An alternative is on-demand mapping using low-level memory-management APIs such as CUDA Virtual Memory Management (VMM) [39]. However, this path is blocked by *prohibitive mapping latency*. VMM's mapping overhead scales with the number of pages whose mappings should be established or updated, and serialized host-side driver calls can incur millisecond-scale delays. This makes VMM mapping up to three orders of magnitude slower than microsecond-scale kernel execution. Recent systems such as vAttention [45] and GMLake [16] attempt to *hide* this latency through complex

† Jiacheng Zhao is the corresponding author.

scheduling. However, they do not address the root cause: the mapping latency itself remains high, leaving systems vulnerable to latency spikes in dynamic deep-learning workloads.

The conflict is clear: allocating memory on the fly introduces high latency and hurts performance, while pre-allocated memory pools lead to fragmentation and hurt memory utilization. These derivative problems raise a classic operating-systems question: When a foundational abstraction layer is inadequate, should the user-space application layer continue building workarounds, or is it time to fix the foundation itself? Instead of continuing to patch this foundation with user-space workarounds, we ask a fundamental question: *Can we re-architect GPU virtual memory management to address both allocation latency and fragmentation?*

Our key insight is that GPU memory management should not be treated as a serialized OS control task, but as a data-parallel workload ideally suited for the GPU itself. Although promising, translating this theoretical insight into a practical system requires bridging two fundamental challenges:

Challenge 1: How can the GPU maintain its page table efficiently? Existing GPUs lack privileged instructions for page table manipulation from user space. How can we enable direct GPU control over page tables without hardware modifications?

Our solution. We propose MOONBRIGHT, which leverages both the massive parallelism and ultra-high memory bandwidth of modern GPUs to efficiently construct and update page tables directly on the device. First, by mapping the multi-level page table region into the virtual address space, MOONBRIGHT allows CUDA kernels to natively read and write page-table entries. Second, all modifications are executed by MOONBRIGHT-generated kernels specifically tuned to fully saturate the GPU's multi-TB/s bandwidth, slashing page-table update latencies to mere microseconds.

Challenge 2: How can we minimize TLB flushes while maintaining coherence? CPU-issued TLB shootdown is a fundamental component of current GPU memory management. Commodity GPUs require the CPU to initiate TLB shootdowns, and each flush can impose a global CPU-GPU synchronization point before memory operations proceed. This creates a major performance bottleneck and prevents page-table updates from being integrated cleanly into *stream-ordered execution*.

Our solution. MOONBRIGHT introduces a *Deferred TLB Coherence* protocol to decouple memory allocation from expensive global synchronization. The key mechanism is an *Always-Fresh* virtual address (VA) allocation strategy. By guaranteeing that every new allocation receives a previously unused VA, MOONBRIGHT ensures that new mappings inherently avoid conflicts with stale TLB entries. This invariant allows MOONBRIGHT to safely bypass TLB flushes on the critical allocation path, relegating explicit coherence operations strictly to exceptional cases, such as VA recycling, remapping, or permission modifications.

Method	Fast Alloc.	Stream Order	Flexible Map	Defrag.
cudaMalloc	✗	✗	✗	✗
cudaMallocAsync	✓	✓	✗	✗
CUDA VMM	✗	✗	✓	✓
Userspace Caching Allocator	✓	✓	✗	✗
Ours	✓	✓	✓	✓

Table 1: Comparison of memory primitives. **Fast Alloc.**: Low allocation latency on the critical path; **Stream Order**: Non-blocking, stream-aware allocation semantics; **Flexible Map**: Decoupling of virtual and physical memory for arbitrary mappings; **Defrag.**: External-fragmentation mitigation. MOONBRIGHT uniquely achieves all four properties.

Together, these techniques allow MOONBRIGHT to support GPU-side page-table updates while maintaining the coherence guarantees required by modern GPU runtimes. MOONBRIGHT exports several primitives and composes them into a familiar runtime API surface, including `Malloc`, `MallocAsync`, and VMM-style interfaces, while reducing mapping latency and external fragmentation.

Our evaluation shows that MOONBRIGHT reduces mapping latency by up to three orders of magnitude, and that these low-level improvements translate into end-to-end benefits: MOONBRIGHT improves TTFT by up to 8.2× for LLM inference compared with vAttention, and mitigates external fragmentation across training workloads compared with PyTorch's caching allocator.

This paper makes the following contributions:

- **Bottleneck Analysis.** We identify the *CPU-centric* memory management model and *synchronous TLB flushes* as fundamental architectural bottlenecks, which impose severe synchronization overheads on GPU memory management.
- **GPU-Centric Architecture.** We propose a *GPU-centric* design and, to our knowledge, present the first device-side page-table management mechanism on commodity GPUs, moving critical-path operations off the host.
- **Deferred Coherence Protocol.** We introduce an *Always-Fresh* virtual address allocation strategy. This ensures TLB coherence without frequent TLB shootdowns, removing synchronization cost from the common allocation path.
- **System Implementation.** We implement MOONBRIGHT as a purely software mechanism on commodity NVIDIA and AMD GPUs, requiring no hardware modifications and integrating transparently with CUDA and HIP runtimes.

To facilitate further research in GPU systems, we have open-sourced the implementation of MOONBRIGHT at MoonBright-project.

2 Background and Motivation

2.1 Managing GPU Memory

We use CUDA to illustrate modern GPU memory management, but the same design patterns and limitations also apply to HIP/ROCm. CUDA provides three classes of device-memory management interfaces: the `cudaMalloc`, `cudaMallocAsync`, and the `CUDA Virtual Memory Management (VMM) API`. These interfaces occupy different points in the design space of allocator flexibility, synchronization overhead, and fragmentation.

CUDA VMM API. The Low-Level GPU Virtual Memory Management interface (e.g., `cuMemAddressReserve`, `cuMemCreate`, `cuMemMap`, `cuMemSetAccess`) exposes low-level virtual memory primitives. It decouples virtual address reservation, physical memory creation, mapping, and access control, allowing page-granular management of device memory. In the CUDA VMM path, `cuMemMap` binds physical allocations to reserved virtual ranges, while `cuMemSetAccess` installs access permissions and makes the mapping visible to the device. Current implementations keep this path host-driven and can trigger global CPU-GPU synchronization, resulting in long operation latency [16,45] and preventing stream-ordered execution.

cudaMalloc. The traditional GPU memory allocation API can be seen as a fixed sequence of `VMM` operations. The runtime reserves a contiguous virtual address range, allocates physical memory of the same size, maps the two, and installs access permissions. These calls also impose global synchronization, so allocation and deallocation cannot overlap with kernel execution and often dominate critical-path latency.

cudaMallocAsync. To reduce allocation latency, CUDA provides `cudaMallocAsync` and `cudaFreeAsync`, which operate on a runtime-managed memory pool. Requests are served from cached blocks rather than invoking VMM operations. This achieves low latency but fixes allocation granularity to pool blocks. Because the allocator cannot flexibly remap virtual pages to physical pages, fragmentation accumulates under workloads with diverse or long-lived allocations.

Userspace caching allocators. To mitigate the high mapping latency of `cudaMalloc`, modern frameworks often deploy custom userspace allocators, such as those in PyTorch and TensorFlow. These allocators follow the same design principle as `cudaMallocAsync`: they overprovision a large memory pool using `cudaMalloc` and manage it with best-fit or similar placement policies. As a result, they inherit the same fundamental limitation. Once the pool develops holes, subsequent allocations may be satisfiable only by non-contiguous free regions, yet the allocator lacks the ability to manipulate page tables to eliminate fragmentation. Consequently, memory utilization degrades over time, especially in long-running or dynamically shaped workloads.

Alloc. Size	Book-keeping	Phys. Alloc.	PT Build	TLB Flush	CUDA Total	Ours Total
2 MB	0.8	8	47	3.7	59	**24**
16 MB	1.1	9	422	5.1	437	**27**
128 MB	1.2	10	949	6.3	966	**32**

Table 2: Latency breakdown of `cudaMalloc` for different allocation sizes. All values are in microseconds. Page-table construction dominates the CUDA path; MOONBRIGHT's total latency is shown for comparison.

2.2 Architectural Bottlenecks

The aforementioned limitations are not merely engineering artifacts of specific APIs; they stem from deeper architectural choices in how GPUs manage memory control paths.

2.2.1 Dissecting Allocation Latency.

We find that allocation latency arises fundamentally from the *CPU-centric* page-table model. Historically, the CPU maintains the authoritative page tables, while GPU-resident page tables act as device-side replicas. Consequently, every allocation, deallocation, remapping operation, or permission update is first processed on the CPU, serialized through the vendor driver, and then propagated to GPU-resident translation structures. Once the GPU page table is updated, the host triggers a TLB flush to maintain coherence across the GPU's translation caches.

Table 2 breaks down the latency of a `cudaMalloc` operation on an NVIDIA A100 GPU. By instrumenting the driver and runtime phases, we decompose the end-to-end latency into four components: *Logical bookkeeping* (tracking VA metadata), *Physical allocation* (obtaining device pages), *Page-table construction and transmission* (building CPU-resident PTEs and shipping them via PCIe), and *TLB flush*. As shown in Table 2, allocation latency remains high, reaching approximately 1 ms for a 128 MB allocation.

More importantly, *page-table construction and transmission* overwhelmingly dominate the cost, accounting for 80% to 99% of the total latency across the evaluated sizes. This disproportionate expense is not simply a PCIe bandwidth artifact. Modifying translations requires mutating shared address-space state: validating VA ranges, instantiating missing page-table levels, encoding leaf PTEs, and locking structures against concurrent updates. Crucially, while encoding thousands of independent leaf PTEs is an inherently data-parallel task, the CPU-centric model forces the host driver to construct them *serially* within a sequential execution loop. The observed latency is thus a massive compound penalty of this sequential host-side PTE construction, state propagation across the PCIe bus, and conservative coherence enforcement.

Insight 1: GPU-Resident Translation. This observation mo-

tivates MOONBRIGHT's core architectural pivot: making the device page table authoritative for device translations. Once the host supplies the physical-frame list, PTE materialization becomes an inherently data-parallel operation over independent pages. MOONBRIGHT therefore dispatches GPU kernels to directly update device-resident page tables, leveraging the GPU's massive parallelism and multi-TB/s memory bandwidth to bypass serialized CPU driver loops. As highlighted in Table 2, this design reduces the 128 MB page-table update latency to only 32 μs, shifting page-table materialization from a dominant control-plane bottleneck to a lightweight device-side operation.

2.2.2 Dissecting Memory Fragmentation.

To amortize the severe control-path overhead discussed above, deep learning frameworks universally rely on user-space pooling. Allocators such as TensorFlow's BFC [1] and PyTorch's caching allocator [43] acquire massive memory regions from the driver upfront, serving subsequent requests through user-space suballocation. More recently, NVIDIA introduced stream-ordered allocation via `cudaMallocAsync`, which extends this philosophy by serving requests from CUDA-managed pools without enforcing device-wide synchronization.

However, because these designs treat pooling as their sole defense against mapping latency, they inherit the fundamental weakness of pool-based allocation: they cannot manipulate page tables to consolidate memory. Recent studies [16, 19, 25] confirm that the irregular, dynamic tensor lifetimes in large-scale training and inference inevitably misalign with the pool's layout. This mismatch rapidly accumulates severe external fragmentation, wasting device memory and halting scalability.

Ideally, an allocator would cure fragmentation by using Virtual Memory Management (VMM) APIs to transparently remap physical pages behind contiguous virtual addresses. Yet, under the current CPU-centric architecture, any attempt to dynamically remap pages introduces a catastrophic performance penalty. To ensure coherence, a VMM remapping operation demands global device-wide synchronization: the CPU driver must wait for all active kernels across all streams to finish, drain the device entirely, and only then issue a global TLB flush. Even though the hardware flush itself is relatively fast (e.g., 6.3 μs in Table 2), this mandatory global synchronization forces the GPU to completely empty its execution pipelines. This heavy-handed barrier forcibly degrades modern asynchronous, stream-ordered execution back into blocking, synchronous execution, rendering VMM-based defragmentation practically unusable for latency-sensitive frameworks.

Insight 2: Deferred Coherence via Fresh VAs. One of our observations is that GPU workloads require far fewer TLB coherence events than CPU counterparts. While CPUs frequently mutate existing address spaces (e.g., context switches, permission changes), GPU workloads are highly regular, predominantly allocating *new* memory. Our TLB microbenchmarks (§5.5) show that, when a newly allocated virtual address has no stale same-address translation in the TLB, MOONBRIGHT can safely install the mapping *without* a flush. The first access observes a TLB miss and walks the newly materialized page-table entry.

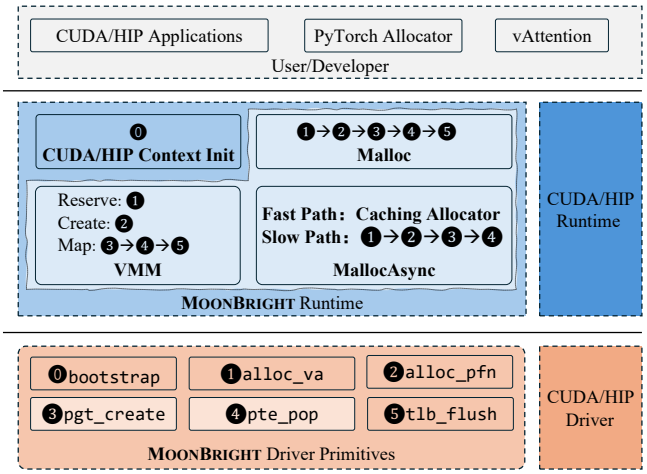

Figure 1: MOONBRIGHT System Overview.

This insight underpins MOONBRIGHT's *Deferred VA Reuse* (Always-Fresh) policy. By ensuring the allocator strictly assigns previously unused virtual address ranges to new allocations, MOONBRIGHT guarantees that new PTEs will not collide with stale TLB entries. This elegantly circumvents the stop-the-world TLB flush, deferring coherence operations only to the rare cases of actual VA recycling. Consequently, MOONBRIGHT can perform asynchronous, low-latency defragmentation in the background without stalling compute streams.

Takeaway. The host-side bottlenecks inherent to the CPU-centric page-table model necessitate a GPU-centric architectural shift. Centralizing page-table construction on the GPU eliminates CPU-mediated serialization latency, and the Always-Fresh virtual address policy eliminates unnecessary TLB flushes. Together, these two pillars form the foundation of MOONBRIGHT, uniquely satisfying the requirements of fast allocation, flexible mapping, and external-fragmentation mitigation (as summarized in Table 1).

3 Design of MOONBRIGHT

MOONBRIGHT introduces two key mechanisms: device-side page-table materialization and deferred TLB coherence. Figure 1 presents the overall architecture of MOONBRIGHT, which adopts a two-layer organization consisting of a driver layer and a runtime layer. The driver layer exposes a set of low-

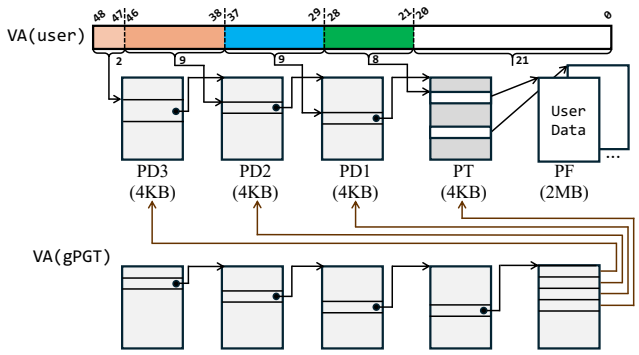

Figure 2: **Bootstrap.** The hardware page table structures backing VA(user) are mapped to a specialized virtual address, VA(gPGT). This pointer allows CUDA kernels to treat the page table as an array.

