the second box in Fig 3. The resulting `SIGSEGV` is intercepted by our *custom signal handler*. The handler then *(i)* enables access to all pages for that thread only *(ii)* emulates the faulting instruction *(iii)* logs the access context and data and finally, *(iv)* returns to normal execution. Without emulation, we would have had to run the faulting instruction again after the handler unlocks all ObjOfInterests. This means that we would have to lock the ObjOfInterests right after running the faulting instruction in order to avoid trace losses. This necessitates adding a breakpoint (`INT3` in-

[7] https://ichnaeatracer.github.io/

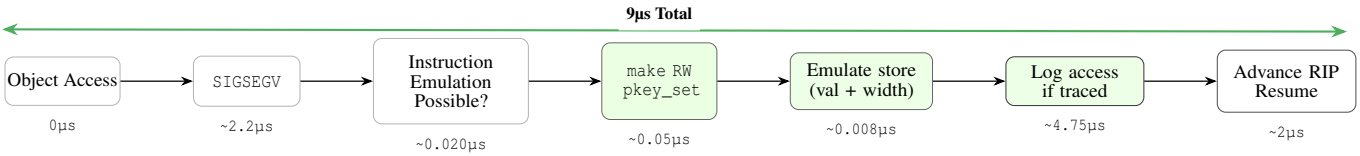

Figure 3: Fault handling sequence in the interrupt handler. Boxes are numbered from right to left starting from 1. Box colors indicate page protection status (Green: Unlocked, Gray: Locked).

struction) right after the faulting instruction. The new trap instruction will run the segfault handler again to lock the ObjOfInterests back. Thus, causing one more round of segfault and handler execution. Furthermore, adding breakpoints in user code during runtime may cause other threads to hit the same breakpoint (*e.g.,* while running a shared `memcpy` on a separate piece of data) causing additional complications.

Also note that emulating all the instructions on x86 is huge engineering effort. Thus for the instructions we do not emulate yet *e.g.,* floating point writes and other complex instructions, the handler takes the *slow path*. The slow path ensures that the non-emulated instruction is executed directly (on the CPU) instead, thus ensuring correct program behavior. However it's slower in comparison to emulation (see appendix A.9 for details). Slow path is an engineering effort as emulating each instruction requires understanding and dissection — while a challenge, it is easy to overcome in production. We will explore this in future work.

Detailed Breakdown of the segfault Handler If the segfaulting instruction can be emulated (third box in Fig 3) and the faulting address corresponds to an ObjOfInterest or happens to fall on the page backing an ObjOfInterest, we implement the following steps in the interrupt handler,

1. *Temporary unlock:* (fourth box in Fig 3) access to all pages marked with the tracer's `pkey` (`Ichnaea` uses only one out of 16 pkeys, to lock all objects) is enabled via `pkey_set()` for that thread. Other threads will still fault if they try to access any ObjOfInterest, including the one unlocked for the current thread, hence alleviating the issue of trace losses.

2. *Emulated store:* (fifth box in Fig 3) the value and size of the access requested by the faulting instruction are extracted from instruction operands by inspecting CPU register states. Access is then emulated to restore original program behavior by reading/writing the appropriate number of bytes at the *effective address*.

3. *Logging:* (sixth box in Fig 3) if the access target was an ObjOfInterest, it is recorded (`thread_id`, IP, call stack, data) in a dedicated trace memory pool.

4. *Advance execution:* (seventh box in Fig 3) after instruction emulation, the instruction pointer (`RIP`) is advanced to the next instruction in order to avoid another *segfault*. Returning from the handler auto-restores key permissions to the pre-interrupt (locked) state so there is no need to re-lock pages.

5. *Exit:* at ProgramUndrTest's exit, `Ichnaea` writes all snapshot data from the memory pool to disk.

All the above mentioned steps are done in `async-signal` safe manner, for instance, by using dedicated local copies of every `libc` function used. Heap allocations (for `Ichnaea`'s own use) are carried out using custom allocators that invoke `mmap` [32]. For each ObjOfInterest access, we log:

(*a*) **who** accessed it, (thread and process id via the `gettid()/getpid()`),

(*b*) **where** it occurred, (instruction pointer `RIP` and call stack via `libunwind()`)

(*c*) **when** it occurred (timestamp via `clock_gettime()`, plus a global access counter) and finally

(*d*) **what** changed (before/after dumps for writes).

All the logs are written to a dedicated memory pool to avoid the overhead of file I/O during runtime. The data is written to disk at program exit.

4.2 Concurrent and Cross-library Accesses

Unlike traditional `mprotect` based techniques, `Ichnaea` only allows ObjOfInterest *access within the current thread*, so other threads will still segfault while accessing other ObjOfInterests that either happen to be on the same page or use atomic operations. This allows our framework to seamlessly support unmodified, highly concurrent applications such as PostgreSQL [44] and Nginx [41].

Since `Ichnaea` works by removing access permissions to the backing page of an ObjOfInterest, any access from a library (*e.g.,* `snprintf` in `libc`, *etc.*) will result in a pagefault that in turn, will log the access. This alleviates the need to statically recompile all the dynamic runtime libraries which might be required for compiler based instrumentation techniques that instrument every load and store.

4.3 Kernel Accesses

A complication arises when the kernel accesses a user-space buffer via syscalls *e.g.,* `read()`, `recvmsg()`, `getcwd()`.

Because these accesses occur in kernel mode, the kernel never triggers a user-space segfault that Ichnaea relies on; instead, the kernel detects the invalid access internally, skips the syscall and returns an error such as EFAULT, indicating that an invalid buffer was encountered. A naïve remedy is to retry the syscall after unlocking the faulting page, but this fails because syscalls are stateful (many of them advance file offsets, consume descriptor buffers or deliver signals), so re-execution can alter program semantics.

We therefore wrap *libc functions*[8]. The wrapper first enables accesses to all ObjOfInterests *(for the current thread)*, inspects syscall arguments to identify which pointers (or I/O vectors) intersect with traced objects to know what's being accessed before forwarding the syscall to the kernel. After the call returns, the wrapper restores the original protection. We further use hashes of ObjOfInterest states to detect changes for syscalls that may be called but don't end up writing to any ObjOfInterests *e.g.,* a `read()` call on an empty file buffer. Details and an example of our wrapper can be found in appendix A.6.

Parsing Syscall arguments, though conceptually simple, is difficult in practice due to:

- variable-length aggregates: Interfaces, *e.g.,* `readv()`, `recvmsg()` *etc.* pass an array of `iovecs` whose length is unknown until runtime, requiring a loop inside the wrapper. This is a huge engineering effort and results in some runtime overhead.
- inline syscalls and virtual dynamic shared object (VDSO) shortcuts: Some performance critical libraries issue syscalls directly via `syscall` or the VDSO page, bypassing libc hooks unless caught with `seccomp` [42] style tracing or binary rewriting [37].

These issues make a full in-kernel solution attractive, but kernel tracing requires elevated privileges and introduces maintenance cost across releases and patches. In contrast, our user-space wrapper keeps Ichnaea self-contained while still covering a significant number of syscalls that perform kernel-to-user copies, *viz.,* `read()`, `write()`, `recv*()` and `ioctl()`, along with output pointers and miscellaneous queries such as `getcwd()` and `getdents64()`. Syscalls for which we cannot find the object addresses (*e.g.,* `ioctl, readv`), we do the following: *(a)* for writes, we keep a hash of last states of traced objects and compare post-syscall state to determine if any change has been made *(b)* and for ObjOfInterest reads, if we can't resolve the read targets by parsing the syscall arguments, we miss those traces. However, this is an engineering limitation, with enough effort a wrapper can potentially dissect all syscall targets. Empty writes (*e.g.,* `read()` on an empty file) are also detected but empty reads (object passed to the syscall for reading but not read by the kernel) are not detected.

[8] Currently, we wrap 20 such functions list on website

4.4 Invocation

First, users need to identify the ObjOfInterests (heap or global) that they wish to trace, *e.g.,* structs such as `ngx_http_core_module` in `nginx` that govern critical aspects of request handling. In a large codebase like `nginx`, determining which components read or modify such structures is difficult to do manually or via static analysis, especially when accesses occur through deep chains of indirection — a common pattern in `nginx`. Similar difficulties arise when tracking unintended accesses to a buffer or diagnosing asynchronous accesses that manifest within otherwise synchronous systems. Listing 4 in appendix A.10 shows the invocation sequence for Ichnaea. Integrating Ichnaea into an existing project requires two minor changes to program source:

1. **Build-time change:** Add the header *tracer.h* and insert our API call to `ichnaea_register_object()` for every object that should be traced. No additional build-system edits are necessary. An *optional* flag `-rdynamic` can be added while building to improve the quality of callstack symbols.
2. **Run-time activation:** Launch the program with the tracer library pre-loaded as follows:
   `LD_PRELOAD=libIchnaea.so ./myBinary`
   The `LD_PRELOAD` can be set for the whole environment as Ichnaea stays dormant until a program initializes it.
3. **Post run data decoding:** At program exit, Ichnaea dumps the binary object data snapshots and related context information in a directory. We provide a Python script to convert binary snapshot data given the structure of objects. A sample of the `JSON` file with traced data from an `nginx` run can be found in Listing 1.

4.5 Tracing Dynamic Heap Allocations

Ichnaea traces dynamically allocated ObjOfInterests without requiring users to manually annotate every `malloc` site. It also isolates ObjOfInterests from unrelated objects to avoid unintended segfaults. To do so, Ichnaea wraps `malloc`/`calloc`/`realloc` to provide two additional capabilities:

(i) *automatic detection* of ObjOfInterest allocations

(ii) *page-isolated slab allocation* for each ObjOfInterest

Annotation and Automatic Detection: Pointer objects (global or heap handles) that hold references to heap buffers are registered via our API call (see section 4.4). In addition, the initialization sites of these pointers are marked with a lightweight compiler annotation (listing 2, Line 2 in appendix A.5). This annotation prevents compilers from optimizing away the store instructions needed to automatically detect the allocation.

At runtime, the interposed allocator (*e.g.,* `malloc`) inspects its caller and identifies the instruction storing the return value;

the destination of this store is compared against registered ObjOfInterest handles to determine whether the allocation belongs to an ObjOfInterest. We validated this mechanism using both `gcc` and `clang`. This allows `Ichnaea` to trace dynamically allocated objects *without requiring users to manually locate allocation sites* in large codebases.

ObjOfInterest Isolation: If the allocation targets an ObjOfInterest, the wrapper allocates a page-aligned, page-sized slab using `memalign()` and returns that pointer; ordinary allocations are forwarded to the native allocator. Because each on-heap ObjOfInterest resides on a private page, unrelated accesses cannot spuriously trigger `SIGSEGV`. Even when tracing say a 1000 objects, the memory overhead would only be around 8 megabytes plus the cost of the `mmap` syscall made by allocators. All of these in our view are acceptable since this analysis is done offline. Appendix A.7 discusses possible refinements. Custom allocators can also be instrumented similarly using a macro (see appendix A.12).

5 Evaluation

We evaluate `Ichnaea` against two tools, *(i)* Intel Pin (SoTA) *(ii)* `mprotect` based tracer. The workloads we used are described in Table 1. **Intel Pin** was chosen since it provides *complete* traces (with the exception of syscalls) without any build system modification and is faster [30] than other complete tracing tools like DynamoRIO [8] or Valgrind [34]. **The `mprotect` based tracer** was chosen as it represents tools like Dthreads [28] that use `mprotect` to trace object accesses. For a fair comparison, we simply changed `Ichnaea`'s implementation to use `mprotect` instead of MPKs (details in appendix A.3). Thus the `mprotect` based tracer gets all benefits and optimizations of `Ichnaea` minus the MPKs. Compiler injected instrumentation based techniques were not selected as even they also instrument almost every load and store and require adding complicated compiler instrumentation passes.

The workloads are part of the *SPECInt* benchmark which represents real world programs (*i.e., gcc, xz, perlbench*) and have exhaustive benchmarks and test suites that ensure that the frequency of object accesses represent real world scenario.

As part of our evaluation, we intend to explore the following research questions:

- **R1**: Can the state of the art for object tracing be improved in terms of Performance? See sections 5.3.1 and 5.7
- **R2**: Can the quality of tracing be improved including completeness, precision and coverage? See section 3.
- **R3**: Can usability/adaptability of object tracing be improved? Section 3.

5.1 Evaluation Setup, Workloads and Metrics

The evaluation platform is running Ubuntu 24.04.2, kernel 6.14.0. Experiments were executed on Intel(R) Xeon(R) Silver 4316 CPU @ 2.30GHz with 64GiB of memory.

Workload	Description	Version
SPEC CPU2017	SPEC CPU2017 Integer Speed Testsuite	1.1.9
Postgres	Highly parallel workload with built-in testsuite	17.5
Synthetic Program	To compare fuzzing overheads	N/A

Table 1: Description of different workloads and their attributes

Table 1 describes the workloads used in our evaluation with version numbers. We selected SPEC CPU 2017 [40] because it is the de-facto industry benchmark for CPU performance and micro architectural studies containing real work benchmarks. Its workloads are compute intensive rather than I/O-bound, so they saturate the memory hierarchy with millions of loads and stores — exactly the traffic pattern we need to stress an object tracer. SPEC CPU is also what Intel Pin used in their evaluation. The *exchange2* from SPEC wasn't included as it's written in Fortran. We ran 5 copies of each workload for this experiment. We also test a highly parallel workload, postgres [44] to highlight `Ichnaea`'s performance under high-concurrency scenarios. We ran `postgres` test suites 3 times for each tracing tool. As seen in Table 2, the main metric we capture is execution times for various test suites under diverse conditions *e.g.,* high-frequency accesses, parallel accesses, low-frequency accesses and runtime with and without traced objects. While running fuzzing experiments, we capture the number of paths covered (*i.e.,* exercised by the fuzzer), the number of paths successfully traced (accesses recorded by tracer) and the runtime overhead relative to native execution.

Table 2: Metrics captured across test suites and fuzzing experiments.

Category	Metric Captured
Execution Time (Test Suites)	High-frequency accesses Parallel accesses Low-frequency accesses Runtime with traced objects Runtime without traced objects
Realistic Use cases (Fuzzing)	Paths covered (i.e., exercised by the fuzzer) Objects traced (ObjOfInterest accesses captured by instrumentation) Total fuzzer runtime

5.2 Object Selection Rationale

We selected `global` objects that were either *(i)* statically allocated at load time or *(ii)* acted as pointers to heap regions that would be allocated later. We don't trace stack allocated objects. For external libraries, it was often hard to locate such

objects directly in the source tree so we relied on the projects' test-suites and benchmark drivers to discover global objects that are actually touched under realistic workloads.

We selected objects with varying access frequencies to highlight their effects on tracing overhead. For example, in SPECInt's *x265* (a HEVC/H.265 video encoder), we traced `cli_input_t input`—an infrequently accessed file pointer; while in *gcc* we traced `input_location`, which experiences frequent runtime accesses. This range of frequencies ensures we capture diverse tracing behaviors across variables. More details are available on our website.[9]

5.3 Comparison with Intel Pin (SoTA)

We compared `Ichnaea` with Intel Pin (state of the art for dynamic tracing tools) using metrics such as performance, features and ease of use. To adapt Intel Pin to mimic `Ichnaea`'s behavior, we devised the following workflow:

1. Compile the ProgramUndrTest with static addresses so ObjOfInterest addresses don't change at runtime
2. Dump all object addresses from the binary to a database
3. Filter out ObjOfInterest addresses from the database
4. Create a pintool [30] aware of ObjOfInterest addresses
5. At runtime, log every store instruction (address + value) whose target address is in ObjOfInterest database
6. For each ObjOfInterest access, fetch context info (*pid, tid, callstack*) through ptrace API

These steps create a pintool closely that mimics `Ichnaea`'s behavior. To trace dynamically allocated heap objects, we manually added hooks to all the allocation sites. These hooks inform the pintool of new allocations to ObjOfInterest.

5.3.1 Performance Comparison with Intel Pin

Figure 4 compares the runtime overhead (lower is better) incurred by `Ichnaea`, *Intel Pin* and a `mprotect` based tracer for SPECInt workloads. The x-axis lists all the application under the SPECWorkloads. The y-axis shows median runtime normalized to un-instrumented baseline (log scale), where a value of 136 means a 36% slowdown. For each benchmark, the green dotted line is the un-instrumented baseline, first bar (orange) is `Ichnaea` runtime, the second bar (yellow) is `mprotect` based tracer and third bar (blue) is Intel Pin runtime. For details on the kind of traced objects see Section 5.2.

Figure 4 shows that in most cases `Ichnaea` significantly outperforms `Intel Pin` — by anywhere from 12 to 60 times. This addresses research question **R1** from Section 5 as we significantly improve performance when compared to SoTA. We also address **R2** since these improvements to tracing techniques mean more efficient analysis pipelines meaning complex software is better understood and thus more resilient, correct and secure.

The relatively low overhead of `Ichnaea` stems from its lightweight design: a single `LD_PRELOAD`-ed shared library

[9] https://ichnaeatracer.github.io/

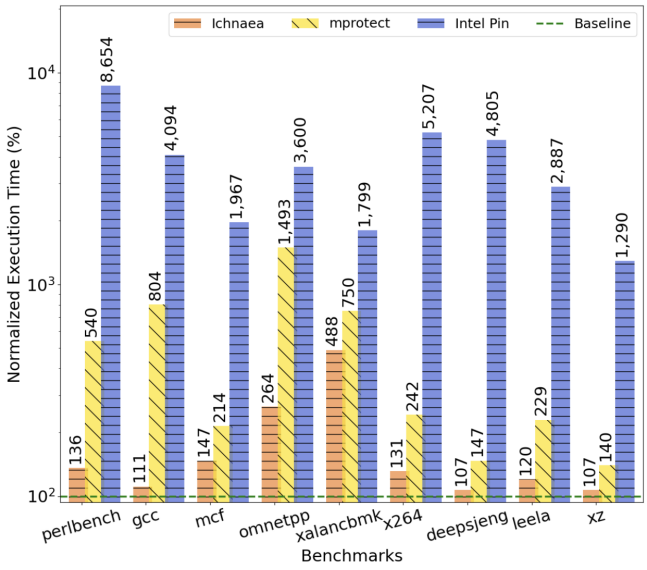

Figure 4: Comparisons of runtimes: `Ichnaea` vs Intel-Pin vs `mprotect` Instrumented for SPECIntSpeed Benchmarks normalized to un-instrumented runtime (red line) [Log Scale]

imposing itself *only on targeted events*. By comparison, Intel Pin's overhead originates from its dynamic binary instrumentation where *all instructions* are analyzed to filter out relevant events such as load and store. This evaluation of every instruction along with heavy components (*e.g.,* code caches, JIT compiler) are responsible for IntelPins' slowdown.

As seen in Figure 4, while `Ichnaea` typically increases runtime by only 1-3× over native execution, its impact on *xalan* is significantly higher (4.8×). This is attributable to the workload's extensive use of global variables that are frequently updated during runtime. Because `Ichnaea` traces several of these hot-path globals, many unrelated objects that reside on the same virtual memory pages and therefore incur the same page-protection and instrumentation overhead. This collateral impact amplifies the runtime cost, resulting in a relatively larger slowdown compared to typical workloads.There are ways to avoid part of these overheads which are described in section 3. However, we did not use any optimizations (*e.g.,* placing globals objects in `.rodata` to cut collateral segfaults) to highlight the worst case performance for the tool. Such optimizations will only improve `Ichnaea`'s performance. Although the overheads are high, they're much lesser than Intel Pin. Further, this kind of analysis is usually done offline hence making our overhead acceptable.

The general variance in `Ichnaea`'s performance (1 to 2×) across benchmarks is largely attributable to the characteristics of the traced objects. Some reside outside the "'hot path"' and incur minimal cost, while others lie directly in high-frequency execution paths, amplifying overheads.

The overhead introduced by Intel Pin during traced runs ranges from 12× to 86×. This variation depends on program

characteristics such as size (larger programs require more instrumentation points) and complexity rather than solely on object access frequency or location. Additionally, applications that perform many syscalls show relatively lower overhead, because Pin does not trace syscalls, limiting visibility into such accesses.

5.3.2 Comparison with `mprotect` tracer

`Ichnaea` outperforms traditional `mprotect` based tracing anywhere from 1.3—7×. This is due to the lower interrupt handling cost as `mprotect` needs to modify the page table entries. In a multi threaded program, page table entry change is sent to all the cores causing TLB flushes thus significantly increasing the cost at runtime as the number of thread increases.

5.4 Performance comparison with Postgres

In table 3 we present the results comparing `Ichnaea` and `Intel Pin` using a highly parallel workload — `Postgres` [44] — using its built-in regression test suite. For these experiments, we traced *five global structures* responsible for maintaining internal state during runtime. The table shows Real, User and Sys times captured in seconds for an uninstrumented binary, `Ichnaea` instrumented and `Intel Pin` instrumented runs of `Postgres`'s test suite.

The table shows that `Ichnaea` runs *26 times faster* than `Intel Pin`. These results highlight `Ichnaea`'s ability to maintain significantly lower runtime overheads even in multi-threaded, state-intensive workloads. The *Sys* time (time spent in kernel mode) consumed by `Ichnaea` is higher (11.2s) than Intel pin (10.4) as interrupts (triggered at object access) are first sent to the kernel, leading to longer kernel code execution. The *User* time (time spent in userspace) is higher for Intel Pin because of it's high overheads. Details about the test environment and workload setup are provided in Table 1. This also addresses research question **R1** as this demonstrates that we can make tracing highly-parallel workloads more efficient.

Table 3: Postgres performance (average of 3 runs) on experimental setup

Configuration	Real (s)	User (s)	Sys (s)
Un-instrumented	17	4.9	4.3
`Ichnaea`	**35**	**15.1**	**11.2**
Intel Pin	944	38.7	10.4

5.5 Object Scaling and Isolation Overheads

We analyze how `Ichnaea`'s overhead scales with the number of traced objects using a synthetic workload of 100, 8 byte objects (50 global, 50 heap-allocated). All objects are accessed 10000 times (split equally between reads/writes), regardless of whether they are traced, keeping the access pattern identical across configurations. Runtimes are normalized to the 2-object baseline as using configurations with no traced

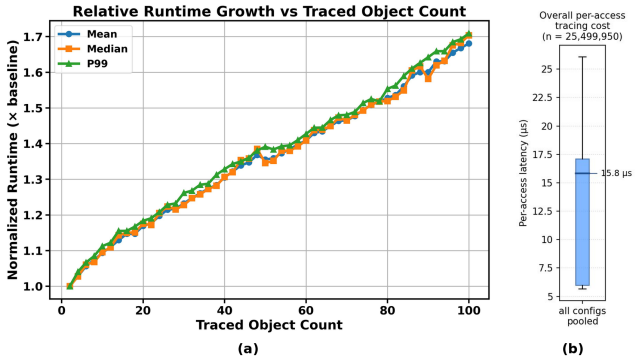

Figure 5: (a) Runtime of `Ichnaea` as traced object count grows from 2 to 100, normalized to the 2-object baseline (20 runs per configuration, 10K accesses per run, evenly split between reads and writes). Mean (blue circles), median (orange squares) and P99 (green triangles) are shown. (b) Box plot of pooled per-object access overhead in microseconds.

objects (*i.e.,* vanilla untraced program) was skewing the results. This is because the untraced version runs 10 times faster as the workload here represents the *absolute worst case* for `Ichnaea`. A value of 1.35 indicates 35% overhead over the baseline.

As Figure 5 (a) shows the overhead grows in a linear fashion — each additional 20 objects add approximately 8–10% runtime. Further, the proximity of the mean, median and tail shows the stability of `Ichnaea`'s overheads even under heavy load. At first glance, one might expect each new traced object to add a full ∼9μs overhead (∼9μs is around 8900% overhead in comparison to a un traced object access that takes 50ns), but this is not what we observe. Since all 50 globals easily fit on a single page (400 bytes vs 4096 bytes page size), locking any one of them faults all global accesses regardless — adding more traced globals therefore increases only logging and stack-unwind costs (less than 5μs each), not fault rate. This would be the case for most applications as a page-sized set of globals is sufficient for most use cases. Traced heap objects each occupy an isolated page and thus contribute genuine "new faults", making them the significant driver of the overhead. The remaining overhead comes from per-access metadata writes, stack unwinds and logging.

Figure 5 (b) shows the pooled box plot of the per object access latency in microseconds. The plot is combined across all runs as the range and median of the box plots for any number of traced objects were almost exactly the same (all medians differed by less than 1% from each other) which means the *object access overhead is consistent as the number of traced objects grow*. In this the median is around 15 μs, since the current experiments rapidly swaps between objects which adds extra cache overheads.

This workload represents a worst case scenario: *every object* is on the hot path and *every access* is traced, unlike real

Table 4: Heap isolation overhead at N=10,000 ObjOfInterests (median of 100 iterations). RSS is resident set size which represents the actual physical memory used by the program.

	Packed	Isolated	Ratio
Total RSS (Memory used)	4.2 MiB	80.3 MiB	19×
Per-object RSS	0.42 KiB	8.03 KiB	—
Per-alloc time	728 ns	5.5 μs	7.6×

programs where traced objects account for a small fraction of total execution. This is reflected in our SPECInt and PostgreSQL results (section 5.3), where overheads are substantially lower. Optimizations such as isolating hot-path globals on a dedicated page would further reduce the overheads seen here.

Memory Overhead of Heap Isolation

We quantify the worst-case cost of `Ichnaea`'s heap-isolation strategy (section 4.5) with many small ObjOfInterests exercised with a microbenchmark that performs 10,000 allocations under two configurations: *packed* (`malloc`) and *isolated* (`posix_memalign` to a full page, exactly mirroring `Ichnaea`'s instrumented allocator). Sizes are drawn from a seeded distribution skewed toward small objects (∼55% in 8–64 B), matching the ObjOfInterest mix in nginx and Postgres. Every allocated object is accessed and kernel optimizations such as THP [27] are disabled to prevent 2 MiB rounding. We exclude the tracer library so the comparison isolates `Ichnaea`'s allocation strategy itself; `Ichnaea`'s allocator interposer adds a further ∼500–600 ns/alloc, independent of object size.

Table 4 shows the cost of using paged isolated slabs for ObjOfInterest allocation. RSS here stands for resident set size which is the true amount of physical ram in use by the program in contrast to virtual memory which could be higher. The heading row shows *packed* (normal allocation where objects are packed together) vs *isolated* (page aligned and page isolated allocations) and the last column shows the ratio between the two. The first row shows the total RSS for both packed and isolated configurations. For *packed*, since objects sized were random and small , the total size of 10,000 objects comes to 4.2MiB. For *isolated* section, however, since each of those 10,000 objects occupy almost two full pages, the cost is ∼80 MiBs (10,000 × 8 × 1024). The second row shows memory overhead per object which is ∼8 KiB/object, twice the 4 KiB lower bound due to kernel bookkeeping (fresh VMAs and page-table entries) when page-aligned requests bypass the `glibc` arena. The ratio here is skipped as sizes of packed allocations vary. The overhead is bounded and linear in N, independent of object size. The third row shows the per allocation time overhead for both configurations, a 7.6× increase is due to the fact that the `glibc` allocators usually have to make a special kernel request for each isolated object allocation. Page-per-object isolation is therefore the right default as the overhead and side effects (`glibc` allocates critical data structures on heap causing problems if those structs segfault) of not isolating could be much higher. Furthermore, such analyses are usually done offline where these overheads are acceptable. For campaigns tracking $\gtrsim 10^3$–10^4 small heap objects, the suballocator sketched in appendix A.7 that packs multiple ObjOfInterests into a shared isolated region that reduces both memory amplification and overhead per allocation. This could be an avenue for future improvements.

5.6 Detailed Analysis of Overheads

We identify 2 sources of overheads introduced by `Ichnaea`:

1. **Runtime Library Overhead**: even when no ObjOfInterests are accessed, `Ichnaea` incurs a one-time startup cost from loading the `LD_PRELOAD`-ed runtime library, plus a continuous cost from its interceptors on allocators and libc functions, which add function-call and context-switching overhead on every invocation.
2. **Object Access Overhead**: the additional latency incurred for each access operation on an ObjOfInterest.

5.6.1 Runtime Library Overhead

We measure the runtime of `Ichnaea` without tracing any objects to measure the overhead added by the `alloc` and `libc` wrappers alone. We do this by running the SPECInt benchmark suite with `Ichnaea`'s runtime library (`libIchnaea`) loaded but without tracing any objects. By design, the runtime library only interposes on allocators and syscalls after the first ObjOfInterest registration. For this experiment, however, we explicitly enabled all interceptions without requiring API calls to measure their overheads in the absence of tracing.

Figure 6 compares SPECint runtimes with and without traced objects under `Ichnaea`. The y-axis shows median runtime normalized to the un-instrumented baseline, where a value of 488 indicates a 388% slowdown. For each benchmark, the dotted green line is the baseline, the yellow bar is `Ichnaea` loaded but with no traced objects and the orange bar is `Ichnaea` with traced objects (for details on selected objects, see Section 5.2 for details).

The experiments show that our runtime library adds overheads even without any traced objects as all allocator functions and select syscalls are still intercepted. The percentage variability in the overheads of un-instrumented vs un-traced runs is due the frequency and the nature of syscalls used in the different workloads. Workloads that tend to use syscalls (*e.g.,* `read()/recvfrom` *etc.*) or heap allocators (*e.g.,* `malloc`) frequently incur higher overhead even when there are no traced objects. But the relative overhead is still low as syscalls are usually way more expensive than a wrapper indirection.

5.6.2 Object Access Overhead

To quantify the cost of writing to ObjOfInterests, we measured the CPU time for each of the event sequence from →attempted

Table 5: Breakdown of fault handling overheads in microseconds (2.4 million writes). Fast path only.

Stage	Name	Description	Fast Path CPU time (μs)		
			Median	99th	Top 1%
1	Handler launch	Time from access to SIGSEGV handler entry	2.2	3.0	6.0
2	`SIGSEGV` Handler	Time from SIGSEGV handler start to return	6.1	16.4	18.2
–	**Total time**	Attempted access to normal exec (end to end)	**9.0**	**19.5**	**21.9**
Metric	**Related Metrics**				
1	`mprotect()` call	Linux `mprotect()` (avg of R/W & RO updates)	2.0	4.5	5.9
2	R/W Window	Untraced window (R/W→AD transition)	4.0	8.8	11.2
3	`pkey_set()` call	Cost of `pkey_set()`	0.05	0.08	0.1

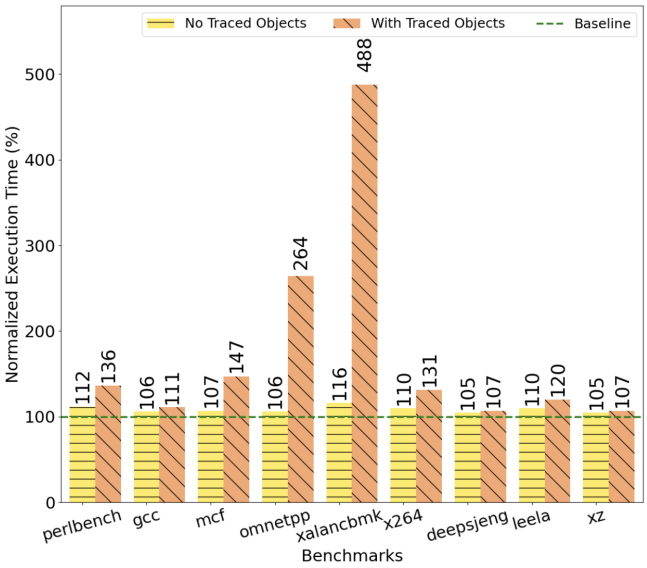

Figure 6: workload runtime comparisons between a `Ichnaea` run *with* and *without* any traced objects with SPECInt suite. Green line is un-instrumented runtime.

ObjOfInterest access →`SIGSEGV` handling →resumption of normal execution. Table 5 reports the CPU times for each stage of the handler (see Section 4.1 and Figure 3). Each row table shows the median, 99th percentile and mean of the top 1% of samples, with times in microseconds. Results are based on 2.4 million writes generated by running a custom write-intensive workload 200 times (1200 writes per run), with writes evenly split between global and heap objects to capture diverse access patterns. We only trace writes as they are more expensive to trace than reads as the written data must be stored in the trace memory pool but reads do not.

5.7 Realistic Use Case

We now explore a realistic use case — fuzzing — used to improve coverage in dynamic analysis use-cases. Table 6 summarizes the performance of *AFL++* [12] fuzzing our custom fuzzing workload[10] under three configurations: native execution (no instrumentation), with `Ichnaea` and with Intel Pin. X/Y means, X out of Y. Did not finish (DNF) means that even after 12 hours, the fuzzer didn't converge to a single Object access, so we stopped the experiment. The synthetic fuzzing target was designed to be memory access intensive with multiple branches, 20% (17) of which led to an ObjOfInterest access. All experiments were run with the same seed for fair comparison. Here, *covered* indicates that the path containing the ObjOfInterest was exercised by the fuzzer, while *traced* indicates that a ObjOfInterest access was successfully captured by the tracer. Time indicates the time it took for the fuzzer to exercise all the sites with ObjOfInterests.

Table 6: Fuzzing configurations: coverage, tracing, throughput and runtime.

Config	Covered ObjOfInterests	Traced ObjOfInterests	Time
Only fuzzer	17/17	**0**/17	4 min
Fuzzer + `Ichnaea`	17/17	**17**/17	25 min
Fuzzer + Intel Pin	**0**/17	**0**/17	DNF

In the experiments, the native fuzzer exercised all paths containing ObjOfInterests within 5 minutes, *without tracing any of them*. With `Ichnaea`, the same coverage was achieved in *25 minutes* and *all 17 accesses to ObjOfInterests were captured*. In contrast, Intel Pin failed to reach any ObjOfInterest paths even after 12 hours. These results show that while `Ichnaea` imposes overheads compared to the native configuration, it enables fuzzing assisted dynamic object tracing and makes it practical. Intel Pin, however, suffers from prohibitive slowdown and integration complexity, making it infeasible for the use case. Adapting Intel Pin was only possible through *AFL-pin* [46], a third-party wrapper that forwards AFL's fork-server and coverage feedback through Pin's instrumentation. This addresses research question `R2`, showing `Ichnaea` provides a

[10] See our website for details

feasible path to fuzzing assisted dynamic object tracing.

6 Discussion

Stack Objects are difficult to trace since locking their backing page would trigger a flood of pagefaults, as most program activity happens on the stack. Padding with variable length arrays [16] (VLAs) to push the ObjOfInterest onto its own page is one workaround, but compiler-driven memory reordering can defeat the isolation.

Tracing Kernel Reads requires detailed parsing of all syscall interfaces to determine which memory regions are being accessed. This is a huge engineering effort. However this is not a fundamental challenge.

Exercising the Program for Dynamic Analysis completely and in a sound manner is an undecidable problem. However for our purpose test suites, benchmarks and fuzzing can generally yield acceptable results.

Engineering limitations, `Ichnaea` has known limitations *e.g.,* bugs, un-optimized code, avoidable 6 μs interrupt handling time (see table 5, stage 2) due to expensive `libunwind` calls, incomplete instruction emulation (see appendix A.9) and `libc` syscall coverage limited to those exercised by our workloads. None are fundamental to our approach and can be addressed with additional engineering effort.

Tracing All objects Since `Ichnaea` is designed to trace a small, predefined subset of the total number of objects, the number of such targets `Ichnaea` can track, while maintaining the low overheads, is highly variable. If we trace all objects, `Ichnaea` may incur overheads higher than some of the existing tools *as every access is now an interrupt* each of which gets quite expensive. The exact point where instrumentation-based approaches overtake `Ichnaea` is dependent on multiple factors such the number of traced objects and their average access frequency.

7 Related Work

Compiler Based Instrumentation techniques *e.g.,* ASAN [38], Gleipnir [19] rely on instrumenting every load and store which effectively has the same overhead since after every load and store, the program needs to check all memory operands of the instruction against all ObjOfInterests, if there is a match, a trampoline call to log accesses and collect metadata. One can also reduce the number of instructions that need instrumentation by pruning it out from routines that can be deterministically said to not modify any ObjOfInterest. However, these pruning techniques fail or suffer from path explosion in complex codebases like postgresSql and nginx that heavily rely on indirect control flow etc. Furthermore, the complexity of adding all these compiler passes to first instrument and then prune is non-trivial and significantly discourages usage. All dynamically loaded libraries need to be instrumented, pruned and compiled into the main binary. We did not find any compiler based tool that was complete and did this with justifiable amount of effort.

Dthreads [28] is tool that enforces deterministic multi-threading for C/C++ program. It uses virtual memory protection technique to keep a check on shared data access. However, to fix the problem of false sharing, they have to split a multi-threaded program into a multiple programs sharing data which may not be idea or even feasible for many applications. Other solutions [3, 20–22] using similar techniques to tracing various things using virtual memory protections also suffer from loses described in section 2.1.3.

Hardware debug registers in X86 [17], ARM [4] also provide a fast and efficient way of tracing often used in debuggers like gdb watchpoints [13] and in [18] to isolate and monitor certain memory regions that contain secret keys. However, there's only a few per-thread word-sized watch points that trap on every access, making them too scarce, fine-grained and context-local to trace multiple (more than 4) arbitrary-sized objects. In gdb, when the system runs out of the few hardware debug registers, it switches to single stepping mode (basically looking at every load and store). Further, combining tools like gdb with test-suites, benchmark and fuzzers may require significant amount of effort.

A Appendix

A.1 Access control granularity

Since modern MMUs enforce protection at *page* granularity, Ichnaea must change access rights for an entire 4 KiB page even when tracing single 4-byte object. For global ObjOfInterests, unrelated objects sharing the same page will also fault on accesses. Ichnaea handles such collateral SIGSEGVs like traced objects but skips logging, limiting overhead to a handler entry-exit cycle. Workarounds exist but trade usability for precision. Dedicated ELF sections aligned to page boundaries avoid interference but require linker scripts; we provide a lightweight macro (ICHNAEA_ISOLATE_GLOBAL) to isolate globals dedicated sections (see Line #1 in Listing 2). Alternatives include wrapping variables in a struct/union, which is portable but intrusive or object renaming, where a global ObjOfInterest is aliased within a page-aligned structure —– effective but Clang-specific. Given these trade-offs, the default strategy is to tolerate rare collateral faults and rely on the handler's fast path to keep overhead low.

A.2 Cost of a *mprotect()* call

Changing page permissions with mprotect [31] is inherently expensive due to several micro-architectural and OS-level effects. First, each permission change requires a transition into the kernel, incurring a syscall and context-switch overhead. Second, updating page permissions forces the kernel to modify page-table entries, which triggers page-table walks and invalidates cached TLB translations. On multicore systems, the kernel must broadcast inter-processor interrupts (IPIs) to flush or synchronize TLB entries across all cores that may have accessed the page, introducing huge additional latency. Collectively, the syscall cost, page-table manipulation and cross-core TLB shootdowns make mprotect() orders of magnitude slow. A mprotect call on a single threaded application roughly costs 2.0µs (see *Related Metrics* in Table 5) which is a significant amount of time, this cost is further multiplied by the number of threads running in the program.

A.3 mprotect based object tracing

Traditional way of access control for memory uses the mprotect. Although it is lossy and slow, this technique is still faster than Intel Pin. To realize this, we modified Ichnaea to use mprotect instead of pkey_set() call to lock and unlock the ObjOfInterests. No further change was required.

A.4 Output Format of Trace

Listing 1 shows a sample of decoded object trace generated by Ichnaea running an Nginx with 50 traced objects. This snapshot shows the runtime state of an ObjOfInterest named *http_core*. It contains details such as the object's type *(ngx_module_t)*, size in memory and the number of snapshots taken so far. Each snapshot then captures the values of its fields (*e.g.,* indices, version, signature, context pointers and names), including both raw values (like numeric IDs or memory addresses) and any resolved symbolic information (such as function names).

Listing 1: Sample of a decoded run in json

```
"http_core": {
 "type":"ngx_module_t",
 "size": 200,
 "total_snapshots": 4,
 "snapshots": {
    "0": {
     "is_read" : false,
     "call_stack" : [......, main+0x55 (nginx) ],
     "pid" : 115200,
     "tid" : 177234,
     "data": {
       "ngx_uint_t␣ctx_index": 18446744073709551615,
       "ngx_uint_t␣index": 18446744073709551615,
       "char␣*␣name": 0,
       "ngx_uint_t␣spare0": [
           "0␣x0",
            {
               "resolved_fn_name␣":"Null"
            }
        ],
       "ngx_uint_t␣spare1": 0,
       "ngx_uint_t␣version": 1024000,
       "const␣char␣*␣signature": 103329564877648,
       "void␣*␣ctx": [
           "0␣x5dfa4a04e0e0",
            {
               "resolved_fn_name␣":"Unknown"
            }
        ],.......
```

A.5 Annotating Custom Allocators

Listing 2 shows how Nginx's custom allocator can be instrumented with Ichnaea 's macros. The ICHNAEA_ISOLATE_GLOBAL and ICHNAEA_MARK_PTR directives identify global pointers to be traced, while ICHNAEA_MARK_ALLOC_CHK tags allocator calls so that newly created objects are automatically tracked at runtime. This lightweight annotation ensures that heap-allocated ObjOfInterests can be identified and traced by the tracer.

Listing 2: Sample of Nginx's custom allocator instrumented with our macro

```
void * heap_obj_ptr ICHNAEA_ISOLATE_GLOBAL;
ICHNAEA_MARK_PTR(heap_obj_ptr);

ngx_pool_t *
ngx_create_pool(size_t size, ngx_log_t *log)
{
    ICHNAEA_MARK_ALLOC_CHK(size , ngx_pool_t * )
    ngx_pool_t  *p;
    ...........
    return p;
}
```

A.6 Example of LibC Wrapper

Listing 3 illustrates how a standard libc *read* call is wrapped to trace kernel writes. Before invoking the real read, the wrapper temporarily unlocks only those pages that contain ObjOfInterests, ensuring that kernel writes to traced objects can proceed safely. Once the syscall completes, the same pages are re-locked to restore protection. This mechanism guarantees that updates originating from the kernel are observed without disrupting normal I/O behavior.

Listing 3: Sample read libc call wrapper for tracing kernel writes

```
ssize_t read(int fd, void *buf, size_t nbytes)  {
  void * pg_aligned_addr_of_buffer =
    (void *)(((uintptr_t)buf) & ~(PAGE_SIZE - 1));

  wrapper_objsnf_unlock_all_objs_or_one(
    pg_aligned_addr_of_buffer
    );

  size_t rtn =
    wrapper_objsnf_real_read(fd, buf, nbytes);

  wrapper_objsnf_lock_all_objs_or_none(
    pg_aligned_addr_of_buffer
    );

  return rtn;
}
```

A.7 Improving Isolated heap allocations

Isolating heap objects is done by allocating an individual page to each dynamically allocated *ObjOfInterest* even if they are as small as a few bytes. This however wastes memory capacity and in case of workloads that allocate heap *ObjOfInterests* frequently, also requires the actual *libc allocators* to frequently request new pages from the kernel that in turn reduces performance by adding frequent *syscall* overheads. This can be solved by keeping track of what parts of isolated memory that was allocated for an *ObjOfInterest* is unused and use it for allocating future *ObjOfInterests* as well. This is possible with some engineering effort as doing this is equivalent to writing another *malloc* for *ObjOfInterests*. However we do not implement this in our prototype. Details on how we handle heap objects can be found in Section 4.5.

A.8 Feature Comparison with intel Pin

While raw performance is one of the major advantages of our approach, Table 7 highlights how `Ichnaea` also differs in feature coverage and usability. `Ichnaea` uniquely supports tracing kernel writes, a capability Pin doesn't support[11]. Both Pin and our framework can trace global and heap objects. Both Intel Pin and `Ichnaea` don't support tracing of stack variables. However, with significant engineering effort and compiler tricks it is possible for both cases. Neither tool requires manual discovery of write sites. Both Intel Pin and `Ichnaea` can identify dynamic allocations of ObjOfInterests. However, Pin does not support dynamic allocation out of the box.

Finally, with respect to setup and startup, both frameworks are simple to initialize in principle, but Pin's startup phase incurs high cost compared to the lightweight startup of `Ichnaea`. Together, these comparisons emphasize that our contributions go beyond speed alone — they also expand what can be traced and reduce the practical burden on users while providing rich context info. This further answers **R1** since making tracing easily usable and efficient increases its adoption in software pipelines thus improving software reliability.

Table 7: Feature comparison between Intel Pin and `Ichnaea`.

Feature	**Intel Pin**	**`Ichnaea`**
Supports Global / Heap / Stack	Yes / Yes / No	Yes / Yes / No
Needs manual write-site discovery?	No	No
Needs manual alloc-site discovery?	No	No
Lossy?	No	No
Runtime cost	High	Very Low
Supports Fuzzing	No	Yes[12]
Kernel writes tracing	No	Yes
Setup cost	Moderate	Low
Startup cost	High	Low

A.9 Fallback strategy to instruction emulation

Due to complexity, emulating all x86 instruction is challenging and requires considerable engineering effort. When `Ichnaea` encounters such instructions, it employs a slower fallback path by planting a breakpoint at the instruction immediately following the faulting one and then allowing the original instruction to execute on the CPU after making the ObjOfInterest accessible. This approach introduces a subtle hazard in multi-threaded workloads: the injected breakpoint resides in the process's shared `.text` section, making it visible to all threads. If another thread happens to be executing the same code path while operating on unrelated data it will still hit the breakpoint and be diverted into the handler, potentially corrupting execution despite object independence. Although this scenario requires both code-path overlap and precise timing between the writing thread and other concurrent threads and is therefore unlikely and hard to measure, it cannot be ruled out even when each thread operates on disjoint objects since the code segment itself is inherently

[11] Tracing kernel writes is possible in pin by mimicking our technique, however, due to pin's design it will incur significant overhead thus reducing usability even further

[12] `Ichnaea` supports fuzzing with, see Section: 5.7

Listing 4: Invocation Example of Ichnaea

```
#include <stdio.h>
......
// ------ Inclusion of our header file ---------
// The header file defines weak refs to our main API
// calls to signal runtime definition
#include <.../ichnaea.h>
....
double object_of_intrest;

int main () {
    // ------ API Usage Example ---------

    // Runtime check to verify availability of API
    if (ichnaea_register_object) {
        // Main API Interface
        ichnaea_register_object(
              &object_of_intrest,
            sizeof(object_of_intrest),
            "Object␣of␣Intrest",
            "double"
        ); ......
    }}
// ------ Invocation example ---------

Compile the program under test
user@machine:~$ make -j`nproc`

Run the program under test using:
~$ LD_PRELOAD=libIchnaea.so ./my_binary ..
```

shared. However, we can get rid of this problem given enough engineering effort.

A.10 Invocation

A sample of `Ichnaea`'s invocation procedure is shown in listing 4

A.11 Slow Path (Breakpoint-Based Handling).

If decoding or emulation fails (*e.g.,* atomic instructions, SIMD stores), the handler falls back to a *"slow"* path. The slow path can be eliminated with engineering effort as it causes some unconventional problems. The slow path does the following:*i.e.,*

1. *instruction analysis:* the faulting instruction is disassembled to determine its length

2. *breakpoint insertion:* a software interrupt (also called breakpoint or INT3) is injected immediately *after* the instruction; the existing byte of memory that the interrupt replaced is saved in a per-thread interrupt context

3. *temporary unlock:* the page containing the object is marked RW

4. *resume execution:* the faulting instruction *re-executes* and completes the write natively. Execution then continues to the next instruction which is the software interrupt we inserted in step (2).

The subsequent interrupt `SIGTRAP` is again handled by our custom interrupt handler . The handler then does the following:

1. *Relock:* the object's page is returned to RO.

2. *Restore instruction:* the original byte replaced by the breakpoint location is restored from interrupt context.

3. *Logging:* if the write target is a traced object, the store is logged into the memory pool.

4. *Resume execution:* the instruction pointer is set to the original restored instruction.

5. *Exit:* at ProgramUndrTest's exit, `Ichnaea` gathers all snapshot data collected in the memory pool and writes it to disk.

A.12 Handling Custom Allocators.

The mechanism assumes that the application invokes the *glibc* allocator directly (*e.g., malloc calloc/realloc*). However, if a workload introduces its own layer on top of *libc allocs*, (*e.g.,* a `custom_malloc()` that wraps `malloc()`), `Ichnaea` only sees the intermediate function and cannot match the request to a traced variable. In such cases, developers must annotate the helper itself using our macro. Listing 2 in appendix shows an example with `nginx`, where the macro `ICHNAEA_MARK_ALLOC` is applied to custom allocators. The macro takes the requested size and type cast as arguments and if the allocation is for a traced object, it overrides the custom allocator to return a private, isolated page. If the user needs to modify the allocated memory in their custom allocator, we also provide a macro that returns a boolean that can be used to write custom allocation logic for ObjOfInterest allocation. Our original mechanism is easily adaptable to custom allocators using simple macros (see Listing 2 for details).

Extracting Database Access-Control Policies From Web Applications

Wen Zhang* *UC Berkeley*
Dev Bali *UC Berkeley*
Jamison Kerney *UC Berkeley*
Aurojit Panda *NYU*
Scott Shenker *UC Berkeley and ICSI*

Abstract

To safeguard sensitive user data, web developers typically rely on implicit access-control policies, which they implement using access checks and query filters. This ad hoc approach is error-prone as these scattered checks and filters are easy to misplace or misspecify, and the lack of an explicit policy precludes external access-control enforcement. More critically, it is difficult for humans to discern what policy is embedded in application code (i.e., what data the application may access)—an issue that worsens as development teams evolve.

This paper tackles *policy extraction*: the task of extracting the access-control policy embedded in an application by summarizing its data queries. An extracted policy, once vetted for errors, can stand alone as a specification for the application's data access, and can be enforced to ensure compliance as code changes over time. We introduce Ote, a policy extractor for Ruby on Rails web applications. Ote uses concolic execution to explore execution paths through the application, generating traces of SQL queries and conditions that trigger them. It then merges and simplifies these traces into a final policy that aligns with the observed behaviors. We applied Ote to three real-world applications and compared extracted policies to handwritten ones, revealing several errors in the latter.

1 Introduction

Protecting sensitive data from unauthorized access is a critical concern for today's web applications. Therefore, when building web applications, developers must determine what *access-control policy* the application should enact—for example, a university might want a policy that ensures a student's grades are visible only to the student and their instructors.

In today's applications, access-control policies are embedded in application code. Furthermore, in most cases they are spread across several functions and in the filter predicates of multiple database queries. This practice is error-prone: Missing or misspecified access checks have previously led to sensitive-data exposure [10, 36, 46, 47, 57, 89]. But more fundamentally, because the policy is never stated explicitly, it is difficult for anyone other than the application's developer to understand *what* policy is embedded in the code. Worse, as time passes, even the application development team is unlikely to remember the policy, and is unlikely to be able to reconstruct it from application code. While there have been research frameworks that require explicit policy specification [2, 6, 11, 105, 106], we aim to address legacy applications rather than requiring them to be rewritten in such frameworks.

This paper tackles the task of *policy extraction*: extracting a web application's implicitly embedded access-control policy by summarizing its possible data accesses. A human then reviews the extracted policy to better understand the application's data accesses, ensuring they are within the bounds of intended data revelations. If not, the application likely has an access-check bug to be fixed. Once reviewed, the policy can stand alone as a specification for the application's data accesses and can optionally be enforced using an enforcer [56, 58, 107] to ensure continued compliance.

We present an approach for extracting policies from legacy web applications. Our approach begins by exploring execution paths through application code using concolic execution [35, 83], producing transcripts that record the conditions under which SQL queries are issued (§ 4). These transcripts are then merged and simplified to derive a policy that allows each recorded query to be issued under its conditions (§ 5).

A key challenge here is scalability: Web-backend code is often complex with many branches, making exhaustive path exploration infeasible. But we empirically observe that the logic governing query issuance typically relies on only a small set of simple operations (§ 4.1). We thus tailor concolic execution to track only those operations, reducing the path space (and implementation effort). We further prune exploration using an LLM-based relevance judge (§ 4.6) that identifies and ignores branches unrelated to data access, reducing exploration time from potentially days to mere hours.

We implemented this approach in Ote, a policy-extraction tool for web applications written in Ruby on Rails. We

*Now at Google.

then applied Ote to three real-world applications, two of which we had previously written policies for by hand [107]. When we compared the extracted policies to the handwritten ones (§ 7.6), we identified several formerly unknown errors in the latter—including a few overly permissive views that reveal sensitive data to unauthorized users. This underscores the difficulty of understanding access-control logic in complex legacy applications and the utility of policy extraction in aiding this understanding. A further review of the extracted policies uncovered a subtle bug we had inadvertently introduced into application code that silently disabled an access check. These findings show that extracting and then inspecting policies results in a clearer understanding of what the program does—and should do—than current practice provides.

Due to its use of concolic execution and an LLM relevance judge, Ote cannot guarantee that the extracted policy covers all possible queries or captures every condition under which queries are issued (§ 3.2). Ote also needs the user to specify certain input constraints (§ 3.1) and to review the relevance judge's results (§ 4.6), supports only a subset of SQL (§ 3.2), and could use a better user interface for policy auditing. Even so, our evaluation (§ 7) demonstrates that for real-world applications, Ote extracts policies that are immediately useful, identifying several errors in handwritten policies and application code. These results show that Ote already provides concrete, practical value and represents a meaningful step toward improving data security in existing web applications.

2 Motivation and Background

2.1 Challenges of Policy Creation

We were prompted to tackle the policy-extraction problem by our earlier experience hand-crafting policies for existing web applications. A few years ago, while investigating externally enforced access control for web applications,[1] we took open-source applications, chose several representative URL endpoints, and tried our best to write down policies allowing the data accesses needed for their intended function [107, § 8.1].

This process was extremely tedious and time-consuming. We reviewed documentation, inspected database schemas, experimented with the applications using sample data, and read their source code. Using this information and common sense, we formulated policies that we thought would allow the endpoints to function correctly while protecting sensitive data. Despite our best efforts, we often discovered errors in our drafts, including an omission that would have leaked sensitive data—one that we only later discovered by chance.

Our struggle was not unique: Policy creation is known as a major challenge across security domains including role-based [69, § 6.5], attribute-based [27, p. 39], and relationship-based [20] access control, securing cloud resources [81], and sandboxing syscalls [71]. While solutions have been proposed for some domains (§ 8), generating database policies for web applications has remained an open problem that is uniquely challenging, due to both the dynamism of web applications and the fine granularity of the policies required.

[1] By "externally enforced", we mean having an enforcer program mediate the application's database queries, preventing accesses deemed unauthorized according to an access-control policy [49, 56, 58, 107].

Listing 1 A handler that displays a course's grade sheet.

```
def view_grade_sheet(db, session, req):
  role = db.sql(
    "SELECT * FROM roles "
    "WHERE user_id = ? AND course_id = ?",
    session["user_id"], req["course_id"])
  if role is None: raise Http404
  if not role.is_instructor: raise Http403
  all_grades = db.sql(
    "SELECT * FROM grades "
    "WHERE course_id = ?", role.course_id)
  return format_html(all_grades, ...)
```

Listing 2 An example policy for the handler in Listing 1.

(V_1)
```
SELECT * FROM roles
WHERE user_id = MyUserId
```
A user can view their role (if any) in any course.

(V_2)
```
SELECT grades.* FROM roles, grades
WHERE roles.user_id = MyUserId
  AND roles.is_instructor
  AND grades.course_id = roles.course_id
```
An instructor for a course can view all grades.

2.2 Policy as SQL View Definitions

Before delving into how Ote extracts policies, we first describe how our access-control policies are specified.

We target web applications that store data in a relational database; when a user visits a page, the application issues SQL queries on the user's behalf and renders the page using the query results. In this context, a classic way to specify access-control policies is to use a list of *view definitions* [62, 78, 79], which are SQL `SELECT` statements—parameterized by session parameters like the current user ID—that define information in the database that a user is allowed to access.

Under a view-based policy, a query is allowed only if it can be fully answered using the views. This criterion extends to a program that (conditionally) issues multiple queries, by treating the program as "one big query" that returns the results of its constituent queries. These notions can be made precise based on *query determinacy* [65], but in the interest of space, we omit the formal definitions and offer an example instead.[2]

Example 2.1. Suppose a course-management site has a web request handler that displays a course's grade sheet (Listing 1).

[2] We refer interested readers to the literature for both theoretical [3, 50, 65, 109] and practical [14, 15, 78, 107] treatments of this subject.

It ensures that the user is an instructor before fetching grades.

Note that the handler has access to both *session parameters* (user ID) and *request parameters* (course ID). Session parameters are trusted (e.g., set by an authentication mechanism), and may appear in the policy and dictate the extent of allowed data access. Request parameters are untrusted (e.g., parsed from an HTTP request) and must not appear in the policy.

A policy for this handler might look like Listing 2, where `MyUserId` denotes the user-ID session parameter. Notably, it does not reference the course-ID request parameter, instead allowing the handler's queries *for any course ID*. This policy precisely captures the information the handler can query. ◀

Like prior work in database access control [4, 14, 15, 49, 56, 78, 86, 107], we focus on extracting policies for database *reads* (`SELECT`s) only. Similar techniques can be used to extract conditions for other operations, although our policy language (§ 3.2) and algorithms (§ 5) would need to be extended.

3 Overview

Given an application, the ideal policy extractor would produce a view-based access-control policy that satisfies:

Completeness Allows all queries the application can issue.

Tightness Reveals as little information as possible subject to completeness.

Conciseness Has a short representation in SQL.

For example, given Listing 1 (but written in a real web framework), we would like to extract the policy in Listing 2.

Policy extraction is challenging, and Ote is not guaranteed to meet all three goals (see § 3.2). Nevertheless, we show in § 7 that Ote produces policies that are useful in practice.

3.1 Workflow

Before discussing how we approach these goals, we first describe Ote's workflow from a user's perspective (Figure 1).

Suppose a user wants to extract a policy from a web application. We assume that the application is written in a supported framework (Ruby on Rails) and that the user is familiar with the application's functionality.

The user starts by declaring the handlers to analyze and providing the application's *database constraints*. Ote supports two forms of database constraints, which cover all the constraints we encountered:

1. *A set of columns in a table is unique.* For example, a uniqueness constraint on `roles(user_id, course_id)` states that a user has at most one role in a course.
2. *A query Q_1's result is contained in a query Q_2's result.* Such constraints are commonly used to express foreign-key invariants: e.g., every `assignments.course_id` must appear as some `courses.id`.

These constraints describe the application's valid database states; Ote uses them to keep exploration within those states during concolic execution (§ 4.4) and to simplify the generated policy (§ 5.2). To reduce the user's burden, Ote provides a tool that can automatically generate most required constraints from a Ruby on Rails application's schema and models (§§ 6 and 7.1.3).

The user then packages the application into a Docker container and invokes Ote, which:

1. Explores execution paths through the handlers via concolic execution, producing *transcripts* that record the branches taken and the SQL queries issued (§ 4);
2. For each individual handler, analyzes the transcripts to generate a preliminary policy allowing each query to be issued under its recorded conditions (§§ 5.1 to 5.3);
3. Merges the individual policies and prunes any redundant views, producing a final policy (§ 5.4).

Next, the user inspects the generated policy, using their domain knowledge of the application's privacy requirements:

- A policy that is too broad can indicate an access-control bug. The user can investigate the queries that yielded a too-broad view using inputs logged by concolic execution (§ 6) and modify the application if appropriate.
- A policy that is too tight can be *broadened* to permit more intended data accesses. This may simplify the policy by removing filters or by replacing multiple views with a single one. Ote assists with policy broadening: The user adds a broader view to the policy, either before or after view pruning, and then invokes pruning (Step 3) to automatically remove now-redundant views (§ 7.7).

Once satisfied, the user can optionally enforce the policy to ensure the application's current and future compliance.

3.2 Assumptions, Scope, and Utility

Queries At its core, Ote supports project-select-join (PSJ) queries in set semantics. These are queries that (1) always return distinct rows, and (2) have the form:

```
SELECT [DISTINCT] col1, col2, ...
FROM tbl1, tbl2, ... WHERE ...
```
(PSJ)

Also supported are common queries that Ote can mechanically rewrite into this form, such as queries with inner joins or of the form `SELECT 1 FROM tbl1, tbl2, ... WHERE ... LIMIT 1`.

We found that the distinct-rows assumption does not limit utility—we have never encountered queries that may return duplicate rows in our evaluation. But applications do issue queries more complex than PSJ; this is handled differently in different stages: The concolic-execution driver precisely models richer SQL features (§ 4.4), but view generation and pruning must approximate complex queries using PSJ (§§ 5.3 and 7.3). We plan to extend our prototype to support more complex queries.

Policies Ote generates policies consisting of PSJ views, which are expressive enough for the applications we studied.

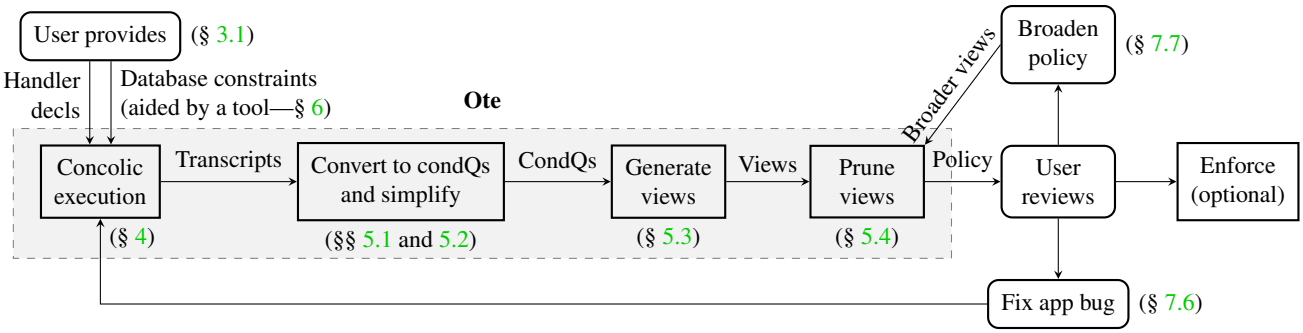

Figure 1: Policy extraction workflow. "CondQs" stands for conditioned queries (§ 5.1).

A notable limitation is that PSJ views cannot generally express negations (e.g., "Q_1 is allowed only if Q_2 returns no rows"). Negations complicate approximating a query's information content [97, §2.2] and can slow down enforcement [107, §6], so we defer handling negations to future work.

Non-guarantees Ote *does not guarantee* completeness or tightness: It may generate a policy that disallows a query issued by the application, or one that can be tightened while allowing the same application queries. This is because:

- Concolic execution can miss execution paths as the input space explored is bounded.
- Uninstrumented operations in the *query-issuing core* can lead to incomplete path conditions (§ 4.1).
- A pruning optimization uses an LLM-based relevance judge, which can make mistakes (§ 4.6).
- Approximating complex queries using PSJ can make a policy more, or less, restrictive than ideal (§ 7.3).

In general, complete-and-tight policy extraction for Turing-complete code is impossible [77]. But in practice, Ote can produce policies more accurate than handwritten ones (§ 7.6).

Similarly, Ote *does not guarantee* that it produces the most concise SQL representation, but its simplification and pruning steps (§ 5) make it feasible to inspect the policy (§ 7.6).

Application assumptions Ote uses a modified Ruby interpreter and Ruby on Rails framework for concolic execution (§ 4.5), and so it supports only applications written in Rails. However, our approach generalizes to other languages.

Ote's effectiveness depends on a "simple query-issuing core" assumption (§ 4.1). In short, we assume that the application's SQL query issuance depends only on *simple expressions*—ones that use only operations instrumented by Ote's Ruby interpreter. Most notably, Ote does not instrument string formatting (doing so would complicate SMT solving), and so it requires the application to issue SQL queries in parameterized form rather than splicing parameters into query strings within Ruby. Fortunately, idiomatic Rails code already issues parameterized queries by default, and the few places in our evaluation where this is not the case were easy to fix (§ 7.1).

4 Exploring Executions

Ote begins by exploring paths through application code via concolic execution. We open this section with some empirical observations about typical web applications that motivated our use of concolic execution.

4.1 Observation: Simple Query-issuing Cores

Given a web application's codebase, consider all program statements that issue SQL queries. Informally, imagine the backward program slice [100] from these statements. This slice, which we call the *query-issuing core*, is the part relevant to policy extraction: It consists of the program components on which query issuance has a control- or data-dependence. Thus, it includes code that computes query parameters or determines whether later queries are issued, but excludes code used only for localization, formatting, HTML/JSON generation, logging, etc. In Listing 1, for instance, the two queries (Lines 2 and 8) are in the query-issuing core, as are the emptiness and instructor checks (Lines 6 and 7) that determine whether the second query is issued; the final HTML-rendering line (Line 11) is outside the core.

While the codebase as a whole can be complex, it has been observed [24, 84] that the query-issuing core of a typical web application is often *simple*. We confirm this observation—for the applications we studied, the core consists mostly of:

1. Conditionals that test if a query's result set is empty [84, § 2] or check basic conditions on primitive values (e.g., checking for equality or nullity) [85, § 6.2];
2. Loops over a query's result set [84, § 2] with no loop-carried dependencies [24, § 4]; and
3. Trivial data-flow to query statements—e.g., passing a value returned by one query to another. (Given that the application issues parameterized SQL queries, no query-string formatting operation appears in the data flow.)

Our goal is therefore to analyze this simple query-issuing core without spending resources on the surrounding codebase. This is challenging because the query-issuing core is not syntactically isolated. For instance, in a typical Ruby on

Rails application, SQL queries may be issued from controller actions, view templates, view helpers, and external libraries, each of which can also contain substantial code unrelated to query issuance. To address this challenge, we use concolic execution, which allows Ote to analyze the query-issuing core without syntactically isolating it.

4.2 Concolic Execution: What and Why

In concolic execution [35, 83], a program is executed repeatedly using concrete inputs that have symbolic variables attached. As the program runs, its state is tracked both concretely and symbolically. When the program branches on a symbolic condition, the condition and its outcome are recorded. This produces a conjunction of constraints—the *path conditions*—that led execution down a path. The conjuncts are then negated using a solver to generate new inputs (up to a bound) that will steer execution down other paths.

We chose concolic execution because it offers a "pay-as-you-go" model for symbolic tracking: We selectively instrument the operations that might appear in the query-issuing core, and the rest will simply execute concretely by default. This strategy reduces not only our instrumentation effort, but also the number of paths explored—a branch on an uninstrumented condition will not lead to a new path.

Note that if an application's query-issuing core is *not simple*—so it contains uninstrumented operations—then Ote may miss certain queries or conditions, leading to a policy that is either broader or tighter than ideal. We discuss this case, with examples and mitigations, in § 4.7.

4.3 System Architecture

Ote has a *driver* that generates inputs and concurrent *executors* that run application code on each input. The driver tracks explored paths in a prefix tree; for every prefix, it negates the last condition and invokes an SMT solver to generate a new input. (The driver keeps the prefix tree in memory and generates inputs sequentially, but both can be relaxed to improve performance.) It then sends the input to an executor, which runs a handler using an instrumented Ruby interpreter and Ruby on Rails framework (§ 4.5) and sends back a *transcript* capturing the path conditions and queries issued (§ 4.4). Exploration terminates when all prefixes have been visited.

4.4 Symbolic Modeling and Input Generation

Concolic execution requires symbolically modeling the handler's inputs, consisting of the database and session/request parameters. To ensure termination, the input space must be bounded. Following prior work [23], we model the database as tables containing a bounded number of symbolic rows (our prototype uses a bound of 2). The driver asserts the application's database constraints (§ 3.1), so it explores only valid database states. Inspired by UrFlow's loop analysis [24, § 4.2], we also restrict the input space so that each query returns at most one row. For simplicity, we will describe our algorithms under this assumption, even though they can be extended to handle queries returning multiple rows.

Under this modeling, a transcript is a sequence of operations performed by the application with two types of records:

1. $\textsc{Query}_i(sql, params, isEmpty)$, meaning the i^{th} query issued was the query *sql* with parameters *params*, and the result set was empty if *isEmpty* is true.[3] If not empty, a symbol r_i is introduced to represent the result row.
2. $\textsc{Branch}(cond, outcome)$, meaning the condition *cond* was branched on, and the *outcome* (either true or false) branch was taken. The condition can reference session and request parameters as well as columns returned by previous queries (e.g., "$r_5.author_id = MyUserId$").

Listing 3 shows an example transcript from a run of the handler in Listing 1, when the user is an instructor.

Our SMT encoding represents bounded database tables using conditional tables [38] and uses the theory of integers to model all database values [37], including timestamps and strings. Each nullable value is accompanied by a boolean indicating if it is `NULL`. This simple encoding naturally supports equality and arithmetic operations but not string operations, a limitation that can be lifted using a string solver [16, 53].

Similar to prior work [37], we encode a subset of SQL into SMT on bounded symbolic tables. Our encoding supports left- and inner-joins and count- and sum-aggregations. One notable unsupported feature is ordering, which we have not needed under the assumption that each query returns at most one row.[4] We implement several optimizations for input generation: reusing Z3 AST objects, calling the solver incrementally, and caching conflicts (resulting in infeasible paths) using unsat cores [82].

4.5 Instrumentation and Tracking

To maintain symbolic state, we modified the JRuby interpreter [42] to add an optional "symbolic expression" field to each Ruby object. For each class that we want represented symbolically, we implement a `with_sym` method that returns a clone with a symbolic expression attached, and amend methods that we want instrumented to attach symbolic expressions to their results. Unmodified methods simply return an object with no expression attached, concretizing the result as desired.

We implemented symbolic representations of ten classes (`String`, `Fixnum`, etc.) covering all symbolic inputs in our evaluation, and instrumented simple operations (equality, null-check, etc.) that appear in the query-issuing core. We ensured that instances of a singleton object (`true`, `false`, `nil`) with

[3] Ote assumes that the application always inspects the result set of a query by branching on its emptiness, and does not track it as a separate BRANCH.

[4] Ordering cannot be ignored when a `LIMIT` clause can truncate a result set with multiple distinct rows; we encountered no such queries in our evaluation.

Listing 3 A transcript from a run of the handler in Listing 1, when the user is an instructor for the course.

1. QUERY$_1$(`SELECT * FROM roles WHERE user_id = ? AND course_id = ?`, $\langle$`MyUserId`, `CourseId`$\rangle$, $isEmpty = false$)
2. BRANCH($r_1.is_instructor, outcome = true$)
3. QUERY$_2$(`SELECT * FROM grades WHERE course_id = ?`, $\langle r_1.course_id \rangle, isEmpty = false$)

different symbolic expressions are treated as equal, and that a mutating method clears an object's symbolic expression by default.

To track queries and branches, we added a library for maintaining transcript records, exposing methods `record_query` and `record_branch` (§ 4.4). We modify the Rails database layer to call `record_query` after every query, and modify JRuby's `isTrue` and `isFalse` methods (which evaluate an object's truthiness and falsiness) to call `record_branch` with the object's symbolic expression if it has one. The `record` methods also save the stack trace at which the query or branch is evaluated, for use in relevance-based pruning (§ 4.6).

4.6 Skipping Irrelevant Branches

Concolic execution suffers from *path explosion*: The number of feasible paths can grow exponentially with the number of branches. Ote is no exception: Without further optimization, five web handlers in our evaluation (§ 7.3) failed to finish after ten hours and would likely have required days. Thus, we must aggressively reduce the paths explored, but without missing any query-issuing behavior.

Irrelevant conditionals Even with selective instrumentation (§ 4.2), many tracked branches lie outside the query-issuing core.[5] Consider the following example:

Listing 4 An irrelevant conditional from Autolab.

```
<% if submission.version == 0 then %>
  <font size=-2>Unofficial</font>
<% else %>
  <%= submission.version %>
<% end %>
```

The highlighted conditional affects only HTML generation and has no bearing on data access; negating such conditionals produces new paths that reveal no new query behavior. Skipping these *irrelevant* conditionals can reduce the exploration space dramatically, since each may cut the path count in half.

Identifying irrelevance using an LLM Statically identifying irrelevant conditionals is hard in Ruby on Rails [88] due to dynamic language features and runtime template compilation [72, § 6.2]. However, many irrelevant branches follow recognizable patterns—e.g., conditionals that issue no queries and mutate no state. Rather than manually encoding such patterns as heuristics, we draw on recent successes in using LLMs to complement software analysis [51, 63, 90, 95] and delegate the identification of irrelevant conditionals to a *relevance judge* implemented using an LLM-based coding agent.

[5] Even if the core is simple, not every simple condition is in the core!

Listing 5 An abridged relevance-judge output for the conditional in Listing 4, produced by `gpt-5` in 24 seconds (§ 7.5).

```
IRRELEVANT

The conditional `submission.version == 0` [...]
    only controls presentation text:
- If true, it renders the literal "Unofficial".
- If false, it renders the numeric `submission.
    version`.
[...]
```

When Ote encounters a conditional, it creates a prompt containing a definition of irrelevance, the conditional, and the stack trace at which the conditional was evaluated. It sends the prompt to a coding agent, which autonomously inspects source files and answers "relevant", "irrelevant", or "unsure" (treated as relevant), plus an explanation. The prompt is generic and contains no framework- or application-specific details. Ote records the verdict and explanation for later inspection; see Listing 5 for an example.

Because the relevance judge can take minutes to render a verdict (§ 7.5), Ote calls it asynchronously. Exploration carries on, assuming the conditional is relevant; if the judge later designates a conditional as irrelevant, the driver retroactively records it as such and takes it into account in the future.

Ote avoids calling the relevance judge when (1) the conditional's designation is known (e.g., "Q returns non-empty" is relevant if Q's result is used in another query), or (2) the conditional is *vacuous*—i.e., its negation is infeasible given the relevant conditionals that precede it. Because a conditional's vacuousness may depend on the relevance of its predecessors, when Ote marks a conditional as irrelevant, it recomputes the vacuousness of any formerly-vacuous later conditionals.

Pruning Using the judge's verdicts, the driver avoids negating irrelevant conjuncts in path conditions, skips paths whose subsequence of *relevant* conditions is already covered, and drops irrelevant conditions from the final transcript.

Accuracy Because the relevance judge uses an LLM, it cannot guarantee accuracy. To defend against mistakes, Ote exposes the verdicts and explanations for human review, and al-

lows the human to guide the judge by adding inline comments prefixed with "RELEVANCE-HINT", which the LLM agent is instructed to consider. In our evaluation (§ 7.1), we added hints primarily to compensate for the coding agent's limited understanding of Rails and external libraries. With these hints, we verified the judge's irrelevance verdicts to be accurate.

4.7 When the Core Is Not Simple

The simple query-issuing core assumption (§ 4.1) is not true for all practical applications. It can be violated in two ways.