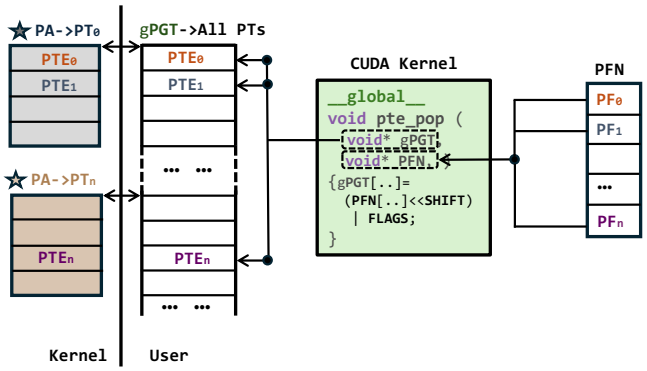

Figure 3: Workflow of the parallel PTE population kernel (`pte_pop`). MOONBRIGHT utilizes massively parallel GPU threads to dynamically synthesize Page Table Entries (PTEs) directly into the global GPU Page Table (*gPGT*).

level memory-management primitives (e.g., page-table manipulation, virtual-address allocation, and fine-grained mapping operations). The runtime layer orchestrates these primitives to implement standard memory allocation interfaces compatible with existing GPU software, from native CUDA/HIP applications to deep-learning frameworks such as PyTorch.

3.1 Composable Low-Level Primitives

MOONBRIGHT fundamentally shifts page table construction to the GPU by defining updates as data-plane workloads. To ensure the host (Control Plane) maintains a consistent view of the device-resident state without costly synchronization, we introduce a *Linearized Page Table Abstraction*. This allows the CPU to deterministically calculate the location of any page table entry (PTE) in GPU memory using purely arithmetic operations, eliminating the need for costly round-trip PCIe communications.

❶ ***Bootstrap: Linearized View Construction.*** Triggered upon CUDA context creation, this primitive initializes the GPU-resident metadata required to manage the hardware's multi-level page table hierarchy ($PD_3 \rightarrow PD_2 \rightarrow PD_1 \rightarrow PT$). As shown in Figure 2, MOONBRIGHT must make the physical pages that hold the hardware page-table hierarchy reachable through a device virtual address before a CUDA kernel can update them. Specifically, MOONBRIGHT obtains the physical addresses of the multi-level page-table pages and bootstrap-maps those pages into a contiguous virtual range, creating the *GPU Page Table* (*gPGT*) view. *Abstraction Provided:* This primitive exposes the multi-level page table as a flattened, linear array ($gPGT[va_idx]$). This abstraction allows both the CPU and GPU to index PTEs using a simple offset calculation ($Base + VPN \times sizeof(PTE)$), enabling fast coordination between host orchestration and device execution.

MOONBRIGHT exposes five *composable primitives* that serve as the building blocks for customized memory allocators:

❶ ***Virtual Address Allocation (alloc_va).*** Managed by a CPU-resident Red-Black tree, this primitive governs the logical layout of the application's virtual address space. It allocates virtual memory ranges (VAs) and maintains high-level metadata (e.g., valid/free status).

❷ ***Physical Page Allocation (alloc_pfn).*** This primitive interfaces with the low-level physical resource manager (e.g., NVIDIA GPU System Processor (GSP) or HIP Buddy Allocator) to acquire available physical pages. It requests physical page frame numbers (PFNs) and ensures the allocated memory remains resident and accessible to the device. Crucially, it captures the *Allocation Layout State* alongside the raw PFNs. This state serves as a coordination protocol for downstream primitives, providing the necessary physical address metadata required for the subsequent parallel mapping operation.

❸ ***Page Table Construction (pgt_create).*** This primitive serves to populate sparse regions of the page table hierarchy. Upon detecting a missing directory level for a target range, it validates the request against the virtual address state maintained by ❶. Subsequently, it allocates the requisite physical backing for the directory (e.g., *PT*) and executes a GPU kernel to install the physical pointers into the global page table array (*gPGT*), ensuring the structural integrity of the mapping tree.

❹ ***Parallel PTE Population (pte_pop).*** This core primitive unifies the transformation of physical addresses into hardware-compliant Page Table Entries (PTEs) and their population into the GPU page table. Unlike standard drivers that perform serialized PTE population from the host CPU, MOONBRIGHT first transfers raw Physical Frame Numbers (PFNs) to a GPU-resident buffer, termed the *GPU PFN Buffer* (*PFN*).

As illustrated in Figure 3, the mapping workflow executes as a single, high-bandwidth parallel kernel that fuses construction and population. At runtime, thousands of GPU threads op-

erate in parallel to execute a two-step process: First, **On-the-fly Construction**: The GPU kernel reads raw page frame numbers (*PFN*) and dynamically synthesizes hardware-compliant PTEs. This is achieved by combining physical addresses with user-specified access permission bits (e.g., Read/Write flags) using efficient bitwise operations. Second, **Population**: The generated PTEs are immediately written into the destination slots of the GPU Page Table (*gPGT*).

By keeping both the source data (*PFN*) and the destination structure (*gPGT*) resident in high-bandwidth device memory, this design transforms memory management into a pure, on-device data movement task. It leverages the GPU's massive parallelism to populate page tables at memory-bandwidth limits, executing substantially faster than CPU-driven approaches. Furthermore, because this stage is implemented via a programmable *GPU Kernel* rather than rigid driver callbacks, MOONBRIGHT allows developers to utilize standard parallel programming models to express diverse mapping paradigms, dynamically routing PFNs to arbitrary virtual addresses.

❺ ***TLB Flush (tlb_flush).*** This primitive is invoked when an update can leave stale translations for the same virtual address, such as unmapping, permission changes, or remapping an existing VA. It triggers a host-initiated hardware TLB shootdown and therefore introduces a GPU-wide synchronization point. Fresh-VA mappings do not use this primitive: subsequent kernels observe the new PTEs through normal stream ordering, and no stale same-VA translation can exist.

3.2 User-Facing Memory API Design

In this subsection, we present how to construct memory allocators based on MOONBRIGHT's primitives.

3.2.1 Reconstructing `Malloc`

To demonstrate the composability of our primitives, we present a high-performance implementation of a standard synchronous memory allocator. Designed as a functional equivalent to `cudaMalloc`, this implementation orchestrates the primitives defined in §3.1 into a cohesive pipeline, addressing the granularity mismatch between user requests and hardware pages via a standard slab layer.

Large Allocation. For requests exceeding the slab threshold, the runtime orchestrates a sequential primitive pipeline: resources are first secured via ❶ and ❷, followed by hierarchy instantiation using ❸. The mapping is then materialized by the ❹ parallel kernel. If the allocation uses a fresh VA, no TLB flush is required. A ❺ flush is appended only when the allocator must recycle an old VA or update an existing mapping.

Small Object Management. Since hardware physical pages are fixed at a coarse granularity (e.g., 2 MB) while user requests might be fine-grained (e.g., 1 KB), we employ a classic slab [8] allocation strategy to manage sub-page objects. The allocator maintains user-space metadata organized by size classes. For requests with smaller objects, it locates available slots within active slabs via bitmap scanning. This operation is performed entirely in user space, avoiding the latency of driver interactions or hardware primitives. Only when a slab is fully exhausted or a request exceeds the slab threshold does the allocator invoke the underlying primitive layer to acquire fresh physical resources.

De-allocation. The de-allocation process (`MemFree`) executes a strictly ordered sequence to ensure memory consistency. First, the runtime enforces a device-side synchronization barrier to ensure all active kernels accessing the target memory have completed. Subsequently, it invokes a specialized unmapping kernel to atomically invalidate the PTEs in the GPU-resident page table by zeroing out the corresponding entries. Once the source mappings are invalidated, a TLB flush is immediately issued to evict any stale translations, thereby enforcing coherence. Only after this sequence is confirmed does the runtime return the physical page frames to the system allocator via the inverse of *alloc_pfn*. To minimize reconstruction overhead during future allocations in the same region, the upper-level page table hierarchy associated with the virtual address range is preserved.

3.2.2 Fragmentation-Mitigating `MallocAsync`

We propose an asynchronous memory allocator that exposes fast, fragmentation-free allocation as a virtual-memory primitive rather than as a framework-specific caching policy.[2] By moving allocation efficiency into the virtual-memory layer, MOONBRIGHT provides a common substrate that can serve existing frameworks directly or simplify their caching allocators, rather than requiring each framework to independently engineer fragmentation mitigation.

Deterministic TLB Coherence via Fresh Virtual Addressing. The central challenge in asynchronous allocation is maintaining TLB coherence without global synchronization caused by TLB flushes. Standard allocators require explicit flushes to ensure both correctness and performance determinism. This is necessitated by the *non-coherent* nature of GPU MMUs: hardware lacks a mechanism to actively propagate page table updates to the TLB, risking the usage of stale or inconsistent entries (e.g., negative caching artifacts [74]) if not flushed.

To eliminate this hazard without blocking execution, we propose an *"Always-Fresh" Virtual Address (VA)* allocation strategy. By ensuring that new allocation occupies a fresh, previously unused VA range within the current coherence epoch, we guarantee the absence of stale same-VA TLB entries; therefore, no flush is needed on this fast path. This strategy is architecturally feasible for two reasons.

[2] Internal fragmentation due to page granularity is a separate policy trade-off and is orthogonal to the virtual-memory mechanism studied in this paper. Unless otherwise stated, fragmentation refers to external fragmentation.

First, MOONBRIGHT provides the high-throughput mapping primitive needed to sustain rapid VA consumption. Second, the required virtual-address space can be sized using a theoretical guideline. We adopt Robson's worst-case allocation analysis [53] as a conservative estimate for provisioning the VA buffer: $M(1+\frac{1}{2}\log_2 n)$, where M is the physical memory size and n is the ratio between memory size and page size. For an 80 GB GPU with 2 MB pages, this estimate is approximately 693 GB. This footprint is well within the hundreds-of-TB virtual address spaces exposed by modern GPUs and incurs only modest overhead for additional page-table structures. Guided by this theoretical estimate, MOONBRIGHT manages VA space as a large buffer with lazy reclamation, ensuring TLB coherence through spatial separation rather than frequent synchronization.

Correctness of Always-Fresh VA. The key invariant behind MOONBRIGHT's TLB-flush avoidance is that a newly installed mapping never reuses a virtual address that may have had a valid same-address translation cached in the GPU TLB. For fresh virtual addresses, there cannot exist a stale same-address valid translation, because the address has not previously been mapped or successfully translated by the device. Therefore, installing a fresh mapping does not require invalidating old translations.

Speculative translation activity does not violate this invariant. Hardware page walkers or translation prefetchers may probe nearby virtual addresses and cache negative translation results, but such entries encode the absence of a valid mapping rather than a *VA-to-physical-frame* binding. They therefore cannot redirect a future access to an old physical frame. Once MOONBRIGHT installs a valid PTE for a fresh VA, the first access either observes the new translation or triggers a page walk that reloads the updated PTE. In this way, MOONBRIGHT replaces a global TLB shootdown with a translation miss, without compromising correctness.

Finally, always-fresh allocation is bounded by the available virtual-address space. MOONBRIGHT treats VA exhaustion as a rare slow-path event. When the current VA epoch approaches exhaustion, MOONBRIGHT waits for outstanding GPU work that may reference the old epoch, performs a global TLB invalidation, and then starts a new epoch in which previously used virtual addresses may be recycled. Thus, VA reuse occurs only after device quiescence and TLB invalidation, preserving the same-address freshness invariant.

Asynchronous Memory Pool Architecture. To provide an allocator with semantics familiar to users of `cudaMallocAsync`, we implement a high-performance memory pool built directly upon our decoupled primitives. The foundation of this architecture is a massive virtual address ring buffer. By maintaining the page table entries (PTEs) in GPU-resident memory, we remove the CPU from the critical path of mapping updates. This design allows the runtime to generate static code with fixed pointers, even as the physical backing memory changes dynamically via the *pte_pop* primitive. Furthermore, this buffer design enables lazy reclamation: when an object is freed, MOONBRIGHT quarantines its VA range instead of handing that VA out immediately. The range becomes reusable only at a recycle epoch, where MOONBRIGHT performs a batched *tlb_flush* before the ring wraps around. This amortizes synchronization across many allocations while keeping the common path flush-free.

Fast Path: Caching Allocator. The first tier of the allocator is designed for the "fast hot path," handling high-frequency allocations. To achieve a low-latency hot path, this tier operates entirely in user space, avoiding the overhead of kernel transitions. Drawing inspiration from the memory management designs of established deep learning frameworks [1, 43], MOONBRIGHT adopts the Best-Fit with Coalescing (BFC) strategy. This approach maintains a user-space memory pool to efficiently satisfy variable-sized requests while actively mitigating fragmentation through immediate block coalescing.

Slow Path: Physical Backing and Orchestration. When the user-space cache is exhausted, or an allocation request exceeds the threshold, the system transitions to the *Slow Path* to acquire fresh backing resources. This process executes a coordinated sequence of primitives: First, the runtime invokes ❶ (`alloc_va`) to reserve a virtual address range from the frontier of the circular buffer and ❷ (`alloc_pfn`) to request physical page frames from the operating system. If the target address range falls within a sparse region of the page table hierarchy, the runtime triggers ❸ (`pgt_create`) to instantiate the necessary page directory structures. Subsequently, the runtime materializes the mapping by launching ❹ (`pte_pop`). This primitive acts as a parallel interpreter, reading mapping directives and populating device-resident page tables at device memory-bandwidth speeds. Since `pte_pop` operates as a standard compute kernel, it follows CUDA stream semantics and can be dependency-tracked together with other GPU work. This allows the page-table population phase to be scheduled asynchronously and, when independent work is available, overlapped with concurrent computation, reducing the exposed latency of mapping construction. Upon *deallocation*, cached blocks are recycled into the Fast Path's free lists rather than being immediately released.

Defragmentation. MOONBRIGHT reduces external fragmentation without data movement. When the allocator lacks a contiguous free block in its pool despite sufficient fragmented physical pages, MOONBRIGHT allocates a fresh contiguous VA range and maps discontiguous physical pages into it. This *logical defragmentation* creates a virtually contiguous buffer from fragmented physical resources solely through parallel page table updates, avoiding the prohibitive overhead of memory compaction and, on the fresh-VA path, TLB flushes.

3.2.3 High-Performance VMM

To provide a familiar programming model while enabling high-performance GPU-centric management, we expose a

driver interface that mirrors the semantics of standard Virtual Memory Management (VMM) APIs. These APIs serve as high-level wrappers around the primitives defined in §3.1, offering granular control over virtual-to-physical mappings while fundamentally redefining the underlying execution mechanism. Consistent with standard protocols like `cuMemMap`, MOONBRIGHT mandates that all operations be aligned to page granularity.

MemAddressReserve. While exporting an interface behaviorally consistent with `cuMemAddressReserve`, this API implements a lightweight booking mechanism via ❶ (alloc_va). It performs logical address reservation by updating the user-space layout tracker, thereby decoupling virtual allocation from physical resource commitment.

MemCreate. This API handles the acquisition of physical backing storage. Corresponding to the primitive ❷(alloc_pfn), it requests a set of physical page frames from the system allocator, ensuring the memory is pinned and accessible to the device. It enforces alignment to the hardware's fixed page granularity (e.g., 2 MB) and retrieves the raw Physical Frame Numbers (PFNs). Instead of keeping these PFNs opaque in the driver, this API exposes them to the runtime's PFN buffer, preparing the data plane for the subsequent, high-bandwidth construction and mapping phases.

MemMap. This API performs the critical binding of physical pages to virtual addresses by orchestrating ❸ (pgt_create) and ❹ (pte_pop). The caller invokes ❺ (tlb_flush) only when the operation can create stale same-VA translations, such as remapping, permission changes, or address reuse. This design addresses the limitations of the split *Map* and *SetAccess* model employed by CUDA and HIP. In existing implementations, the `cuMemSetAccess` call acts as a performance bottleneck by triggering an expensive driver trap. These systems remain constrained by a *CPU-centric control plane*, where access updates require host-side page-table reconstruction, serialized PCIe transfer, and conservative global TLB shootdowns. In contrast, MOONBRIGHT redefines mapping as a high-throughput, data-parallel workload. By offloading these operations to the device and avoiding flushes for fresh mappings, MOONBRIGHT improves mapping latency by orders of magnitude.

De-allocation. To recycle memory resources, MOONBRIGHT provides two complementary primitives: `MemAddressFree` reclaims the virtual address range, while `MemRelease` returns the physical page frames to the system allocator. Crucially, the underlying unmap operation maintains strict TLB coherence, ensuring that stale translations are evicted with the same consistency guarantees as a standard `free` operation.

3.2.4 Stream-Ordered Memory Operations

MemMapAsync. We expose the mapping capability through `MemMapAsync`, which implements page-table updates in a stream-ordered manner. Because `pte_pop` is a normal GPU kernel, mapping tasks are dependency-tracked by the target stream and can overlap with independent compute. For fresh VA ranges, `MemMapAsync` does not require a host-initiated TLB flush. A key advantage of this architecture is the capability to map distinct virtual address ranges to shared physical page frames without data duplication. This mechanism provides zero-copy aliasing of shared physical pages across multiple virtual ranges, which is useful for prefix sharing and beam-search state forking. For operations that overwrite an existing valid mapping, MOONBRIGHT inserts the required coherence point and invokes `tlb_flush`; these same-VA updates are therefore supported, but they are not on the flush-free fast path.

4 Implementation

Our core implementation consists of ≈14.1 KLoC across kernel-space modifications to the open-source NVIDIA [12] and AMD GPU drivers [6], alongside the user-space runtime.

4.1 Adaptation to NVIDIA CUDA GPUs

For NVIDIA CUDA GPUs, our prototype builds on NVIDIA's `open-gpu-kernel-modules` driver, version 560.35.03 [12]. During implementation, we observed two NVIDIA-specific hardware behaviors that affect backend policy choices; we characterize both in §5.4.

First, GSP physical-frame allocation exhibits a size-dependent latency cliff beyond approximately 512 MB. Since MOONBRIGHT does not require physical contiguity, it avoids the cliff by splitting oversized slow-path requests into smaller physical-frame allocation subrequests.

Second, guided by [74], we identify an NVIDIA-specific TLB behavior: aggressive translation prefetching can create *negative caching*, where nearby invalid translations are prefetched and later cause replayable faults. As shown in §5.4, spacing new virtual addresses by the prefetch width avoids this cliff, reducing fault-induced latency by 40.2× at a 32 MB gap. MOONBRIGHT therefore adopts a prefetch-width aligned allocation strategy: new virtual addresses are aligned to 32 MB boundaries so that fresh mappings incur deterministic cold misses rather than costly replayable faults. The 32 MB alignment increases the conservative Robson-style VA budget by 16×, from ≈693 GB to ≈11 TB, still well within the 128 TB user-level VA region exposed by our NVIDIA prototype.

4.2 Adaptation to AMD ROCm GPUs

For AMD GPUs, our prototype builds on AMD's open-source ROCm software stack, version 6.4.0. The AMD backend uses a buddy allocator for physical-frame management. Since we did not observe the large-allocation latency cliff or aggressive

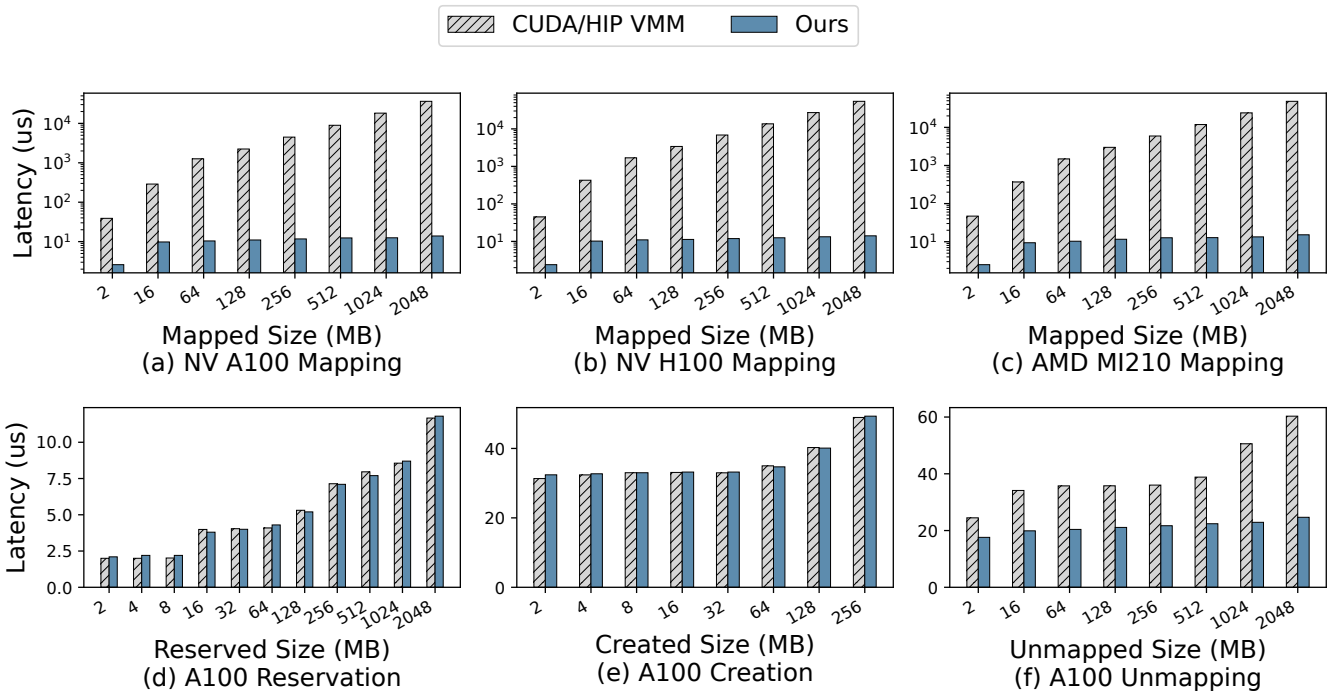

Figure 4: Performance and scalability of low-level virtual-memory APIs across NVIDIA and AMD GPUs.

TLB prefetching seen on NVIDIA GPUs, MOONBRIGHT disables the large-request splitting heuristic and implements the *Always-Fresh VA* strategy without additional virtual-address padding.

5 Evaluation

In this section, we evaluate MOONBRIGHT by answering two research questions:

RQ1: Low-Level Efficiency. Does MOONBRIGHT reduce mapping and allocation overhead across primitives and general GPU workloads while preserving TLB coherence?

RQ2: Application Impact. Do these improvements translate into end-to-end benefits, including lower inference latency, dynamic memory operations, and reduced external fragmentation?

5.1 Experimental Setup

Baselines. We test MOONBRIGHT on a diverse set of GPU architectures to ensure generalizability, including *NVIDIA A100, H100*, and *AMD MI210*. We organize baselines by the functionality and workload targeted by each experiment. For low-level memory primitives, we compare MOONBRIGHT's virtual-memory interface against the vendor CUDA/HIP VMM APIs and runtime allocation primitives such as `cudaMalloc` and `hipMalloc`. For framework-level training workloads, we compare against PyTorch's default caching allocator [43] and GMLake [16], a representative CUDA-VMM-based virtual-memory stitching system for DNN training. For LLM serving workloads, we compare against vAttention [45], which uses VMM-based remapping for KV-cache management, and vLLM [25], which uses software-managed paging.

5.2 Performance of Low-Level APIs

We first evaluate the performance and scalability of MOONBRIGHT's low-level memory-management primitives, which provide functionality comparable to the CUDA/HIP driver VMM APIs.

To ensure a fair comparison against vendor-provided driver-level VMM APIs, we use the same 2 MB page granularity returned as the minimum CUDA VMM granularity on our platform, and vary the mapping range from 2 MB to 2 GB. As shown in Figure 4, MOONBRIGHT consistently outperforms CUDA VMM across all evaluated sizes.

Mapping Cost. For a fresh mapping over a single 2 MB page, MOONBRIGHT reduces mapping latency from ≈ 45 μs with CUDA VMM to 2.6 μs. Here MOONBRIGHT updates only one PTE with one GPU thread, so latency is dominated by fixed device-side mapping overhead, not bulk page-table writes. The gap widens with range size: mapping a fresh 2 GB region takes 36 ms with CUDA VMM, but only 14 μs with MOONBRIGHT, a reduction of over 2,500×.

This improvement comes from a fundamental architectural

shift. As discussed in §3.2.3, CUDA VMM is constrained by a host-mediated control path: page-table construction, state propagation, and conservative synchronization are serialized through the CPU driver and the CPU–GPU interconnect. Even on newer architectures such as H100, page-table updates remain bounded by this off-device control path. In contrast, MOONBRIGHT offloads PTE population to the GPU and treats page-table materialization as a data-parallel device-memory operation, exploiting on-device HBM bandwidth instead of serialized CPU driver loops. Because the mapping operation is expressed as a normal GPU kernel, it also obeys stream ordering: MOONBRIGHT can enqueue the mapping kernel immediately before the computation kernel that consumes the fresh mapping, while independent GPU work in other streams can proceed concurrently.

Initialization Cost. As shown in Figure 4(d) and Figure 4(e), MOONBRIGHT exhibits latency comparable to CUDA VMM for both `reserve` and `create`. This behavior is expected, as these operations remain on the same driver-side critical path: red-black tree manipulation for VA management and GSP invocation for PFN acquisition.

Unmapping Cost. This experiment unmaps each region as a single contiguous range, rather than at a fine-grained 2 MB granularity. As shown in Figure 4(f), under this range-level pattern, MOONBRIGHT consistently outperforms CUDA VMM across region sizes from 2 MB to 2 GB. The absolute latency of CUDA VMM unmapping is much lower than its mapping latency shown in Figure 4(a), because range-level unmapping avoids accumulating fine-grained operation overheads, and invalidating an existing PTE range requires less construction work than installing new physical mappings.

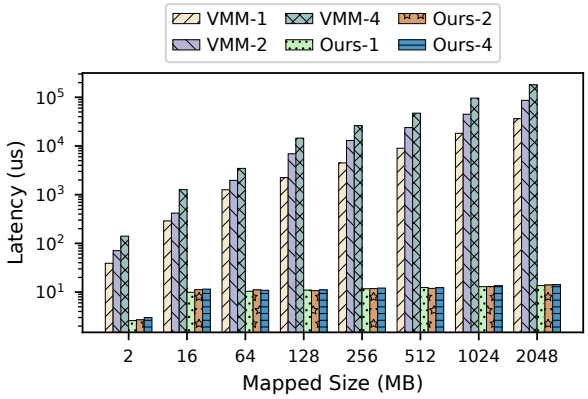

Figure 5: Mapping cost on 1, 2, and 4 A100 GPUs.

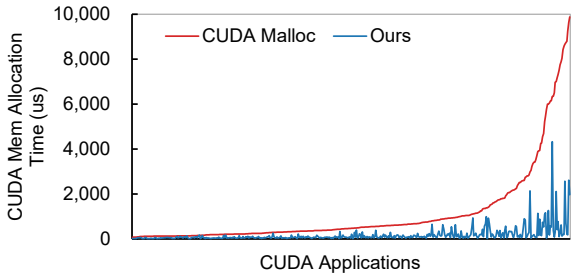
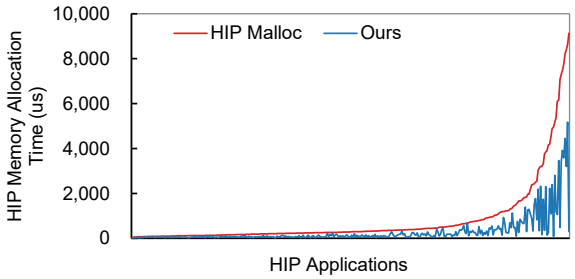
Multi-GPU Scalability. We also evaluate the scalability of MOONBRIGHT, which is particularly important for managing memory across multiple GPUs in the era of large language models (LLMs), where VMM is increasingly used to manage and share KV caches [72]. Figure 5 depicts the mapping latency of CUDA VMM and MOONBRIGHT when the number of GPUs ranges from one to four on a single node. When mapping operations are triggered simultaneously across multiple GPUs within a single machine node using CUDA VMM, we observe that the latency grows approximately linearly with the number of devices. For example, the mapping latency grows from 36 ms on one GPU to 86 ms and 180 ms on two and four GPUs, respectively, for a 2 GB mapping. In comparison, MOONBRIGHT remains nearly constant when mapping on multiple GPUs. On a four-GPU setup, MOONBRIGHT is 12,700× faster than CUDA VMM at 2 GB. Because MOONBRIGHT performs mapping operations locally on each GPU in parallel, its latency remains constant regardless of the number of active GPUs. CUDA VMM, in contrast, is severely limited by repeated synchronization operations, such as lock-/unlock in the CUDA driver and the OS kernel, which are required for each page mapping.



(a) On NVIDIA GPU (including CUDA samples and HeCBench).



(b) On AMD GPU (including ROCm samples and HeCBench).

Figure 6: Memory allocation time on different platforms, sorted by baseline allocation latency.

Performance of Allocation We next evaluate a large set of standard benchmarks to quantify the speedup MOONBRIGHT achieves compared to the vendor-provided memory allocators, including `cudaMalloc` and `hipMalloc`. For this large-scale study, we utilize the official *CUDA Samples* [41], *ROCm Samples* [7], and the *HeCBench suite* [22], which collectively cover a diverse range of scientific and compute-intensive kernels for *NVIDIA GPUs* and *AMD GPUs* (via the HIP interface). The combined test suite contains a total of *1,013* distinct test cases, with the HeCBench suite specifically contributing *864* cases, representing a wide variety of allocation patterns

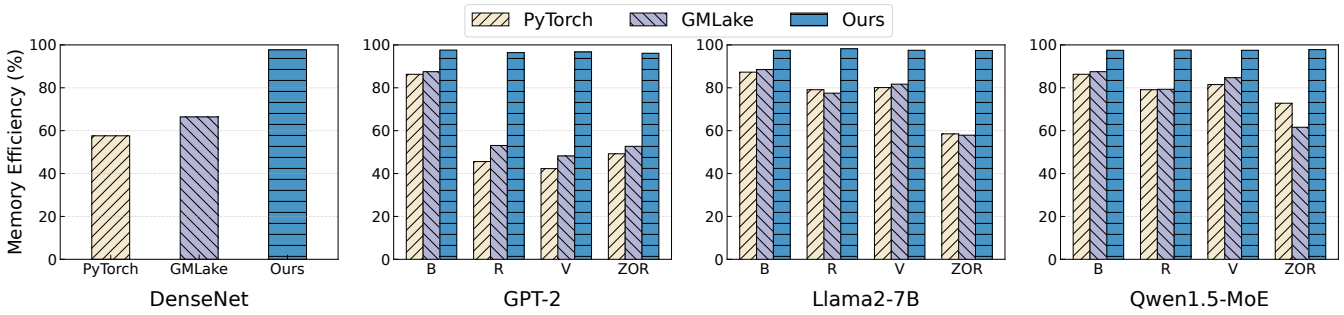


Figure 7: Training memory efficiency on four models across different allocators and optimization combinations: basic (B), recomputation (R), Virtual Pipeline (V), ZeRO (Z), and offload (O).

and memory footprints. This suite provides a broad view of allocation behavior across common GPU workloads.

In each test, we intercept all vendor allocation APIs (e.g., `cudaMalloc`, `hipMalloc`) to measure end-to-end memory-management time. Our objective is to quantify the latency reduction achieved by moving control-plane operations to the data plane. Figure 6 reports absolute memory-management time in μs for MOONBRIGHT and the vendor-provided baseline, with benchmark cases sorted by baseline latency.

As shown in Figure 6, MOONBRIGHT shows consistent latency reductions across NVIDIA and AMD GPUs. On the *NVIDIA GPU* platform, MOONBRIGHT reaches a peak latency reduction of 99.3% and an average reduction of 76.5% across all tested samples. On the *AMD GPU* benchmark suite, MOONBRIGHT shows similar reductions: 98.3% peak and 60.3% on average. We observe a positive correlation between allocation intensity (i.e., size and frequency) and the magnitude of the reduction: benchmarks with heavier memory-management demands benefit more from our approach. These gains come from two effects: MOONBRIGHT performs PTE population on the GPU instead of serializing it through the CPU, and its fresh-VA path avoids unnecessary TLB flushes when no stale same-VA translation can exist.