Complex control-flow conditions This case arises when a query's issuance depends on a complex expression. For example, diaspora crashes if a photo's `url` is not a valid URL, thus preventing later queries; the URL-validity condition relies on regex-matching operations, which Ote does not instrument.

Suppose a query Q is issued conditioned on an expression C with some uninstrumented operations. This may cause Ote to generate a policy that is either broader or tighter than ideal:

1. If Ote happens to generate an input that satisfies C (this is not guaranteed because the driver is unaware of C), then Q will appear as a conditioned query *without* C in its condition, leading to a policy broader than ideal.
2. If Ote never generates an input that satisfies C, then Q may not appear in any transcript, leading to a policy that may not allow Q—which is tighter than ideal.

In practice, Case 1 has not been a problem for us because (1) the complex condition C typically reflects business logic and has no privacy implications (§ 7.7), and (2) query Q is likely also issued elsewhere under a simpler condition. Case 2 is problematic for validations (e.g., URL validity); we handle this by manually setting the input using database constraints (e.g., setting URLs to always be `http://foo.com`).

If an uninstrumented operation turns out important for an application domain, we would update Ote's Ruby instrumentation, SMT encoding, and SQL generation to support it.

Complex data flow This case arises when the transcript contains an expression derived from a symbolic value through uninstrumented operations—a problematic scenario because the symbolic value is concretized. For example, the conditional `if uid < uid * uid` may insert a BRANCH record for $uid < 16$ into the transcript, as multiplication is not instrumented. In such cases, the driver might fail to terminate because a "new path condition" emerges for every value of `uid`. Even if we cut off the exploration, the generated policy would be overly strict and verbose, littered with concrete filters like $uid < 16$.

To detect such harmful concretizations, the driver reports each new constant and new query it encounters (there should be a bounded number of these). This mechanism alerted us to a few non-parameterized SQL queries (§ 7.1), where symbolic values were formatted into the query string. We encountered no concretization issues in our final evaluation, and we plan to implement more precise detection of such "partially concrete" conditions via heavier-weight data-flow tracking.

5 Generating a Policy

After exploration, Ote merges and simplifies the transcripts and creates a preliminary set of views for each handler. It then gathers the views for all handlers explored and removes redundancy by leveraging an existing enforcement tool, Blockaid [107]. We now delve into this policy-generation process.

5.1 Preprocessing Into Conditioned Queries

As a first step, Ote processes the transcripts for each handler into a set of *conditioned queries*. A conditioned query is a tuple $\langle sql, params, conditions \rangle$, where *conditions* is a list of prior QUERY and BRANCH records.[6] It associates each query with the conditions under which it is issued; one conditioned query is generated for each query issued in each transcript. As Ote does not currently support negations in policies (§ 3.2), it drops from *conditions* any QUERY record with $isEmpty = true$ (i.e., a condition that a prior query returns empty).

5.2 Simplifying Conditioned Queries

For each handler, Ote simplifies the set of conditioned queries by removing redundancy. At a high level, the simplifications remove conditions that do not affect whether a query is issued.

For example, suppose two conditioned queries have the same SQL and parameters, but one is guarded by $C \wedge b$ and the other by $C \wedge \neg b$. Since the query is issued regardless of the branch outcome, Ote replaces the pair with a single conditioned query guarded only by C. Similarly, a conditioned query guarded by C subsumes one guarded by $C \wedge d$ with the same SQL and parameters. Database constraints expose another source of redundancy, allowing Ote to remove conditions that are guaranteed to hold, such as a prior lookup that must succeed because of a foreign-key dependency.

Ote performs these and other simplifications by following the steps shown in Algorithm 1:

- Remove BRANCHes that *must* be taken due to an input constraint or a prior condition (Line 2);
- Unify variables that are constrained to be equal by query filters (Line 3);
- Remove identical QUERY records from each conditioned query's *conditions* (Line 4);
- Drop *vacuous* QUERY records—for queries that *must* return a row due to, e.g., a foreign-key dependency—whose result is not subsequently referenced (Line 7);

[6] A prior QUERY represents the *condition* that a query Q returned empty or not; the *action* of Q's issuance is captured by Q's own conditioned queries.

Algorithm 1 Simplifying a set of conditioned queries (§ 5.2).

```
1:  for all conditioned query do
2:      remove vacuous branches
3:      propagate equalities
4:      remove duplicate queries
5:  repeat
6:      for all conditioned query do
7:          remove vacuous-and-unused query records
8:      repeat merge branches until convergence
9:  until convergence
10: remove subsumed
```

- Merge pairs of conditioned queries that differ only in the outcome of a single BRANCH record (Line 8)—the query is issued no matter which way the branch goes;
- Remove a conditioned query if another exists with the same *sql* and *params* but only a subset of the *conditions* (Line 10)—the latter subsumes the former.

Each step is parallelized across cores. Due to the large number of conditioned queries, we designed these steps to favor efficiency over optimality. Any missed opportunities for simplification will be caught by the final pruning step (§ 5.4).

5.3 Generating SQL View Definitions

Ote now generates one SQL view per conditioned query. The view should reveal the same information as the conditioned query's path if its conditions are met, and no information otherwise. For this, Ote uses an iterative algorithm that "conjoins" each condition record onto an accumulated query definition A. It maintains the invariant that query A:

- Returns empty if any previous condition is violated;
- Returns the Cartesian product of all prior queries' results (i.e., concatenations of one-row-per-query) otherwise.

Query A serves two purposes: It captures the branching conditions, and it exposes query results to be referenced by later records. Lastly, the algorithm conjoins the final query onto A.

Before fully specifying the view-generation algorithm, let us walk through an example.

Example 5.1. Consider Listing 3. We shall generate the view for the conditioned query associated with QUERY_2.

The algorithm starts with the query A that returns the empty tuple. After the first record (QUERY_1), A is updated to A_1:

```
SELECT * FROM roles
WHERE user_id = MyUserId
  AND course_id = CourseId
```

(We use CamelCase for request and session parameters.)

After the second record (the BRANCH), A is updated to A_2:

```
SELECT * FROM roles
WHERE user_id = MyUserId
  AND course_id = CourseId
  AND is_instructor
```

Algorithm 2 View generation from conditioned query (§ 5.3).

```
1:  procedure GENERATESQLVIEW(cq)
2:      A ← {⟨⟩}    ▷ Constant query returning empty tuple
3:      M ← {} ▷ Maps query result column to A's column
4:      for all cond ∈ cq.conds do
5:          if cond is BRANCH(θ, outcome = true) then
6:              A ← σ_{θ[M]}(A)
7:          else if cond is BRANCH(θ, outcome = false) then
8:              A ← σ_{¬θ[M]}(A)
9:          else if cond is QUERY_ℓ(sql, params) then
10:             Q_ℓ ← SQLTORA(sql, params)
11:               ▷ Converts SQL query to relational algebra
12:             (A, M) ← CONJOINQUERY(Q_ℓ, A, M)
13:     Q_{ℓ+1} ← SQLTORA(cq.sql, cq.params)
14:     (A, M) ← CONJOINQUERY(Q_{ℓ+1}, A, M)
15:     return RATOSQL(A)
16: procedure CONJOINQUERY(Q_ℓ, A, M)
17:     let Q_ℓ = π_{j_1,...,j_m} σ_θ(S_1 × S_2 × ···)    ▷ Normal form
18:     n ← arity(A)                ▷ Number of columns in A
19:     θ' ← θ[k ↦ k + n][M]                ▷ ∀ column index k
20:     A ← π_{1,...,n,n+j_1,...,n+j_m} σ_{θ'}(A × S_1 × S_2 × ···)
21:     M ← M ∪ {r_ℓ.i ↦ i + n | 1 ≤ i ≤ m}
22:     return (A, M)
```

Observe that A indeed returns the same rows as QUERY_1 if the branch condition holds, and an empty result otherwise.

Then, QUERY_2 is conjoined onto A, resulting in view V:

```
SELECT roles.*, grades.* FROM roles, grades
WHERE roles.user_id = MyUserId
  AND roles.course_id = CourseId
  AND roles.is_instructor
  AND grades.course_id = roles.course_id
```

Note that QUERY_2's sole parameter, $r_1.\textit{course_id}$, has been replaced by the `course_id` column exposed by A_2. A final step remains to remove the `CourseId` parameter, which we will discuss at the end of this subsection. ◀

A generated view can be thought of as a natural generalization of the conditioned query to cases where a SQL query can return multiple rows: The view allows a query to be issued for every combination of rows returned by the prior queries, as long as the branching conditions are met. This would allow the program to have loops over result sets in the form we assume in the simple query-issuing core (§ 4.1).

We specify the view-generation procedure in Algorithm 2, which uses relational algebra notation (under the unnamed perspective) [1, § 3.2] for conciseness. The algorithm works for PSJ queries in normal form [1, Prop. 4.4.2]. It does not currently handle general joins or aggregations; when these arise, we approximate them using supported constructs (§ 7.3).

Algorithm 2 essentially follows the steps illustrated by Example 5.1. It maintains a mapping $\mathcal{M}$ from result columns of prior queries to columns in A (e.g., mapping $r_1.\textit{course_id}$

to the third column of A). It then uses this mapping to resolve references to results from prior queries.

Removing request parameters Recall from Example 2.1 that request parameters like `CourseId` must not appear in view definitions. So strictly speaking, Example 5.1 has produced not one view, but a set of views:[7]

$$\{V[\texttt{CourseId} \mapsto x] : x \in \text{dom}(\texttt{roles.course_id})\}$$

To collapse this set into one view, we use the following fact.

Fact 5.2 (Informal)**.** *Let* $V[\texttt{X}]$ *be a view definition of the form:*

```
SELECT col_1, col_2, ... FROM tbl_1, tbl_2, ...
WHERE col_j = X AND f
```

where $\texttt{col}_j$ *is a non-nullable column,* X *is a request parameter, and* f *does not refer to* X*. Then the set of views* $\{V[\texttt{X} \mapsto x] : x \in \text{dom}(\texttt{col}_j)\}$ *reveals the same information as the view:*

```
SELECT col_j, col_1, col_2, ...
FROM tbl_1, tbl_2, ... WHERE f
```

While this fact applies only to queries of a specific form, it already covers all cases encountered in our evaluation. We leave a theoretical study of the general case to future work.

Example 5.1 (continuing from p. 8)**.** Starting from view V, Ote removes the condition `roles.course_id = CourseId`, but refrains from adding `roles.course_id` to the `SELECT` statement because it is redundant with the already-present `grades.course_id`. This brings us to the final view $V^\star$:

```
SELECT * FROM roles, grades
WHERE roles.user_id = MyUserId
  AND roles.is_instructor
  AND grades.course_id = roles.course_id
```

The view $V^\star$ differs from the handwritten view V_2 only by retaining extra columns. However, conditioned on the existence of V_1 (which Ote would have generated from another conditioned query), $V^\star$ reveals the same information as V_2 and so is equally tight. For simplicity, Ote outputs $V^\star$ without removing extraneous columns, since we find $V^\star$ just as concise and readable as V_2. ◀

Outputting SQL Ote outputs SQL views in the form:

```
SELECT ... FROM tbl1, tbl2, ... WHERE ...
```

similar to $V^\star$ above. It uses standard query-optimization passes to make the query shorter and easier to read.

5.4 Pruning Views via Enforcement

Lastly, Ote minimizes the set of views for each handler—producing a subset that reveals the same information—and then takes their union and minimizes it again. To minimize a set $\mathbf{V}$ of views, Ote goes through each view $V \in \mathbf{V}$ and checks whether the information revealed by V is already contained in that revealed by $\mathbf{V} \setminus \{V\}$; if so, it removes V. Heuristically, Ote sorts the views by the number of joins in decreasing order, so that longer views have a chance of being removed first.

It remains to check information containment. This is the same problem as policy enforcement: checking whether issuing V *as a query* is allowed under the policy $\mathbf{V} \setminus \{V\}$. To tackle this, we repurpose an existing enforcement tool, Blockaid [107], which we extended with a command-line interface to be invoked by Ote. Finally, Ote outputs the minimized set of views for human review.

[7] We let $V[\texttt{X} \mapsto x]$ denote the view definition V with each occurrence of X replaced by x, and $\text{dom}(\texttt{col})$ denote the set of valid values for column `col`.

6 Implementation and Practical Aspects

Driver and Policy Generator Ote's concolic-execution driver and policy generator are implemented in Scala 3. The driver uses Apache Calcite [13] to convert SQL queries into relational algebra, and invokes Z3 using its Java binding [28]. It communicates with executors using Protobuf messages, and saves program inputs and transcripts to compressed JSON files. The policy generator uses Calcite's query analyses and optimizations for conditioned-query simplification (§ 5.2), and uses Scala's parallel collections [74] for parallelization.

For the relevance judge (§ 4.6), Ote invokes parallel instances of the Codex CLI [70] coding agent using the non-interactive `exec` subcommand. Ote parses the agent's textual output for the verdict and logs the details for human review, treating any "unsure" verdict or malformed output as relevant.

Executors Ote's library uses RSpec [80] to invoke handlers ("controller actions") with inputs from the driver. At startup, the executor clears the database. For each input, it begins a database transaction, populates the database, installs symbolic request parameters by patching the `params` hash, and sets two symbolic session parameters: the user ID and the current time. It then invokes the handler and rolls back the transaction.

We disable Rails's fragment and low-level caching to expose queries issued only on cache misses. As an optimization, we also disable Rails's query cache, which introduces branches that do not affect what data is fetched. We execute handlers on MySQL backed by an in-memory `tmpfs`, and configure string columns to use a case-sensitive collation [108] as our SMT encoding (§ 4.4) does not support case insensitivity.

Generating database constraints To help the user write down an application's database constraints (§ 3.1), Ote provides a tool that generates common types of constraints for a Rails application, by inspecting the database schema's SQL constraints and the Active Record models' validators, associations, and inheritance hierarchy. The user may then supplement the list with constraints not covered by the tool (§ 7.1),

Table 1: Number of database constraints (§ 7.1.3).

	Application Logic		For Ote	
	Generated	Manual	Manual	**Total**
diaspora	347	63	2	412
Autolab	185	42	4	231
Odin	116	9	1	126

a task we hope to automate using LLMs in the future.

Tracing a view back to the application To help users understand why a view was generated, Ote records with each view the ID of an execution from which the view is derived. Using this ID, the user can recover the corresponding input and re-run the execution—optionally under a debugger—to inspect the program state when a query was issued.

7 Evaluation

We applied Ote to three existing applications:

1. diaspora [30], a social network with over 850 k users;
2. Autolab [22], a platform for managing course assignments used at over 20 schools; and
3. The Odin Project (Odin) [92], a site where over a million users take web development classes and share their work.

We chose open-source Ruby on Rails applications with nontrivial access-control logic, while staying within the scope of the Ote prototype. Within this space, diaspora and Autolab were natural choices because we had written policies for them by hand before [107, § 8.1], allowing us to compare those policies with the extracted ones. Odin provides a complementary case: We had never worked with it before, so our experience applying Ote to Odin was not biased by prior knowledge.

The key takeaways from this evaluation are:

- Ote can extract a policy within a few hours (§ 7.4).
- The extracted policies avoided several errors present in the handwritten policies and revealed an access-check bug in the application code (§ 7.6).
- Applying Ote required limited manual setup and review effort (which we summarize in § 7.8).

7.1 Application Setup

All applications run on MySQL in our experiments. Their database schemas are nontrivial: diaspora has 50 tables and 387 total columns, Autolab has 26 tables and 269 total columns, and Odin has 17 tables and 152 total columns.

7.1.1 Code changes

We used versions of diaspora (v0.7.14) and Autolab (v2.7.0) that had previously been modified to work with Blockaid. To summarize the most relevant modifications:

- We had modified a few code locations to issue parameterized queries. (Most queries were already parameterized, but some needed a rewrite—see below for an example.)
- We had modified the applications to fetch sensitive data only if it affects output. (These modifications allow for finer-grained policies but are *not required by Ote*; we kept them for an apples-to-apples policy comparison.)
- We had rewritten one query to an equivalent form supported by Ote. (This modification is *not fundamentally required*—it could have been implemented in Ote itself.)

In addition, we modified seven lines in Autolab to save query results in variables for reuse. This simple refactor helped the relevance judge identify more irrelevant conditionals by clarifying that accessing the variables does not trigger a query.

For Odin, we made three changes (over commit `f6762f0`):

- We modified two locations to issue parameterized SQL queries: e.g., from `where('expires >= ?', Time.now)` to `where(expires: Time.now..)`, because the former inserts `Time.now` into the query string within Ruby, resulting in non-parameterized SQL.
- We deleted one line to prevent an aggregation from appearing in the *conditions* portion of conditioned queries (currently unsupported by Ote); this change preserved application behavior.

7.1.2 Relevance hints

We added seven `RELEVANCE-HINT` comments (§ 4.6): one to diaspora and six to Autolab. (Odin had few enough branches that the relevance-judge optimization was not needed—see Table 2.) Two of the hints clarify how an external library affects queries; three note that an already-loaded expression does not trigger a query; one notes that an expression *may* issue a query; and one encodes the assumption that an Autolab scoring function issues no queries.

All of these hints, except the last, compensate for limitations in the LLM-based coding agent's reasoning. We expect these hints to become unnecessary with improvements in the agent's capabilities, or in how it is used: e.g., providing the agent with library documentation, details on Rails's ORM, and runtime information about where queries originate.

7.1.3 Database constraints

Table 1 summarizes the database constraints supplied to Ote. Over 80 % were auto-generated (§ 6). The rest were added manually: Some were transcribed from application logic, while those in the "For Ote" column were introduced to scope the extracted policy or reduce exploration time.

Of the manually written application-logic constraints, many captured application-level invariants—e.g., two diaspora posts cannot be reshares of each other—and could not be auto-generated. For fields with constraints either unsupported by

Table 2: Statistics and performance. "✂" marks runs that used the relevance judge (§ 4.6). Under Statistics, "#Cond. Queries" shows the number of conditioned queries before and after simplification (§ 5.2); "#SQL Views" shows the number of views after per- and cross-handler pruning (§ 5.4). Under Running Time, "Simplify" stands for conditioned-query simplification and view generation (§§ 5.2 and 5.3), "Prune" for per-handler view-pruning, "Final Prune" for cross-handler view-pruning (§ 5.4), and "Total" for the total sequential running time.

	Statistics				Running Time				
Handler	#Paths	#Cond. Queries	#SQL Views		Explore	Simplify	Prune	Final Prune	**Total**
diaspora								36 min	**4.7 h**
`People#stream` ✂	163 832	189 412 → 188	148	→ 134	1.1 h	8 min	35 min		
`Posts#show` ✂	73 489	47 256 → 208	87		32 min	1 min	20 min		
`People#show` ✂	27 480	1318 → 35	27		15 min	33 s	4 min		
`Notifications#index` ✂	32 907	1018 → 75	54		16 min	38 s	9 min		
`Conversations#index`	57 534	93 368 → 134	39		14 min	4 min	12 min		
`Comments#index`	3607	41 → 23	17		2 min	24 s	3 min		
Autolab								29 min	**3.9 h**
`Assessments#show` ✂	217 543	391 621 → 1592	138	→ 144	1.9 h	28 min	32 min		
`Assessments#gradesheet`	15 681	9020 → 46	35		6 min	1 min	6 min		
`Assessments#index`	7839	9993 → 86	27		4 min	50 s	7 min		
`Submissions#download`	79	53 → 21	18		1 min	21 s	3 min		
`Courses#index`	36	17 → 8	5		2 min	21 s	50 s		
`Metrics#getNumPending`	11	14 → 8	7		57 s	20 s	59 s		
The Odin Project								8 min	**59 min**
`Lessons#show`	48 670	49 459 → 152	46	→ 24	13 min	3 min	13 min		
`Courses#show`	4462	3133 → 37	25		3 min	30 s	4 min		
`ProjectSubmissions#index`	3052	2615 → 39	17		3 min	31 s	3 min		
`Users#show`	2003	2059 → 14	9		2 min	29 s	1 min		
`Paths#index`	28	26 → 6	4		2 min	19 s	38 s		
`Sitemap#index`	28	13 → 4	3		1 min	20 s	27 s		

our SMT encoding (e.g., URL validity) or related to the external environment (e.g., an Autolab course name must correspond to a directory on disk), we constrained them to a fixed set of valid values after creating any required external state.

We wrote seven additional constraints specifically for policy extraction. To save exploration time, we required nullable string fields to be non-empty (as the two cases are typically treated identically), limited the Autolab analysis to non-admin users (as admin policies are trivial to write), and fixed the diaspora user's language to English. In Autolab, we disabled scheduler actions (which are not governed by user-specific policies) and disallowed zero score-penalties because our prototype does not track float operations (this preserves application features as a `0.0` penalty is equivalent to no penalty).

7.2 Experiment Setup

We ran experiments on Google Compute Engine using a `c3-standard-176` instance. The driver launched 48 parallel executors and used Z3 v4.11.2 for SMT solving. It invoked Codex CLI (v0.58.0) using the `gpt-5` model and medium reasoning effort, with a maximum parallelism of 16, a timeout of 5 min, and at most three retries after timeout.For view pruning, it invoked Blockaid with a timeout of 5 s. Executors ran a modified version of JRuby v9.3.13.0 atop OpenJDK 21.

We ran path exploration on each handler three times; Table 2 shows the data from the runs with median exploration time. To save on LLM calls, we enabled relevance-based pruning (§ 4.6) only for those handlers whose unpruned exploration exceeded 15 min (marked with ✂ in Table 2).

7.3 Paths, Conditioned Queries, and Views

Table 2 shows that while the number of explored paths can be large, Ote is able to reduce the number of views to between 24 and 144—a manageable number for human review.

For view generation, we had to approximate some SQL features unsupported by either our Ote prototype or Blockaid:

- We rewrite a `LEFT JOIN` into an equivalent `INNER JOIN` if possible. Otherwise, we split it into an `INNER JOIN` (for rows that match) and a `SELECT` (for rows that don't).
- We rewrite a `SELECT COUNT(*) FROM tbl` in the query portion into `SELECT id FROM tbl`, and omit aggregations in the condition portion.[8]
- We omit date-timestamp comparisons and replace "`Now + 1 second`" with "`Now`".

[8]The latter did not end up affecting the final policies because every aggregation present in the condition was redundant.

Table 3: Relevance-judge verdicts and running times. "Rel." denotes relevant; "Irrel." denotes irrelevant (§ 7.5).

Handler	Counts		Duration (min)
	Rel.	Irrel.	(mean ± std)
diaspora			
`People#stream`	31	242	1.3 ± 0.4
`Posts#show`	13	171	1.4 ± 0.4
`People#show`	16	86	1.6 ± 0.4
`Notifications#index`	21	82	1.9 ± 0.7
Autolab			
`Assessments#show`	46	54	1.0 ± 0.3

These approximations are "lossy": They can broaden or tighten the policy and must be applied with human discretion.

For Autolab, we applied a simple broadening immediately after view generation (Figure 1). The `Assessments#show` handler queries the `score_adjustments` table under many complex conditions, producing a large number of views. Since the table contains only non-sensitive metadata, we added a single broad view: `SELECT * FROM score_adjustments`, which caused view pruning to eliminate all narrower views involving the table. Table 2 reports results with this broadening applied. We give a more involved example of broadening in § 7.7.

7.4 Performance

Table 2 (right) shows the running times for each phase of policy extraction. Overall, end-to-end extraction completes within five hours at most. When we ran path exploration on the handlers marked with ✂ *without* the relevance-judge optimization (§ 4.6), all timed out after ten hours (not shown in the table) and, by our estimate, would have required *many days* to finish. This demonstrates that relevance-based pruning is essential for exploring real web-application code at scale.

7.5 Calls to the Relevance Judge

Table 3 reports relevance-judge verdicts (it never returned "unsure") and call-duration statistics. We manually reviewed every irrelevant verdict to confirm its accuracy. Although there were over 600 irrelevant verdicts, they arose from a limited set of code locations (e.g., in diaspora, a profile-picture helper invoked along many paths), making grouped auditing more straightforward. We note that the call durations include LLM reasoning time and serving latency, both outside our control.

7.6 Findings From the Extracted Policies

We now compare the extracted policies with the handwritten diaspora and Autolab policies from our prior work [107, § A]. For Odin, where no handwritten policy was available, we manually inspected the extracted policy and found it accurate for the handlers analyzed.

Table 4: View count in extracted vs handwritten policies. Extracted policies contain more views because they often preserve conditions that handwritten policies relax (§ 7.6).

	diaspora	Autolab	Odin
Extracted policy	134	144	24
Handwritten policy	66	37	–

Expectations We expect extracted policies to be tighter (more restrictive) than handwritten ones: Ote aims to produce the tightest possible policy, whereas humans often relax non-privacy-critical conditions and allow accesses beyond what the application requires (§ 7.7). Thus, extracted policies are generally longer because they encode conditions omitted from handwritten policies (Table 4). In our evaluation, this extra detail remained manageable for human review.

Where handwritten policies reveal too much But not all relaxations by the human policy-writer are benign. When we compared the extracted Autolab policy against the handwritten one, we found that the latter granted course assistants access to five types of records in a "disabled" course, when the application's logic states that only *instructors* should have access. Such an erroneous policy, if enforced, would allow a future code change to leak sensitive data to course assistants.

Where handwritten policies reveal too little Unexpectedly, there is also information revealed by the extracted policy but not by the handwritten one. To investigate, we used Blockaid to check whether each extracted view is allowed as a query under the handwritten policy. We found that:

- The handwritten diaspora policy failed to reveal the pod of a "remote" person and data for `MentionedInPost` and `MentionedInComment` notifications.
- The handwritten Autolab policy overlooked granting instructors access to all attachments in their courses.

Enforcing a policy with such oversights would disrupt application functionality by denying legitimate data accesses.

A defective access check While reviewing the extracted Autolab policy, we noticed that none of the submissions-related views checked the `assessments.exam` column. This was suspicious because Autolab is supposed to prohibit students from downloading prior exam submissions.

It turned out that we had introduced a bug years earlier when adapting Autolab for access control. When configuring the `lazy_column` gem [55] to defer loading sensitive fields, we mistakenly listed the column using its query method name

`exam?` instead of its actual name `exam`. This caused the gem to override `exam?` to always return `nil` (which is falsy), silently disabling the exam-check logic. So a correct-looking access check was rendered a no-op due to a misuse of an external library elsewhere in the codebase—a subtle bug that we discovered only after reviewing the policy extracted by Ote.

7.7 Broadening the Extracted Policy

Sometimes, an extracted policy includes many combinations of conditions under which data can be accessed, reflecting business logic rather than privacy concerns. For example, the extracted diaspora policy has 39 views (out of 134) that reveal a profile under various conditions: if it belongs to the current user, or to the author of a public post, etc. But based on our understanding, a diaspora user's profile is intended to be public, except for a few columns guarded by the `public_details` flag. This means we can simplify the policy by *broadening* it.

We can broaden the policy with the help of Ote's view pruning (§ 5.4). First, we write down four simpler, broader views to capture the relaxed conditions for accessing profiles:

1. ```
   SELECT id, first_name, ... FROM profiles
   ```
   (For all profiles, some columns are always visible...)
2. ```
   SELECT * FROM tags, taggings
   WHERE tags.id = taggings.tag_id
     AND taggings.taggable_type = 'Profile';
   ```
   (...and so are the profile taggings.)
3. ```
   SELECT * FROM profiles
   WHERE public_details = TRUE
   ```
   (All columns are visible if the profile's "public details" flag is set...)
4. ```
   SELECT * FROM profiles, people
   WHERE profiles.person_id = people.id
     AND people.owner_id = MyUserId
   ```
   (...or if the profile belongs to the current user.)

We add these to the policy and re-run view-pruning, which removes 36 of the 39 profile-related views as redundant. This process spares the human from having to reason about view subsumption, which can be tedious and tricky. (For example, the remaining three views, which pertain to the current user's contacts, are *not* subsumed by the ones that we added!)

7.8 Manual Effort and Expertise Required

The steps involved in applying Ote required varying degrees of SQL, Rails, and application knowledge. Before extraction:

- The *code changes* (§ 7.1.1) were mostly compatibility edits that required general Rails and SQL familiarity. The only application-specific changes—fetching sensitive data only when it affects output—were inherited from our prior work and are not required by Ote.
- Writing *relevance hints* (§ 7.1.2) required Rails knowledge to determine whether particular expressions or library calls could issue queries.
- Writing manual *database constraints* (§ 7.1.3) required familiarity with the application's data model, including its schema, Rails model associations and validators, and invariants encoded only in application logic.

After extraction:

- *Query approximations* (§ 7.3) required SQL knowledge to assess their effect on the policy, and application familiarity to decide whether they were appropriate.
- *Policy review* (§ 7.6) required application and SQL knowledge to explain policy differences as policy mistakes, application bugs, or benign discrepancies.
- *Policy broadening* (§ 7.7) required application familiarity to identify non-privacy-relevant distinctions, and SQL knowledge to write the broader views.

8 Related Work

Symbolic execution Symbolic execution [45] is a classic path-exploration technique that maintains symbolic program state. We decided not to use it because implementing it for an interpreted language is challenging (more so than for lower-level languages [21, 61, 87]) due to the dynamic features and functionality implemented outside the language [18, § 2.2].

Bug finding Many tools use symbolic or concolic execution to find bugs in web applications [9, 23, 99], typically aiming to trigger certain statements or states. Policy extraction requires not only reaching the query-issuing statements, but also gathering the conditions under which they are reached. Other systems infer security-relevant behavior from code to discover violations. AutoISES [91] infers expected security checks around OS operations and reports omissions; iHunter [54] finds privacy violations in iOS SDKs by recovering privacy-sensitive data flows; and Derailer [66] and Space [67] check for security bugs in web applications by validating data exposures against human input or a catalog. Such tools use inferred behavior as evidence of bugs, whereas Ote produces an access-control policy for review and enforcement.

Syscall filtering Abhaya [71] synthesizes Seccomp-bpf and Pledge policies by statically analyzing a program's syscall behavior and finding a tight policy expressible in the target sandbox language. SysPart [75], C2C [33], and Sysfilter [29] similarly harden binaries by inferring the set of syscalls a program may invoke and restricting the allowed syscalls to this set. These systems are conceptually similar to Ote in that they infer policies from programs. However, they typically rely on static analysis (sometimes complemented by dynamic observations) and reason about a smaller policy space: syscall identities and, in some systems, predicates over syscall arguments. In contrast, Ote targets a dynamic scripting language and extracts expressive relational database policies, including the conditions under which SQL queries are issued.

Instrumentation strategies Some systems track symbolic values in dynamic languages by performing instrumentation *within* the target language. They represent symbolic objects through proxying [17, 98] or inheritance [12], and track path conditions using Boolean-conversion hooks [12, 17] or debug tracing [98, § 4.1.2]. These approaches avoid the need for a custom interpreter and support standard environments [8]. In contrast, Ote performs *offline* analysis, allowing us to modify the interpreter for better transparency [26] and performance.

Learning models of applications Konure infers models of database-backed applications [84, 85] by generating targeted inputs to probe the application as a black-box. This work informed our formulation of the simple query-issuing core assumption (§ 4.1). However, black-box probing cannot effectively recover conditions of query issuance [85, § 6.2], whereas Ote can extract them directly via instrumentation.

Policy mining Policy-mining systems share our goal of generating access-control rules that capture existing practices. Most take existing access-control lists [19, 102, 103], operation logs [32, 40, 60], or human interactions [39], and produce role- [32, 60, 102], attribute- [40, 103, 104], or relationship-based [19, 39] rules, often via statistical techniques. Unlike these systems, Ote does not require live data and instead analyzes the application, which provides the visibility needed to produce fine-grained policies. AutoArmor [52] is closer to Ote in that it analyzes application code to generate access-control policies, but it targets inter-service calls in microservice applications whereas Ote extracts database access-control policies from web applications.

9 Discussion and Future Work

Ote enables better data security in existing web applications: by extracting the access-control policy embedded in application code, it makes that policy explicit, allowing an admin to understand and ultimately enforce the intended policy.

Although Ote is semi-automated and provides no formal guarantees, these traits are shared by most policy-assistance tools. RBAC and ABAC policy-mining tools (§ 8) routinely depend on human-curated inputs [31], require humans in the loop [59, § 7.2], and offer no guarantees as they operate on partial [25, 44, 60] or noisy [7, 64, 101] data using statistical methods. Yet these tools have consistently proven effective in helping admins develop practical policies [41, 59, 68, 94, 96]. These broader successes, together with our own, give us confidence that Ote can provide similar—if not greater—value, particularly because Ote generates far finer-grained policies than typical RBAC or ABAC rules.

We conclude with a few avenues for future work:

Automation bias and complacency A policy extractor may create a false sense of security when reviewers accept a plausible-looking policy without sufficient scrutiny. This risk is an instance of *automation bias and complacency*: Reviewers may over-rely on computer output and abdicate their decision-making responsibility [73]. Future work should investigate these effects in the context of policy extraction and adapt established mitigations to this setting [34].

Policy comprehension SQL is precise and familiar, but SQL views can become verbose when they encode many application-level conditions. A natural next step is a concise policy domain-specific language (DSL) that preserves SQL-view semantics while making policies easier to read, compare, and audit. Such a DSL should draw on query-language usability studies [5, 76] and ORM abstractions [93]; verified lifting techniques [43, 48] could translate generated SQL views into this DSL while preserving their meaning.

Coding agents The rapid improvement of coding agents raises a natural question: Could an agent simply read source code and extract a policy directly? In principle, yes—human experts can do this, albeit slowly and imperfectly, and a capable enough agent might automate it. But the goal is not merely to produce a plausible policy; it is to produce one whose provenance a human can audit and understand.

Ote has limitations: it applies only under stated assumptions and relies on certain heuristics. But these limitations are explicit. Ote decomposes policy extraction into well-defined subproblems grounded in concrete traces, derives policies through explicit transformations, and produces intermediate artifacts that help reviewers trace a policy fragment to its source.[9] An end-to-end agent may also make mistakes, but those mistakes can be harder to localize because they arise from an opaque reasoning process with unclear failure modes.

Rather than replacing Ote's structure, agents could operate within it: modeling complex application logic, flagging suspicious views, suggesting policy broadenings, etc. This way, agents are used for well-scoped subtasks whose outputs are attached to explicit artifacts, so that increased automation does not come at the cost of auditability.

Acknowledgments

We thank the anonymous reviewers and members of the UC Berkeley NetSys Lab and Sky Computing Lab for their feedback. This work is supported in part by NSF grant 2145471 and by gifts from Accenture, Algorithmic SuperIntelligence Labs, Amazon, AMD, Anyscale, Broadcom, cmpnd, Google, IBM, Intel, Intesa Sanpaolo, Lambda, Lightspeed, NVIDIA, Samsung SDS, and SAP.

[9] Even when Ote uses an LLM-based relevance judge, it records the judge's verdicts and explanations for audit.

A Artifact Appendix

Abstract

This artifact provides the Ote implementation, including the concolic-execution driver and supporting modifications to JRuby and Blockaid, along with the modified applications and setup needed to reproduce the evaluation.

Scope

The artifact reproduces Tables 2 to 4 in a PDF and writes the extracted policies to separate output files.

Contents

The artifact includes the source repositories for Ote's concolic-execution driver (§ 4.3), the JRuby interpreter modified for symbolic tracking (§ 4.5), Blockaid modified to support view pruning (§ 5.4), and the three modified applications used in the evaluation (§ 7.1). It also provides a prebuilt virtual-machine image with the scripts and configuration files needed to reproduce the evaluation.

Ote uses an LLM-based relevance judge implemented with OpenAI's Codex CLI (§ 7.2). To save resources, the artifact includes a "mock judge" that, instead of calling an LLM, returns a verdict after an configured delay. By default, the artifact's experiment script uses the mock judge with a 90-second per-call delay, approximating the real judge's latency.

Hosting

The artifact is hosted under the ote-project GitHub organization (https://github.com/ote-project). Table 5 lists the hosting location for each component.

Requirements

The artifact was tested on Google Cloud using a Compute Engine c3-standard-176 instance. Importing the VM image requires access to a Google Cloud Storage bucket for uploading the image before import. Running Ote with the real Codex-based relevance judge requires an OpenAI account.

iLand: An Instruction-Level Dynamic Binary Instrumentation framework for iOS

Kaitao Xie, Yizhuo Wang, and Xiaolong Bai*
Alibaba Group
{easylyou.xkt,xrosheart926,bxl1989}@gmail.com

Abstract

Dynamic binary instrumentation (DBI) enables monitoring and modification of executing programs and forms the foundation for a range of program analysis and security testing. On iOS, however, no DBI is available for non-jailbroken devices. Existing approaches on other platforms (e.g., Android) rely on JIT compilation, which is prohibited by the iOS sandbox. The limited CPU and memory resources of mobile devices further constrain the practical deployment of DBI.

We propose *iLand*, a novel instruction-level DBI framework for iOS. Instead of JIT compilation, it translates instructions into predefined micro-operations and interprets using precompiled atomic execution units. To reduce CPU and memory overhead, it employs application-only emulation: only the app's code is interpreted, while system libraries run natively. We implement *iLand* as a standard sandboxed iOS app capable of emulating other apps. It preserves the emulated apps' original functionality and user experience such as dynamic UI rendering, real-time interaction, live video streaming.

Based on this DBI framework, we further implemented an instruction-level dynamic tracing tool and used it to study policy-violation behaviors on 60 top-ranked App Store apps. We found that 13 (21%) apps are still invoking private APIs, of which 2 invoke APIs explicitly prohibited by Apple. Our analysis further revealed the new and stealthy methods employed by apps to evade Apple's App Review. In particular, in 15 (25%) of the apps, we observed a new way to collect sensitive information by direct invocation of the SVC instruction.

1 Introduction

Dynamic binary analysis is widely used in software testing and security research [10, 25, 31, 50, 52, 59]. On iOS, one of the most popular mobile operating systems, such techniques are particularly valuable because App Store apps are mostly closed-source. However, Apple's sandbox—including mandatory code signing and runtime hardening—imposes significant limitations: the dynamic code generation and loading of unsigned binaries are not allowed.

As a consequence, dynamic analysis on iOS is primarily based on two approaches: code injection on jailbroken devices [15, 45] and app repackaging on non-jailbroken devices [6, 51]. Code injection in jailbroken conditions exploits kernel-level vulnerabilities to bypass the sandbox. However, publicly available jailbreaks support only up to iOS 16, incompatible with the recent iOS versions. App repackaging involves unpacking the app bundle, injecting custom libraries, modifying the main binary's load commands, and then resigning and repackaging the app. The limitation is that it typically instruments apps at the API-level rather than instruction-level. Both methods either rely on a jailbroken environment or compromise the integrity of the app binary, where apps may detect and behave differently from their original functionalities.

The requirements to adhere to the system sandbox while maintaining transparency lead us to explore DBI techniques. DBI techniques enable the insertion of probes and user-supplied analysis routines into running programs. Conventional DBI frameworks, such as Valgrind [46] and Dyninst [8], have demonstrated utility and effectiveness across numerous application domains [1,5,18,19,21,24,28,35,37,44,49,54,56]. However, they are not applicable to iOS currently due to two major challenges. First, the sandbox forbids dynamic code generation: DBI cannot allocate RWX (readable, writable and executable) memory pages. Second, the limited CPU and memory resources of mobile devices constrain practical deployment. For instance, iPhone 15 and iOS 17 were both released in 2023, where system libraries consume 3.3 GB memory and device has only 6 GB RAM. All system libraries are collected into Dyld Shared Cache (DSC), mapped and shared by all app processes. This means a DBI framework has to allocate a large region for guest app's DSC while retaining its own DSC mapping, which can quickly exhaust memory and trigger Jetsam [3] (iOS's out-of-memory killer).

In this paper, we present *iLand*, a dynamic binary instrumentation framework for iOS that monitors and alters the execution of guest apps at the instruction-level. To avoid

*Xiaolong Bai is the corresponding author.

JIT-compiled code, *iLand* adopts a translation and interpretation approach: it translates instructions into predefined micro-operations with equivalent semantics, and interprets these using precompiled atomic execution units. To fit the memory constraints, *iLand* employs *application-only emulation*: it interprets only the app's own code while allowing library code to run natively, avoiding the need to interpret the large DSC while making use of native libraries for CPU-intensive tasks such as video codecs and cryptographic operations.

Application-only emulation introduces a challenge absent from conventional DBI: native library code may return to or call back into interpreted app code (N→I transitions), yet the library code is immutable and the iOS sandbox prohibits generating executable code at runtime, making it fundamentally difficult to recapture control. To address this, we introduce a *stateless control-flow manager* that constructs trampolines via shared memory pages and `pc-relative` instructions, redirecting N→I transitions back to the interpreter without per-call state or RWX memory. Building on this, we employ a layered approach combining static analysis, runtime interception, and signal-based fallback to capture all N→I transitions.

We implement *iLand* as a standard sandboxed app, able to emulate guest apps. To evaluate performance, our tests on the SPEC CPU 2017 benchmark reveal that while *iLand* incurs higher overhead compared to JIT-based DBI, it achieves a 10x speedup over the qemu-tci interpreter. To evaluate real-world compatibility, we run 64 top-ranked apps from the US App Store under *iLand* and manually test their main functionality (e.g., login, browsing, search, video). Of these, 49 (77%) worked correctly, 11 showed partial functionality loss (e.g., app detected anomalies of environment and refused login); and 4 terminated abnormally (e.g., app's watchdog timeouts triggered termination). Overall, 60 apps reached a usable state with working UI interactions.

Built on *iLand*, we implement an instruction-level dynamic tracing tool that records control-flow transfers of interest, including indirect calls and SVC invocations for 60 top-ranked apps in the compatibility test. We found that 13 (21%) apps are still invoking private APIs, which are not allowed according to App Store Guidelines. Like prior works [15, 17], we treat undocumented APIs as private, yet Apple neither publishes an authoritative list of private APIs nor specifies exactly which calls trigger rejection. To validate our finding, we developed a test app invoking such APIs and upload it to TestFlight, Apple's pre-release distribution platform. We found 2 invocation are explicitly prohibit by TestFlight automated review. Our analysis further revealed the new and stealthy methods employed by current apps to evade Apple's App Review, including runtime symbol resolution, direct SVC invocations, `dlopen` of generated binaries and constructing return-oriented programming (ROP) chains. Notably, 15 (25%) apps we observed employ a new way of collecting sensitive information via direct SVC invocation. These findings demonstrate that *iLand* enables effective dynamic analysis of iOS apps.

In summary, this paper makes the following contributions:

- We present *iLand*, an instruction-level DBI framework for iOS, and propose application-only emulation.
- We propose a stateless control-flow manager to handle frequent boundary crossings.
- We implement *iLand* as a standard sandboxed iOS app, apply it to 64 top-ranked iOS apps and manually test main functionality. 60 of them reached a usable state.
- We build tracing tool on top of *iLand* and study the 60 apps. We found 13 (21%) apps invoked private APIs, 15 (25%) apps employed SVC invocation to collect system information, and we revealed four new stealthy methods that current apps used to evade Apple's App Review.

2 Background and Motivation

In this section, we first introduce the iOS sandbox and jailbreaking. We then present the fundamentals of DBI and the challenges in porting it to iOS. Finally, we provide real-world motivating examples discovered by *iLand* that highlight the importance of dynamic analysis in iOS security research.

2.1 iOS Sandbox and Jailbreak

The iOS sandbox, including code signing and runtime hardening, restricts apps' access to system resources and user data, thus strengthening platform security. Code signing is mandatory on iOS: the app's main Mach-O binary is signed with a developer certificate, establishing identity. The signature is verified at runtime by Apple Mobile File Integrity (AMFI for short) [41], a built-in kernel extension. To ensure code integrity, AMFI detects unauthorized code execution (unsigned, modified or injected code), and enforces termination (SIGKILL). Entitlements, embedded in the code signature, declare capabilities; a provisioning profile issued by Apple authorizes a specific set of entitlements for a signed app. However, certain entitlements that grant access outside the app sandbox are restricted to Apple-signed system apps.

Runtime hardening protects runtime integrity by blocking JIT execution and unsigned-library loading. Specifically, apps need the *com.apple.security.cs.allow-jit* entitlement to use RWX (readable, writable, and executable) memory and *com.apple.security.cs.disable-library-validation* to load unsigned libraries. Both entitlements are private to Apple, so third-party apps cannot declare them or generate code at runtime.

While sandbox strengthens iOS security, it constrains dynamic analysis of App Store apps. To conduct runtime analysis, prior works [30, 38, 53, 58] resort to jailbreak technique, which exploits vulnerabilities in older iOS releases to gain arbitrary kernel execution, modify kernel memory, and bypass sandbox restrictions. We argue that jailbreak-based analysis is unsustainable: i) jailbreaks are version-specific and rarely track the latest releases; ii) operating in a sandbox-bypassed

Table 1: Popular publicly available jailbreak tools.

iOS Version	Public Jailbreak Tools
14.8	uncOver [47]
15.4.1	fugu15 [32]
16.6.1	dopamine [23]
16.7.12	palera1n [11]
17.0	
18.0	no available tool
26.0	

environment affects app behavior—apps may detect jailbreaking and behave differently—undermining result validity; and iii) Apple's rapid patching and hardening have made public jailbreaks increasingly scarce.

Table 1 summarizes publicly available jailbreak tools: current advanced jailbreaks target up to iOS 16 (released in 2022), with no working jailbreak for iOS 17 or later. We therefore advocate a jailbreak-independent dynamic analysis framework.

2.2 Porting DBI to iOS

DBI inserts extra code into programs to monitor and alter their runtime state. Pin [43], DynamoRIO [9], Valgrind [46] and Dyninst [8] are widely used DBI frameworks, providing instruction-level instrumentation across architectures and operating systems. Although Dyninst supports Arm64 and Valgrind supports macOS, none currently support non-jailbroken iOS. Figure 1 shows a typical DBI architecture: the `JIT Compiler` decodes app binaries and compiles basic blocks at runtime, rewriting control-flow transfers so the DBI can mediate every change. Translated blocks are placed in `Code Cache` for execution. On control-flow events (e.g., function calls) or analysis-relevant conditions, the `Context Switcher` decides whether to compile or dispatch the next block, invoke analysis routines, or hand control to the OS. This design fundamentally relies on RWX memory for the `Code Cache`, which iOS prohibits, making conventional DBI hard to port.

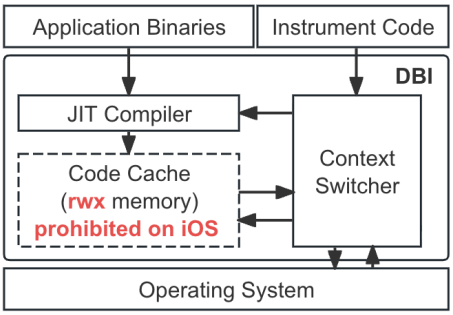

Figure 1: The typical DBI architecture. Code Cache, a key component, requires RWX memory that is prohibited on iOS.

CPU emulation executes programs by decoding and interpreting instructions to faithfully reproduce state transitions. The interpreter-based approaches avoid RWX memory while enabling instruction-level instrumentation. Popular frameworks include QEMU [7] (interpreter mode) and Bochs [40], but they currently do not support iOS.

Table 2: The RAM size and Dyld Shared Cache (DSC) footprint in recent iPhone and iOS version.

iPhone	iOS	Released	RAM	DSC	
				Whole	Code
13	15	2021	4 GB	2.3 GB	1.7 GB
14	16	2022	6 GB	2.7 GB	2.0 GB
15	17	2023	6 GB	3.3 GB	2.4 GB
16	18	2024	8 GB	3.9 GB	2.8 GB
17	26	2025	8 GB	4.6 GB	3.4 GB

However, a full-system interpreter is impractical on iOS due to the limited available memory. Table 2 summarizes usable physical memory and DSC footprint on recent iOS devices. iOS aggregates all system libraries into a single DSC, which is mapped and shared by every app process. On a 6 GB device, the DSC exceeds 3 GB; interpreting both the DSC and app binaries would quickly exhaust memory.

The practical solution is *application-only emulation*: interpret only the app's own code while letting system libraries execute natively. This avoids the memory problem and preserves native performance for CPU-intensive library routines. However, application-only emulation introduces a new challenge that does not arise in conventional DBI:

Bidirectional control-flow transitions without RWX memory. In conventional JIT-based DBI, the framework controls all code execution, so transitions between app and library code are handled implicitly. In application-only emulation, execution alternates between interpreted app code and native library code. Native-to-interpreter (N→I) transitions—where native libraries return to or call back into app code—are fundamentally difficult: native library code is immutable, and the iOS sandbox prohibits generating executable code at runtime. Moreover, N→I transitions arise through diverse mechanisms with distinct calling conventions. Correctly and efficiently recapturing control across all these paths is the central technical challenge that *iLand* addresses.

Accurate and efficient interpretation. The Arm64 instruction set is extensive, with over 60 general mnemonics and more than 380 SIMD mnemonics for float and vector computations, resulting in a large engineering effort. In addition, interpretation overhead directly affects usability; excessive latency triggers UI timeouts and renders apps unusable.

2.3 Motivating Examples of App vetting

Under Apple's App Store Guidelines, apps that use private APIs are not approved for App Store distribution. In our motivating examples, we focus on reject APIs—a subset of private APIs that are reliably flagged by Apple's TestFlight automated review. Such API usage is expected to be rejected during formal App Store review. To ensure typicality, the following cases, identified by *iLand*, are drawn from four top-ranked

free apps among the 60 evaluated, show the stealthy methods to evade App Review and demonstrate *iLand*'s runtime capabilities to reliably detect potentially risky behaviors:

Indirect call. `SecTaskCopyValueForEntitlement` is a reject API on iOS. *iLand* observed that the App_a (top 40) constructs the symbol name at runtime by concatenating `SecTaskCopyVa` and `lueForEntitlement` into a temporary NSString, resolves it via `dlsym`, and then invokes it. This deliberate indirection may reduce the recall of static detectors.

System call. `_dyld_get_shared_cache_range` is a reject API; equivalent functionality can be available via the `SYS_shared_region_check_np` syscall. *iLand* observed that App_b (top 50) reaches hand-written inline assembly at runtime, issuing SVC instruction to invoke this syscall. Such syscall-based invocation patterns are worth vetting, as they may complicate detection of private-API usage.

Indirect jumps via ROP chains. Prior work [55] had shown that return-oriented programming (ROP) can be used to evade App Review by directly manipulating registers to reorder control flow absent from the original binary. *iLand* found that App_c (top 10) searched the DSC for a `SVC RET` gadget—for example, within `mach_msg_trap`, a three-instruction syscall wrapper whose second and third instructions is the desired gadget—and then crafts the stack and the link register to synthesize call sites.

Loading of generated binaries. On iOS, `dlopen` of a valid signed binary is permitted, but generating and loading code at runtime (e.g., a downloaded binary) is considered improper by Apple. *iLand* found that App_d (top 60) issues SVC to invoke `SYS_open` and `SYS_write`, generates a binary to disk, and calls `dlopen`. Our manual analysis indicates the generated binary lacks a valid code signature; `dlopen` would succeed only on sandbox-bypassed devices. We hypothesize this pattern is used to detect jailbreaks. Although the intent may not be evil, such behavior may pose risks to users.

3 Overview

We design *iLand*, an instruction-level dynamic binary instrumentation framework for iOS. Figure 2 depicts the architecture of *iLand*, which comprises four components:

- **The translator** converts Arm64 instructions into the intermediate representation (IR), and inserts analysis code via custom plugins.
- **The loader** loads guest app binaries and the generated IR at appropriate memory locations and protections.
- **The interpreter** interprets the generated IR based on pre-compiled execution units located on the RX memory and monitors guest app control-flow transfers.
- **The Virtual Environment Manager** handles interactions between the guest app and the system, preserving transparency for the guest app.

iLand fundamentally diverges from JIT-based DBI in two respects. First, it replaces JIT compilation with a translation-and-interpretation pipeline: the translator converts app code into an IR of predefined micro-operations, and the interpreter executes these using precompiled execution units residing in RX memory. The original code and IR reside in read-only memory, complying with the iOS sandbox. Translation is performed ahead-of-time (AOT) so that pre-translated code is prepared for repeated use.

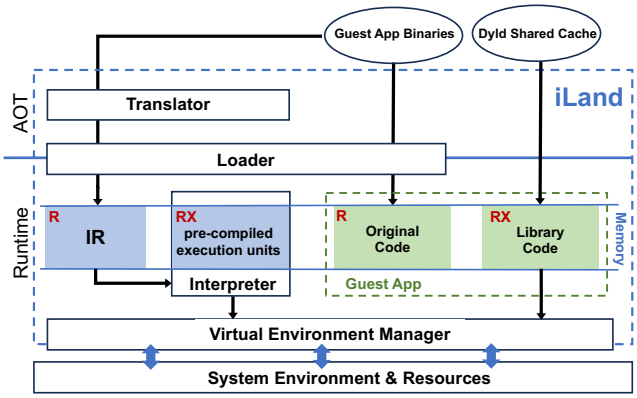

Figure 2: Architecture of *iLand*.

Second, and more significantly, *iLand* adopts application-only emulation, which introduces a control-flow management problem absent from conventional DBI (§ 6.3). Since library code runs natively, the framework must recapture control on every N→I transition. *iLand* introduces a *stateless control-flow manager* (§ 6.2) that constructs trampolines via shared memory pages, requiring no RWX memory and no per-call state. Building on this, a layered strategy captures diverse N→I paths—including C++ virtual methods, Objective-C (ObjC in short) dynamic dispatch, Swift witness tables, ObjC blocks, and stack unwinding.

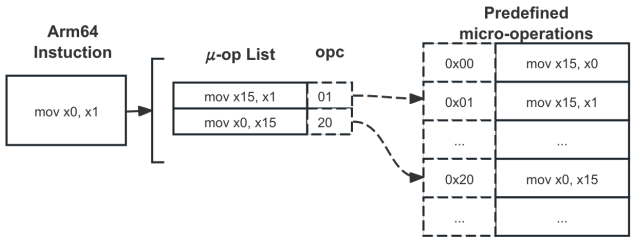
4 Translator

The translator converts native instructions into an IR. We first describe the IR design and the set of reserved registers, and then summarize the translation process.

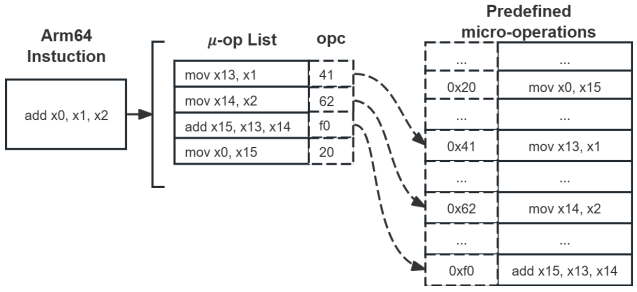
4.1 IR

Each IR in *iLand* IR comprises a 16-bit opcode and optional operands. The opcode indexes a predefined micro-operation that implements semantics equivalent to the corresponding native instruction. These operations, called μ-op, are precompiled execution units in the interpreter's code segment. A native instruction is typically decomposed into three μ-ops using dedicated preserved registers:

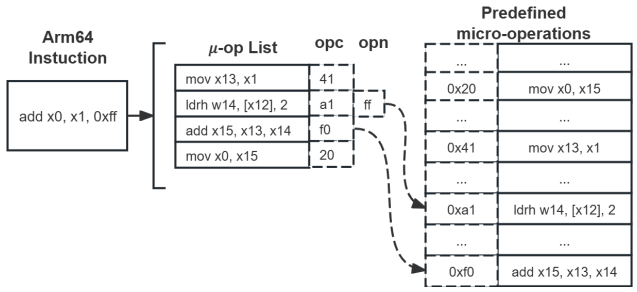
1. μMOV_{src}: Transfers source registers to the fixed preserved source register $X_{\mu src}$.
2. μOP: Performs the original instruction operation and stores the result in the fixed preserved destination register $X_{\mu dst}$, e.g., μADD and μLDR.



(a) Register transfer translation



(b) Register-register addition translation



(c) Register-immediate addition translation

Figure 3: Translation case studies. Registers x12-x15 are preserved by *iLand*. Guest accesses to these registers trigger safe translation to alternative operations.

3. μMOV_{dst} (conditional): Transfers results from $X_{\mu dst}$ to destination registers if required.

This design ensures semantic preservation while maintaining μ-op complexity at $O(n)+O(m)$, where n is the instruction mnemonic count and m is the register quantity. By separating register transfer logic from operations, we avoid the combinatorial explosion of $O(n \cdot m^x)$ (where x represents the maximum register operands per instruction), achieving a practical trade-off between performance and space efficiency. For instructions with immediate operand, we embed the immediate values in IR operand field, and replace the μMOV_{src} with μLDR_{opnd}, which loads the operand value into $X_{\mu src}$. We take `MOV` and `ADD` instructions as examples to demonstrate the relationship between the Arm64 instruction and μ-op.

`MOV` instruction. Figure 3a demonstrates the translation of the register transfer instruction, i.e., `MOV`. *iLand* decomposes general register moves into two μ-ops: first moving the source register to preserved register x15, then transferring from x15 to the destination register. This approach reduces 1,024 potential Arm64 move instructions to 64 reusable units.

`ADD` instruction. Figures 3b and 3c illustrate translations of arithmetic `ADD` instruction. As per Arm64 specifications, register-register and register-immediate additions is distinct handling. The second case employs register transfer plus a unified μADD (`add x15, x13, x14`), and the third case demonstrates immediate loading through operand field encoding (0xff). *iLand* uses variable-length operand encoding to avoid additional μ-op. This strategy enables multiple instruction variants to share common μ-ops, minimizing code footprint while maintaining full architectural coverage.

With this design, *iLand*'s μ-ops form a carefully curated set of Arm64 instruction units (implemented by 6,709 execution units $\leq$128KB), capable of representing all possible combinations of instruction mnemonics and operands.

4.2 Preserved Registers

We adopt a selective register preservation strategy in μ-ops. Only designated subset of registers (x10-x15) is preserved for emulation, while guest apps directly access the remaining registers. Any guest access to preserved registers is transparently redirected to per-thread register shadows in thread-local storage (TLS). This design reduces the conventional register-switching overhead, as context preservation requires saving or restoring only the designated registers, thus efficiently supporting frequent switching during application-only emulation.

The preservation strategy optimizes for performance considerations: i) shadow memory access latency grows with the number of reserved registers, ii) register pressure minimization requires avoiding frequently-used registers in iOS runtime. Through empirical analysis of Arm64 register usage patterns in Mach-O binaries compiled with Apple's toolchain, we observe:

- x0-x7: primary function parameter passing and return
- x8: large structure returns (AAPCS64 compliance)
- x16: syscall number carrier and long-jump usage in `__stub` sections
- x17: `objc_msgSend` dispatch register
- x20: swift method context pointer (`self` pointer)
- x20-x28: caller-saved registers
- x29-x31: frame pointer (FP), link register (LR), and stack pointer (SP)

This observations motivates our selection of x10-x15 as preserved registers, achieving dual objectives: i) Minimizing conflicts with iOS runtime conventions through unused register selection, ii) Enabling efficient SIMD operations (e.g., `LD1 x10-x13, [x15]`) through contiguous register usage The chosen registers demonstrate negligible utilization in sampled iOS applications while maintaining compatibility with ARMv8.4 vector instruction requirements.

4.3 Translation Process

During translation, guest code segments are mapped as read-only. Our static translation engine directly processes instruc-

tions as raw 4-byte quantities:

1. Linearly fetch instructions, leveraging Arm64's fixed-width instruction encoding
2. Parse the instruction type and operands
3. Select corresponding μMOV_{src} (or μLDR_{opnd}), μOP, and μMOV_{dst} accordingly
4. Encode the IR using the μ-ops's indexes in interpreter and optional operands
5. Flow-insensitive optimization preserving original instruction ordering

The translation output is a position-independent data file (*ir* file) containing generated IRs with embedded metadata for runtime interpretation. The loader maps the *ir* file into read-only memory at runtime. It contains 2 major sections as:

$Section_{\mathbf{IR}}$: This section contains the translated IRs. The IRs are linearly arranged as their represented instructions in the original executable file's code segment.

$Table_{\mathbf{IR_offset}}$: During runtime, the interpreter needs to map original instruction addresses to their corresponding IR instances. Because IR length varies (depending on operand presence), IR positions within $Section_{\mathrm{IR}}$ cannot be deterministically computed. *iLand* therefore builds $Table_{\mathrm{IR_offset}}$, an array that records the byte offset of each IR instance. Each 4-byte entry (matching fixed instruction width) corresponds to one native instruction in the original code segment. The benefits of $Table_{\mathrm{IR_offset}}$ include: i) Maintain O(1) lookup complexity through direct offset calculation; ii) Preserve architecture-specific alignment; iii) Enable position-independent IR storage through base-plus-offset addressing.

5 Loader

The loader is the first component to run in the runtime environment, establishing memory layout at guest emulation startup. It performs two major functions: i) loading standard Mach-O files and the generated *ir* files, ii) implementing initialization routines to support ObjC runtime and exception handling.

Mach-O and IR files loading. The loader builds on the open-source dyld [2] from Apple, which loads Mach-O binaries with valid code signatures and identities. While inheriting dyld's core functionality, it introduces three enhancements:

- Specified address memory allocation. The loader implements a `dlopen` to load targets at specific addresses, enabling deterministic memory management.
- Non-executable code segment support. The loader maintains strict read-only permissions for the loaded code.
- Interpreted initialization execution. To complement initialization, the loader forwards the initialization routines (`load` methods of ObjC, `_init_offsets` of C and `__mod_init_func` of C++) from Non-Executable segments to the interpreter in the standard order.

In addition to these three enhancements, to preserve semantics under address space layout randomization (ASLR) while loading *ir* files, the loader performs IR operand patching by iterating through IRs that are sensitive to base addresses.

Initialization routines implementation. The ObjC runtime feature and exception handling both rely on the default dyld's initialization capabilities, including: i) ObjC metadata synchronization, where dyld parses ObjC metadata and integrates them into the `libobjc` data structures; and ii) dyld function pointer fixups, where dyld resolves pointers in libraries that point to dyld implementations for initialization.

To address ObjC metadata synchronization, the loader parses the DSC's local symbol table to locate the private function `notifyObjCMapped` in `libobjc`. By invoking this function, the loader registers ObjC metadata within loader-managed Mach-O files.

Because the DSC is initialized before any *iLand* code runs, the loader needs to locate function pointers initialized by dyld and redirect them to the loader's own implementations. For instance, the loader redirects private function `_dyld_find_unwind_sections` in `libunwind` to its own implementation, which retrieves unwind table information from correct loader-managed Mach-O files, thereby correctly processing exception of guest and directing control flow to appropriate guest's catch blocks.

6 Interpreter

The interpreter executes the initialization routines produced by the loader and then proceeds to `main` in guest's main Mach-O binary. Throughout this process, the interpreter manages all control flow transfers.

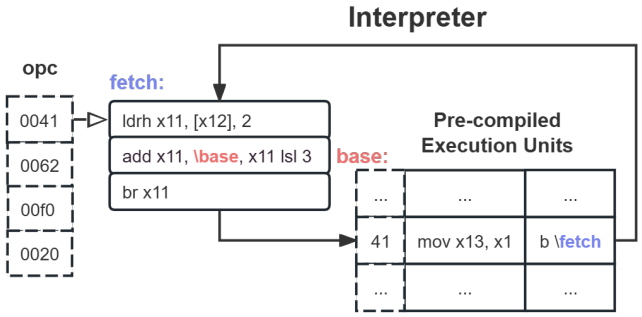


Figure 4: μ-op Interpretation Workflow. Blue markers denote instruction-fetch boundaries, red indicates base address mapping for first-instruction anchoring.

6.1 Interpretation Engine

As mentioned in § 4.1, each opcode indexes a precompiled execution unit, i.e., implementation of μ-op. For efficiency, we set opcode as the offset of the corresponding unit in interpreter's precompiled execution section. The interpreter's core engine employs a straightforward μ-op dispatch-loop: it iteratively fetches the opcode and jumps to the unit indexed by the opcode. In this loop, it uses a preserved register (`X12`)

pointing to the IR (within the mapped *ir* file). To form a tight interpreting loop, each execution unit performs three functions: i) performing the semantics specific to μ-op definition, ii) advancing the `X12` pointer to the next IR if operands are present, and iii) jumping back to the dispatch-loop header.

With this design, the dispatch-loop header requires only three instructions (Figure 4):

- Load opcode pointed at `X12`
- Add opcode with the base of the execution units
- Branch to the unit

The entire dispatch-loop, including the dispatching header and all the execution units, is implemented in hand-written assembly with precise constraints on preserved registers.

6.2 Stateless Control Flow Management

During emulation, target programs inevitably require access to program counter (PC) values through `ADR` instructions or branch instructions (e.g., `B` or `BR`). For direct branches, we resolve the branch target using $Table_{\text{IR_offset}}$ and encode the target IR locations into IR operands. Indirect branches are handled by extracting target register values, followed by IR address lookup via $Table_{\text{IR_offset}}$. In short, direct branch targets are resolved at translation time, whereas indirect branch targets are resolved at runtime.

Although *iLand* manages all control-flow transfers between IR blocks, certain execution mode transitions remain outside its direct control. Transfers occur between interpreting mode (I-state) and native executing mode (N-state). A primary I→N transition occurs when the guest invokes system library functions under application-only emulation. Correspondingly, the reverse N→I transition occurs when native functions return or invoke callbacks passed as function pointer parameters (e.g., `pthread_create()` parameter of `start_routine`). I→N transitions are handled by restoring the preserved registers only; no additional invocation state must be saved.

N →I transitions are more complex because RWX memory is forbidden. To enable stateless transitions, we implement a *trampoline* mechanism. Every guest instructions is associated with a trampoline in $Section_{tpl}$. For a given guest code address ($Addr_{\text{x}}$) and its trampoline ($Tramp_{\text{x}}$), transitioning from N to $Addr_{\text{x}}$ in the guest program is semantically equivalent to transitioning from N to $Tramp_{\text{x}}$ in *iLand*'s interpreter.

$Section_{tpl}$ achieves dynamic adaptation via shared pages, which combines immutable code and writable data while exploiting `pc-relative` instructions. Each trampoline page set consists of three code pages and one data page (Figure 5). Within the `TPL Code Page`, each $Tramp_{\text{x}}$ consists of two instructions:

- `stp x15, lr, [sp, #-0x10]`
- `bl L_stub_page`

$Tramp_{\text{x}}$ preserves two registers at the stack's top, then branches to `TPL Stub Page`. Code in `TPL Stub Page` reconstructs $Addr_{\text{x}}$ from LR together with data in the `TPL Data Page`. It then branches to unified entry point to start interpreter's loop at $Addr_{\text{x}}$. Notably, this process requires no additional state and does not overwrite any registers.

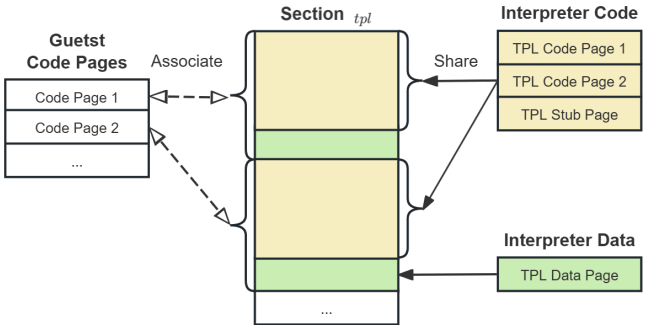

Figure 5: Trampoline memory layout. Memory pages with identical color are shared with same pages.

Each trampoline in $Section_{tpl}$ has a fixed length, enabling efficient address conversion between $Addr_{\text{x}}$ and $Tramp_{\text{x}}$ via bitwise operations rather than expensive table lookups.

We take the system function `pthread_create` as an example to demonstrate how *trampolines* are used in the N→I transition. Before native call to `pthread_create`, the interpreter identifies the native return address ($Addr_{\text{ret}}$) and the `start_routine` parameter ($Addr_{\text{start_routine}}$). It then replaces $Addr_{\text{ret}}$ and $Addr_{\text{start_routine}}$ with their trampoline addresses, i.e., $Tramp_{\text{ret}}$ and $Tramp_{\text{start_routine}}$. The substitution ensures N→I transition as:

- $Tramp_{\text{ret}}$ lets the caller thread resumes IR interpretation at IR_offset_{ret} after `pthread_create` returns
- $Tramp_{\text{start_routine}}$ lets the created thread begins IR execution at $IR_offset_{\text{start_routine}}$

The trampoline mechanism both preserves register state and ensures faithful entry into the interpreter's loop, exhibiting stateless characteristics and complying with diverse calling conventions. Notably, pages in $Section_{tpl}$ are shared and reused, thus i) they consume little additional physical memory despite $Section_{tpl}$'s large virtual size; and ii) they comply with the iOS sandbox because the code is always immutable.

6.3 Application-Only Emulation

Due to limited resource on mobile device, *iLand* focuses on emulating the app's own code, and allows system library functions to execute natively. This strategy requires *iLand* to regain control on N→I. Besides the return address and function-pointer parameters, other N→I scenarios that application-only emulation must handle include:

- **C++ virtual methods** of the guest app's C++ object lead to N→I transitions, e.g., objects' virtual destructors are invoked in `delete`.
- **ObjC message**, the dynamic dispatch to invoke ObjC methods defined in the guest app, leads to N→I transitions. In addition, ObjC runtime operations, including class creation and method swizzling, may also cause

N→I transitions.

- **ObjC block**, similar to function pointers, is the callback mechanism defined in ObjC. When calling system functions, apps pass `Block` parameters to receive callbacks.
- **Swift function pointers**, generated during compilation for reflection, e.g., witness table of Swift type, can behave like the C++ virtual methods invocation.
- **Stack unwinding**, used to implement exception handling (e.g. *try-catch*), transfers control to catch code block defined in the app, leading to N →I transition.

iLand utilizes a layered approach to ensure that N→I transitions are successfully captured and replaced by trampoline.

Initialization optimization driven by static analysis. As mentioned in Section 5, *iLand* employs a loader resolving dependencies and symbols. This specialized loader enables early-stage analysis before the guest app starts, including three optimizations for N→I transitions:

- Address fixups, where code pointers within data segments are identified via ASLR relocation information. Unidentified pointers fall through to the signal-based fallback, affecting only performance, not correctness.
- Symbol resolution, where specialized handling is implemented for `extern` decorated global function pointers in system libraries.
- ObjC pre-initialization, where all ObjC method function pointers are replaced with trampoline wrappers prior to class registration.

Runtime interception. *iLand* intercepts invocations on external C/C++/ObjC/Swift functions. As with our handling of `pthead_create`, during interception *iLand* replaces return addresses, function pointer parameters and ObjC block arguments with their corresponding trampolines. Additionally, return address modification requires special handling for stack unwinding. *iLand* addresses this by instrumenting private function pointers in `libunwind` to recognize trampoline points, enabling correct backtraces.

Signal handling with replicated memory layout. *iLand* preserves the guest app original memory layout, including binary code segments. If *iLand* fails to capture an N→I transition with a trampoline, control transfers into the original read-only code region, causing a `SIGSEGV` or `SIGBUS` generated by the kernel. *iLand* uses POSIX signal handling to intercept these exceptions and regain control.

However, this method incurs significant performance overhead, resulting in operations up to a thousand times slower than native execution. Consequently, this approach is used only as a fallback when previous mechanisms fail.

Lazy optimization during signal handling. *iLand* implements a lazy optimization strategy in its general signal handling. On each signal, *iLand* performs analysis:

- Resolve C++ vtable pointers using the object `this` pointer (the `X0` register) and vtable structure metadata
- Identify ObjC hybrid callback patterns by leveraging the ObjC object layout conventions

This approach incurs a one-time overhead per signal occurrence while maintaining optimal performance for subsequent invocations, and is applied primarily to C++ virtual method and ObjC block callback scenarios.

Interpreting libraries. In edge cases where libraries frequently transfer back to the guest app and *iLand* may fail to capture the transition, *iLand* continues to interpret the libraries to reduce the enormous overhead caused by frequent signal handling. A prominent example is `libswiftcore`, the Swift runtime library. Swift objects carry variable-length metadata structures containing multiple compressed function pointers (e.g., witness tables), whose diversity makes it impractical to statically enumerate all callback targets.

7 Virtual Environment Manager

The manager serves as the primary interface between the *iLand* and iOS, handling interactions between the guest app and the system. Utilizing the control-flow monitor capabilities provided by the interpreter, the manager intercepts and forwards library calls and syscalls, ensuring correct access to app and system resources while remaining transparent to the guest app. Specifically, the manager virtualizes a sandboxed filesystem and provides an in-process isolated memory.

File system virtualization. The manager implements a sandboxed file system that is visible only to the guest app and supports standard file operations. Each app's sandbox comprises a data container for app data storage and a bundle container for the app's code and resources. The guest app can reuse *iLand*'s data container since *iLand* does not store data in the container. As for the bundle container, *iLand* redirects the bundle path of the app to a clean folder. Specifically, *iLand* places the guest app's bundle in a private app group path and hijacks the bundle path by intercepting all file-related library calls and system calls.

In-process isolated memory. Leveraging the loader's capability, *iLand* loads the guest app into a designated memory region. The manager takes over the app's memory access, making this memory appear as the app's isolated memory. Specifically, iOS apps can access memory via three mechanisms: i) library APIs (e.g., `mach_vm_read`); ii) SVC invocations (e.g., Mach syscall); and iii) memory access instructions (e.g., `LDR`). The manager enforces memory isolation for cases (i) and (ii) by intercepting memory-access library calls and syscalls. Because *iLand*'s own memory is coalesced into a continuous region that lies at a lower virtual address than the guest-viewed region, with a randomized gap, guest apps generally do not probe unavailable address via raw load/store instructions (doing so typically triggers `SIGSEGV` termination). Accordingly, it is safe to omit case (iii). Although we have extended execution units of memory-access instructions, this feature is disabled by default for performance reasons.

8 Implementation

We implement *iLand* with more than 300 KLOC of C++/ObjC code, including 6,709 hand-written assembly execution units (each typically 1–3 assembly instructions), cross-compiled into an iOS dynamic framework.

Empirical optimization. Considering *iLand*'s sensitivity to performance, we made deliberate trade-offs in the translator and interpreter implementation. By moderately increasing the IR count, IR operand length, and memory footprint, we achieved relative performance improvements:

- Immediate value optimization. For instructions with immediate operands (e.g., 0-128), we introduced specialized μ-ops that directly assign values to registers instead of fetching them from IR operand. This increases IR count but eliminates one memory read operation.
- High-Frequency register operation acceleration. To reduce register spilling overhead, we add dedicated μ-ops that operate directly on the accessed registers. A notable example is for stack pushing instruction `STP X29,X30,[SP,#-0x10]!` frequently seen at function prologues. Adding a specialized μ-op avoids two register move cycles by directly handling `X29` and `X30`.
- Trampoline precomputation. Discussed in § 6.2, *iLand* replaces return addresses with trampolines during system library invocation. By extending `BL/BLR` instruction operands to encode precomputed trampolines into operands, we optimize the N→I transition. This reduces a multi-memory-access computation into a single memory read, increasing memory usage but reducing latency.