5.3 Application Impact

5.3.1 Defragmentation for Model Training

We evaluate allocator-level fragmentation in PyTorch-based training stacks and a VMM-based allocator baseline [16, 51, 58] using four NVIDIA A100 GPUs. We use multiple configurations to expose fragmentation under diverse allocation patterns and tensor lifetimes. These stacks combine data, model, and pipeline parallelism [30, 37] with memory-saving techniques such as recomputation (R), virtual pipeline scheduling (V), ZeRO-style distributed optimization (Z), and offload (O) [11, 50, 52]. These techniques reshape tensor lifetimes and allocation sizes, while CUDA tensor allocation remains largely mediated by the framework allocator.

We run DenseNet [44], GPT-2 [49], Llama-2-7B [64], and Qwen1.5-MoE-A2.7B [48], and sweep batch size until out-of-memory. We use *Memory Efficiency*, defined as peak allocated memory over peak reserved memory ($M_{\text{alloc}}/M_{\text{reserved}}$) [16], as a diagnostic metric for allocator-level fragmentation. As shown in Figure 7, MOONBRIGHT improves DenseNet efficiency from 57.6% to 97.7%, and maintains at least 96.1% efficiency on GPT-2, Llama-2-7B, and Qwen1.5-MoE. Under the most dynamic Qwen1.5-MoE Z+O+R setting, PyTorch drops to 72.8%, leaving device memory reserved but unavailable to useful tensor allocations. In contrast, MOONBRIGHT reaches 97.8% by stitching fragmented physical pages into contiguous virtual ranges, effectively reducing external fragmentation. For GMLake, we use a 512 MB granularity as a practical engineering tradeoff between CPU-driven VMM overhead and internal slack [16, 19]; nevertheless, its coarse granularity leaves residual slack under irregular allocations. MOONBRIGHT avoids such slack through fine-grained virtual remapping and preserves end-to-end training performance.

5.3.2 Efficient LLM Inference

We evaluate inference performance on a single NVIDIA A100 GPU across diverse large language model inference scenarios, comparing against vAttention for long-context and prefix-caching scenarios.

Both MOONBRIGHT and vAttention benefit from contiguous, non-paged attention kernels in long-context workloads. As shown in Figure 8, computation increasingly dominates execution at these sequence lengths, reaching 85% at 192K [45]. This leaves limited room for memory-management optimizations; nevertheless, MOONBRIGHT is still up to $\sim$5% faster by eliminating residual host-driven mapping overhead through device-centric page-table updates.

Prefix caching changes this balance. By reusing precomputed KV Cache across requests, it reduces prefill computation and shifts the bottleneck toward memory-management operations that stitch cached blocks into the virtual address space. In this regime, vAttention relies on CPU-driven CUDA VMM and must issue thousands of serialized page mappings, whereas MOONBRIGHT performs these mappings in

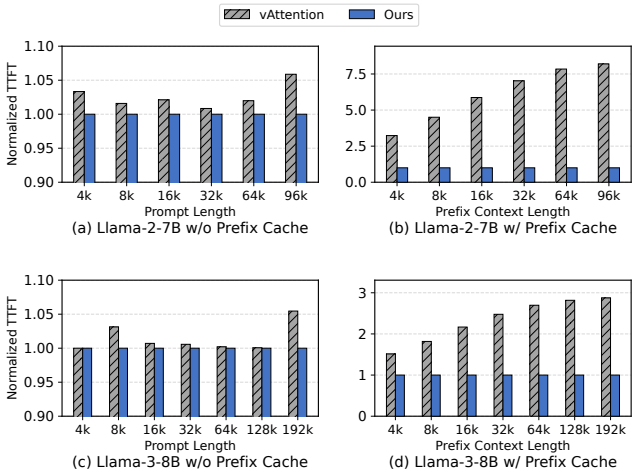

Figure 8: Normalized TTFT for Llama-2-7B and Llama-3-8B under long-context and prefix-caching inference. The first row shows Llama-2-7B; the second row shows Llama-3-8B. For each model, the left panel shows full-prefill long-context requests and the right panel shows prefix-cached requests. Lower is better; all values are normalized to MOONBRIGHT.

microseconds. As a result, MOONBRIGHT achieves up to 8.2× lower TTFT on Llama-2-7B and 2.9× lower TTFT on Llama-3-8B. The difference in gains is primarily explained by the remapping intensity: Llama-3-8B uses grouped-query attention (GQA) [5], which reduces the number of KV heads and shrinks the KV Cache footprint, leaving fewer cached blocks to remap and therefore less CPU-driven VMM overhead for MOONBRIGHT to eliminate.

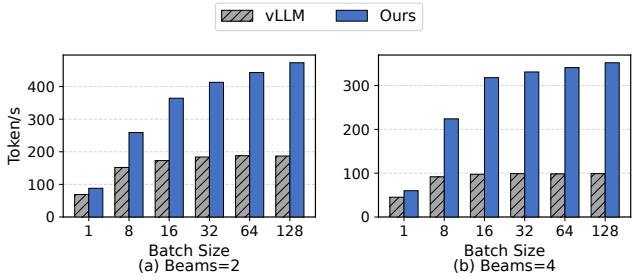

Figure 9: Beam-search inference throughput on Llama-3-8B under beam widths of 2 and 4.

5.3.3 Dynamic Memory Mapping

Finally, we compare Beam Search on MOONBRIGHT against vLLM, a system characterized by step-wise dynamic memory operations governed by data-dependent control flow. In vLLM, each new beam requires a memory fork to update per-sequence states, which is executed on the CPU by deep-copying block metadata. This introduces serialized per-fork overhead, incurring *452* and *780* fork operations per request at beam widths of 2 and 4, respectively. As beam width and batch size increase, this accumulated CPU overhead dominates the runtime. Conversely, MOONBRIGHT offloads fork operations natively to the GPU, aliasing physical pages via lightweight mapping updates. As shown in Figure 9, MOONBRIGHT consistently out-scales vLLM on Llama-3-8B; at batch size 128, MOONBRIGHT achieves 2.5× and 3.6× higher throughput at beam widths of 2 and 4, respectively.

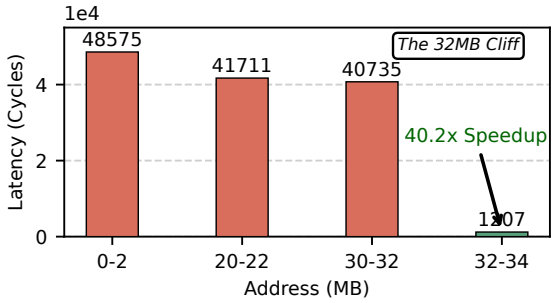

Figure 10: Microbenchmark of zero-flush memory allocation latency. Access latency after a zero-flush fresh mapping is placed at different distances from a previously probed invalid VA. Latency drops after the 32 MB prefetch window, motivating prefetch-width VA padding on NVIDIA.

5.4 Hardware-Guided Policy

MOONBRIGHT's core design, GPU-side page-table materialization and deferred VA reuse, is vendor-agnostic. Platform-specific measurements only tune backend parameters, rather than altering the first principles of the design. In this section, we characterize two NVIDIA-specific effects that inform MOONBRIGHT's backend configuration: TLB prefetching and GSP physical-frame allocation.

TLB prefetching. Figure 10 shows an NVIDIA-specific prefetch cliff. When a fresh VA is placed within the 32 MB prefetch window of a previously probed invalid VA, the first access suffers replayable faults and exceeds 40k cycles. Once the gap reaches 32 MB, latency drops to roughly 1.2k cycles. This observation motivates the 32 MB VA-alignment policy used by MOONBRIGHT on NVIDIA GPUs: new virtual addresses are spaced by the prefetch width so that fresh mappings incur deterministic cold misses rather than replayable faults.

GSP physical-frame allocation. Figure 11 shows another NVIDIA-specific effect: GSP physical-frame allocation remains nearly flat below approximately 512 MB, but increases sharply beyond this point. The undocumented GSP firmware prevents us from identifying the exact cause, but the behavior is consistent with expensive large contiguous-frame allocation. Since MOONBRIGHT does not require physical contiguity, its

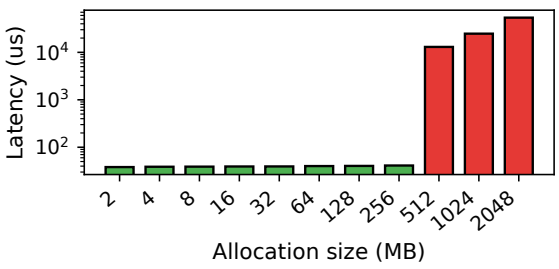

Figure 11: Latency of NVIDIA GSP physical-frame allocation. Allocation latency remains nearly flat below approximately 512 MB and increases sharply beyond this threshold. Green bars are below the observed cliff; red bars are above it.

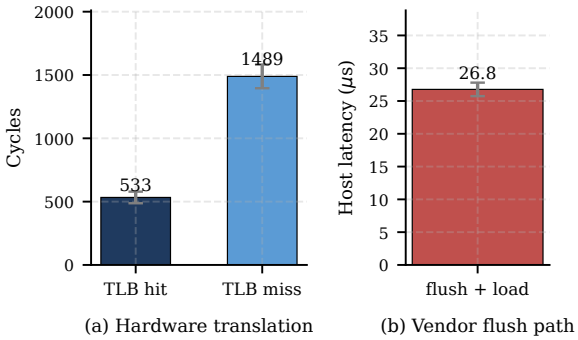

Figure 12: TLB cost decomposition on an NVIDIA A100. **(a)** Device-side cost of a single load under a TLB hit and a forced TLB miss. **(b)** Host-side latency of the conservative vendor flush path.

NVIDIA backend avoids this latency cliff with a simple slow-path heuristic: large physical-frame requests are split into smaller subrequests below the observed threshold. This heuristic only calibrates the backend's physical-frame allocation policy; it does not affect MOONBRIGHT's virtual-memory abstraction or its GPU-side page-table update mechanism.

On platforms where these effects are absent, the corresponding policies can be retuned; for example, our ROCm backend does not use the NVIDIA large-request splitting heuristic.

5.5 Stability of Always-Fresh VA

First-Touch Translation Cost. Always-Fresh VA avoids eager shootdowns for fresh mappings by ensuring that no stale same-address TLB entry can exist. The remaining cost is a first-touch translation by the hardware page walker. Since current GPU counters do not provide a portable way to attribute a specific access to a TLB miss or page walk, we use timing microbenchmarks.

Figure 12(a) shows that modern GPU page walks are fast: on an NVIDIA A100, a pre-warmed TLB hit takes 533 cycles, while a forced miss that walks to a valid PTE takes 1489 cycles, adding only 956 cycles. This miss cost is only one hardware component of the first load. In contrast, Figure 12(b) shows that the conservative CUDA Driver VMM flush path takes 26.8 μs, dominated by host-device synchronization. Thus, Always-Fresh VA replaces a tens-of-microseconds global shootdown on the fresh-allocation path with a small local first-touch translation cost, while deferring global flushes to rare VA-epoch wrap points.

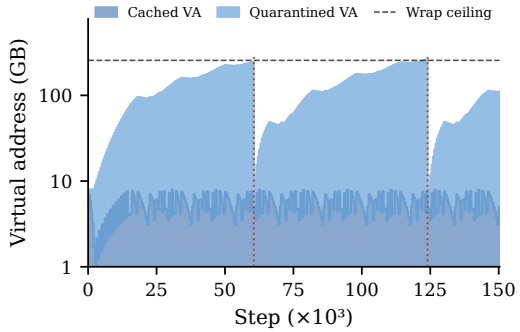

Figure 13: VA footprint under the synthetic stress workload. *Cached VA* denotes reusable VA held by the slow-path block pool, while *Quarantined VA* denotes unmapped VA from evicted segments that awaits batch reclamation at the next epoch boundary.

Quarantine Pressure and Epoch Wrap Behavior. To rigorously evaluate the *Always-Fresh VA* policy under worst-case conditions where allocations are not served from cached blocks, we construct a cache-defeating stress workload. The workload uses non-repeating allocation sizes, extended lifetimes, and high-frequency cadence to defeat cached-block reuse, forcing most requests to reserve fresh VA and advance the frontier at a sustained rate. With a conservative 256 GB wraparound threshold, Figure 13 shows that cached VA remains bounded, while quarantined VA accumulates safely until batch reclamation. At the epoch boundary, MOONBRIGHT performs one batched reclamation with a microsecond-scale `tlb_flush`, as measured in Figure 12. These results show that MOONBRIGHT turns costly per-allocation TLB shootdowns into rare, configurable epoch-boundary events. Furthermore, expanding the epoch size to further reduce flush frequency incurs negligible overhead: flattening a 256 GB VA range requires under 2 MB of page-table memory (using 2 MB pages), and scaling to a 1 TB epoch requires only ∼8 MB.

6 Discussion

This section discusses MOONBRIGHT's scope, limitations, and relationship to existing GPU memory-management mechanisms.

Security and Multi-Tenancy. MOONBRIGHT currently targets trusted and cooperative deployments, such as dedicated LLM inference clusters or single-tenant GPU environments,

where applications and kernels are known to the operator. Under this threat model, compute kernels are assumed to be non-malicious, and page-table update kernels are generated only by the trusted MOONBRIGHT runtime. Extending MOONBRIGHT to untrusted multi-tenant settings raises additional challenges because exposing page-table state to device code creates privileged state that malicious kernels could misuse. MPS does not eliminate this concern, as it targets cooperative multi-process execution rather than protection from malicious device code. MIG provides a stronger hardware partitioning boundary and can help confine cross-instance effects when MOONBRIGHT runs within a single instance. A KASLR-style randomized page-table view can reduce accidental corruption and casual discovery, but is not a security boundary; untrusted deployments still need hidden page-table state, driver ownership checks, capability handles, and sandboxed or verified mapping kernels. We view this as an important open problem for GPU-resident memory management and leave a complete security architecture to future work.

Relation to UVM. NVIDIA Unified Memory (UVM) exposes managed memory through a unified CPU–GPU virtual address space. In demand-paged mode, GPU accesses to non-resident managed pages trigger hardware fault reporting; the driver resolves residency and coherence, updates mappings, and replays the faulting access. MOONBRIGHT is complementary to UVM rather than a replacement. UVM targets transparent host–device sharing through a fault-driven path, whereas MOONBRIGHT targets latency-critical device-resident memory by proactively installing stream-ordered mappings and materializing PTEs on the GPU. Applications can therefore use UVM-backed regions for transparent sharing and MOONBRIGHT-backed regions for low-latency GPU-resident allocation and remapping within the same CUDA context.

7 Related Work

GPU allocators and memory managers. Early GPU allocators such as ScatterAlloc [62] and XMalloc [18] target fine-grained, kernel-initiated allocation for massively parallel programs. They are effective for dynamic parallelism but do not match the dominant memory-management pattern in DL frameworks, where the host/runtime allocates coarse tensors and KV-cache regions. Gallatin [36] improves general-purpose allocation on the device, but it does not address the CPU-driven virtual-memory control plane that dominates page-granular remapping latency. FineMem [66] reduces memory waste in fine-grained disaggregated memory, while Unified Memory simplifies programming by providing a shared address space; prior studies show that UVM can introduce unpredictable transfer and synchronization overheads for latency-sensitive workloads [26, 29]. MOONBRIGHT is complementary: it focuses on making GPU page-table updates low-latency and stream-compatible on commodity devices.

Defragmentation and virtual-memory stitching. Classic defragmentation and compaction techniques move live objects to recover contiguous space [35, 59, 65]. Such approaches are portable but expensive for GPU workloads because they require data movement, pointer rewriting, and synchronization. Model-specific approaches such as memory-efficient DenseNet training [44] hand-tune buffer sharing to reduce activation memory, but do not provide general allocator-level defragmentation. Recent DL systems and allocators address waste through virtual-memory stitching or planning: PyTorch's experimental expandable segments grow VMM-backed segments to reduce allocation slivers [46], GMLake [16] applies CUDA VMM to DNN training, vAttention [45] remaps KV caches, and STAlloc [19] plans training allocations over space and time. These systems demonstrate the value of memory-aware allocation, but they inherit CPU-centric mapping costs or operate above the hardware mapping substrate. MOONBRIGHT targets the root cause by materializing PTEs on the GPU and deferring TLB coherence when mappings use fresh VAs.