Prototype iOS app. Based on *iLand*, we implement a standard sandboxed iOS app. Although apps' main binaries are uniformly encrypted after distributed on App Store, researchers can get decrypted versions by tools (e.g., `trollde crypt` [57]) or public Internet (e.g., `decrypt.day` [14]). Our prototype processes decrypted packages:

Translator (§ 4) first performs ahead-of-time (AOT) translation on all binaries (including the main binary and embedded frameworks) int the IPA package. This batch translation generates *ir* files which are stored in the private app group path of our prototype app, together with the unpacked IPA contents. After translation, the stored artifacts are used in further interpretation. At startup, the loader (§ 5) coordinates the dynamic loading of *ir* files and the corresponding native binaries. The interpreter (§ 6) executes the μ-ops and manage control-flow transfers. The virtual environment manager (§ 7) transparently redirects sandbox resource access.

9 Evaluation

In this section, we perform a systematic assessment of *iLand*, focusing on four key dimensions: efficiency, capability, compatibility, and usability.

Table 3: Experimental setup. QEMU-jit represents the standard user-space emulator, while QEMU-tci denotes a built with the TCI (tiny code interpreter) backend.

Hardware	OS	Test Suite	Tool
iPhoneX Apple A11 Bionic 2.4GHz,3GB MEM	iOS 16.7.7	SPEC CPU ®2017	native Valgrind *iLand*
Alibaba Cloud ECS Yitian710 [42] 2.7GHz,4GB MEM	Linux 5.10.134 AArch64	SPEC CPU ®2017	native QEMU-jit QEMU-tci
iPhone14 Pro Apple A16 Bionic 3.4GHz,6GB MEM	iOS 17.3.1	AppStore Top Rank iOS Apps	*iLand*

9.1 Experimental Setup

We set up three groups of experiments to evaluate *iLand*'s performance (Groups 1 and 2) and real-world compatibility, usability (Group 3). The hardwares, OS, test suites, and tools used for comparison in each group are detailed in Table 3.

Group 1 setup. Group 1 is designed to assess the performance of *iLand* against other tools on the iPhone. Among existing tools, only Valgrind supports Apple OS. However, it natively supports only macOS, and its extended version for iOS([15] in 2015) lacks 64-bit support. Therefore, we ported the latest Valgrind (v3.24.0) to iOS, enabling DBI for command-line programs. As Valgrind relies on JIT-compiled code, we conducted the comparative experiments on a jailbroken device, specifically using an iPhone X running iOS 16.7.7, which supports Palera1n [11](v2.0) jailbreak. As for the test suite, we selected the SPEC CPU benchmark, which, although lacking an official iOS port, supports macOS Arm64 architectures. We performed cross-compilation of its v1.1.7 release on an Apple M1 Pro device to support iOS. Out of the original 19 benchmarks evaluating integer and floating-point performance, we excluded 11: 8 due to incompatibility with the iOS compilation toolchain (written in Fortran), and 3 failing to execute natively on the iOS platform.

Group 2 setup. Since *iLand* is designed to operate on iPhones where RWX memory is restricted, we use Group 2 to demonstrate its interpretation efficiency. Given the lack of comparable tools on iOS, we selected `qemu-tci`, which operates based on interpretation. Considering the platform differences, we ran both on their respective platforms and compared their slowdown factors relative to their native executions. We used the same SPEC CPU benchmark as in Group 1, and measured the performance slowdown of `qemu-tci` running on Elastic Cloud Server (ECS). Then we compare these results to the slowdown observed with *iLand* on the iPhone.

Group 3 setup. To demonstrate real-world compatibility and usability, we select an iPhone 14 Pro running iOS 17.3.1, for which no public jailbreak is currently available, and apply *iLand* to 60 top-ranked iOS apps, obtained from the US App Store in April 2025.

Table 4: Performance on SPEC CPU®2017. Numbers of Column 3-8 are the execution time in seconds.

Suite Name	Description	Group 1: on iPhoneX			Group 2: on Yitian710		
		native	Valgrind	*iLand*	native	QEMU-jit	QEMU-tci
perlbench_s	Perl interpreter	10.2	99.4	875.3	7.0	96.1	1981.0
gcc_s	GNU C compiler	19.6	228.0	973.6	16.6	147.8	2850.8
mcf_s	Route planning	60.4	272.6	785.4	40.1	230.1	3431.4
xalancbmk_s	XML to HTML conversion	34.2	415.6	3228.2	27.5	535.5	8622.4
x264_s	Video compression	12.5	111.0	1244.2	13.4	153.7	4512.3
xz_s	General data compression	23.2	61.8	663.7	16.8	66.1	1450.9
imagick_s	Image manipulation	21.0	353.8	911.8	16.0	613.4	10612.4
nab_s	Molecular dynamics	6.4	46.1	206.7	5.0	114.4	2033.0

9.2 Performance Efficiency

We conduct evaluation on iPhone X with `SPEC CPU®2017`. Given that the resource constraints of mobile devices, we employed the reduced-scale dataset `train` rather than `ref` as input throughout our evaluations. Adequate time intervals were implemented between consecutive test suites to cool down, preventing CPU throttling that may compromise benchmark accuracy. During testing, both of Valgrind and *iLand* run without any instrumentation. The execution times for native execution, Valgrind, qemu-jit, qemu-tci, and *iLand* in Groups 1 and 2 are listed in Table 4.

The results of Group 1 reveal that, compared to native execution, Valgrind and *iLand* exhibited a 5-10x and 15-90x increase in execution time, respectively. *iLand* translates each Arm64 instruction into several micro-operations, which results in a substantial increase in the number of instructions. In contrast, Valgrind natively run generated instructions and enabling a more lightweight instruction expansion. The performance gap between *iLand* and Valgrind (5-10x) is expected: Valgrind executes JIT-compiled native instructions, whereas *iLand* interprets micro-operations without RWX memory. Despite this gap, *iLand* remains practical for interactive use.

To contextualize *iLand*'s interpretation efficiency, Group 2 compares it against `qemu-tci`, another interpreter-based system. Because `qemu-tci` does not run on iOS and *iLand* does not run on Linux, we compare their respective slowdown factors relative to native execution on each platform, rather than absolute times. The results show that `qemu-tci` incurs 100-600x overhead over native execution, while *iLand* achieves 15-90x—a 5-15x advantage, especially on floating-point benchmarks. This advantage stems from *iLand*'s tight interpreting loop, which reduce dispatch overhead compared to `qemu-tci`'s generic tiny-code interpreter.

9.3 Instrumentation Capabilities

We categorize instrumentation capabilities along three dimensions: instruction-level, library call (libcall), and system call (syscall) instrumentation. Instruction-level instrumentation represents the most comprehensive capability, enabling arbitrary code insertion at any location without length constraints. Libcall and syscall instrumentation represent the ability to intercept standard library calls and hook supervisor calls (typically via `SVC`), respectively. Additionally, we consider maintaining instrumentation transparency to be an essential requirement, which involves evaluating whether the user-instrumented code preserves its original behavior.

We analyzed and compared the capabilities of *iLand* and existing popular instrumentation tools, as listed in Table 5. Only DBI tools and QEMU can achieve the three dimensions of instrumentation. Although QEMU shares equivalent instrumentation capabilities with *iLand*, it cannot support closed-source iOS. Compared to the other two DBI tools, only *iLand* can operate without relying on JIT and support iOS. Valgrind, even under jailbroken conditions, is limited to supporting GUI applications with basic functionality due to memory constraints, while Pin does not support Arm64.

Compared with Static Binary Instrumentation (SBI) tools, *iLand* exhibits technical superiority by code insertion at any instruction without constraints, whereas SBI tools suffer from instrumentation limitations dependent on both target instruction locations and surrounding code patterns. Notably, E9Patch encounters failures when processing specific instruction sequences, while ARMore demonstrates failures for binaries exceeding 256MB in size.

Compared to Frida and Cydia Substrate, which are widely used in iOS ecosystem, only *iLand* can insert arbitrary code at any position on the instruction-level. Substrate, designed to operate on jailbroken iOS devices, utilizes inline hooking, which requires space for several instructions to establish control flow hijacking. Frida's repackaging-based code injection mechanism offers limited analytical capacity, restricted to basic libcall hooks (via Global Offset Table modification), while lacking support for syscall interception.

9.4 Real-world Compatibility

We manually assess the compatibility of *iLand* across 64 apps from the US App Store's Top Free Apps list, downloaded in April 2025. We decrypted them by `trolldecrypt` [57] tool and emulated them using *iLand*, then manually tested whether their core functionality remained usable.

We list the tested apps in Appendix A.1. The apps cover 16

Table 5: Capabilities of DBA tools. ✓ denotes features that are deliberately designed and built-in supported. ○ indicates partial implementation with limitations or conditional constraints. × represents unsupported characteristics.

Type	Tool	Instruction Level Instrument	Library Call Intercept	System Call Intercept	Arm64 Support	JIT-free	iOS Adaptation	Instrument Transparency
DBI	*iLand*	✓	✓	✓	✓	✓	✓	✓
	Valgrind [46]	✓	✓	✓	✓	×	○	○
	Pin [43]	✓	✓	✓	×	×	×	○
SBI	E9Patch [16]	○	✓	✓	×	✓	×	×
	ARMore [6]	○	✓	✓	✓	✓	×	×
Other	QEMU [7]	✓	✓	✓	✓	✓	×	✓
	Frida [22]	×	✓	×	✓	✓	✓	×
	Substrate [12]	×	✓	✓	✓	×	✓	×

categories, with binary sizes broadly distributed between 40 and 400 MB. Of the 64 apps, 49 complete their core functionality under *iLand*—including login, browsing, search, video, and common app-specific features. These results indicate that *iLand* exhibits good compatibility. Notably, `Gmail`, a popular mail app, works correctly when logging in and browsing emails. `Youtube`, a well-known video app, plays video smoothly without lag or stutter, and other widely used social media apps, such as `X`, `Threads` and `Discord`, also support logging in and browsing real-time posts. Qualitatively, during manual testing the 49 working apps felt responsive: UI interactions (scrolling, tapping, typing) proceeded without perceptible delay, because UI rendering and media decoding are handled by native system libraries. These cases demonstrate the effectiveness of application-only emulation.

As for the other 11 apps that exhibited functional anomalies and 4 apps that self-terminated, our manual analysis indicated that these issues were mainly caused by their detection of *iLand*'s monitoring. A typical case involved an app attempting to delete files under its own bundle directory. Such operations are prohibited and failed on real iOS devices, but succeed within *iLand*'s virtualized environment, resulting in behavioral differences in subsequent executions. In theory, monitoring can be extended by monitor and instrumentation capabilities to further hide these traces, but how to find and hide the traces is beyond the scope of this paper.

9.5 Usability of App Vetting

Apple's App Review process substantially reduces the prevalence of malicious apps. However, prior work [15, 17] shows that policy-violating behavior can be embedded in complex app logic and may bypass review. We analyzed 60 top-ranked apps in the compatibility test and implemented a dynamic tracing plugin on top of *iLand* to collect four complementary types of evidence indicative of private-API use:

- Static SVC instructions. We count SVC occurrences in apps' binaries. Given that syscalls have convenient C wrappers, resorting to hand-written assembly is rare.
- Runtime syscall execution. We record executed SVC instructions and syscall function call, including the arguments passed to each syscall.
- Runtime dlsym usage. We log arguments passed to `dlsym` at runtime. Since the standard practice is to include headers and rely on link-time symbol resolution (simpler and faster), `dlsym` usage is rare.
- Indirect jumps to non-imported symbols. Using DBI's control-flow monitoring, we track all transfers into the DSC. We filter out transfers to imported symbols and known callbacks, and analyze the remaining targets.

Results. Across the 60 apps we tested, 24 embedded SVC instructions in their binaries, totaling 2,914 occurrences. Table 6 enumerates syscalls whose C-level wrappers are private APIs. Additionally, 15 apps invoke filesystem-related syscalls (e.g., SYS_lstat64, SYS_unlink) to access system directories.

Leveraging *iLand*'s control-flow monitoring, we traced all occurrences of transfers into non-imported symbols in DSC. We then resolved targets using the DSC local symbol table and filtered out 1,078 reasonable calls (e.g., Swift metadata accessor or ObjC callback). We manually verified the remaining targets and identified 13 apps that invoke private APIs. We list these APIs in Table 7. Among these, `SecTaskCopyValueForEntitlement` and `iokit_user_client_trap` are reject APIs; apps should not use them.

Discussion. We classify the motives for the private-API uses we found into three categories:

(A) Device fingerprinting [39] via system information that can be used to uniquely identify a device. Such data enables cross-account and cross-app tracking, which may raise privacy risks. For example, `statfs64` can reveal characteristics of the root file system that can be combined into fingerprinting features.

(B) Environment attestation and anti-tampering. Apps detect jailbreaking or repackaging by verifying code or signature integrity; for instance, the `SYS_csops` syscall can retrieve process's code-signing information; Apps may also search for injected code by enumerating memory with `vm_region`, or compare results from semantically equivalent APIs (e.g., syscalls versus libc wrappers) to detect tampering of API results.

Table 6: Uses of syscall detected by iLand in 60 top-ranked iOS apps.

Syscall Number	Corresponding C wrapper (Private API)	Functionality	Apps	Potential intent categories
SYS_csops	SecTaskCopyValueForEntitlement SecTaskCopyTeamIdentifier SecTaskCopySigningIdentifier	Fetch the process's code-signing status and entitlements	1	B
SYS_proc_info	proc_regionfilename proc_pidinfo proc_listpidspath	Fetch the process's path inforamtion	1	B
SYS_ptrace	ptrace	Prevent LLDB attaching	1	B
SYS_shared_region _check_np	_dyld_get_shared_cache_range	Fetch the DSC mapped start address and length	1	B
SYS_statfs64 SYS_statfs SYS_getfsstat64	statfs64 statfs getfsstat64	Get filesystem unique information	9	A
SYS___mac_syscall	__mac_syscall	Check if the process is in sandbox	2	B

Table 7: Uses of private APIs detected by iLand.

Indirect call to non-imported function	Functionality	Apps	Potential intent categories
iokit_user_client_trap	Interact to IOKit	1	B
SecTaskCreate- FromSelf SecTaskCopyValue- ForEntitlement	Get entitlements	1	B
task_dyld_process_- info_notify_get	Get loaded dylib	1	B
ubrk_* e.g., ubrk_next	Use lowlevel unicode processor	1	C
uregex_* e.g., uregex_start	Use lowlevel regex engine	2	C
vm_region_64 vm_region_recurse_64	Get memory mapping	5	B
ptrace	Prevent LLDB attaching	2	B
__sel_registerName	Register ObjC selector in another way	1	B
__syscall	System call in another way	2	B

(C) Performance or capability gains via low-level, undocumented APIs, aiming for faster execution or access to functionality that not publicly exposed.

We assess categories (A) and (B) as potential privacy risk for users, whereas category (C) can introduce stability risks for the app itself across OS updates.

We find that several private APIs can be invoked via direct system calls, yet syscall-based usage appears to receive insufficient attention during app review. For example, `SYS_csops` retrieves code-signing and entitlement information. The three `SecTaskCopy*` APIs (Table 6) that offer similar functionality are reject APIs; calls to those C APIs are rejected by TestFlight's automated review, but the syscall-based invocation bypassed the review. Beyond this, we observed 15 apps covertly reading system files via `SYS_open` and `SYS_read`—for instance, a system file in path */private/var/containers/...* accidentally contains device fingerprinting, which poses privacy risk. The syscall route is rather stealthy: i) syscall numbers are passed in registers and are therefore observable at runtime, complicating static analysis; and ii) whether a syscall is suspicious depends on its arguments—for example, `SYS_open` on sandboxed paths is benign, whereas attempts to open system directories are worth further scrutiny. *iLand* can reliably monitor such covert syscall activity.

We further performed reverse engineering to analyze how these apps evade App Review—for example, some construct control flow via ROP. We detail these techniques in § 2.3.

Limitation. Our case studies did not further analyze ObjC private-API usage, although *iLand* can instrument ObjC message sends and capture argument values. As with other dynamic analyses, achieving full path coverage is challenging. To mitigate this in our experiments, we manually completed account registration and login flows to drive deeper app logic. Following prior work [15], forced execution can improve coverage; *iLand* may support this in future work.

10 Related Work

Dynamic binary instrumentation (DBI) has many mature technologies. DynamoRIO [9], Intel Pin [43], Dyninst [8] and Valgrind [46], the most popular general DBI tools, achieve efficient instruction-level instrumentation through JIT-compiled code. To further improve traditional DBI, researchers proposed multiple optimization approaches, including translation optimization [13, 27, 34, 60], multi-thread efficiency improvement [29, 33, 48], and LLVM backend integration [19, 44, 59]. Although researchers have extended DBI capabilities to diverse platforms [4, 21, 26, 54], the closed-source iOS, running on limited-resource devices, carries a barrier to porting.

Several instrumentation solutions have been developed for iOS, such as Cydia Substrate [12], Dobby [36] and Fishhook [20]. These solutions require code injection on jailbreaking devices, overwriting the original instructions to jump to the inserted code when implementing inline-hook instrumentation, which is not transparent and is limited by instruction space, preventing instrumentation at arbitrary locations. As a result, there is a lack of a DBI solution capable of performing arbitrary instruction instrumentation on iOS.

11 Conclusion

In this paper, we present *iLand*, an instruction-level dynamic binary instrumentation framework for iOS. *iLand* translates and interprets binary instructions using its IR and atomic execution units without RWX memory. We propose application-only emulation, where system libraries run natively without interpreting, addressing mobile device memory and performance constraints. We implement the prototype of *iLand* as a standard iOS app and evaluate it on 64 top-ranked iOS apps from the App Store. In our compatibility study, 49 apps completed their core functionality under emulation, and 60 apps reached a sufficiently usable state for our app-vetting study. We also conducted an app-vetting study on these 60 apps and found 13 apps are still invoking private APIs. Our further analysis revealed new and stealthy methods to evade App Review, and found a new way of collecting sensitive information via direct SVC instruction invocation.

Acknowledgments

We thank the OSDI reviewers and our shepherd for their insightful feedback and guidance, which significantly improved this paper. We are also grateful to Alibaba Group for its support of this work and its research incentive policies.

A Appendix

The table lists the 64 evaluated apps by decreasing binary size and all were drawn from the App Store's Top Free list in April 2025 on iOS 16.7.7.

Table A.1: Compatibility evaluation. `Binaries` represents the total size of the app's binaries. `Eval.` delineates the outcomes, where ✓, ○ and × indicate full, partial, no functionality, respectively.

Abstract

Training trillion-parameter models relies on pipeline parallelism to scale across thousands of accelerators. However, architectures exemplified by the Qwen family are evolving from uniform Transformer blocks into heterogeneous compositions that combine sparse Mixture-of-Experts (MoE) with different attention variants. This heterogeneity breaks the uniformity assumption behind existing pipeline systems: partitions chosen from serial layer costs become imbalanced after communication is overlapped with computation, because different layer combinations hide different fractions of their communication. Furthermore, at the scale of 10K+ GPUs, MoE routing variation adds a runtime source of stalls, creating transient idle slots that static plans cannot anticipate.

We present Tessera, a framework that co-optimizes partitioning and overlap scheduling for heterogeneous pipeline training, and adapts to runtime dynamics. Tessera introduces: (1) an *overlap scheduler* that synthesizes fine-grained interleavings for each layer combination; (2) an *overlap-aware partitioner* that uses profiled post-overlap cost to select partitions balanced for parallel execution; and (3) a *dynamic bubble optimizer* that fills routing-induced idle slots with movable tasks at runtime. Deployed on production clusters for pre-training Qwen3 and Qwen3-Next, Tessera improves throughput by 20%–33% over our production baseline across five workloads at scales from 4,096 to 12,288 GPUs, reaching 39% MFU on a trillion-parameter model. In controlled experiments against Megatron-Core MoE with public recipes, Tessera achieves up to 1.24× higher MFU.

1 Introduction

Foundation models are evolving from uniform Transformer stacks into heterogeneous compositions that mix hybrid attention variants with sparse Mixture-of-Experts (MoE) blocks [3, 24, 37]. The uniform overlap and partitioning policies behind current pipeline systems no longer transfer cleanly. In training the **Qwen3** and **Qwen3-Next** model families on production clusters exceeding 10,000 GPUs, we find that structural heterogeneity, most visible in Qwen3-Next, breaks the assumptions these systems rely on.

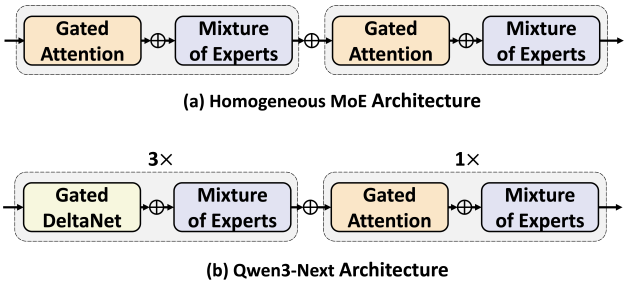

Figure 1: **Heterogeneity in Qwen3-Next Architecture.** (a) standard Transformer layer; (b) Qwen3-Next interleaves Gated DeltaNet and standard attention layers.

The cost this heterogeneity exposes lies in how communication is overlapped with computation. MoE layers require heavy All-to-All (A2A) communication for token dispatch and combination [8, 11, 26]. Pipeline schedules can hide this cost by overlapping A2A transfers with computation from other in-flight microbatches. For uniform architectures (Fig. 1(a)), every stage has a similar compute-to-communication ratio, so a single overlap strategy applied uniformly suffices.

Qwen3-Next (Fig. 1(b)) breaks this assumption. It interleaves linear-attention layers (Gated DeltaNet) with standard softmax-attention layers, each followed by a sparse MoE block. These layer types have different compute profiles, especially at long sequence lengths. When such diverse layers are grouped into pipeline stages, different combinations present different compute-communication timelines. A fixed overlap strategy applies one interleaving to all; it fits some combinations but leaves more communication exposed in others. In our measurements, the resulting overlap gain differs by 3×.

This variation creates a cyclic dependency between partitioning and overlap scheduling. The partition determines which layer combinations co-execute and thus which overlaps are possible. Choosing a good partition, however, requires accurately estimating each combination's post-overlap cost, which requires scheduling it and measuring the resulting execution on hardware. A partition balanced for serial execution cost can become the pipeline bottleneck after overlap, because stages that look equal in serial time hide vastly different fractions of their communication. Existing pipeline systems sidestep this coupling by assuming uniform overlap efficiency—an assumption that holds for homogeneous models but fails under heterogeneity. In our experience, domain experts then spend weeks hand-tuning this interplay for each new model architecture.

Even after static co-optimization addresses the predictable structural coupling, MoE routing stochasticity leaves residual runtime bubbles: the number of tokens dispatched to each expert fluctuates across iterations, creating ephemeral idle slots that a static schedule cannot reliably anticipate or exploit.

We present Tessera, a pipeline parallelism framework that co-optimizes overlap scheduling and partitioning, and adapts to runtime dynamics. Designed as a plug-in to the host training framework, it requires no invasive modifications to the existing training loop. Within a given pipeline schedule (e.g., interleaved 1F1B), Tessera synthesizes a specialized overlap schedule for each layer combination and uses its measured post-overlap cost to guide partition selection. At runtime, a *Dynamic Bubble Optimizer* monitors routing metadata to predict idle slots and fills them with deferred work. The design has three parts:

- **Overlap Scheduling.** Tessera observes that overlap efficiency depends on the specific layer combination, not just aggregate arithmetic cost. It replaces fixed strategies by synthesizing and profiling a specialized overlap schedule for each combination.
- **Overlap-Aware Partitioning.** Using profiled post-overlap costs, Tessera selects a partition that balances measured post-overlap cost rather than serial arithmetic, breaking the cyclic dependency via a profile-then-partition sequence.
- **Dynamic Bubble Optimization.** At runtime, Tessera predicts routing-induced idle slots from token-distribution metadata and fills them with deferred tasks, recovering throughput that static planning leaves unexploited.

We implemented Tessera atop Alibaba's internal Megatron-LM and deployed it on production clusters with over 10,000 NVIDIA Hopper GPUs for pre-training the Qwen3 and Qwen3-Next families. Compared to our production-optimized internal baseline, Tessera improves throughput by 20%–33% across five workloads at scales from 4,096 to 12,288 GPUs,

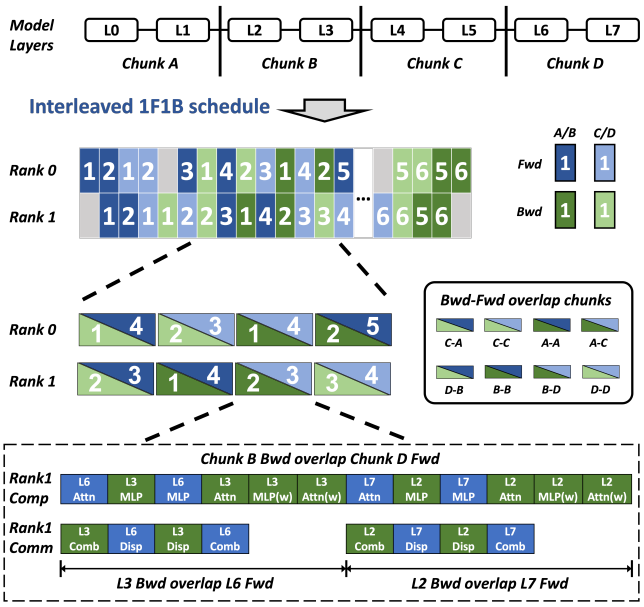

Figure 2: **Mechanism of Inter-Microbatch Overlap.** The bottom panel illustrates how the backward pass of Chunk *B* is overlapped with the forward pass of Chunk *D* by interleaving decomposed operations.

with peak MFU reaching 39% on a trillion-parameter run. In controlled experiments on a 256-GPU cluster against Megatron-Core MoE with publicly available per-model recipes, Tessera achieves up to 1.24× higher MFU. Tessera has been in continuous production use since April 2025.

2 Background and Motivation

2.1 Pipeline Execution and Overlap Pairs

This section defines the pipeline execution model that underlies the rest of the paper. Whereas Tensor Parallelism [22] splits operators within a layer and Context Parallelism [18] partitions the sequence dimension across devices, **Pipeline Parallelism (PP) [7]** partitions the model *across* layers into groups called *chunks*. Each chunk is assigned to a pipeline stage mapped to a specific device topology. To reduce the idle time (bubble) inherent in sequential stage execution, each training batch is further split into *microbatches* that can be pipelined through stages concurrently. A schedule governs how microbatches are dispatched. The widely adopted 1F1B schedule [22] alternates one forward and one backward microbatch per stage to bound memory while keeping the pipeline busy. Its *interleaved* variant further reduces bubble by assigning each physical rank multiple "virtual" stages, each corresponding to a distinct model chunk.

Inter-microbatch overlap. In an interleaved schedule, adjacent operations on a rank can come from different chunks and microbatches, allowing one chunk's communication to

overlap another's computation. We refer to communication-computation overlap across different microbatches as *inter-microbatch overlap*. As shown in Fig. 2, chunks from different microbatches alternate on the same rank, and the A2A communication of one chunk's backward pass (e.g., Chunk *B*) can execute concurrently with the computation of a subsequent chunk's forward pass (e.g., Chunk *D*). We call two chunk operations that share such a concurrent execution window an *overlap pair*. An overlap pair includes the execution direction of each chunk, such as backward-on-*B* overlapped with forward-on-*D* in Fig. 2. Thus, pair types such as `B-D` and `D-B` are not merely unordered chunk sets; they can represent different directional overlap cases. For each overlap pair, the relevant performance metric is not the serial sum of its constituent operations, but the *post-overlap cost*: the resulting makespan of the co-scheduled overlap pair.

The uniformity assumption. Traditional PP overlap strategies rely on a strong implicit assumption: the model consists of uniform "Transformer bricks" with similar arithmetic intensity and communication patterns [33]. Under this assumption, all overlap pairs are structurally identical, so a hand-crafted fixed overlap template combined with layer-count balancing naturally yields both effective overlap and a load-balanced pipeline. Next-generation architectures break this uniformity.

2.2 Heterogeneous MoE Architectures

To scale Mixture-of-Experts (MoE) models, experts are partitioned and distributed across multiple devices [11]. This distribution necessitates All-to-All (A2A) communication for token dispatch and combination. At scales beyond several thousand GPUs, A2A latency constitutes a substantial fraction of iteration time, making it the primary target for overlap.

Prior works like Comet [39] employ *intra-microbatch overlap*, fusing communication with computation from the *same* microbatch. However, for heterogeneous models this approach forces kernel fragmentation by slicing the sequence dimension, reducing arithmetic intensity (detailed in §5). Inter-microbatch overlap avoids this fragmentation but shifts the hard problem: given a pipeline stage partition, which overlap pairs are induced, and how should their sub-operations interleave? Exploiting this form of overlap requires decomposing layers into fine-grained schedulable units so that communication and computation from different chunks can be interleaved. We refer to each such unit as a *task* (e.g., `Dispatch`, `MLP`, `Combine`).

Qwen3-Next: a concrete case of pair diversity. Qwen3-Next adopts a hybrid attention design in which every four consecutive layers follow a 3:1 pattern: three Gated DeltaNet (GDN) linear-attention layers followed by one full softmax-attention layer. Each layer is followed by a sparse MoE feed-forward block. Under production sequence lengths, this operator mix produces up to 10× compute-time asymmetry between adjacent attention operations. As shown in Fig. 3, when these

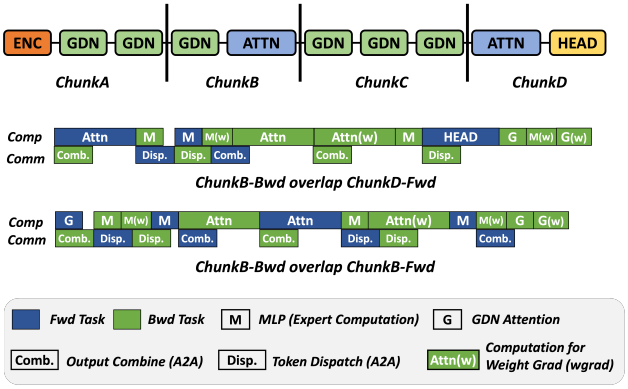

Figure 3: **Combinatorial Explosion of Overlap Patterns.** The Qwen3-Next architecture produces asymmetric chunks, resulting in diverse overlap pairings that require structurally different fine-grained plans. For clarity, MoE blocks following the GDN and standard attention are not shown.

asymmetric chunks are assigned to virtual stages, they form overlap pairs with diverse compute-communication profiles. Each letter (A, B, C, D) denotes a chunk type defined by its attention/MoE composition. Even a simple 2-stage pipeline produces up to eight distinct pair types (e.g., `B-D`, `D-B`), each requiring a different fine-grained interleaving. A single overlap template cannot serve this diversity.

2.3 The Co-Optimization Problem

Existing systems optimize pipeline training as a waterfall: first partition by serial layer cost, then apply a fixed overlap template, then execute the resulting static plan. Heterogeneous MoE violates each step of this pipeline. We identify three compounding failures: the overlap scheduling space is combinatorial (§2.3.1), the partition objective is misleading (§2.3.2), and runtime variation leaves residual idle slots that static planning cannot predict (§2.3.3). The first two form a static planning cycle that requires joint optimization. The third motivates runtime adaptation.

2.3.1 Combinatorial Overlap Space

Template-based schedulers cannot handle the pair diversity created by heterogeneous chunk types. In a homogeneous model, every overlap pair is identical (e.g., `A-A`), and a single interleaving strategy works universally. In Qwen3-Next, even a single partition of the minimal 2-stage case produces up to eight distinct pair types, each requiring a unique fine-grained schedule: a computation-intensive chunk might successfully hide a communication-intensive chunk's A2A, whereas two communication-heavy chunks may result in significant exposed latency. Existing systems rely on rigid templates (e.g., always aligning "forward combine" with "backward attention"). With asymmetric chunks, the optimal interleaving de-

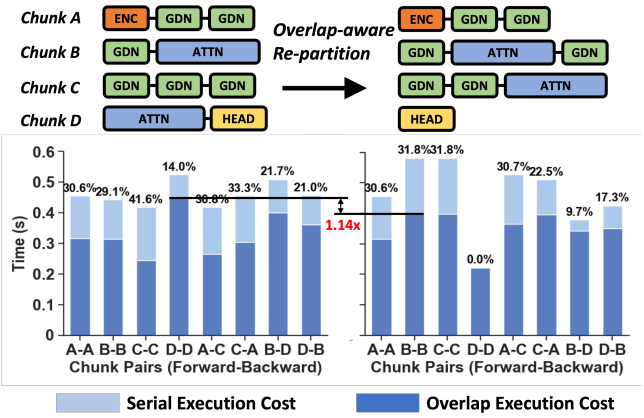

Figure 4: **Impact of Variable Overlap Efficiency.** Variation in overlap gains under two partition plans. Data collected from training 8 layers of the Qwen3-Next-80B model with sequence length 256K on 128 GPUs. Left: A partition balanced for serial execution becomes imbalanced in post-overlap execution. Right: Tessera's overlap-aware partitioner finds a plan that balances the post-overlap cost.

pends on the specific hardware resource usage of the constituent chunks. Manually engineering schedules for this combinatorial space is impractical.

2.3.2 Variable Overlap Efficiency

Standard partitioners sum the sequential execution time of layers and balance this sum across stages. This strategy implicitly assumes that *overlap efficiency*, the fraction of communication hidden, is constant across the model.

In heterogeneous MoE models, overlap efficiency varies drastically. Fig. 4 (Left) presents profiling data from a balanced partition for the model architecture illustrated in Fig. 3. The chunk pair `C-C` achieves a 41.6% reduction in latency via overlap, while pair `D-D` achieves only 14.0% because both sides are computation-dominated with little A2A communication to hide. A partition balanced for serial execution can thus manifest severe imbalances during parallel execution.

An optimal partitioner must be *overlap-aware*: it should deliberately create serially "imbalanced" assignments if those pairings have complementary compute/communication profiles that maximize overlap. As shown in Fig. 4 (Right), the serial-cost-balanced partition has a 1.14× higher bottleneck post-overlap cost than the overlap-aware partition.

Moreover, the dependency is bidirectional. The overlap schedule determines how much communication each pair hides, which in turn determines which partition minimizes the bottleneck. A partition that appears serially imbalanced may yield the lowest post-overlap cost when its pairings have complementary profiles. Partition quality therefore cannot be evaluated without first scheduling and measuring each candidate pair. Partitioning and overlap scheduling are thus cyclically dependent.

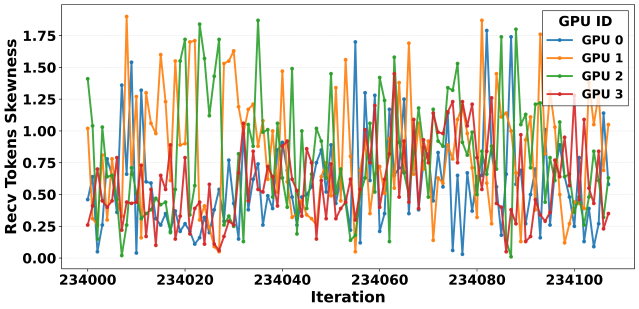

Figure 5: **Runtime Token Load Variation.** The distribution of received tokens per device varies across iterations, creating dynamic imbalance that static planning cannot address.

2.3.3 Runtime Stochasticity

Even an optimal static plan is vulnerable to runtime stochasticity. The number of tokens routed to specific experts fluctuates across iterations, causing the duration of MoE compute kernels to vary. In Qwen3-Next, this effect is amplified by fine-grained sparse routing: each token activates only 10 of 512 experts, so each expert receives a smaller expected share of the token pool. This lower routing coverage increases the relative variation of per-expert and per-rank token counts across iterations, as reflected in the per-device load-skewness fluctuations shown in Fig. 5. These fluctuations create ephemeral idle slots that no static schedule can predict.

The key observation that makes runtime optimization feasible is that not all rank-local work lies on the microbatch critical path. We call the critical-path tasks that define stage latency the *backbone tasks*. The remaining timing-flexible tasks (e.g., weight-gradient computation, gradient reduction) that can fill transient gaps are called *movable tasks*. Deferring movable tasks and injecting them into routing-induced idle slots can recover throughput that static planning leaves unexploited.

Summary. Partitioning and overlap scheduling are cyclically dependent: partition boundaries determine which overlap pairs form, while overlap efficiency determines which partition is optimal. Runtime routing variation adds a dynamic dimension that no static solution can address. Together, these challenges render stratified optimization pipelines inadequate for heterogeneous MoE training.

3 Tessera Design

To resolve the partitioning–overlap cycle (§2.3.2), Tessera fixes the high-level pipeline schedule (e.g., interleaved 1F1B) and co-optimizes partitioning and overlap scheduling within it. A static planner produces an execution plan (§3.1), and a plan-agnostic execution engine (§4) interprets it at runtime,

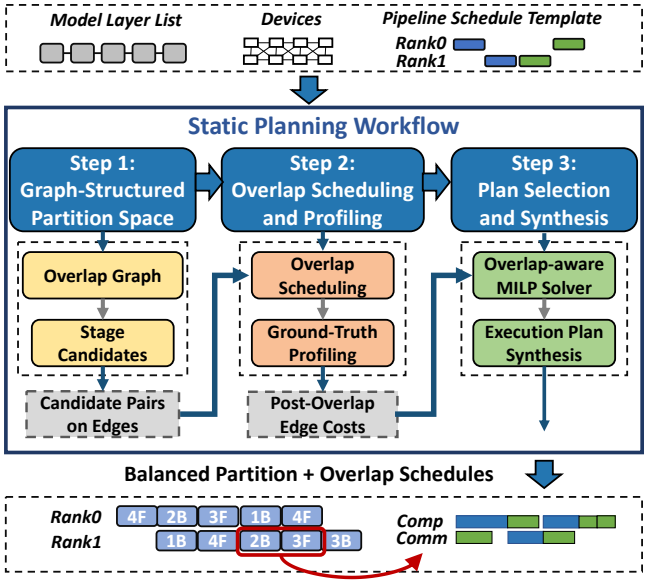

Figure 6: Overlap-aware static planning workflow.

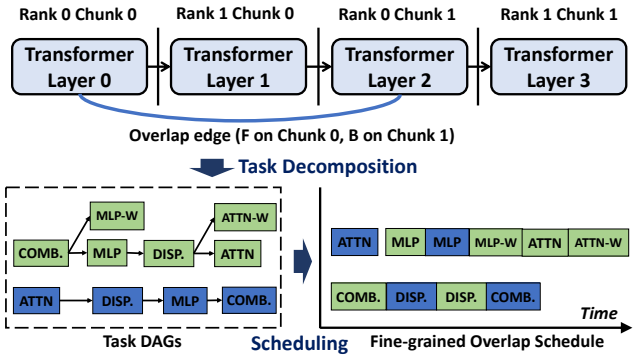

Figure 7: Decomposing an overlap edge into task DAGs and synthesizing a fine-grained overlap schedule. The figure highlights one forward–backward overlap edge on Rank 0, omitting other pass-direction edges. Each stage contains a single layer for clarity.

decoupling scheduling logic from the host framework. To handle stochasticity that the static plan cannot predict, a *Dynamic Bubble Optimizer* fills routing-induced idle slots with eligible movable tasks, without changing partition boundaries or the planned order of backbone tasks (§3.2).

3.1 Static Planning

We refer to the fixed high-level pipeline schedule (e.g., interleaved 1F1B) as the *pipeline schedule template*. Given this template, Tessera resolves the static partitioning–overlap cycle through a *candidate-generation-and-profiling* workflow. Fig. 6 summarizes this workflow. Step 1 constructs an overlap graph from the template and attaches bounded stage candidates to each virtual stage (§3.1.1). Step 2 instantiates each candidate pair on an overlap edge as a concrete overlap pair, synthesizes its fine-grained overlap schedule, and profiles its post-overlap cost on a reference device group (§3.1.2). Step 3 selects one candidate per stage via MILP to minimize the bottleneck post-overlap cost, then materializes the selected partition and per-pair schedules into the final execution plan (§3.1.3).

3.1.1 Step 1: Overlap Graph and Candidate Space

The pipeline schedule template determines a set of virtual stages and which of them may execute microbatch operations concurrently on the same rank. These relationships define an *overlap graph* $G=(\mathcal{S},\mathcal{E})$. Each node $s \in \mathcal{S}$ is a virtual pipeline stage under the template. Tessera adds an *overlap edge* $e=(s,t) \in \mathcal{E}$ for each overlap opportunity that the template creates on a pipeline rank, where endpoints s and t may be the same virtual stage. Each edge records the pass directions of the two endpoint operations, so the same endpoint pair may yield multiple edges, e.g., forward-on-s with backward-on-t and backward-on-s with forward-on-t. A self-loop denotes an overlap opportunity between operations of the same virtual stage from different microbatches. With the graph topology fixed by the template, the layers each node carries remain to be selected.

Tessera starts from a serial-cost-balanced baseline partition as the initial assignment of layers to virtual stages. To explore alternative partitions, Tessera generates a candidate set C_s for each stage s. A *stage candidate* $c \in C_s$ specifies one possible model chunk for virtual stage s: a contiguous layer range generated by perturbing boundaries around the baseline. For any candidate pair $(c \in C_s, d \in C_t)$ on an overlap edge $e=(s,t)$, the post-overlap cost lies between $\max(T_c, T_d)$ (perfect overlap) and T_c+T_d (zero overlap), where T_c and T_d denote the serial costs of candidates c and d respectively. Tessera restricts candidates to a bounded neighborhood around the baseline to keep overlap scheduling and profiling tractable.

Together, the overlap graph and stage candidates define the search space for joint optimization. Selecting one candidate per node determines a concrete pipeline partition. Each edge poses a scheduling subproblem: for a given pair of endpoint candidates, Tessera must synthesize a fine-grained overlap schedule and measure its post-overlap cost. The profiled edge costs then feed the partition solver that minimizes the bottleneck post-overlap cost across the graph.

3.1.2 Step 2: Overlap Scheduling and Profiling

Once candidates c and d are assigned to the endpoint stages of edge e, the layer ranges, pass directions, and device topology are fully determined, specifying a concrete overlap pair. For each such pair, Tessera synthesizes a fine-grained overlap schedule and measures the post-overlap cost $T_{e,c,d}$.

Algorithm 1 Event-driven scheduling for overlap-pair task DAGs

Input: task DAGs D_1, D_2 (overlap pair)
Output: Overlap schedule S for tasks in $D_1 \cup D_2$

Ready $\leftarrow$ initial tasks with no unsatisfied dependencies
Running $\leftarrow \emptyset$; *Pending* $\leftarrow \emptyset$; *Time* $\leftarrow 0$
while *Ready* $\cup$ *Running* $\neq \emptyset$ **do**
  for resource $r \in \{Comp, Comm\}$ where r is idle **do**
    $\tau \leftarrow$ SELECT(*Ready*$[r]$) ▷ backbone-first gap-fit selection
    if $\tau = \perp$ **then continue**
    if ISMOVABLE(τ) **and** *Running* $\neq \emptyset$ **and** SHOULDDEFER(τ, *Time*) **then**
      move τ from *Ready*$[r]$ to *Pending*$[r]$ ▷ defer to protect backbone completion
    else
      remove τ from *Ready*
      SCHEDULE(τ, *Time*)
  Time $\leftarrow$ next task completion event
  Update *Ready* with newly unblocked tasks in D_1, D_2
  ▷ Backfill deferred movable tasks
for $\tau \in$ *Pending* in reverse readiness order **do**
  BACKFILL(τ, S) ▷ best-fit residual slot or tail

Tessera decomposes each overlap pair into two task DAGs, one per chunk, as illustrated in Fig. 7. Each task is an atomic scheduling unit with a duration, resource type, and dependency constraints. These attributes determine when a task becomes ready, which resource it can use, and whether it fits the current gap.

Given these DAGs, Tessera uses an event-driven list scheduler (Algorithm 1) to minimize the pair's makespan on two resources (Comp, Comm). At each event, SELECT applies two heuristics. (i) *Backbone-first alignment*: backbone tasks take precedence, and a gap-fit rule picks the task whose duration is closest to the remaining window on the complementary resource. (ii) *Conditional deferral*: movable tasks are placed when they fit the current gap without extending the pair's makespan. SHOULDDEFER defers a movable task that would extend the pair's makespan. Once backbone placement is complete, deferred movable tasks are backfilled into residual slots within their lifetimes using a best-fit rule; tasks with no suitable slot are placed at the tail.

Tessera executes the synthesized schedule on a *reference device group*, a dedicated device set configured with the same TP/EP topology as the target rank, to measure *ground-truth post-overlap cost*. Physical profiling is necessary because real hardware interference causes the true overlapped cost to deviate from analytical estimates (§5). To bound overhead, Tessera profiles each distinct overlap pair only once: when multiple edge-candidate pairs yield identical chunk specifications, pass directions, and device topologies, their profiles are shared. Results are cached by device-mesh class and chunk specification for reuse across ranks and replicas with matching GPU type and interconnect pattern.

3.1.3 Step 3: Overlap-Aware Partition Selection

With all post-overlap costs $T_{e,c,d}$ profiled, partition selection reduces to a graph labeling problem. Pipeline iteration time depends on the full critical path through the fixed schedule. Under the fixed template, Tessera targets the steady-state overlap opportunities that recur across microbatches: a selected edge with high profiled post-overlap cost would repeatedly expose a straggler. Tessera therefore uses the maximum selected post-overlap edge cost as a surrogate objective for partition selection. Formally, binary variable $y_{s,c}$ selects candidate c for node s; $z_{e,c,d}$ activates the candidate pair selected on edge $e{=}(s,t)$. Each node selects exactly one candidate, and each edge variable is consistent with its endpoint selections:

$$
\begin{aligned}
\min \quad & T_{\text{dom}} \\
\text{s.t.} \quad & \sum_{c \in C_s} y_{s,c} = 1 && \forall s \in \mathcal{S}, \\
& \sum_{d \in C_t} z_{e,c,d} = y_{s,c} && \forall e{=}(s,t) \in \mathcal{E},\, c \in C_s, \\
& \sum_{c \in C_s} z_{e,c,d} = y_{t,d} && \forall e{=}(s,t) \in \mathcal{E},\, d \in C_t, \\
& T_{\text{dom}} \geq \textstyle\sum_{c,d} T_{e,c,d}\, z_{e,c,d} && \forall e \in \mathcal{E}, \\
& y_{s,c},\ z_{e,c,d} \in \{0,1\},
\end{aligned}
\tag{1}
$$

$T_{e,c,d}$ is the profiled *post-overlap* cost of candidate pair (c,d) on edge e. The bottleneck constraint charges each overlap edge by the cost of its selected pair. The full solver additionally enforces contiguous non-overlapping layer ranges, device-topology compatibility, and per-rank memory capacity constraints.

Complexity and Profile-Guided Pruning. By decoupling the search into stage-level variables and linking adjacent stages via consistency constraints, this MILP formulation reduces the binary variable count from $O(N \cdot K^{vp})$ in rank-level enumeration to $O(N \cdot vp \cdot K^2)$, where N is the number of pipeline ranks, vp is the number of virtual stages per rank, and K is the candidate count per stage; bottleneck constraints scale as $|\mathcal{E}|$, one per overlap edge. To further accelerate the solver, Tessera applies safe profile-guided pruning. The bottleneck post-overlap cost of the baseline partition, T_{base}, serves as an upper bound on T_{dom}: any candidate pair whose profiled cost exceeds T_{base} is discarded, since selecting it cannot improve upon the baseline. If a stage candidate c loses all valid pairs on its incident edges, it is removed from the search space. In practice, this significantly reduces the MILP size while preserving all solutions with $T_{\text{dom}} \leq T_{\text{base}}$.

Plan Synthesis. The selected node labels on the same physical rank compose that rank's assignment. The solver's output is materialized into the final execution plan by instantiating the pipeline schedule template and substituting each edge with the fine-grained overlap schedule synthesized in Step 2.

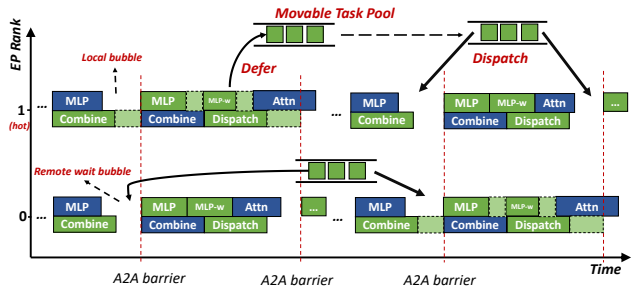

Figure 8: Dynamic scheduling of movable tasks into bubbles.

3.2 Dynamic Bubble Optimization

Static planning assigns each movable task a default execution position within the overlap schedule. At runtime, MoE routing variation changes task durations, shifting the size and location of idle slots in ways that no static plan can predict. The *Dynamic Bubble Optimizer* may defer eligible movable tasks and dispatch them into predicted idle slots, recovering throughput that static planning leaves unexploited.

3.2.1 Bubble Prediction and Slot Sizing

Runtime variability is primarily driven by token routing decisions. To detect routing-induced bubbles before they occur, Tessera reuses routing metadata that becomes available before expert dispatch. Within each EP group, ranks exchange only per-expert token counts via a lightweight collective that piggybacks on the existing MoE dispatch path. Because the exchange is scoped to the EP group and carries scalar counts rather than tensor payloads, it introduces no cluster-wide synchronization. An imbalance monitoring mechanism uses these counts to estimate the workload assigned to each rank. Deviations from the profiled static schedule predict where and how large idle slots will form.

Tessera pre-annotates target slot locations during static planning. Whether a slot materializes, and how large it is, is determined at runtime. As illustrated in Fig. 8, load imbalance typically prolongs specific operations (e.g., MLP on hot experts), inducing local idle time and cross-device wait states.

To capture these routing-induced gaps, Tessera locates structural boundaries directly after MoE computation tasks within the overlap schedule (§3.1.2). The two chunks in an overlap pair can originate from different microbatches with independent token distributions; their latencies can shift in opposite directions, so the idle window at these boundaries fluctuates widely across iterations. Pre-annotating these locations provides Tessera with effective insertion points for movable tasks.

Target Slot Sizing. To ensure that task injection does not stall the training pipeline, Tessera must estimate slot sizes asynchronously. Token distribution is resolved during the forward dispatch, so load information becomes available several steps before the target slot. The sizing calculation thus overlaps with useful computation. Using the observed token distribution and the offline-profiled static schedule, Tessera estimates the fillable idle window b_β at each pre-annotated target slot β. Non-positive windows are skipped.

Algorithm 2 Dynamic Bubble-Filling

Input: Token distribution $\mathbf{T}$, offline profile $\mathcal{P}$, movable task pool Q

▷ Retrieve pre-annotated target slots
$\mathcal{B} \leftarrow$ GETTARGETSLOTS() ▷ From static plan
▷ Fill predicted slots from movable task pool
for each target slot $\beta \in \mathcal{B}$ **do**
  $b_\beta \leftarrow$ ESTIMATEBUBBLESIZE($\mathbf{T}, \mathcal{P}, \beta$) ▷ Asynchronous
  if $b_\beta > 0$ **then**
    $r \leftarrow \beta$.rank, $t_{\text{start}} \leftarrow \beta$.time
    $\mathcal{C} \leftarrow \emptyset$
    for each task $\sigma \in Q$ **do**
      if σ is ready on r **and** σ.duration $\le b_\beta$ **and** $t_{\text{start}} +$ σ.duration $\le \sigma$.deadline **then**
        $s \leftarrow$ COMPUTESCORE(σ, b_β)
        $\mathcal{C} \leftarrow \mathcal{C} \cup \{(\sigma, s)\}$
    if $\mathcal{C} \neq \emptyset$ **then**
      $\sigma^* \leftarrow \arg\max_{(\sigma,s)\in\mathcal{C}} s$
      SCHEDULE(σ^*, on r, start at t_{start})
      Remove σ^* from Q

3.2.2 Movable Task Injection

Movable Task Pool. Tessera fills predicted slots from a pool of movable tasks whose deadline slack (the margin between readiness and deadline minus execution time) is positive. It organizes these tasks into priority queues ordered by deadline urgency. For example, `Wgrad` is enqueued as soon as its preceding backward computation completes, and is assigned a hard deadline corresponding to the iteration end. We observe that this pool is typically well-provisioned in production, as `Wgrad` tasks naturally accumulate off the critical path during load imbalance events. The pool is bounded by a configurable per-GPU capacity and the available memory headroom. Once either bound is reached, newly ready movable tasks are kept at their original positions rather than deferred.

Guaranteed Execution. If a movable task's deadline slack approaches zero without a suitable target slot being found, the runtime preemptively injects it into the main stream, prioritizing correctness over optimization.

Bubble-Filling Policy. With the fillable window b_β resolved asynchronously, Tessera triggers the injection logic immediately prior to launching the overlapped tasks. The dynamic scheduler employs a greedy heuristic (Algorithm 2) to scan the pool and select the feasible task σ with the highest score $S(\sigma, b_\beta)$, which prioritizes tight duration fit and small deadline slack. If no suitable task is found, the slot remains empty. Because the pool search space is restricted and each b_β is computed asynchronously before its target

slot, the combined overhead of slot sizing and task selection is negligible ($< 10\,\mu$s). Furthermore, by triggering this logic asynchronously ahead of the sparsely pre-annotated target slots rather than after every task, this mechanism minimizes the interference of dynamic scheduling with the continuous pipeline execution.

4 Implementation

Tessera is implemented as a standalone library (11,000 lines of Python and 2,000 lines of C++) integrated with Megatron-LM [22] (as a host framework).

Plan-Agnostic Execution Engine. To execute the diverse overlap patterns required by asymmetric overlap pairs without invasive modifications to the host framework's imperative loops, Tessera implements a *Plan-Agnostic Execution Engine* in C++. This engine decouples schedule definition from execution by interpreting the static plan as a specification rather than hard-coded control flow. It coordinates execution via a lock-free finite-state machine (FSM). The main Forward and Backward Torch threads drive their respective tasks, pausing at designated yield points to synchronize with the engine's global state and achieve the planned inter-microbatch overlap. Concurrently, an additional background thread processes movable tasks registered with the engine, such as `Wgrad`, according to the execution plan. This architecture enables the runtime to execute diverse pipeline execution plans generated by the static planner without relying on hard-coded pipeline schedule control flow.

Customizing Task Boundaries and Overlap Schedules. Instead of requiring developers to refactor MoE model definitions into isolated task functions, Tessera exposes task boundaries through lightweight execution probes inserted in the existing forward and backward code. The `advance(TaskName)` API marks host-side probe points where the execution engine may block or release the current forward/backward execution thread, slicing the continuous execution into named tasks without moving tensor computation out of the host framework. For movable tasks that lie off the backbone, such as `Wgrad`, Tessera uses `register_task()` to expose the callable after its dependencies become available. Listing 1 illustrates this pattern inside a schedulable MoE operator.

By default, the system automatically constructs overlap schedules from these tasks using its built-in scheduler (§3.1.2). Thanks to Tessera's *Plan-Agnostic Execution Engine*, users can alternatively specify custom interleaving strategies via a YAML configuration file. As shown in the second half of Listing 1, this interface allows experts to define fine-grained, device-specific execution sequences for interleaved streams—enabling domain-specific overlap optimizations when default heuristics are insufficient.

User Interface. Tessera exposes a declarative API that separates *schedule control* from the *tensor computation* managed by the host framework. Users invoke `build_execution_plan` to trigger the Static Planner, which ingests the model structure, applies task decomposition rules, and synthesizes the execution plan. `run` then accepts this plan and hands control to the Pipeline Execution Engine. To ensure correctness within complex training loops, Tessera utilizes standardized hooks (e.g., `pre_fwd`, `post_fwd`, `post_iter`) to inject framework-specific logic (e.g., loss aggregation, gradient reduction) into the execution flow, keeping such logic localized in hooks.

Listing 1: Customizing task boundaries and overlap schedules.

5 Engineering Experience and Discussion

We deployed Tessera in the production pre-training of the Qwen3 and Qwen3-Next model families, scaling beyond 10,000 NVIDIA Hopper GPUs. Scaling to this magnitude exposes fracture points where theoretical scheduling abstractions break down under physical realities. In this section, we discuss the operational challenges encountered and the engineering solutions adopted to sustain high efficiency at scale.

Intra-microbatch vs. Inter-microbatch Overlap. We evaluated *intra-microbatch* overlap (partitioning input tokens to hide MoE dispatch) against Tessera's *inter-microbatch* approach. While intra-microbatch overlap offers theoretical latency hiding, we found it operationally fragile at scale. Par-

titioning along the sequence dimension fragments GEMM operations, reducing arithmetic intensity below the threshold where compute throughput dominates. Aggressive kernel fusion (e.g., Comet [39]) can recover efficiency, but in our production stack the resulting coupling between MoE kernels and specific communication backends complicates independent backend upgrades. In contrast, Tessera's inter-microbatch approach maintains full GEMM computational intensity and backend modularity.

Theoretical Overlap vs. Silicon Reality. Static overlap schedulers estimate an overlap pair's makespan from the task DAG, using task durations, resource types, and dependencies to determine the expected computation–communication overlap. This theoretical estimate is useful for synthesizing candidate schedules, but large-scale production deployments reveal a small, non-uniform gap between the idealized schedule and silicon execution [4, 10]. Across Qwen3-Next pre-training workloads, the theoretical cost underestimates measured overlapped execution in most cases, with an average deviation of around 5%. One major source is SM contention: EP communication kernels reserve ∼20 SMs for All-to-All dispatch and combine, causing a stable 10–20% slowdown when they overlap with Attention or MoE-MLP kernels. We also observe that each task is a coarse scheduling unit rather than a single kernel (e.g., a communication-dominant task may contain small compute kernels), which can leave residual interference, or even serialization, that prevents the idealized schedule from achieving perfect overlap.

Granularity of Cost Profiling. Chunk-pair profiling is affordable for our production workloads: even for trillion-scale models, profiling completes within one hour because repeated model structure bounds the number of distinct overlap pairs. We also explored a lower-cost alternative, *primitive-level profiling*, which profiles reusable overlap patterns between pairs of task primitives and composes the measured interactions to estimate a full chunk-pair timeline. Compared with the purely theoretical estimate above, primitive-level profiling reduces average error by capturing stable pairwise effects such as SM contention. However, its residual error remains uneven across overlap pairs, reaching up to 15% in tail cases. This tail behavior is problematic for partition selection because the MILP relies on relative cost comparisons among candidate stage assignments; a few misestimated overlap pairs can change the selected bottleneck edge or partition boundary. The residual gap arises from cross-primitive effects, including relay overlaps across consecutive kernels, cumulative execution state in caches and communication libraries, and host-side launch overhead. We therefore use chunk-pair profiling as the default, while keeping primitive-level profiling as a lower-cost fallback.

Infrastructure Jitter. Scaling beyond 10,000 GPUs reveals that infrastructure noise is a persistent source of throughput instability. Network congestion and switch contention cause stochastic variation in pipeline communication latency, both across iterations and across ranks. While the Static Planner addresses structural heterogeneity, these transient fluctuations require runtime adaptation. We have explored extending DBO to absorb infrastructure jitter by reusing its bubble-filling mechanism. Leveraging the observation that jitter often exhibits short-term temporal correlation, a history-based predictor (moving average of the last 10 iterations) estimates upcoming bubble sizes, and per-rank injection fills these transient gaps with locally pooled movable tasks. This approach is architecturally feasible since infrastructure-induced bubbles enter the same prediction path as routing-induced ones. Systematic validation of this extension under controlled jitter conditions remains future work.

Memory Pressure Trade-off. While the *Dynamic Bubble Optimizer* improves throughput by delaying movable tasks to fill idle pipeline slots, this strategy introduces a subtle memory trade-off: delaying a `Wgrad` task prolongs the liveness of its associated activation and gradient tensors, increasing peak memory consumption. In our production runs, aggressive bubble filling occasionally triggered out-of-memory (OOM) errors on memory-constrained workloads. In practice, we rely on the bounded movable-task pool described in §3.2.2, configuring its per-GPU cap from observed memory headroom. This cap limits how many deferred tasks can keep activations and gradients live at once. When memory headroom is tight, Tessera can also represent memory-management operations, including activation offloading and recomputation, as *movable tasks* and schedule them into suitable pipeline bubbles.

Decoupling System Constraints via Padding. A major friction point in large-scale training is the conflict between hyperparameter tuning and system constraints. The standard interleaved 1F1B schedule [22] theoretically mandates that the number of microbatches (M) per iteration must be perfectly divisible by the pipeline parallel size (K). In production, however, M is dictated by the global batch size required for model convergence, while K is constrained by device memory limits. Forcing $M\%K = 0$ often requires suboptimal batch size adjustments that degrade model quality. Tessera resolves this by decoupling these constraints via *microbatch padding*. We inject `shadow` actions, null operations that skip computation but perform necessary pipeline communication (sending pseudo-tensors), to satisfy structural dependencies without altering the mathematical equivalence of the batch. Shadow actions are excluded from loss accumulation, gradient scaling, and optimizer accounting. Leveraging Tessera's configuration interface, this padding is achieved by simply specifying a compliant plan file, avoiding invasive code changes. Empirically, this mechanism introduces negligible overhead (∼0.5%) while maximizing configuration flexibility.

Table 1: **Specification of Qwen Models in Experimentation.** Model Scale: Small <100B, Medium 100–500B, Large 500B–1T, Trillion >1T.

Models	TopK / #Experts	Model Scale	Publicly Available
Qwen3-235B	8 / 128	Medium	Yes
Qwen3-Next-80B	10 / 512	Small	Yes
Qwen3-L	8 / 128	Large	No
Qwen3-XL	8 / 128	Trillion	No
Qwen3-Next-M	10 / 512	Medium	No
Qwen3-Next-L	10 / 512	Trillion	No
Qwen3-Next-XL	10 / 512	Trillion	No

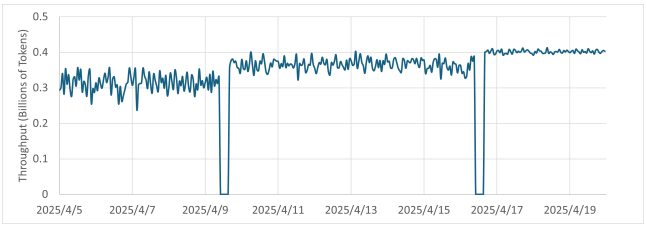

Figure 9: **Phased Impact of Tessera Deployment.** A 2-week production trace (April 5 – April 19, 2025) from the 8,192-GPU Qwen3-XL training job. The first step-change (April 9) marks the deployment of Tessera's *Static Planner*, which resolves structural bottlenecks. The second jump (April 16) marks the activation of the *Dynamic Bubble Optimizer*, which absorbs runtime stochasticity to stabilize throughput at peak levels.

6 Evaluations

6.1 Experimental Setup

We conduct experiments on Alibaba's production cluster, comprising NVIDIA Hopper GPU servers (each equipped with 8 GPUs) interconnected via a high-performance RoCE network. Our production evaluation focuses on pre-training the **Qwen3** and **Qwen3-Next** model families. For the controlled open-source comparison (§6.3), we additionally evaluate DeepSeek-V3 and Nemotron-3 Super. All experiments use a mixture of proprietary internal datasets and open-source datasets. We measure system performance based on Model FLOPs Utilization (MFU), end-to-end throughput, and planning overhead. For the primary production results in Table 2, each workload is run with and without Tessera under the same cluster configuration and hyperparameters.

Baselines. We benchmark Tessera against two baselines that serve complementary evaluation purposes: (1) **Internal Optimized Baseline (§6.2):** For production-scale evaluation on clusters of up to 12,288 GPUs, we compare against Alibaba's internal Megatron-LM fork, the production training stack used for the same Qwen3-family workloads before enabling Tessera. This baseline already includes interleaved 1F1B scheduling, native communication overlap, and production-tuned FLOPs-balanced stage partitioning for the same cluster configuration. This setup isolates the incremental benefit of Tessera's optimizations on top of an optimized production stack. (2) **Megatron-Core MoE (v0.16.1) [36]:** For controlled, reproducible experiments on a 256-GPU cluster, we compare against Megatron-Core MoE using public per-model recipes from Megatron-MoE-ModelZoo (1ca7da9) [35] and Megatron-Bridge v0.4.1 [23]. These recipes enable Megatron-Core's built-in MoE optimizations, including EP communication overlap.

6.2 End-to-End Production Performance

We first present primary results on the massive-scale cluster. As standard open-source frameworks require significant customization at this scale, we benchmark against the *Internal Optimized Baseline* defined in §6.1—a production-hardened Megatron-LM tuned by domain experts. Note that, Tessera's planning scope does not grow with the full cluster size: Tessera generates one execution plan for a model-parallel device mesh and replicates it across data-parallel ranks, so scaling increases the number of plan instances rather than the planning problem size. DBO likewise operates within each EP group with no cross-replica coordination.

Performance Consistency. Table 2 summarizes the gains. Tessera consistently improves MFU by 20%–33% across all workloads. The **standard MoE (Qwen3 family)** repeats the same Attention+MoE block across layers, achieving high baseline MFU (29.7%–32.0%) due to strong arithmetic intensity; the trillion-parameter Qwen3-XL further improves baseline MFU by amortizing communication overheads. For these models, the primary gains come from mechanisms that do not require layer-type diversity: fine-grained inter-microbatch overlap hides A2A communication, while DBO fills routing- and pipeline-induced bubbles. The overlap-aware partitioner still contributes because production partitions include non-uniform boundary chunks (e.g., embedding/output-head chunks), and boundary shifts can change the post-overlap costs of the resulting stage pairs. The **Qwen3-Next family** interleaves GDN and full softmax-attention layers, producing structurally heterogeneous chunks. It employs an extremely sparse MoE architecture (TopK=10/512). As newly deployed models lacking mature full-stack optimizations, such as kernel fusion or communication coalescing, their baseline MFU is significantly lower (15.9%–19.6%), reflecting reduced compute intensity and higher system integration overhead under extreme sparsity. Despite this, Tessera delivers 20.0%–32.8% MFU gains, demonstrating robustness across model scales, cluster sizes, and deployment maturity levels.

A Phased Deployment. To disentangle the contributions of Tessera's components, Fig. 9 illustrates a 2-week "hot up-

Table 2: **Production Performance Gains across Diverse Workloads.** Tessera demonstrates consistent MFU improvements across controlled production-scale pre-training workloads, spanning model scales, MoE sparsities, and cluster sizes from 4,096 to 12,288 GPUs.

Workload Task	TopK / #Experts	Model Scale	Cluster Scale	Baseline MFU	Tessera MFU	Speedup
Qwen3-L	8 / 128	Large	8,192 GPUs	29.7%	**36.3%**	+22.0%
Qwen3-XL	8 / 128	Trillion	8,192 GPUs	32.0%	**39.0%**	+21.8%
Qwen3-Next-M	10 / 512	Medium	4,096 GPUs	16.7%	**20.0%**	+20.0%
Qwen3-Next-L	10 / 512	Trillion	8,192 GPUs	19.6%	**24.0%**	+22.5%
Qwen3-Next-XL	10 / 512	Trillion	12,288 GPUs	15.9%	**21.1%**	+32.8%

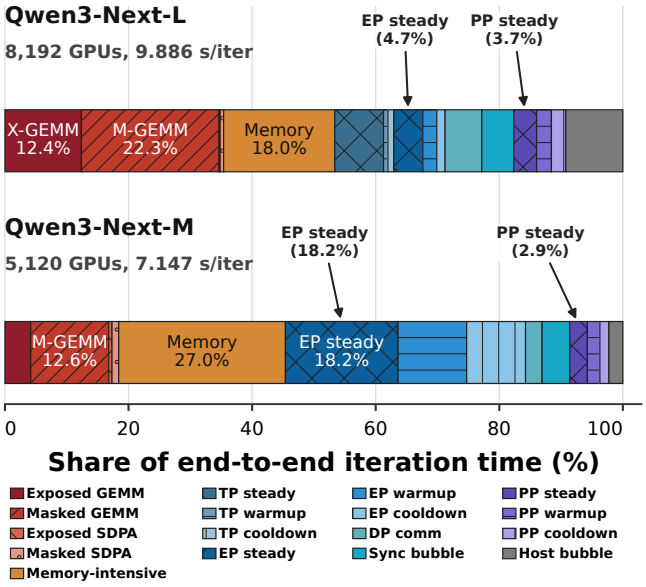

Figure 10: **Iteration-time breakdown for two production Qwen3-Next workloads.** Steady, warmup, and cooldown refer to pipeline phases.

grade" of the Qwen3-XL training. **Phase 1 (Static Planner):** On April 9, replacing the baseline with Tessera's static plan yielded an immediate ∼13% throughput boost. Decomposition reveals this gain came from (1) *Load Balancing* (∼9%), where our overlap-aware partition balanced post-overlap stage costs, and (2) *Latency Hiding*, masking the All-to-All communication overhead. **Phase 2 (Dynamic Optimizer):** On April 16, enabling dynamic bubble filling elevated MFU to 39.0%. As evidenced by the flattened trace, dynamic task injection reduced production throughput variability after DBO activation.

Production Case Study. To understand when Tessera's overlap gains are most effective and where residual bottlenecks remain, we further decompose iteration time for two Qwen3-Next production workloads in Fig. 10. In both cases, Tessera's overlap-aware partitioning compresses steady-phase PP bubbles to roughly 3% of iteration time, confirming effective load balancing across pipeline stages. Yet the two workloads exhibit sharply different overlap efficiency. On the trillion-scale Qwen3-Next-L (8,192 GPUs), Tessera compresses exposed EP communication in the pipeline steady phase to 4.7% of iteration time. Including warmup and cooldown, 73% of EP communication is hidden behind computation, leaving exposed EP at only 8.3% of iteration time. On a separate 5,120-GPU Qwen3-Next-M run (distinct from the 4,096-GPU production result in Table 2), however, steady-phase exposed EP alone reaches 18.2% of iteration time. Including warmup and cooldown, only 26% of EP communication is hidden, with total exposed EP reaching 38.9% of iteration time. The root cause is compute intensity. Qwen3-Next-M has fewer parameters per expert, producing shorter GEMM durations relative to A2A transfer time and leaving each overlap pair with insufficient computation to hide the A2A latency. This contrast shows that Tessera's overlap gains scale with the workload's compute-to-communication ratio.

Gap to Ideal Execution. Even in the favorable regime (the top bar of Fig. 10), 27% of EP communication remains exposed (819 ms), over 40% of which originates from warmup and cooldown phases. Beyond exposed EP, PP bubbles contribute another 8.5% (835 ms), split between residual stage imbalance (366 ms) and structural warmup/cooldown cost (469 ms) inherent to interleaved 1F1B. Together, exposed EP communication and pipeline idle time account for 17% of iteration time, which we target in ongoing optimization.

Bitwise Equivalence. Tessera modifies only *when* and *where* tasks execute on the device timeline; the computation graph, operator semantics, and reduction order are unchanged. Gradient equivalence therefore holds by construction. We verify this empirically on a trillion-scale Qwen3-Next workload by comparing runs with and without Tessera's optimizations under deterministic mode. The two runs produce bit-identical loss trajectories. This confirms that Tessera's scheduling transformations introduce zero numerical divergence, and the system has since sustained months of production pre-training without observed quality regression.

6.3 Comparison with State-of-the-Art

To complement the production evaluation against our internal Megatron baseline (§6.2), we compare Tessera against **Megatron-Core MoE** [36] on a 256-GPU cluster. We evaluate three open-source MoE models: (i) **Qwen3-235B** [37],

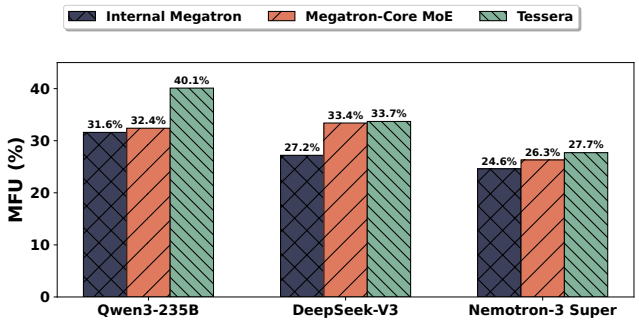

Figure 11: MFU comparison among Internal Megatron, Megatron-Core MoE, and Tessera on a 256-GPU cluster. Tessera remains competitive with publicly available Megatron-Core MoE recipes on the non-Qwen workloads while consistently improving over the internal Megatron baseline across all three models.

a standard Transformer MoE (128 experts, top-8, sequence length 4K); (ii) **DeepSeek-V3** [3], which combines a dense prefix, compressed MLA attention, an MTP head, and a sparse MoE (256 experts, top-8, sequence length 4K); and (iii) **Nemotron-3 Super** [24], a hybrid Mamba/Attention model with latent MoE and MTP layers (512 experts, top-22, sequence length 8K). For Megatron-Core MoE, we follow the per-model recipes from the public Megatron-MoE-ModelZoo [35] and Megatron-Bridge [23].

As shown in Fig. 11, Tessera improves MFU over the internal Megatron baseline by 1.27×, 1.24×, and 1.13× on Qwen3-235B, DeepSeek-V3, and Nemotron-3 Super, respectively, showing that Tessera's optimizations generalize beyond the Qwen3 family to architecturally diverse MoE workloads. Against the recipe-tuned Megatron-Core MoE baseline, Tessera improves MFU by 1.24× on Qwen3-235B and achieves comparable MFU on non-Qwen models.

We attribute Tessera's gains to three mechanisms: (i) the overlap scheduler and DBO jointly mask exposed EP communication; (ii) the overlap-aware partitioner reduces stage-level load imbalance; and (iii) DBO overlaps deferred `Wgrad` with PP send/receive, shrinking the pipeline bubble. On Qwen3-235B, Megatron-Core MoE's A2A overlap removes most exposed EP communication but leaves PP wait intact. Relative to the internal Megatron baseline, Tessera cuts exposed EP communication by ∼75% and PP wait by ∼90%. On DeepSeek-V3, both Tessera and Megatron-Core MoE's hand-tuned recipe mask over 70% of EP communication and yield balanced PP stages; Tessera's DBO further overlaps deferred `Wgrad` with PP send/receive, reaching slightly higher end-to-end MFU. On Nemotron-3 Super, Megatron-Core MoE's A2A-overlap implementation relies on a hand-crafted Transformer-layer decomposition and currently handles at most one MTP layer. EP communication outside this supported pattern therefore remains unoverlapped. Tessera reduces exposed EP communication by 40% and the pipeline bubble by 30%, yielding higher end-to-end MFU than Megatron-Core MoE.

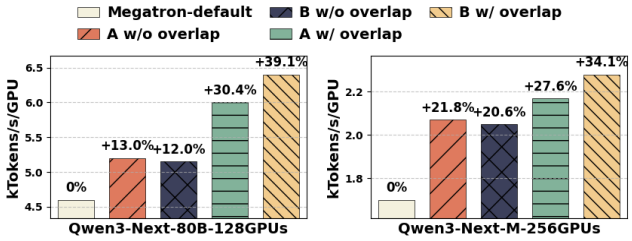

Figure 12: Impact of co-optimizing partitioning and overlap scheduling.

6.4 Co-optimizing Partitioning and Overlap

We evaluate the impact of co-optimizing overlap scheduling and partitioning through two experiments: training Qwen3-Next-80B on 128 GPUs and Qwen3-Next-M on 256 GPUs. Both setups utilize an interleaved 1F1B schedule with a micro-batch size of 1 per GPU, a pipeline-parallel size of 4 with an interleave size of 2, and an expert-parallel size of 32. To support a sequence length of 64K, we enable Context Parallelism. For a controlled comparison of static execution plans, we employ a mock router that uniformly distributes tokens and disable DBO, isolating static plan efficiency from dynamic runtime variance.

We establish Megatron-LM's native uniform partition as the baseline. Against this, we compare two alternative strategies, each evaluated with and without Tessera's fine-grained overlap scheduling: (1) **Partition A**: a latency-guided partition balanced by serial execution time; and (2) **Partition B**: Tessera's overlap-aware partition. As shown in Fig. 12, the two partitions exhibit markedly different sensitivities to inter-microbatch overlap. When overlap scheduling is disabled, Partition A achieves slightly higher end-to-end throughput than Partition B, as indicated by the A w/o overlap and B w/o overlap bars. However, once overlap scheduling is enabled, the relative advantage shifts: Partition B attains significantly greater overlap gains and ultimately delivers the highest end-to-end throughput (B w/ overlap vs. A w/ overlap). These results confirm that partitioning decisions must be co-optimized with overlap scheduling rather than optimized in isolation.

6.5 Overlap Scheduling

We evaluate overlap scheduling on the candidate overlap pairs enumerated by Static Planning, before partition selection. For Qwen3-Next-M at sequence length 4K, the EP32 and EP8 regimes produce 690 and 536 scheduling instances. We compare four strategies: FIFO schedules tasks in topological order without priority or alignment; +ALIGN adds backbone-priority and gap-fit alignment (§3.1.2); +DEFER adds conditional deferral of movable `Wgrad` tasks; and ILP solves

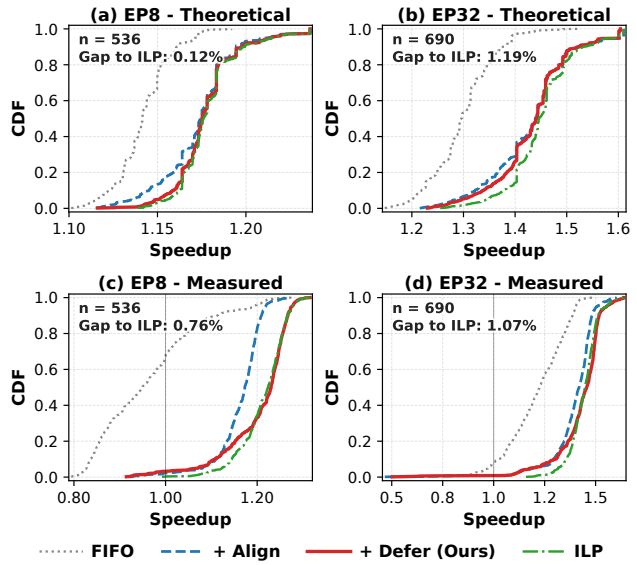

Figure 13: CDF of per-instance speedup over serial execution for four overlap schedulers. Top row: analytical makespan; bottom row: measured post-overlap cost on hardware. +DEFER (red) closely tracks the ILP reference (green) across the full distribution at both EP widths.

the resource-constrained DAG with CBC [5] under a 300-s per-instance budget.

As shown in Fig. 13, EP32 exposes larger overlap gains than EP8 because EP communication accounts for a greater share of each pair's serial cost. In both cases, the measured CDFs closely follow the analytical predictions, with the offset consistent with the theory-to-silicon gap discussed in §5. The curves also show that +ALIGN alone captures most of the gain over FIFO. +DEFER's mean gain over +ALIGN is modest, but some instances gain over 10%. Taken together, the two heuristics close to within 1.19%/0.12% of ILP on EP32/EP8 in analytical makespan, and 1.07%/0.76% on measured post-overlap cost.

Quality vs. solving-time trade-off. Solving all instances with CBC takes hours to days. Per-instance solve time is long-tailed: many hit the 300-s budget without a proven optimum. Tessera's event-driven scheduler finishes in under a minute, staying within $\sim 1\%$ of ILP on profiled post-overlap cost. We therefore adopt the heuristic as the production default.

6.6 Dynamic Bubble Optimization

We evaluate DBO's speedup, overhead, and memory cost on Qwen3-Next-M (256 GPUs, 4K sequence length). To isolate DBO's contribution from static planning decisions, we run DBO on top of two static plans. The *Baseline Partition* balances serial FLOPs across pipeline stages; the *Overlap-Aware Partition* is selected by Tessera's partitioner using profiled post-overlap costs. Following the bounded-pool policy in §3.2.2, we cap the per-GPU movable-task pool at 8. For each plan we report three configurations: (i) *static*, DBO disabled; (ii) *w/ DBO*, full DBO active; and (iii) *always-keep*, which runs the full DBO monitoring, slot-sizing, and injection-decision paths but keeps every movable task at its original position instead of deferring it. The always-keep row isolates the steady-state overhead of DBO without the benefit of task reordering.

Table 3: Performance and peak-memory cost of Tessera's Dynamic Bubble Optimizer (DBO) on Qwen3-Next-M. Peak mem. denotes the maximum allocated memory normalized by the per-GPU memory budget.

Metric	Baseline Partition	Overlap-Aware Partition
Iter-time (s), static	8.28	6.98
Iter-time (s), w/ DBO	7.83	6.67
Iter-time (s), always-keep	8.34	7.06
Peak mem., static	69.3%	67.4%
Peak mem., w/ DBO	72.9%	70.0%

Table 3 summarizes the results. DBO cuts iteration time by 5.4% on Baseline and 4.4% on Overlap-Aware. The larger gain on Baseline is expected: serial-balanced partitions leave larger PP wait, which DBO overlaps with deferred `Wgrad` tasks; overlap-aware partitioning already shrinks this wait during static planning. Always-keep adds about 1% over the corresponding static run, so the monitor and injection paths are lightweight on their own. On the memory side, DBO increases peak memory by 2–4 percentage points of the per-GPU memory budget, since deferred movable tasks prolong the liveness of their input activations and gradients. This increase is consistent with the bounded per-GPU movable-task pool. The capacity can be raised for more bubble-filling, or lowered to reduce peak memory.

Production-Scale Validation. Two production deployments confirm DBO's effectiveness beyond the 256-GPU ablation. On the 8,192-GPU Qwen3-XL job (§6.2, Fig. 9), end-to-end MFU reached 39.0% after DBO activation. On a 6,144-GPU Qwen3-L run (distinct from Table 2), DBO alone reduced PP bubble time by 641 ms, yielding a 3.4% throughput gain. For production-scale overhead, DBO runs independently within each EP group, so scaling to more GPUs increases the number of independent instances without adding cross-group coordination.

6.7 Planning Overhead Analysis

Tessera's static planning is offline and consists of profiling distinct overlap pairs and solving the partitioning MILP. We evaluate on Qwen3-Next-M and Qwen3-Next-L under an 8,192-GPU target configuration with PP8-C2 and PP8-C4, denoting 2 or 4 chunks per pipeline rank under pipeline parallel

size 8. Profiling runs on a 64-GPU reference device group. Across sequence lengths from 4K to 128K, repeated model structure bounds the distinct overlap-pair count to 237–327 under PP8-C4 and 575–637 under PP8-C2. Measured profiling time grows with sequence length and peaks at about 3,050 seconds at 128K for the trillion-scale PP8-C2 case, still below one hour.

Table 4: **MILP problem scale and solve time.** Pruning removes candidate pairs whose post-overlap cost exceeds T_{base}.

Configuration	#Decision Variables	#After Pruning	Solve Time
M-PP8-C2	9,358	1,782	0.34s
L-PP8-C2	23,180	6,993	1.51s
M-PP8-C4	16,192	5,505	0.82s
L-PP8-C4	35,904	12,207	4.22s

Table 4 reports the MILP scale and solve time. The edge-based formulation introduces stage-selection and edge-pair activation variables, scaling as $O(S{\cdot}K + E{\cdot}K^2)$ and avoiding K^{vp} rank-level enumeration. Profile-guided pruning (§3.1.3) removes all candidate pairs whose post-overlap cost exceeds T_{base}, reducing the effective problem size by roughly 3–5×. All tested configurations are solved within five seconds on a 64-core server.

7 Related Work

Pipeline Model Parallelism. Pipeline parallelism was established by GPipe [7], PipeDream [21], and Interleaved 1F1B [22]. It remains a core scaling primitive in recent large-scale MoE training systems and workloads [30, 32, 37]. Specialized variants target bidirectional execution (Chimera [13]), bubble minimization (Zero Bubble [25]), sequence-level partitioning (Seq1F1B [27]), activation checkpointing (Mario [20]), and memory efficiency (MEPipe [29]). These systems largely rely on static templates that lack the expressivity for the misaligned overlap patterns of heterogeneous MoE layers; Tessera instead decomposes operations into fine-grained task graphs for flexible interleavings.

Communication-Computation Overlap. Flux [1] and Comet [39] employ *intra-microbatch overlap*, fusing MoE communication with computation, but often require invasive kernel fusion that hinders modularity. For *inter-microbatch overlap*, DualPipe [3] orchestrates microbatch execution to hide communication, while WeiPipe [14] overlaps weight transfers. Inter-microbatch approaches still rely on manually designed or workload-specific schedules. Tessera automates inter-microbatch overlap discovery through global planning and task decomposition.

Automated Model Partitioning. Symbolic partitioners such as Alpa [40], Tessel [15], nnScaler [16], and Colossal-AI [12] use analytical cost models, while Aceso [17], AdaPipe [28], Koala [31], and GraphPipe [9] use profiling. Mist [41] and PipeWeaver [34] begin to account for overlap effects. However, most frameworks still optimize partitioning separately from overlap scheduling, balancing serial costs rather than post-overlap execution. Tessera profiles post-overlap cost directly and partitions for parallel execution.

Dynamic MoE Load Balancing. Runtime imbalance in MoE has driven two directions: token/expert redistribution via replication or linear programming (FasterMoE [6], Janus [19], PopFetcher [38], LPLB [2]), and system-level adaptation via dynamic kernel tuning (Tutel [8], DeepSpeed-MoE [26]). Tessera is complementary: rather than trying to perfectly balance stochastic token loads, it accepts routing variation and absorbs the resulting pipeline bubbles by dynamically scheduling movable tasks, such as gradient reduction and offloading, into idle slots.

8 Conclusion

Training trillion-parameter heterogeneous MoE models exposes a cyclic dependency between pipeline partitioning and communication overlap that traditional stratified optimization cannot resolve. Tessera breaks this cycle by profiling post-overlap cost for each layer combination to co-optimize partitioning and overlap scheduling, while a Dynamic Bubble Optimizer fills routing-induced idle slots with movable tasks at runtime. Deployed on production clusters for pre-training Qwen families, Tessera improves throughput by 20%–33% across five workloads at scales from 4,096 to 12,288 GPUs, reaching 39% MFU on a trillion-parameter model and up to 1.24× higher MFU than Megatron-Core MoE in controlled experiments. Tessera demonstrates that a unified, profile-driven co-optimization approach systematically outperforms manual heuristics, providing a practical foundation for training next-generation heterogeneous AI models.

Acknowledgments

We thank our shepherd and the anonymous reviewers for their careful reading and constructive feedback. We would like to express our gratitude to the following individuals for their contributions to this work. For algorithmic insights, we are especially grateful to Bo Zheng, Rui Men, Yuqiong Liu, and Hao Ge, whose ideas and discussions have significantly shaped this work. For systems development and engineering, we thank Linlang Jiang, Zhixiang Ruan, Hongqing Chen, Yunfei Mao, Siyu Wang, Xing Wang, and Chang Si, who have continuously advanced the underlying system that made this work possible. Abstract

The Single-Program Multiple-Data (SPMD) paradigm provides a unified abstraction to annotate various parallel dimensions in distributed deep learning (DL) training. With SPMD, users can write training programs from the viewpoint of a single device, and the system will automatically deduce the tensor sharding and communication patterns. However, with the recent development in large-scale DL models, distributed training exhibits *spatial* and *temporal* workload heterogeneity, arising from both device disparities (e.g., mixed hardware, failures) and data variations (e.g., uneven sequence lengths). Such heterogeneity violates SPMD's assumption of symmetric workload partitioning, which restricts its ability to express and optimize heterogeneous parallel strategies effectively.

To address this, we propose HSPMD within the Hetu v2 system to achieve general and scalable DL training. HSPMD extends SPMD's *declarative annotations* to support asymmetric sharding and composes standard communication primitives for hierarchical communication, all while retaining the simplicity of a single-device programming model. HSPMD handles *spatial* heterogeneity through progressive graph specialization, enabling device-specific execution logic, and addresses *temporal* heterogeneity via dynamic graph switching. Evaluations on (a) heterogeneous devices, (b) unstable devices, and (c) mixed-length data scenarios show that HSPMD matches or outperforms specialized systems, providing a flexible and efficient solution for modern distributed DL training. Code is available: https://github.com/PKU-DAIR/Hetu.

1 Introduction

The rapid advancement of large-scale deep learning (DL) models, particularly large language models (LLMs) [17, 34, 83, 85, 89, 93], has pushed the boundaries of distributed training systems. Models like GPT [55], Gemini [64], and DeepSeek [15] routinely span billions of parameters, requiring a large number of devices working in concert for efficient training.

To meet this demand, parallel strategies have evolved from singular approaches to sophisticated hybrid schemes combining data [45, 91], sequence [5, 28, 47], tensor [37, 51, 60], and pipeline [27, 35, 50, 57] parallelism. Within this landscape, the Single-Program Multiple-Data (SPMD) paradigm has emerged as a dominant abstraction due to its simplicity and scalability. By augmenting a single program with *declarative annotations*, SPMD enables automatic parallelization while abstracting away low-level deployment details. For example, systems such as GSPMD [86] and Alpa [92] annotate tensors with sharding semantics like *Split* and *Duplicate*, while DeepSpeed [28, 58] and Megatron [37, 51, 60] annotate model layers with distributed variants (e.g., extending Linear into ColumnParallelLinear and RowParallelLinear). This approach decouples parallel strategy specification from the DL model, facilitating more scalable distributed training.

At the core of this declarative SPMD paradigm lies a fundamental premise: the training workload should be uniformly partitioned and distributed. This is because SPMD primitives are built to symmetrically shard tensors or layers across devices, following the assumptions that **(i)** hardware resources are homogeneous and stable, and **(ii)** training burdens from all input data are equivalent. However, as DL training continues to scale, heterogeneous workloads have become increasingly prevalent. In practice, both hardware devices and input data introduce heterogeneity, as summarized in Table 1, leaving the standard SPMD design poorly suited to such scenarios.

Multifaceted heterogeneity. (i) From the device perspective, heterogeneous and unstable devices are common in real-world cluster/cloud environments. On the one hand, due to the GPU shortage problem [62, 88], modern MLaaS platforms typically host mixed GPU generations [30, 79], and the scarcity of high-end GPUs (e.g., A100, H100) has led cloud providers to leverage heterogeneous GPUs with divergent capabilities (e.g., computation FLOPS, memory capacities, network bandwidth) for training [25, 63]. On the other hand, device instability like GPU/node failures [30] occurs frequently. For example, Llama 3's training underwent 419 unexpected interruptions over 54 days, with 148 attributable to faulty GPUs [18]. **(ii)** From the data perspective, the symmetric design of SPMD is a good fit when all input data are associated with equiva-

Table 1: Example heterogeneous scenarios arising from device and data aspects, along with their characteristics and representative specialized SPMD training systems addressing each scenario.

Scenarios	Characteristics		Representatives
	Spatial	Temporal	
Heterogeneous Devices	✓		HexiScale [87] Sailor [63], etc.
Unstable Devices	✓	✓	Oobleck [29], ReCycle [21], etc.
Mixed-length Data	✓	✓	HotSPa [23], WLB-LLM [78], etc.

lent workloads (e.g., preprocessed tabular datasets). However, to achieve general intelligence, modern DL models are often trained with unstructured, raw data, which demonstrates inherent length variations (e.g., varying text lengths [38], diverse image resolutions [16], differing video/audio durations [10]).

In short, these pervasive forms of heterogeneity fundamentally break the symmetry assumption of the standard SPMD paradigm and give rise to an urgent demand for asymmetric execution to effectively tackle heterogeneity.

Current solutions and limitations. As illustrated in Figure 1 (left), one alternative is the Multiple-Program Multiple-Data (MPMD) paradigm, which uses distinct programs to encode different execution logic. However, MPMD often suffers from limited scalability and user-friendliness, as discussed in §2.3. Consequently, most distributed DL training systems addressing heterogeneity still adhere to the SPMD paradigm. As summarized in Table 1, a wide array of recent studies have extended standard SPMD to specific heterogeneous scenarios, including: heterogeneous devices [31,41,61,63,71,84,87,90], unstable devices (i.e., elastic training) [3, 21, 29, 69], and mixed-length data [7,22,23,33,76,78]. A common approach among them is to integrate custom schedulers (e.g., HexiScale's heterogeneous pipeline scheduler [87], Oobleck's elastic pipeline scheduler [29]) to enable asymmetric execution behaviors beyond standard SPMD, as shown in Figure 1 (middle). However, although these schedulers address heterogeneity in their respective scenarios, they are largely scenario-specific and built into the system with tight coupling to particular workloads. This design limits their flexibility and prevents them from serving as a general-purpose solution.

Our solution and contributions. Compared with prior case-by-case solutions, we propose HSPMD (Hierarchical and Heterogeneous SPMD) within Hetu v2, a system that addresses multifaceted heterogeneity from a more general and fundamental perspective. **(i) Primitive-level extensions.** As shown in Figure 1 (right), instead of layering extensive scheduler-level efforts, HSPMD pushes extensibility down to the primitive level of *declarative annotations*. Specifically, we design the HSPMD sharding annotations (§4) and hierarchical communication resolution (§5), which enable asymmetric sharding and communication beyond SPMD's inherent symmetry. While preserving SPMD's core principle of separating

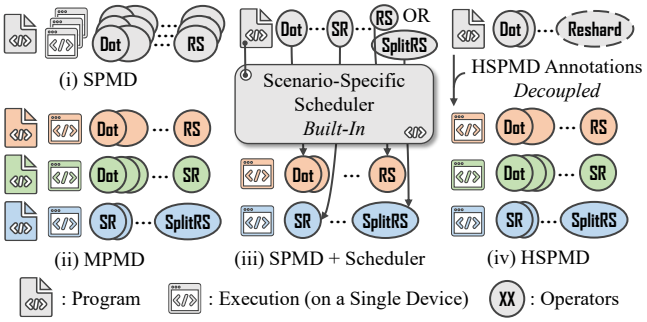

Figure 1: Comparison of SPMD, MPMD, scheduler-enhanced SPMD variants, and HSPMD. While SPMD imposes strict symmetry, the others enable asymmetric execution to tackle heterogeneity.

the parallel strategy from a single programming view of the DL model, HSPMD's primitives enable asymmetric execution natively, without the need for crafting scenario-specific schedulers. **(ii) Characteristic-driven abstractions**. Departing from prior work that categorizes solutions by application scenarios (Table 1), we revisit and disentangle heterogeneity through its intrinsic characteristics: *spatial* and *temporal* (detailed in §2.3). *Spatial* heterogeneity is due to the imbalanced workload and necessitates spatially heterogeneous parallel strategies (Figure 2), while *temporal* heterogeneity arises from dynamic workload changes and requires temporal reconfiguration across strategies (Figure 3). Accordingly, we introduce graph specialization (§6) and graph switching (§7), respectively. While these abstractions are scenario-agnostic individually, they serve as modular building blocks that can be composed into scenario-specific solutions, allowing HSPMD to generalize beyond single-purpose SPMD variants.

In summary, this paper makes the following contributions.

- We introduce primitive-level extensions to break SPMD's inherent symmetry, directly bridging single-device programming with heterogeneous parallelization.
- We present a general system design methodology that builds upward from fundamental heterogeneity characteristics, rather than starting from specific heterogeneous scenarios and customizing downward as in prior specialized systems.
- We evaluate HSPMD across diverse training scenarios, covering (a) heterogeneous devices, (b) unstable devices, and (c) mixed-length data. Empirical results show that HSPMD is at least on par with, and in most cases surpasses, state-of-the-art SPMD systems and specialized SPMD variants.

2 Background and Motivations

2.1 Sharding and Communication in Training

As model sizes increase, the computational and memory resources of a single device become insufficient to support training, necessitating the adoption of distributed training. This introduces two critical challenges: **(i)** how to effectively manage the **sharding** of different training components across devices; and **(ii)** how to efficiently coordinate their **communi-**

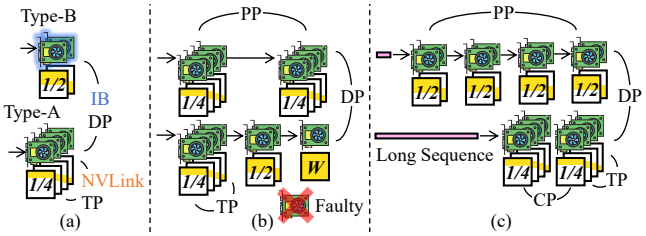

Figure 2: Use spatially heterogeneous parallel strategies to tackle spatial heterogeneity in scenario (a)-(c). "DP, CP, TP, PP" represent data, context, tensor, and pipeline parallelism, respectively. And scenarios (a), (b), and (c) refer to heterogeneous devices, unstable devices, and mixed-length data, respectively.

cation. To address these challenges, a variety of parallelisms and distributed training techniques have been proposed.

Data sharding. Data parallelism (DP) [45, 91] shards the input data along the batch dimension, enabling different model replicas to process data simultaneously and synchronize gradients via all-reduce. For long sequences, techniques like sequence or context parallelism (SP [28] or CP [5, 47]) can be applied to further shard the sequence dimension. These require additional communication (e.g., all-to-all or ring-based send-receive) to ensure correctness of the attention [73].

Model sharding. Pipeline parallelism (PP) [24, 27, 35, 50, 57] shards model weights across layers, where activations are communicated between pipeline stages via send-receive. Besides, tensor parallelism (TP) [37, 51, 60] shards model weights along the hidden size dimension, requiring frequent all-gather and reduce-scatter on activations at each layer.

Optimizer states sharding. Optimizer states consume significant memory. ZeRO [58] fully shards them across devices, necessitating all-gather and reduce-scatter operations, while some other methods [8, 9, 43] use finer-grained sharding, balancing storage redundancy and communication costs.

These techniques are often combined [42, 46, 48, 74, 75, 77], creating complex sharding and communication patterns that challenge system-level expression and handling at scale.

2.2 SPMD Training Systems

DL training can be modeled as a directed acyclic graph (DAG), where nodes represent operations and edges denote data dependencies. Tensors are the fundamental units flowing through the graph, carrying numerical values and metadata (e.g., shape, type). Operators transform input tensors into outputs (e.g., dot, attention). Following this, SPMD has emerged as a powerful paradigm (e.g., GSPMD [86], Alpa [92], Unity [72], DTensor [67, 68]). As shown in Figure 4 (left), by specifying the DAG with *declarative annotations*, SPMD decouples the programming from the complexities of parallelization, enabling automatic derivation and accommodation for diverse sharding and communication patterns.

Limitations. Despite its advantages, the SPMD paradigm imposes strict symmetry constraints. First, existing SPMD

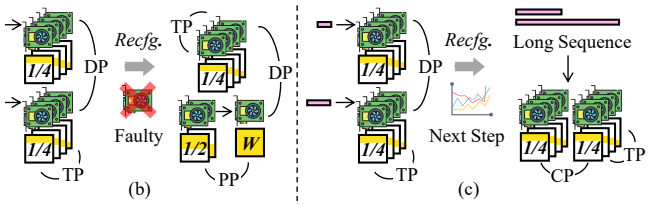

Figure 3: For scenarios (b) and (c), beyond the spatial heterogeneity shown in Figure 2, heterogeneity may also evolve over time, demanding temporal reconfiguration between parallel strategies. (Scenario (a) is omitted because it exhibits only static spatial heterogeneity.)

annotations are confined to the uniform partitioning of tensors across regular device meshes. Additionally, SPMD-style collective communication primitives, such as all-reduce, all-gather, and reduce-scatter, require symmetric participation from devices. These two constraints make it challenging for SPMD to handle **asymmetric sharding** and **communication**.

2.3 Other Paradigms and Our Motivations

As mentioned earlier, both devices and data can induce heterogeneity, leading to scenarios such as: (a) heterogeneous devices, (b) unstable devices, and (c) mixed-length data.

MPMD vs. SPMD. Due to its symmetry constraints, SPMD is ill-suited for these diverse heterogeneous scenarios. As shown in Figure 1 (left), one alternative is the MPMD paradigm (e.g., Pathways [4], Ray [49]). However, MPMD is more suited for multi-task settings (e.g., RL for LLMs [44, 59]), where heterogeneity manifests across tasks. By contrast, in single-task training with intra-task heterogeneity, MPMD typically requires generating and managing thousands of distinct programs across a large cluster, incurring substantial compilation overheads [39] and leading to a poor user experience. As a result, the scalability and simplicity of the single-program paradigm in SPMD remain highly desirable at large scale.

Scheduler-enhanced SPMD variants. Consequently, many systems continue to build upon SPMD but integrate a high-level scheduler to enable heterogeneous execution logic, as shown in Figure 1 (middle). While maintaining a single programming model, this approach requires workarounds to bypass SPMD's inherent symmetry, which introduces extensive control and branching logic within the scheduler. More critically, these schedulers are built-in and scenario-specific, making such SPMD variants only applicable to a single scenario.

Motivations. This motivates a more principled approach beyond scheduler-level customization. Specifically, we ask: can SPMD itself provide intrinsic support for asymmetry? A natural direction is to extend its *declarative annotations*. Compared with built-in schedulers, this approach offers better decoupling, natively expresses asymmetric parallelization, and provides a unified substrate across diverse scenarios.

Moreover, prior work treats each heterogeneous scenario as an isolated case, requiring dedicated system mechanisms and ad hoc extensions, which is fundamentally unscalable. This

motivates us to seek a more essential characterization that cuts across diverse scenarios. Specifically, we distill two fundamental dimensions underlying multifaceted heterogeneity: *spatial* heterogeneity and *temporal* heterogeneity (Table 1).

Spatial heterogeneity refers to workload imbalance at a given moment, calling for spatially heterogeneous parallel strategies. For example (Figure 2): (a) for heterogeneous devices, one can adopt a higher TP for memory-constrained GPUs and a lower TP for others; (b) for unstable devices, heterogeneous TP grouping and PP composition allow the remaining GPUs (e.g., 15 GPUs) to be fully utilized when one GPU fails; (c) for mixed-length data, GPUs can be partitioned into subgroups optimized for distinct sequence lengths (e.g., employing larger TP or CP for long sequences).

Temporal heterogeneity reflects workload variation over time, necessitating dynamic reconfiguration of parallel strategies. For example (Figure 3): (b) for unstable devices, when a GPU/node becomes unavailable, the overall parallel strategy must be reconfigured; (c) for mixed-length data, when the distribution of sequence lengths shifts across training steps (e.g., a step with very long sequences appears), reconfiguring to a strategy tailored for long sequences is essential to ensure better performance or to avoid out-of-memory (OOM) errors.

To this end, we introduce HSPMD within Hetu v2. **(i)** At the primitive level, as illustrated in Figure 4 (right), HSPMD extends SPMD to natively support asymmetric sharding (§4) and communication (§5), while preserving single-program semantics and collective operations. **(ii)** At the abstraction level, to address *spatial* and *temporal* heterogeneity, we propose graph specialization (§6) and graph switching (§7), enabling heterogeneous deployment and dynamic reconfiguration, respectively. Together, these innovations establish HSPMD as a general system for multifaceted heterogeneity.

3 HSPMD Design and Overview

In this section, we provide a walkthrough of HSPMD's core design and workflow. As depicted in Figure 5 (left), following prior work [32, 45, 92], HSPMD adopts a graph-based representation. Users provide a single *defined graph* consisting of three types of operators: **(i)** Leaf operators (e.g., placeholders, parameters) that produce data, model parameters, or optimizer states; **(ii)** `Reshard` operators, introduced by HSPMD as abstract markers to indicate potential resharding of intermediate results (e.g., gathering activations, resharding half-precision parameters); **(iii)** All other operators that encode the model's computation logic. An *annotation plan*, either user-specified or generated by an external planner, is then associated with the *defined graph*. This plan assigns output sharding annotations (§4) to **(i)** leaf and **(ii)** `Reshard` operators, defining the initial sharding layout and resharding behavior of critical tensors, thereby collectively specifying the parallel strategy.

Given the *defined graph* and the *annotation plan*, HSPMD deduces the output sharding of **(iii)** all other operators and resolves how each `Reshard` operator can be concretely achieved by communication operators (e.g., reduce-scatter, all-gather) automatically (§5).[1] Additionally, HSPMD will transparently handle the deployment and execution of parallel strategies, allowing users to write a single program by simply providing the *defined graph* (and optionally the *annotation plan*), without engaging in manual orchestration of distributed training.

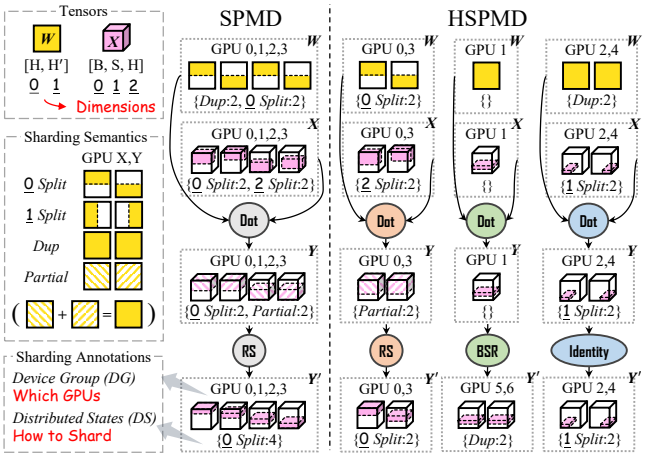

Figure 4: Left: Standard SPMD-style sharding annotations (e.g., DTensor [67, 68]) and their deduction when employing DP and TP across GPU 0-3. They can only express symmetric sharding and communication. Right: An example of HSPMD expressing asymmetry: TP between GPU 0,3 and GPU 5,6; PP between GPU 1 and GPU 5,6; CP between GPU 2,4; and DP across them. "`RS`, `BSR`" represents reduce-scatter and batched-send-receive (§5.3), respectively.

HSPMD leverages two abstractions to tackle heterogeneity (Figure 5, middle). Firstly, to address *spatial* heterogeneity, where devices may require divergent execution logic, we introduce graph specialization (§6). Once the *defined graph* and *annotation plan* are in place, each device specializes its local operators, generating a device-specific *executable graph* for deployment and execution. Secondly, to address *temporal* heterogeneity, where the parallel strategy needs to be reconfigured, we introduce graph switching (§7). When a new *annotation plan* (e.g., changes in parameter sharding) is introduced, HSPMD facilitates seamless switching between parallel strategies by online resharding the necessary weights between *executable graphs*, without requiring a restart.

As illustrated in Figure 5 (middle and right), these two abstractions, graph specialization and switching, are modular building blocks that can be flexibly combined to accommodate diverse heterogeneous scenarios. **(a) Heterogeneous devices** (*spatial* heterogeneity only): An expert user or scenario-specific planner provides an *annotation plan* specifying a heterogeneous parallel strategy. *Executable graphs* are specialized once offline (line 1) and remain fixed throughout training (line 9). **(b) Unstable devices** (*spatial* + unknown

[1] Not all communication needs to be explicitly represented via `Reshard`. For example, CP involves ring-based send–receive within attention [47]. We provide a fused `ParallelAttn` operator to encapsulate such implicit communication, keeping it transparent to the annotation system.

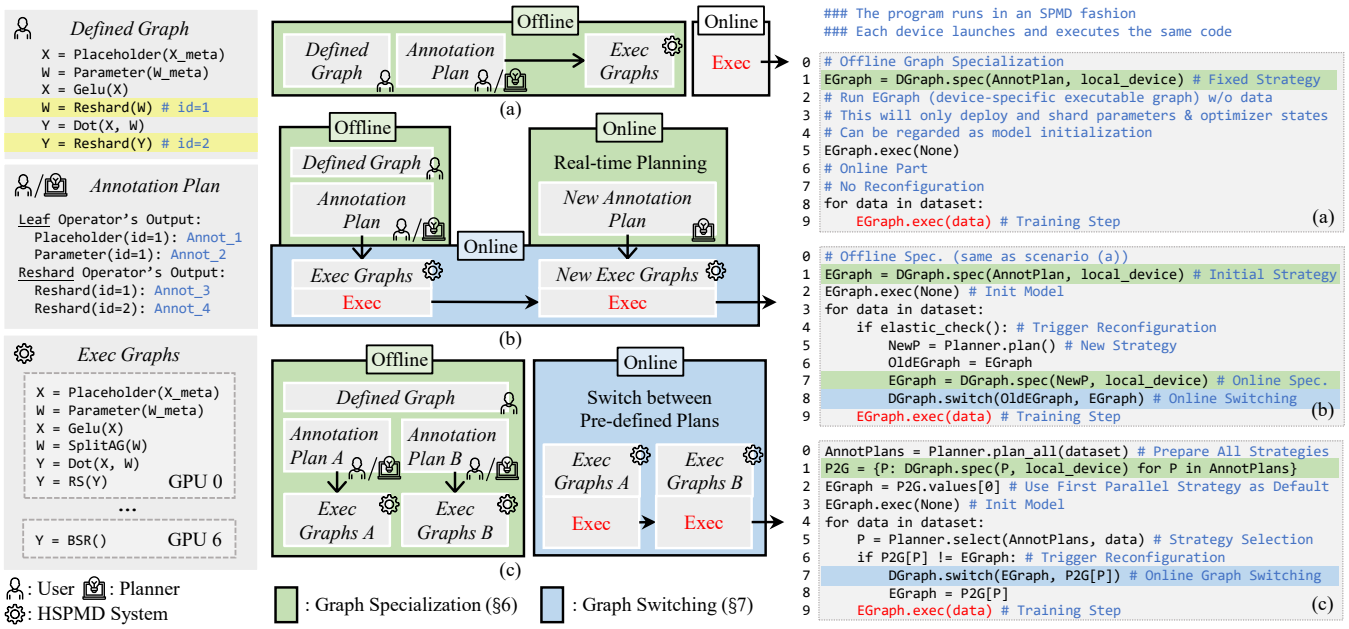

Figure 5: HSPMD's workflow and code snippets (DL operators align with Figure 4). Our system relies on two abstractions: graph specialization (§6), which generates device-specific *executable graphs* from a *defined graph* (provided by users) and an *annotation plan* (provided by users or planners); and graph switching (§7), which enables switching between arbitrary *executable graphs*. These two abstractions act as building blocks that can be flexibly applied to: (a) heterogeneous devices, (b) unstable devices, and (c) mixed-length data.

temporal heterogeneity): The initial setup mirrors case (a). Upon triggering a reconfiguration (e.g., due to changes in device availability), an automatic planner generates a new *annotation plan* (line 5), and the system specializes new *executable graphs* at runtime (line 7). Graph switching then seamlessly transitions model and optimizer states (line 8), ensuring uninterrupted training (line 9). **(c) Mixed-length data** (*spatial* + predictable *temporal* heterogeneity): Users or planners prepare multiple *annotation plans* (line 0), each optimized for a particular sequence length distribution, with corresponding *executable graphs* pre-specialized offline (line 1). During training, the system dynamically selects and switches to the optimal plan when input distribution shifts (line 5-8).

Although scenario-specific planners are needed (e.g., for *annotation plan* generation and selection), HSPMD is designed as a general framework to address diverse forms of heterogeneity, rather than to optimize automatic planning for a single scenario. Our focus is on introducing system core designs, while keeping the planner modular and easily replaceable. In the following, we first detail the sharding annotations (§4) and communication resolution (§5), which facilitate asymmetric sharding and communication, respectively. We then show how HSPMD addresses *spatial* heterogeneity with graph specialization (§6) and *temporal* heterogeneity via graph switching (§7). Finally, we briefly introduce HSPMD's planners (§8).

4 Sharding Annotations

This section introduces HSPMD's sharding annotations, which hierarchically extend SPMD-style annotations through a bottom-up approach to support asymmetric sharding. Compared to crafting high-level specialized schedulers on top of SPMD, this low-level extension enables SPMD itself to express asymmetry and generalize to diverse scenarios.

4.1 Basic SPMD-style Annotations

Following existing SPMD-style *declarative annotations* such as GSPMD [86] and DTensor [67, 68], we associate each tensor with two attributes: **(i) *Device Group (DG)***, which specifies the devices where the tensor resides; **(ii) *Distributed States (DS)***, which defines how the tensor is sharded across these devices. While some critical tensors (e.g., data, parameters, `Reshard` outputs) have their *DG* and *DS* explicitly specified by the *annotation plan*, others are deduced automatically.

As shown in Figure 4 (left), the *DG* is represented as an ordered list of GPU indices, and the *DS* is an ordered dictionary where the key *dim* corresponds to a logical distributed dimension (a virtual axis for sharding), and its corresponding value represents the number of shards along *dim*. Following previous works, there are three sharding semantics: **(i) *Split*** ($dim \geq 0$), where the tensor is uniformly split along its physical shape dimension *dim*; **(ii) *Duplicate*** ($dim = -1$), where the tensor is fully replicated; **(iii) *Partial*** ($dim = -2$), where the tensor's values are partially stored. These annotations come with inherent deduction rules. For instance in Figure 4 (left), given the annotations of W and X, the annotation of their `Dot` result can be derived: Y retains the same *DG* as the inputs, while its *DS* transforms the original *split* into *partial*.

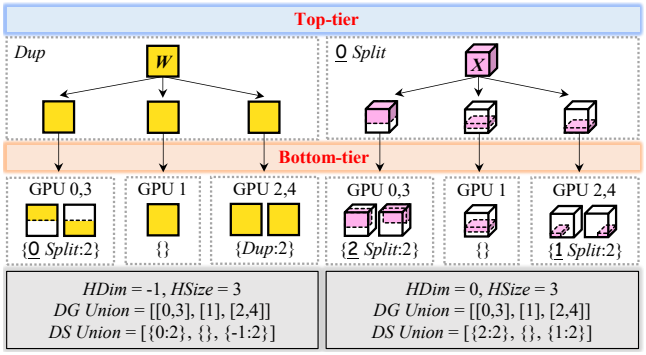

Figure 6: HSPMD's sharding annotations (aligned with Figure 4). The tensor is first sharded along the *HDim* dimension into *HSize sharding subgroups*. The devices in each *sharding subgroup* are given by the corresponding *DG* within the *DG Union*. And each *sharding subgroup* applies a *DS* from the *DS Union*. In this example, both W and X contain 3 *sharding subgroups* (*HSize* = 3).

4.2 Hierarchical & Heterogeneous Extensions

Building on basic SPMD annotations, we introduce hierarchical constructs to support asymmetric sharding, enabling heterogeneous execution logic as shown in Figure 4 (right).

(I) *Device Group Union (DG Union)* and *Distributed States Union (DS Union).* As illustrated in Figure 6, we generalize the single *DG* and *DS* associated with each tensor to multiple *DG* partitions and *DS* configurations, forming *DG Union* and *DS Union*. Each *DS* configuration in the union corresponds to a *DG* partition in the union, describing sharding within that particular device subgroup, referred to as a *sharding subgroup*.[2] We term the sharding within each subgroup as **bottom-tier sharding**. This approach enables the simultaneous representation of multiple sharding patterns.

(II) *Heterogeneous Dimension (HDim)* and *Heterogeneous Size (HSize).* To model relationships between *sharding subgroups* in a union, we further introduce *Heterogeneous Dimension (HDim)* and *Heterogeneous Size (HSize)*. As illustrated in Figure 6, *HSize* specifies the number of distinct *sharding subgroups*, while *HDim* describes the sharding across them. For instance, $HDim = 0$ for tensor X implies splitting the tensor's first dimension across subgroups, while $HDim = -1$ for tensor W indicates full replication across subgroups. We refer to this as the **top-tier sharding**.[3]

4.3 Discussions

HSPMD's annotations can be viewed as a sharding extension layered atop standard SPMD annotations. Although this extension introduces additional system complexity, much of it remains hidden from the users' view. For one thing, as introduced in §3, users only need to define a logical computation graph (*defined graph*) and optionally provide a small set of annotations (*annotation plan*), the rest can be automatically deduced by our system. For another, HSPMD's annotation deduction can be decomposed into multiple standard SPMD deductions within each *sharding subgroup*, thereby simplifying the deduction procedure (this will be detailed in §6.1).

Readers might wonder whether it is more preferable to consider a more granular multi-tier hierarchy, or a simpler scheme that only shards data unevenly across devices. We discuss these two alternatives below.

- *Why two-tier, not multi-tier:* Introducing a multi-tier hierarchy is unnecessary. *HDim* and *HSize* at the top tier already suffice to express complex asymmetric shardings while keeping the added complexity minimal. Moreover, the two-tier design matches how compute resources are organized in practice: a node or node group is internally load-balanced under SPMD, while heterogeneity exists across nodes or node groups. Adding further tiers would enlarge the planning space and deduction complexity without yielding additional expressiveness for today's cluster deployment.
- *Why not simply shard data unevenly:* Sharding data alone, without a fundamental change at the annotation level, is insufficient. **(i)** For *temporal* heterogeneity, it is ineffective: when a GPU fails (Figure 3(b)), the TP/PP degrees must be reconfigured, which cannot be handled by data re-sharding alone. **(ii)** For *spatial* heterogeneity, it is suboptimal: under low inter-cluster bandwidth, heterogeneous DP requires exchanging full gradients, whereas heterogeneous PP only transfers activations for a single layer, with much smaller volume. Capturing such PP strategies requires annotation-level support beyond simple data sharding.

Once tensor annotations are specified by the *annotation plan* or deduced by the system, HSPMD will determine the exact communication pattern for each `Reshard` operator and will instantiate it with device-specific communication operators that can be executed directly. The next section (§5) will describe how the asymmetric communication operators (e.g., `BSR` in Figure 4,5) are derived from the given annotations.

5 Hierarchical Communication Resolution

As depicted in Figure 7, to reshard from a source annotation to a destination one, we develop a comprehensive classification procedure to determine the appropriate communication operators. Aligning with the concepts of bottom-tier and top-tier sharding, we classify communication into two categories: **bottom-tier communication** and **top-tier communication**. Bottom-tier communication operates independently within each *sharding subgroup*, determined solely by changes in bottom-tier sharding (§5.1). In contrast, top-tier communication requires interactions across *sharding subgroups* and is influenced by the entire annotation hierarchy (§5.2).

During this procedure, we prioritize the use of collective communication operators, decomposing asymmetric communication into multiple symmetric collective communications

[2] *Sharding subgroups* must consist of mutually exclusive device subsets.

[3] The shape of each shard can vary and is determined at runtime, which is decoupled from the static annotation system (as elaborated in §6.3).

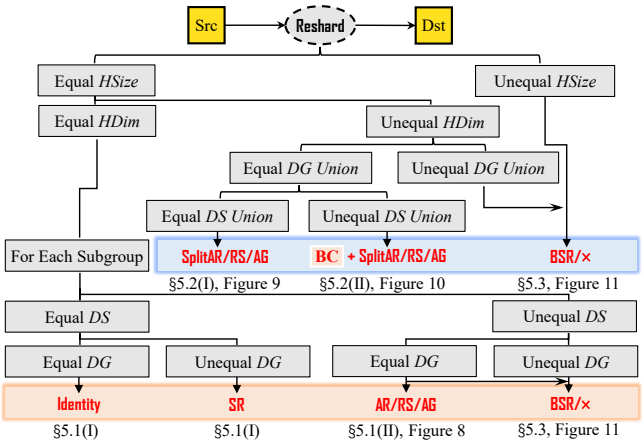

Figure 7: HSPMD's communication resolution. Orange denotes bottom-tier communication, executed independently within *sharding subgroups*; blue indicates top-tier communication, involving interactions between *sharding subgroups*. "SR": send-receive; "AR, RS, AG": all-reduce, reduce-scatter, all-gather; "BSR": batched-send-receive; "×": unsupported; "BC": bottom-tier communication.

when possible. For one thing, collective communication libraries (CCLs) have been extensively optimized [13, 26, 40, 54], often achieving higher performance than hand-crafted kernels. For another, modern GPU cluster network topologies (e.g., Multi-rail [1, 2], Clos [80]) are typically organized into multiple tiers [19], which aligns well with our hierarchical design. Specifically, **(i)** bottom-tier communication within *sharding subgroups* is usually operated on homogeneous devices (intra-machine or inter-machine with uniform links, typically high bandwidth) and can exploit fast symmetric collective primitives, whereas **(ii)** top-tier communication handles potentially heterogeneous inter-subgroup links (e.g., IB/TCP mixtures, often slower). When collective communication is infeasible, we develop a batched-send-receive (BSR) operator (§5.3) to accomplish sophisticated communications.

5.1 Bottom-tier Communication

When the source and destination annotations share the same *HSize* and *HDim*, it implies that the top-tier sharding remains unchanged. Consequently, all *sharding subgroups* can individually perform communication, typically reducing to standard SPMD resolution. As illustrated in Figure 7, for each *sharding subgroup*, we consider the following cases:

(I) Subgroup's source *DS* equals destination *DS*. We then determine whether the *DG* changes from the source to the destination, in which case each corresponding device executes either an Identity or send-receive (SR) operator to directly transfer the local shard.

(II) Subgroup's source *DS* does not equal destination *DS*. If the source and destination share the same *DG*, the device composition of the subgroup is unchanged, and only intra-subgroup resharding is required. As shown in Figure 8, we analyze the *DS* to select the appropriate collective operator,

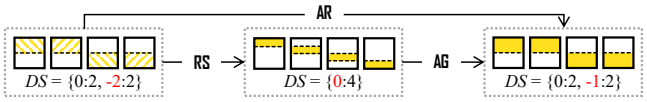

Figure 8: Bottom-tier collective communication.

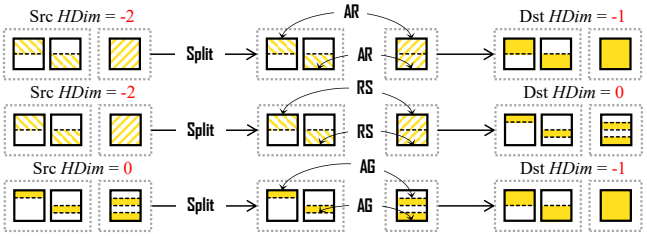

Figure 9: Top-tier collective communication. In scenarios where only *HDim* is altered, each shard can be split to the finest granularity, followed by multiple collective communication operators.

e.g., all-reduce (AR), reduce-scatter (RS), or all-gather (AG).

If these collective communication conditions are unmet, or if the *DG* differs, the system will instead employ batched-send-receive (BSR). Its mechanism will be detailed in §5.3.

5.2 Top-tier Communication

Next, we examine the scenario where the *HSize* of the source matches that of the destination, but their *HDim* values differ. If the *DG Union* of the source is identical to that of the destination (i.e., every *DG* in the union is equivalent), the transformation between the source and the destination can still be efficiently realized using collective communication operators. We analyze the following two cases:

(I) Source *DS Union* equals destination *DS Union*. In this case, only the *HDim* changes between the source and destination. As depicted in Figure 9, the transformation can be achieved through three distinct operators: split-all-reduce (SplitAR), split-reduce-scatter (SplitRS), and split-all-gather (SplitAG). The process starts by identifying the finest-grained slices of all *sharding subgroups*. Subsequently, based on the *HDim* change, collective communication is performed across these *sharding subgroups* for each slice, while maintaining the bottom-tier sharding within each subgroup.

(II) Source *DS Union* does not equal destination *DS Union*. As illustrated in Figure 10, in this case we first use bottom-tier communication (e.g., RS, Identity) to align the *DS Union*, reducing the problem to (I). We then apply top-tier communication (e.g., SplitAG) to align the *HDim*.

For scenarios where the *DG Unions* of the source and the destination are not identical, or where the *HSize* values differ, we once again resort to the BSR operator (§5.3).

5.3 Batched-Send-Receive Mechanism

When it does not involve *Partial*, any complex resharding can be decomposed into multiple send and receive operators, referred to as batched-send-receive (BSR), which is particularly useful for handling complex communication patterns that cannot be supported by collective communications.

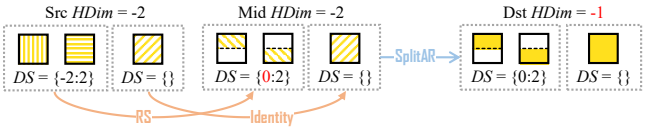

Figure 10: Top-tier collective communication succeeded by bottom-tier communication. In scenarios where both *HDim* and *DS Union* are modified, we first align the *DS* within each *sharding subgroup*, followed by aligning the *HDim* across different *sharding subgroups*.

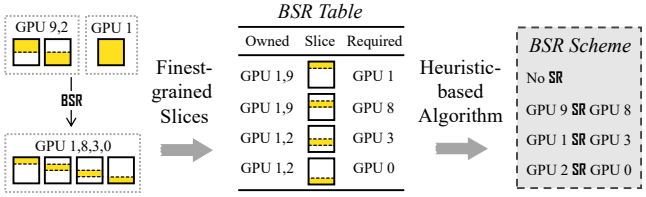

Figure 11: Batched-Send-Receive (BSR) mechanism. Based on the annotations of the source and destination, we construct a *BSR table* and subsequently generate the *BSR scheme* for communication.

As depicted in Figure 11 (left), we begin by identifying the finest-grained slices, based on which we construct a *BSR table* that maps each slice to its owner devices and the devices that require it. Subsequently, a *BSR scheme* is generated to describe how the slices are transmitted. Particularly, as illustrated in Figure 11 (right), we generate the *BSR scheme* by sequentially scanning the *BSR table* and applying the following heuristics: **(i)** If the slice is already owned, we perform a direct copy without communication; **(ii)** We prefer links with higher bandwidth (e.g., GPU 9 sending to GPU 8 via NVLink); **(iii)** If bandwidths are equal, we balance the cumulative send load (e.g., GPU 1 and GPU 2 send alternately).

Discussions. Since each slice may have multiple senders (owner devices) and receivers (required devices), deriving the optimal *BSR scheme* necessitates solving a Generalized Assignment Problem (GAP) [81], which is NP-hard. Our heuristic approach reduces the solving complexity to $O(pq)$, where p is the number of entries in the *BSR table* and q is the maximum number of receivers per entry. Here, p corresponds to the partition granularity of the finest-grained slices (e.g., $p = 4$ in Figure 11) and does not increase with cluster scale, since scaling is typically achieved by replication along the DP dimension rather than finer per-tensor partitioning. As a result, the solver remains tractable even at a large scale.

Our solver models only P2P bandwidth, which may be insufficient under highly heterogeneous network topologies. In such cases, a single P2P transfer may traverse multiple physical links, and the true bottleneck can reside in a specific link along the path. A more fine-grained model that captures per-link characteristics could better expose such intra-path bottlenecks. However, in practice, the BSR overhead is already small relative to computation (see §10), suggesting that further optimizing the solver would yield limited benefits. Overall, though our heuristic-based algorithm may not achieve the optimal, it is more practical and easier to implement, with strong performance and low overhead (see §10).

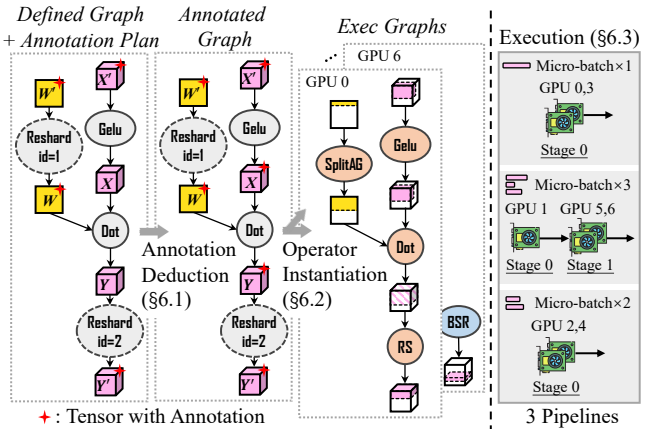

Figure 12: HSPMD 's graph specialization. We systematically deduce and parse annotations from a unified *defined graph*, transforming it into device-specific execution logic to support heterogeneous parallelization. The annotations remain consistent with Figure 4.

Last but not least, BSR is infeasible when *Partial* is involved. However, in practice, *Partial* tensors are typically intermediate results associated with collective communication, which can be handled by other top-tier or bottom-tier communication mechanisms. Given that complex resharding for *Partial* tensors is generally unnecessary, we omit such scenarios, yet our work can be easily extended by integrating BSR with all-reduce (when source involves *Partial*) or numeric division (when destination involves *Partial*).

6 Progressive Graph Specialization

In this section, we detail the abstraction of graph specialization that tackles *spatial* heterogeneity. As shown in Figure 12, the process starts from a *defined graph* with initial annotations specified by the *annotation plan* (i.e., the output sharding of leaf and Reshard operators). We then propagate these annotations to all remaining tensors, resulting in a fully *annotated graph* (§6.1). Next, we resolve the concrete communication of Reshard (as detailed in §5) and instantiate device-specific operators to generate distinct *executable graphs* for each device (§6.2), which are then deployed for pipelined execution (§6.3). Starting from a single-program abstraction, this specialization process incrementally derives divergent execution logics across devices, enabling the expression of heterogeneous parallel strategies that address *spatial* heterogeneity.

6.1 Annotation Deduction

As shown in Figure 12, we start by deducing the unspecified annotations (e.g., the output tensor X of Gelu and the output tensor Y of Dot). For simple unary operators like Gelu, the input tensor's annotation is straightforwardly propagated to the output. However, more complex operators, such as Dot, require a more intricate deduction process. Below, we outline the general methodology of annotation deduction.

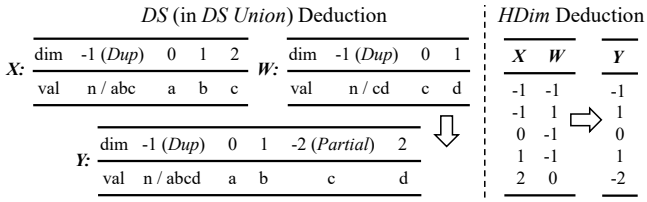

Figure 13: The deduction rules of *DS Union* and *HDim* for a 3D × 2D `Dot` operator. *n* is the number of GPUs in the *sharding subgroup* and *a-c* are values along different sharding dimensions.

Deduction of *DG Union* and *HSize*. For any standard operator, the output tensors inherit the same *DG Union* and *HSize* as the inputs. This requirement stems from a semantic constraint enforced by HSPMD: all inputs and outputs of an operator must have matching *DG Union* and *HSize*, ensuring that the operator executes locally on its assigned device, consuming inputs to produce outputs without implicit cross-device resharding. For multi-input operators with mismatched *DG Union* or *HSize*, users must explicitly insert `Reshard` operators before certain inputs to resolve the discrepancy.

Deduction of *DS Union* and *HDim*. The deduction of *DS Union* and *HDim* depends on the specific characteristics of each operator and is governed by the rules of distributed computation. To illustrate this process, we analyze the `Dot` operator, which takes a 3D tensor X and a 2D tensor W as inputs, as a concrete example. In the *DS Union* deduction process (Figure 13, left), since the *DG Union* and *HSize* are aligned, the deduction simplifies to sequentially deriving the *DS* for each *sharding subgroup*. This mirrors the SPMD deduction, where sharding values for X, W, and Y are derived using straightforward, rule-based logic. As for *HDim* deduction, top-tier sharding is essentially a simplified 1D sharding, following a similar rule-based logic. For example, as shown in Figure 13 (right), if X has a *HDim* of 0 and W has a *HDim* of -1, the output tensor Y retains a *HDim* of 0, preserving the heterogeneous top-tier *Split* after the `Dot` operator.

Discussions. We support annotation deduction for a wide range of operators. As shown in Table 2, for the vast majority, the annotation is propagated from inputs to outputs without modification. Deviations from this default behavior are limited: only `Reshard` may alter *DG Union* and *HSize*, while changes to *DS Union* and *HDim* are confined to a few specific operators (e.g., `Dot`) that inherently transform sharding patterns and thus employ custom deduction logic. This design, where most operators reuse a common propagation procedure, allows HSPMD's deduction to be efficient and scalable.

6.2 Operator Instantiation

Upon obtaining the annotations for all tensors, we instantiate a unique *executable graph* for each device. This process primarily consists of two key steps.

Non-Local operator removal. First, operators whose inputs and outputs do not involve the local device in their *DG Union* are excluded from its *executable graph*. For instance in Figure 12, since no tensors prior to Y' are placed on GPU 6, all operators except `Reshard` (id=2) are removed. This pruning step is essential for enabling pipeline execution (§6.3).

Table 2: Operator annotation deduction behaviors.

Operators	Modified Annotation Attributes
`Reshard`	*DG Union*, *HSize*, *DS Union*, *HDim*
`Dot`, `Sum`, `Reshape`, etc.	*DS Union*, *HDim*
All other operators	—

Reshard instantiation. For all remaining `Reshard` operators, we apply the hierarchical communication resolution (§5) to instantiate them with the exact communication operators.

(I) Bottom-tier communication. For bottom-tier communication, each *sharding subgroup* independently determines its communication operator and instantiates it accordingly: In Figure 12, `Reshard` (id=2) is classified as bottom-tier, leading GPU 0 and GPU 6 (belonging to different *sharding subgroups*) to instantiate it with `RS` and `BSR`, respectively.

(II) Top-tier communication. For operators classified as top-tier, all GPUs in the *DG Union* apply the same instantiation logic: In Figure 12, `Reshard` (id=1) is identified as `SplitAG` and uniformly instantiated on GPU 0–4.

6.3 Execution

At runtime, operators in the *executable graphs* are not invoked directly. Instead, they are organized into pre-/post-processing steps and forward/backward passes, which are repeatedly scheduled in a pipelined fashion. HSPMD supports various scheduling strategies (e.g., GPipe [27], 1F1B [50]) and allows pipelines to independently process different micro-batch counts and sizes (Figure 12, right). While the *annotation plan* defines the sharding patterns and indicates the `Reshard` behaviors (Figure 5, line 1), the concrete shapes of the input data and the intermediate tensors (e.g., tensors to be communicated) are determined dynamically on each device at runtime (Figure 5, line 9), independent of the static *executable graphs*. This decoupling between graph specialization and runtime execution enables flexible pipeline scheduling and supports variable-length inputs. Due to the space constraint, we refer interested readers to Appendix A.2 for more details.

6.4 Discussions

Below we summarize the data structures maintained per device (i.e., GPU). Following the SPMD paradigm, HSPMD runs one process per device, and each process independently maintains its own copy of: **(i)** a device-agnostic *defined graph* of the user program, **(ii)** a device-agnostic *annotation plan*, **(iii)** the corresponding device-specific *executable graph* derived via graph specialization, **(iv)** operator metadata, including the *BSR tables* for all `BSR` operators in its *executable graph*.

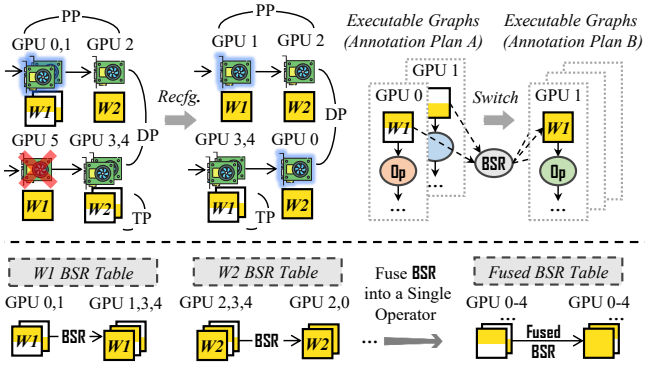

Figure 14: Top: Online reconfiguration is achieved by transforming weight annotations using `BSR` across *executable graphs*. Bottom: Fusing `BSR` into a single operator further enhances efficiency.

Among these, **(i)** and **(ii)** are identical in content across processes, while **(iii)** and **(iv)** are unique to each process. Since these structures encode only parallelization and execution logic (excluding model parameters and activations), each process keeps them in the CPU DRAM of its host. In practice, they occupy only a few MiB per CPU host.

7 Dynamic Graph Switching

HSPMD's graph specialization abstraction addresses *spatial* heterogeneity by generating device-specific parallel execution logic given an *annotation plan*. However, *temporal* heterogeneity, which evolves over time, demands dynamic reconfiguration of the overall parallelization. This necessitates switching from one *annotation plan* to another (Figure 5(b),(c)).

As illustrated in Figure 14 (top), to enable fast reconfiguration, we avoid reloading from checkpoints under the new sharding format. Instead, we reshard the weights from the old *executable graphs* by leveraging the high interconnect bandwidth among devices. Since weight annotations do not involve *Partial*, each weight can be directly resharded using the `BSR` operator (§5.3) to bridge the old and new plans.

To further optimize communication, rather than executing a separate `BSR` operator for each weight, we consolidate all *BSR tables* into a fused one (Figure 14, bottom), so that the corresponding *fused BSR scheme* can balance the communication load across all GPUs. Moreover, we fuse multiple send-receive operators between the same GPU pair into a single operator, significantly reducing kernel launch overhead. By executing this `Fused BSR` operator, the system can therefore efficiently transition to the new *annotation plan* and resume execution without restart or checkpoint reloading.[4]

Discussions. A natural concern is whether maintaining the data structures of different parallel strategies (i.e., multiple plans and graphs) incurs prohibitive overhead as the system scales to large and heterogeneous clusters. The answer is no.

[4]If a slice is missing from the fused *BSR table* (i.e., no GPU currently owns that slice), reconfiguration falls back to checkpoint reloading.

A key observation is that the number of strategies is independent of cluster scale or heterogeneity. For unstable devices, only a single strategy is maintained at any time, as the previous one is discarded after each reconfiguration. For mixed-length data, we pre-generate a set of strategies, each optimized for a specific maximum sequence length (e.g., one for batches with maximum length up to 16K and another up to 32K), and select the appropriate strategy at runtime based on the actual maximum sequence length of each batch. As a result, the number of strategies scales only with the granularity of the maximum-sequence-length partitioning, rather than with the cluster itself. Consequently, the overall maintenance overhead remains bounded regardless of cluster scale or heterogeneity.

8 HSPMD's Planner

This section presents the key implementation aspects of HSPMD's planner, which automatically generates *annotation plans* and thus frees users from constructing them by hand. In HSPMD, the planner is treated as an external component that can be readily replaced by alternative implementations.

Cost model and plan generation. Following existing works on automatic parallelism [48, 72, 92], our default implementation adopts a profiling-based approach, building a *cost model* for each operator on each hardware resource: for example, a compute operator (e.g., `Attention`) on a specific device (e.g., H20 or H800 GPU), or a communication operator (e.g., `AR`, `BSR`) on a given interconnect (e.g., NVLink or IB). We profile representative configurations (e.g., model sizes, tensor parallel degrees, input lengths) and fit cost models. To evaluate a plan, the planner decomposes its dataflow into operators and aggregates their predicted costs. Based on these estimates, it generates optimized *annotation plans* using ILP, MINLP, or dynamic programming, implemented with PuLP [65] and Pyomo [6]. Details are deferred to Appendix A.1.

Overhead of the planner. An *annotation plan* is a JSON dictionary with negligible storage cost. The planning consists of an offline phase (pre-generation) and an online phase (generation or selection). As shown in Figure 5, the offline phase runs before the training loop and is therefore off the critical path, while the online phase depends on the scenario: **(a)** heterogeneous devices require no online planning, **(b)** unstable devices trigger only a single re-generation upon cluster changes; **(c)** mixed-length data uses pre-generated plans with lightweight online selection. The overhead is therefore well controlled, with a detailed breakdown provided in Appendix A.1.

Generalizability to evolving models and clusters. The *cost model* is operator-centric rather than configuration-specific, so it generalizes naturally across model architectures and cluster settings. Model structural properties (e.g., layer count) and cluster factors (e.g., device count and topology) therefore do not affect it. Re-profiling is only required when new operators or new hardware resources are introduced (e.g., a new

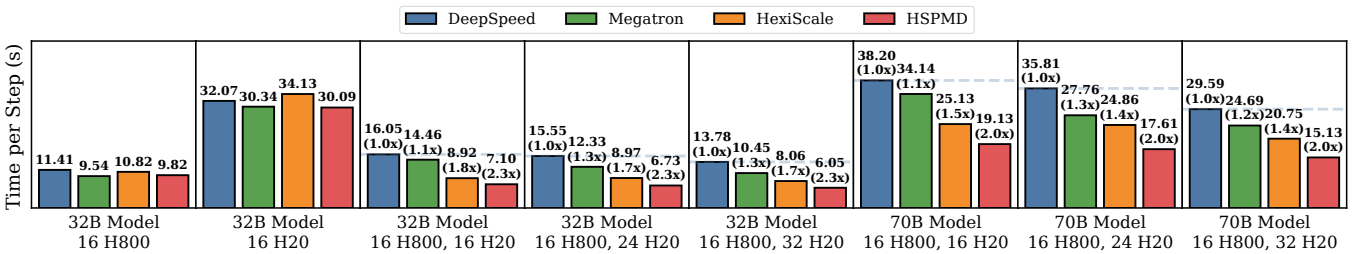

Figure 15: Scenario (a): Training performance across different device configurations and model size.

compute operator, a new GPU type, or a new interconnect).

Sensitivity to annotation plan quality. End-to-end performance is directly influenced by the quality of the *annotation plan*. Nevertheless, a clear lower bound is always guaranteed: in the extreme case, the planner can fall back to a fully homogeneous strategy, under which HSPMD reduces to standard SPMD execution. Since our goal is to establish HSPMD as a general and flexible framework for heterogeneous execution rather than to optimize scenario-specific planners, improving planner optimality is left to future work.

9 Evaluations

In this section, we evaluate HSPMD under three representative scenarios: (a) heterogeneous devices, (b) unstable devices, and (c) mixed-length data (the workflow of each is depicted in §3). Our evaluation aims to answer two central questions:

- How does HSPMD outperform standard SPMD in the presence of diverse *spatial* and *temporal* heterogeneity?
- Why does extending low-level *declarative annotations*, as in HSPMD, provide greater effectiveness than relying on high-level schedulers, as in other SPMD variants?

Baselines. As shown in Table 3, we select two categories of baselines. The first category includes standard SPMD training systems: **(i)** DeepSpeed [28, 58], which supports DP (with ZeRO-series) and SP; **(ii)** Megatron [37, 51, 60], which supports DP (with ZeRO-1), TP, PP, and CP. The second category consists of scenario-specific systems that enhance SPMD with dedicated schedulers: **(iii)** HexiScale [87], a framework built on top of Megatron, employing a heterogeneous GPipe [27] scheduler to support varying pipeline stages and TP degrees across stages; **(iv)** Oobleck [29], an elastic training framework that maintains fault tolerance with pre-defined pipeline templates, and features a scheduler for dynamic reconfiguration by merging and borrowing resources between pipeline templates; **(v)** HotSPa [23], which utilizes a hot-switchable scheduler to reconfigure between several pre-defined homogeneous strategies (DP, TP, PP) to handle sequences of varying lengths, without incurring the overhead of cold-start.

Experimental setup. Our testbed consists of 16 H800 and 32 H20 GPUs (detailed in Appendix C.1). Given that LLMs represent the most significant DL workload today, and that existing baselines predominantly focus on LLMs, our evaluation centers on them as well. We adopt the widely-used Llama

Table 3: Baselines: Two scenario-agnostic SPMD systems, and three scheduler-enhanced SPMD variants designed for specific scenarios.

Systems	Scenarios	Paradigms
(i) DeepSpeed **(ii)** Megatron	(a)-(c)	Standard SPMD
(iii) HexiScale	Only (a)	+ Hetero. Pipeline Scheduler
(iv) Oobleck	Only (b)	+ Elastic Pipeline Scheduler
(v) HotSPa	Only (c)	+ Hot-Switchable Scheduler

architecture [70] in various model sizes, with a default context length of 4K and a global batch size of 64, measuring per-step training time. All baselines are carefully tuned to their optimal performance. For HSPMD, we employ profiling-based planners (detailed in Appendix A.1) to generate and select the *annotation plan*. Strategies are provided in Appendix C.

(a) Heterogeneous devices. We first evaluate performance under static *spatial* heterogeneity through experiments on heterogeneous devices. As shown in Figure 15, on homogeneous devices, all systems perform similarly, confirming that performance differences do not stem from engineering artifacts. On heterogeneous devices, however, HSPMD consistently outperforms the baselines. DeepSpeed and Megatron are constrained by symmetric sharding, which hinders workload balance on devices with varying capabilities. HexiScale, on the other hand, has two key limitations: **(i)** its built-in scheduler tightly couples the heterogeneous parallel strategy specification with execution, making it difficult to flexibly support complex pipeline scheduling schemes like 1F1B; and **(ii)** its scheduler lacks support for generalized asymmetric communication, relying instead on coarse-grained broadcasts. In contrast, HSPMD leverages *declarative annotations*, which decouple heterogeneous specifications from automatic pipeline execution (§6.3) and enable hierarchical communication constructs (§5), thus facilitating flexible pipeline scheduling and efficient communication, resulting in improved performance.

(b) Unstable devices. We next evaluate elastic training performance under *spatial* and unknown *temporal* heterogeneity. Notably, DeepSpeed and Megatron employ a checkpoint-and-restart approach upon reconfiguration and use optimal training strategies under each configuration. Both HSPMD and Oobleck [29] disable ZeRO-1 [58] to retain DP-dimension redundancy for recovery without checkpoint-and-restart. This design is common across fault-tolerant training systems (in-

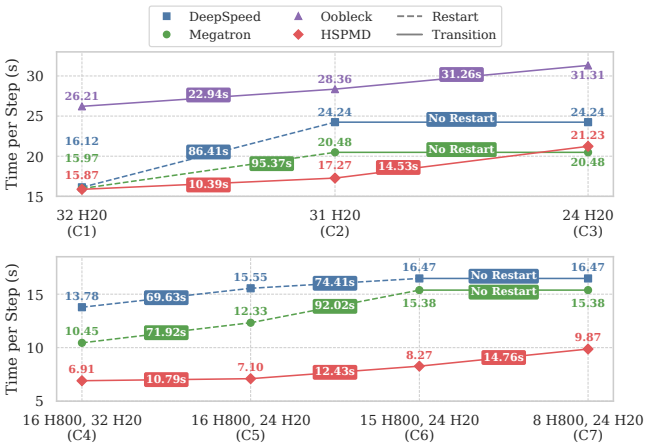

Figure 16: Scenario (b): Elastic training traces on homogeneous and heterogeneous clusters. We annotate the per-step training time for each configuration, along with the reconfiguration overhead.

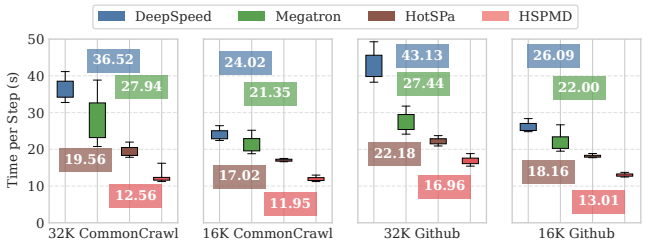

Figure 17: Scenario (c): Training performance with mixed-length data using different context lengths and datasets on 32 H20 GPUs. Box plots show time distributions with mean values annotated.

cluding other recent works like Recycle [21]). Thus, both our generalized system and the specialized baseline inherently trade some training performance for fault tolerance. As shown in Figure 16, we conduct experiments training a 32B model using two traces, each incorporating GPU and node failures.

Upon a GPU failure, DeepSpeed and Megatron are constrained by their symmetric sharding and must discard the entire node (*spatial*). In contrast, HSPMD can leverage all remaining GPUs, leading to improved performance (e.g., C2). Moreover, their significant restart overhead further makes them less suitable for elastic environments (*temporal*).

On the other hand, Oobleck enables restart-free reconfiguration but underperforms compared to other systems because its elastic pipeline scheduler confines fault tolerance strategies to predefined pipeline templates. By comparison, HSPMD employs tensor-level *declarative annotations* rather than rigid pipeline-level templates to specify parallelization, which enables exploration of a much broader strategy space. Furthermore, while Oobleck's elastic scheduler only supports naïve model broadcasting during reconfiguration, HSPMD 's *declarative annotations* allow more general per-tensor send-receive analysis to form a more balanced `Fused BSR` (as evaluated in §10), significantly reducing reconfiguration overhead.

(c) Mixed-length data. Finally, we evaluate the mixed-length data scenario to assess performance under *spatial* and predictable *temporal* heterogeneity. We train a 32B model for 100 steps on CommonCrawl and GitHub datasets using 32 H20 GPUs with a batch size of 200K tokens, testing different context lengths (32K and 16K). As baselines, DeepSpeed and Megatron pack mixed-length sequences into the fixed context window, truncating any excess [38]. HotSPa also employs data packing and additionally switches between pre-defined strategies for different length intervals. Results are shown in Figure 17, while Figure 18 illustrates a specific case: HSPMD pre-generates two heterogeneous strategies—Strategy A, which is slower but handles longer sequences, and Strategy B, optimized for shorter ones. HSPMD dynamically selects and switches between them across training steps (as depicted in Figure 5(c)). All reported per-step timings include strategy reconfiguration overhead for both HotSPa and HSPMD.