LLM serving memory systems. LLM serving systems optimize memory use and scheduling at several layers. ORCA [70], FastServe [68], and Sarathi [4] improve batching, prefill/decode scheduling, or distributed serving. FlexGen [57] and PowerInfer [61] target memory-constrained serving through offloading or hybrid CPU/GPU execution. Mooncake [47], Jenga [73], CacheGen [33], Pensieve [71], and DroidSpeak [32] optimize KV-cache placement, reuse, compression, streaming, or sharing. vLLM [25] introduced PagedAttention for block-based KV-cache management, while S-LoRA [56] and Punica [10] manage serving many LoRA adapters. These systems are effective above the memory-management substrate, but their mechanisms are tied to model/runtime semantics and often require specialized kernels or metadata paths. MOONBRIGHT instead accelerates the hardware MMU mapping path, preserving hardware-level virtual contiguity while supporting dynamic remapping and sharing.

8 Conclusion

GPU memory management remains largely host-driven, leaving device parallelism unused on the allocation critical path. This paper presented MOONBRIGHT, a GPU-centric memory-management substrate that materializes page-table updates on the GPU and avoids unnecessary TLB shootdowns with *Always-Fresh* virtual addressing. By turning translation updates into data-parallel device work, MOONBRIGHT reduces mapping latency by up to three orders of magnitude and improves allocation latency and memory efficiency across training and inference workloads.

Nixie: Efficient, Transparent Temporal Multiplexing for Consumer GPUs

Yechen Xu Yifei Wang Nathanael Ren Yiran Chen Danyang Zhuo

Duke University

Abstract

Consumer machines are increasingly running large ML workloads such as large language models (LLMs), text-to-image generation, and interactive image editing. Unlike datacenter GPUs, consumer GPUs serve single-user, rapidly changing workloads, and each model's working set often nearly fills the GPU memory. As a result, existing sharing mechanisms, such as NVIDIA Unified Virtual Memory (UVM), suffer from severe memory thrashing and consume excessive CPU pinned memory when multiple applications are active.

We design and implement Nixie, a system service that enables efficient and transparent temporal multiplexing on consumer GPUs without requiring any application or driver changes. Nixie coordinates GPU memory allocation and kernel launch behavior to efficiently utilize the CPU-GPU bi-directional bandwidth and CPU pinned memory. A lightweight scheduler in Nixie further improves responsiveness by automatically prioritizing latency-sensitive interactive jobs using MLFQ-inspired techniques. Our evaluations show that, compared to UVM-based approaches, Nixie improves the latency of interactive code-completion tasks co-located with a long-running LLM by up to 3.8× and reduces CPU pinned memory usage by up to 66.8% under the same latency requirement.

1 Introduction

Modern consumer machines increasingly run large and sophisticated machine learning (ML) workloads. Consumers now routinely run large language models (LLMs) [29, 37], text-to-image diffusion models [18], interactive image editing [35], and video processing [5, 32] locally on their desktops equipped with consumer GPUs, such as NVIDIA's RTX 4090 and 5090. This trend is driven by the desire for privacy, interactivity, and reduced hardware costs, as well as by rapid advances in model quantization and optimized inference runtimes [13, 17, 42] that make local ML execution practical.

Despite this wave of local ML execution, today's consumer GPUs are fundamentally designed for a single active application. In contrast to datacenter GPUs, where workloads are typically long-running, batched, and multi-tenant, consumer workloads are rapidly changing, heterogeneous, and strongly user-driven. A single user may frequently switch between very different models and applications: querying an LLM, generating an image, editing a photo, or running a background batch job such as OCR or video processing. These applications interact in two common ways. Some form dependent workflows, such as using an LLM to rewrite a prompt before invoking a diffusion model. Others run independently but compete for responsiveness, such as interactive code completion while an autonomous agent or batched generation job continues in the background. Batch sizes for interactive applications are almost always one, and interactive workloads are expected to provide low-latency responses. These characteristics create a unique resource-management environment that differs substantially from datacenter GPUs.

A central challenge is that *the working set of each ML application often nearly saturates GPU memory*. Models such as modern LLMs or diffusion pipelines require tens of gigabytes of active parameters, activations, and temporary workspace. Users often prefer more accurate and larger models. As a result, when two or more applications run concurrently, the combined working set trivially exceeds GPU memory.

Existing GPU multiplexing mechanisms perform poorly under these conditions. Naive stop-and-restart approaches such as llama-swap [21] introduce substantial delays: each switch requires restarting applications and reloading large models, leading to multi-second or even longer response times. Application-level model swapping (e.g., Ollama [25]) is restricted to a single application and cannot coordinate with other applications. Prior systems such as Prism [39] and Aegaeon [36] require manual integration and primarily target scenarios with many small models sharing a large GPU, which does not reflect the consumer GPU setting where each model's working set nearly fills the GPU memory.

NVIDIA Unified Virtual Memory (UVM) [1] provides a form of transparent GPU multiplexing, but it relies on demand paging and implicitly assumes that the combined working set

fits in GPU memory to sustain good performance. When multiple large applications are active, UVM exhibits severe thrashing: pages repeatedly migrate between GPU and CPU memory, causing drastic throughput degradation and large, unpredictable latency spikes. Systems such as TGS [34] and nvshare [3] mitigate some of UVM's thrashing behavior, but their workload assumptions remain restrictive and do not reflect consumer GPU usage patterns. Moreover, they inherit UVM's fundamental limitations, including excessive use of CPU pinned memory, which significantly limits scalability for large, memory-intensive models.

We design and implement Nixie, a system service that provides efficient and transparent temporal multiplexing on consumer GPUs without requiring any application or driver changes. Nixie interposes on GPU memory allocation and kernel-launch behavior. The key idea behind Nixie is to explicitly control when applications occupy GPU memory and when they yield it, ensuring that a single application's working set fully resides in GPU memory at any given moment. This avoids the pathological thrashing behavior inherent to UVM and maintains predictable performance for each application. For fast context switching, Nixie fully utilizes the bi-directional bandwidth between GPU and CPU.

Nixie also incorporates a lightweight scheduler that automatically identifies latency-sensitive interactive applications and prioritizes them, without requiring any user annotations for application priorities. Nixie uses an MLFQ-like scheduler. It dynamically adapts application priorities by tracking applications' CUDA kernel launch patterns and prioritizes applications that can finish execution within their allocated time window. Lower-priority applications have larger time windows to minimize the context switch frequency and amortize scheduling overhead.

We evaluate Nixie on a consumer-grade NVIDIA RTX 5090 GPU using widely adopted applications (e.g., `llama.cpp` [13], Ollama [25], SGLang [42], ComfyUI [9]) and popular models (e.g., Qwen3 [37], Gemma3 [29], Z-Image [31], Qwen-Image [35]). Compared to application-managed solutions such as Ollama, as well as UVM and the UVM-based GPU multiplexing system nvshare [3], Nixie reduces context-switch overhead by 29.7-82.3% across configurations and cuts CPU pinned memory usage by up to 66.8%. Nixie delivers 1.3-1.6× speedups on diverse multi-application workloads (e.g., using an LLM to generate prompts for image generation). Nixie also improves interactive code-completion latency by 3.1-3.8×, while maintaining competitive throughput on background batch-processing workloads. Our source is available at https://github.com/XOR-op/Nixie.

Our paper makes the following contributions:

- A new system architecture that jointly manages GPU memory usage and kernel dispatch, eliminating UVM-style thrashing without requiring any driver or application changes. The new architecture efficiently uses CPU pinned memory and bi-directional bandwidth between CPU and GPU.
- A lightweight, MLFQ-inspired scheduler for GPU workloads that automatically identifies and prioritizes interactive applications to reduce latency while preserving overall GPU throughput.
- An implementation that supports unmodified, state-of-the-art GPU applications (e.g., `llama.cpp`, SGLang, and ComfyUI) and delivers substantial improvements across diverse consumer GPU workloads.

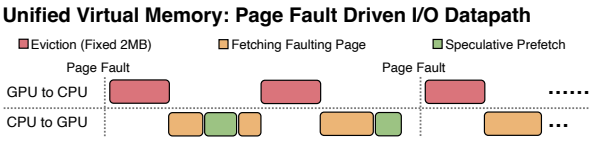

Figure 1: UVM's page-fault-driven migration. UVM can only utilize half of the link bandwidth for full-duplex PCIe channel.

2 Motivation

Here we motivate why the consumer GPU multiplexing problem is a fundamentally different problem from datacenter GPU multiplexing.

2.1 Local ML Workloads on Consumer GPUs

Recent advances in model quantization and optimized inference runtimes have enabled users to run large machine learning (ML) models directly on their personal machines. Applications such as local LLM inference (e.g., `llama.cpp`, SGLang, vLLM), text-to-image generation, and interactive image editing pipelines (e.g., ComfyUI, diffusion-based tools) have become increasingly common. Users are motivated by privacy, offline capability, more fine-tuning opportunities and reduced hardware costs.

Unlike traditional datacenter GPU workloads, a single user may concurrently run or frequently switch between multiple large models: querying an LLM, generating an image, editing a photo, running background AI tasks, among other applications, all on a shared consumer-grade GPU. For interactive applications, the batch size is almost always one. At the same time, modern consumer GPUs (e.g., RTX 4090/5090) offer substantial compute but limited GPU memory relative to model size. Users often run the largest models that can fit in memory to maximize quality. However, this means each individual application may nearly saturate GPU memory.

2.2 Limitations of Existing Multiplexing Approaches on Consumer GPUs

Existing Approach #1: Shut Down an Application and Run the Next Application. A straightforward solution is to

run only one application at a time. For example, the community tool `llama-swap` [21] enables switching by terminating the current application and launching the next. However, unloading and reloading large models introduces multi-second delays, making even moderate task switching impractical for interactive consumer workflows (e.g., prompting an LLM to generate image descriptions that will be used immediately in a diffusion-based text-to-image application).

Existing Approach #2: Application-Specific Approaches. Applications such as Ollama [25] provide model switching by unloading the current model and loading a new one. However, this mechanism is tightly coupled to a single application's internal execution and cannot coordinate with other GPU applications.

Another line of work makes an inference system's GPU memory usage elastic. Prism [39], for example, allows an LLM framework to dynamically shrink its KV cache, freeing GPU memory for other applications. While effective for LLMs, this approach is highly domain-specific: diffusion models, image-editing pipelines, and many other consumer workloads do not use KV caches and therefore cannot benefit from this mechanism. Moreover, these systems require explicit software-level integration into each application or inference framework. As a result, they cannot provide transparent, system-wide multiplexing across the diverse set of applications on consumer GPUs.

Existing Approach #3: NVIDIA Unified Virtual Memory (UVM). UVM is a fully transparent mechanism for handling GPU memory oversubscription. Its basic idea mirrors CPU demand paging: when a GPU kernel accesses a page that is not resident in GPU memory, the hardware raises a page fault interrupt to the driver. The driver's handler then selects pages for eviction, migrates data between GPU and CPU memory, and resumes kernel execution. UVM works well for: (1) a single application whose total memory footprint exceeds GPU capacity but whose working set fits in GPU memory, and (2) multiple applications whose combined working sets fit within GPU memory.

While UVM's fully transparent abstraction is appealing, it has four fundamental limitations in the consumer setting. First, UVM lacks coordinated control over compute and memory management, making it highly susceptible to thrashing. Consider two applications, A and B, running concurrently on a 32 GB GPU and generating one token each in a round-robin fashion. Suppose each model requires 24 GB of parameters; then each forward pass triggers the migration of at least 16 GB of data to and from GPU memory. Even with state-of-the-art PCIe 5.0x16 bandwidth (64 GB/s), this migration takes roughly 250 ms. By comparison, a forward pass without migration typically takes only 20-75 ms. Thus, data movement alone induces a 4-12× slowdown.

Second, UVM utilizes only one direction of the PCIe bandwidth at a time, even though the PCIe channel is full-duplex. Figure 1 shows the IO path between CPU and GPU during page fault handling for UVM. During a page fault, UVM first evicts pages from GPU to CPU memory, and only after eviction completes does it fetch the demanded page and possibly several prefetched pages from CPU to GPU memory. A single fault may trigger multiple evictions followed by multiple fetches, but these transfers never overlap: eviction uses only GPU to CPU bandwidth, while fetching and prefetching use only CPU to GPU bandwidth. As a result, half of the available PCIe bandwidth remains idle.

Third, due to limited visibility into application behavior, UVM relies on a Least Recently Used (LRU)-based eviction policy to select pages during GPU page faults [4]. However, UVM only updates its LRU metadata when page faults occur, which provides a highly incomplete view of an application's true memory access pattern. As a result, pages that will be accessed imminently are often mistaken for cold pages, which leads to unnecessary page eviction and thrashing.

Fourth, host memory becomes a major bottleneck when UVM is used on consumer GPUs. To maximize PCIe transfer performance, UVM allocates CPU pinned memory inside the kernel for DMA operations. When UVM serves as the backing store for multiple GPU applications, every page resident on the GPU must have a corresponding pinned page on the CPU. This creates substantial memory overhead: even data that will never be evicted from the GPU still consumes unswappable, incompressible CPU pinned memory. On consumer machines equipped with modest RAM, this CPU pinned memory footprint competes directly with other applications and can significantly degrade overall system usability.

Several GPU multiplexing systems build on top of UVM to mitigate some of its thrashing issues (e.g., TGS [34] and nvshare [3]). For example, TGS assigns priorities to applications so that low-priority applications run only when high-priority ones are idle. However, because these systems rely on UVM as their underlying GPU memory virtualization mechanism, they inherit UVM's fundamental limitations: page-fault-driven migration, single-directional PCIe transfers, and large pinned-memory consumption.

3 Overview

Our design is guided by three key goals. First, we aim to provide a UVM-like abstraction that supports unmodified CUDA applications, while enabling coordinated control over compute and memory virtualization. Second, we seek to redesign virtual memory management to exploit a hierarchical memory system spanning GPU memory, CPU pinned memory, CPU paged memory, and disk, while ensuring that CPU-GPU data transfers fully utilize the full-duplex PCIe bandwidth. Third, similar to a standard OS kernel scheduler, we aim to optimize latency for interactive applications without sacrificing

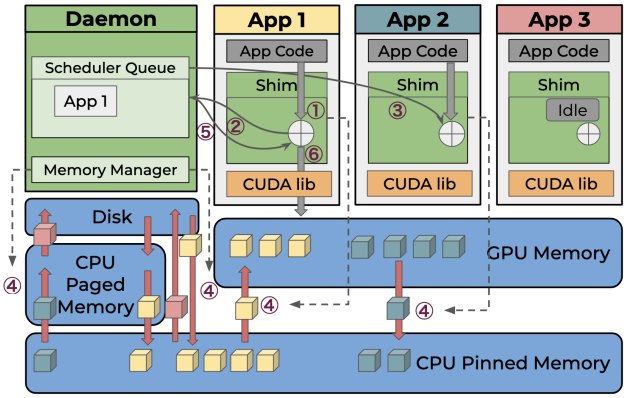

Figure 2: Nixie's architecture overview. Green components belong to Nixie. Cubes with different colors stand for memory blocks from different applications.

throughput for background batch-processing workloads.

Figure 2 presents the architecture of Nixie. The system consists of two components: a lightweight application library, Nixie Shim, and a centralized system service, Nixie Daemon. To provide transparency, Nixie Shim interposes on an application's CUDA Runtime API calls. Nixie Daemon performs global coordination and enforces multiplexing policies, but all kernels continue to execute using the application's own CUDA context to minimize runtime overheads on kernel launches. When App 1 launches a new kernel to execute GPU jobs, it ① checks the execution flag in the Nixie Shim; ② if App 1 cannot execute, Nixie Shim then uses interprocess communication (IPC) to enqueue a schedule request in daemon's scheduler queue. When the scheduler in Nixie Daemon decides App 1 is allowed to run, ③ Nixie Daemon uses IPC to pause the execution of App 2, waiting for its completion of outstanding CUDA kernels. Then ④ Nixie Daemon moves all the memory blocks belonging to App 1 into shared pinned memory, and each Nixie Shim migrates its own memory blocks into or out of GPU memory. After the memory blocks are ready for App 1, ⑤ Nixie Daemon notifies Nixie Shim in App 1 to enable the execution flag; App 1 then ⑥ resumes its execution. When all of App 1's data is ready, App 1 only executes steps ① and ⑥, bypassing IPC with Nixie Daemon.