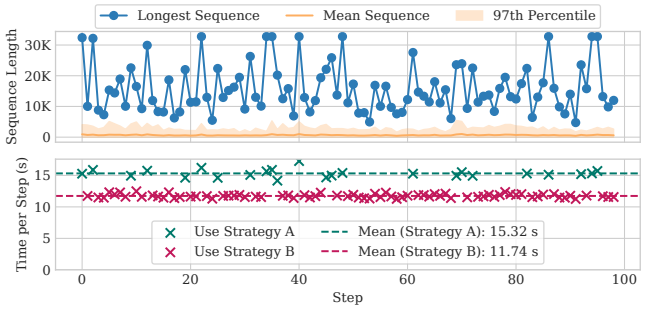

Figure 18: Sequence length variation and strategies employed by HSPMD in the "32K CommonCrawl" case. HSPMD dynamically switches between heterogeneous strategies (A and B) across different steps to optimize performance when sequence lengths shift.

DeepSpeed and Megatron, constrained by the symmetric nature of SPMD to a fixed homogeneous strategy, perform poorly because most sequences are much shorter than the context limit (97% < 8K in Figure 18), making long-context-oriented strategies inefficient for packed short sequences. While HotSPa's hot-switchable scheduler allows dynamic adjustment to length-tailored parallel strategies in the temporal dimension, it remains constrained by the symmetry of SPMD and cannot support spatially heterogeneous parallel strategies. This leads to lower performance compared to HSPMD, which addresses both *spatial* and *temporal* heterogeneity through a unified abstraction of extended *declarative annotations*.

Summary. Our evaluation across diverse scenarios reveals two findings: **(i)** standard SPMD is inadequate for tackling heterogeneity, and **(ii)** scheduler-enhanced SPMD variants can address specific scenarios but have intrinsic limitations. First, compared to primitive-level extensions, addressing heterogeneity at the scheduler level is coarse-grained, which constrains the design space of heterogeneous strategies and the flexibility of strategy reconfiguration (e.g., HexiScale cannot support flexible pipeline schedulers, Oobleck relies on fixed pipeline templates, and HotSPa uses rigid homogeneous strategies), thereby limiting their performance. More importantly, these approaches work around SPMD's symmetry by

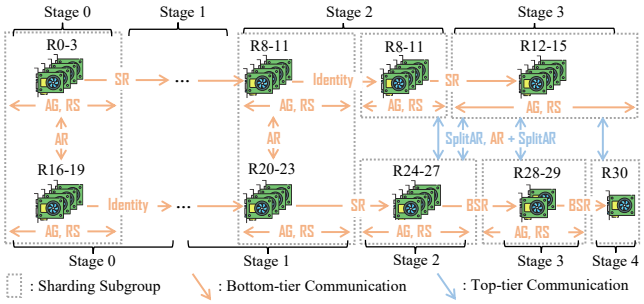

Figure 19: Parallel strategy employed in C2. "R" represents rank.

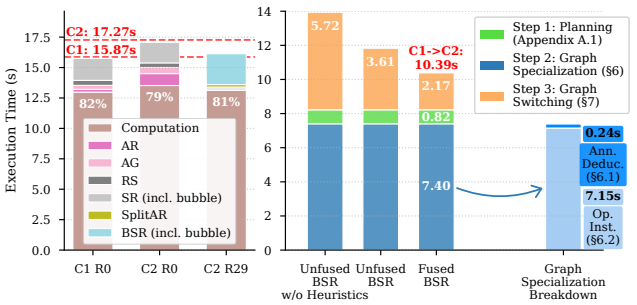

Figure 20: Left: Time per step breakdown for homogeneous (C1) and heterogeneous (C2) parallel strategies. Right: Reconfiguration overhead from C1 to C2 with different `BSR` algorithms.

building a top-down system stack tailored to particular scenarios, making them effective only in isolated cases. In contrast, HSPMD introduces low-level extensions on *declarative annotations*, directly bridging the gap between SPMD's symmetric nature and the asymmetric demands of heterogeneous environments. This enables a versatile, bottom-up system stack that provides general solutions across diverse scenarios.

10 Case Study

In this section, we provide an in-depth analysis of HSPMD's components, using the C2 configuration and the C1-to-C2 reconfiguration process (in Figure 16) as key examples.

Strategy deployment and communication resolution. Figure 19 shows HSPMD 's deployment and communication patterns under C2 (31 H20 GPUs), forming two independent pipelines. Most stages use 4 GPUs, except the last two in the second pipeline, which use 2 and 1 GPU(s). Within each stage, TP is applied via `AG` and `RS` (§5.1(II)). And inter-stage communication within a pipeline employs `SR` (§5.1(I)) or `BSR` (§5.3). For cross-pipeline gradient synchronization, `AR` (§5.1(II)), `SplitAR` (§5.2(I)), and subgroup-specific `AR` following `SplitAR` (§5.2(II)) are used. Besides, we also provide the loss curves of C1 and C2 in Appendix B, which further confirm that the heterogeneous strategy and the introduced communication operators do not affect convergence.

Strategy execution time breakdown. We then analyze the per-step computation and communication time for each rank in C2. Figure 20 (left) contrasts ranks 0 and 29, which follow asymmetric execution logic, against rank 0 in the homogeneous C1 as a reference. The results reveal that: **(i)** the heterogeneous strategy achieves balanced workload distribution across ranks; and **(ii)** similar to the homogeneous strategy, computation remains the dominant runtime component. The additional overhead introduced by `SplitAR` and `BSR` is minimal, indicating that HSPMD's asymmetric communication does not incur significant performance degradation.

Strategy reconfiguration overhead. We eventually evaluate the overhead of reconfiguring from C1 to C2, which consists of three sequential phases (Figure 5(b)): planning (Appendix A.1), graph specialization (§6), and graph switching (§7). As shown in Figure 20 (right), the planner generates

Table 4: Distribution of C1-to-C2 communication volume under different `BSR` algorithms. We show the total communication volume each rank sends via NVLink and InfiniBand (IB).

Format: *Sender Rank ID: NVLink Vol. (MB) | IB Vol. (MB)*

R27: 0|748	R28: 5517|0	R29: 11496|0	R30: 8222|0

the *annotation plan* with minimal latency. Graph specialization then follows, dominated by operator instantiation (§6.2), which involves adjusting the graph and creating new CCL communication groups but typically completes within 10s, while the cost of annotation deduction (§6.1) is negligible.

As for graph switching, we compare three `BSR` algorithms: **(i)** A baseline without heuristics (using minimal rank IDs for broadcasting); **(ii)** Non-fused per-tensor `BSR` with heuristics; **(iii)** Our `fused BSR`. Results show that our approach achieves the lowest end-to-end switching overhead despite maintaining the same total communication volume. As shown in Table 4, this improvement stems from evenly distributed traffic across ranks and better utilization of high-bandwidth NVLink.

11 Discussions and Future Work

In this section, we discuss two additional aspects of HSPMD: **(i)** its support for Mixture-of-Experts (MoE) models under expert imbalance, and **(ii)** its interoperability with existing SPMD frameworks. Both represent promising directions enabled by HSPMD's design, which we leave to future work.

Support for MoE and expert imbalance. MoE models are typically trained with expert parallelism (EP) [39], which shards experts across devices, but they often suffer from load imbalance due to skewed token routing. A representative mitigation is EPLB [14], which replicates heavily loaded experts to distribute the workload. HSPMD naturally supports such strategies through its two-tier sharding annotations: at the

top tier, HSPMD applies *Split* on the hidden-size dimension to split across different experts, and at the bottom tier, it uses different *Dup* degrees to replicate different loaded experts. When expert workloads shift substantially during training, HSPMD can reconfigure the overall *annotation plan* via graph switching, without requiring any further extension.

Interoperability with existing SPMD frameworks. Any prior annotation-based SPMD framework (e.g., Alpa [92], GSPMD [86], and DTensor [67, 68]) can be extended to support HSPMD's annotations by adding one additional tier on top of its existing SPMD annotations, which amounts to introducing two extra attributes (*HDim* and *HSize*) and promoting the original annotation structure to a list of such structures. On top of this, HSPMD's communication resolution, graph specialization, and graph switching mechanisms can be plugged in to enable heterogeneous parallelization, while the framework's existing parallelization primitives (e.g., operator-level sharding rules, automatic annotation deduction, and its standard parallelism implementations such as DP, TP, PP, and CP) can be reused as-is. By contrast, frameworks that realize parallelism by specifying particular layers, such as Megatron [60] and DeepSpeed [58], are harder to build HSPMD on top of, since they do not expose a unified, operator-level annotation surface and instead rely on ad-hoc, per-layer specifications (e.g., `ColumnParallelLinear`).

12 Related Work

12.1 Tackling Workload Heterogeneity

Recent works have tackled workload heterogeneity in large-scale DL training through scenario-specific optimizations.

(a) Heterogeneous devices. HAP [90] uses a sharding ratio to handle uneven TP partitioning. Whale [31] partitions workloads by splitting the global graph into heterogeneous task graphs. AMP [41] and HetHub [84] support heterogeneous layer partitioning in PP, while Metis [71] extends Alpa [92] for heterogeneous strategy search. HexiScale [87] enables more fine-grained heterogeneous 3D parallelism, and Sailor [63] further optimizes the search cost for such strategies.

(b) Unstable devices. Varuna [3] uses checkpoint restarts and adjusts DP and PP to find optimal strategies after failures. Bamboo [69] achieves fault tolerance via redundant storage on adjacent pipeline stages, Oobleck [29] employs multiple pipeline templates for fault tolerance and strategy tuning, and ReCycle [21] rebalances the workload from failed pipelines.

(c) Mixed-length data. FlexSP [76] uses dynamic SP for varied sequences, while ByteScale [22] and DCP [33] adopt dynamic CP. HotSPa [23] assigns homogeneous strategies to different length intervals. WLB-LLM [78] addresses load imbalance specifically in CP and PP, while Zeppelin [7] achieves finer-grained control over attention and NIC imbalance.

In contrast to these specialized solutions, HSPMD introduces a unified abstraction via low-level *declarative annotations* instead of high-level schedulers. This design offers greater generality and could serve as a foundational substrate for addressing diverse heterogeneity. Furthermore, prior works have proposed planning algorithms tailored to targeted scenarios, which can be seamlessly integrated with our work by encoding their strategies through our annotations.

12.2 SPMD and MPMD Training Systems

Beyond the SPMD training systems discussed above, another line of work adopts the MPMD paradigm, such as Pathways [4], JaxPP [82], and Piper [20]. One motivation behind their MPMD design is the observation that pipeline parallelism (PP) is not inherently SPMD, as different devices naturally execute different model stages. Nevertheless, SPMD remains the dominant paradigm in mainstream training systems for its scalability and simplicity (see §2.3), and PP is typically encoded in an SPMD style, where devices share a global program but diverge at runtime. For example, GSPMD [86] treats PP as layer-wise sharding, while Megatron [60] employs a light scheduler to execute subgraphs. HexiScale [87] and Oobleck [29] further introduce more advanced schedulers for heterogeneous execution. These approaches effectively encode PP within SPMD. HSPMD takes the same stance: rather than switching to MPMD, it extends SPMD with *declarative annotations* for asymmetry, preserving single-program simplicity while enabling the heterogeneous execution of various parallelism schemes including PP (see §6.3).

13 Conclusion

We present HSPMD, a novel system that extends the SPMD paradigm to support heterogeneous parallelization and dynamic reconfiguration, addressing both *spatial* and *temporal* heterogeneity. Through low-level sharding annotations and hierarchical communication, HSPMD bridges the gap between SPMD's inherent symmetric constraints and the emerging demands of asymmetric execution in large-scale DL training. Extensive evaluation across (a) heterogeneous devices, (b) unstable devices, and (c) mixed-length data demonstrates HSPMD's effectiveness and broad applicability.

A Implementation Details

HSPMD is designed to accommodate diverse forms of heterogeneity, which requires additional computation graph representations and dynamic adjustments. However, extracting computation graph information in PyTorch [56] is non-trivial. To address this, we have developed a prototype framework comprising 87.9K lines of C++ code and 16.9K lines of CUDA code, supporting graph-based distributed DL training. The framework implements all major parallelism paradigms, including data parallelism (DP), tensor parallelism (TP), pipeline parallelism (PP), and context parallelism (CP), as well as complementary techniques such as ZeRO-1, offloading, activation recomputation, and mixed-precision training.

Within the total 87.9K lines of C++, 16.9K lines implement the core logic of HSPMD, covering sharding annotation, communication resolution, graph specialization, and graph switching. An additional 14.7K lines of C++, largely consisting of pybind [66] bindings, serve as glue code that exposes HSPMD APIs to Python. Together with 12.5K lines of Python, these APIs allow users to define tensors, operators, and training workflows, enabling seamless deployment and reconfiguration of heterogeneous strategies.

Our prototype system is optimized for large language models (LLMs) training, with collective communication primitives implemented via NCCL [54] and computation kernels accelerated using libraries such as FlashAttention [11, 12], cuBLAS [52], and cutlass [53]. When evaluated with homogeneous parallel strategies, HSPMD achieves performance comparable to Megatron [37, 51, 60] (as evaluated in §9(a)). While our current implementation and experiments focus on LLMs—due to their extreme model sizes and demand for massive GPU clusters—the proposed designs are broadly applicable to other deep learning workloads.

Below, we provide additional details on the implementation that are not covered in the main text.

A.1 Scenario-specific Planning

In this section, we present our approach for automatically generating and selecting *annotation plans* (§3) for the three representative scenarios in §9. The primary focus of this paper is on the underlying system design rather than on optimizing the planning process. To that end, the planner is implemented as a modular component that users can readily replace or extend—for example, by incorporating algorithms from prior scenario-specific work. The implementation described here represents just one of many possible planning algorithms, provided to demonstrate HSPMD 's flexibility in supporting diverse application settings.

Our approach starts by profiling execution time and memory usage for homogeneous parallelism configurations on a single model unit (e.g., an `Attention` operator), given the target model and workload specifications (i.e., context length and batch size). Based on these measurements, we develop a regression-based *cost model* to estimate per-device execution time and memory usage for any heterogeneous parallel strategy expressible in HSPMD. This is achieved by analyzing the dataflow and aggregating results from different *sharding subgroups*, each of which employs homogeneous parallelism and can be estimated individually. Below, we detail the algorithms used in each scenario.

(a) Heterogeneous devices. Using our *cost model*, we formulate a two-level optimization problem. The objective is to minimize the maximum estimated execution time across all devices while satisfying memory constraints:

- **Pipeline configuration** (first-level): We determine the number of pipelines (§6.3) along with their parallel methods, stage counts, and device-to-stage mappings. This is formulated as a Mixed-Integer Nonlinear Programming (MINLP) problem.
- **Layer & micro-batch assignment** (second-level): We assign model layers to different pipeline stages and calculate optimal micro-batch configurations (i.e., micro-batch size and count) for each pipeline, solved as multiple Integer Linear Programming (ILP) problems.

The combined solution yields a unique *annotation plan* for deployment.

While the ILPs can be solved efficiently, the MINLP remains computationally expensive. Instead of solving the original MINLP directly, we adopt a heuristic-guided greedy search to prune suboptimal solutions upfront, thereby shrinking the strategy space and reducing the solving overhead while preserving solution quality.

(b) Unstable devices. Our elastic training approach begins by generating an optimal initial *annotation plan* using the same planner as in (a). When reconfiguration is required, profiling is unnecessary since the model and workload remain unchanged. Moreover, we intelligently prune the MINLP search space using intermediate results from the initial planning phase. This optimization enables the first-level problem to be solved significantly faster during reconfigurations, while the second-level ILPs (remaining identical to the initial solution) continue to be resolved with minimal overhead.

(c) Mixed-length data. For datasets with variable sequence lengths, our methodology begins by analyzing the dataset distribution to obtain sequence length statistics. Based on these statistics, we employ a dynamic programming algorithm that jointly determines both the optimal sequence length intervals for partitioning variable-length sequences and the corresponding parallel method for each interval. Different pipelines, each tailored to a specific interval and parallel method, are then combined into a single heterogeneous parallel strategy. Recognizing that per-batch sequence length distributions may deviate from global dataset statistics, we prepare multiple parallel strategies optimized for different maximum sequence

Table 5: Workflow and time breakdown of different scenarios. Step 1 (planning) is automated by our planner module (users may optionally provide the *annotation plan* manually), while Step 2 (graph specialization) and Step 3 (graph switching) are handled by HSPMD. The planner generates the *annotation plan* (offline/online) and may select the optimal plan if multiple candidates exist (online). *Executable graphs* are specialized upon receiving the *annotation plan* (offline/online), and different *executable graphs* can be switched on-the-fly (online). Note that all online overheads are included in §9's end-to-end results.

Scenario	**Step 1: Planning**	**Step 2: Graph Specialization (§6)**	**Step 3: Graph Switching (§7)**
Heterogeneous Devices	**Offline:** Single *annotation plan* generated before training (6.4s-18.2s).	**Offline:** Executed once before training (6.8s-8.3s).	—
Unstable Devices	**Offline:** Initial *annotation plan* generated before training (9.1s-18.2s). **Online:** New *annotation plan* generated whenever device availability changes (0.05s-1.2s).	**Online:** Executed each time a new *annotation plan* is generated (6.2s-7.9s).	**Online:** Triggered after new *executable graphs* are specialized (2.2s-5.3s, switch both FP32 parameters & optimizer states).
Mixed-length Data	**Offline:** Multiple *annotation plans* generated before training (24.1s-26.8s). **Online:** *Annotation plan* selection for next training steps (1.5s-2.1s, overlapped with the current step's training).	**Offline:** Executed for each *annotation plan* before training (14.8s-16.2s).	**Online:** Triggered between training steps if different *annotation plans* are favored (0.8s-1.3s, switch only BF16 parameters).

lengths. During execution, for each incoming batch, our system leverages the *cost model* again to distribute sequences among pipelines and dynamically select the strategy with the lowest estimated execution time. This data assignment and strategy selection process runs concurrently on CPU resources, carefully orchestrated to overlap with GPU training. By parallelizing the planning of upcoming steps (e.g., preparing the next 10 steps during the current step's execution) across available CPU cores, our implementation effectively amortizes and hides the planner's runtime overhead.

Across all scenarios, we leverage PuLP [65] for solving ILPs and Pyomo [6] for solving MINLPs. As detailed in Table 5, we provide overhead measurements including planning, graph specialization (§6), and graph switching (§7) for each scenario, accompanied by thorough workflow descriptions. The results indicate that our planners either introduce minimal overhead or run offline, ensuring negligible impact on online training.

A.2 Execution

In this section, we provide the details not covered in §6.3 on how to recognize heterogeneous pipelines and coordinate their execution, as well as how to support dynamic input shapes during execution without relying on the sharding annotation system.

Pipeline construction and scheduling. HSPMD supports various scheduling schemes, including GPipe [27] and 1F1B [50], while enabling independent pipelines to process micro-batches with different sizes and quantities. This functionality is achieved through two key steps: **(i)** determining the pipeline structure based on current sharing annotations (i.e., identifying device-to-stage and device-to-pipeline mappings); and **(ii)** coordinating device execution according to the selected pipeline scheduler (e.g., 1F1B).

As illustrated in Figure 21 (left), after *executable graphs* are specialized (§6), we further partition each device's *executable graph* into four types of *executable subgraphs*:

- **Pre-processing** (*Pre*): Includes operators such as precision conversion (e.g., FP32 to BF16) for mixed-precision training, and parameter gathering (e.g., `AG`, `SplitAG`) for ZeRO [58] sharding.
- **Post-processing** (*Post*): Includes operators for gradient accumulation (e.g., `Sum`), gradient synchronization (e.g., `RS`, `SplitRS`), and optimizer updates (e.g., Adam [36]).
- **Forward** (*F*): Includes operators for the DL forward pass

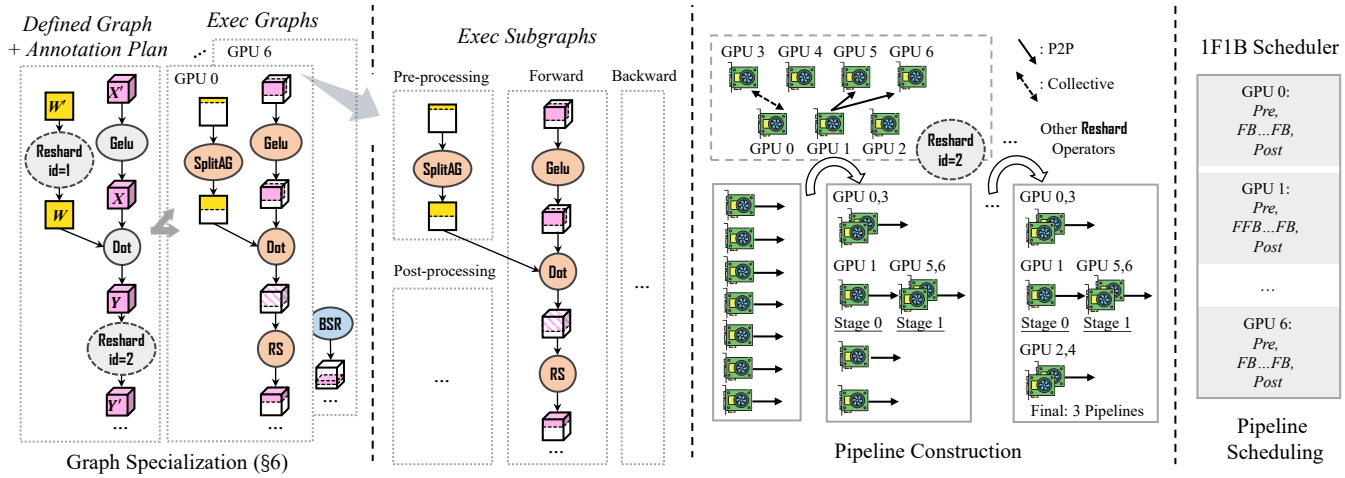

Figure 21: Pipeline construction and scheduling. The *executable graph* associated with each device is divided into multiple *executable subgraphs*. Once the pipelines are constructed, each device is assigned a schedule that dictates the execution order of its *executable subgraphs*. This figure aligns with Figure 12.

(e.g., `Dot`, `AttentionFwd`).

- **Backward** (*B*): Includes operators for the DL backward pass (e.g., `Dot`, `AttentionBwd`).

These *executable subgraphs* serve as the scheduling units for subsequent execution given the pipeline scheduler.

Below, we describe the process of constructing pipelines, whereby each device identifies its stage number and pipeline number, ensuring that all devices are aware of their roles during pipeline scheduling. We design an algorithm for constructing pipelines in a step-by-step manner. As illustrated in Figure 21 (middle), we initially construct a separate pipeline for each device. Subsequently, we sequentially analyze all `Reshard` operators involved in the forward and backward *executable subgraphs*. In Figure 21, we identify that `Reshard` (id=1) is executed only once at the beginning, which belongs to the pre-processing *executable subgraph* and does not participate in forward or backward passes, so the first communication operator actually analyzed is `Reshard` (id=2). For this communication operator, we decompose its internal communication into two categories: collective communication and peer-to-peer (P2P) communication. All devices involved in collective communication are merged into the same pipeline, while devices involved in P2P communication are concatenated into subsequent stages of the pipeline. For example, in Figure 21 (middle), after processing `Reshard` (id=2), the pipelines containing GPU 0 and GPU 3 are merged into one, while GPU 5 and GPU 6 are appended to the pipeline containing GPU 1 as the next stage. Through iterative application of this process, all pipelines are eventually fully constructed.

After pipeline construction, the system orchestrates execution according to the pipeline structure during runtime. Each device is assigned a schedule that defines the execution order of its *executable subgraphs*. For instance, in Figure 21 (right), when using the 1F1B scheduler, GPU 0 (located at the final stage) follows the schedule $Pre, FB \ldots FB, Post$, whereas GPU 1 (on the first stage) executes according to $Pre, FFB \ldots FB, Post$. Here, *Pre* and *Post* denote the pre- and post-processing *executable subgraphs*, respectively, and *F* and *B* represent forward and backward *executable subgraphs*, respectively.

Symbolic shape extension. During execution, HSPMD dynamically adapts to variations in input tensor shapes across different pipelines (e.g., to facilitate load balancing, data packing, and other runtime optimizations). While static sharding annotations define the high-level sharding pattern, the concrete shapes of individual shards are resolved at runtime.

To support this dynamic behavior, HSPMD extends tensor metadata with symbolic variables, which represent unknown dimensions of the shape (e.g., **S** for sequence length). These variables are propagated through tensor operations on each device while maintaining dimensional constraints. For instance, splitting a tensor along its sequence dimension would generate the constraint $\mathbf{S}' = \mathbf{S}/2$, preserving algebraic relationships between the symbols of the two tensors. The system resolves these symbols to concrete arithmetic values only when actual input tensors are provided at runtime to each device. This design allows different ranks to process dynamically shaped data. Additionally, HSPMD enforces both compile-time and runtime checks to detect invalid symbol usage. For example, defining $\mathbf{S}' = \mathbf{S}/2$ without satisfying the constraint $\mathbf{S} \equiv 0 \pmod 2$ is illegal and may lead to shape mismatches during cross-rank communication.

B Training Convergence

In this section, we present a comparative analysis of training loss under two configurations (C1 and C2, totally aligned with

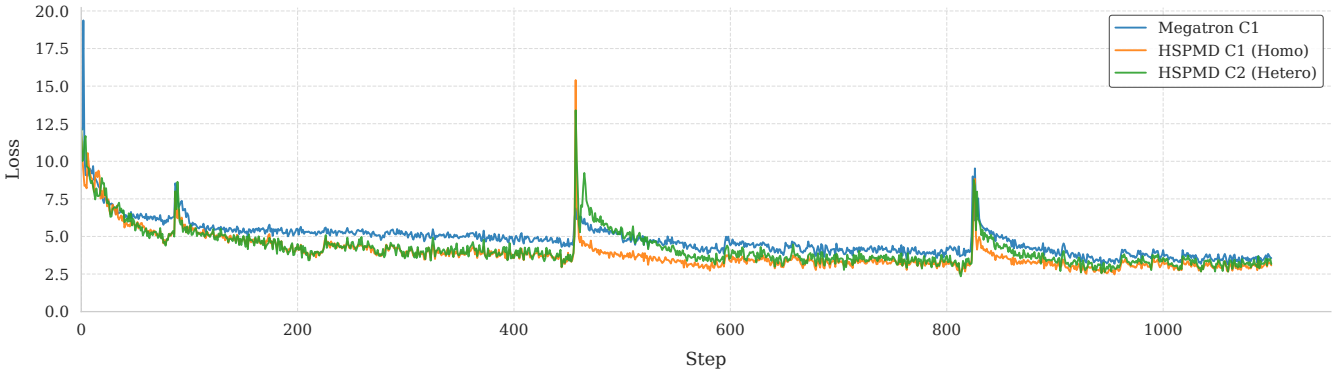

Figure 22: Training loss comparison.

§10). In both configurations, a 32B Llama model is trained using HSPMD, yet they differ in GPU resources and parallel strategies:

- C1: The model is trained on 32 H20 GPUs under a homogeneous parallel strategy.
- C2: The model is trained on 31 H20 GPUs under a heterogeneous parallel strategy.

Comprehensive descriptions of these parallel strategies are documented in Appendix C.3, while the full training setup is summarized in Table 6.

Table 6: Training setup.

Category	Parameter	Value
Model Configuration	**Number of Layers**	60
	Hidden Size	6,656
	Attention Heads	64
	FFN Hidden Size	17,920
	Vocabulary Size	50,304
	Query Groups	64
	Activation Function	SwiGLU
	Normalization	RMSNorm
	Position Encoding	RoPE
	Dropout	None
Hyperparameters	**Precision**	BF16
	Optimizer	Adam
	Learning Rate	1×10^{-4}
	Warm-up Steps	0
	Scheduler	Constant
	Weight Decay	0
	Adam β_1	0.9
	Adam β_2	0.999
	Adam ε	1×10^{-8}
	Gradient Clipping	None
	Dataset	Github
	Epoch	1
	Context Length	4,096
	Batch Size	64

We also train a model using Megatron, employing the same homogeneous parallel strategy and training setup as in C1. As shown in Figure 22, the results show that HSPMD achieves good convergence under both homogeneous and heterogeneous settings. In the homogeneous setting (C1), the convergence behavior closely matches that of the Megatron baseline, with minor differences in absolute loss values attributable to framework-level implementation variations. Besides, the heterogeneous setting (C2) exhibits convergence nearly identical to C1, with only marginal fluctuations observed during training irregularities. These findings demonstrate that the introduction of asymmetric sharding and diverse asymmetric communication patterns does not compromise training convergence.

C More Experimental Details

This section provides a comprehensive analysis of HSPMD's heterogeneous parallel strategies across diverse scenarios and compares them against baseline methods. While these strategies (formulated as *annotation plans*) are automatically generated by scenario-specific planners (Appendix A.1), users also have the flexibility to define customized strategies by manually supplying their own *annotation plan*.

C.1 Cluster Setup

Table 7 presents the configuration of our computing cluster. The H800 GPU offers higher computational power but lower intra-node (NVLink) communication bandwidth, whereas the H20 GPU provides lower computational performance but higher communication bandwidth. Additionally, the two GPUs differ slightly in memory capacity, posing challenges for heterogeneous parallel computing on this setup.

C.2 Scenario (a): Heterogeneous Devices

Table 8 summarizes the optimal parallel strategies for DeepSpeed and Megatron, the two baselines, across different model

Table 7: Heterogeneous GPU cluster.

GPUs	Memory	BF16 Tensor Core	NVLink
16 H800	81559 MB	990 TFLOPS	400 GB/s
32 H20	97871 MB	148 TFLOPS	900 GB/s

sizes and heterogeneous device setups. These strategies were derived through an exhaustive search process, systematically evaluating various combinations of parallelisms and training optimizations to determine the most efficient ones.

Table 8: Optimal parallel strategies for DeepSpeed and Megatron. "DP" refers to the data parallel degree, "TP" to the tensor parallel degree, "PP" to the pipeline parallel degree, and "SP" to the sequence parallel (Ulysses-SP) degree. "AC" signifies the use of activation checkpointing, while "bs" denotes micro-batch size. All DeepSpeed configurations employ ZeRO-3 optimization, whereas Megatron implementations utilize ZeRO-1.

Model Size & GPUs	DeepSpeed	Megatron

Next, as shown in Table 9, we sequentially present the optimal strategies for HSPMD across different heterogeneous device setups. These strategies are given by our static planner (as introduced in Appendix A.1). Each cell represents a tensor parallel group, detailing the assigned rank IDs (denoted as "R") and the corresponding layer IDs (denoted as "L"). Yellow cells correspond to H800 GPUs, while white ones represent H20 GPUs. The leftmost column indicates the micro-batch size (denoted as "bs") and the number of micro-batches (represented by the preceding coefficient) for each pipeline. Between pipelines, data parallelism is utilized to synchronize gradients.

Notably, across all strategies, we utilize ZeRO-1 to partition FP32 parameters and optimizer states across data parallel replicas. This memory optimization enables the adoption of more memory-intensive parallel strategies (i.e., those with higher data parallel degrees). While homogeneous parallel strategies use standard `AG` (all-gather) for parameter collection and `RS` (reduce-scatter) for gradient synchronization, our heterogeneous approach requires specialized operators. Specifically, when tensor parallel degrees differ across data parallel groups, the inserted `Reshard` operators (responsible for parameter collection and gradient synchronization) are instantiated with `SplitAG` and `SplitRS` operators (detailed in §5.2). This adaptation facilitates the asymmetric communication required when integrating ZeRO-1 with heterogeneous pipelines.

Table 9: Optimal parallel strategies for HSPMD on different heterogeneous clusters. R0-15 are H800 GPUs and R16-47 are H20 GPUs.

C.3 Scenario (b): Unstable Devices

Table 10 presents the optimal strategies of DeepSpeed and Megatron after each reconfiguration in the unstable devices scenario. Notably, GPU failures occurred during the reconfigurations from C1 to C2 and from C5 to C6. However, due to the system's inability to support non-uniform sharding, they failed to utilize the remaining seven functional GPUs in the machine. Consequently, the entire machine was treated as

failed, which is why the strategy for C2 matches C3, and C6's strategy aligns with C7's.

Table 10: Optimal parallel strategies for DeepSpeed and Megatron. "DP" refers to the data parallel degree, "TP" to the tensor parallel degree, "PP" to the pipeline parallel degree, and "SP" to the sequence parallel (Ulysses-SP) degree. "AC" signifies the use of activation checkpointing, while "bs" denotes micro-batch size. All DeepSpeed configurations employ ZeRO-3 optimization, whereas Megatron implementations utilize ZeRO-1.

Upon changes in GPU availability, we invoke our online planner (Appendix A.1) to determine the optimal parallel strategy. Table 11 reports the strategies adopted by HSPMD on homogeneous clusters (C1–C3). In our setup, we deploy two pipelines and disable ZeRO-1 to ensure fault isolation. Failures in one pipeline do not cause permanent loss of model weights, eliminating the need for restarting. This setting is consistent with Oobleck, which also disables ZeRO-1 and achieves fault tolerance through data-parallel replication, making our comparison fair. Notably, the same design is followed by many elastic training systems (e.g., Recycle [21]).

Table 11: Parallel strategies for HSPMD during elastic training on homogeneous clusters.

C1: 32 H20				
16 × bs2 (4 Stages)	R0-3 L0-14	R4-7 L15-29	R8-11 L30-44	R12-15 L45-59

In Table 12, we detail the strategies (C4–C7) adopted by HSPMD on heterogeneous clusters, with yellow and white cells representing H800 and H20 GPUs, respectively. Following the homogeneous cluster approach, we disable ZeRO-1 and configure two pipelines to enable fault tolerance.

However, disabling ZeRO-1 increases memory overhead, precluding the use of the optimal parallel strategy. For instance, the strategy in C4: 16 H800, 32 H20 (with a data parallel degree of 2) differs from that in Table 9 for standard heterogeneous clusters (32B, 16 H800, 32 H20, with a data parallel degree of 4). Consequently, training performance degrades by approximately 15%, increasing the per-step training time from 6.05s to 6.91s (shown in Figure 15 and Figure 16).

Despite this performance degradation, HSPMD's heterogeneous sharding effectively balances workloads, still maintaining superior performance compared to the homogeneous parallel strategies used in DeepSpeed and Megatron (shown in Figure 16).

C.4 Scenario (c): Mixed-length Data

Table 13 presents the optimal parallel training strategies for the mixed-length data scenario using DeepSpeed and Megatron, with context lengths of 32K and 16K (using the 32B model on 32 H20 GPUs). Due to the substantially longer context lengths, these frameworks must adopt larger sequence/-context or tensor parallelism. However, in practice, only a small fraction of sequences per training step actually reach the maximum context length. As a result, most shorter sequences are processed inefficiently, missing opportunities for more optimized training strategies.

Table 13: Optimal parallel strategies for DeepSpeed and Megatron. "DP" refers to the data parallel degree, "TP" to the tensor parallel degree, "PP" to the pipeline parallel degree, "CP" to the context parallel degree, and "SP" to the sequence parallel (Ulysses-SP) degree. "AC" signifies the use of activation checkpointing, while "bs" denotes micro-batch size. All DeepSpeed configurations employ ZeRO-3 optimization, whereas Megatron implementations utilize ZeRO-1.

Context Length	DeepSpeed	Megatron
32K	DP4SP8AC, bs1	DP2TP8CP2, bs1
16K	DP8SP4AC, bs1	TP8PP4, bs1

Table 14 presents the parallel strategies adopted by HotSPa across different sequence length intervals. By partitioning sequences into buckets based on length and processing them sequentially within a training step (with gradient accumulation before weight updates), this approach maintains mathematical equivalence to standard training while enabling length-adaptive parallel strategies.

Although this method incurs frequent switching overhead within the step, such costs are substantially outweighed by the benefits of parallel strategies optimization, ultimately resulting in performance improvements.

Table 14: Optimal parallel strategies for HotSPa. "DP" refers to the data parallel degree, "TP" to the tensor parallel degree, and "PP" to the pipeline parallel degree. "bs" denotes micro-batch size. All configurations employ ZeRO-1 optimization.

Context Length	Interval-based Parallel Strategies
32K	16K-32K: DP2TP16, bs1 4K-16K: DP2TP8PP2, bs1 0-4K: DP4TP4PP2, bs1
16K	4K-16K: DP2TP8PP2, bs1 0-4K: DP4TP4PP2, bs1

Tables 15 and 16 further present the heterogeneous strategies adopted by HSPMD for context lengths of 32K and 16K, respectively. In Table 15, Strategy A and Strategy B correspond to those illustrated in Figure 18.

For HSPMD, steps with varying maximum sequence lengths are processed using either Strategy A or B, while sequences of different lengths within a step are distributed across multiple pipelines to balance the load based on the *cost model* we designed. Once all data within a step has been processed across the pipelines, gradients are synchronized to perform the step update. This approach further improves performance compared to HotSPa by eliminating frequent strategy switching within a step and more effectively addressing workload imbalance through the use of heterogeneous strategies, rather than homogeneous ones.

Table 15: Heterogeneous parallel strategies for HSPMD with 32K context length, where the strategy is dynamically selected based on the maximum sequence length (MaxSeqLen) at each processing step.

Strategy A: MaxSeqLen ∈ (16K, 32K]	
Long Sequence Pipeline-1 (1 Stages)	R0-15 L0-59

Abstract

Communication has become a first-order bottleneck in large-scale GPU workloads, and existing distributed compilers address it mainly by overlapping whole compute and communication kernels at the stream level. This coarse granularity incurs extra kernel launches, forces device-wide synchronizations at kernel boundaries, and leaves substantial slack when the slowest tile or kernel stretches the communication tail. We present Syncopate, a compiler and runtime that enable automatic fine-grained overlap around a single fused compute kernel. Syncopate introduces a communication chunk abstraction that decouples communication granularity from kernel structure and backend mechanisms, allowing chunk-level plans to be ported from existing distributed compilers, written directly by users, or instantiated from reusable templates. Given a local Triton kernel and a chunk schedule, Syncopate performs transformations to align computation with chunk availability. Implemented as a source-to-source compiler on Triton, Syncopate delivers an average end-to-end speedup of 1.3× and up to 4.7× on multi-GPU workloads. Our code is open-sourced at https://github.com/tie-pilot-qxw/syncopate.

1 Introduction

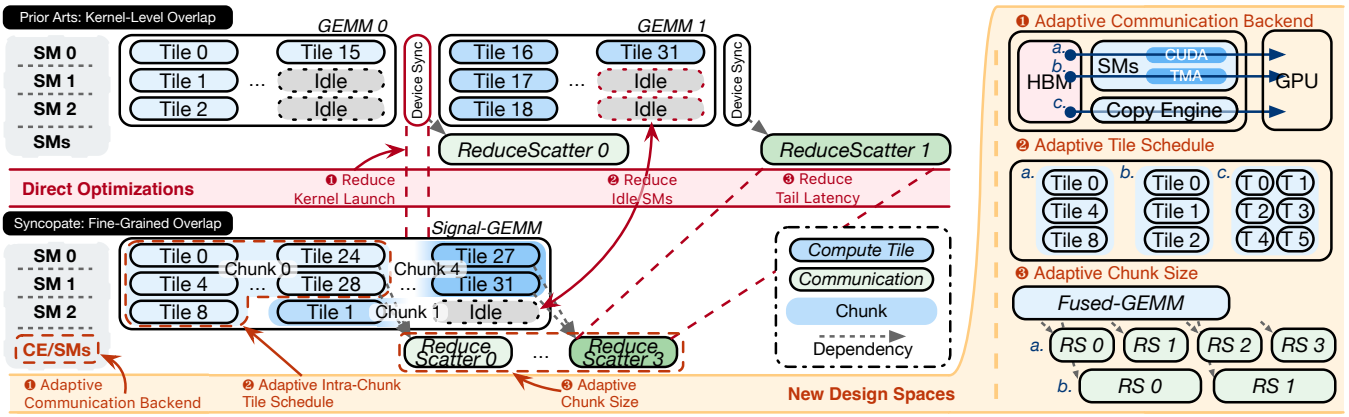
Communication has become a first-order bottleneck for training and serving large neural networks on multi-GPU systems. Even with high-bandwidth interconnects such as NVLink [23] and NVSwitch, collective operations like AllGather, ReduceScatter, and All-to-All frequently dominate end-to-end latency for tensor-parallel feed-forward layers and attention layers. To hide this cost, recent systems and distributed compilers aggressively search for schedules that overlap computation and communication at the kernel level. Given a computation graph and a device mesh, these compilers select parallelization strategies, insert communication kernels, and assign compute and communication kernels to streams so that multiple kernels can run concurrently. This kernel-level overlap [4, 10, 31, 36, 38, 47] has become the default mechanism for improving utilization in distributed settings.

However, kernel-level overlap is fundamentally insufficient for fully hiding communication latency. As illustrated in Fig. 1, this kernel-level scheduling forces a device-wide synchronization at every kernel boundary and incurs extra launch and sync overhead for each communication phase (❶). Moreover, by splitting computation into multiple shorter kernels, the work within each launch is further partitioned into waves of compute tiles on each SM, increasing the fraction of time SMs sit idle; even when part of the data needed by later kernels is already available, tiles in the current wave must wait for the slowest tile to finish (❷). Finally, the coarse granularity of kernel-level overlap leaves a long segment of communication at the end of the timeline that receives little or no overlap (❸).

This motivates us to overlap computation and communication at a finer intra-kernel granularity. Such fine-grained overlap opens up new design space for improving end-to-end efficiency. As shown by the yellow region in Fig. 1, Syncopate launches communication directly from within the fused kernel, rather than delegating to external communication libraries, giving the compiler explicit control over which hardware backend to use for each transfer (copy engine, tensor memory accelerator, or load/store on CUDA cores) as shown with ❶. This also allows us to explore much smaller communication granularities without incurring additional kernel-launch overhead, and to tune the chunk size that best balances link throughput against synchronization cost (❷). Finally, because tiles and communication are orchestrated inside a single kernel, we can reshape the intra-kernel tile schedule to track communication progress while still preserving locality in the register, shared-memory, and cache hierarchy (❸).

We present Syncopate, a compiler that turns the vision of fine-grained overlap for distributed kernel generation into a practical and general system. At the heart of Syncopate is the notion of a communication chunk, which represents a logical block of data associated with a particular communication operation and the tiles that produce or consume it. This abstrac-

*Xinwei and Yue contributed equally.



(a) Comparison of compute–communication overlap at different levels

(b) New design space for fine–grained overlap

Figure 1: Motivating example of Syncopate. Red numbers show the direct improvements gained by fine-grained overlap over kernel-level overlap, while orange numbers show the additional improvements from the new design space enabled by Syncopate.

tion is motivated by a key observation: fine-grained overlap requires a communication granularity that flexibly matches how tiles generate data and how communication backends consume it, rather than assuming that tile-level or full-kernel granularity is always appropriate. By making chunks explicit, Syncopate can represent a wide range of overlap patterns and enable the compiler to reason about when each chunk becomes available, which tiles produce or use it, and how these dependencies interact with fused multi-stage tensor programs and potentially irregular collectives. This abstraction exposes a small set of principled knobs, including chunk size, backend choice, and tile order, that define the design space later explored by our autotuner.

Building on this abstraction, Syncopate implements a source-to-source compiler and runtime that transform standard Triton [34] kernels and a high-level chunk-based communication plan into fused distributed kernels capable of fine-grained compute–communication overlap. The compiler restructures the kernel's tile execution to follow communication progress and selects appropriate backends to realize each chunk transfer, while a lightweight runtime executes these transfers and integrates seamlessly with PyTorch distributed [2] so that Syncopate kernels can replace standard operators with only minimal changes to user code. Syncopate further performs inter- and intra-chunk autotuning, adjusting chunk sizes, backend choices, SM allocations, and tile schedules, to consistently achieve high performance across diverse operators. This implementation strategy makes the abstract chunk-based model concrete, enabling rapid prototyping of new overlap policies while remaining compatible with real distributed workloads and production communication stacks.

In summary, this work makes the following contributions:

- We introduce a chunk-based abstraction that decouples high-level overlap intent from low-level implementation, enabling fine-grained compute-communication overlap inside distributed kernels.
- We design and implement a compiler pipeline and runtime that takes annotated local kernels and chunk-level communication plans, then generates efficient fused distributed kernels with inter- and intra-chunk autotuning.
- We evaluate Syncopate on a diverse set of distributed workloads and observe an average speedup of 1.3× on common operators, with improvements reaching up to 4.7× in the best cases.

2 Background and Related Works

2.1 Distributed Compilers

As model sizes grew, tensor compilers [5, 6, 9, 29, 40, 43] incorporated basic multi-GPU support [1, 16, 27, 30, 37, 41], typically by composing single-GPU kernels with predefined collective primitives. Systems like Alpa [44], Mercury [13], and other recent distributed compilers extend this idea by searching over communication patterns and schedules at the level of whole kernels: given a parallelization strategy, they first construct a communication plan containing AllGather, ReduceScatter, or All-to-All operators, and then explore different mappings of compute and communication kernels to streams in order to maximize kernel-level overlap (Table 1). This design has made distributed training far more accessible, but it also bakes in a rigid abstraction boundary: communication is planned as a sequence of full-kernel collectives whose launch and completion times are the basic units of scheduling. As a result, all these distributed compilers focus their search on the communication plan at the kernel level and are fundamentally blind to finer-grained opportunities inside kernels, such as overlapping per-shard or per-tile communication with computation, reusing remote data across tiles, or exploiting topology-aware pipelining within a fused kernel. Once a kernel is chosen and its associated collective is placed, the compiler can only treat it as an atomic black box, leaving

Table 1: Comparison of projects on distributed operations.

Syncopate	Chunk	Auto	Auto	Template	✔✔✔

significant intra-kernel overlap potential untapped even under an "optimal" kernel-level schedule.

2.2 Manual Kernel Designs

A complementary line of work pushes beyond kernel-level overlap and instead hand-crafts fine-grained pipelines that interleave communication and computation at the level of tiles, tokens, or shards. Flux [3] fuses GEMM with collectives at tile granularity and over-decomposes work to maximize overlap for both training and inference, while Comet [42] targets MoE with a shared-tensor abstraction and NVSHMEM-backed buffers to overlap token-wise communication with tile-wise compute at production scale. FlashOverlap [14] uses lightweight readiness signaling and layout reordering to trigger overlap with standard NCCL collectives without modifying existing compute kernels, and systems like TritonDistributed [45,46] introduce tile-centric or OpenSHMEM-style primitives to Triton [34] that make it easier to author overlapped kernels (e.g., fused AllGather/GEMM or GEMM/ReduceScatter) in a domain-specific language.

Despite these advances, all of these systems fundamentally rely on manual, operator-specific engineering: experts must design fused kernels, choose tiling and buffering schemes, and reason about synchronization and communication protocols for each new model architecture or hardware platform. The resulting implementations are highly optimized but difficult to generalize or retarget, and they do not provide a general compiler abstraction for expressing and reusing fine-grained overlap patterns across operators. Emerging fine-grained DSLs and primitives greatly lower the barrier to writing overlapped kernels, but they still place the burden of discovering effective overlap strategies, encoding dependency structure, and validating correctness squarely on the programmer. In practice, users still need to write or modify DSL-level communication and computation code, explicitly manage signal/wait, buffer ownership, and memory ordering, and revalidate these low-level details for each operator and communication pattern.

2.3 Communication Backends

Modern GPU systems [19] expose several mechanisms for moving tensors across devices, each with distinct performance and programmability trade-offs (Tbl. 2). Copy Engines saturate NVLink [23] at 400 GB/s per direction on H100 and run independently of the SMs. Therefore, they do not consume compute resources and are ideal when communication can be decoupled from computation. However, they are typically driven by host APIs and can only transfer contiguous data, so high-dimensional strided tensors must be decomposed into many smaller transfers, each requiring a separate launch costing around 2-3μs, which can significantly reduce the effective bandwidth as each transfer time is also very short.

Table 2: Comparison of various GPU communication mechanisms.

	Hardware	Programming	Collective	Bandwidth
Copy Engine	Copy Engine	Host Launch	✗	✔✔✔
TMA	SM	Async. Instruction	✗	✔✔
Load/Store	SM	Sync. Instruction	✔	✔

Tensor Memory Accelerator (TMA) [19] paths achieve high bandwidth using dedicated asynchronous tensor-copy hardware, and can achieve a throughput of 300+ GB/s with only about 16 SMs issuing TMA instructions. This makes TMA attractive for overlapping structured tensor movement with computation within a node. At the same time, TMA must be launched by SM threads and does not currently support inter-node communication or in-network (switch-based) collective reduction, which limits its applicability to intra-node, point-to-point patterns.

Finally, plain load/store-based communication, often combined with registers and shared memory, attains slightly lower peak bandwidth than copy engines or TMA [33] but is significantly more flexible. These mechanisms integrate naturally with switch-based collective reduction (NVSHARP [20]), enabling fine-grained per-shard communication and in-network reductions. The downside is that they consume SM resources and are synchronous from the issuing warp's perspective, so they are harder to pipeline and require careful scheduling to hide communication latency.

3 Motivation

To fully exploit modern GPUs, distributed training systems must overlap computation and communication. Prior work mainly relies on coarse, kernel-level partitioning of computation kernels, which leaves substantial performance on the table. In this section, we revisit the motivating example in Figure 1 using detailed microbenchmarks (Figure 2), and show three key insights:

> ★***Insight 1: Limitations of Kernel-Level Overlap.*** *Kernel-level overlap is fundamentally limited by SM under-utilization and kernel-launch overheads.*

Figure 2(a) reports SM utilization for different GEMM

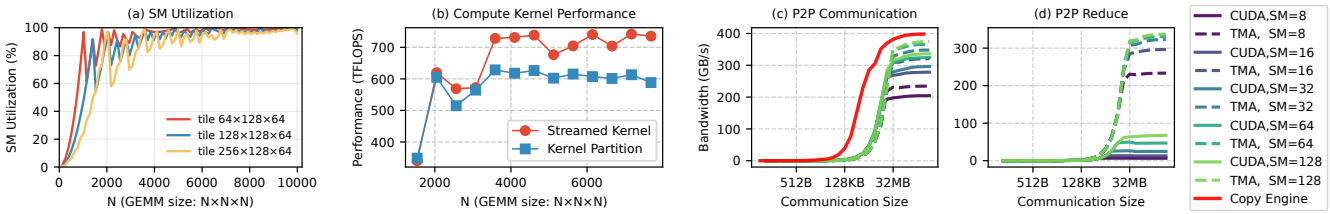

Figure 2: Motivation experiment results. (a) SM utilization under different GEMM sizes and tile sizes. (b) Performance comparison between a streamed GEMM kernel and a kernel-partitioned baseline. (c,d) Bandwidth of different communication backends under varying message sizes.

sizes under several commonly used tile-size configurations. Large GEMMs provide enough tile waves to saturate the SMs across all configurations. As the GEMM size decreases, fewer tile waves are generated, and the partially filled last wave dominates a larger portion of execution, causing SM utilization to drop due to wave quantization. Partitioning a GEMM into many sub-kernels forces each launch to operate on a smaller shape, pushing execution into exactly this low-utilization regime. This effect directly limits the benefit of kernel-level partition-based overlap (corresponding to ❷ in Figure 1), since overlapping many small kernels simply wastes SM capacity.

Figure 2(b) compares the end-to-end performance of (i) a baseline that partitions GEMM into multiple small kernels for overlap and (ii) a streamed GEMM kernel that internally pipelines tiles. Although both variants execute the same arithmetic operations, the kernel-partitioned baseline incurs substantial performance loss due to extra kernel launches (❶) and the SM under-utilization observed in Figure 2(a). In contrast, the streamed kernel maintains high utilization by exposing fine-grained compute tiles within a single launch, enabling overlap without fragmenting the workload. These results show that simply launching more kernels is not an effective path toward overlap; we need mechanisms that expose intra-kernel concurrency while preserving efficient GPU execution.

> ★***Insight 2: Granularity and Backend Effects.*** *Communication efficiency varies sharply with transfer granularity and backend selection.*

Communication efficiency varies sharply with transfer granularity and backend behavior. Figures 2(c) and 2(d) show the achieved bandwidth of different communication backends as we vary the transfer size and the number of SMs. Each backend shows distinct scaling behavior: some reach peak bandwidth at moderate transfer sizes, while others require larger transfers or more SMs to reach their full potential. Moreover, different backends support different communication patterns, such as point-to-point transfers versus reductions.

Taken together, these granularity and backend effects imply that the optimal configuration depends jointly on (i) the compute tile size, which determines the cadence at which results become available, (ii) the communication transfer size, which trades off latency and bandwidth, and (iii) the choice of communication backend. Coarse-grained kernel-level overlap cannot flexibly coordinate these parameters, since compute and communication are implemented as separate kernels with rigid interfaces. Intra-kernel overlap, by coordinating computation and communication at the same time, can align tile production with backend-specific sweet spots and select transfer granularities that sustain high utilization across SMs and copy engines.

> ★***Insight 3: A Unified Unit for Intra-Kernel Overlap.*** *Effective intra-kernel overlap therefore requires a communication unit with tunable granularity and a stable interface across communication backends.*

The combined granularity and backend effects indicate that effective overlap requires a communication unit whose size can match both the rate at which tiles produce data and the efficiency points of different communication backends. At the same time, this unit must provide a stable boundary between the high-level communication schedule and its backend-specific realization, so that schedules need not be rewritten for each backend. We therefore introduce a chunk abstraction that offers both tunable intra-kernel granularity and a unified interface for mapping communication onto diverse backends.

4 Overview

Syncopate is a compiler and runtime framework that turns locally written Triton kernels into distributed, fine-grained overlapped kernels. Rather than asking programmers to manually fuse communication and computation, Syncopate takes an existing local kernel and a high-level distribution specification as input, and automatically synthesizes an intra-kernel schedule that interleaves tile-wise communication with computation according to the available communication backends.

Input and User Interface. On the compute side, Syncopate consumes unmodified local Triton kernels annotated with

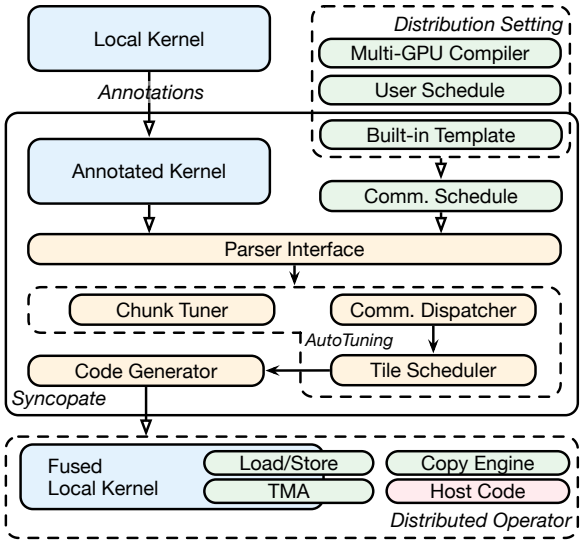

Figure 3: System overview of Syncopate.

                        op=TransferOp.PULL,
                        dst_buf=buf, dst_region=r,
                        src_buf=buf, src_region=r,
                        peer=peer, shard_idx=peer,
                    ...))
    return plan
```

lightweight scheduling metadata (Listing 1). Programmers write kernels as if they were running on a single device, using standard Triton primitives for indexing, tiling, and tensor descriptors. Lightweight Syncopate annotations (e.g., axis counts, tile identifiers, and dispatch regions) are required to identify the logical tiles and iteration structure but do not change the kernel's semantics. On the distribution side, Syncopate uses a communication plan that encodes the desired global data movement pattern and device topology (Listing 2). This plan is expressed using a small API defined by the users or imported directly from higher-level compilers searching parallel schedule.

To end users, Syncopate exposes a small set of APIs for (1) registering local kernels with their annotations, (2) constructing or selecting predefined communication plans (such as 1D/2D AllGather or ReduceScatter swizzles), and (3) compiling these into executable distributed kernels. High-level frameworks can wrap these APIs so that model authors only specify tensor partitioning and desired collectives, while Syncopate automatically generates the corresponding overlapped kernels. This separation of concerns allows experts to encode distribution and communication strategies once, while ordinary users invoke the resulting distributed operators through familiar, library-style calls.

Syncopate Architecture and Output. Given a local kernel and its communication plan, Syncopate lowers them into a unified dependence representation over tiles, shards, and communication operations. The compiler then searches for a fine-grained schedule that maps tiles to devices, assigns communication operations to appropriate backends (e.g., copy engine, TMA, or load/store), and inserts the necessary synchronization to respect both compute and communication dependencies. The output preserves the original numerical semantics while tightly pipelining asynchronous communication and computation around a single fused compute kernel. From the user's perspective, the generated operator can be invoked with the same signature as the original local kernel, plus standard distributed-runtime arguments (e.g., rank, world size, mesh), and integrated into existing training or inference code without further changes.

5 Syncopate: Fine-Grained Overlap Compiler

Syncopate automatically transforms locally written kernels into fine-grained overlapped distributed kernels by aligning the execution of local computation tiles with a global communication schedule. At a high level, we introduce a *chunk-centric* compilation pipeline that treats communication and computation symmetrically: communication is described as transfers of logical chunks, while computation is expressed as tiles that consume and produce these chunks. The compiler then derives dependencies between chunks and tiles,

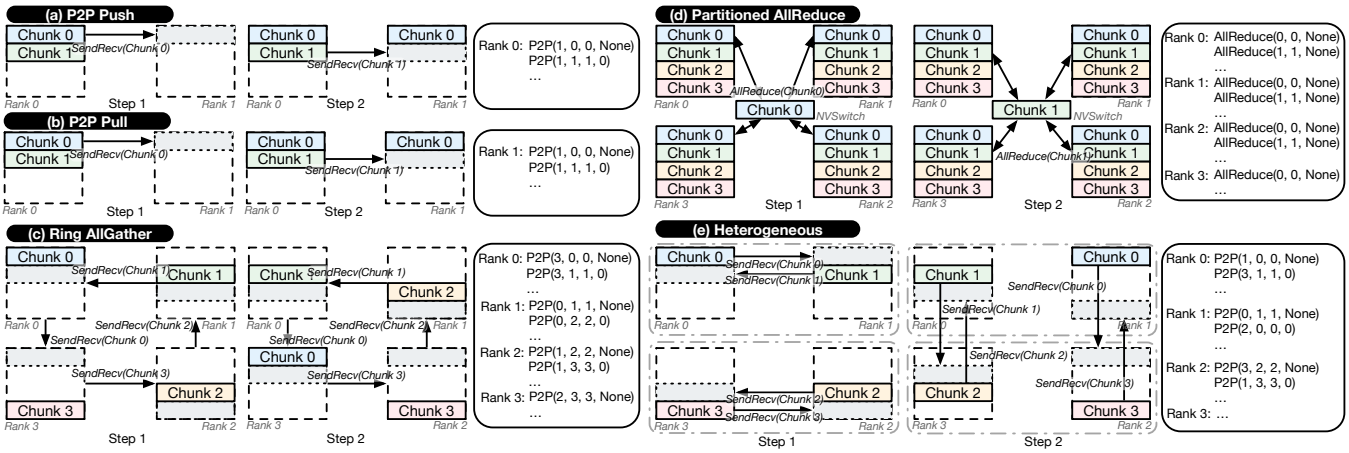

Figure 4: Communication schedule abstraction. (a) and (b) illustrate the same point-to-point exchange expressed as push and pull variants, respectively. (c) shows a ring-based AllGather pattern. (d) represents a partition-based AllReduce schedule. (e) depicts a heterogeneous swizzled AllGather pattern that pipelines communication across multiple hierarchy levels.

rewrites the tile scheduler to follow the communication order, inserts the necessary synchronization, and finally explores several implementation choices to generate high-performance overlapped code.

5.1 Communication Schedule Abstraction

We first define a communication-side abstraction that captures how data moves across devices independently of any particular local kernel implementation. This abstraction is built around the notion of a *chunk*, an intermediate layout between the global logical tensor and the local computation tiles. By operating at this intermediate granularity, the abstraction is expressive enough to describe a wide range of distributed schedules while remaining compatible with both partition-based and loop-based IRs in existing distributed compilers.

Definition. A *chunk* is a logical block of data that is communicated as a unit. Each chunk contains one or more tiles, where a tile is the basic unit of computation in the local kernel. Importantly, the chunk size in the communication schedule specifies *logical* transfers; the same logical chunk may later be implemented using different physical communication patterns or backends during lowering.

Conceptually, a chunk can be represented as: `chunk = Chunk(sizes=[...] , layout=..., tensor=...)`. Based on this abstraction, we define communication operators over chunks. We consider two primary classes of operators: point-to-point (P2P) transfers and collective communications.

- **P2P transfer** is represented as `P2P(src_rank, dst_rank, src_chunk, dst_chunk, dependency)`. This operator moves a chunk from a source rank to a destination rank, optionally guarded by a dependency on other chunks or operations. Note that for a pair of P2P operations on the source and destination ranks, we only include the operation on one side. If the P2P operation is defined on the source side, it represents a push operation; otherwise, it represents a pull operation. This will lead to different implementation choices during lowering.
- **Collective communication** is represented as `Collective(collective_type, src_chunk, dst_chunk, ranks, dependency)`. This operator applies a collective operation (e.g., AllGather, ReduceScatter) over a set of ranks on a given chunk with explicit dependency control. When explicitly defined as collective operations, the compiler can leverage the optimized collective implementations provided by the communication backends.

For both operator types, the `dependency` field encodes any ordering constraints that must be respected between communication operations. Specifically, it is represented as a `(rank, index)` tuple, indicating that the current operation cannot start until the specified operation on the given rank has completed. This allows us to express complex communication patterns, such as ring exchanges or multi-stage collectives, by chaining dependencies between chunks.

Upon this abstraction, a *communication schedule* is defined as a sequence of chunk-level communication operations with their associated dependencies on each rank as `schedule := [rank:Int, operations:List[CommOp]]:List`. Since there is no restriction on the operation for each rank, the communication schedule can express heterogeneous communication patterns where different ranks perform different operations on different chunks at different times.

Expressiveness. Despite its simplicity, the chunk abstraction is sufficiently expressive to capture a wide range of communication schedules covering all the overlap patterns used in practice (Fig. 4). To elaborate, (a) and (b) show the same P2P communication between two ranks expressed as push and pull operations, respectively, demonstrating the flexibility of

pull/push semantics. (c) illustrates a ring-based AllGather pattern, which is a common pattern for asynchronous distributed operators [18], where each rank sends and receives chunks in a pipelined manner, with dependencies ensuring the correct order of operations. (d) depicts a partition-based collective AllReduce pattern, where each rank contributes a chunk to the collective operation and performs the accumulation over the communication fabric. This pattern is often used in partition-based distributed compilers for kernel-level overlap. Finally, (e) shows a complex heterogeneous swizzled AllGather pattern advancing (c). By utilizing the port abstraction, each rank processes communication at different mesh hierarchy levels, enabling fine-grained pipelining and overlap across multiple dimensions. With this abstraction, different collective patterns, pipelined P2P exchanges, and hybrid schemes that combine intra-node and inter-node communication can all be written as sequences of chunk-level P2P and collective operators with explicit dependencies. Because chunks are defined in terms of logical tensor regions rather than concrete buffers, the same schedule can be reused across different kernels and tensor shapes, and later specialized by the compiler.

Lowering from Higher-Level Compiler IRs. Communication schedules in this abstraction can either be defined manually or automatically derived from existing distributed compiler IRs. In the manual case, users construct chunk objects and communication operators directly using our API as shown in Listing 2. In most cases, manual schedules are parameterized communication algorithms, not fully unrolled per-world-size plans: ring-based algorithms, for example, can be expressed with loops over ranks, chunks, or mesh levels, and Syncopate specializes them to the concrete world size, topology, and chunk configuration. Syncopate also provides predefined templates such as 1D/2D AllGather or ReduceScatter swizzles for the common communication patterns. The user can instantiate these templates with different chunk sizes, mesh topologies, communication axes, and pipeline stages to generate reusable communication schedules.

When integrating with a higher-level distributed compiler, Syncopate provides frontends for both partition-based and loop-based IRs. For partition-based IRs, we analyze the global data partitioning and the implied communication pattern between partitions to infer chunk sizes, participating ranks, and the corresponding P2P or collective operators. For loop-based IRs, we traverse loop nests, identify communication points, and group the communicated regions into chunks according to the chosen granularity. In both cases, the result is a uniform chunk-level schedule that decouples the high-level communication intent from any particular implementation (Listing 3). Specifically, the collective operators can be directly inserted ("direct") into our communication plan, or they can be further lowered to P2P communication operators using our templates ("template") or using some collective synthesis algorithms ("synth") such as TACOS [39].

Listing 3: Lowering from Higher-Level IR.