Nixie Daemon centralizes three decisions: which application may launch kernels, where memory should reside, and the order in which required transfers are issued. Nixie Shim and Nixie Daemon then enforce those decisions with a small set of CUDA-facing mechanisms: intercepting CUDA calls, blocking new kernel launches at safe points, synchronizing outstanding kernels, remapping CUDA VMM allocations, and issuing asynchronous memory copies. The rest of this section describes these mechanisms and the decision logic built on top of them.

Nixie Daemon maintains a chunk-level virtual memory system. Instead of relying on page-fault-driven migration, Nixie manages memory at the granularity of CUDA-allocated chunk (i.e., the units returned by cudaMalloc). Each chunk may reside in one of four locations: (1) GPU memory, (2) CPU pinned memory, (3) CPU paged memory, or (4) disk. Unlike UVM, chunks placed in GPU memory do not require CPU pinned memory. To avoid fragmentation in CPU pinned memory or paged memory, we split a chunk into 2 MB blocks, where a block is the unit of data migration between locations.

Nixie's design follows two key principles. First, Nixie coordinates the control over both compute and memory allocation. When the scheduler selects an application to run, it proactively migrates that application's chunks into GPU memory while simultaneously evicting other applications' chunks to CPU memory or disk. By coupling scheduling with memory placement, Nixie ensures that when an application begins executing, it has both GPU compute and the necessary GPU-resident data available, avoiding demand-paging stalls and eliminating thrashing. Second, Nixie prioritizes interactive workloads automatically. Nixie determines whether an application is interactive by tracking its kernel launch behavior. Borrowing ideas from MLFQ, Nixie adjusts each application's priority and time window dynamically. If an application does not issue a kernel during its assigned time window, Nixie classifies it as interactive, halves its window size, and increases its priority. Conversely, if the application fully uses its assigned time window, Nixie doubles the window size and lowers its priority. At each decision point, the scheduler selects the highest-priority application and grants it GPU access for its current window. This approach allows Nixie to automatically prioritize latency-sensitive applications without any user annotations or application modifications, while preserving throughput for background batch-processing applications.

4 Supporting Unmodified CUDA Applications

Nixie is transparent to CUDA applications, similar to UVM. In UVM, a user replaces all CUDA memory allocations from `cudaMalloc` with `cudaMallocManaged`, and it is easy to make this fully transparent by static rewriting or `LD_PRELOAD`.

Nixie uses `LD_PRELOAD` to hook the CUDA library and interpose several functions. Besides memory allocation and free, Nixie also interposes CUDA kernel/graph launches in order to control compute behavior. Further, Nixie intercepts any APIs that implicitly allocate memory (e.g., `cudaStreamCreate`) or report memory usage (e.g., `cudaMemGetInfo`). Applications sometimes require correct memory usage reporting to function correctly. For example, SGLang reads GPU memory in order to decide how much KV cache memory to be allocated. Nixie Shim provides such interceptions and also communicates with Nixie Daemon via a UNIX domain socket.

To make sure applications can run correctly without being aware of the existence of Nixie, we need to keep an identical running environment before pausing and after resuming, and no invalid GPU operations should be introduced by Nixie.

Maintaining consistent virtual memory addresses. Classic approaches like `cudaMalloc` and `cudaFree` cannot guarantee that virtual memory addresses remain consistent after another call. Applications that use the previous addresses will access memory regions that are no longer valid. Nixie leverages CUDA VMM API [24] to reserve GPU virtual addresses and map these addresses to different physical allocations before and after chunk migrations.

Valid memory access during migration. GPU kernel execution is mostly asynchronous. When migration starts, there can be outstanding kernels still executing, and invalid memory accesses can happen when the accessed pages have been migrated. Before the currently running application is migrated, Nixie blocks any new kernels from launching and performs a CUDA synchronization to complete all the outstanding kernels. This prevents an application from using the migrated chunks.

CUDA graph compatibility. CUDA graph is widely used to reduce kernel launch overhead. When applications are constructing CUDA graph, unexpected API calls can disrupt the graph capture and lead to unexpected behavior. Nixie ensures Nixie Shim does not call any CUDA APIs until the graph capture finishes by interposing on the start and end of capture events.

GPU memory information. Some applications assume they have exclusive access to the entire GPU, and use device-wide statistics to make decisions for tensor placements or buffer allocations. Nixie reports GPU memory usage as the sum of allocations from the process itself, preventing applications from unnecessarily spilling data to CPU.

5 Virtual Memory Management

We first describe the granularity of memory management in Nixie, and then describe how to migrate memory chunks within hierarchical memory.

5.1 Memory Granularity and Hierarchy

Nixie intercepts all GPU memory allocations in applications, and it is thus naturally aware of all memory allocations. Nixie manages memory at the granularity of each allocation and migrates these units as a whole, which we refer to as *chunks*. Each chunk is placed at a specific tier of the memory hierarchy. Some applications (e.g., `llama.cpp`) put all the model weights into one big allocation. To prevent excessively large chunks, Nixie caps each chunk's size at 128 MB. Larger allocations are subdivided accordingly, allowing portions of the same allocation to reside in different memory hierarchy tiers. For example, a 256 MB allocation may be split so that roughly

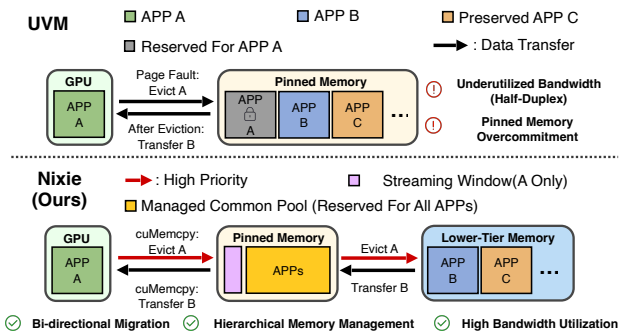

Figure 3: Nixie's memory hierarchy and chunk migration.

half resides in CPU pinned memory while the remainder is placed in CPU paged memory.

Allocations naturally vary in size because tensors (e.g., weights, activations) have diverse shapes. If Nixie managed memory solely at the chunk level, this variability would lead to severe fragmentation. To address this, Nixie introduces blocks for fine-grained control. Each block has a fixed size of 2 MB, which is the smallest physical allocation unit supported by the VMM API. A chunk is composed of one or more blocks (up to 64). Using uniformly sized blocks simplifies placement, migration, and bookkeeping, enabling Nixie to manage memory efficiently while avoiding fragmentation.

Nixie does not treat tier X as a cache backed by tier $X+1$. Instead, each chunk has *exactly one copy* within the entire memory hierarchy and is migrated between tiers as needed. Figure 3 shows Nixie's memory hierarchy. Nixie Daemon is the only component that issues data migration and has all the information needed to decide chunk locations in the memory hierarchy. Nixie Daemon can proactively perform background migrations without involving or interrupting applications. This design avoids keeping a pinned-memory backing copy for every GPU-resident chunk.

5.2 Speeding Up Context Switches

Migration is needed when GPU memory cannot fit the next application that will run, and long migration time directly affects user experience. To shorten migration, Nixie must keep both PCIe directions and the lower-tier memory links busy. Figure 4 illustrates the common case: application B is about to run and its blocks must be fetched into GPU memory, while blocks from the currently resident application A must be evicted.

A straightforward design would issue local transfers between adjacent tiers and rely on back-pressure to create free space. This performs poorly in a multi-tier hierarchy. A fetch from pinned memory to GPU may first require evicting GPU blocks to pinned memory; that eviction may require moving pinned-memory blocks to CPU paged memory; and the CPU paged tier may in turn need to spill blocks to disk. Serializing this chain leaves one or more links idle. It can also create

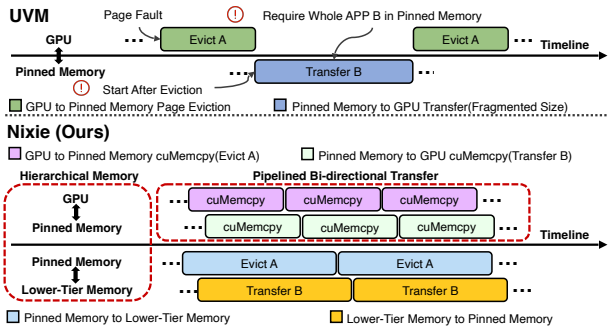

Figure 4: Nixie's communication bandwidth usage (1) between GPU memory and CPU pinned memory, and (2) between CPU pinned memory and lower-tier memory (e.g., CPU paged memory, disk).

avoidable traffic: if B fills the pinned tier while being fetched upward, A's evicted blocks may be forced to move farther down the hierarchy than necessary, or the system may deadlock waiting for space that can only be created by transfers blocked behind the fetch.

Nixie avoids these local decisions by separating *planning* from *orchestration*. The planner decides what moves are needed and where each block ends up; the orchestrator decides when and how to issue the actual data transfers. The planner creates a plan, i.e., a list of block moves, where each entry records the block identifier, current tier, destination tier, transfer direction, and migration order to prioritize blocks that will need further migration. The planner also computes the final state of each tier, so it can determine the minimal migration needed without exceeding any capacity constraints.

For an incoming application B, the planner first identifies all B blocks that are not already resident in GPU memory. It then computes the number of GPU blocks that must be freed and selects that many non-B GPU-resident blocks as eviction candidates. The eviction policy minimizes unnecessary movement: blocks are evicted only when needed to admit B, and each evicted block is placed in the highest lower tier with available non-reserved capacity. Blocks that cannot fit in pinned memory are assigned to CPU paged memory or disk before migration begins: they are transmitted at the beginning of the migration, rather than being pushed down only when one tier is full. When the scheduler already exposes a likely next application, the planner treats its blocks as less attractive eviction candidates, which preserves useful prefetching state. An example is shown in Figure 5.

The migration orchestrator executes the plan as faithfully as possible. It maintains separate queues for upward transfers (toward GPU) and downward transfers (away from GPU), and gives priority to moves that unblock the opposite direction. In the example of Figure 4, the orchestrator reserves a small pinned-memory streaming window for A's evicted blocks. This reservation ensures that GPU-to-pinned eviction can proceed even while B is being staged through pinned memory.

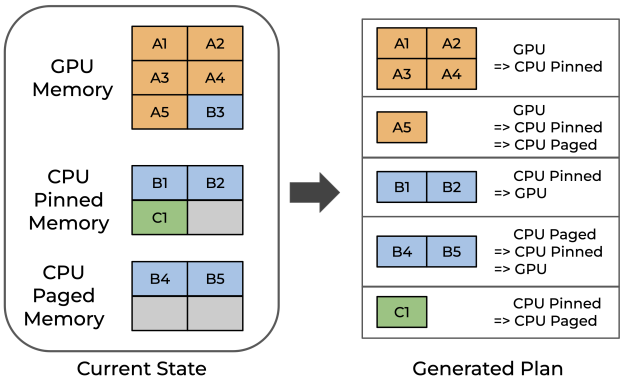

Figure 5: Migration plan given existing chunks' locations.

One issue we observed is that the block transfers may be stragglers with high latency, which comes from OS resource management or underlying CUDA runtime. In this case, to avoid deadlock with the staging buffer, the orchestrator can dynamically adjust the plan by evicting a small number of blocks to unblock the transmission.

For the actual data movement, Nixie Daemon moves incoming blocks into CPU pinned memory using multiple worker threads to saturate DRAM bandwidth. Once B's blocks are present in pinned memory and their GPU destinations are available, Nixie Daemon sends block identifiers and offsets to Nixie Shim via IPC. Nixie Shim then issues asynchronous CUDA copies between the 2 MB pinned-memory blocks and the application's reserved GPU virtual addresses.

6 Scheduling

Similar to traditional CPU scheduling, our goals are: (1) interactive applications should receive higher priority than batch-processing applications, and (2) users should not be required to manually specify application priorities. On CPUs, multi-level feedback queues (MLFQ) are the canonical mechanism to achieve both goals.

GPUs, however, provide neither CPU-style yield/blocking signals nor cheap context switches. The scheduler therefore has to infer when an application has stopped using the GPU and distinguish short, bursty applications from long-running applications without user annotations.

In the following, we describe how Nixie detects applications that are not using GPUs and then infers application priority. Finally, we discuss how to use prefetching to augment an MLFQ-like scheduling system tailored for GPU workloads.

6.1 Idleness Detection

In traditional CPU scheduling, a scheduler is typically invoked when (1) a time window expires or (2) a thread voluntarily relinquishes the CPU, for example by issuing `yield()` or invoking a blocking system call (e.g., I/O). These signals

allow the CPU scheduler to switch to another thread of execution. However, neither signal exists in GPU applications. First, Nixie needs to support applications with long-running services (e.g., SGLang, Ollama), so there is no notion of "task completion." Second, GPU applications do not expose equivalents of yield or blocking system calls to indicate periods of inactivity. As a result, letting applications run until the time window expires, regardless of whether an application is doing useful work, leads to poor GPU utilization and high latency for interactive workloads.

To address this, we design a mechanism to detect when a GPU application becomes idle. A straightforward approach is to observe GPU utilization using device APIs such as NVML. Unfortunately, this has two drawbacks. First, GPU-level APIs are coarse-grained and update slowly. In our experiments, NVML takes roughly 600 ms to report that a workload has become idle. Second, on consumer devices, background tasks (e.g., rendering or video decoding) introduce noise that makes these signals unreliable.

We use a timeout-based mechanism to detect application idleness. CUDA APIs fall into two categories: non-blocking operations (e.g., kernel launches, asynchronous calls) and blocking operations (e.g., synchronization). Nixie treats an application as idle only if the time elapsed since its most recent API return exceeds a fixed threshold. For blocking APIs, Nixie Shim intercepts the call both before and after execution to ensure the application is not mistakenly classified as idle while it is blocked inside the runtime. In our implementation, we use a 100 ms threshold. When the timeout fires, Nixie Shim sends an idleness notification to Nixie Daemon and Nixie Daemon marks the application as inactive. This notification invokes the same scheduling loop used when a time window expires. Idleness helps Nixie Daemon perform potential background migration and adjust scheduling priorities accordingly, as described in the following sections.

6.2 Priority Inference

Classic MLFQ decreases priorities over time and periodically resets all priorities to the highest level. This works well on CPUs, where time windows are short. In Nixie, however, GPU time windows are much longer. Blindly resetting all priorities erases useful history and may unexpectedly preempt interactive workloads.

We introduce a soft priority recovery policy. The scheduler records three timestamps for each application a: (1) the time it became idle i_a, (2) the time of last priority update p_a, and (3) the time of its most recent scheduling request q_a. Ideally, when an application stays idle for a sufficiently long period, it indicates the usage pattern may have changed (e.g., an LLM generating a long response for one prompt now may generate a short response for another prompt), so its priority should be increased to re-estimate the runtime characteristics. However, if the application is already in the scheduler queue pending further execution, promoting it immediately would preempt the currently running application and reduce the effective time window of every application in that priority level. To address this issue, we exclude pending time from consideration. Let R denote the multiplying factor applied to the pending time. If $R \geq 1$, an application could potentially starve at low priority whenever high-priority jobs are continuously running. Therefore, we dynamically adjust R based on the number of applications N at the same priority level, ensuring that $R < 1/N$. The detailed priority inference algorithm is shown in Algorithm 1.

Algorithm 1 Nixie Priority Inference

Require: Application a, pending time factor R, set of multi-level feedback queues $\{Q\}$ and corresponding time allotment $\{T\}$

```
p ← current priority of a
t_a ← accumulated execution time of a in current priority
if t_a > T_p then                          ▷ Standard MLFQ Demotion
    Move a to lower priority queue
    t_a ← 0
else if a is idle then
    i_a ← time since last execution
    p_a ← time since last priority change
    q_a ← time since a enqueued (0 if no new request)
    if p_a > T_p then                      ▷ Prevent priority jitter
        // Compensate idleness and prevent starvation
        if i_a − R · q_a > T_{p−1} + t_a then
            Move a to higher priority queue
        end if
    end if
end if
```

6.3 MLFQ with Prefetching

Nixie uses K queues $(Q_1, Q_2, \ldots, Q_k)$ where the priorities are in descending order from Q_1 to Q_k. The scheduler prioritizes applications with higher priority levels; when multiple applications share the same priority, they are scheduled in round-robin fashion, beginning with the application that has waited longest. Upon reaching a preemption threshold S, the scheduler preempts the current application if another application exists at the same priority level. We set the time allotment for priority demotion to $T = 8$s and the preemption threshold to $S = 4$s for the highest priority queue; each successive lower-priority queue doubles these parameters. The scheduler periodically checks for new scheduling decisions and updates priorities. Upon receiving an idleness notification from the currently running application, the scheduler performs the same operations.

In Nixie's hierarchical memory design, moving data from a lower to a higher tier requires a long time. We leverage information from the scheduler to reduce migration time:

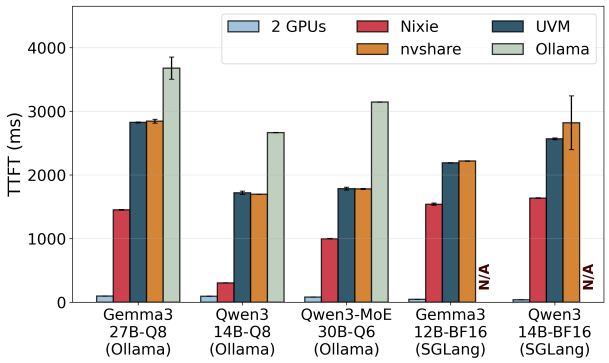

Figure 6: Context switch performance comparison. Error bars represent standard deviations.

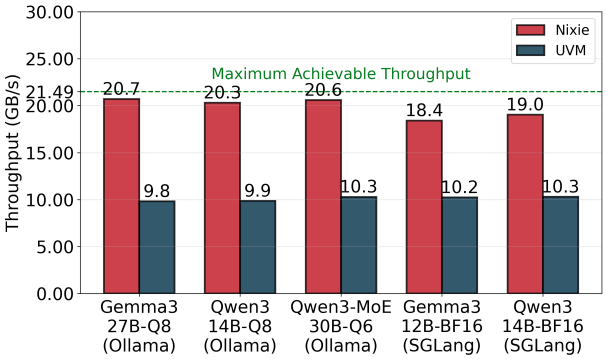

Figure 7: CPU from/to GPU memory copy throughput.

when there is already an application at the head of scheduler queue, it is most likely to run after the current application is scheduled out. Nixie thus prefetches data belonging to the next application to reduce migration time.

7 Evaluation

We have prototyped Nixie using ~10,000 lines of Rust code. Nixie Shim has ~1,900 lines of code, and Nixie Daemon has ~7,400 lines of code, with ~700 lines of shared code. Next, we microbenchmark Nixie 's context-switching latency as well as its compute and memory overheads. We then evaluate a set of representative use cases to demonstrate Nixie 's practical benefits. Following the previous work [6], we report average end-to-end time for these evaluations.

Setup. Our experiments are conducted on a desktop machine equipped with an AMD Ryzen 9 9950X CPU and 96 GB of dual-channel DDR5 memory at 3600 MT/s. The system includes two 32 GB RTX 5090 GPUs, each connected via PCIe 5.0x8. Unless noted, all Nixie, UVM, nvshare, Ollama, and TGS experiments use a single GPU; the second GPU serves only the *2 GPUs* baseline, which assigns one application to each GPU to approximate the zero-context-switch upper bound for multi-application performance. The desktop machine runs Debian 12 with CUDA version 12.9 and NVIDIA driver version 580.95.05. We run ML models using Ollama [25] (version 0.12.11), SGLang [42] (version 0.5.4.post1), `llama.cpp` [13] (version b7027) and ComfyUI [9] (commit eaf68c9). We pick a variety of models from Qwen3 [37], Gemma3 [29], Z-Image [31] and Qwen-Image [35] with different sizes and quantizations. For example, Qwen3-MoE 30B-Q6 means that it is the 30B variant of Qwen3-MoE with 6-bit quantization.

Baselines. We compare Nixie with Ollama [25], UVM [1], TGS [34], and nvshare [3]. The UVM baseline is implemented by hooking only `cudaMalloc`, `cudaFree`, and `cudaMemGetInfo` three APIs. We include Ollama as both an application atop Nixie and as a baseline: Ollama executes ML models and can switch between models natively. We only evaluate TGS using case studies and exclude TGS from microbenchmarks because TGS only supports exactly two applications and requires users to explicitly designate one as high priority and the other as low priority, making it incompatible with our microbenchmark workloads.

7.1 Microbenchmarks

Context Switch Performance. We evaluate context-switch performance by running an application executing a model and then switching to another identical instance of the same application and model on a single GPU. Figure 6 reports the Time-To-First-Token (TTFT) under five settings: *2 GPUs*, Nixie, UVM, nvshare, and Ollama. Here, *2 GPUs* places the two applications on separate GPUs, and thus reflects TTFT assuming the context switch is effectively free.

Overall, Nixie reduces TTFT by 44.0%-82.3% for Ollama cases and 29.7%-36.3% for SGLang cases compared to UVM and nvshare. Ollama uses a simple `mmap`-based strategy to unload and reload models, which results in the worst performance among all solutions tested.

We highlight two interesting observations. First, for MoE models (e.g., Qwen3-MoE), the performance benefit of Nixie for TTFT is smaller because the prefill only activates a subset of experts. Second, Nixie provides larger benefits for Ollama than for SGLang. SGLang aggressively allocates KV-cache memory that remains unused; Nixie proactively offloads all unused KV-cache pages to CPU memory, while UVM moves such pages in a delayed manner.

To understand why Nixie shortens context switch time compared to UVM and nvshare, we measure the bi-directional data-transfer throughput between host and GPU memory. Figure 7 shows the results. For reference, the dotted line marks the maximum achievable bi-directional throughput on our testbed, measured by NVIDIA's `nvbandwidth` [22] tool.

Nixie nearly saturates the available bi-directional bandwidth and achieves around 2× the throughput of UVM. The remaining gap between Nixie and the theoretical maximum primarily comes from memory allocation overheads. Ollama ex-

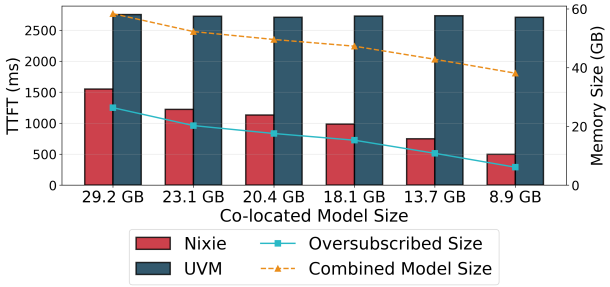

Figure 8: Performance comparison under different amounts of memory oversubscription. Oversubscribed size = Combined model size - GPU memory size.

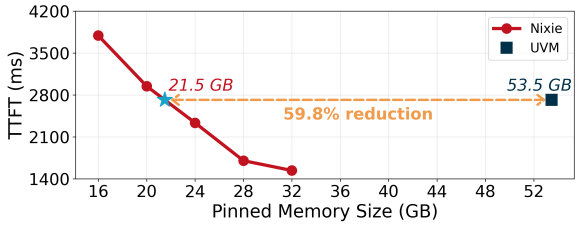
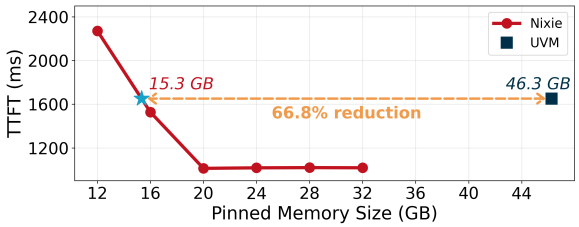


(a) Gemma3 27B-Q8



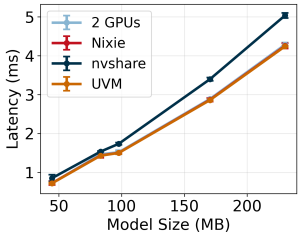
(b) Qwen3-MoE 30B-Q6

Figure 9: Pinned Memory Versus TTFT

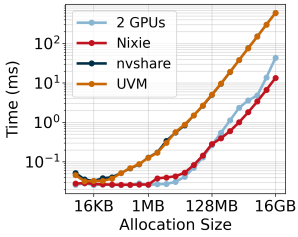
hibits a simple, large size allocation pattern, whereas SGLang has a more complex and non-uniform size pattern. Consequently, Nixie is able to reach higher bi-directional throughput when running Ollama than when running SGLang.

In Figure 8, we analyze the effect on TTFT when co-locating with applications of varying sizes. We use `llama.cpp` as our primary application and Gemma3 27B-Q8 as the model for measuring TTFT. As total GPU memory oversubscription decreases, Nixie achieves improved context switch performance, whereas UVM maintains constant context switch overhead due to its LRU policy, regardless of the extent of GPU memory oversubscription.

Sometimes, users may have insufficient CPU memory when they have to work with other applications. UVM leverages pinned memory for DMA to achieve the best migration performance. We vary the total amount of CPU pinned memory Nixie can use from 16 GB to 32 GB. In Figure 9, we show that Nixie can achieve the same performance as UVM with only 33.2% to 40.2% of the CPU pinned memory used by UVM.



(a) Inference latency



(b) cudaMalloc latency

Figure 10: Nixie's runtime overheads.

Runtime Overheads. During the time an application is scheduled to run on a GPU, Nixie should have minimal performance overheads on kernel launch, even when the kernel itself is small. This is because during the window the application is scheduled to run, the CUDA launch calls directly go through the corresponding CUDA userland driver and do not need to be handled via Nixie Daemon.

Figure 10a displays inference latencies of various small ResNet models ranging from ResNet-18 to ResNet-152 at a batch size of 1. Nixie shows the identical performance with vanilla execution from *2 GPUs* and simple UVM interception. The overhead from nvshare mainly comes from its CPU thread synchronization and GPU synchronization under certain conditions.

Memory Overheads. In Figure 10b, we measure the latency of `cudaMalloc()` with varying allocation sizes. We execute a subsequent `cudaMemset()` to eliminate the effects of lazy initialization. For allocations below 2 MB, Nixie directly uses `cudaMalloc()`, achieving performance comparable to the vanilla implementation. Between 2 MB and 128 MB, Nixie exhibits slightly higher allocation times compared to the vanilla implementation. Because the CUDA runtime is closed-source, we can only hypothesize why Nixie outperforms the vanilla implementation once the allocation size exceeds 128 MB. Our hypothesis is that Nixie allocates memory using multiple contiguous 128 MB physical regions, whereas the vanilla implementation may attempt to allocate a single, maximally contiguous region. UVM and UVM-based nvshare shows worse performance because UVM adopts a first-touch allocation policy, which defers physical memory allocation until the initial access, introducing more overhead.

7.2 Case Studies

We present four representative use cases. Cases #1 and #2 are multi-application execution workflows, where applications interact with each other. Cases #3 and #4 are concurrent workloads, where multiple workloads are independent and have no dependency.

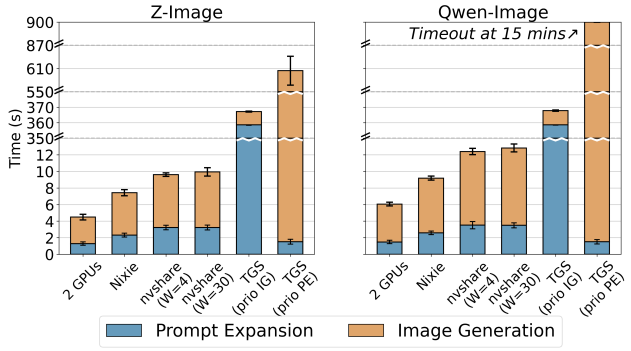


Figure 11: Using Qwen3-MoE 30B-Q6 to extend the text-to-image prompt for better image quality. Error bars represent standard deviations.

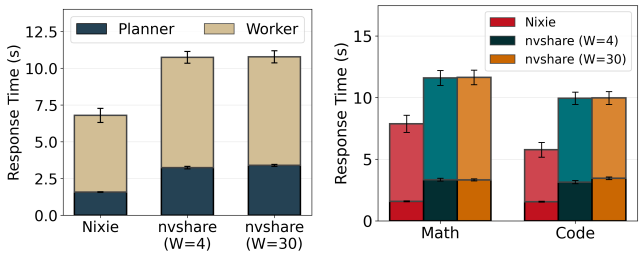
Case #1: Prompt-expanded image generation. Prompt expansion [10, 19] is a standard technique for image generation. When the user wants to generate an image given a prompt, an LLM is then used to expand the prompt to make the description of the image more precise and contain more concrete details. This workflow requires cross-application collaboration between an LLM inference application and an image generation application.

We evaluate this workflow with `llama.cpp` and ComfyUI. For prompt expansion, we use Qwen3-MoE 30B-Q6 [37]. For image generation, we select two commonly used models: (1) 6B Z-Image [31] with BF16, and (2) 20B Qwen-Image [35] with FP8. We use the DreamBench++ dataset [26] for our prompts. We compare Nixie against nvshare under two window configurations: W = 4 s, which matches Nixie's preemption threshold of the highest priority, and W = 30 s, which is the default setting of nvshare. Since TGS requires explicit priority assignment, we include two variants: one that prioritizes image generation (prio IG) and one that prioritizes the LLM-based prompt expansion (prio PE).

Figure 11 reports the results. Nixie is 1.4× and 1.3× faster than nvshare (W = 4) and achieves 65.9% and 60.4% of the performance of using two dedicated GPUs for Qwen-Image and Z-Image, respectively. Notably, even though ComfyUI frequently allocates and frees GPU memory during Qwen-Image generation, Nixie maintains higher performance, indicating that the performance of Nixie is robust to memory allocation and deallocation on the data path.

TGS exhibits significantly degraded performance and cannot finish image generation for Qwen-Image within 15 minutes. There are two primary reasons: (1) TGS assumes that the high-priority job must sustain a constant throughput, which does not hold for most consumer-oriented applications. Consequently, the TGS rate limiter fails to function effectively in this scenario. (2) Under memory oversubscription, TGS forces low-priority jobs to access host memory directly via DMA without migration, essentially stalling computation.



(a) Overall Latency (b) Latency by Request Type

Figure 12: Multi-agent orchestration for math and code tasks. Error bars represent standard deviations.

Case #2: Multi-agent systems. Multi-agent systems are an increasingly common way to structure complex LLM applications. Instead of relying on a single monolithic model, a *planner* agent decomposes a user request into subtasks and dispatches each subtask to a specialized *worker* model. This planner-worker orchestration pattern appears in current coding assistants, tool-using agents and many recent multi-LLM workflows, and serves as a canonical multi-agent workload [12, 15, 33].

We instantiate this model-orchestration workload using the open-source multi-agent framework KVCOMM [38]. For routing, we use Qwen3 14B-Q8 to decide the best downstream model. Following model-level benchmarks [5, 29, 30, 37], we select Qwen3-VL 32B-Q6 as the math expert and Qwen3-Coder 30B-Q6 as the coding expert. All models are served through `llama.cpp` on a single GPU; the only difference between configurations is the GPU sharing mechanism. We compare Nixie against nvshare with W=4 and W=30. We issue a mixed stream of math and coding requests (shuffled from GSM8K [8] and HumanEval-FIM [7]) and record end-to-end latency per request, as well as its breakdown into planner and worker components.

Figure 12 shows our results. Across all requests, Nixie is 1.6× faster than both nvshare configurations. The gains are consistent across request types as well: for math and coding tasks, Nixie is 1.5× and 1.7× faster, respectively. These results indicate that Nixie offers strong flexibility across multiple applications, enabling efficient model orchestration on a single shared GPU without sacrificing the interactivity of the multi-agent workflow.