```
def emit_steps(steps, mesh, path="template"):
    comm = CommPlan()
    for step in steps:
        if step.is_p2p(): # push/pull/local_copy
            for rank in mesh:
                emit_p2p(comm.plans[rank], step, rank)
        else:  # collective
            for rank in mesh:
            # Path in ["direct", "synth", "template"]
                emit_collective(path, comm.plans[rank],
  step, rank)
    return comm

def lower_partition_ir(part_ir, axis_info, mesh, path="
 template"):
    steps = []
    for tensor in part_ir.tensors:
        layout = part_ir.placement[tensor]
        meta = axis_info[tensor]
        steps.extend(parse_partition_to_steps(tensor,
 layout, meta))
    return emit_steps(steps, mesh, path)

def lower_loop_ir(loop_ir, mesh, path="template"):
    steps = []
    for node in walk(loop_ir):
        steps.extend(parse_comm_intents(node))
    return emit_steps(steps, mesh, path)
```

5.2 Chunk-based Code Generation

Given a chunk-level communication schedule, the next step is to reorganize local computation so that tiles are executed in an order that aligns with the arrival and consumption of chunks. Intuitively, we want the kernel to compute exactly those tiles whose data has already been communicated, and to defer tiles whose input chunks are still in flight. This *compute chunk scheduling* bridges the gap between the communication abstraction and the tile-level structure of the original local kernel.

Compute Kernel Annotations. To make tile-level scheduling explicit, users provide lightweight annotations on the local computation kernel using Syncopate's API. These annotations do not change the numerical semantics of the kernel; instead, they expose its tiling structure and iteration order to the compiler. Although expressed as Python comments, they follow a structured directive format analogous to OpenMP [25] pragmas, allowing the compiler to reliably parse and verify them. Concretely, we require three pieces of information:

- **Tile size:** the logical shape of each tile along the relevant dimensions (e.g., GEMM blocks), which allows us to map tiles to chunks.
- **Tile index identifier:** a program variable (or tuple of variables) that uniquely identifies the tile being processed in a given iteration.
- **Tile scheduler:** the loop or control structure that advances the tile index and determines the order in which tiles are visited.

These annotations can often be derived from existing index-

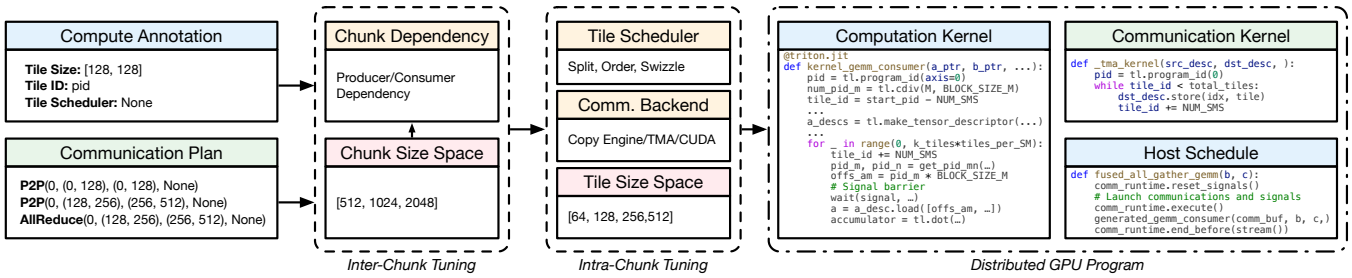

Figure 5: Compilation pipeline. In this example, we show communication using specialized SM as an independent kernel synchronized with signals. It can also be a fused kernel depending on the communication backend.

ing expressions and loop bounds with minor code changes, as illustrated in the overview section. These annotations are compiler metadata. They only expose the tile space, the tile identifier, and the mapping from a tile id to logical tensor-axis coordinates. Syncopate uses this information to relate the local Triton tile scheduler to the chunk-level schedule.

Dependency Parsing. With both the communication schedule and the annotated compute kernel in hand, Syncopate constructs a dependence graph over chunks and tiles according to the user-specified dependency intent in the plan, including how communication chunks depend on each other and how communication axes map to computation axes. For each chunk, we track its producer(s) and consumer(s), as well as any explicit ordering constraints encoded in the communication schedule (e.g., pipeline stages). For each tile, we determine which chunks it reads and writes based on its tile index, tensor layout, and the chunk-to-compute-axis mapping.

From this graph, the compiler identifies the minimal set of synchronization points needed to respect all data dependencies. Concretely, we insert wait operations in the kernel so that a tile that consumes a given chunk cannot start until the corresponding communication operator has completed. This synchronization can be implemented using different mechanisms depending on the chosen backend, but is always derived from the same chunk-level dependency structure.

Communication Code Generation. Once the communication schedule and tile scheduler have been aligned, Syncopate lowers the abstract chunk-level plan into concrete communication code. As illustrated in Fig. 7, the same logical schedule can be realized by several backends that differ in how they move chunks and how they allocate SM resources. Concretely, we support five realizations: (1) using the dedicated copy engine, (2) using TMA on a specialized SM, (3) using TMA on a co-located SM, (4) using operator-instruction load/store on a specialized SM, and (5) using operator-instruction load/store on a co-located SM. In all cases, tiles are produced on one side and consumed by operations on the other side, but the mechanism for signaling readiness and the division of compute versus communication work across SMs differ.

For each operator, Syncopate first builds a dependency graph over tiles and communication steps from the chunk schedule, then lowers this graph into backend-specific code that enforces all dependencies by construction. When targeting the copy engine or a specialized SM, the compiler emits global-memory signals and kernel launches so that communication progresses asynchronously relative to the main compute tiles. When targeting co-located SM backends, it instead generates shared-memory barriers and index bookkeeping to coordinate communication and computation within the same SM. Because all five realizations share the same logical schedule but expose different latency/bandwidth and resource tradeoffs, they form a search space for the autotuner: Syncopate automatically generates all valid implementations, measures their end-to-end performance, and selects the best-performing backend for each operator and hardware configuration.

Tile-Scheduler Swizzling. As visualized in Fig. 6, the communication plan and the original computation kernel typically induce different layouts over the global tensor: communication groups tiles into chunks based on where data needs to move, while the kernel groups tiles into waves based on its own traversal order. Prior work reconciles this mismatch by explicitly reordering data between communication and computation, paying extra global-memory traffic and synchronization. In contrast, Syncopate keeps the communicated chunks in-place and instead *swizzles* the tile scheduler at the intra-kernel level. We reorder the sequence of waves so that each chunk is consumed as soon as it arrives, and apply an intra-chunk swizzle that visits tiles in an order that preserves locality within the chunk. This chunk-based tile schedule aligns compute with communication progress without additional reordering kernels, enabling fine-grained overlap purely through scheduling. This transformation has two levels: at the chunk level, Syncopate reorders chunks to follow the communication schedule and consume chunks as they become ready; within each chunk, it applies a finer-grained tile scheduler, using the local kernel's original tile traversal by default while allowing alternative axis-based traversals when needed.

5.3 Communication-Centric Auto-Tuning

The chunk abstraction also provides a natural space for communication-centric auto-tuning. Because chunks sit exactly at the boundary between the global communication

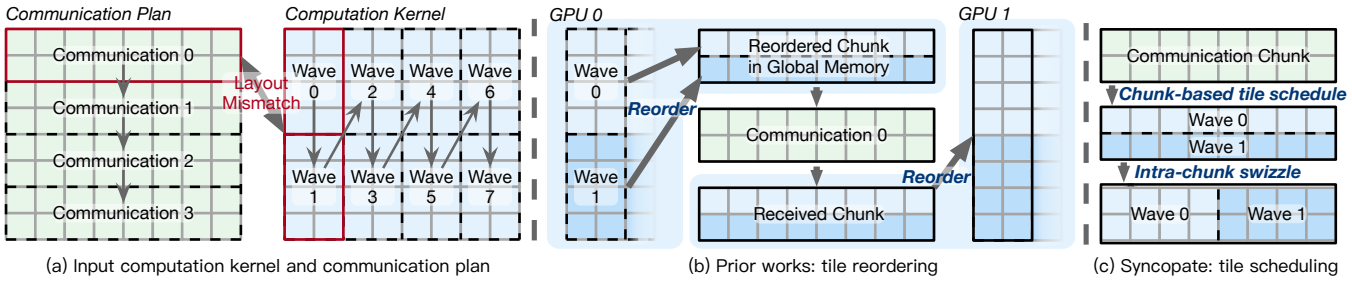

Figure 6: Tile scheduler transformation. (a) Computation and communication naturally follow different tile/chunk layouts, creating misalignment. (b) Prior approaches resolve this by inserting explicit data reordering between the two paths. (c) Syncopate instead rewrites the tile schedule to follow chunk order and applies intra-chunk swizzles for locality, aligning compute with communication progress without extra data movement.

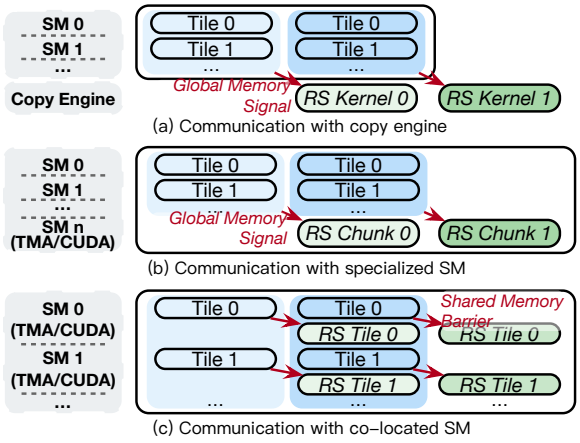

Figure 7: Communication backend selection. (a) Communication issued by the copy engine with global-memory signaling. (b) Dedicated SMs drive transfer. (c) Communication is co-located with compute on the same SM.

schedule and the local tile scheduler, changing chunk-level parameters simultaneously reshapes how data moves across ranks and how computation is ordered within each kernel. Rather than only tuning conventional kernel parameters (e.g., block sizes), Syncopate exposes a higher-level search space whose knobs directly control overlap and resource sharing. Given a local kernel and a chunk-level communication schedule, Syncopate uses an enumerate-and-measure tuning pass. The per-candidate compilation overhead is low because Syncopate performs lightweight source-to-source rewriting on Triton kernels and relies on the existing Triton JIT backend for code generation.

At the *inter-chunk* level, we tune the chunk size, shape, and split factor for each logical transfer. Larger chunks tend to achieve higher effective bandwidth on copy engines and TMA but reduce the granularity of overlap, while smaller chunks enable more fine-grained pipelining at the cost of higher per-chunk overhead and more synchronization. Different operators and model sizes favor different trade-off points: communication-heavy A2A-GEMM and GEMM-AR, for example, benefit from intermediate split factors that balance bandwidth and overlap, as confirmed by our sensitivity study in §6. The tuner searches this space under hardware-specific constraints (e.g., minimum efficient transfer size for copy engines and TMA alignment rules) and prunes configurations that would violate these hardware limits.

At the *intra-chunk* level, we tune both the computation tile configuration and how each chunk is realized by a communication backend. Given a fixed logical schedule, the compiler can instantiate each transfer using any of the backends in Fig. 7 (copy engine, intra- or inter-SM TMA, or CUDA load-/store on specialized or co-located SMs) and can vary the number of SMs assigned to communication when applicable. Some schedules benefit from using TMA for intra-node tensor movement and load/store-based communication for small, reduction-heavy shards, while others favor copy engines for large bulk transfers with minimal SM involvement. In parallel, the autotuner explores different tile sizes and intra-tile orders that better align compute waves with the chosen chunk layout, improving locality and avoiding long communication tails.

Crucially, all of these decisions operate on top of the same chunk-level dependence graph. Changing the backend, SM allocation, or tile order never requires re-deriving the global communication plan; instead, Syncopate reuses the existing schedule and regenerates backend-specific code that enforces the same dependencies. This separation of logical schedule from physical realization is what makes the search space both rich and manageable: as our ablation results show, reasonable but suboptimal settings can easily leave more than a factor of two in performance, while the tuned configuration found by our communication-centric autotuner consistently coincides with the most balanced point between computation, communication, and hardware utilization.

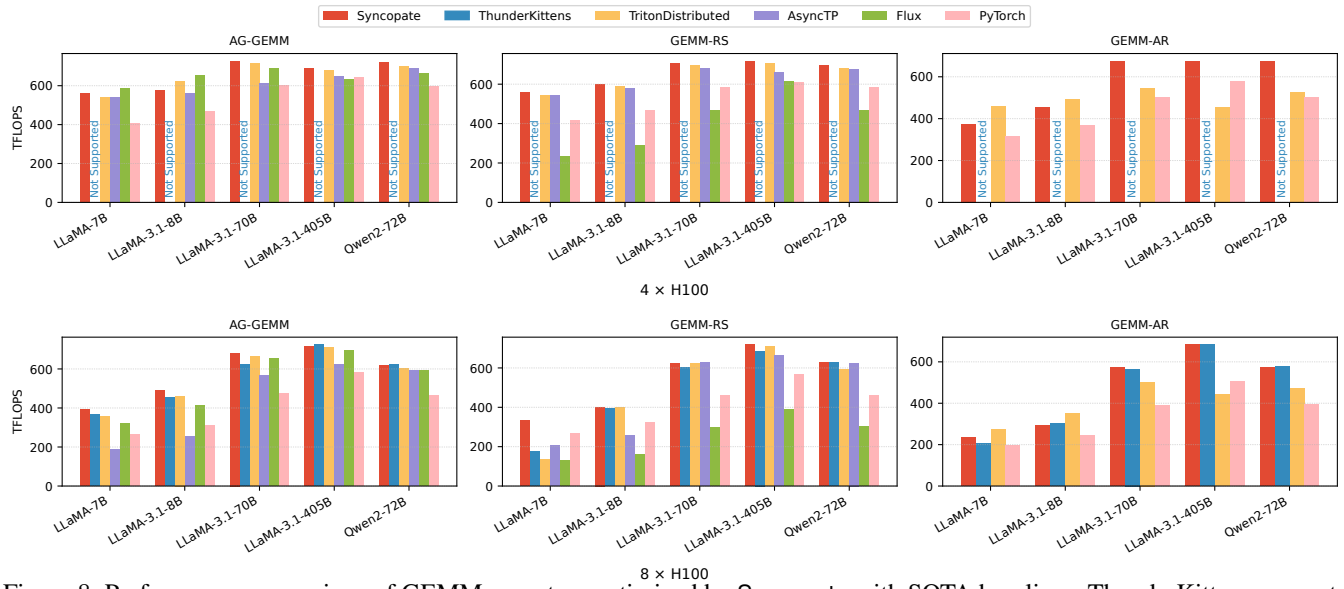

Figure 8: Performance comparison of GEMM operators optimized by Syncopate with SOTA baselines. ThunderKittens supports only 8 GPUs; 4-GPU is unsupported. When both settings are unsupported, the bar is omitted.

6 Evaluation

6.1 Experimental Setup

Testbed. We evaluate Syncopate on a server with 8 NVIDIA H100 GPUs connected via NVLink with an aggregate bandwidth of 900 GB/s, which is a representative single-node setting used in prior multi-GPU kernel studies [3, 13, 33, 46]. Unless otherwise stated, all measurements are taken on a single node using all 8 GPUs; in later experiments, we vary the number of active devices to study scalability and portability. Syncopate is implemented with CUDA v12.9, NVSHMEM v3.3.9, and PyTorch v2.7, and we run all baselines on the same software stack to ensure a fair comparison.

Workloads. We use Syncopate to optimize representative multi-GPU operators that dominate the cost of modern LLM workloads: general matrix multiplication (GEMM) and attention [7, 8, 28, 35]. For GEMM, we benchmark three distributed variants: AllGather–GEMM (AG-GEMM) and GEMM–ReduceScatter (GEMM-RS), and GEMM–AllReduce (GEMM-AR), which appear in tensor-parallel [31] or sequence parallel [17] feed-forward network (FFN) layers. For attention, we evaluate both head-parallel (HP) [15] and sequence-parallel (SP) schedules, including the overlapped RingAttention (Ring-Attn) [18] variant.

Operator shapes are derived from the FFN layers and attention layers of open-source Llama-3 [11] and Qwen [26] models, covering a range of hidden dimensions, head counts, and parallelism configurations that are typical of large-scale LLM deployments. For attention, we sweep over multiple sequence lengths to reflect common short- and long-context use cases under different distribution strategies. Overall, this workload suite exercises Syncopate across both regular GEMM-heavy and more irregular attention patterns.

Baselines. To assess the effectiveness of operators generated and tuned by Syncopate, we compare against both state-of-the-art manually engineered kernels and fully automatic compiler-based approaches. As manual baselines, we include built-in operators from fine-grained overlap DSLs such as ThunderKittens [32, 33] and TritonDistributed [45, 46], as well as highly optimized implementations including AsyncTP [38], Flux [3], and Triton kernels paired with NCCL [24] collectives.

To isolate the benefit of Syncopate's automatic fine-grained overlap, we further compare against automatic operators produced by existing distributed compiler frameworks, including Domino [36], Alpa [44], and Mercury [13]. For these comparisons, we transform the communication schedules found by each compiler into our chunk-level representation and reuse the same high-level plans in Syncopate, so that any performance difference reflects our intra-kernel overlap and backend-selection mechanisms rather than differences in global parallelization strategy.

Overlap Granularity. AsyncTP, Flux, TritonDistributed, and ThunderKittens perform fine-grained intra-kernel overlap by explicitly coordinating communication and computation inside specialized kernels or DSL programs. Domino, Mercury, and the PyTorch RingAttention baseline use inter-kernel overlap, while the remaining baselines execute communication through separate library collectives without overlap.

Base Triton Kernels. Our GEMM local kernels are off-the-shelf Triton GEMM kernels with only Syncopate annotations added. For attention, we start from standard Triton attention kernels and make minor modifications to support split-KV ex-

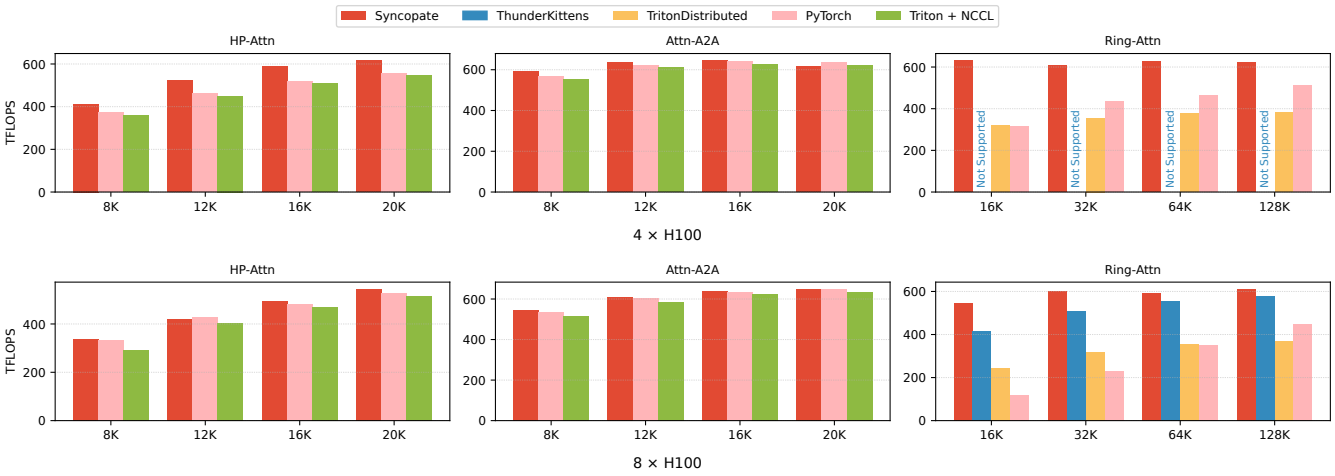

Figure 9: Performance comparison of operators optimized by Syncopate with SOTA baselines.

ecution, which is not exposed by the original kernels. In both cases, the kernels remain local compute kernels; Syncopate generates the communication logic, synchronization, backend selection, and tile-schedule transformations.

6.2 Performance Benchmark

Operator Results. Across all evaluated settings, Syncopate generates automatically optimized operators that are competitive with carefully hand-engineered baselines, while showing even larger gains over fully automatic distributed compilers. As summarized in Fig. 8 and Fig. 9, Syncopate sustains high TFLOPS on both GEMM and attention operators under multiple communication patterns (AG-GEMM, GEMM-RS, GEMM-AR, HP/SP attention, and Ring-Attn) and model configurations derived from Llama-3 and Qwen.

In Fig. 8, Syncopate is at or near the best-performing curve in almost every GEMM configuration. On common, heavily optimized AG-GEMM and GEMM-RS cases where manual kernels such as ThunderKittens, TritonDistributed, AsyncTP, and Flux already sit close to the hardware limits, Syncopate essentially matches their peak throughput on both 4- and 8-GPU settings, achieving on average 99.8% of the best baseline on 4 GPUs and 104% on 8 GPUs. For GEMM-AR, Syncopate is marginally below TritonDistributed on 7B/8B shapes, yet it scales more effectively and becomes the top-performing kernel on larger model configurations. These results indicate that our generic compilation pipeline can recover the same highly tuned overlap patterns that experts design by hand. The small advantage over the strongest baseline in some 8-GPU cases comes from the chunk-level abstraction. By grouping multiple tiles under a communication chunk, Syncopate reduces the number of fine-grained readiness checks and synchronization points while still preserving overlap.

In Fig. 9, we observe a similar trend for attention operators. Under standard HP attention with moderate sequence lengths, Syncopate closely tracks the best manual implementations, confirming that the chunk-based abstraction does not sacrifice performance even for workloads that already benefit from hand-optimized kernels. As the problem becomes harder, moving to Ring-Attn, longer sequences, and 8-GPU runs, the gap widens in favor of Syncopate. Our compiler maintains high TFLOPS while baseline kernels degrade more rapidly, since it can reshape chunks, rebalance compute and communication, and choose different backends as the sequence length and parallelism strategy change. Notably, on the most communication-intensive Ring-Attn settings, Syncopate delivers the best performance despite not being tailored specifically for this operator.

Integration Results. We further evaluate how Syncopate composes with existing automatic distributed compilers that search for the communication schedule among devices, using their communication plans as our inputs. As summarized in Fig. 10, for each of Domino, Alpa, and Mercury, we keep the original parallelization strategy and the searched communication schedule fixed, convert that schedule into our chunk-level representation, and let Syncopate generate the fine-grained overlapped kernels. Across both GEMM and attention workloads on 4- and 8-H100 configurations, integrating Syncopate consistently reduces end-to-end operator latency compared to the native implementations shipped with these systems, showing that chunk-based intra-kernel overlap exposes an additional optimization dimension on top of their global parallelization decisions.

This experiment also illustrates that Syncopate can be cleanly integrated with both partition-based and loop-based compiler stacks. Domino and Alpa operate on partitioned IRs and expose their communication plans as sequences of collectives between logical tensor partitions, while Mercury is built around a loop-centric IR for ring [18] and double-ring attention [12]. Because our interface only requires a well-defined, implementation-agnostic communication schedule and lightweight annotations on the local kernels, these systems can plug into Syncopate with minimal source modifications. This

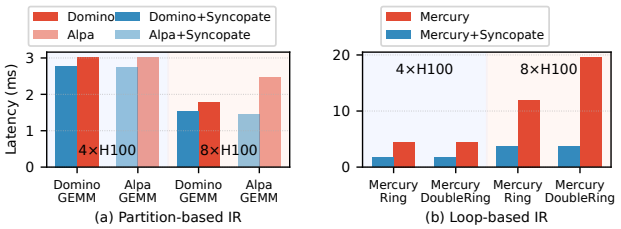

Figure 10: Evaluation of lowering partition-based and loop-based IRs generated by higher-level distributed compilers into Syncopate.

compatibility allows practitioners to reuse mature distributed compilers for global partitioning, while relying on Syncopate to automatically realize high-performance, fine-grained overlap within each generated operator.

6.3 Ablation and Sensitivity Studies

We next evaluate the effect of Syncopate's chunk-based code generation and communication-centric auto-tuning components through a series of ablation and sensitivity analyses in Fig. 11. Each subplot corresponds to one of the key design choices introduced in §5: communication backend selection and SM allocation, chunk size (split factor), and intra-tile scheduling.

Communication Backend and SM Tuning. Fig. 11(a) and (c) study how different realizations of the same logical communication schedule perform under the backends described in § 5.2, and how tuning the number of active SMs further refines this choice. In (a), for GEMM-RS and AG-GEMM, copy-engine and intra-SM TMA backends achieve the highest TFLOPS, while purely CUDA load/store realizations saturate at much lower throughput. The gap between the best and worst backend for the same logical schedule is comparable to the gap between our final implementation and several baselines in Fig. 8, indicating that backend selection alone can determine whether overlap is effective. This confirms that the ability to instantiate the same chunk schedule with different backends is crucial: no single mechanism dominates across operators, and picking a suboptimal backend can leave more than half of the available performance on the table. In (c), for a fixed backend, varying the number of SMs devoted to communication reveals a clear sweet spot where computation and communication are balanced. For both 405B and 70B GEMMs, allocating too few SMs underutilizes the link bandwidth, whereas allocating too many starves the main kernel. The optimal SM count also shifts with model size, which matches the design of our backend code generation: the autotuner treats SM allocation as a first-class knob and automatically selects a near-optimal point for each operator/hardware pair instead of relying on a single hard-coded ratio.

Chunk Size Tuning. Fig. 11(b) varies the number of chunks (split factor) used to realize the same high-level schedule for A2A-GEMM and GEMM-AR. Smaller split factors correspond to larger chunks with higher single-transfer efficiency but fewer overlap opportunities, while larger split factors increase overlap at the cost of per-chunk overhead. The curves exhibit a clear non-monotonic trend, with performance peaking at an intermediate split (e.g., 2–3 splits, about 128MB for GEMM-AR) and degrading when chunks become either too coarse or too fine. Notably, naive choices that are convenient to implement by hand (such as a single large chunk or splitting once per rank) sit far from the optimum. This behavior directly reflects the trade-off discussed in our chunk-based code generation: practitioners cannot reliably pick a single "good" chunk size by hand, whereas Syncopate searches this space automatically and selects the configuration that best matches the operator's compute/communication balance.

Intra-Tile Scheduling. Finally, Fig. 11(d) explores different intra-tile scheduling strategies for a representative GEMM configuration, varying the order in which tiles within each chunk are visited. Each point corresponds to a valid schedule with tile size on M, N, K dimensions and the pipeline stages that preserve program semantics but change locality and load balance. To represent different search candidates, we calculate the consumed shared memory size and plot the performance of these valid schedules. The wide spread in TFLOPS shows that tile order alone can introduce more than a 2 × performance difference, reinforcing the importance of the tile-scheduler transformation in § 5.2. High-performing schedules cluster around orders that align tile waves with the communication chunk order introduced in our chunk-based code generation, whereas poorly performing ones repeatedly revisit tiles in a way that destroys locality or creates long tails of unfinished work. By generating and evaluating these schedules automatically, Syncopate converges on tile orders that co-optimize cache reuse and SM utilization, without requiring users to reason manually about low-level tiling and swizzling policies.

Taken together, these studies demonstrate that Syncopate's chunk abstraction is not only expressive but also forms a practical search space: the same logical schedule can be realized via multiple backends, chunk sizes, SM allocations, and tile orders, and the differences between reasonable but non-optimal choices and the tuned configuration are often comparable to, or larger than, the gaps between systems in our main benchmarks. The auto-tuning framework in § 5.3 systematically explores this space using the code generation mechanisms of § 5.2, turning what would otherwise be a brittle, hand-tuned process into a robust, compiler-driven optimization.

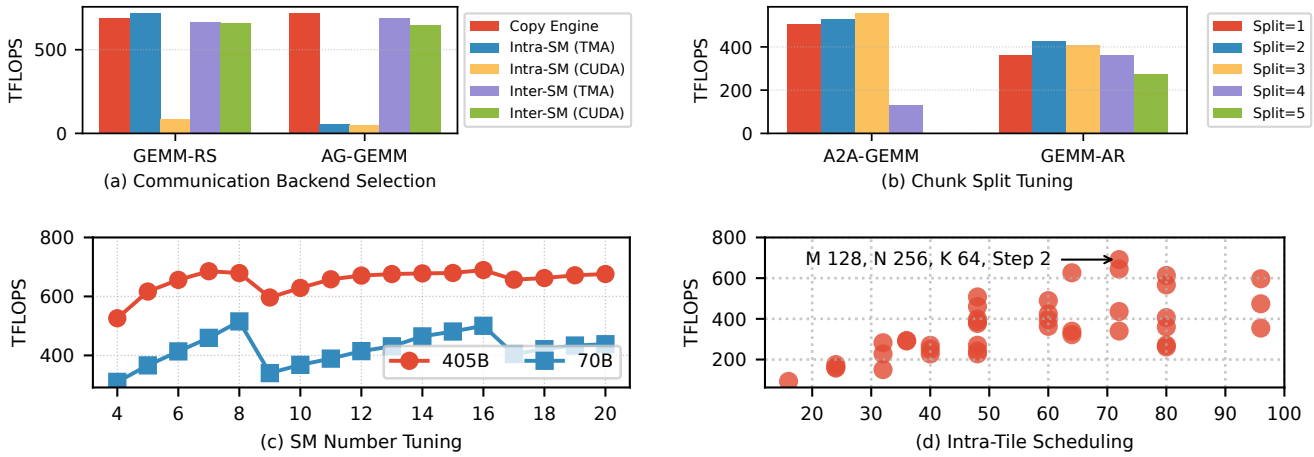

Figure 11: Ablation and sensitivity studies of Syncopate's auto-tuning design space.

7 Discussion and Future Work

Extending to other DSLs. Syncopate is implemented as a Triton source-to-source compiler, but the core abstraction only requires a tile-centric frontend that exposes tile shapes, tile identifiers, tile traversal order, and tile memory regions. Thus, DSLs such as CuTeDSL [21] or cuTile [22] could be supported with an additional frontend/lowering layer, as long as kernels are written in a tiled style. The chunk schedules, dependency construction, and backend-selection logic would remain reusable.

Scope of compute-memory overlap. Syncopate targets fine-grained overlap between tiled computation and explicit inter-GPU communication. Overlapping independent compute-bound and memory-bound kernels, as in NanoFlow-style optimizations [47], is largely orthogonal and can often be handled by stream-level scheduling. Such optimizations could be modeled by Syncopate only when the stages must be coordinated as chunked producer-consumer relationships with tile-level dependencies.

Dynamically shaped workloads. Syncopate currently specializes kernels to a fixed operator shape or a small set of common shape buckets. For variable sequence lengths, the chunk schedule can usually be re-instantiated with the new shape parameters; when chunk ranges are stored as device-side metadata, a lightweight update kernel can refresh these values before launching the generated kernel. A full dynamic-shape runtime that automatically manages shape buckets and metadata updates is left to future work.

Multi-node settings. Syncopate's chunk abstraction naturally extends to multi-node settings, since larger chunks are also a suitable unit for bandwidth-efficient NIC transfers. The main extension is not to generalize tiles or chunks, but to enrich the communication plan with a channel dimension that distinguishes intra-node and inter-node paths. Different channels can progress concurrently, allowing NVLink transfers and NIC transfers to be scheduled and overlapped independently. The compiler can then assign chunks to channels according to the topology and use different backend realizations for each channel. Supporting this setting requires additional backend and runtime support for inter-node communication, which we leave to future work.

Why a compiler abstraction? Syncopate is not meant to replace expert-written kernels for a fixed operator and hardware target. Its goal is to avoid re-encoding the same fine-grained overlap logic, signal/wait protocol, and backend-specific communication code for each schedule or parallel configuration. The chunk abstraction lets users or higher-level compilers specify the logical communication policy once, while Syncopate lowers it to concrete dependencies, synchronization, backend choices, and tile schedules.

8 Conclusion

Syncopate bridges the abstraction gap between communication planning and fine-grained overlapping by introducing a chunk-based interface that unifies communication plans with tiled GPU computation. By automatically aligning tile schedules with communication progress and selecting among heterogeneous backends, Syncopate turns intra-kernel overlap into a general compiler capability rather than a hand-engineered optimization. The framework integrates cleanly with existing distributed compilers, complementing their global parallelization strategies with backend-aware, fine-grained scheduling. This decoupled design provides a foundation for systems that co-schedule computation and communication and accommodate diverse communication backends.

A Artifact Appendix

Abstract

The Syncopate artifact contains the source code for the chunk-centric compiler and runtime described in this paper, together with unit tests, end-to-end multi-GPU tests, experiment entry points, and a Dockerfile for the GPU software environment. A short CPU-only workflow validates the core communication-plan representation, signal planning, lowering logic, and compiler passes. On a multi-GPU NVIDIA Hopper-class system, the artifact also supports correctness and performance evaluation of generated GEMM and attention operators.

Scope

The artifact can be used to validate three central claims of the paper: (1) chunk-level communication plans can express reusable communication schedules and lower them to per-rank execution plans; (2) Syncopate can transform local tiled kernels into correct fine-grained overlapped multi-GPU kernels; and (3) the generated operators can be benchmarked across communication backends and scheduling choices. The CPU-only tests validate the compiler abstractions and passes, while the GPU tests validate generated-kernel correctness against unfused references and report execution time.

Reproducing all absolute performance numbers and comparisons in the paper requires a 4- or 8-GPU Hopper server with NVLink/NVSwitch connectivity and the external baseline implementations. Several external baselines are not vendored in the artifact; the repository documents this limitation and points to their upstream repositories.

Contents

The repository is organized as follows:

- `syncopate/communication/`: communication-plan descriptors, signal planning, code generation, and runtime support;
- `syncopate/computation/`: GEMM and attention kernel templates and the source-to-source transformation pass;
- `syncopate/interface/`: lowering from communication plans to per-rank schedules and tile schedules;
- `tests/`: CPU-only compiler tests and end-to-end multi-GPU correctness/performance tests;
- `experiments/`: figure-oriented experiment entry points for the operator, attention, compiler-integration, and ablation results; and
- `utils/`: the distributed launcher, communication microbenchmarks, and helper scripts.

Hosting

The artifact is publicly available under the MIT license at `https://github.com/tie-pilot-qxw/syncopate`. The version evaluated for OSDI '26 Artifact Evaluation is commit `ce2b13e496eb6629ab42aac2aec1d9e31e084ba6`. Evaluators and readers should check out this commit to obtain the fixed artifact version.

Requirements

The CPU-only validation requires Linux, Python 3.10 or newer, PyTorch, and `pytest`; it typically completes in under five minutes. Full generated-kernel and performance experiments require Linux, Docker with the NVIDIA Container Toolkit, and a single node with at least four NVLink/NVSwitch-connected NVIDIA Hopper-class GPUs; some experiments require eight GPUs.

Abstract

Data pipelines play a critical role in the performance of large-scale pre-training jobs running on thousands of GPUs. In this work, we present a comprehensive quantitative analysis of data access patterns from production workloads and reveal three previously underreported bottlenecks. First, cross-datacenter (cross-DC) traffic emerges as a major source of latency when evaluating in-training models using remote checkpoints. Second, checkpoint loading during startup phases frequently suffers from I/O contention that delays job initialization. Third, data transformation during loading becomes a significant and CPU-intensive bottleneck for multimodal models. Guided by these findings, we introduce three optimizations: global-namespace-based predictive checkpoint replication, proactive hot-file replication, and offloading data transformation to storage-tier CPU resources. Crucially, we demonstrate that these optimizations are not system-specific but address fundamental architectural mismatches in the LLM era. They are broadly applicable to both legacy and modern storage systems, offering a high-return path to upgrade infrastructure with minimal engineering intrusion. Together, these techniques reduce wasted GPU hours per evaluation from 16,800 to 4,000, shorten checkpoint loading time at each training start by 40.8%, and reduce training stalls caused by data loading by 63.2%.

1 Introduction

The training of foundation models has shifted the center of gravity in systems infrastructure [1, 7, 13, 18, 25, 56]. Training models with over 100 billion parameters now requires the coordination of thousands of GPUs across massive clusters for extended periods. The systems community has aggressively optimized compute scheduling [15, 16, 24, 34, 40, 46, 59, 60] and network collectives [10, 20, 41, 55] to maximize Model FLOPs Utilization (MFU) [6]. However, the data pipelines responsible for loading, transforming, and delivering exabytes of training data have received significantly less scrutiny.

This oversight is critical because the data pipeline is no longer a passive utility. It is a primary performance determinant. In this paper, we present a comprehensive analysis of data access patterns from production pre-training workloads. Our environment manages tasks ranging from billion-parameter text models to trillion-parameter multimodal models. We rely on the Hadoop Distributed File System (HDFS) [47] as our storage backbone due to its cost-effectiveness and capacity to hold exabytes of data.

We analyze 30 thousand training job traces collected over a 90-day period to characterize the interaction between modern pre-training jobs and traditional storage architectures. Our analysis reveals three distinct bottlenecks that arise when general-purpose storage systems confront the extreme scale of large model training.

First, we identify a Cross-DC Latency Trap. To ensure model quality, production training runs rely on *companion evaluation*, an out-of-band validation pipeline that periodically loads recent checkpoints and runs benchmark suites in parallel with training. Because evaluation jobs have different scheduling and hardware requirements from training, they often run in remote datacenters. We find that fetching checkpoint shards across the Wide Area Network is bound by the Round-Trip Time of thousands of small tensor reads rather than available bandwidth. This latency dominance results in severe delays and wastes millions of GPU hours.

Second, we observe an Initialization I/O Storm. Large-scale training involves frequent restarts due to debugging or failures [4, 51, 57]. Job initialization triggers a synchronous surge of read operations where thousands of workers contend for a small set of hot files, such as global metadata and shared embedding parameters. This contention saturates storage nodes and creates tail latencies that block the entire cluster.

Third, we encounter a Transformation Wall in multimodal training. Unlike text-only models, multimodal training involves CPU-intensive transformations like video and image

*Equal contribution.
†Work done during internships at ByteDance Seed.
‡Corresponding authors.

decoding. We show that host CPUs on training nodes cannot keep pace with GPU consumption. This shifts the bottleneck from storage I/O to local compute and causes significant pipeline stalls.

We argue that these bottlenecks persist because storage systems operate *reactively* while training workloads are inherently deterministic. To address this, we introduce three software-defined optimizations that expose application-level patterns to the storage layer.

- **Predictive Checkpoint Replication.** We leverage the regular schedule of evaluation jobs to replicate checkpoints and prioritize urgent feedback signals. This reduces companion evaluation I/O time by **76.1%**.
- **Proactive Hotspot Prediction.** We implement a cooperative mechanism where the training framework signals hot files to the storage system before execution. The storage layer proactively replicates these files to diffuse the I/O storm. This reduces checkpoint loading time by **40.8%**.
- **Storage-Side Transformation Offloading.** We utilize underutilized CPUs on storage nodes to perform data processing. This Just-in-Time mechanism pipelines transformation with training and reduces data loading stalls by **63.2%**.

Our work demonstrates that legacy Big Data systems like HDFS can meet the rigorous demands of exabyte-scale large model training without requiring a complete architectural replacement. Our contributions are as follows:

1. We characterize pre-training data access patterns using production traces and identify three key bottlenecks that have long been overlooked: cross-DC latency traps for companion evaluation, synchronous initialization I/O storms, and the multimodal transformation wall.
2. We propose software-defined optimizations leveraging workload determinism, including predictive checkpoint replication to mask latency, proactive hot-file replication to diffuse contention, and storage-side offloading for CPU-intensive transformations. These optimizations substantially reduce wasted training time and improve overall efficiency.
3. We demonstrate that these optimizations serve as a generalizable framework for addressing architectural mismatches in the LLM era. By bridging the gap between infrastructure and training, we provide a practical blueprint for evolving general storage to meet LLM demands. We validate these findings in a production environment and plan to release the anonymized traces to support future research.

2 Background and Motivation

2.1 Pre-training Data Pipeline

We present the data pipeline architecture that supports pre-training jobs on thousands to tens of thousands of GPUs in our production environment. We choose HDFS [47] as our storage infrastructure, because it was the existing, cost-effective infrastructure capable of holding exabytes of data. As shown in Figure 1, the pipeline consists of two primary components: a storage tier and a dataloader.

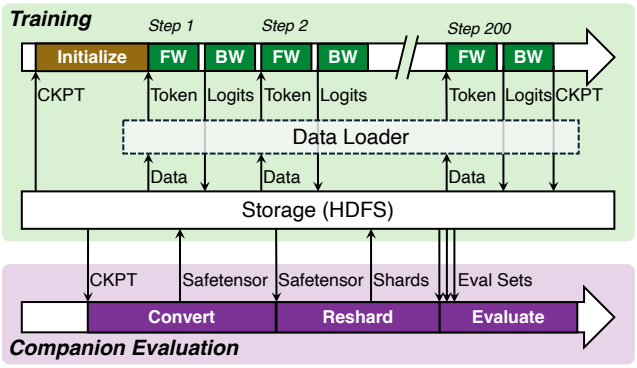

Figure 1: Data Pipeline in Pre-training

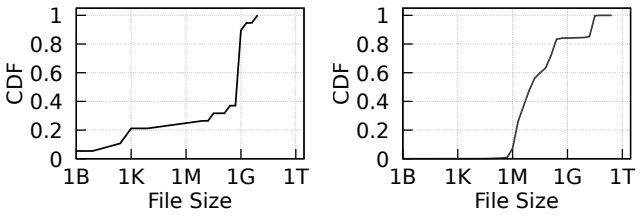
The storage tier persists all artifacts required during pre-training, including training datasets, model checkpoints, and logits. Training datasets encompass heterogeneous modalities such as text, images, and videos. Checkpoints contain metadata together with sharded tensors for model parameters and optimizer states [21] and serve as the authoritative record of training progress. Logits capture the raw, unnormalized prediction vectors emitted after each forward pass, which are typically not used during training but are essential for debugging and monitoring model behavior.

The dataloader sits between storage and the training framework. It transforms raw data into the formats expected by the model and coordinates data movement through CPU memory onto GPUs. The transformation operations include computationally intensive steps such as video and image decoding, spatial resizing for vision inputs, tokenization and sequence packing for text data [30, 33]. The dataloader thus acts as both a transformation engine and a staging mechanism that prepares and pipelines data efficiently to the accelerator stack.

Pre-training jobs interact with the data pipeline through two I/O paths. They issue direct reads and writes to the storage tier when initializing from checkpoints, persisting checkpoints, and emitting logits. In parallel, they obtain training data through the dataloader, which performs storage reads and executes sample transformation. Together, these interactions define the steady state and bursty I/O patterns imposed on the storage subsystem.

We characterize pre-training execution as consisting of three phases: **initialization**, **iterative training**, and **companion evaluation**, each with different data access behaviors.

During the **initialization phase**, the training framework issues blocking operations on the critical path. Specifically, it loads the full model checkpoint, including parameters and optimizer states, from the storage tier. These tensors are distributed or replicated across thousands of *ranks*, i.e., the



(a) T-L Dataset (b) MM-L Dataset

Figure 2: The file size distribution in datasets used in T-L and MM-L traces.

worker processes participating in distributed training that typically own one GPU each, according to the adopted parallelization strategy [40, 46, 59].

After initialization, the job enters the **iterative training phase**, which executes a sequence of *training steps*. We define a step as the processing of a full batch of data, culminating in a single model parameter update after the necessary forward and backward passes. During this phase, storage access proceeds largely asynchronously with GPU computation. The dataloader continuously prefetches and transforms data for future steps, while the training framework writes logits after every forward pass and periodically persists checkpoints to storage. These activities generate sustained read and write traffic throughout the training run.

The **companion evaluation phase** runs periodically in parallel with iterative training on separate evaluation clusters, as evaluation usually imposes different scheduling and resource needs compared to training. Since training metrics such as loss are often insufficient to detect issues such as quality degradation or model collapse, companion evaluation provides an external measurement of progress by assessing the model on a recent checkpoint and on data that is distinct from the training set (i.e., real-world benchmarks [14, 26, 27]). Each evaluation cycle loads the latest checkpoint from storage, merges the sharded tensors into unified formats, and then loads both the merged checkpoint and benchmark suites, before executing inference and writing the results back to storage. Although logically separate from training, the results of companion evaluation can feed back to the training control plane and trigger a rollback.

2.2 Data in Pre-training

2.2.1 Traces

To investigate I/O access patterns, we select a set of five representative training tasks from a pool of 30 thousand traces collected over a 90-day period. As detailed in Table 1, these tasks exemplify state-of-the-art production workloads, accounting for 70% of total GPU hours while capturing diversity in:

- **Modality:** We cover mainstream training domains spanning text-only and multimodal workloads.
- **Scale:** The tasks range from small (billions-parameter) to large (trillion-parameter) models, utilizing training cluster sizes between approximately 4K and 20K GPUs.
- **Training strategy:** We incorporate diverse distributed strategies, including FSDP [59], FSDP2 [37], and Megatron [46], which constitute the dominant paradigms in our training environment.

To characterize these workloads, we employ a multi-layered tracing approach that spans both the training framework and the storage layer. At the storage layer, we collect per-operation records from HDFS client and server endpoints, including the access path, operation type (e.g., `open`, `read`, `pread`, `write`, and `close`), request size, start and end timestamps, and observed latency. At the training layer, we use PyTorch Profiler [38] and manual instrumentation to record the start and end times of major phases, including checkpoint loading and saving, dataloader fetch and transformation, forward and backward computation, logits saving, and companion-evaluation merge and resharding. We then join these records using timestamps to distinguish raw storage service time from framework-visible end-to-end latency, which is necessary for interpreting the data loading measurements in Table 2. We will release the traces once anonymized.

2.2.2 Data Types

Based on our sampled traces, we classify the data flowing through the pipeline into three primary types: datasets, checkpoints, and logits. Table 2 quantifies the distinct I/O patterns, including average I/O sizes per training host, average I/O latency, and I/O frequency, exhibited by each type across our production workloads.

Dataset: During each training step, the dataloader retrieves part of the dataset from storage, transforms each sample into model-ready tensors through operations like decoding, cropping and tokenization, and feeds the result to the GPU for computation. The modality of the model significantly influences the characteristics of the dataset. For instance, in the text-based T-L training task, the dataset occupies approximately 20 TB across 20K files. In contrast, the multimodal MM-L task employs a vastly larger dataset containing diverse file types, with a total size of about 6 PB and a file count exceeding 3 million. Figure 2 illustrates the file size distribution for these datasets. Table 2 reports the end-to-end data loading latency, which includes both the retrieval and the transformation steps; we further break this down in Section 5.

Checkpoint data: A training checkpoint consists of model parameters, optimizer states, dataloader states, and miscellaneous metadata. At regular intervals (e.g., every 100 or 500 steps), this checkpoint data is persisted to the underlying storage system to ensure fault tolerance [29, 50]. We detail the checkpoint sizes for the sampled traces in Table 1. The trace-level view in Table 2 further shows per-host checkpoint read

Table 1: Model training strategies, types, and checkpoint sizes of the representative trials sampled for this study. Each trial runs on a production cluster with thousands of GPUs.

Trace	Strategy	Type	Checkpoint Size
Text Small (T-S)	FSDP2	Text	≈1 - 5 TB
Text Large (T-L)	Megatron	Text	≈5 - 10 TB
MultiModal Small (MM-S)	FSDP	Multimodal	≈1 - 5 TB
Multimodal Large (MM-L)	FSDP2	Multimodal	≈1 - 5 TB
Multimodal Omni (MM-O)	FSDP	Multimodal	≈5 - 10 TB

Table 2: Average I/O size, latency, and interval statistics. Values represent the average size per training host. Each metric reports the end-to-end data pipeline latency observed by the training framework. The symbol '–' indicates data is unavailable because the feature was disabled during model training.

	Read checkpoint		Data loading			Save checkpoint			Save logits			Step
Trace	**Size (GB)**	**Lat (s)**	**Size (GB)**	**Lat (s)**	**Interval (step)**	**Size (GB)**	**Lat (s)**	**Interval (step)**	**Size (GB)**	**Lat (s)**	**Interval (step)**	**Time (s)**
T-S	688	137.58	0.01	5.77	1	11.21	56.27	500	–	–	–	14.03

MM-S	351.27	300.33*	0.05	8.64	1	1.40	106.83	200	–	–	–	19.20
MM-L	373.81	139.25	0.02	5.29	1	5.84	68.31	200	0.18	2.34	1	18.17
MM-O	1133.63	106.83	0.01	6.16	1	13.93	128.605	200	–	–	–	14.39

* Denotes that this data is obtained before predictive hotspot prediction (Section 4)

and save sizes, which differ substantially due to deduplicated writes; Section 4 explains the source of this asymmetry in detail.

Logits data: Logits represent the raw, unnormalized prediction vectors output by the final layer on each rank. Depending on the model configuration, this results in approximately 30 MB to 300 MB of data. Unlike checkpoints, which are required for fault tolerance, logits are mainly persisted for debugging and monitoring. Developers optionally enable logits saving during phases such as early training, configuration updates, or divergence diagnosis, while stable steady-state runs often disable it to conserve I/O bandwidth. When enabled, logits are generated after every forward pass and persisted at every step.

2.3 Emerging Storage Challenges

During pre-training, distinct data types are accessed at specific phases of the lifecycle, often generating I/O operations that consume a significant portion of the total timeline. In this paper, we characterize the unique I/O bottlenecks inherent to each distinct phase and present our production mechanisms to address them.

1. Cross-DC I/O in companion evaluation (§3). Companion evaluation is critical for validating pre-training models, but is bottlenecked by the need to fetch checkpoints from remote (cross-DC) training clusters due to scheduling and hardware constraints. This creates significant I/O challenges: a "small-IO latency trap" where fetching thousands of small tensors is bound by WAN RTT rather than bandwidth, and severe bandwidth contention from concurrent background tasks. To mitigate these issues, we introduce Predictive Checkpoint Replication, which leverages the regular evaluation interval to pipeline and batch checkpoint replication in advance, and Signal-Driven Prioritization, which allocates bandwidth to urgent evaluations triggered by training anomalies.

2. The initialization I/O storm (§4). The initialization phase is bottlenecked by an "I/O storm" where synchronous checkpoint loading triggers massive data contention on a small set of hot files (e.g., global metadata and replicated parameters). This contention saturates storage nodes, creating straggler reads that block the entire cluster and waste significant GPU cycles. To resolve this, we introduce Proactive Hotspot Prediction, a cooperative mechanism where the training framework explicitly signals deterministic access patterns to the storage layer. This allows the system to pre-replicate hot files before the job starts, diffusing contention and converting unpredictable tail latency into constant-time access.

3. The transformation wall (§5). For multimodal (e.g., MM-L) pre-training, data loading shifts from being I/O-bound to compute-bound due to the high cost of transforming video and image data (e.g., decoding, cropping). This "transformation wall" creates severe straggler issues where slow host-side processing forces GPUs to idle, wasting significant compute resources during the iterative training phase. Offline transformation is infeasible due to extreme storage amplification

($50\times \sim 100\times$) and inflexibility to hyperparameter changes. To resolve this, we introduce Storage-Side Transformation Offloading. By leveraging the predictable ordering provided by our deterministic dataloader and underutilized CPUs on storage nodes, we push compute-intensive transformations down to the storage tier. This "Just-in-Time" processing pipeline overlaps transformation with training and reduces both latency and stall time.

3 Cross-DC Companion Evaluation

Training large-scale foundation models with hundreds of billions of parameters is a costly and extended process that involves thousands of GPUs running for weeks or months. In this environment, detecting training issues early is essential. Although monitoring training loss is common practice [48, 56], our production experience shows that in-loop signals such as loss and gradient norms are not reliable indicators of model health. A model may show stable training loss while already exhibiting forgetting or collapse on downstream tasks. This gap motivates the use of *companion evaluation*, a continuous, out-of-band validation pipeline that assesses model performance in parallel with training. In our deployment, companion evaluation serves as a critical safeguard that helps prevent the training system from progressing on an already diverging model state.

In our production environment, companion evaluations execute on separate clusters that are often located in different datacenters. This design is driven by two primary constraints. First, pre-training jobs demand strict synchronous execution across thousands of GPUs, relying on gang scheduling [12] to maintain lockstep progress; consequently, inserting evaluation tasks into the same cluster would fragment scheduling and degrade training throughput. On the other hand, while pre-training necessitates the latest accelerator generation with high-speed interconnects to minimize the step time, evaluation workloads are throughput-oriented and can run effectively on older, more cost-efficient hardware. These evaluation clusters are typically deployed wherever power and space are available, often resulting in physical separation from training resources.

3.1 Companion Evaluation Workflow

The bottom part of Figure 1 illustrates the end-to-end workflow of companion evaluation. Each evaluation run transforms a distributed training checkpoint [8] into an inference-ready model and then executes benchmark workloads. The workflow proceeds in three stages.

First, *checkpoint merging* converts distributed checkpoint shards into inference-ready modality submodels. During training, the training framework writes checkpoints as many distributed shards optimized for parallel writes on large training clusters [50]. For evaluation, however, these shards must be converted into a standard inference format such as `safetensors` [42]. The evaluation cluster therefore retrieves the relevant parameter shards from remote storage and performs merging separately for each modality: it reconstructs the complete parameter tensors, discards optimizer states and other tensors that are unnecessary for inference, and writes each merged modality submodel to local storage as `safetensors` files.

Table 3: Data read/write sizes and time consumption for the MM-L model. The checkpoint merging phase dominates I/O time due to cross-DC traffic.

Stage	Read (GB)	Write (GB)	Total (Time)	I/O (Time)
Merging	**2631***	**1742**	**2h 03m**	**2h 03m**
Reshard	**872**	**1435**	**18m**	**18m**
Evaluation	**8954**	0	**1h 55m**	**4m**

* Denotes Cross-DC Traffic

Next, *model resharding* reorganizes the merged checkpoint to match the device topology and parallelism configuration of the evaluation cluster. This reshaping ensures that inference can be executed efficiently across the available devices.

Finally, the *model evaluation* stage uses a client-server architecture. The server component loads the resharded model and initializes the HTTP serving endpoint, while the client simultaneously executes inference across benchmark datasets to quantitatively assess model quality. The system writes the resulting metrics to storage, and the training control system subsequently ingests them.

This workflow requires substantial data movement and local processing, and its efficiency is directly shaped by the network and storage behavior observed during checkpoint merging. Table 3 shows the data sizes and time distribution of these stages.

3.2 Checkpoint Merging Bottlenecks

Our study spans a 30-day observation window covering 19 pre-training tasks across models ranging from small to large parameter counts. During this period, the system executed 3,589 companion evaluations, which contributed to operational efficiency by identifying 156 critical model regressions.

The value of this mechanism depends on timely feedback. When evaluation results are delayed, training continues to advance on a divergent model state, which both wastes training GPU time and makes recovery harder.

The root of this delay lies in data I/O. For a representative multimodal large model (MM-L), Table 3 shows that a single evaluation cycle can exceed four hours, with data I/O accounting for approximately 56.6% of the end-to-end time. The cost of this I/O bottleneck is substantial: across the 156

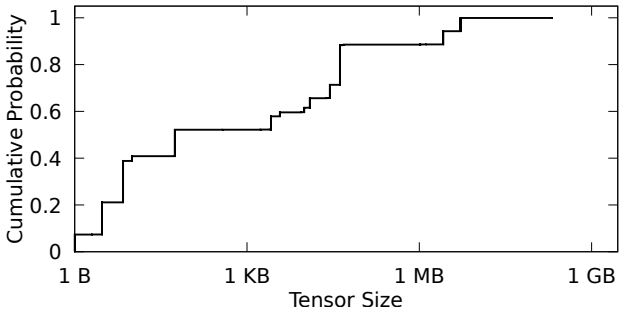

Figure 3: CDF of tensor sizes in a typical checkpoint. The prevalence of small tensors exacerbates the latency penalty of cross-DC reads.

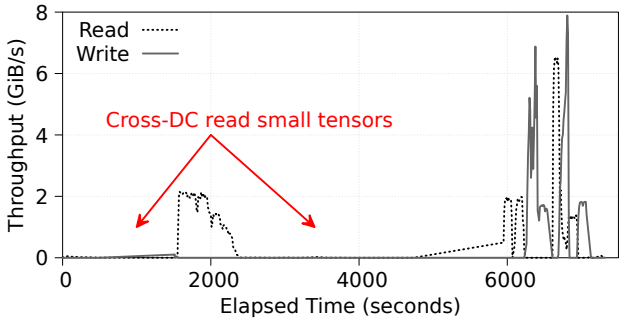

Figure 4: Throughput during Checkpoint Read. The performance is limited by the high RTT of cross-DC links when fetching small tensors.

regressions in our dataset, I/O-induced delays wasted approximately 2.6 million GPU hours, offsetting nearly half of the 5.5 million training GPU hours that the evaluation system would otherwise have saved.

Of this long data I/O time, we further find that 84.8% is consumed by the checkpoint merging phase, which must read approximately 2.6 TB of data over the Wide Area Network. Unlike later stages that operate entirely on local storage, checkpoint merging requires retrieving tensors across datacenters, which makes it the principal source of evaluation delay. Specifically, we identify two primary causes of the delay:

Small-I/O latency trap. Transformer-based models consist of thousands of disjoint tensors, particularly small *LayerNorm* parameters and *Biases*. As illustrated in Figure 3, over 60% of the tensors in the MM-L checkpoint are smaller than 16 KB. Because the per-modality merge described in Section 3.1 retrieves only the parameter tensors needed for each submodel, the resulting reads are issued at tensor granularity rather than as bulk transfers. Even when the merge server fetches tensors concurrently, each request still requires several cross-DC WAN round trips. This fragmentation interacts poorly with the underlying distributed file system, which is optimized for coarse-grained 128-MB blocks. This mismatch produces two effects:

- **Read amplification.** Fetching a 4 KB tensor often requires reading a significantly larger block on HDFS data nodes, incurring about 1.5× read amplification.
- **RTT-bound throughput.** On a high-latency WAN link (typical 100 ms RTT), the throughput for these thousands of small tensor reads becomes bound by latency rather than bandwidth. This manifests as the "sawtooth" throughput pattern in Figure 4, where effective utilization drops to a fraction of the available link capacity (i.e., 60 Gbps).

Bandwidth contention. Even for large tensors, cross-DC bandwidth remains a scarce resource contended for by hundreds of concurrent tasks (208 on average), including data migration, log aggregation, and parallel evaluations. Figure 5 illustrates this contention; the average available bandwidth per task fluctuates significantly and often degrades to less than 1 GB/s. A naive "First-Come, First-Served" policy fails in this context because it treats latency-critical evaluations indistinguishably from background archival jobs.

3.3 Training-Aware I/O Optimization

To address the cross-DC I/O bottlenecks identified earlier, we apply two training-aware optimizations that require no dedicated network hardware.

Predictive checkpoint replication. Companion evaluations follow a predictable interval, typically every one thousand training steps. This regularity allows us to initiate pipelined checkpoint replication as soon as the training system begins saving a checkpoint at the scheduled interval. Rather than letting the merge script issue thousands of tensor-granularity WAN reads, the storage system batches the required checkpoint shards into large contiguous transfers and caches them in the evaluation cluster's storage tier. A lightweight server-side namespace service, NNProxy, then directs evaluation jobs to read from these local cached shards when they are available. This converts many Wide Area Network reads into local reads and removes both cross-DC RTT and small-read fragmentation from most scheduled evaluations.

Signal-driven prioritization. Not all evaluations have equal urgency. While periodic evaluations follow a fixed schedule, others are triggered by training anomalies such as loss spikes or abnormal gradient behavior. These events require faster feedback. We introduce a simple priority signal that combines model scale, task importance, and anomaly severity. The storage scheduler uses this signal to preempt background traffic and allocate network bandwidth to urgent evaluations, reducing delay when fast diagnosis is needed.

3.4 Evaluation

By applying the above optimizations, we convert previously unmanaged I/O contention into predictable resource alloca-

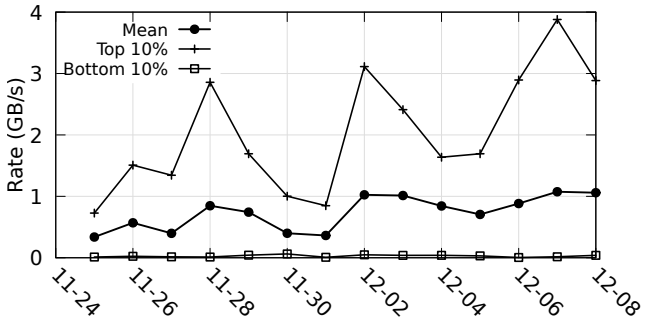

Figure 5: The average cross-DC data transmission rate in our production environment. The bandwidth is highly contended and bursty.

tion. These training-aware mechanisms reduce average checkpoint merging latency by 76.1%, with improvements reaching 89.3% for the T-S model and 70.8% for the MM-L model. They also cut I/O-induced compute waste per regression from 16,800 GPU hours to 4,000 GPU hours. In total, these optimizations recover nearly 2 million GPU hours across our observation window.

3.5 Future Directions

To further improve performance across geographically distributed clusters, we plan to implement vertical co-design between training frameworks and storage layers. Two directions are especially promising.

Training informed storage control. Training frameworks should expose signals such as evaluation interval and convergence indicators to the storage control plane. These signals would allow the storage system to anticipate latency-sensitive operations, allocate resources accordingly, and avoid interference from background traffic.

I/O-Aware checkpoint formats. Standard distributed checkpoint layouts are optimized almost exclusively for high-throughput, parallel writes during training, which inherently introduces the structural fragmentation that plagues selective cross-DC reads. A promising direction is the design of layout-agnostic or multi-layout checkpoint formats. By restructuring how tensors are grouped, such as packing fragmented parameters (e.g., LayerNorm layers and biases) into contiguous, storage-block-aligned extents while segregating volatile optimizer states, the framework could natively support zero-overhead, selective WAN streaming without requiring extensive server-side merging.

4 Initialization I/O Storm

Large-scale model training is characterized not by continuous execution, but by frequent interruptions and restarts; these arise from hardware failures, automated system maintenance, and, most notably, intensive debugging cycles during model development [18, 51]. Initialization is a fully synchronous barrier because training cannot resume until every rank has reloaded its share of the latest checkpoint from storage. When thousands of ranks restart in lockstep, they issue concurrent reads against a small set of hot files at the same instant, turning the storage tier into the bottleneck of the start phase.

Table 4: Breakdown of training startup latency.

Stage	Operation	Time (s)
Job Init.	Cluster Startup	23
	Dist. Context Init.	130
Model Const.	Model Construction	118
Ckpt. Recovery	Coordination	76
	Downloading from HDFS	**300**
	Parameter Loading	104
Total		**751**

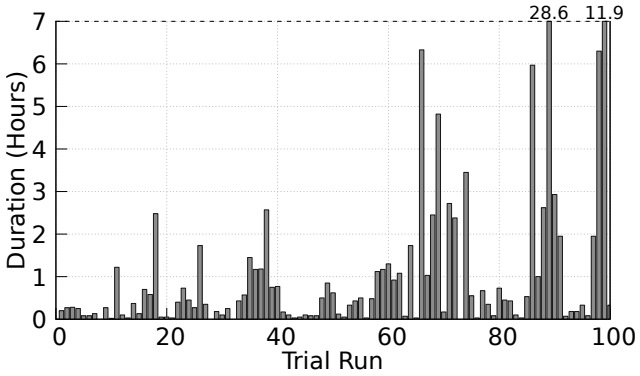

Figure 6: Duration of continuous training sessions between restarts in the MM-S trace. Short bars indicate frequent restarts, while long bars indicate longer uninterrupted training periods.

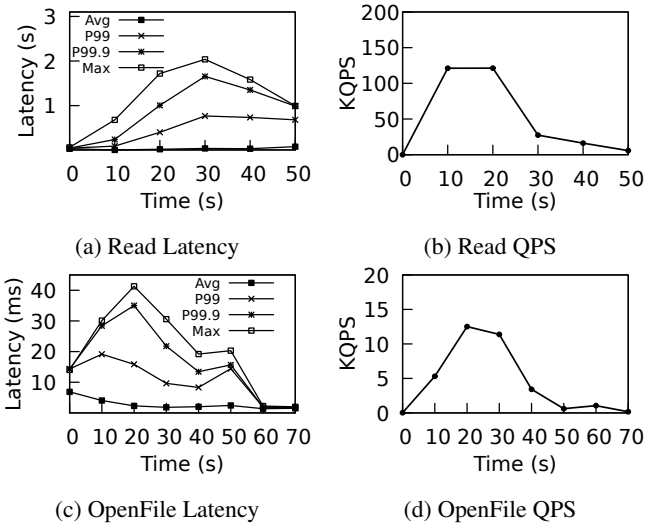
4.1 Synchronized Loading Bottleneck

In our production environment, we observe that job initialization is a significant overhead. The breakdown of training startup latency in the MM-S trace, as shown in Table 4, reveals that blocking I/O operations during file download are the primary bottleneck, consuming 39.95% of the total startup duration.

The operational impact of this latency is magnified by the bursty nature of job restarts. Figure 6 depicts the restart distribution from our MM-S trace. Each bar corresponds to one restart interval, with the y-axis showing the elapsed training time before the next restart. We observe distinct clusters of activity where developers repeatedly restart jobs for code updates or hyperparameter tuning. For instance, within a single



(a) Read Latency (b) Read QPS

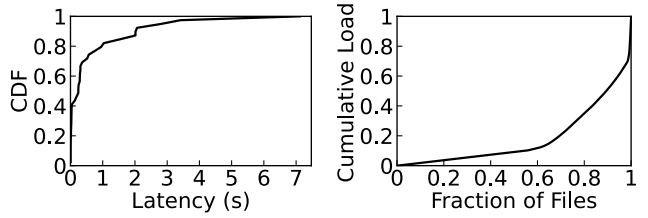
Figure 7: Latency and throughput (QPS) for Read and OpenFile operations under the default 3-replica policy.



(a) Access latency CDF. (b) Cumulative load distribution.

Figure 8: Characterization of I/O contention. (a) Latency distribution for file downloads. (b) Load distribution relative to the fraction of files.

111-minute debugging window, a job underwent 4 consecutive restarts. With an average downloading cost of 5 minutes per run, this I/O overhead accounts for 18.02% of the total wall-clock time, severely throttling developer velocity and wasting costly GPU cycles. Extrapolating to our cluster-wide operation, the startup delay would result in a loss of more than one million GPU hours annually.

4.2 The Anatomy of an I/O Storm

To pinpoint the root cause of slow checkpoint loading, we conduct a controlled experiment scaling to 2,048 GPUs. We instrument the storage client to decompose the latency of every I/O request.

Contrary to common assumptions that metadata operations (e.g., `open`, `getattr`) are the bottleneck in distributed file systems [23], our analysis reveals that *data contention* is the primary culprit. As illustrated in Figure 7, `open` latencies remain low and stable. However, `read` operations exhibit extreme tail latencies that correlate perfectly with QPS spikes.

Figure 8a plots the CDF of download latency. The distribution exhibits a pronounced long tail, indicating that while the majority of downloads complete quickly, a small fraction of tasks suffer from significantly high latency. Our breakdown shows that these few straggler reads dominate the completion time, accounting for 67.97% of the total wait.

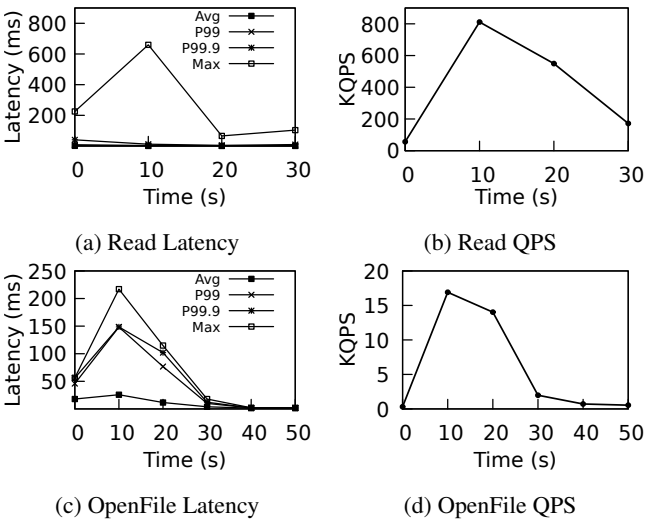
By calculating the peak QPS for each file within 0.5-second windows, we observe a heavy-tailed distribution in Figure 8b. The cumulative load represents the contribution to the aggregate peak QPS (i.e., the sum of all individual file peaks). Specifically, the top 5% of files account for 38.8% of this total pressure. These hotspots are typically caused by two sources: global metadata files (e.g., `.metadata` or `common_states`) accessed by all ranks, and more significantly, access skew resulting from redundancy elimination.

This skew is a byproduct of current checkpointing systems [8, 35, 50, 52], which prioritize write throughput and storage efficiency by employing *parallel saving* coupled with *redundancy elimination*. While effective for writing, this approach causes loading asymmetry. We illustrate this issue using the Embeddings and MoE layers. For Embeddings (which are replicated parameters), the system persists only a single copy to minimize overhead; consequently, restoring this layer triggers a one-to-many access storm where hundreds of ranks concurrently contend for a solitary file. Under the standard 3-replica policy, the limited replicas are overwhelmed by such concurrent requests, causing latencies to increase sharply. In contrast, MoE experts (which are sharded parameters) are saved as distinct files corresponding to their parallel groups. This allows subsets of ranks to access different files concurrently, effectively distributing the load and avoiding the single-point bottlenecks observed in the embedding layer.

4.3 Proactive Hotspot Prediction

Facing this challenge, traditional storage systems employ reactive replication [3, 54]: they detect heat via runtime monitoring and trigger replication when thresholds are breached. In the context of training startup, this approach is fundamentally flawed for two reasons. First, the contention window is transient (often lasting only tens of seconds). By the time the system detects the hotspot and creates new replicas, the loading phase is already over. Second, initiating replication traffic during the I/O storm competes for the already saturated network bandwidth, exacerbating the bottleneck rather than relieving it. To address these limitations, mitigation must be proactive, leveraging the training framework's information to prepare the storage layer before the storm begins.

We propose a cooperative mechanism in which the training framework explicitly informs the storage system about upcoming access patterns via a `SetReplicationHints` interface. Since training configurations (parallelism strategy, world size) are known at job submission, the set of hot files is deterministic. The framework identifies two categories of



(a) Read Latency (b) Read QPS

(c) OpenFile Latency (d) OpenFile QPS

Figure 9: Latency and throughput (QPS) for Read and OpenFile operations under the default 128-replica policy.

data: global metadata, where the target replication factor is set proportional to the job's world size N, and replicated tensors, where access demands are aggregated based on tensor-to-rank mappings to determine the expected concurrency degree ω_f for each file f. Upon receiving these hints, typically immediately after a checkpoint is written or before a job is scheduled, the storage system proactively replicates the identified hot files using a heuristic policy:

$$R_{target}(f) = \lceil \frac{\omega_f}{C_{load}} \rceil \quad (1)$$

where C_{load} represents the safe concurrent load capacity of a single replica. To prevent storage bloat, these ephemeral replicas are tagged with a Time-To-Live (TTL) and automatically reclaimed after the startup phase concludes.

4.4 Evaluation and Discussion

We evaluate proactive replica expansion on the 2,048-GPU training job. Based on the job scale and the predicted checkpoint access pattern, the policy increases the replication factor of hot metadata and replicated-parameter files to 128 before checkpoint recovery begins.

As shown in Figure 9, replica expansion improves checkpoint loading in two ways. First, the peak aggregate Read QPS increases, indicating that compute nodes spend less time blocked on storage and can issue requests more aggressively. Second, and more importantly, the average read latency decreases because the hottest files are no longer served by only a small number of replicas. By eliminating straggler reads, the total checkpoint loading time decreases from 38.48 s to 22.78 s, a 40.8% improvement.

While the absolute saving in this controlled 2,048-GPU experiment is on the order of seconds, the operational impact grows with training scale. Without intervention, synchronized checkpoint recovery creates increasingly severe contention as more ranks restart together. By preparing replicas before the recovery phase, proactive replica expansion turns an unpredictable, scale-dependent storage bottleneck into a more stable loading process. Based on these results, we have codified replication guidelines for our production environment: 64 replicas for 10k-GPU clusters and 128 replicas for 20k-GPU clusters.

The benefit of replica expansion depends on how the training parallelism strategy materializes model state during checkpointing. In the most favorable case, fully sharded data parallelism already spreads parameter shards across ranks and files. The remaining imbalance usually comes from a small set of shared structures, such as checkpoint metadata, common states, or other non-sharded tensors. Expanding only these structures is often enough to make the recovery load well balanced across storage replicas, with little storage overhead. The common production case is less ideal but still highly targeted: each rank typically saves a small number of tensors, often a single tensor, so most files have clear ownership while replicated tensors and global states still create a few hot files. Replica expansion is effective here because the system only needs to expand this small hot subset instead of increasing the replication factor of the entire checkpoint. A less favorable case arises when a replicated tensor is packed together with much larger sharded parameter shards in the same checkpoint file. Since the replication decision is made at file granularity, expanding the file for the shared tensor also replicates the unrelated sharded data.

4.5 Future Directions

To further improve checkpoint recovery at larger training scales, future systems could better align checkpoint file layout and recovery-time fanout with replica expansion.

Deduplication-aware checkpoint packing. A natural extension is to consider recovery-time replication when partitioning tensor saving tasks. Tensors that are aggressively deduplicated, and therefore likely to be read by many ranks during recovery, should be placed in dedicated files or co-packed with tensors that require similar replica expansion. This layout keeps file-level replica decisions aligned with tensor-level demand: expanding a hot file increases capacity for shared reads without also copying large unrelated shards.

Communication-assisted checkpoint loading. The loading plan of checkpoint recovery already indicates which ranks share the same checkpoint shards, providing the information needed to organize communication-assisted fanout. Depending on deployment scale, rank locality, and framework-integration constraints, future systems could serve a hot shard through additional storage replicas, a scoped broadcast path, or a hybrid of both.

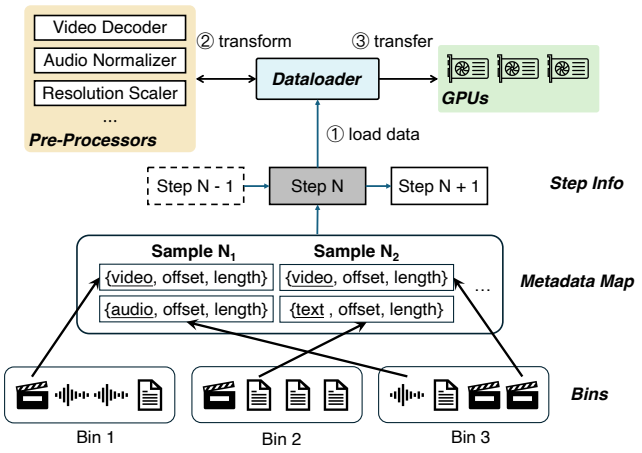


Figure 10: Structure of the on-disk format and the data loading pipeline for the deterministic dataloader.

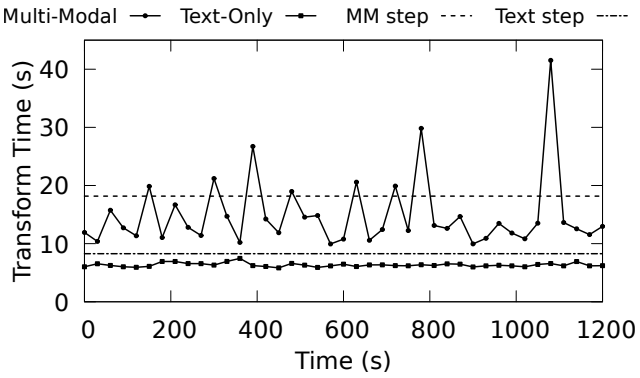

Figure 11: Maximum dataloader latency: Text (T-L) vs. Multimodal (MM-L). MM-L suffers from extreme tail latency due to heterogeneous transformation costs.

5 MM-L Transformation Wall

In conventional text-only model training, the data loading process is effectively hidden behind GPU computation. Data reads and lightweight tokenization finish well before each step starts, leaving the training loop compute-bound. However, as training moves from text-only models to multimodal models, the dataloader must serve not only text but also heterogeneous data such as audio, video, and images. As a result, data loading for multimodal training can no longer be fully overlapped with GPU execution, causing the input pipeline to exceed the compute time by a wide margin and become the dominant source of training stalls.

5.1 Deterministic Dataloader

Multimodal training in our environment uses a deterministic dataloader architecture. Unlike standard loaders such as the PyTorch DataLoader [39] or streaming dataloaders [32] that incur runtime overhead from dynamic shuffle computation and complex state management, our approach utilizes an offline-generated global execution plan. This guarantees strict deterministic ordering across thousands of workers and achieves global random shuffling.

Figure 10 illustrates the three data formats used to organize and serve raw training data. Under the hood, the system relies on *consolidated binary bins* where raw multimodal data including audio, video, and concatenated image and text is stored as large contiguous binary files in the global storage system. We choose a bin size of 20 GB to balance file management overhead against the cost of merging bins, providing precise byte range access without the read amplification common in columnar formats like Parquet [49]. To enable fast lookup, we employ *metadata maps* that serve as a logical-to-physical translation layer, converting sample identifiers into byte offsets and lengths within the binary bins. Our production datasets contain roughly ten thousand map files totaling about 0.7 TB. Finally, we utilize *per-step info files* to manage ordering. Since each training epoch consumes all samples in a shuffled order, we generate a file listing the exact sequence of sample identifiers to be read. This allows shuffling to be performed entirely by permuting index entries offline, achieving a new global order without touching or rewriting the underlying physical data.

During training, the dataloader performs the following sequence to prepare data for the next training step:

- **Metadata resolution.** The dataloader begins by reading the per-step info file to get the sample identifiers required for the upcoming batch. It then consults the metadata maps to translate these identifiers into byte offsets and lengths within the consolidated binary bins.
- **Data retrieval.** Using the resolved offsets, the dataloader issues `read` or `pread` system calls to fetch the corresponding byte ranges from the binary bins. This stage performs random access into the underlying files to retrieve only the specific samples needed for the current batch.
- **Sample transformation.** Once the raw bytes are retrieved, the dataloader applies modality-specific transformations. For instance, video samples will go through a series of operations such as video decoding, frame extraction, and cropping, followed by conversion to tensors, while image samples will be decoded, resized, and transformed into tensors. These operations are executed on the host CPU to avoid the large memory overhead of GPU-based transformation and to keep GPU resources focused on model computation. The resulting tensors are staged for transfer to the GPU at the start of the next step.

Table 5: Breakdown of Data Loading Latency in MM-L. Transformation dominates the pipeline, and high variance (Max vs. Avg) indicates severe straggler issues.

	Read (s)		**Process (s)**	**Other (s)**	**Total (s)**

Max	0.506	0.266	41.52	0.428	42.72

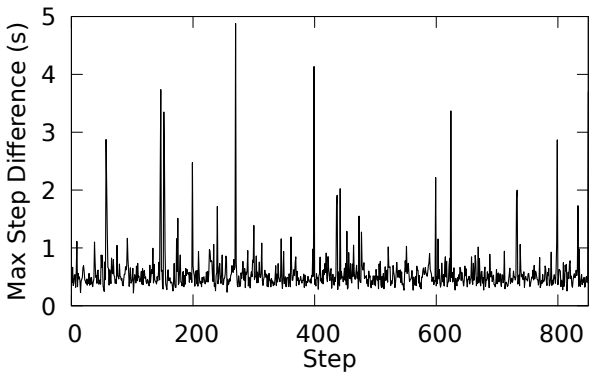

Figure 12: The time difference in training step time across different machines.

5.2 Transformation Stalls

Table 5 decomposes the data loading latency into four phases in the MM-L training trace: metadata resolution, data retrieval, transformation, and runtime overheads such as timing and threading. Transformation overwhelmingly dominates the critical path, accounting for 94.4% of the total data loading time (5.05 s of 5.35 s). I/O retrieval itself is negligible, averaging only 13.6 ms. This shows that MM-L workloads are compute-bound: limited CPU capacity, rather than storage bandwidth, drives up the time required for transformation.

The heterogeneous nature of multimodal data, mixing short text with high-resolution images and long video clips, introduces substantial variability in transformation cost. Figure 11 compares the maximum data loading latency across hosts for T-L and MM-L traces. While T-L workloads show tightly clustered latencies, MM-L workloads exhibit a pronounced long tail. For instance, the slowest host can take 42.72 s in our sampled period, where the average data loading time for that step is 5.35 s. This produces a 37.4 s gap in that single step.

This variability is driven by sample-length variance in multimodal datasets rather than by a transient storage issue. To preserve training coverage, MM-L batches include both lightweight samples and long video clips whose transformation cost scales with duration, codec complexity, and the number of sampled frames. As GPU step time continues to shrink, this host-side long tail becomes increasingly difficult to hide behind model computation. In our sampled phase, a host processing a 161.9 MB sample requires 41.5 seconds to finish the transformation, causing the time variation. In contrast, other hosts process an average of only 20 MB and complete the transformation in 5.05 seconds. In extreme cases, a machine assigned a 500 MB H.264 video of about 10 minutes requires over 2.18 minutes for decoding and frame extraction, even with `decord` using hardware-accelerated decoding and four concurrent decoding threads. Such stragglers force thousands of GPUs to idle, waiting for them to complete. Figure 12 illustrates the variance in training step duration. We find that for a single step, the execution time difference across hosts can reach up to 5 seconds, forcing other nodes to wait for the straggler. This temporal skew directly translates to a waste of over 10,000 GPU hours per day.

5.3 Storage-Side Transformation Offload

Addressing this bottleneck requires reducing the cost of the transformation phase. While performing offline transformation (i.e., decoding and transforming raw samples into ready-to-train tensors before training) seems like a straightforward solution, it is not viable at the production scale for two fundamental reasons. First, *storage amplification* makes storing decoded data prohibitive. High-resolution images and videos are typically archived in space-efficient formats such as JPEG [19] and H.265 [17]. Decoding them into float tensors causes extreme storage expansion: video footprints increase by more than 40×, while images exhibit a smaller but still substantial expansion of several tens of times. At the petabyte scale, the decoded representation would demand storage in the exabyte range, merely shifting the bottleneck from online CPU transformation to raw storage capacity. Second, offline transformation suffers from inherent *inflexibility*. The required transformations depend heavily on model hyperparameters such as crop size, frame count, and resolution, all of which vary across pre-training runs. Any alteration to the model architecture or data augmentation policy necessitates a complete regeneration of the pre-transformed dataset. This process consumes millions of GPU hours and significantly hampers model development velocity.

Instead, we exploit a resource that is already paid for: *storage nodes in high-throughput clusters often have underutilized CPU capacity*. While training hosts are saturated by model computation and media processing, storage nodes are typically bottlenecked by network or disk bandwidth, leaving significant compute capacity idle.

This opportunity arises from a fundamental I/O-compute mismatch in our cluster. We observe that while training nodes are Compute/Memory saturated, storage nodes are typically bounded by HDD seek latency or Network Interface Card (NIC) limits. Our telemetry indicates that storage node CPUs often sit at 20–30% utilization waiting for I/O interrupts, a resource gap we exploit to hide the format conversion cost.

We redesign the storage layer to act not just as a data repository, but as a *Disaggregated Pre-processing Engine*. This design is fundamentally enabled by the strict determinism of our deterministic dataloader (Section 5.1). Since the data consumption sequence is fixed in the global index, the storage system can accurately predict future data access patterns, allowing it to perform transformation using its idle cores. We implement a *Pushdown Transformation Engine* with three core mechanisms:

Schedule synchronization. Upon training initialization, the training framework shares the dataset identifier and step progress with the storage system. Storage nodes, having access to the per-step info files, autonomously resolve the sequence of upcoming data blocks. This eliminates the need for the training client to issue millions of data and metadata operation RPCs during the critical path.

Just-in-Time (JIT) transformation. Storage nodes maintain a *Consumer Queue* for the training job. They speculatively read raw binary data and execute the registered transformation graph such as decoding, random cropping, and normalization in the background. This pipelining ensures that while the GPU computes Step N, the storage layer is already preparing tensors for Step $N+1$. For video samples, the storage-side engine also applies frame sampling before data is sent back to the training cluster. This keeps the network payload bounded despite the temporary expansion caused by decoding and prevents format inflation from becoming a new tail-latency source.

Load-aware fallback. To prevent saturating the storage node, we implement dynamic backpressure to guarantee storage stability, which is a hard constraint in our shared production environment. If a storage node's CPU usage exceeds a safety threshold (e.g., 80%), it aborts the transformation and returns raw bytes to the training dataloader. The training client detects the data format (Tensor vs. Binary) and falls back to local processing. This hybrid approach allows us to absorb transformation spikes using the aggregate compute power of the storage fleet while protecting the storage control plane from overload.

5.4 Evaluation

This architecture yields significant improvements in our production environment, validating the effectiveness of moving compute to the storage tier. Specifically, by offloading heavy lifting to the storage pool, the P99 data loading latency drops by 85.7%, effectively mitigating the straggler effect. In terms of training efficiency, stall time due to transformation stragglers is reduced by 63.2%, translating to a relative 10.8% improvement in MFU. Finally, for resource utilization, we observe a 94% reduction in data loading CPU usage on training hosts, practically eliminating the host-side bottleneck.

5.5 Future Directions

Storage-side transformation offload depends on co-located compute headroom in the storage tier. This assumption holds in our environment because the same storage clusters support large-scale data processing and often have idle CPU cycles while waiting on disks or network. It may not hold for cloud object stores or lean storage appliances that expose little programmable compute near the data [2, 28]. In such cases, other techniques are also possible to improve the transformation performance and reduce the training slowdown:

Processed-sample caching: Caching preprocessed samples [22, 30, 58], as previous work suggests, can complement storage-side offload when training repeatedly revisits data. In large-scale pre-training, which is the focus of this paper, globally shuffled samples are rarely revisited within the useful lifetime of a cache, so processed-data caching provides little hit-rate benefit while adding consistency and capacity pressure. In regimes with repeated sample access, such as reinforcement learning or repeated fine-tuning over a smaller corpus, caching becomes effective and can store the transformed outputs produced by the storage-side engine.

Predictive transform-aware batching: Since the deterministic dataloader knows the exact sample sequence offline, a lightweight cost model can be used to predict each sample's transformation cost in advance, based on metadata such as raw sample size, codec, resolution, and clip duration. With these estimates, batches can then be composed to balance transformation cost across hosts, mixing heavy and light samples so that no single host is assigned a disproportionate share of expensive clips.

6 What If?

Building an efficient data pipeline for exabyte-scale pre-training necessitates navigating trade-offs between storage cost, compute efficiency, and engineering complexity. Along our operational journey, we critically evaluated several alternatives that we eventually discarded as impractical at scale. We structure this discussion as a series of "What If" questions.

Q1: What if we used Peer-to-Peer (P2P) distribution for model loading?

In Section 4, we address the initialization storm by proactively replicating data on storage nodes. While P2P distribution (e.g., NCCL [10] and UCX [45]) theoretically scales linearly with cluster size, we strictly prioritize a hierarchical client-server model to mitigate multi-tenancy interference and tail latency sensitivity.

First, large GPU clusters concurrently execute multiple training tasks. P2P's unstructured, all-to-all traffic pattern induces network congestion, saturating buffers and disrupting the latency-sensitive NCCL collectives of concurrent jobs. Second, training initialization functions as a synchronous barrier constrained by the slowest node. P2P performance re-

mains inherently probabilistic; a single slow peer—suffering from throttling or local congestion—delays the startup of the entire gang. In contrast, our hierarchical replication guarantees a deterministic SLA with confined north-south traffic, effectively isolating the cluster from cross-tenant interference and probabilistic tail latencies.

Q2: What if we deploy a dedicated transformation cluster as an alternative to storage-side processing?

In Section 5, we address multimodal transformation overhead by offloading compute to storage nodes. An alternative is a dedicated sample transformation cluster, a fleet of CPU-rich machines that decode and transform data before forwarding tensors to training hosts. This architecture, exemplified by tf.data service [33] and Ray Data [31], decouples data preparation from training. We reject this design due to significant network amplification and operational overhead.

First, decoded tensors dwarf their compressed sources. Video decompression inflates data volume by 50–100×; transferring these tensors over the datacenter network shifts the bottleneck from CPU to bandwidth and saturates the shared fabric. Second, a standalone cluster introduces provisioning complexity: capacity must be sized for peak multimodal demand yet remains idle during text-only workloads. In contrast, our storage-side offloading exploits spare CPU cycles already provisioned on storage nodes, avoiding network amplification and eliminating the need for a dedicated resource pool.

Q3: What if we migrate to a specialized AI-native storage system as a modern alternative to HDFS?

Recent works propose specialized AI storage systems (e.g., 3FS, AIStore) offering superior small-file performance and kernel-bypass networking. We retain and optimize a legacy Big Data system over a greenfield solution primarily due to data gravity and operational continuity.

HDFS serves as our unified data lake, hosting exabytes of data across diverse business lines beyond AI training. Migrating this volume to a new system is operationally infeasible and cost-prohibitive. Moreover, AI-native systems often require specific hardware configurations (e.g., all-NVMe) or custom clients that break compatibility with the broader ecosystem (e.g., Spark-based cleaning pipelines). Our work demonstrates that by exposing application-level patterns, legacy systems like HDFS can meet strict LLM training requirements without wholesale replacement. This software-defined approach enables iterative infrastructure evolution while maintaining service stability.

7 Related Work

Storage infrastructure for model training. Traditional Parallel File Systems (PFS) such as Lustre [44] and GPFS [43] provide high checkpointing bandwidth but degrade under the massive metadata pressure of multimodal datasets. Conversely, disaggregated object stores like S3 [2] and Azure Blob [28] offer scalability but incur high latency and limited random access throughput. While emerging AI-native systems (e.g., 3FS [11], AIStore [9]) address these limitations via kernel-bypass networking and specialized caching, they often require greenfield deployments. As detailed in Section 6, migrating exabytes of legacy data to specialized stacks is operationally infeasible. Our work demonstrates that by exposing application-level determinism, general-purpose Big Data systems (HDFS [47]) can meet strict training SLAs without fundamental architectural replacement.

Data loading and global coordination. Prior research optimizes data loading through domain-specific caching (e.g., Quiver [22] and SiloD [58]) or coordinated fetching (e.g., CoorDL [30]). These systems are primarily reactive, depending on runtime hit rates. In contrast, our deterministic dataloader (Section 5.1) exploits the determinism of LLM training to convert random access into sequential streams. Regarding data formats, solutions like TFRecord [33], WebDataset [53], and Lance [36] mitigate random seeks by aggregating samples but complicate global shuffling. Our index-based approach ensures global randomness without physical data movement. Finally, while works like CrossPipe [5] optimize pipeline schedules, we address the storage logistics of companion evaluation (Section 3) by leveraging namespace-level predictive checkpoint replication to mask cross-DC latency.

8 Conclusion

We identify critical storage bottlenecks in large-scale pre-training, including cross-DC latency during companion evaluation, initialization storms, and multimodal transformation overhead. By leveraging workload determinism, we implement software-defined optimizations such as predictive checkpoint replication, proactive replication, and storage-side offloading to convert the storage tier into a proactive partner. These mechanisms significantly reduce companion evaluation latency, startup time, and data loading stalls. Our work demonstrates that legacy systems like HDFS can effectively support exabyte-scale training through vertical co-design.

Acknowledgments

We are grateful to the anonymous reviewers and shepherd for their constructive feedback. We also thank our colleagues from the storage, training infrastructure, and pre-training teams for their support in deploying and evaluating the techniques described in this paper. Abstract

Machine learning (ML) models memorize and leak training data, causing serious privacy issues to data owners. Training algorithms with differential privacy (DP) have been gaining attention as a solution. However, these algorithms add noise at each training iteration and degrade accuracy, limiting their real-world adoption. To improve accuracy, a new family of approaches adds carefully designed *correlated noises*, so that noises cancel out each other across iterations. We performed an extensive characterization study of these new mechanisms and show they incur non-negligible overheads when the model is relatively large or uses large embedding tables compared to the hardware capacity. Motivated by the analysis, we propose Cocoon, a framework for efficient training with correlated noises. Cocoon stores and processes the large noise history across CPU, GPU, and memory extension module, introduces optimizations for sparse embedding tables, and leverages to-be-commercialized near-memory processing (NMP) devices. On a real system with an FPGA-based NMP device prototype, Cocoon improves the performance by 1.23–10.82×.

1 Introduction

Machine learning (ML) models are vulnerable to memorization and leakage of their training data—sometimes by accident, or when model is subjected to an adversarial attack. This poses a serious *privacy risk* because ML models are often trained with sensitive user data (*e.g.*, medical data [108], audio [66] or keyboard inputs [82,113], personal chat logs [103], *etc.*). The threat is not hypothetical but imminent: a recent study demonstrated the feasibility of attacking the popular ChatGPT [68] to extract its training data that contains sensitive information. Similar attacks have been shown to be possible for other models [9, 10, 28, 50]. The privacy risks can deter user participation in data collection and training, degrading the quality of real-world ML-based services [60].

Differential privacy (DP) [25] is one of the most principled and widely adopted approaches for mitigating such privacy risks. DP theoretically bounds the information leakage of private data through its statistics. In the context of ML training, this translates to a mathematical bound on the probability that an adversary can successfully extract information of the training data from the trained model [36,37,39,49,70]. DP is not a premature research concept; already deployed in several real-world applications, including the US Census [3], Apple's device analytics [86,91], and Google Chrome's behavior telemetry [26]. The use of DP for ML training is also gaining increased attention. For instance, Google publicly announced its use of DP for training all of their current and future smart keyboard (Gboard) models [101,113], and also recently released VaultGemma [89], an LLM that was trained with DP from scratch. Microsoft has also limitedly deployed a DP-trained model on their SwiftKey keyboard [2].

Most DP training algorithms add Gaussian noise to the gradient at each training iteration to provide a theoretical privacy guarantee [1, 21]. This Gaussian noise accumulates over training and significantly degrades the model accuracy, which is the primary barrier to DP's widespread adoption. To counteract the accuracy issue, a recent line of works [13–16,48,63–65,79,109] proposed to use noises that are ***correlated*** across iterations, allowing noises added in later iterations can partially cancel out earlier noises. *Correlated noise mechanisms* have demonstrated both theoretical [13,55] and empirical [13–16,48,63–65,79,109] benefits over simply adding Gaussian noise. The mechanism has already been successfully deployed in real-world products [101,113], and adopted into popular ML privacy libraries [32,33]. Their rapid adoption send a strong signal of their importance.

Despite their growing popularity, the system implications of correlated noise have not been thoroughly studied. Existing literature mostly focused on accuracy rather than system efficiency, training relatively small models with a large number of TPUs/GPUs (*e.g.*, using 1024 machines to train a billion-parameter model [63]). In these *resource-abundant* environments, noise-related overheads are small. However, our study reveals that correlated noise incurs significant system overheads, including a memory footprint that exceeds the pa-

rameter size by over an order of magnitude, and causing up to 14.49× runtime slowdown. Such costs are particularly severe for *economical* setups with fewer TPUs/GPUs, which is a configuration frequently studied to enable large model training on small and mid-sized entities [5, 83–85, 110]. This overhead arises because generating correlated noises involve storing and processing noise history from past iterations, which can scale up to hundreds of gigabytes or even terabytes. It becomes especially problematic for (1) models with large embedding tables and (2) large-scale, billion-parameter models (*e.g.*, LLMs).

We introduce *Cocoon*, a framework for efficient at-scale DP training with correlated noises. Cocoon splits the large noise history between CPU, GPU, and (if present) additional memory extension module, and processes them in a distributed fashion to maximize performance. To mitigate managing noise history for large embedding tables, Cocoon precomputes and stores the noise for embedding tables in a compact format by exploiting their gradient sparsity (Section 4.2). Furthermore, when part of the noise history is offloaded to a memory extension module, we show that leveraging emerging near-memory processing (NMP) solutions [46, 87] can greatly improve performance and reduce the cost of deployment (Section 4.3). Our evaluation on a real system, with an FPGA-based industry prototype NMP device, showed 1.23–10.82× speedup on various models and training scenarios. We summarize our contributions:

- We present an extensive system characterization study of emerging DP training methods that use correlated noises. Our analysis reveals that, on an economical setup where the number of GPUs is moderate, correlated noise generation can introduce non-negligible slowdown.
- We introduce Cocoon, a highly-optimized, PyTorch-based DP training library that uses correlated noises. Cocoon splits and processes noise history on CPU, GPU, and (if present) emerging NMP devices.
- Cocoon introduces a noise pre-computing and coalescing optimization that accelerates training with large embedding tables by 2.33–10.82×. With to-be-commonly-deployed NMP devices, Cocoon can achieve 1.23–2.32× speedup over the baseline when training large models, which we demonstrate with a real industry prototype.

2 Background and Motivation

2.1 Differentially Private Training Algorithms

Differential privacy. Differential privacy [25] (DP) provides a robust guarantee that the outcome of a randomized mechanism does not change significantly when a single entry in the input dataset changes. When applied to ML training, DP ensures that the final trained model does not depend significantly on a single sample (or user [11, 19]) in the training corpus, which effectively limits an adversary's capabilities. For example, DP parameters can theoretically bound the attack success rate for adversaries attempting to infer whether a user participated during training [49, 70] or trying to directly reconstruct the original training data [36, 37, 39] from a DP-trained model. A model trained with DP can be used for multiple inferences over time, and it will not leak additional information beyond the privacy cost paid upfront during training. This is in contrast with inference-time DP techniques [31, 54, 94, 97], which leak more information about the corpus with more inferences [80, 97].

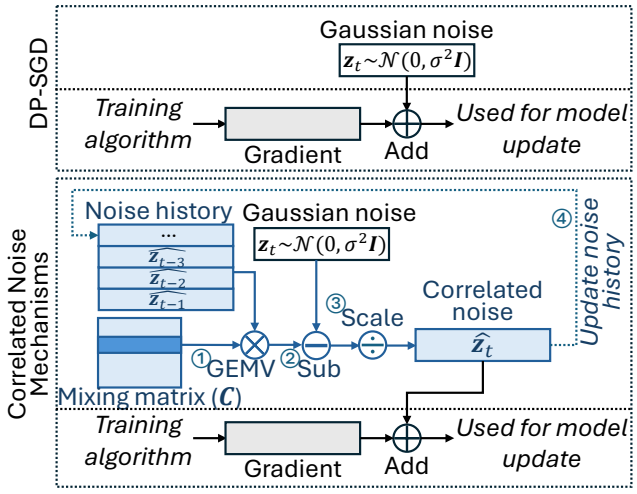

Figure 1: Independent Gaussian vs. correlated noise.

Training with Gaussian noise. The most common method to train a model with DP is using DP-SGD [1] or its variants. DP-SGD introduces three key modifications to regular SGD. First, the batch in each iteration is formed through random sampling with replacement. Second, unlike SGD, which calculates an average gradient across the batch, DP-SGD first calculates per-sample gradients, scales (clips) each one individually, and then averages the scaled gradients. Finally, an independently sampled Gaussian noise is added to the averaged gradient before it is applied to update the model [1]. While these steps provide stronger privacy guarantees, DP-SGD significantly compromises the trained model's accuracy.

Several follow-up works have introduced optimizations to improve the model accuracy over the DP-SGD algorithm. Most of this research still relies on *independent Gaussian noise* and focuses on optimizing other components of DP-SGD (e.g., sampling [20], clipping [7, 67], hyperparameter [21], feature engineering [96], post-processing after noise addition [34, 112], optimizer [12, 29, 92, 93, 102], and architecture [21, 74]). These optimizations still suffer from accuracy degradation due to Gaussian noise. Figure 1 (top) highlights the independent Gaussian noise added to each gradient in DP-SGD.

Correlated noise mechanisms. Instead of adding independent Gaussian noise, a recent line of works [13–16, 48, 63–65, 79] proposed to add noise that is *correlated* across iterations. When generating correlated noises at iteration t, these mechanisms mix noises that were used in the previous $\hat{b}-1$ iterations (*i.e.*, noise history), where $\hat{b}$ is called the *band size*.

Mathematically, correlated noises are generated as follows. For a model with m trainable parameters trained through n training iterations, let $\mathbf{z}_t \in \mathbb{R}^m$ be a Gaussian noise sampled at iteration t. Each noise is as large as the trainable parameters (m), and training a large model requires using a noise that is as large. For a specific *mixing matrix* $\mathbf{C} \in \mathbb{R}^{n \times n}$, the correlated noise at iteration t, $\hat{\mathbf{z}}_t \in \mathbb{R}^m$, can be calculated as:

$$\hat{\mathbf{z}}_t = (\mathbf{z}_t - \sum_{\tau=1}^{\min(t,\hat{b}-1)} \mathbf{C}[t,t-\tau]\hat{\mathbf{z}}_{t-\tau})/\mathbf{C}[t,t]. \quad (1)$$

Figure 1 (bottom) visualizes how $\hat{\mathbf{z}}_t$ is calculated. First, a ① *weighted average* of the $\hat{b}-1$ previous noises is performed. The result is ② subtracted from a newly-sampled Gaussian noise ($\mathbf{z}_t$) and ③ properly rescaled, which becomes the new correlated noise ($\hat{\mathbf{z}}_t$). As in DP-SGD, $\hat{\mathbf{z}}_t$ is added to the gradient, and the noisy gradient is used to update the model. At the same time, ④ $\hat{\mathbf{z}}_t$ is saved to the noise history, so that it can be used to generate future noises.

The weighting/rescaling factors at t-th iteration are defined by the t-th row of the mixing matrix $\mathbf{C}$, and the weighted averaging can be done through a *matrix-vector multiplication (GEMV)* between the stacked noise history (matrix of size $(\hat{b}-1) \times m$) and the t-th row of $\mathbf{C}$ (each row is of size n but only has $\hat{b}-1$ nonzero elements). $\mathbf{C}$ should be carefully designed to guarantee DP, and different prior works developed different designs of $\mathbf{C}$ [15, 48, 65]. When $\hat{b}=1$ and $\mathbf{C}=\mathbf{I}$ (an identity matrix), this reduces to independent Gaussian noise.

Generality and importance of correlated noise. As Figure 1 shows, correlated noise can almost serve as a drop-in replacement for independent Gaussian noise[1]. Thus, making the correlated noise generation efficient is likely to benefit a wide range of DP training algorithms that currently use independent Gaussian noise. Several recent works have demonstrated that correlated noise has theoretical [13, 55] and empirical [13–16, 48, 63–65, 79, 109] benefits over independent Gaussian noise. Google recently adopted correlated noise in its production (Gboard training [101, 113]) and has been exploring using it for larger models [63, 79], which strongly signals its practical importance. A recent 212-page report [79] summarizes the latest efforts around correlated noise. Its generality and importance motivate our study.

[1]When using correlated noise, it puts a restriction on what data sampling method can be used, but other parts of the training do not need to change.

2.2 Training of Embedding Tables

An embedding table is a trainable data structure that converts categorical features into a dense vector. It is commonly used in deep learning recommendation models (DLRMs) or large language models (LLMs). Especially in DLRMs, embedding tables are very tall and dominate the model size [38, 62, 71]. During each training iteration, only rows (entries) of the table corresponding to the present feature values of the input are used, which leads to several unique behaviors. First, the training speed grows sub-linearly with its size compared to other models, because only a tiny subset is used even when the entire table is large. Second, unused entries in each iteration have zero gradients. Still, DP training requires noise addition to these zero gradients for privacy [62, 72]. Third, only the entries accessed in each iteration contribute to the gradient calculation at that iteration. As we will show later, the first characteristic leads to a unique overhead when using correlated noises, and the latter two will be leveraged by Cocoon's optimizations (Section 4.2).

2.3 CXL and Near-memory Processing (NMP)

Compute express link (CXL) is an open industry interconnect standard based on PCIe, which allows high-speed loads and stores for memory expansion modules plugged into the PCIe slot. Memory expansion module connected through CXL, or *CXL memory*, has emerged as a way to expand memory capacity. We study the use of such CXL memory to expand the device memory capacity when the noise history is too large to be hosted on main memory.

While CXL memory provides larger memory, data access through CXL is much slower than the main memory of the CPU. Several recent works [35, 51, 53, 78, 88, 107] have proposed to put additional compute units in the CXL controller to reduce data movement through PCIe, and some have made it into (near-)real products [46, 87]. In Section 4.3, we show how such emerging *near-memory processing (NMP) CXL memory* products can accelerate Cocoon.

3 Characterization of Correlated Noise

To study the system overheads of correlated noise, we trained various models with independent Gaussian noise and correlated noise. We used a correlated noise mechanism called BandMF [15]. Our study can be generalized to other mechanisms, because other mechanisms only differ in the derivation of mixing matrix $\mathbf{C}$ (Section 2.1), and are computationally equivalent. Our study highlights that correlated noise mechanisms experience non-negligible memory (Section 3.1) and compute (Section 3.2) overheads.

For the study, we trained popular models from prior DP training literature on a dual-socket Intel Xeon Gold 6330 CPU with 256GB DRAM and 8x NVIDIA A5000 GPUs, which

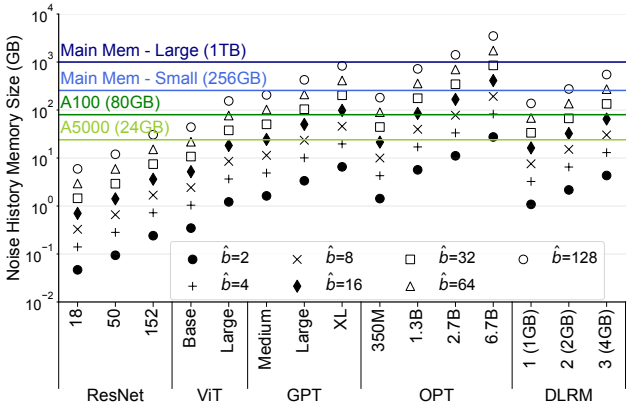

Figure 2: Noise history size of various ML models and $\hat{b}$.

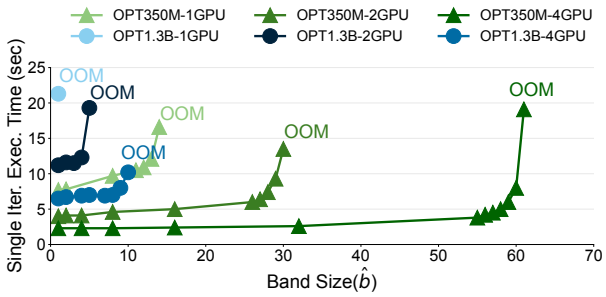

Figure 3: Training time of OPT [111] on 1–4 A5000 GPUs.

represents an economical setup of a small/mid-sized entity. The models we trained include: ResNet [41], ViT [24], LLMs (GPT [81] and OPT [111]), and DLRM [71]. Measurements were done on our custom DP training code with correlated noise support, which we built as part of our Cocoon library (Section 4). We only highlight the most interesting results.

3.1 Memory Overhead

Generating correlated noise involves storing $\hat{b}-1$ past noises, each of which is as large as the number of trainable parameters (m). This introduces several capacity and performance issues.

Capacity issue. Figure 2 summarizes the memory footprint of the noise history for various models and $\hat{b}$, along with common GPU memory and main memory (CPU DRAM) sizes. The footprint frequently exceeds the GPU/CPU memory, and the noise history must be offloaded to main memory or secondary memory (*e.g.*, CXL memory or SSD) to run the training at all in these cases. Performance implications of these fallbacks are discussed in Section 3.2. Some works [63, 79] found such offloading to be unnecessary, but this was because they had enough GPUs/TPUs, unlike our economical setup.

Takeaway 1: The noise history can become larger than the aggregate GPU/TPU memory or even the main memory.

Performance issue. Even when the entire noise history fits into the GPU, the performance can degrade if too little memory is left for training. Figure 3 shows the training latency of two OPT models [111], where different lines correspond to different models and GPU counts. It can be seen that the training time increases with $\hat{b}$ for all setups, until an out-of-memory (OOM) error is triggered. This is because if too little memory is left, training must use smaller microbatches, underutilizing the GPU [98].

Takeaway 2: Even when storing the entire noise on the GPU is possible, it may degrade the training performance.

Why not re-generate noises? Instead of storing past noises, prior work [48] considered only storing the seed and re-generating noises on every iteration. However, doing so requires re-generating all the noises from the beginning $(\hat{\mathbf{z}}_1, \ldots, \hat{\mathbf{z}}_t)$ and not just the past $\hat{b}-1$ noises, because each noise generation recursively requires its past $\hat{b}-1$ noises. This incurs $O(n^2)$ overhead for n training iterations, which becomes too large unless n is very small. Another prior work [79] similarly observed that this approach scales poorly with n.

3.2 Compute Overhead

The weighted averaging of prior noises (GEMV between the noise history and the mixing vector) also incurs a computational overhead. We mainly consider economical setups where part of the noise history is stored in main/secondary memory.

For the parts hosted outside the GPU, we studied two options for processing them: (1) *GPU-GEMV* performs GEMV only on the GPU. While GEMV is fast on a GPU, this design requires additional data transfer from the main/secondary memory to GPU through the slow PCIe bus. (2) *CPU-GEMV* performs GEMV on the CPU for the subset of the noise history stored in main/secondary memory, and only sends the result to the GPU. While CPU's GEMV is slower, this design enjoys the higher bandwidth between the CPU and main memory, compared to the PCIe bus. Also, CPU-side GEMV can happen *in parallel* with GPU-side training and can be partially or completely hidden.

Overheads of DLRM. Correlated noises incur a unique overhead on DLRMs due to their large embedding tables (Section 2.2). Figure 4 shows the training time of three DLRMs with different embedding dimensions (DLRM-1/2/3). We only characterized a single-GPU setup because the single-iteration latency was too small (near 100ms) to make data parallel training effective. GPU-GEMV's latency consists of the GPU-side training and GEMV ("Train (GPU)"), and data transfer from the main memory ("Transfer (Main Mem)"). CPU-GEMV's latency is governed by the slower of the two parallel tasks shown in side-by-side bars: the GPU-side training, and the CPU-side GEMV ("GEMV (CPU)") plus the

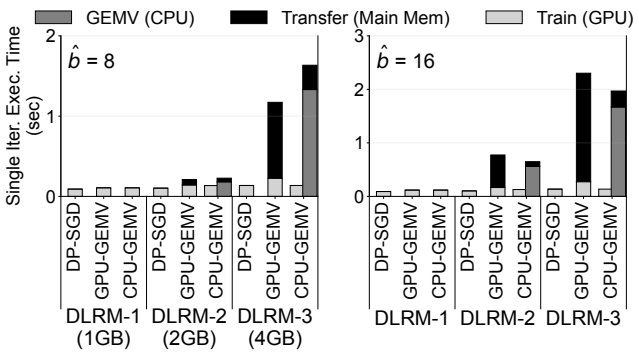

Figure 4: Training time breakdown for DLRM.

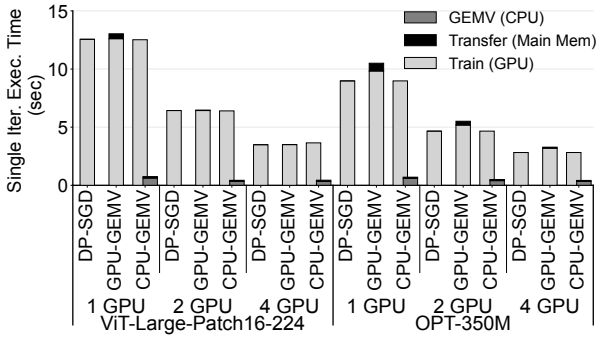

Figure 5: Training time breakdown when the noise history entirely fits into main memory.

transfer of the GEMV result to the GPU ("Transfer (Main Mem)").

In general, GPU-GEMV is better when the model and/or $\hat{b}$ is small, and CPU-GEMV outperforms when they are larger. However, except for uninteresting cases where the entire noise history fits into GPU (DLRM-1), both baselines still incurred non-negligible slowdown. Even the better baseline between the two incurred **2.03–8.62**× ($\hat{b}$=8) and **6.28–14.49**× ($\hat{b}$=16) slowdown. This was due to the noise-related overheads growing much more linearly with m compared to the training time, which grows sub-linearly with m (Section 2.2).

Takeaway 3: For DLRM, correlated noises incur significant slowdown compared to using independent noises.

Overheads of non-DLRM. Models other than DLRM experienced similar trends: the exact type mattered less, and their absolute size (m) mattered more. Specifically, the behavior depended on whether the noise history overflowed the main memory and involved secondary memory.

Figure 5 shows the result from training ViT-L and OPT-350M with $\hat{b}$=16. In these setups, the entire noise fits into the main memory. The slowdown was only 0.6–18.2% for GPU-GEMV, and there was negligible slowdown for CPU-GEMV. Other small models (CNNs, ViTs, and sub-billion LLMs) showed similar behaviors, which we omit.

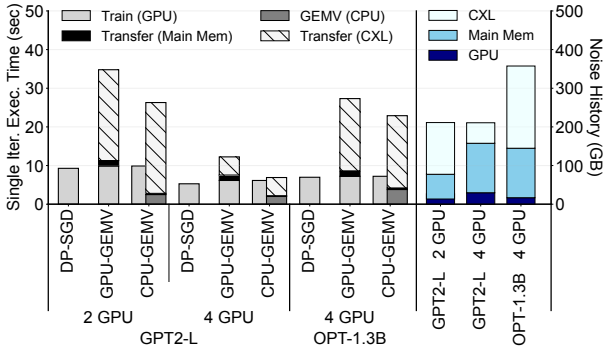

Figure 6: Training time breakdown with noise history partially stored in CXL memory.

When the model size and $\hat{b}$ get larger, noise history must be partially offloaded to secondary memory which incurs a non-negligible slowdown. We only focused on CXL memory due to its relatively better read speed. Slowdown will be higher for slower alternatives like SSD. Figure 6 shows the training time breakdown (left), along with the information on where different portions of the noise history are stored (right). When training GPT2-L with 2 GPUs, 63% of the noise history was placed in CXL memory, leading to **2.83–3.75**× slowdown. When more GPUs are added (GPT2-L with 4 GPUs), some noises could move from CXL memory to GPU memory, improving the slowdown to 1.30–2.31×. With a larger OPT-1.3B, the slowdown again increases to **3.28–3.91**×.

Takeaway 4: For non-DLRM models, the overhead is small if the noise history can fit into main memory. When the noise history overflows main memory, data traffic to secondary memory adds significant latency.

When CPU is highly utilized. We additionally note that CPU-GEMV may incur a larger slowdown when the CPU suffers from resource contention. As an illustration, we trained OPT-350M with $\hat{b} = 64$ on 4 GPUs, and varied the number of cores used by the CPU-side GEMV. We observed that the training starts to slow down if not enough CPU cores can be dedicated to GEMV. With only 4–7% of the cores, the training slowed down by 1.52–2.77×.

Takeaway 5: CPU-GEMV may incur additional overhead when the CPU is highly congested.

4 The Cocoon System

We introduce Cocoon, a framework for efficient DP training with correlated noise. Cocoon stores and processes large noise history across GPU, CPU, and CXL memory device with NMP to maximize performance on an economical setup (Figure 7). For large embedding tables of DLRM, Cocoon provides a dedicated optimization that pre-computes and stores correlated noises in a coalesced format (Section 4.2). When

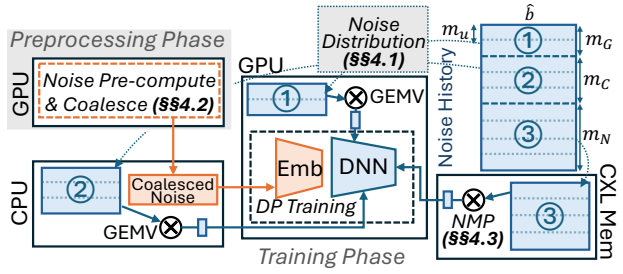

Figure 7: Overview of Cocoon. Cocoon distributes the large noise history across ① GPU, ② CPU, and ③ CXL memory, and performs GEMV near each memory unit to minimize data movement (Section 4.1). Cocoon introduces a preprocessing phase for large embedding tables (Section 4.2), and GEMV inside the CXL memory is done through NMP (Section 4.3).

the CXL memory with NMP exists, Cocoon offloads part of the GEMV to the NMP device to further improve performance (Section 4.3). Cocoon is built on top of Amazon's fastDP [8] and tested on a node with multiple GPUs and an industry prototype CXL NMP device. Cocoon can leverage other NMP devices as long as they support GEMV [46, 87].

Threat model. DP training methods provide guarantees against an adversary who can access (1) the final model and (2) all the intermediate gradients. Cocoon assumes the same adversary except for its embedding table optimization (Section 4.2), where it assumes a weaker-but-practical adversary who can access only the final model and not the intermediate gradients. Assuming an attacker with full knowledge about the intermediate gradients is an artifact of DP-SGD's underlying math and is often considered excessively strong [70]. The weaker-but-practical adversary we assume for the embedding table optimization reflects the most common real-world threat, such as attackers attempting to extract training data from ML services via APIs [68] or through open-sourced weights [9, 10], where intermediate gradients are unavailable. Many other works adopt this same practical adversary model [17, 27, 62, 69, 70, 72, 99].

4.1 Distributing Noise with Profiling

Cocoon splits the $\hat{b} \times m$ noise history in its parameter (m) dimension and distributes slices of size $\hat{b} \times m_G$, $\hat{b} \times m_C$, and $\hat{b} \times m_N$ to GPU, CPU, and NMP device, respectively ($m_G + m_C + m_N = m$). The goal is to minimize the overall training latency while ensuring none of the devices experience an out-of-memory error. Cocoon achieves this through simple profiling, whose cost can be amortized across multiple training iterations.

The goal is solve the following optimization problem:

$$\min_{m_G, m_C, m_N} \quad \max\Big(\mathrm{Lat}_{\text{train-}G} + \mathrm{Lat}_{\text{gemv-}G}(m_G, \hat{b}), \mathrm{Lat}_{\text{gemv-}C}(m_C, \hat{b}), \mathrm{Lat}_{\text{gemv-}N}(m_N, \hat{b})\Big)$$

$$\text{s.t.} \quad m_G + m_C + m_N = m,$$
$$Mem_{\text{total-}G} \geq Mem_{\text{train-}G} + \mathrm{Size}(m_G \times \hat{b}) + Buf,$$
$$Mem_{\text{total-}C} \geq Mem_{\text{train-}C} + \mathrm{Size}(m_C \times \hat{b}),$$
$$Mem_{\text{total-}N} \geq \mathrm{Size}(m_N \times \hat{b}),$$

where $\mathrm{Lat}_{\text{train-}G}$ refers to the single training iteration latency on the GPU, $\mathrm{Lat}_{\text{gemv-}X}(m_X, \hat{b}), X \in \{G, C, N\}$ is the GEMV latency on GPU (G), CPU (C), and NMP (N) with the given noise history, $Mem_{\text{total-}X}, X \in \{G, C, N\}$ refers to each device's total memory capacity, and $Mem_{\text{train-}X}, X \in \{G, C\}$ is the peak memory usage of GPU and CPU for training (NMP is not used for training). Buf is a space reserved in GPU for receiving the GEMV result from CPU and NMP plus avoiding out-of-memory (OOM) due to noise in the estimation, and is a design parameter that depends on the implementation. In short, Cocoon minimizes the overall latency, which is bottlenecked by the slowest among the three devices (GPU training + GEMV, CPU GEMV, and NMP GEMV), while ensuring no out-of-memory.

Finding an optimal split requires accurately estimating each term. $\mathrm{Size}(m_X \times \hat{b})$ and $Mem_{\text{total-}X}$ can be known exactly offline, and $\mathrm{Lat}_{\text{train-}G}$ and $Mem_{\text{train-}X}$ can be upper-bounded by running a few training iterations. $\mathrm{Lat}_{\text{gemv-}X}$ cannot be easily estimated because the GEMV latency is not necessarily linear with the matrix size, especially when the matrix is small. We simplify the optimization goal by defining a minimum unit of allocation, m_u, that perfectly divides m, and choose m_G, m_C, and m_N to be a multiple of m_u. This simplifies the GEMV latency estimation because if m_u is large enough, GEMV becomes memory-bottlenecked and almost linearly scales with the number of m_u processed in each device, *i.e.*, $\mathrm{Lat}_{\text{gemv-}X}(m_X, \hat{b}) \approx \frac{m_X}{m_u} \times \mathrm{Lat}_{\text{gemv-}X}(m_u, \hat{b})$. Measuring $\mathrm{Lat}_{\text{gemv-}X}(m_u, \hat{b})$ for $X \in \{G, C, N\}$ once and plugging the approximation back in the optimization objective gives us a linear objective that can be solved to get m_G, m_C, and m_N. Our implementation also receives GEMV results from CPU and NMP devices to the GPU in m_u-granularity, which means that Buf should be at least $2m_u$ to temporarily hold GEMV results sent from CPU/NMP.

As an example, consider training OPT-1.3B with $\hat{b}$=64 on 4×A5000 GPUs (24GB each, $Mem_{\text{total-}G}$=96GB across 4 GPUs), 128GB DRAM ($Mem_{\text{total-}C}$=128GB), and a 256GB NMP device ($Mem_{\text{total-}N}$=256GB). The noise of the $m \approx$1.4B model is sharded across the GPUs, CPU, and NMP memory. Training takes about 72GB across 4 GPUs ($Mem_{\text{train-}G}$=72GB) and 22GB of CPU DRAM

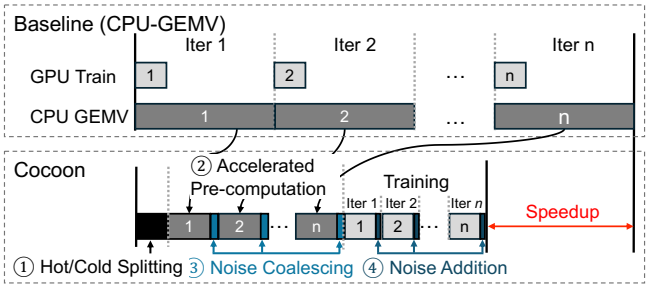

Figure 8: Cocoon's embedding table optimization. Cocoon replaces the per-iteration CPU-GEMV bottleneck (top) with accelerated noise pre-computation (bottom).

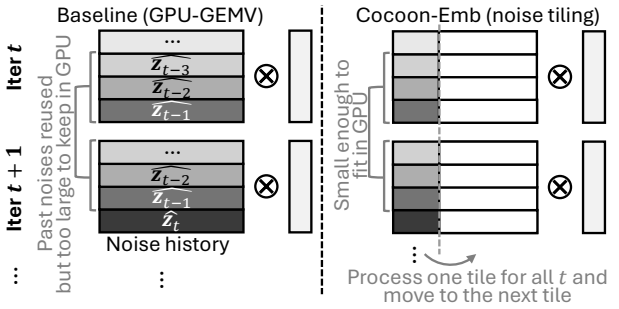

Figure 9: Cocoon's noise tiling for embedding tables. Cocoon (right) tiles the noise history to fit within GPU memory during pre-computation, avoiding the memory spilling required by the baseline (left) when data exceeds GPU capacity.

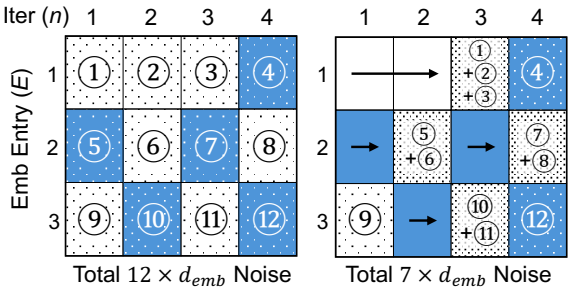

Figure 10: Noise coalescing (d_{emb}: embedding dimension). Cocoon (right) reduces storage overhead (12 to 7 units) by aggregating noise until an entry is accessed (filled blue), replacing the per-iteration baseline (left).

($Mem_{\text{train-}C}$=22GB). If we heuristically set m_G=m_u and Buf=1.5GB per GPU, solving the above optimization problem gives m_u=m_G ≈71M, meaning that m_u divides the parameter m into 20 equal slices. GPUs hold one slice across 4 GPUs, CPU holds 5, and NMP can hold the remaining 14. Varying Buf had little effect on the overall performance, as the GPU-side overhead is mostly due to training, which is independent of Buf. Thus, a reasonable value that would not cause OOM suffices.

4.2 Optimizations for Embedding Tables

Figure 8 summarizes Cocoon's optimization for embedding tables. For embedding tables, Cocoon ① splits the table entries by access frequency into either hot or cold, ② efficiently pre-computes all the correlated noises to be used for the cold entries, ③ coalesces and stores the noises in a compact format, and ④ runs training using the pre-computed noises.

Noise pre-computing. Instead of performing GEMV on each iteration (Figure 8, top), Cocoon *pre-computes* correlated noises for all the future iterations of the embedding tables before the actual training (Figure 8, bottom). The pre-computed results cannot be reused across jobs for privacy, so pre-computing must be done efficiently to not bottleneck the entire training. While pre-computing performs the same amount of GEMV as the baselines, it can be done much faster due to two benefits. Compared to CPU-GEMV, pre-computing can use the faster GPU, which idles before the training starts. Compared to GPU-GEMV, Cocoon maximizes data reuse inside the GPU and minimizes data transfer through PCIe with *noise tiling*.

Figure 9 explains noise tiling. Between consecutive iterations, the most recently updated $\hat{b}-2$ out of $\hat{b}-1$ rows of the noise history are reused (Figure 9, left). However, the reused data ($(\hat{b}-2)\times m$) is often too large to be kept inside the GPU, and GPU-GEMV must spill it to main memory between iterations. Instead, Cocoon splits the noise history into smaller tiles and performs noise pre-computing for each tile, while choosing the tile size so that the reused data always fits inside the GPU (Figure 9, right). After generating all future noises from one tile, Cocoon moves on to the next tile. Noise tiling is only possible during pre-computing, where we can choose to compute noises for all future iterations for one tile before computing the next tile. GPU-GEMV cannot benefit from noise tiling, as it must immediately compute the entire noise (*i.e.*, for all the tiles) before proceeding to the next iteration.

Noise coalescing. Without any optimization, the size of the entire pre-computed noises to be used over n training iterations is $m \times n$, which is too large to store. Cocoon uses a technique called *noise coalescing* to solve this issue. As discussed in Section 2.2, only a few entries in embedding tables are used at each iteration, and unused entries do not contribute to that iteration's gradient. Thus, we do not need to accurately update (*i.e.*, add proper noise) all the entries in every iteration. Instead, it is sufficient to add an equivalent, *aggregated* or *coalesced* noises, as long as they are added before an entry is accessed.

Figure 10 shows a toy example of an embedding table with three entries trained over four iterations. Colored boxes indicate in which iteration each entry is accessed, and dotted

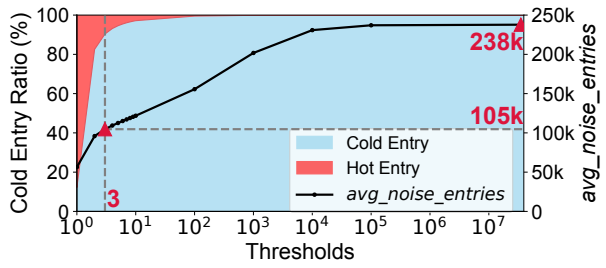

Figure 11: Hot/Cold threshold analysis. Lowering the threshold to 3 reduces *avg_noise_entries* (memory overhead) by 2.3× compared to not using hot/cold splitting.

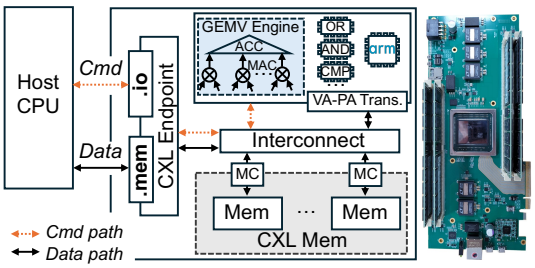

Figure 12: NMP prototype. FPGA-based CXL board featuring an integrated GEMV engine for near-memory acceleration.

numbered boxes indicate when noises are added to each entry's gradient. For example, entry 1 is only accessed in the 4th iteration. Without coalescing (Figure 10, left), noises must be added to all the entries in all the iterations. Instead, noise coalescing (Figure 10, right) only adds an equivalent, aggregated noise right before each entry is accessed or training ends. For example, no noise is added to entry 1 in iterations 1–2, and an equivalent noise (①+②+③) is added at the end of iteration 3. During pre-computing, Cocoon merges and only stores the aggregated noise (*e.g.*, stores ①+②+③ instead of storing three noises separately). In our toy example, only 7 (instead of 12) aggregated noises need to be stored. The benefit is much larger for real models.

Implementing noise coalescing requires knowing exactly when each entry will be accessed during training. This can be known by using a random batch sampler with the same random seed both during pre-computing and training. Cocoon stores the coalesced noise (Figure 10, right) in a compressed sparse column (CSC) format. Cocoon does not pre-compute noises for the rest of the model (*e.g.*, MLP layers) and simply uses GPU-GEMV/CPU-GEMV as they are small.

Hot/cold splitting. The size of the coalesced noise is directly proportional to *avg_noise_entries*, the average number of entries that need noise to be added in each iteration (*avg_noise_entries*=$\frac{7}{4}$ in our example), which is correlated with the average access frequency of each entry. Typically, most entries are scarcely accessed, but a few "hot" entries [71] drive up *avg_noise_entries*. To reduce *avg_noise_entries*, Cocoon classifies each entry as either "hot" or "cold" and only pre-computes and coalesces noise for cold entries. Hot entries, just like MLP layers, rely on CPU-GEMV/GPU-GEMV. As there are usually only a few hot entries [71], the additional overhead is moderate. We use a simple threshold to classify entries as hot or cold based on their access frequency.

Figure 11 illustrates the relationship between the threshold and the *avg_noise_entries* for Criteo Kaggle [47] dataset. The dataset has 39 million samples, and the model used for this dataset has 33 million unique embedding table entries. A lower threshold labels more entries as hot. For example, using 3 as a threshold labels 7% of the entries as hot, lowering *avg_noise_entries* from 238K to 105K (2.3× memory reduction), compared to not using hot/cold splitting. We empirically choose the threshold to balance the memory overhead and additional GEMV overhead.

4.3 Leveraging Near-Memory Processing

When the noise history is too large and must be partially stored in CXL memory, Cocoon leverages a near-memory processing (NMP) device if available to greatly reduce the data movement overhead. In particular, we demonstrate the benefit by adopting an FPGA-based industry prototype CXL memory device with NMP capabilities, provided through our industry partner. The benefit of adopting an NMP device will become larger for cases where the CPU is heavily utilized.

NMP device overview. Figure 12 shows the prototype device from our industry partner. The prototype is implemented as an add-in card (AIC)-type custom board that integrates a CXL controller and an NMP engine into a Xilinx Versal (VP1502) FPGA (Figure 12, right). The board is equipped with DDR4 mounted in DIMM slots. The device receives commands from the CPU via CXL.io and data via CXL.mem, and can act either as normal CXL memory or perform GEMV with data in its memory. The hardware is equipped with MAC and ACC (accumulation) hardware IP, which Cocoon uses to run the desired GEMV. The prototype additionally contains the complete set of basic logic blocks required to compose SQL and ML operators, which Cocoon did not use. The hardware performs a simple virtual-to-physical address translation through saving and looking up memory offset for each matrix and using it to locate them in CXL memory. When there are multiple jobs running on the host, their commands are queued and processed in a first-come-first-served fashion.

Integration to Cocoon. Figure 13 illustrates how correlated noise generation is partially offloaded to the NMP device. The $\hat{b}-1$ past noises have the size of a $(\hat{b}-1)\times m$ noise history matrix. Noise used at step t is stored at the $(t \pmod{(\hat{b}-1)})$-th row, updating the rows in a circular manner (*i.e.,* storing

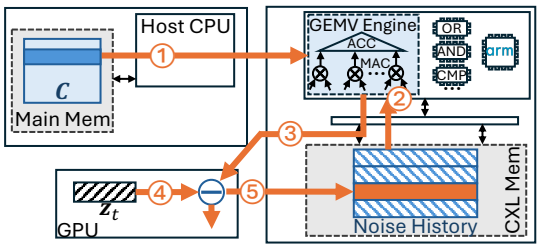

Figure 13: Correlated noise generation with NMP. CPU offloads GEMV to NMP (①-③) with Gaussian noise generation (④) to produce correlated noise that updates the noise history and model (⑤).

noise history in a ring buffer). At each iteration, the CPU ① passes an appropriate mixing vector to the NMP device, ② initiates GEMV between the mixing vector and the noise history, and ③ the GEMV result sent to GPU. ④ the GPU generates Gaussian noise (noise generation can be done by others as well for perfect parallelism, but we use the GPU due to its high throughput). Finally, ⑤ the generated noise updates the noise history and model. These process can be done in parallel while the GPU performs training. Cocoon pre-normalizes the mixing vector ($\mathbf{C}[t,t-\tau]$ in Equation 1) and the Gaussian noise ($\mathbf{z}_t$) by the (t,t)-th entry of $\mathbf{C}$ prior to GEMV to avoid later scaling. As the noise history table is updated in a circular fashion, the mixing vector must also be properly reordered, which is done statically before training.

Cocoon sends the mixing vector once to the NMP device, stores it in an internal buffer, and reuses it m times. For reasonably large models, this amortizes the vector transfer cost. The GEMV operation is implemented with MAC and ACC (accumulation) hardware IP, and the memory bandwidth is maximized through memory-channel interleaving. The prototype device we used achieved 47.9GB/s peak GEMV throughput. The performance may improve in the future with faster DRAM technologies (*e.g.*, DDR5). While the current implementation detail is specific to the prototype we used, we believe similar integration will be possible with other NMP devices [53, 78, 88], as long as they allow GEMV. Coherence is controlled by flushing at the end of every iteration.

5 Evaluation

5.1 Experimental Setup

Hardware. Most of our evaluation was done on a dual-socket Intel Xeon Gold 6330 CPU with 256GB DRAM and 8 NVIDIA RTX A5000 GPUs. When needed, we ran additional experiments on a more powerful dual-socket AMD EPYC 7763 CPU server with 1TB of DRAM and 8 NVIDIA A100 (80GB) GPUs. We additionally used the industry prototype NMP device. Unless noted otherwise, DLRMs were trained on a single GPU without NMP, and LLMs were trained on four GPUs with NMP. CPU-side GEMV used Intel MKL (Intel) and OpenBLAS (AMD) in Pytorch (v.2.4.0).

Due to its early-stage engineering, our NMP prototype exhibited a suboptimal memcpy throughput of 5–7GB/s. This is significantly lower than what a typical CXL memory can achieve (32GB/s for gen5 8x). To *emulate* the end-to-end performance of a mature system, we separately measured the NMP device's overhead and analytically scaled the memcpy overhead assuming a 22GB/s memcpy throughput, which was measured from a similar in-house CXL memory. During training, we run a separate process that adds the estimated NMP device overhead to the training latency, while the rest of the CPU/GPU runs training end-to-end. Although the end-to-end performance is emulated when NMP is involved, except for the memcpy performance, all the overheads were from real measurements. When NMP is not involved, our results are from direct end-to-end measurement. We assume all resources (CPU cores, PCIe bandwidth, CXL memory capacity, *etc.*) are divided evenly across GPUs.

Datasets/models. For DLRM, we used the Criteo Kaggle dataset [47] and the architecture from [71]. We additionally generated synthetic datasets to study the impact of varying the number of embedding entries and data skewness. Synthetic datasets were generated by first ensuring all embedding entries are accessed at least once, and generating the remainder such that the entry accesses follow a Zipfian distribution with a varying α. For non-DLRMs, we used ImageNet [22]-sized dummy data and E2E dataset [73], although the datasets do not impact performance, and architectures from TorchVision/HuggingFace.

Hyperparameters. The training batch size B and band size $\hat{b}$ crucially influence the correlated noise overheads. We used the following values from the literature: $B = 1024$ for vision and language models [6, 8], $B = 65536$ for DLRMs [20], and $\hat{b}$=2–256 [15, 29, 64]. The impact of these hyperparameters is additionally evaluated in the sensitivity studies.

5.2 Performance Improvements: DLRM

5.2.1 End-to-End Training Time

Figure 14 compares the DLRM training time of Cocoon with the baselines. All the bars are normalized to the training time of DP-SGD. For $\hat{b} > 8$, Cocoon consistently outperforms the baselines. Compared to the better baseline, Cocoon improves the overall training time by **2.46–4.87**$\times$ for $\hat{b} > 8$. The speedup generally increases with $\hat{b}$ (2.46$\times$ for $\hat{b} = 16$ and 4.87$\times$ for $\hat{b} = 64$). The breakdown shows that pre-computing dominates the Cocoon-Emb latency.

When $\hat{b} < 8$, the entire noise history fits into the GPU. For these *trivial cases*, the training time of both baselines becomes identical (we only show GPU-GEMV) and close to DP-SGD, and our optimization simply adds unnecessary overheads.

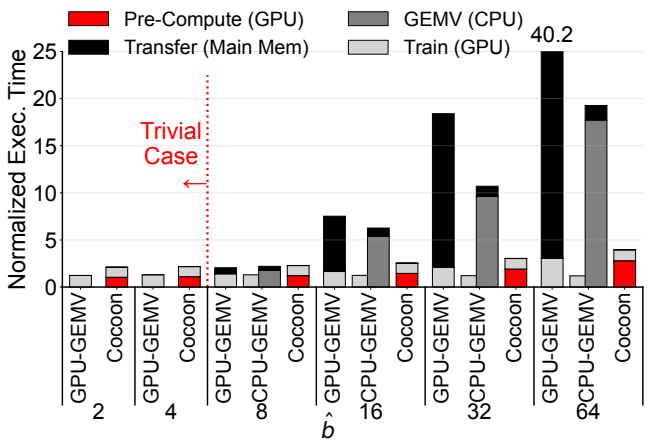

Figure 14: Normalized training time of Cocoon with DLRM. When the entire noise history fits into GPU memory (trivial case; $\hat{b}$=2–4), our optimization can be turned off.

Such trivial cases can be easily detected by comparing the noise history size with the GPU memory capacity, and our optimization can be turned off.

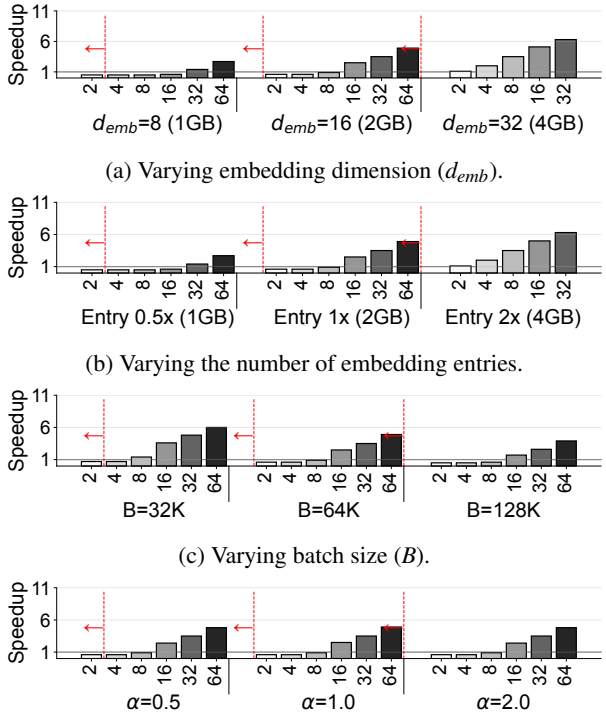
5.2.2 Sensitivity Study

Figure 15 shows the speedup of Cocoon over the better baseline between CPU-GEMV and GPU-GEMV, while varying different dimensions of the model and dataset. Again, bars located at the left side of the red vertical line are trivial cases, and our embedding table optimizations can be turned off.

Model size. Figures 15a and 15b show the speedup of Cocoon while varying the model size, adjusting the embedding dimension (d_{emb}) or the number of embedding entries. The speedup improves with the model size: if we compare the bars at $\hat{b} = 32$, the speedup improves from 3.51× to **6.27-6.35**× when the size is doubled, and reduced to 1.37× when halved. This is because larger models must offload more noise history to main memory and penalize the baselines more severely. Cocoon will become more effective as models grow.

Batch size. Figure 15c shows that the speedup decreases with an increasing batch size. When considering $\hat{b} = 32$, the peak speedup increased from 3.51× with $B = 64K$ to **4.79**× with $B = 32K$, and reduced to 2.57× with $B = 128K$. This is because the correlated noise generation overhead (which Cocoon optimizes) stays the same regardless of the batch size, while the training latency (which Cocoon cannot optimize) becomes larger with bigger B. While not shown, Doubling the entries accessed per sample (*i.e.*, pooling factor [71]) has nearly the same effect as doubling the batch size.

Skewness. Figure 15d shows the speedup of Cocoon when the access frequency of each embedding entry experiences different skewness. The skewness was controlled by varying α of the Zipfian distribution of our synthetic dataset. Interestingly, the skewness had only a minor effect on training time.



(a) Varying embedding dimension (d_{emb}).

(b) Varying the number of embedding entries.

(c) Varying batch size (B).

(d) Varying skewness (larger Zipf α means more skewed).

Figure 15: Speedup of Cocoon under various models and datasets. Numbers below each bar indicates $\hat{b}$.

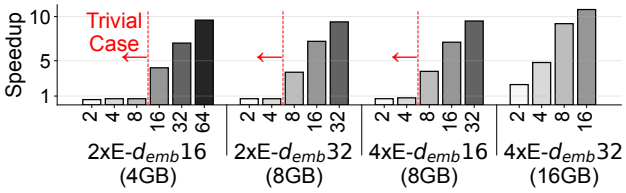


Figure 16: Speedup of Cocoon with various model sizes on an A100 GPU. Numbers below each bar indicates $\hat{b}$.

We will later show that skewness is a critical factor in the memory footprint in Section 5.3.

Hardware. Figure 16 shows the speedup of Cocoon on more powerful A100 GPUs. As A100 has more memory, we used larger models (4–16GB) with a larger number of embedding entries (2–4× larger, denoted as 2×E/4×E) and bigger embedding dimensions (d_{emb}=16–32). Cocoon achieved a speedup of **2.33–10.82**× for non-trivial cases, which is generally larger than the results on the A5000. Cocoon's speedup is larger on A100 because its computation (GPU-side GEMV and training) is much faster than on the A5000, but overheads related to correlated noises (GPU-main memory data transfer, CPU-side GEMV), which Cocoon optimizes, are similar.

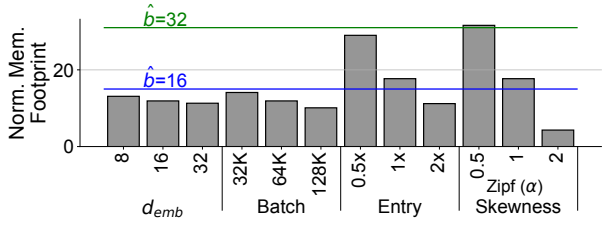

Figure 17: Memory footprint of coalesced noise normalized by the model size. Memory footprint of a noise history without pre-computing for different $\hat{b}$ are in horizontal lines.

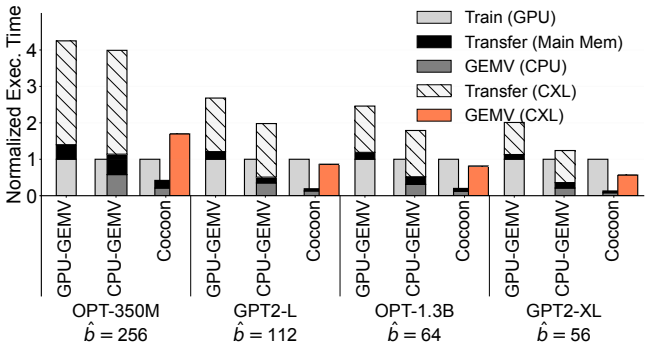

Figure 18: End-to-end normalized training time of Cocoon +NMP and the baselines. Model sizes are in an ascending order. $\hat{b}$ is chosen, so that over 200GB of the noise history is offloaded to CXL memory.

5.3 Memory Overhead: DLRM

5.3.1 Overall Memory Overhead

Unlike CPU-GEMV and GPU-GEMV, which incur a fixed $O(\hat{b}m)$ memory overhead, the overhead of Cocoon with its embedding table optimization depends on the effectiveness of its noise coalescing. In the worst case, Cocoon must hold all the pre-computed noises ($O(nm)$ with n iterations), which can be much larger than that of CPU-GEMV/GPU-GEMV (usually, $n \gg \hat{b}$). However, the actual memory overhead is much less thanks to noise coalescing.

Figure 17 evaluates the memory footprint of the coalesced noise of Cocoon while varying the embedding dimension (d_{emb}), batch size, number of embedding entries, and entry access distribution skewness. The bars are normalized to the model size m. For this figure, we used $n = 1800$ (three epochs using Criteo Kaggle [47] dataset with $B = 64K$), so the worst-case overhead is $1800\times m$. However, the actual memory overhead is only 4.3–31.6×, which is *less* than the memory overhead of the baselines in many cases (shown in horizontal lines for $\hat{b}$=16 and $\hat{b}$=32). The memory overhead of Cocoon is independent of $\hat{b}$ and only depends on the entry access pattern, while the overheads of the baselines grow linearly with $\hat{b}$.

5.3.2 Sensitivity Study

Figure 17 shows how different models and datasets affect the efficacy of noise coalescing. It can be seen that the efficacy decreases with reducing d_{emb} and batch size, but the effect is small. Conversely, decreasing the number of embedding entries and using datasets with less skewed patterns significantly increases the memory overhead. This meets our expectation because noise coalescing works better when batched samples are mostly accessing the same entries, which leads to lower *avg_noise_entries*. Decreasing the number of entries has a similar effect to reduced skewness, because the accesses are hashed into the remaining entries.

Table 1: Hardware cost and power estimate (GPT2-XL, $\hat{b}$=64).

1 HW Unit: 4×NIVIDA A5000 (4×$2K), 1× Intel Xeon Gold 6330 (1×$2.1K), 8×16GB DDR4 3200MHz (8×$0.15K)			
	GPU-Only	CPU-GEMV	**Cocoon**
HW Unit	10	3	1 + NMP [78]
Cost ($)	113K	33.9K	18.3K
Peak Power (KW)	11.6	3.5	1.2
Normalized Throughput	1	0.33	0.13

5.4 Performance Improvement with NMP

5.4.1 End-to-End Training Time

Figure 18 plots the training time and breakdown for the baselines and Cocoon with the NMP hardware prototype, when the models are large enough to involve CXL memory. Cocoon has three bars side-by-side, indicating the GPU-side training, CPU-side GEMV, and the GEMV happening inside the NMP device, all happening in parallel. $\hat{b}$ values are chosen for each model to ensure over 200GB of the noise history is offloaded to CXL memory, to avoid trivial, uninteresting setups.

Figure 18 shows that Cocoon consistently outperforms the baselines, achieving **1.23–2.32**× speedup compared to the better baseline. Cocoon achieves high speedup by eliminating the large data transfer overhead between the CXL memory and CPU/GPU ("Transfer (CXL)"), while incurring a moderate GEMV overhead inside the CXL controller ("GEMV (CXL)"). When the GEMV overhead of Cocoon is less than the training time and can be completely hidden (GPT2-L, OPT-1.3B, GPT2-XL), training becomes the critical path. Our noise distribution strategy minimizes the overall latency, trying to put the minimum noise history on the bottlenecked device.

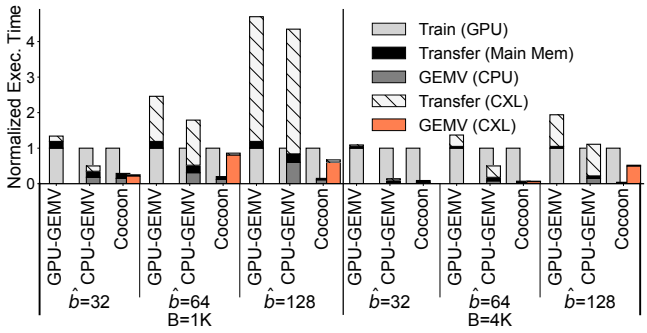

Figure 19: End-to-end normalized training time of Cocoon +NMP and the baselines with OPT-1.3B. $\hat{b} = 128$ number assumes a hypothetical CXL device with an expanded memory capacity, as it does not fit into our current CXL prototype.

5.4.2 Power and Cost

Table 1 compares the estimated hardware cost and peak power of Cocoon with the NMP device against two alternative setups (GPU-Only, CPU-GEMV), which do not involve CXL memory and instead scale out the GPU (GPU-Only) or CPU (CPU-GEMV) to hold the large noise history. GPU-Only represents prior works' setups [63, 79] where enough GPUs hold the entire noise history. We assume GPT2-XL training with $\hat{b}$=64 (∼413GB of noise history). As there can be many different ways to scale out, we simplify the estimation by considering our current single-socket configuration (4xA5000 + 1xIntel Xeon Gold + 128GB memory) as one hardware unit, and estimating how many such units are needed to support noise generation. As our prototype NMP device does not have a public power/cost number, we use numbers from prior work that used a similar device [78]. The device from [78] is more powerful than our prototype, so the power/cost numbers are likely to be an *upper bound*. We do not model the extra cost (*e.g.*, network, power supply) of scaling out beyond a single node. All of these simplistic estimations *favor other baselines*, and Cocoon's actual benefit is likely to be higher.

Table 1 shows that Cocoon can realize training with much less power and hardware cost. This is because instead of using expensive GPU/CPU memory, Cocoon can use CXL NMP memory to partially host and process noise history, which is expected to be much cheaper and lower power than CPU/GPU [78]. However, as the throughput also increases with the hardware units, the baselines also achieve better throughput. If you compare the ratio between the normalized throughput numbers and the cost/power, Cocoon is similar to CPU-GEMV, while being much more cost/power-efficient than GPU-Only. This is because GPU-GEMV introduces too many GPUs, and GPUs can become underutilized. The result indicates that scaling out CPU/GPU is better when high throughput is the main goal, while Cocoon with NMP can be useful if one has a limit on the power/cost budget.

5.4.3 Sensitivity Study

Model size. Figure 18 also shows that smaller models (models to the left) achieve more speedup than larger models (models to the right), when the noise history size inside the CXL memory is similar. This is because the training time ultimately becomes the major bottleneck and limits achievable speedup in larger models.

Band size. Figure 19 plots the end-to-end training time and breakdown for OPT-1.3B while varying $\hat{b}$. When using $\hat{b} = 128$, the noise history is too large to fit into our CXL memory, and we cannot currently run it on our CXL prototype. For $\hat{b} = 128$, we provide an analytical projection assuming a hypothetical future device with expanded memory capacity, but otherwise identical characteristics (GEMV throughput, interconnect bandwidth, *etc.*). This additional datapoint shows how the idea can scale to larger CXL memory devices in the future to support even larger models and band sizes. When $\hat{b}$ is small (*e.g.*, $\hat{b}$=32), Cocoon and CPU-GEMV both perform similarly to DP-SGD, because the training time dominates and all the other overheads are hidden. With larger $\hat{b}$, both the baseline and Cocoon start to incur slowdown, and Cocoon outperforms the best baseline by 2.26×.

Batch size. Figure 19 shows that the speedup decreases when we increase the batch size from B=1K to B=4K. This is because the training time increases with larger batch sizes, and the rest of the overheads can be hidden behind this increased training time. With B=4K, Cocoon showed speedup over the best baseline only when $\hat{b}$=64; otherwise, both Cocoon and the baseline performed on-par. The result indicates that Cocoon's benefit will decrease when using larger batches, but would still show speedup when $\hat{b}$ is large enough.

5.5 Performance Improvement: DLRM+NMP

Our current evaluation only covers the use of NMP with LLMs, not DLRMs. This is because our NMP prototype's limited GEMV throughput was insufficient to benefit DLRM, whose single-iteration latency was on the order of hundreds of milliseconds. Currently, all the GEMV for DLRM (during both pre-compute and actual training) is done on the GPU to operate near this timescale, as detailed in Section 4.2. However, DLRM can also benefit from NMP if its GEMV throughput improves in the future. For example, [78] claimed that building an NMP device with TB/s of internal bandwidth is possible. If such a high bandwidth is indeed possible, we can use the NMP device to accelerate pre-computing of the noise history for the embedding tables. If we assume the throughput from [78], our analytical projection shows that DLRM training would be accelerated by an additional **2.4**×.

6 Related Work

DP-SGD for large models. In the earlier days of DP training research, it was thought that DP training only works well for small models [21]. Recently, many studies have shown that DP training can work well for larger foundation models [4, 7, 8, 11, 19, 40, 43, 61, 64, 98, 104, 105, 112] and DLRMs [18, 20, 23, 30, 62, 72] as well. Google recently released an LLM that was fully trained from scratch with DP [89].

System optimizations for DP training. Several works studied how DP-SGD can be made faster through optimizing the software [6, 8, 58, 95] and hardware [75]. These works mainly focused on efficiently calculating the per-example gradient and are orthogonal to this work. There are also works that studied how to accelerate DP-SGD for DLRMs [30, 62, 72]. LazyDP [62], the closest to our work, also leveraged the fact that one can defer adding noise until an entry is accessed and add an equivalent, aggregated noise. However, [62] relies on the fact that the sum of independent Gaussians is also a Gaussian, and it cannot be extended to (non-independent) correlated noises. Our optimization for DLRM is entirely different from LazyDP. The others [30, 72] modify the DP algorithm itself, affecting privacy and accuracy.

Near/in-memory processing. Near-memory processing (NMP) runs memory-intensive workloads closer to memory. Prior works explored running compute inside the CXL controller (*e.g.*, for LLM inference [35, 78], vector database search [53, 88], and DLRM inference [51, 107]), DIMM (*e.g.*, for DLRM [52, 56, 77] and database operations [52]), network switches [44, 45], and SSD controllers [90, 100]. Processing-in-memory (PIM) embeds compute logic directly in the memory hardware to enjoy even higher bandwidth [42, 57, 59, 76, 106]. Cocoon leverages NMP on a CXL controller for correlated noise generation.

6.1 Applicability to Large-scale Training

While our evaluation focuses on single-node configurations (economical setups), the idea of Cocoon naturally extends to multiple nodes, because correlated noise generation of each model dimension is independent (noise generation for different dimensions can be easily parallelized across nodes). However, if additional nodes provide sufficient aggregate CPU/GPU memory, the relative benefit of the CXL NMP device diminishes. We leave the exploration of these scaled-out setups as future work.

7 Conclusion

DP training with correlated noise is an emerging technique whose system implications have yet to be thoroughly studied. We conducted a systematic study of the new technique and found several major bottlenecks when applied to DLRMs and billion-parameter models on an economical setup. We introduced Cocoon, a framework for efficient DP training with correlated noise. When baseline approaches fail to deliver competitive performance, hardware/software designs of Cocoon can deliver 1.23–10.82× speedup.

A Artifact Appendix

Abstract

Our artifact is available on GitHub. The repository contains our implementation of Cocoon, a system for differentially private training with correlated noise, along with scripts to reproduce the experiments in this paper. This codebase extends `fastDP` with noise distribution, generation, CPU offload pipelines, and noise preprocessing for embedding.

Scope

This artifact allows readers to validate the performance claims in the paper. Figures 3, 5, 14, 15 and 18 are scripted runs, and all other figures can be reproduced with appropriate changes. The getting-started script checks correctness and throughput on a single GPU in less than 30 minutes.

Contents

The repository consists of five directories: `fastDP/` contains the core library including the engine and noise worker. `examples/` holds experiment scripts for LLM, DLRM, and image classification. `benchmark/` provides a getting-started script with correctness checks and throughput benchmarks. `pfl/` contains BandMF matrix solvers from pfl-research. `train_utils/` provides shared training utilities.

Hosting

The artifact is available on GitHub (https://github.com/psu-paws/Cocoon), `osdi26` branch. The `main` branch of the GitHub repository will be actively updated.

Requirements

All main experiments were run on a machine with two sockets of 4× NVIDIA RTX A5000 24GB GPUs and an Intel Xeon Gold 6330 CPU with 128 GB DRAM. Parameters must be tuned to match the machine's topology and memory configuration.

Abstract

Database Management Systems (DBMSs) are crucial for data processing in many large-scale applications. However, detecting logical bugs in DBMSs remains challenging, as defining what constitutes a correct query result is inherently difficult. Metamorphic testing (MT) addresses this issue by checking relations between systematically transformed queries. However, existing MT approaches mainly rely on *equivalent* or *set-semantic* relations, and thus fail to detect subtle bugs that preserve the result set while corrupting value semantics, such as faulty aggregation, ordering, or numeric computation.

In this paper, we propose a unified *SQL query approximation* model that integrates set-semantic and value-semantic reasoning. Beyond result set inclusion or equivalence, our model captures how value-level changes affect query correctness. Based on this model, we develop ValScope, which generates and mutates SQL queries using predefined mutators and performs approximation propagation analysis to reason about global semantic effects. We evaluate ValScope on 6 widely used DBMSs and uncover 67 unique logical bugs, many of which were missed by prior approaches. The results show that ValScope substantially broadens the spectrum of detectable logical bugs beyond existing MT techniques.

1 Introduction

Database Management Systems (DBMSs) play a critical role in applications such as online banking and e-commerce [14, 44]. Like other large-scale systems, DBMSs involve complex code logic and a wide range of functionalities, making them prone to bugs [4, 19, 22]. Among these, logical bugs are particularly critical as they silently lead to incorrect query results in DBMSs [23, 34]. To detect logical bugs, existing approaches [12, 17, 21, 34–36, 38–40] generate SQL queries to test DBMSs and check whether the produced results follow the expectations. One of the fundamental technical challenges in this process is to define what constitutes a correct result for a given query, which is a classical problem in software testing—known as the test oracle problem [18]. To address the test oracle problem, many approaches have been proposed, including differential testing [8, 37], oracle-guided synthesis [36] and metamorphic testing (MT) [12, 17, 21, 34–36, 38–40]. Differential testing cannot reveal bugs that manifest only in a single DBMS implementation and is often inapplicable when queries contain dialect-specific features [17]. Similarly, oracle-guided synthesis provides limited coverage because it reasons about only one pivot row at a time, causing it to miss many logical bugs [17]. These limitations have led to the increasing adoption of MT, which overcomes the oracle challenge by establishing expected semantic relations between pairs of systematically transformed queries [17, 27].

Although MT has become the most effective paradigm for detecting logical bugs in DBMSs, existing MT approaches [12, 17, 21, 34–36, 38–40] still struggle to capture many subtle semantic inconsistencies. Current MT approaches can be broadly divided into two categories: those based on **equivalent metamorphic relations** and those based on **approximation metamorphic relations**. The first category, represented by NoREC [34] and TLP [35], defines the MR as strict output equivalence between the original and transformed queries. NoREC transforms an optimizable query into a non-optimizable form to verify that both forms produce identical results, while TLP partitions query predicates into multiple subqueries whose combined outputs are expected to equal the original result. While these equivalence-based frameworks have proven effective in detecting optimizer and predicate-related inconsistencies, they remain insufficient to expose many deeply hidden bugs [17]. This limitation arises because, under a constrained mutation space, the pair of equivalent queries often still share the same buggy operators or functions, ultimately producing identical yet incorrect results [17]. Consequently, such approaches are restricted to surface-level correctness and fail to uncover deeper semantic flaws that preserve structural equivalence yet violate relational semantics internally.

The second category, exemplified by Pinolo [17], generalizes this paradigm through **set-semantic approximation**.

```
CREATE TABLE t1 (c1 INT , c4 INT);
INSERT INTO t1 (c1,  c4) VALUES (3584,  36);
CREATE UNIQUE INDEX idx_t1_pk_c4 ON t1 (c1, c4);

-- Original Query
SELECT t1.c1 AS c1, SUM(DISTINCT t1.c4*2) AS col_1, DENSE_RANK()
OVER (ORDER BY 1 = 1) AS col_1_2 FROM t1 AS t1 WHERE (NOT
REGEXP_LIKE(t1.c1, '[0-9]{3}-[0-9]{2}-[0-9]{4}'))  GROUP BY t1.c1;
--result:   3584 |     72 |         1

-- Mutated Query
SELECT t1.c1 AS c1, SUM(DISTINCT t1.c4) AS col_1, DENSE_RANK()
OVER (ORDER BY 1 = 1) AS col_1_2 FROM t1 AS t1 WHERE (NOT
REGEXP_LIKE(t1.c1, '[0-9]{3}-[0-9]{2}-[0-9]{4}')) GROUP BY t1.c1;
--result:   3584 |     36 |         1          --(expected)
--result:   3584 |     NULL |   1          --(actual)
```

Figure 1: **An example of a logical bug detected by ValScope in MySQL (Bug #119321).**

Instead of requiring exact equality, Pinolo relaxes query predicates to generate over- and under-approximate variants and checks whether the resulting sets satisfy inclusion or containment relations. This relaxation significantly expands the detectable bug space, allowing the detection of subtle semantic inconsistencies that equivalence-based approaches often overlook. However, set-semantic approximation reasons about inclusion or containment relations among result tuples, rather than how tuple values are computed. Operations such as aggregation or arithmetic collapse a (multi-)set of input values into scalar results, whose correctness depends on numeric computation rather than tuple membership. When such value-level computation is corrupted but the underlying tuple set remains unchanged, the resulting outputs can still satisfy the same set relations. Consequently, inconsistencies that arise from value semantics fall outside the expressive scope of set-semantic approximation.

Figure 1 shows a real bug from MySQL (Bug #119321) [2], where the DBMS incorrectly handles `SUM(DISTINCT)` during aggregation. The original query computes `SUM(DISTINCT t1.c4 * 2)` and returns `72`. After applying a semantics-preserving mutation by removing the arithmetic multiplication and evaluating `SUM(DISTINCT t1.c4)` directly, the expected result should be `36`, since both queries operate on the same tuple set and the distinct value remains unchanged. However, MySQL wrongly returns `NULL`, indicating a silent value-level corruption in numeric computation and aggregation. However, set-level approximation approaches Pinolo fail to detect this bug. Although Pinolo's predicate relaxation effectively captures inconsistencies caused by set expansion or contraction, its checking mechanism focuses solely on tuple-set containment. Since this bug arises entirely within the value semantics of aggregation—while the tuple set remains unchanged—no containment relation is violated, causing the error to fall outside Pinolo's detection capability.

A significant portion of logical bugs manifest not through changes to the result set, but through subtle corruption of value semantics in the computed output. To effectively detect these hidden inconsistencies, we introduce the notion of **value-semantic approximation**, which models value-level behavior through the monotonic direction and magnitude of expected changes. This perspective complements set-semantic approximation: when a mutation preserves the tuple set but alters an aggregation or arithmetic expression, the result should follow a predictable monotonic relationship. By seamlessly integrating set-semantic and value-semantic approximation, we establish **a unified SQL query approximation model** capable of reasoning about both structural and value semantics. This unified model allows us to predict how local mutations propagate through the AST and how the final result should change. Any violation of these predicted approximation relations reveals a semantic inconsistency—precisely the class of deeply hidden logical bugs that existing MT frameworks fundamentally cannot capture.

Based on the proposed SQL query approximation model, we design a novel approach, ValScope which detects logical bugs in DBMSs by jointly reasoning about both set-semantic and value-semantic approximation. ValScope follows a generate–mutate–verify paradigm. It first generates syntactically valid and semantically diverse SQL queries and then systematically mutates them according to the defined approximation mutators. For each pair of original and mutated queries, ValScope performs approximation propagation analysis to determine how local semantic mutations (e.g., changing `MAX` to `MIN` or relaxing predicates) affect global query behavior along the SQL abstract syntax tree (AST). Finally, both queries are executed on the target DBMS, and their outputs are compared against the predicted approximation relation. Any violation of the expected set- or value-level relationship indicates a potential logical bug.

We implement our approach as a practical DBMS testing tool and evaluate it on 6 widely-used and extensively-tested DBMSs, MySQL, MariaDB, OceanBase, Percona, PolarDB and TiDB. In total , ValScope find 67 logical bugs, including 23 in MySQL, 10 in MariaDB, 7 in OceanBase, 10 in Percona, 12 in PolarDB and 5 in TiDB. Among these bugs, 57 are confirmed. These results demonstrate the effectiveness of ValScope in finding logical bugs in DBMSs. Overall, we make the following contributions:

- We propose a unified model, SQL query approximation, that combines set-semantic and value-semantic reasoning to detect logical bugs in DBMSs.
- We implement a novel MT framework, ValScope, which systematically generates, mutates, and verifies SQL queries based on the proposed approximation relations, effectively identifying logical bugs in DBMSs.
- We evaluate ValScope on 6 real-world DBMSs. In total, we found 67 logical bugs. To further facilitate research on DBMS testing, we open-source the tool at https://github.com/linli1724647576/ValScope

2 Background

2.1 Database Management Systems and SQL

Database Management Systems. Database Management Systems (DBMSs) are fundamental to modern software ecosystems, offering systematic mechanisms for storing, organizing, and accessing large volumes of structured data. This work focuses on *relational DBMSs*, which manage data according to the relational model [11]. In such systems, data is organized into tables, each containing tuples (records) that represent real-world entities.

SQL. Structured Query Language (SQL) [9] is the standard interface for interacting with relational DBMSs. It provides a unified syntax for defining, manipulating, and querying data, and can be broadly classified into four categories: Data Definition Language (DDL), Data Manipulation Language (DML), Data Query Language (DQL), and Data Control Language (DCL). Among them, DQL, represented primarily by the `SELECT` statement, forms the core of data retrieval in relational DBMSs. The `SELECT` statement supports rich semantics including filtering, grouping, aggregation, and joining across multiple relations, making it the most fundamental yet semantically complex component of SQL. In this work, we focus on detecting logical bugs in DQL, as they constitute the majority of real-world query workloads and are crucial to ensuring the correctness and reliability of DBMS query processing.

2.2 Logical Bugs in DBMSs

Logical Bugs. Logical bugs are one of the most critical types of bugs in DBMSs, silently causing incorrect query results without triggering system crashes [17, 27]. Unlike crash bugs that exhibit obvious failures, logical bugs corrupt query outputs in subtle ways, posing serious risks to data integrity and application reliability.

Existing Logical Bug Detection Approaches. Existing research on detecting logical bugs mainly relies on automated testing techniques. However, designing an effective testing framework is challenging due to the **test oracle problem**—it is difficult to determine the correct result of a complex SQL query for comparison. To address this issue, researchers have explored three main categories of approaches [17]. The first is differential testing [8, 37], which executes the same query across multiple DBMSs and compares their outputs; inconsistencies reveal potential logic flaws, but dialect differences and heterogeneous semantics often limit its applicability. The second, oracle-guided synthesis [36], generates queries expected to return a specific pivot row and reports an error when the row is missing, but it only captures localized issues and fails to expose deeper semantic inconsistencies. The third and most prominent category is metamorphic testing, which establishes expected semantic relations between pairs of systematically transformed queries. This approach enables *oracle-free* verification, offering better scalability and generality. We will provide an in-depth analysis in the following section.

2.3 Metamorphic Testing

In recent years, metamorphic testing (MT) has become the most effective and widely adopted approach for detecting logical bugs in DBMSs [17, 27]. The core idea of MT is to construct multiple SQL statements whose results are expected to satisfy a specific relation, known as a metamorphic relation (MR). When the actual query results violate this relation, it indicates that at least one query triggers a logical bug in the tested DBMS.

Equivalent MR. Traditional MT, such as NoREC [34] and TLP [35], define the metamorphic relation as strict equivalence between the outputs of the original and transformed queries. Although this equivalence-based strategy effectively bypasses the lack of ground truth, it constrains the search space of test cases: the transformations typically preserve all operators, functions, and predicates of the original query, merely changing structural forms. As a result, such approaches are limited to verifying surface-level correctness and often fail to reveal deeper semantic errors—particularly those that do not produce directly inconsistent result sets but still violate relational semantics internally [17].

Approximation MR. To overcome the over-restrictive nature of equivalence-based testing, PINOLO [17] introduces the concept of set-semantic approximation relations, relaxing the equivalence assumption. By expanding or constraining query predicates, it generates over- and under-approximate queries and judges correctness through inclusion or containment relations between result sets. This relaxation enables the detection of a broader spectrum of logical bugs, uncovering deeper semantic inconsistencies that equivalence-based approaches often miss [17].

However, approximation at the set level still overlooks subtle semantic shifts that occur at the value level, such as incorrect aggregations, ordering, or numeric deviations that preserve the same tuple set but alter the meaning of the result. Building on this insight, our work extends MT from set semantics to value semantics. We propose a new class of value-semantic approximation relations that reason about the direction and magnitude of result changes while maintaining structural consistency. By integrating set-semantic approximation with value-semantic approximation, our framework establishes a unified, multi-dimensional criterion for logical bug detection—enabling the discovery of more nuanced and deeply hidden semantic faults that existing MT frameworks cannot capture.

3 SQL Query Approximation

In this section, we introduce a comprehensive notion of SQL Query Approximation, which unifies two complementary per-

spectives of query behavior: the **set-semantic** and **value-semantic** dimensions. The set-semantic dimension characterizes differences in the returned tuple sets, while the value-semantic dimension captures monotonic variations in the computed or aggregated values over those tuples. Together, these two dimensions form a unified framework for expressing and reasoning about semantic consistency, enabling the construction of more expressive test oracles that can detect both set-level and value-level inconsistencies in DBMS behavior.

3.1 Set-Semantic Approximation

We first formalize the notion of approximation at the set level. This relation captures inclusion or containment among query result sets.

Definition 3.1 (Set-Semantic Approximation Relation)**.** Given a database D, let q_1 and q_2 be two SQL queries whose result sets are $R(q_1,D)$ and $R(q_2,D)$, respectively. We say that q_1 is the *set-level under-approximation* of q_2 over D, denoted by $q_1 \preceq^s_D q_2$, if and only if:

$$R(q_1,D) \subseteq R(q_2,D)$$

Conversely, q_1 is the *set-level over-approximation* of q_2 over D, denoted by $q_1 \succeq^s_D q_2$, if and only if:

$$R(q_1,D) \supseteq R(q_2,D)$$

Here, $R(q,D)$ represents the multi-set returned by evaluating query q on database D, and $\subseteq$ and $\supseteq$ denote inclusion and containment relations between two multi-sets.

Intuitively, the set-semantic approximation forms a partial order over queries: $q_1 \preceq^s_D q_2$ means that q_1 produces a narrower or more restrictive result than q_2, while $q_1 \succeq^s_D q_2$ means that q_1 yields a broader or less restrictive result. These two relations are inverses of each other and together define the lattice of set-level approximations.

Example 3.1. Consider a database $D = \{t_1\}$, where $t_1(c_1) = \{-1,0,1\}$. Now consider the following queries:

$$q_1 : \textbf{SELECT } c_1 \textbf{ FROM } t_1 \textbf{ WHERE } c_1 \leq 0$$

$$q_2 : \textbf{SELECT } c_1 \textbf{ FROM } t_1 \textbf{ WHERE TRUE}$$

The corresponding query results are:

$$R(q_1,D) = \{-1,0\}, \quad R(q_2,D) = \{-1,0,1\}$$

Clearly,

$$R(q_1,D) \subseteq R(q_2,D)$$

which establishes the set-semantic approximation relation:

$$q_1 \preceq^s_D q_2$$

Intuitively, q_1 is a restricted version of q_2; relaxing the selection predicate expands the result set and induces a containment relation between their outputs.

3.2 Value-Semantic Approximation

To overcome the limitation of purely set-level inclusion, we extend the approximation relation from the set-level to the value-level. Unlike the set-level relation that focuses on tuple inclusion, the value-semantic relation captures monotonic changes in target columns—columns whose values depend on value-level computation semantics (e.g., aggregation, arithmetic, or other scalar transformations), rather than on tuple membership. This allows the framework to detect logical bugs where queries return identical tuples but diverge in their value semantics.

Definition 3.2 (Value-Semantic Approximation Relation)**.** Given a database D, let q_1 and q_2 be two SQL queries whose result sets are $R(q_1,D)$ and $R(q_2,D)$, respectively. Let $C_t \subseteq \text{Cols}(R(q_1,D)) \cap \text{Cols}(R(q_2,D))$ denote the target columns whose values will be compared. Let G denote the grouping or ordering basis, determined as follows:

If the query contains a `GROUP BY` clause, G corresponds to the group-by keys. Otherwise, G represents a deterministic ordering over non-target columns (e.g., primary key or lexicographic ordering of attributes) to align tuples for comparison.

We say that q_1 is the *value-level over-approximation* of q_2 over D, denoted by $q_1 \succeq^v_D q_2$, if and only if:

$$\forall g \in G^*, \forall c \in C_t,\ V_{q_1}(g,c) \geq V_{q_2}(g,c)$$

where G^* is the set of all comparable tuple groups under G, and $V_q(g,c)$ denotes the value of column c in group g (or tuple position) produced by query q.

Conversely, q_1 is the *value-level under-approximation* of q_2, denoted by $q_1 \preceq^v_D q_2$, if and only if:

$$\forall g \in G^*, \forall c \in C_t,\ V_{q_1}(g,c) \leq V_{q_2}(g,c)$$

This definition unifies two cases: group-wise comparison for aggregation queries, and order-aligned comparison for non-aggregated results. The comparison operators $\geq$ and $\leq$ are interpreted under the total order induced by the SQL data type of column c, following standard SQL comparison semantics.

Intuitively, the *set-semantic approximation* ($\preceq^s_D$) describes inclusion of tuples, while the *value-semantic approximation* ($\preceq^v_D$) reflects monotonicity among the values of corresponding tuples.

Example 3.2. Consider a table $t_1(c_1,c_2)$ as follows:

$t_1 =$

c_2	c_1
A	10
A	20
B	5
B	7

Let the following two queries be defined:

$$q_1 : \textbf{SELECT } c_2,\ \text{MAX}(c_1) \textbf{ FROM } t_1 \textbf{ GROUP BY } c_2$$

q_2 : **SELECT** c_2, MIN(c_1) **FROM** t_1 **GROUP BY** c_2

The results are:

$R(q_1,D) =$

c_2	MAX(c_1)
A	20
B	7

$R(q_2,D) =$

c_2	MIN(c_1)
A	10
B	5

Under the grouping basis $G = \{c_2\}$ and target column $C_t = \{c_1\}$, we have for each $g \in G^* = \{\text{A}, \text{B}\}$:

$$V_{q_1}(g, c_1) \geq V_{q_2}(g, c_1)$$

Hence, $q_1 \succeq^v_D q_2$. Intuitively, both queries return identical group sets (thus $q_1 \equiv^s_D q_2$), but differ monotonically in their value semantics: the aggregated value of q_1 in each group is no smaller than that of q_2.

3.3 Approximation Propagation

The approximation relations introduced in the previous section capture the semantic correspondence between two complete SQL queries by comparing their result sets or value outputs. However, in practical DBMS testing, a mutation usually affects only a local part of the query—for instance, a predicate, an operator, or an aggregation function—rather than the entire query. To describe and reason about such fine-grained changes, we first define the concept of an *approximate mutator*, which serves as the smallest structural unit that can induce a local approximation within a query.

Definition 3.3 (Approximate Mutator)**.** Let q denote an SQL query represented as an abstract syntax tree (AST) and $n \in q$ a node of this tree. An *approximate mutator* μ is an operator that transforms n into a semantically related variant n' such that the two nodes satisfy an approximation relation $n \preceq^\alpha_D n'$ or $n \succeq^\alpha_D n'$, where $\alpha \in \{s, v\}$ indicates the set-semantic or value-semantic level. Each mutator μ is characterized by:

- **Scope:** the AST node type it applies to, such as predicate, arithmetic expression, aggregation function, or subquery.
- **Transformation rule:** the syntactic or semantic change performed on the node (e.g., <→<=, `MAX`→`MIN`, adding a conjunct condition).
- **Approximation type:** the type of approximation induced by the mutation, determined by both the direction and the semantic level of the change. The direction can be either *under-approximation* or *over-approximation*, while the semantic level can be either *set-semantic* approximation or value-semantic approximation.

We denote the application of a mutator as $n' = \mu(n)$, and the resulting local approximation relation as $n \preceq^\alpha_D n'$ (or its inverse).

An approximate mutator represents the atomic semantic deviation within a query that can propagate through its parent operators and affect the overall query result. To understand how such a local change influences the final query output, we extend the discussion from the semantic level of full-query comparison to the structural level of SQL. Specifically, we define the concept of *approximation propagation*, which describes how a local approximation relation established at one node of the query's AST can be transmitted through its parent operators and clauses, thereby determining how a single mutation impacts the overall approximation behavior of the query.

Definition 3.4 (Approximation Propagation)**.** Let D be a database, and let n_1, n_2 denote two semantically comparable nodes (e.g., subqueries, predicates, or expressions) in the SQL AST. These nodes may correspond directly to a mutation site introduced by an approximate mutator ($n_2 = \mu(n_1)$ for some mutator μ), or they may represent ancestor nodes whose semantics are indirectly affected by the propagation of such a local mutation. We use the unified notation $n_1 \preceq^\alpha_D n_2$ to represent an *approximation relation* of type $\alpha \in \{s, v\}$ where s and v correspond to the set-semantic and value-semantic levels, respectively. The relations defined in §3.1 and §3.2 describe query-level approximations between complete queries. In contrast, approximation propagation extends these relations to the structural level, capturing how local approximations between AST nodes can influence or induce approximations at higher layers of the query.

At the higher layers of the query, operators (such as aggregation functions or filtering conditions) are applied to the nodes and affect the overall query's approximation behavior. Formally, each operator op is characterized by two semantic properties. First, a *mapping* ($\alpha_{\text{in}} \to \alpha_{\text{out}}$) specifies how op transforms the approximation level between the set dimension ($\alpha = s$) and the value dimension ($\alpha = v$). Second, a *direction indicator* $\sigma(op) \in \{+1, -1\}$ specifies whether op preserves or reverses the approximation order. Specifically, $\sigma(op) = +1$ indicates that the operator is *order-preserving*, i.e., it maintains the direction of approximation , whereas $\sigma(op) = -1$ indicates that the operator is *order-reversing*, i.e., it flips the approximation direction . Based on these two attributes, the propagation of a local relation $n_1 \preceq^\alpha_D n_2$ through an operator op can be organized into four canonical forms:

- **(Set → Set)**: Let two nodes n_1 and n_2 satisfy a set-semantic approximation $n_1 \preceq^s_D n_2$. When both nodes are uniformly embedded under a set-level operator op_s , the resulting parent nodes $op_s(n_1)$ and $op_s(n_2)$ satisfy:

  $$op_s(n_1) \preceq^{s,\sigma(op_s)}_D op_s(n_2).$$

  Here, $\sigma(op_s) = +1$ for monotone set operators such as `EXISTS` that preserve tuple inclusion, and $\sigma(op_s) = -1$ for antitone operators like `NOT` or `NOT EXISTS` that reverse tuple inclusion.

- **(Set → Value)**: Given $n_1 \preceq_D^{s} n_2$, let f be an aggregation or set-to-value mapping operator. Applying f to both nodes induces a value-semantic approximation:

$$f(n_1) \ \preceq_D^{v,\sigma(f)} \ f(n_2).$$

  Here, $\sigma(f) = +1$ for aggregation functions whose outputs grow monotonically with the input set (e.g., `MAX`, `SUM`, `COUNT`), and $\sigma(f) = -1$ for antitone ones (e.g., `MIN`).

- **(Value → Value)**: Let two value-producing nodes satisfy $n_1 \preceq_D^{v} n_2$. For a scalar operator op_v applied to both nodes, the resulting values satisfy:

$$op_v(n_1) \ \preceq_D^{v,\sigma(op_v)} \ op_v(n_2).$$

  Here, $\sigma(op_v) = +1$ if op_v is order-preserving with respect to the value-semantic approximation (e.g., `x + c` with $c \geq 0$), and $\sigma(op_v) = -1$ if op_v reverses the order (e.g., negation).

- **(Value → Set)**: Let two value expressions satisfy $n_1 \preceq_D^{v} n_2$. If both expressions are consumed by a predicate or filtering operator op_s, the induced result sets satisfy:

$$op_s(n_1) \ \preceq_D^{s,\sigma(op_s)} \ op_s(n_2).$$

  Here, $\sigma(op_s) = +1$ for monotone-increasing predicates (e.g., `x > c`, where larger values of `x` make the condition more likely to hold and thus expand the result set), and $\sigma(op_s) = -1$ for monotone-decreasing ones (e.g., `x < c`, where larger values of `x` make the condition less likely to hold, causing the result set to shrink).

Remark. In this definition, n_1 and n_2 are not restricted to complete queries. They can represent corresponding subqueries, expressions, or predicates within a single query or across two query variants. The relation $\preceq_D^{\sigma}$ thus captures how a local semantic approximation propagates through SQL operators according to their monotonic behavior, bridging the value- and set-level semantics within the same unified framework.

Intuitively, the propagation mechanism provides the semantic bridge between *tuple-level inclusion* and *value-level monotonicity*. Set-level approximations can trigger value changes through monotone o perators, while value level changes can, in turn, alter the query result set when the affected values participate in predicates. This bidirectional propagation enables comprehensive reasoning over multi-layer SQL dependencies.

Example 3.3 (Set → Value Propagation)**.** Consider two queries over a table $t_1(c_1, c_2)$:

$$q_1 : \textbf{SELECT MAX}(c_1) \ \textbf{FROM} \ t_1 \ \textbf{WHERE} \ c_2 < 100$$

$$q_2 : \textbf{SELECT MAX}(c_1) \ \textbf{FROM} \ t_1 \ \textbf{WHERE} \ c_2 < 200$$

In the query structure, let n_1 and n_2 denote the `WHERE` clause nodes of q_1 and q_2, respectively. The condition $c_2 < 100$ in n_1 is stricter than $c_2 < 200$ in n_2, so the rows selected by n_1 form a subset of those selected by n_2. The parent node of these filters is the aggregation operator `MAX`, which is monotone increasing: when more rows are included, the maximum value of c_1 can only increase or remain the same. As a result, the difference at the set level (fewer or more tuples) propagates upward to a difference at the value level (smaller or larger aggregated value).

Intuitively, n_1 and n_2 illustrate how a local change in the filter condition at the set level can influence the aggregated result value, demonstrating the propagation from Set to Value.

Example 3.4 (Value → Set Propagation)**.** Consider two semantically related queries over a table $t_1(c_1)$:

$$q_1 : \textbf{SELECT} * \ \textbf{FROM} \ (\textbf{SELECT MAX}(c_1) \ \textbf{AS} \ x \ \textbf{FROM} \ t_1) \ \textbf{AS} \ \textit{subq} \ \textbf{WHERE} \ x > 100$$

$$q_2 : \textbf{SELECT} * \ \textbf{FROM} \ (\textbf{SELECT MIN}(c_1) \ \textbf{AS} \ x \ \textbf{FROM} \ t_1) \ \textbf{AS} \ \textit{subq} \ \textbf{WHERE} \ x > 100$$

The two queries differ only in the inner aggregation. Let n_1 and n_2 denote the aggregation nodes `MAX`(c_1) and `MIN`(c_1), respectively. Changing `MAX` to `MIN` decreases the derived value x. Since the outer predicate `x > 100` is monotone increasing in x, smaller x values make the condition harder to satisfy, resulting in fewer output tuples. Consequently, the result of q_2 becomes a subset of q_1, showing a typical Value → Set propagation.

These propagation behaviors connect the two approximation dimensions, allowing a single mutation at any AST node (e.g., `MAX`→`MIN`) to yield predictable, analyzable effects on both result structure and result values. The unified propagation model forms the semantic foundation of our framework.

4 Approach

Based on the SQL Query Approximation model proposed in Section 3, we present a novel approach ValScope for detecting logical bugs in DBMSs. Our approach leverages both set-semantic and value-semantic approximations to identify discrepancies in query results that traditional methods often overlook. In the following, we will provide detailed explanations of our approach.

4.1 Overview

We illustrate the overall workflow of our approach in Figure 2. The entire process follows a generate–mutate–verify paradigm designed to uncover logic bugs in DBMSs. In the pre-processing phase, we randomly populate multiple tables in a test database, following standard DBMS random testing practices [36]. This randomized setup provides a diverse and

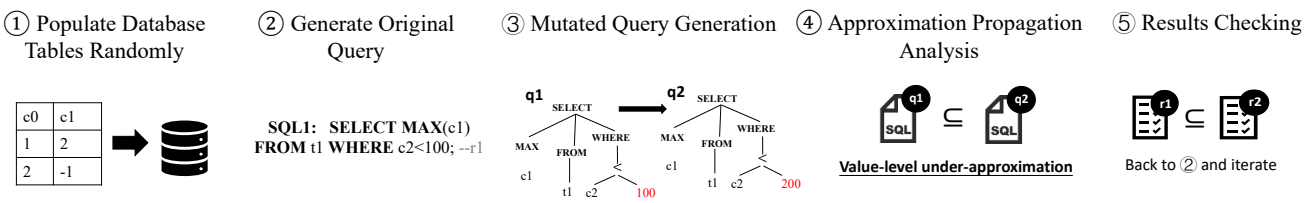

Figure 2: **Overview of our approach.**

unbiased data distribution for subsequent query evaluations. Next, our system generates a syntactically valid SQL query that serves as the original query. It then parses the query and traverses its AST to identify which grammatical constructs can be safely mutated. Based on the SQL query approximation models defined in Section 3, the system automatically synthesizes several approximate queries by mutating the original queries. After the mutated queries are constructed, the framework performs approximation propagation analysis to reason how local semantic changes at the mutated node propagate through the SQL AST. This analysis establishes the global query-level approximation relation (either at the set level or the value level) between the original and mutated queries. Finally, both queries are executed on the tested DBMS instance, and their outputs are compared against the predicted approximation relation. Any violation of this expected relation indicates a potential logical inconsistency in the DBMS.

In the following sections, we introduce each core component in detail, including the construction of the original query (Section 4.2), the design of approximate mutators (Section 4.3), the propagation algorithm (Section 4.4), and the result checking procedure (Section 4.5).

4.2 Construction of the Original Query

To support diverse SQL structures in testing, our framework constructs original queries based on a compact yet expressive SQL grammar, as illustrated in Figure 3. This grammar extends the baseline adopted in PINOLO [17] by incorporating a richer set of syntactic components, enabling the generation of more varied queries. Compared with PINOLO, which mainly focuses on basic `SELECT-FROM-WHERE` statements, our implementation supports a broader range of SQL features, including comprehensive `JOIN` types and conditions, `WITH`-clause based common table expressions (CTEs), and row-level locking modes such as `FOR UPDATE`. It also introduces extended functionalities such as `GROUP BY` with `HAVING` filters and `ORDER BY` clauses, nested function calls with type casting and `CASE` expressions. These extensions collectively allow our system to generate queries that better reflect the syntactic and semantic richness of real-world DBMS workloads.

A key difference between our design and PINOLO lies in the handling of aggregation-related query constructs. PINOLO is built upon set-level approximation relations defined over

Statement	*S*	::=	*Q* | *Q* FOR *LM* | WITH *WI* (, *WI*)* *Q* [FOR *LM*]

Figure 3: **Compact SQL syntax supported by our approach.**

tuple-level query results, which fundamentally limits its applicability to queries whose outputs preserve monotonic inclusion. As a result, queries involving aggregation—such as those with `GROUP BY` or `HAVING` clauses—are not supported, since aggregation collapses sets of tuples into computed values and breaks the set-level monotonicity assumed by its model. By contrast, our approach introduces value-semantic approximation relations (Section 3) that explicitly capture how aggregated and computed values evolve under localized semantic perturbations, thereby enabling systematic testing of queries with aggregation and grouping.

4.3 Approximate Mutators

To instantiate the SQL Query Approximation model proposed in Section 3, we design a collection of *approximate mutators* that introduce controlled semantic deviations into an SQL query. Each mutator corresponds to a localized modification applied to a specific node of the query's AST. The design goal is to cover both set-level and value-level aspects of SQL semantics, enabling the discovery of a broad range of logical bugs in DBMSs. We have designed a total of 26 mutators,

Table 1: **Representative Approximate Mutators.** Transforming **C1** into **C2** achieves the over-approximation; the inverse achieves the under-approximation.

Type	C1	C2
Set-Semantic Mutators		

Relation	`r1 UNION r2`
	`A EXCEPT B`
	`A INTERSECT B`
		`r1 UNION ALL r2`
		`A`
		`A UNION B`

Predicate	`WHERE cond`
	`col LIKE '_abc%'`
	`a < b`
	`INNER JOIN`
		`WHERE TRUE`
		`col LIKE '%abc%'`
		`a <= b`
		`LEFT JOIN`

Value-Semantic Mutators		

Aggregation	`COUNT(DISTINCT c)`
	`AVG(c)`
	`STDDEV_SAMP(c)`
		`COUNT(c)`
		`MAX(c)`
		`VAR_SAMP(c) (c>1)`

Expression	`expr` `expr`	`expr + k (k > 0)` `expr * k (k has the same sign as expr)`

including 17 set-semantic mutators and 9 value-semantic mutators. Due to space limitations, we only present some representative mutators in Table 1. The complete set of mutators can be accessed in our Github repository [1]. Now we provide more explanations on the approximate mutators.

- **Mutating Relations:** These mutators change how data sets are combined or excluded. For example, replacing `UNION` with `UNION ALL` allows duplicates, while replacing `INTERSECT` with `UNION` alters set inclusion behavior. These mutations affect the breadth of the result set.
- **Mutating Predicates:** These mutators modify the query conditions. For instance, changing a `WHERE` condition to `TRUE` includes all rows, while `FALSE` excludes all. Modifying comparison operators (e.g., < to <=) broadens the results.
- **Mutating Aggregations:** These mutators alter aggregation behavior. For example, switching `COUNT(DISTINCT c)` to `COUNT(c)` affects duplicate handling, and replacing `AVG(c)` with `MAX(c)` changes the nature of the result.
- **Mutating Expressions:** These mutators modify arithmetic or logical expressions, such as adding or multiplying by a constant. These changes impact the computed values and affect the final query output.

4.4 Approximation Propagation Analysis

In this section, we further develop an executable algorithm to determine how local semantic changes propagate through the SQL AST. The main purpose of this algorithm is to formalize the top-down reasoning process introduced in Definition 3.4 into a systematic, bottom-up propagation procedure that connects local node mutations with their global semantic consequences at the query level.

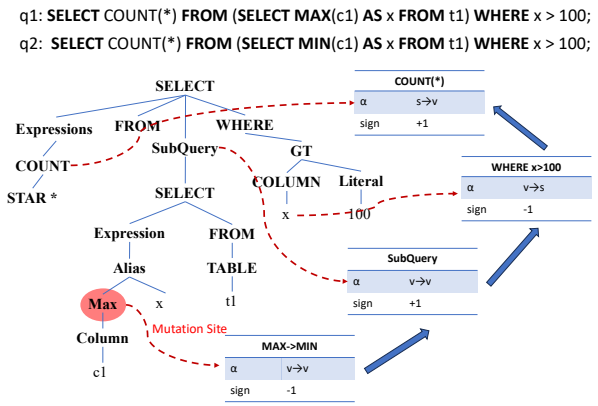

Figure 4: **Example of how the proposed algorithm propagates local semantic changes across the SQL AST.**

Algorithm 1 presents the overall propagation process. Initially (Line 1–3), the algorithm receives the mutated node information $node_info$ and the complete AST of the query. It first identifies the mutated node n_{mut} and constructs its ancestor chain from the mutation site to the query root, represented as list $= [n_{mut}, \ldots, n_{root}]$. This structure enables the algorithm to traverse each parent operator sequentially and reason about how the mutation propagates upward. The algorithm then initializes the local semantic level of the mutation (Line 5–7): if the mutated node involves predicates or subqueries, it starts at the set level ($\alpha(n_{mut}) = s$); otherwise, for expressions or aggregations, it starts at the value level ($\alpha(n_{mut}) = v$). A direction accumulator *sign* is also initialized to $+1$ to indicate that propagation initially preserves directionality. In the propagation stage (Line 9–17), the algorithm iteratively traverses each parent node of n_{mut} in a bottom-up manner. Before propagating, the algorithm invokes $\textsc{DependsOn}(n_i, n_{i-1})$ to check whether the parent node semantically depends on the mutated child node—by referencing its output column (for value-level nodes) or embedding it as a subquery or relation (for set-level nodes). Only dependent nodes are considered for propagation. For each parent operator op_i (Line 9), it consults Table 2 to retrieve the corresponding semantic mapping $(\alpha_{in} \rightarrow \alpha_{out})$ and its monotonic direction $\sigma(op_i) \in \{+1, -1\}$ (Line 13). The semantic level α is updated according to the operator's input-output mapping (e.g., Set→Value for aggregation or Value→Set for predicate filters), while the cumulative direction *sign* is updated multiplicatively ($sign \leftarrow sign \cdot \sigma(op_i)$), preserving or reversing the relation based on operator polarity (Line 14–16). This recursive process effectively tracks the path of semantic transformation from the mutation site to the query output. Finally, at the root node (Lines 19–25), the algorithm materializes the final query-level approximation relation between the original and mutated queries, returning either a set-level or a value-level approximation, depending on the semantic level of the root and the accumulated propagation direction.

Algorithm 1 Approximation Propagation across SQL AST

Input: Mutated node info $node_info$, SQL AST AST
Output: Final query-level approximation between original and mutated queries

// Step 1: Initialization
Identify mutated node n_{mut}.
Build ancestor chain list $= [n_{mut}, \ldots, n_{root}]$.
// Step 2: Local relation at mutation site
Decide initial level $\alpha(n_{mut}) \in \{s, v\}$ by node type.
Set local relation $\mathcal{R}(n_{mut}) \leftarrow (\preceq^{\alpha(n_{mut})})$.
Initialize direction accumulator $sign \leftarrow +1$.
// Step 3: Bottom-up propagation
for each parent node n_i in $list$ (from child to root) **do**
    Determine operator type op_i at n_i.
    if not DEPENDSON(n_i, n_{i-1}) **continue**
    end if
    Lookup rule of op_i in Table 2 to get $(\alpha_{in} \to \alpha_{out}, \sigma(op_i))$.
    Update level: $\alpha(n_{i+1}) \leftarrow \alpha_{out}$.
    Update direction: $sign \leftarrow sign \cdot \sigma(op_i)$.
    Propagate symbolically: $\mathcal{R}(n_{i+1}) \leftarrow \mathcal{R}(n_i)$ with $sign$ applied.
end for
// Step 4: Materialize root-level relation
if $\alpha(n_{root}) = s$
    return $q_1 \preceq^s_D q_2$ with sign $+$,
    or $q_1 \succeq^s_D q_2$ with sign $-$.
else
    return $q_1 \preceq^v_D q_2$ with sign $+$,
    or $q_1 \succeq^v_D q_2$ with sign $-$.
end if

function DEPENDSON(parent, child)
    if $\alpha(child) = v$
        return parent.exprs contains column or alias from child
    else if $\alpha(child) = s$
        return parent.references(child) as subquery or table
    else
        return false
    end if
end function

As illustrated in Figure 4, the mutation occurs at the aggregation node where `MAX(c1)` is replaced by `MIN(c1)`, initializing a value-level relation ($\alpha = v$) with reversed monotonicity ($\sigma = -1$). Following Algorithm 1, the algorithm then traverses its ancestor chain list $= [n_{\text{MAX}}, n_{\text{subq}}, n_{\text{WHERE}}, n_{\text{COUNT}}]$ to evaluate how this local change propagates upward through the query structure. When the propagation reaches the subquery node (`SELECT ... AS x`), the semantics are lifted from the value level to the set level ($\alpha : v \to s$, $\sigma = +1$). According to Table 2, a subquery appearing in the `FROM` clause acts as a data source that preserves tuple inclusion—expanding the underlying relation results in a superset of tuples, thus maintaining positive monotonicity. The subsequent `WHERE x>100` clause applies a filtering operator that preserves the set level but reverses direction ($\alpha : s \to s$, $\sigma = -1$). Finally, the outer `COUNT(*)` operator aggregates the resulting set back to a value-level ($\alpha : s \to v$, $\sigma = +1$). The cumulative sign is therefore $(-1)\times(+1)\times(-1)\times(+1) = +1$, yielding a final value-level approximation $q_1 \preceq^v_D q_2$, which indicates that the output of q_1 forms a value-level under-approximation of q_2.

4.5 Results Checking

The primary purpose of results checking is to verify whether the outputs of the original and mutated SQL queries align with the predicted approximation relations, as defined in the previous section. Unlike traditional methods that rely on strict equivalence or set inclusion checks, which often miss subtle semantic differences, our approach incorporates both set-semantic and value-semantic approximation relations. This allows us to detect a wider range of logical inconsistencies in DBMS query results. In our approach, after executing both queries, we compare their results based on the expected approximation relation (set or value). Specifically, for set-semantic approximation, we check if the result set of the mutated query is a subset or superset of the original query's result set, as predicted by the approximation relation. For value-semantic approximation, we compare the values in the target columns of both queries, ensuring that they satisfy the expected monotonic relationship (either increasing or decreasing). A violation of this relation signals a logical inconsistency in the DBMS's query processing.

5 Implementation

We implemented our approach VALSCOPE as a DBMS testing system, which was written in Python with 13,455 lines of code. The following describes the important implementation details.

Database Population. We adopt the approach PINOLO [17] to generate random database instances from scratch, while also covering most of the data types as specified in the SQL documentation. Unlike existing methods of random database instance generation, VALSCOPE also takes into account type-specific behaviors and boundary cases. For each column, values are generated according to the constraints of the respective data type to ensure validity. This helps prevent common runtime errors such as `INSERT` failures caused by out-of-range or incorrectly formatted values. To increase the likelihood of triggering type-related errors, we also introduce boundary values, including extremely large or small numbers, as well as text with mixed case. Additionally, to test specific arithmetic operations and function-related mutation operators, we explicitly specify the sign (positive or negative) for certain columns.

Test Case Generation and Parsing. Similar to SQL generators like SQLSMITH [5] and GO-RANDGEN [32], we implement VALSCOPE from scratch to generate original queries. VALSCOPE ensures the consistency of data dependencies,

Table 2: **Operator types and semantic propagation rules.**

Operator Type	Semantic Mapping	Monotonic Direction $\sigma(op)$	Example and Interpretation
Aggregation Functions	Set → Value	$+1$: `MAX`, `SUM`, `COUNT` -1: `MIN`	Expanding the input set increases the aggregated result for `MAX`/`SUM`/`COUNT`, or decreases it for `MIN`.
Predicate / Filter	Value → Set	$+1$: $x > c$, $x \geq c$ -1: $x < c$, $x \leq c$	Increasing the compared value makes $x > c$ easier (result set expands) and $x < c$ harder (result set shrinks).
Logical Operator	Set → Set	$+1$: `EXISTS`, `OR`, `AND` -1: `NOT`, `NOT EXISTS`	`OR`/`EXISTS`/`AND` are monotone increasing w.r.t. each input (union/existsintersection); `NOT`/`NOT EXISTS` flip inclusion.
Arithmetic / Expression	Value → Value	Depends on operator sign	Linear arithmetic preserves or reverses direction: `x + k` ($+1$ if $k > 0$), `x * k` ($+1$ if $k > 0$, -1 if $k < 0$), and `-x` flips monotonicity.
Join / Projection / Set Op	Set → Set	$+1$: `JOIN`, `SELECT`, `UNION`, `INTERSECT` mixed: `EXCEPT` (*left* $+1$ / *right* -1)	Structural operators propagate tuple inclusion: `JOIN`, basic `SELECT`, `UNION`, `INTERSECT` are monotone increasing; `EXCEPT` increases with the left input but decreases with the right input.
Subquery / CTE	Context-dependent	$+1$: as `FROM`/CTE source inherits parent: scalar subquery	Monotonicity depends on usage context: (1) In the `FROM` clause (e.g., `SELECT * FROM (SELECT a FROM t)`), it acts as a data source and preserves inclusion ($+1$). (2) As a scalar subquery (e.g., `WHERE x > (SELECT AVG(y) FROM t)`), it inherits the outer predicate's direction ($> \Rightarrow +1$, $< \Rightarrow -1$). (3) For a CTE (e.g., `WITH cte AS (...) SELECT * FROM cte`), it behaves similarly to a `FROM` subquery, typically monotonic ($+1$).

function dependencies, and expression dependencies in query generation. It carefully selects tables and columns based on their usage patterns, applies the correct functions with compatible argument types, and maintains type compatibility across operations, ensuring semantic correctness. This allows ValScope to achieve higher semantic accuracy than existing generators such as SQLSmith and Go-randgen, particularly in handling complex queries with multiple nested subqueries. To apply the approximate mutators to original queries, we use SQLGlot [28], which accepts the same context-free grammar used in seed query generation, to generate ASTs of original queries for mutation.

Bug Report Post-processing. ValScope evaluates queries in the tested DBMS to obtain query results. It is important to note that inconsistent query results often arise during our testing process. To avoid repetitive bug reports and make the test results easier to understand, we first use SQLess [26] to simplify the bugs and pinpoint their root causes. Specifically, SQLess applies a delta-debugging [41] reduction by iteratively removing clauses, expressions, or subqueries from the original query pair, while repeatedly re-executing the reduced queries to check whether the violation still persists. Additionally, we follow the approach from Pinolo [17] to remove duplicates. Concretely, we associate each simplified query pair with the earliest bug-involved version of the tested DBMS in which the violation can be reproduced, and group query pairs that share the same bug-involved version as one bug. Finally, we manually inspect the post-processed results to ensure that each reported bug is minimized and deduplicated before submitting a clear bug report to developers for confirmation.

Supported DBMSs and Adaptation. ValScope is primarily designed around the MySQL syntax, ensuring robust support for MySQL-based databases, such as TiDB and OceanBase. The architecture of ValScope is modular and decoupled, which facilitates easy adaptation to different DBMS dialects. To integrate support for additional DBMS dialects, users only need to modify the relevant components to accommodate the specific syntax, data types, and operations of the target DBMS. This adaptation is similar to extending SQLSmith [5] and can be achieved with just a few hundred lines of code. A more streamlined approach is to leverage the latest extension tool, QTRAN [27], which automates the process of adapting metamorphic-oracle-based logical bug detection techniques for multi-DBMS dialect support.

6 Evaluation

Our evaluation aims to answer the following questions to demonstrate the effectiveness of ValScope:

Q1 Can ValScope find real logical bugs in widely used and extensively tested DBMSs? (Section 6.2)

Q2 Can ValScope find logical bugs that are missed by existing approaches? (Section 6.3)

6.1 Experimental Setup

Tested DBMS. We evaluate ValScope on 6 widely used DBMSs, as summarized in Table 3. These DBMSs were chosen based on their popularity and extensive use in real-world applications. MySQL, MariaDB, TiDB, and OceanBase are widely used, with MySQL ranking second in the DB-Engines ranking, while MariaDB ranks 13th, and TiDB and OceanBase are also prominent players. Percona, a derivative of MySQL, and PolarDB, a cloud-native database, were selected to represent a broader spectrum of DBMSs. All of these DBMSs have undergone extensive testing for both logical [12, 17, 21, 23, 27, 34–36, 38, 40, 42] and crash

bugs [5, 19, 32, 43]. Although finding new bugs in such widely tested systems is challenging, it serves to validate the effectiveness of VALSCOPE. In our experiments, VALSCOPE tests the latest versions of each DBMS. When updates are made to any DBMS, new tests are initiated on the updated versions. The whole experiment takes about one month.

Table 3: **The demographics of the DBMSs under test**

DBMS	Version	GitHub Stars	DB-Engine	First Release
MySQL [29]	9.4.0	11.9K	2	1995
MariaDB [15]	12.0.2	6.7K	13	2009
OceanBase [30]	5.7.25	9.8K	99	2010
Percona [31]	8.0.43-34	1.2K	122	2008
PolarDB [10]	8.0.32	1.6K	105	2017
TiDB [33]	8.0.11	39.4K	85	2016

Environment. We conduct the experiments on one server with 104-cores Intel(R) Xeon(R) Gold 6230R CPU @2.10GHz and 500 GB memory. The server operates under the Ubuntu 20.04 OS, with the 5.4.0-135-generic version of the Linux kernel.

6.2 Bug Detection

Table 4 summarizes the status of the logical bugs found by VALSCOPE for each DBMS. In total, we reported 67 unique logical bugs across six DBMSs, including 23 in MySQL, 10 in MariaDB, 7 in OceanBase, 10 in Percona, 12 in PolarDB, and 5 in TiDB. Notably, all of these bugs were previously unknown, highlighting the effectiveness of VALSCOPE in uncovering hidden logical inconsistencies. Of these, 57 bugs have been confirmed, and 10 are still pending verification.

Bug Importance. Although anecdotal, developer feedback is an important indicator of an approach's effectiveness and the found bugs' importance. Two DBMS companies reached out to us about our testing efforts; both were interested in how we found the bugs, and one invited us to help them find more bugs. For example, a developer from PolarDB commented: "Outstanding work, this tool looks very useful, and we will fully support any technical requirements you may need." Additionally, we received positive feedback on public bug tracking platforms. Among the confirmed bugs, one in MySQL was labeled as a serious bug, indicating it is a high-impact and difficult-to-resolve issue; furthermore, in MariaDB, 10 bugs were labeled as "Major", which represents the highest severity level in the system.

Bug Diversity. We further analyzed the characteristics of the queries that triggered the logical bugs. Among the 57 confirmed bugs, 45 involve subqueries, 17 are related to aggregation functions, and 6 stem from numeric computations within expressions. In addition, 19 bugs are associated with join operations, 22 with `GROUP BY` and `HAVING` clauses. Since a single query may contain multiple constructs, these categories are not mutually exclusive; rather, they show that VALSCOPE can uncover logical bugs arising from rich combinations of subqueries, aggregations, arithmetic expressions, joins, and grouping clauses, instead of being confined to a narrow class of query templates.

Table 4: **Status of logical bugs found by VALSCOPE**

DBMS	Reported	Confirmed	Pending
MySQL	23	23	0
MariaDB	10	10	0
OceanBase	7	6	1
Percona	10	10	0
PolarDB	12	7	5
TiDB	5	1	4
Total	**67**	**57**	**10**

Bug Detected via Approximation Relations. All reported bugs were uncovered through our SQL query approximation framework. Among all confirmed bugs, 43 ultimately violate value-semantic approximation, while 32 require reasoning about cross-dimension propagation between set and value semantics. These results demonstrate the effectiveness of VALSCOPE in jointly modeling set-semantic and value-semantic, enabling the detection of subtle logical bugs that are beyond the reach of prior MT techniques based solely on equivalence or set semantic approximation.

Bug Triggering Rules. To better understand the effectiveness of different mutators, we analyze which mutators are involved in triggering the confirmed logical bugs found by VALSCOPE. Figure 5 shows the top-10 mutators ranked by the number of confirmed bugs they trigger. We observe that the distribution is skewed rather than uniform: a small number of mutators contribute to a large portion of the confirmed bugs. In particular, rule `R1` (removing `DISTINCT`) and `R18` (transforming `COUNT(DISTINCT c)` into `COUNT(c)`) are the most effective, indicating that duplicate handling and aggregation semantics are common sources of confirmed logical bugs in DBMSs. Several other mutators, such as predicate relaxation (`R5`) and join transformation (`R17`), also consistently trigger bugs. At the same time, the fact that multiple mutators contribute to bug discovery suggests that the bug space is diverse, and incorporating a rich set of mutators is necessary to achieve broad coverage. This observation further suggests that extending the mutator set could potentially uncover additional bugs. Due to space limitations, we provide a complete mapping between confirmed bugs and their triggering mutation rules, along with detailed frequency statistics, in our Github repository [25].

Query Generation Efficiency. We evaluate query generation efficiency by measuring the number of test cases generated per second, where each test case consists of an original query and its corresponding mutated query. VALSCOPE achieves query generation throughput comparable to existing methods [5, 13, 32]. Specifically, the generation rates are 2000 queries/sec for MySQL, 1923 for MariaDB, 2000 for OceanBase, 1960 for Percona, 1960 for PolarDB, and 1960 for TiDB.

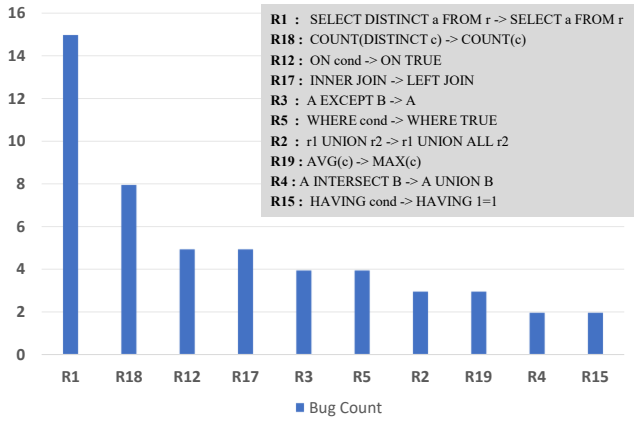

Figure 5: **Top-10 mutators ranked by the number of 57 confirmed logical bugs they trigger.**

In addition to competitive throughput, ValScope achieves high execution success rates across most DBMSs. The execution success rates are 93% for MySQL, 88% for MariaDB, 87% for OceanBase, 91% for Percona, 72% for PolarDB, and 87% for TiDB. These results indicate that ValScope can generate structurally complex queries with nested constructs and inter-query dependencies, while preserving data consistency, functional dependencies, and expression-level correctness. Although the testing campaign lasted for nearly one month, the majority of logical bugs were uncovered at an early stage, with 61 out of the 67 reported bugs (over 90%) detected within the first 24 hours. This observation demonstrates that ValScope is effective at rapidly exposing potential logical flaws, making it well suited for efficient and practical DBMS testing.

Case Study. Figure 6 shows a logical bug in MariaDB [3] found by ValScope, where inconsistent metadata propagation across query branches leads to incorrect result representation. The original query uses `MAX(1)` in the first branch of a `UNION ALL`, while the mutated query replaces it with `AVG(1)`. Under the given database state, both expressions evaluate to the same logical value 1, so the expected result remains `(1), (2025-10-17)`. However, the mutated query instead returns `(0x312E...)` and `(0x32303235...)`—the outputs are silently converted into binary-encoded hex strings. The root cause lies in the implementation of the `AVG()` aggregate function, where the result collation is not properly initialized. Unlike `MAX()` and `MIN()`, which explicitly inherit type and collation metadata from their input via `set_collation`, the `Item_sum_avg` class omits this step, leaving its metadata incomplete. During `UNION ALL` type unification, this missing collation forces the engine to fall back to a binary supertype, leading to incorrect encoding of all result values. The fix restores consistency by adding the missing metadata initialization in `AVG()`, ensuring correct type resolution and human-readable outputs across query branches.

```
-- Original Query
(SELECT MAX(1) AS col FROM t1) UNION ALL
(SELECT CURDATE() AS col);
--result: (1) ,
         (2025-10-17)

-- Mutated Query
(SELECT AVG(1) AS col FROM t1) UNION ALL
(SELECT CURDATE() AS col);

--result: (1) ,                          --- (expected)
         (2025-10-17)
--result: (0x312E3030303030303030) ,     --- (actual)
         (0x323032352D31302D3137)
```

(a) Bug Manifestation: Metadata Erosion and Collation Dissonance in Aggregate-to-Union Projection

Figure 6: **MariaDB Bug #37888: unexpected type changing after changing MAX to AVG.**

6.3 Comparative Study

To demonstrate that ValScope detects logical bugs missed by existing methods, we compare ValScope with state-of-the-art DBMS testing approaches from two perspectives: testing tools and timing of bug detection.

Tool Comparison. At the tool level, we selected six state-of-the-art logical bug detection approaches for comparison: PQS [36], NoREC [34], TLP [35], DQP [7], Pinolo [17] and EET [21]. Since the implementation of TQS [40] is not publicly available, and it belongs to the same class of approaches as DQP [7], we include only DQP as a representative for comparison. We run each tool on the latest version of each supported DBMS, with a testing duration of 24 hours. Since the baseline methods do not support all DBMSs tested by ValScope our comparison is limited to the DBMSs commonly supported by ValScope and each baseline method.

Table 5 shows that ValScope outperforms the other tools in detecting logical bugs across all DBMSs, especially in MySQL. Specifically, ValScope found 28,10,20,36,40 and 23 more bugs than PQS, NoREC, TLP, DQP, Pinolo and EET. Note that the increments are calculated based only on the DBMSs commonly supported by both approaches. The other approaches were less effective in our experiments because we tested the latest versions of the DBMSs. The advantage of ValScope mainly comes from its unified reasoning over both set-semantic and value-semantic approximation. In

Table 5: **Number of logical bugs triggered in 24 hours.**

DBMS	PQS	NoREC	TLP	DQP	Pinolo	EET	ValScope
MySQL	0	-	4	0	2	3	21
MariaDB	-	0	-	0	1	-	10
OceanBase	0	-	-	-	0	-	7
Percona	-	-	-	-	-	-	8
PolarDB	-	-	-	-	-	-	10
TiDB	-	-	2	0	0	0	5
Total	0	0	6	0	3	3	61
Increment	28	10	20	36	40	23	

Note."-" indicates that the tool does not support the DBMS. "Increment" is computed on the commonly supported DBMSs between the baseline tool and ValScope.

contrast, prior approaches are limited to equivalence-based checking, set-level approximation, or narrower oracle assumptions, and therefore cannot effectively capture value-level corruptions or cross-dimension semantic violations. We further study whether existing oracles can detect the logical bugs found by ValScope. For each bug-triggering query found by ValScope, we manually construct the corresponding transformed queries required by each baseline oracle and check whether the bug can still be exposed under that testing pattern. Among the 61 logical bugs found by ValScope within 24 hours, Pinolo can detect 12, TLP can detect 4, NoREC can detect 2, and DQP can detect 6, while ValScope uniquely detects 48 of them (78.9%). This result shows that a substantial portion of the bugs found by ValScope are beyond the detection scope of existing oracles, further demonstrating that ValScope complements prior techniques and is particularly effective at exposing logical bugs involving value-level and cross-dimension semantic inconsistencies.

Temporal Comparison. We also present a comparative study from a temporal perspective following EET [21], aiming to evaluate whether ValScope can uncover logical bugs missed by prior approaches. We analyze the earliest bug-involved version of each of the 57 confirmed logical bugs discovered by ValScope, and examine whether these versions predate the publication of existing approaches [7, 12, 17, 21, 34–36, 38–40]. This enables us to assess the effectiveness of ValScope in identifying long-standing issues overlooked by earlier techniques.

As shown in Table 6, among the 57 confirmed bugs, **48** bugs originated before 2020, indicating that all post-2020 approaches (e.g., PQS [36], TLP [35], NoREC [34]) failed to detect these long-standing issues in their extensive evaluations. In addition, **5** bugs were already present between 2020 and 2023, yet were not identified by testing approaches introduced after 2023, such as EET [21], Pinolo [17], TQS [40] and DQP [7]. These findings show that existing approaches indeed missed a substantial number of long-lived logical bugs. These missed bugs can be attributed to fundamental limitations of existing approaches. First, equivalence-based techniques such as TLP [35] apply coarse-grained query-level mutations that reuse the same faulty operators, causing both queries to return identical—yet incorrect—results. Second, approximation-based methods such as Pinolo [17] rely solely on set semantics and therefore cannot detect value-level corruptions that occur without modifying the tuple set. However, ValScope jointly reasons about set- and value-semantic behaviors and performs fine-grained mutations, enabling it to expose subtle errors that all prior approaches fundamentally overlook.

Furthermore, we investigate the longest latency of the confirmed bugs for each DBMS. As reported in Table 6, ValScope identifies at least one bug with a latency exceeding three years in every tested DBMS, with the longest latency reaching **20 years**. These results demonstrate that ValScope is highly effective at discovering long-standing, previously unknown logical bugs across diverse DBMSs.

Table 6: **Latency of the confirmed logical bugs found by ValScope**

DBMS	Found	Bug-involved year		Longest latency
		< 2023	< 2020	
MySQL	23	19	18	20 years
MariaDB	10	10	9	13 years
OceanBase	6	6	3	5 years
Percona	10	10	10	12 years
PolarDB	7	7	7	7 years
TiDB	1	1	1	3 years
Total	**57**	**53**	**48**	**20 years**

7 Discussion

False Positives. False positives in our approach mainly stem from spec-dependent behaviors rather than true logical bugs, including floating-point imprecision, `NULL` semantics, and vendor-specific implementations. For floating-point computations (e.g., in `SUM` or `AVG`), minor numerical deviations may arise due to rounding, execution order, or precision differences; we therefore adopt a tolerance-based comparison, where two values a and b are considered consistent if $|a-b| \le \varepsilon_{\text{abs}}$ or $|a-b|/\max(1,|a|,|b|) \le \varepsilon_{\text{rel}}$. For `NULL` semantics, discrepancies may result from SQL's three-valued logic and special aggregation behavior (e.g., `COUNT(*)` vs. `COUNT(col)`); we address this via `NULL`-aware comparison rules that treat `NULL` as a distinct semantic category and avoid comparing it as a regular scalar. Finally, certain inconsistencies originate from vendor-specific behaviors (e.g., implicit type conversions or function semantics), for which we perform manual validation. These strategies effectively reduce spurious violations, and in practice we did not observe persistent false positives among the confirmed bugs.

Limitations. Our approach relies on value-semantic monotonicity to reason about expected result changes, which limits its applicability to certain classes of SQL queries. In particular, non-monotonic functions (e.g., `SIN`, `ABS`, `ROUND`, or complex `CASE`-based expressions) do not exhibit a consistent

directional behavior, making it difficult to derive reliable approximation relations. For such functions, small input changes may lead to unpredictable output variations, preventing effective value-level reasoning. In addition, queries involving non-deterministic functions (e.g., `RAND()`, `NOW()`) may produce different results across executions, violating the stability assumption required by our checking mechanism. While non-monotonic but deterministic functions are difficult to reason about directly at the function level, they can still be treated as an atomic expression `exp` and tested through monotonic outer transformations such as `exp + 2` or `exp * k`, which still induce predictable value-level changes. In contrast, queries involving non-deterministic functions are currently out of scope, since their results may vary across executions and thus violate the stability assumption required by our checking mechanism.

8 Related Work

Metamorphic Testing for Logical Bug Detection in DBMSs. A variety of MT approaches have been proposed to detect logical bugs in DBMSs [7, 12, 17, 20, 21, 34–36, 38–40]. For example, NoREC [34] transforms an optimizable query into a non-optimizable form and detects semantic inconsistencies by comparing their outputs. TLP [35] divides query predicates into multiple subqueries and verifies that the union of their results is equivalent to the original query. PQS [36] constructs queries expected to retrieve a specific pivot row, while DQE [38] detects logical bugs by comparing whether different SQL queries with the same predicate access the same rows in the database. PINOLO [17] generalizes this paradigm through set-level approximation, where predicates are relaxed or restricted to generate over- and under-approximate queries, and correctness is judged by inclusion or containment relations between result sets.

As discussed in Section 1 and Section 2, existing MT approaches are primarily limited to equivalence-based testing or set-level approximations. In contrast, our work extends MT by jointly modeling set- and value-semantic approximation, enabling the detection of logical bugs that remain undetectable under prior frameworks.

DBMS Test-Case Generation. A variety of approaches have been proposed for generating diverse test cases for DBMSs, with the aim of improving coverage and revealing potential bugs. These techniques [5, 16, 19, 27, 43] typically focus on generating valid and varied SQL queries, but may not specifically target logical bugs. SQLSMITH [5] is a grammar-based DBMS fuzzer that embeds SQL grammar rules to generate complex SQL queries. It uses a random walk approach to explore the SQL syntax and generate a wide range of queries. SQUIRREL [43] is a mutation-based DBMS fuzzer which introduces an intermediate representation for SQL queries and models dependencies between SQL statements, enabling the generation of queries that contain multiple SQL operations. GRIFFIN [16] uses a grammar-free mutation approach, where it mutates SQL queries based on DBMS state information encapsulated in a metadata graph. QTRAN [27] is a LLM-based approach that can automatically translate test cases from other DBMSs. DYNSQL [19] takes a dynamic approach by interacting with the DBMS to capture the latest state information, allowing for the incremental generation of valid and complex queries. These techniques aim to prevent semantic errors and improve the diversity of generated queries. In addition to general query generation, some approaches have been specifically designed to aid in bug detection. SQLRIGHT [24] leverages code coverage feedback to enhance test-case generation. QPG [6] takes a different approach by recording the query plans covered during DBMS testing and prioritizing the mutation of queries that trigger new query plans.

These general query generation approaches complement VALSCOPE. While approaches like SQLSMITH, SQUIRREL, and GRIFFIN focus on generating diverse queries, VALSCOPE can help identify logical bugs hidden in complex or rarely executed query logic. Conversely, the test cases generated by these methods can provide VALSCOPE with high-quality and varied queries, expanding its ability to uncover bugs. Together, these approaches offer a comprehensive strategy for DBMS testing, improving both query coverage and the detection of logical bugs.

9 Conclusion

In this paper, we propose a unified SQL query approximation model that integrates set-semantic and value-semantic reasoning for detecting logical bugs in DBMSs. Based on this model, we develop VALSCOPE, a metamorphic testing framework that mutates SQL queries and propagates semantic approximations to uncover deep logical inconsistencies. Our evaluation on 6 widely used DBMSs discovers 67 logical bugs, 57 of which have been confirmed at the time of submission. We believe the effectiveness of VALSCOPE can inspire more follow-up research on DBMS testing.

A Artifact Appendix

Abstract

The artifact for VALSCOPE packages the implementation of the SQL generation, seed-query extraction, and mutation-based checking framework described in the paper, together with runnable scripts for six DBMS dialects. It enables users to execute end-to-end testing campaigns, inspect generated SQL workloads and mutation logs, and reproduce representative logical bug reports produced by the system.

Scope

The artifact supports validation of the paper's core systems claims: VALSCOPE combines set-semantic and value-semantic metamorphic testing in one framework, works across multiple MySQL-family DBMSs, and can generate concrete bug evidence including schema setup, original queries, mutated queries, and mismatch or failure logs. The artifact is intended for reproducing the testing workflow and representative bug-finding results rather than re-running every 24-hour campaign reported in the full evaluation.

Contents

The artifact repository contains the VALSCOPE source code, dependency manifest, dialect-specific execution scripts, example generated SQL outputs, mutation logs, and documentation. The main entry points are `main.py` for the core workflow and `scripts/<dialect>/run.sh` for automated evaluation on MySQL, MariaDB, Percona, TiDB, OceanBase, and PolarDB. Generated schemas, queries, and seed queries are written to `generated_sql/`; execution logs are written to `logs/`; and mutation mismatch records are stored under `invalid_mutation/`.

Hosting

The artifact is hosted at https://github.com/linli1724647576/ValScope-AE. The evaluated version is the public `master` branch at commit `ee89ac36840252063e951c5cbb61e430970f5241` (published on May 21, 2026).

Requirements

The artifact requires Python 3.8 or newer and the Python packages listed in `requirements.txt`. The automated evaluation scripts additionally require Docker and a POSIX-compatible shell environment (for example Linux, macOS, or WSL on Windows). The artifact has been prepared and tested with the following DBMS versions: MySQL 9.4.0, MariaDB 12.0.2, Percona Server 8.0.43-34, TiDB 8.0.11, OceanBase 5.7.25, and PolarDB X-Cluster 8.0.32.

Getting Started

Install dependencies with `pip install -r requirements.txt`. A typical short run can be launched with `bash scripts/mysql/run.sh -mutator-type both -run-hours 0.5`. Each script starts the target DBMS, waits for readiness, bootstraps a schema, runs SQL generation and seed-query extraction, and then invokes the value and/or set mutators. Evaluators can inspect the resulting logs and mutation records to verify bug evidence, including mismatching query results and DBMS failures.

The Abstention Protocol: RCA for Clos Fabrics (Operational Systems)

Madhava Gaikwad*
Independent

Deepak Pandey
Microsoft

Abstract

Root cause analysis (RCA) in large datacenter networks is challenging because telemetry is noisy, partial, and asynchronous. Score-based approaches degrade under these conditions, often yielding unstable or incorrect attributions.

We present CORESEC, a production RCA system that replaces weighted fusion with a PAM-style abstention algebra. Telemetry agents are composed using control flags that yield deterministic decisions and explicit abstention when evidence is ambiguous. CoreSec combines this algebra with topology-aware configurations that capture failure surfaces across Clos fabrics and converge monotonically as evidence accumulates.

Deployed at hyperscale, CoreSec provides stable and explainable RCA behavior across diverse environments without retuning. Our experience shows that structured composition with abstention forms a practical foundation for automated RCA in real-world cloud networks.

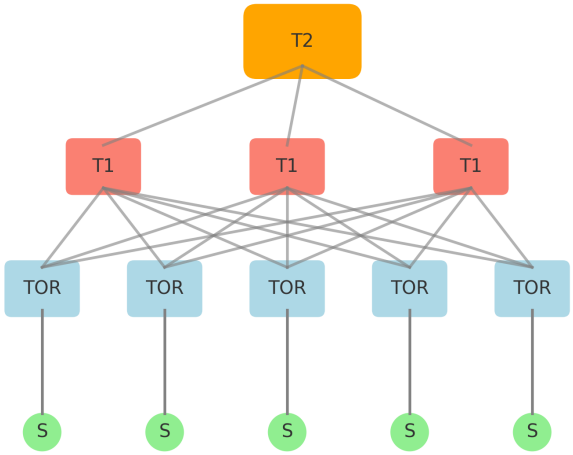

Figure 1: Three-tier Clos topology. Servers connect to TORs, TORs to T1 aggregation switches, and T1s to T2 spines.

1 Introduction

Large cloud networks operate with continuous background faults. In a cluster with thousands of switches, it is normal to see a server-to-TOR (top-of-rack switch) cable with CRC errors, a switch-to-switch link that flaps intermittently, or a TOR in the middle of an upgrade. (A link *flaps* when it rapidly transitions between up and down states.) Clos topologies are multi-stage switch fabrics that provide many equal-cost paths between any two endpoints (Figure 1). They absorb these faults through path diversity, so the fabric continues forwarding traffic. Prior studies of hyperscale networks report the same behavior [1]. But this background noise makes root cause analysis difficult: when a customer workload fails, many entities show faults. Only a subset are related to the incident. Most are routine background failures.

Accurate RCA matters for two reasons. Customers expect precise explanations for connectivity disruptions: what failed, whether it will recur, and what Azure is doing about it. Engineering teams use aggregated RCA data to identify systemic weaknesses in firmware, optics, and operational processes. Patterns across thousands of incidents reveal which hardware families fail most often and which operational changes introduce risk [2–4].

Most failures CoreSec attributes are not fail-stop. They are *gray failures* [5]: partial, probabilistic, or intermittent malfunctions. A device with a loose optical module may drop two percent of packets on one direction of one link. A linecard with a memory bit-flip may corrupt headers only for flows that hash to a particular ECMP path. A firmware bug may periodically reboot a switch and recover before health monitors notice. Their surface symptoms blend into the steady background fault rate (§2), and a fresh on-call engineer cannot tell, just from looking at counters and probes, whether a particular signal indicates the incident under investigation or one of the dozens of unrelated faults always quietly happening somewhere in the fabric.

*This work was performed when Madhava Gaikwad was with Microsoft.

CoreSec runs on top of an existing operational pipeline at Azure. Many of its inputs come from telemetry systems built and deployed before CoreSec, two of which are particularly relevant. Pingmesh [1] runs on every server and continuously measures end-to-end latency and packet loss between server pairs across the fabric. It tells operators *that* something is wrong and *which region* is affected, without saying which device is at fault. NetBouncer [6] sits a layer below: it actively probes paths through the Clos fabric and infers *which links and devices* are unhealthy. Neither answers the question we kept getting paged for: given a specific incident raised against a specific customer service, which network entity *caused it*? At any moment many entities will be unhealthy, most unrelated to the incident under investigation. CoreSec consumes the outputs of Pingmesh, NetBouncer, and a number of other agents (device counters, traffic-derived signals, control-plane events, infrastructure health summaries) and resolves them into a single attribution. We discuss the relationship to these systems in more detail in §11.

Earlier RCA systems at Azure used weighted aggregation of telemetry signals. A *telemetry agent* is a software component that observes some property of the network (active probes, device counters, or traffic flows) and reports a per-entity verdict on whether that property looks healthy. Each agent produced a score, and the entity with the highest weighted sum was blamed. This approach failed in predictable ways. Background faults always contributed some signal, so the system found a culprit even when the network was not at fault. Tuning weights to reduce false positives for one failure mode increased them for another. The false positive rate fluctuated between 18 and 22 percent and could not be controlled [1, 6, 7].

The key observation behind CoreSec is that RCA in this regime is a composition problem. No single telemetry agent is reliable across all failure modes: active probes detect link failures quickly but miss software defects; device counters catch hardware degradation but produce noise; traffic-derived signals reflect customer impact but have sparse coverage. We describe these agent classes in detail in §2 (§2.2). CoreSec assigns each agent a control flag that specifies whether its evidence is required, sufficient, or optional. When evidence conflicts or is missing, the system abstains. This structure is inspired by Pluggable Authentication Modules (PAM) [8], which combines independent authentication checks (password, biometrics, hardware token) by tagging each one as required, sufficient, or optional. The composition problem is the same one we face with telemetry.

This paper makes four contributions:

- **A composable RCA algebra with explicit abstention.** We adapt the control-flag model from PAM to network RCA. Each telemetry agent is assigned a flag: requisite, required, sufficient, or optional. Five configurations run in parallel, each targeting a different failure surface in the Clos topology. The algebra admits a third outcome alongside healthy and unhealthy — the system abstains when evidence is missing or conflicting — and produces deterministic, explainable decisions.
- **Topology-aware heuristics.** We derive a small set of topology thresholds for server-to-TOR, TOR-to-T1, and cluster-level attribution from multi-year analysis of historical incidents [9, 10]. These thresholds (described in §5) sit at the knees of their error curves and generalize across various Azure deployments without recalibration.
- **Three-year production deployment.** CoreSec has processed over 700,000 incidents and reduced false positives from 18-22 percent to below 1 percent. We treat abstentions as explicit false negatives; this rate dropped from 10 percent initially to 1.5 percent over the most recent six months. The system eliminated three full-time engineers worth of manual RCA work.
- **Formal model.** We give an algebraic specification of the merge operator as a three-valued lattice with a short associativity proof, together with absorption and consensus properties (Appendix A) that account for CoreSec's determinism and order-invariance under asynchronous telemetry.

CoreSec is invoked post-incident, not as a continuous monitor: an external detector raises an alert, and CoreSec attributes that specific incident from a sixteen-minute telemetry window. Each of its five configurations targets one component type in the Clos topology (server-to-TOR cable, TOR, switch-to-switch cable, T1, T2). Within a configuration the PAM-style algebra resolves agent verdicts to *healthy*, *unhealthy*, or *indeterminate*; across configurations, topology heuristics (§5.2) decide which layer is responsible when several vote. If no configuration has sufficient evidence, CoreSec abstains. Figure 2 shows this flow.

A walkthrough. To make the flow concrete: suppose three servers fail in a way that points to upstream trouble. Configuration 2 (TOR switch) marks each server's TOR as a candidate. Configuration 4 (T1 switch) checks whether enough TORs in the same T1's fan-out are also unhealthy. If at least two-thirds are, the T1 votes and suppresses the individual TOR candidates. The final RCA is the T1. §5 gives the full numbers.

2 Background and Motivation

Clos Fabrics in Hyperscale Networks Hyperscale cloud networks use multi-stage Clos topologies because they offer predictable bandwidth, uniform latency, and clear fault containment. A three tier fabric connects servers to top-of-rack (TOR) switches, TORs to aggregation switches (T1), and T1s to spine switches (T2). Each server typically connects to one

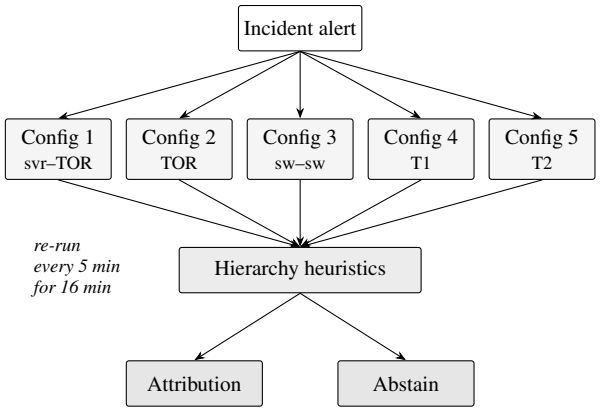

Figure 2: CoreSec dataflow. An incident triggers five parallel configurations; hierarchy heuristics combine their votes into one attribution or an abstention.

or more TORs for fault tolerance, and each TOR has several uplinks to independent T1s. This structure creates many equal-cost paths and allows traffic to be rerouted quickly when a link or device fails [1, 10].

Clos fabrics experience a continuous background rate of faults. Optical modules drift, cables accumulate CRC errors, control plane processes restart, and firmware upgrades proceed on rolling schedules. Studies of deployed clusters show hundreds of transient link faults and dozens of device reboots daily in a single region [10]. Multipath routing absorbs these faults, so they rarely cause visible disruption. It is normal for 0.3 to 1 percent of links to show loss, flaps, or degraded optics at any given time [1].

This baseline complicates root cause analysis. A customer-visible incident often coincides with several unrelated background faults. The topology shapes how failures propagate: a TOR failure typically affects only its rack, while a T1 failure creates correlated symptoms across many TORs. CoreSec's heuristics are built around these propagation patterns.

Telemetry Agents and Failure Signals

Large-scale Clos networks rely on multiple telemetry sources to detect and localize failures. Each source observes the network from a different vantage point and reports at different temporal and spatial resolutions [1, 6, 7].

Active probes. Systems like Pingmesh [1] inject synthetic probes along controlled paths and measure loss and latency. Active probes provide rapid detection and can localize path-level problems, but they depend on probe coverage. Some links may see sparse or no probing during certain intervals.

Device counters. Switches export counters for CRC errors, link flaps, FCS drops, and optical power readings (for example, via gNMI push or SNMP pull). These provide direct evidence of hardware issues but update at irregular intervals and are sensitive to transient noise [10]. Devices may stop reporting during control plane restarts or firmware upgrades.

Traffic-derived signals. Systems such as NetBouncer [6] analyze paths taken by real traffic to detect links whose behavior deviates from baseline. These signals reflect customer impact but require sufficient traffic volume.