Case #3: Code completion with long-running job. LLM-assisted code completion is a representative latency-sensitive task requiring immediate responsiveness. We expect Nixie to naturally prioritize it over long-running jobs, such as autonomous agent operations or extended video generation tasks with the help of the scheduler. To evaluate scheduler's prioritization behavior, we run code completion with a long-running agentic workload. We use Qwen3-Coder 30B-Q6 for Fill-In-Middle (FIM) completion and Gemma3 27B-Q8 to emulate an LLM-based agent. HumanEval-FIM [7] is used as the in-

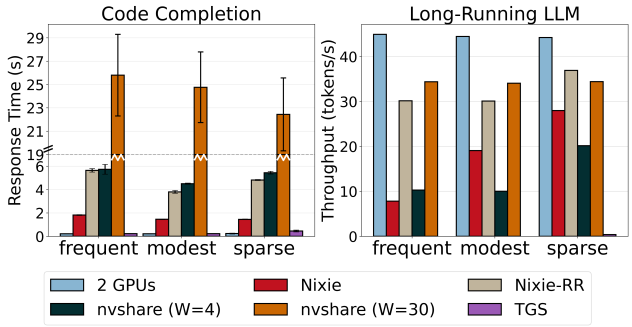


Figure 13: Code completion with long-running generation. Error bars represent standard deviations.

put for code completion. Since the frequency and interval between code completion requests vary depending on individual developers and their tooling implementations, we create three scenarios to represent different usage patterns: frequent (1-second intervals), modest (3-second intervals), and sparse (6-second intervals). Additionally, we run Nixie with a basic round-robin scheduling policy as an ablation to evaluate the effectiveness of our scheduler, noted as Nixie-RR. This variant uses a 4-second time window, consistent with the other experimental settings.

Figure 13 shows the response time of code completion and the throughput of the long-running model. Nixie achieves an average response time of 1.8 s for frequent completion scenario and 1.4 s for modest and sparse scenarios. In contrast, nvshare (W=4) requires 4.5 s to 5.7 s to complete an interactive request depending on the frequency. Nixie is 3.1× to 3.8× faster compared to nvshare (W=4). When nvshare uses the default W=30, the latency exceeds 20 s, rendering LLM code completion impractical for real-world use cases. Notably, without an appropriate scheduling policy, Nixie-RR exhibits long response time for the latency-critical task across different settings.

Regarding the long-running job throughput, Nixie is 90.6% and 39.5% higher than nvshare (W=4) in the modest and sparse scenarios respectively. In the frequent scenario, Nixie throughput is 23.5% lower, which is expected: Nixie prioritizes the interactive jobs and allocates more GPU time for code completion.

These results make the tradeoff explicit: under frequent interactive arrivals, Nixie sacrifices background throughput to keep code-completion latency low; when interactive arrivals are modest or sparse, Nixie achieves both lower interactive latency and higher background throughput than nvshare (W=4). TGS achieves similar performance for code completion task, but fails to allow the long-running model to run. TGS essentially degrades to running only the high priority application.

Case #4: Many Batched Tasks. While Nixie targets interactive workloads, some GPU jobs are sufficiently heavy that they must run for extended periods (e.g., long-document processing, high-volume generation). We therefore evaluate both throughput and fairness in a setting where multiple batched jobs execute concurrently. We also evaluate the fairness of our scheduler design.

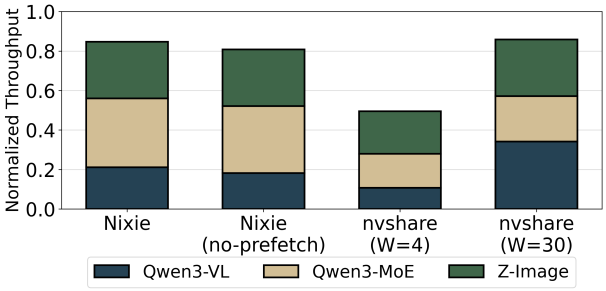

Figure 14: Different Batch Jobs

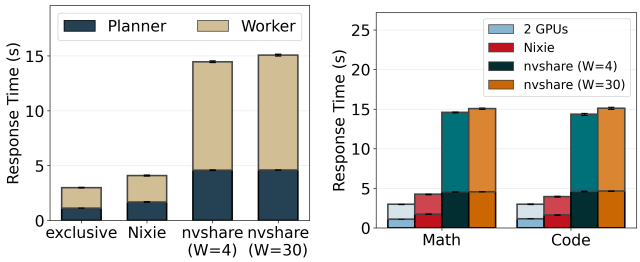
We run three jobs: Qwen3-MoE 30B-Q6, Qwen3-VL 32B-Q6 (long-running LLM request with batch size 1), and Z-Image (batch size 8). We also ablate the effectiveness of our auto-prefetching mechanism in the scheduler. We compare our solution with nvshare configured with W=4 and W=30. All experiments are conducted over a 300-second duration. To account for the heterogeneity of metrics across different applications, we additionally run each application in isolation as a reference, and report normalized throughput relative to its profiled standalone performance.

Figure 14 shows the results. Nixie achieves throughput comparable to nvshare (W=30) achieving 85% of the ideal throughput, even when Nixie employs an adaptive policy to prioritize responsiveness, whereas nvshare utilizes a fixed long time quantum for throughput. Fairness is effectively maintained across all tested configurations. Auto-prefetching yields an additional 5% throughput improvement over the no-prefetch variant, despite context switches already being infrequent in this scenario. In contrast, nvshare (W=4) only realizes 49.5% throughput because of the overhead caused by frequent context switches.

7.3 Performance on Other Hardware

We evaluate Nixie on another server equipped with two AMD EPYC 7352 24-Core Processor CPUs, 1 TB of 16-channel DDR4 memory at 3200 MT/s, and 8x RTX A5000 GPU (24 GB) connected via PCIe 4.0x16. It runs Ubuntu 22.04 with CUDA 12.4 and Nvidia driver version 550.67.

On this platform, we reuse the multi-agent orchestration workload from **Case #2**. Given RTX A5000 has smaller memory, we use Qwen3 14B-Q4 as the planner, Qwen3-VL 32B-Q4 as the math worker, and Qwen3-Coder 30B-Q4 as the coding worker. We add *2 GPUs* variant here given more available GPUs. Figure 15 shows the results. Nixie is 3.4× faster than nvshare in this case and achieves 73% of the performance of *2 GPUs*. The UVM-based solution slows down significantly for this setup. We observed increase in PCIe idleness on this hardware. We suspect the root cause is the older NVIDIA



(a) Overall Latency

(b) Latency by Request Type

driver, and the correspondingly older UVM implementation.

8 Discussion

Generalizability to other operating systems. Nixie leverages CUDA VMM API, which is available on both Linux and Windows. We have prototyped Nixie on Linux, and we believe that it is feasible to port Nixie to Windows, which remains the most widely used operating system for consumers. In contrast, UVM does not support memory oversubscription on Windows [23], and adding such support would require substantial engineering effort in the GPU driver stack on Windows. This distinction makes Nixie a more practical solution for consumer platforms. Furthermore, similar VMM APIs also exist for AMD GPUs [2].

White-box solutions. Nixie is a fully transparent solution that operates without any awareness of tensor semantics. In principle, certain immutable data (e.g., model weights) could be freed directly on the GPU without migrating it back to CPU memory, provided the application retains a separate CPU-side copy. For example, CUDA memory copies inherently leave duplicate data in both CPU and GPU memory. We did not pursue this direction because it would require semantic knowledge of application data structures, compromising transparency. However, incorporating such semantic hints represents an interesting direction for future work.

Policy extensibility. Nixie provides mechanisms for transparent GPU time sharing: orchestrating kernel launches, VMM-based remapping, hierarchical memory placement with migration and migration-scheduling cooperation. In this paper, we deliberately adopt application-agnostic policies that make no assumptions about workload characteristics, prioritizing broad compatibility over peak performance. These policies are intentionally conservative; refining them is a promising direction for future work, for example by learning scheduling decisions from recent execution history or by treating different GPU memory regions (e.g., model weights, activations, KV caches) differently.

Co-locating with small models. Nixie's target workloads are those in which each application utilizes most of the GPU memory, so temporal multiplexing is the only approach. When there is a set of small models, it is possible to perform spatial multiplexing and have different models execute at the same time as existing works on datacenter GPU multiplexing [14, 27, 41]. How to integrate spatial multiplexing into Nixie is a promising future direction.

Security. Nixie Daemon shares the same UID with applications, and applications share the same region of CPU pinned memory for storing migrated GPU data. A malicious process may access the shared data region inside its own address space. However, Linux uses UID for shared memory access control, which means any process under the same UID can access CPU pinned memory, whether the memory is shared by all processes or each process has its own dedicated CPU pinned memory. Since Nixie is for a single-user environment rather than multi-tenancy, this is outside our threat model.

9 Related Work

GPU multiplexing before the era of LLMs. GPU multiplexing has been extensively studied prior to the rise of LLMs. For traditional computer vision workloads, multiplexing allows significant consolidation of hardware by serving many models on shared GPUs (e.g., Nexus [27], Shepherd [41], Clockwork [14]). In these systems, GPU memory stores multiple models simultaneously, and incoming requests are batched and executed across one or more models. Reducing the number of co-located models or lowering batch sizes helps alleviate GPU memory pressure. In this setting, the dominant challenge is maximizing GPU compute efficiency. In contrast, Nixie targets temporal, not spatial, multiplexing: rather than having the GPU run inference for many models, Nixie time-shares it across large, memory-intensive applications whose working sets approach the GPU's full capacity.

GPU multiplexing in the era of LLMs and other large foundation models. LLMs and other large foundation models have fundamentally reshaped the GPU multiplexing landscape. Attention computation is highly memory-intensive, especially with long contexts. Even a single LLM inference often consumes nearly all available GPU memory. As a result, recent research has pivoted toward temporal multiplexing and techniques for handling GPU memory oversubscription.

PipeSwitch [6] introduces a model-aware, layer-based task-switching mechanism, but it requires application modifications. Further, it is less effective as the ratio of migration time to model execution time grows in modern foundation models. ServerlessLLM [11], Aegaeon [36], and Prism [39] address oversubscription by offloading less frequently accessed model components (e.g., entire models or KV caches)

to CPU memory or disk, primarily to meet provider's Service Level Objectives. These systems are designed for datacenter LLM serving, where workloads are controlled by a single provider and can be integrated directly into a specific inference engine. Aegaeon relies on token-granular autoscaling, and Prism relies on on-demand KV-cache allocation. These mechanisms do not apply to many consumer workloads we target, including diffusion, image editing, and video pipelines, which do not expose an LLM KV cache. They also require integration with a particular serving stack, whereas Nixie remains transparent to unmodified applications on a single user's desktop. Conversely, Nixie is not a replacement for these systems in datacenter serving. Nixie assumes whole-application context switches over the CPU-GPU link, with each application's working set nearly saturating the GPU. It does not distinguish model weights from KV cache or reason about prefill/decode phases, so it cannot selectively resize KV cache or reload only the requests about to run. Those application-level optimizations are precisely where Aegaeon and Prism reduce transfers across concurrent LLM models and requests.

Improving UVM. UVM provides a transparent abstraction for GPU memory oversubscription, which is appealing. Systems such as DeepUM [16] optimize UVM performance by incorporating tensor-level prefetching. G10 [40] adds disks to UVM and uses compiler to help manage pipelined data transfer. These solutions require hardware changes or driver changes to GPUs. Further, Nixie is not purely a virtual memory system. It does not depend on page faults and can coordinate compute and memory management at the same time to mitigate memory thrashing.

GPU scheduling. Multiple works discuss multitasking scheduling. XSched [28] presents a framework that allows for preemptive XPU scheduling. Agentix [20] incorporates application dependencies into LLM scheduling. Our scheduling policy is quite simple, and we do not need any application-level information. Our scheduling goal is to prioritize interactive applications.

10 Conclusion

Consumer machines increasingly execute large ML workloads such as LLM inference, text-to-image generation, and interactive image editing. Unlike datacenter environments, consumer GPUs must handle multiple applications concurrently, and each application often nearly saturates GPU memory. We have built Nixie, enabling efficient and fully transparent temporal multiplexing on consumer GPUs without requiring any modifications to applications or GPU drivers. Nixie coordinates GPU memory allocation with kernel-launch behavior to minimize thrashing. Nixie's scheduler further enhances interactivity by automatically identifying and prioritizing latency-sensitive applications. Nixie improves the latency of interactive code-completion workloads by up to 3.8×, while reducing CPU pinned-memory usage by up to 66.8% under equivalent latency constraints.

A Artifact Appendix

The artifact is used to reproduce the evaluation of this paper, and released under Apache-2.0 license. It includes the source code of Nixie, as well as scripts for evaluations and figure creation.

Hosting

We use two GitHub repository to host the artifact. The repository in https://github.com/XOR-op/Nixie hosts the main project source code, and the repository in https://github.com/XOR-op/nixie-eval hosts the code and scripts for evaluations and figure creation.

Requirements

The ML models selected for evaluation are targeted specifically for the 32 GB RTX 5090. If a GPU with a different VRAM capacity is used for evaluation, we suggest using models that fit into the GPU while maximizing VRAM usage, to best reflect our settings.

Abstract

FPGAs are widely adopted in cloud environments to meet the growing demand for high-performance, energy-efficient computing, thanks to their unique reconfigurability and programmability. However, the state-of-the-art design of FPGA shells is built for monolithic applications, creating a fundamental architectural mismatch with real-world applications that are highly modular and composable. Modern applications consist of diverse, independent tasks that are often instantiated as standalone hardware modules on FPGAs. The current FPGA shell design statically connects these modules to compose an application-specific, monolithic accelerator on a single virtual FPGA (vFPGA), leading to fundamental challenges such as limited flexibility, poor scalability, resource inefficiency, high scheduling overheads, and programmability issues.

To bridge this research gap, we introduce μShell, a new hardware-OS co-design that addresses these challenges by applying microkernel principles to FPGA acceleration. μShell treats accelerators as a collection of shareable, composable hardware modules, deploying them into distinct vFPGAs and dynamically linking them with a novel inter-process communication (IPC) mechanism. This approach is further supported by capability-enforced isolation and a component-aware task scheduler. Our implementation of a μShell prototype and its evaluation against a state-of-the-art monolithic shell demonstrate that it effectively deploys real-world applications with improved performance, flexibility, and resource efficiency.

1 Introduction

In cloud environments, hardware accelerators such as GPUs [32,34], ASICs [23], and FPGAs [8,31,90] are now widely used for high-performance computing. In particular, FPGAs have emerged as a promising computing platform because of their unique characteristics, e.g., programmability and energy efficiency, allowing us to reconfigure custom hardware logic specialized for compute-intensive tasks. Their versatility has driven FPGA-based acceleration in domains including video and image processing [58, 63], data compression [26, 48], databases [22, 82], security [42, 52], and AI/ML [6, 114, 134].

Modern FPGA systems typically pair a static *shell*, managing I/O and common services, with a dynamic, reconfigurable region for custom user logic [2, 7, 55]. While state-of-the-art shells [27, 64, 71, 76, 103] leverage partial reconfiguration (PR) to divide this dynamic region into multiple virtual FPGAs (vFPGAs), *they are primarily designed for monolithic applications*—single, independent accelerators that occupy an entire vFPGA.

This paradigm clashes with *the modular, composable nature of modern applications* (§ 2.2). More specifically, real-world applications are modular and composable. They are composed of diverse, independent tasks, and exhibit a high degree of correlation (up to 93%) due to the use of shared functions. To maximize throughput, they use direct data paths between hardware modules, avoiding CPU-driven synchronization and improving performance by up to 2.63×. Existing shells enable such communication only by statically wiring all modules into a single monolithic accelerator on a single vFPGA, at the cost of their modularity and composability.

This architectural mismatch imposes significant challenges on modern FPGA platforms. ***First,*** *the monolithic approach leads to limited flexibility*, as any change to a single module requires a costly redevelopment of the entire accelerator. ***Second****, it severely restricts scalability* by limiting the logic size to the capacity of a single vFPGA. ***Third,*** *it results in resource inefficiency* because the monolithic design instantiates all hardware modules for every application, even if they are shareable. ***Fourth,*** *monolithic accelerators incur substantial scheduling overheads* due to the need to fully reconfigure the entire logic when switching between applications. ***Lastly,*** *existing FPGA APIs offer limited support for dynamic I/O configurations* needed to compose modular applications effectively.

To address these research gaps, we aim to answer the following question: *Can we design a new FPGA platform that enables deploying and executing modern applications on FPGAs in a modular and composable manner?*

To build this on modern FPGA architectures, we need a new FPGA management principle that *(i)* enables partial updates and reuses of user logic designs, *(ii)* fully utilizes PR regions (vFPGAs), *(iii)* allows applications to share overlapped modules, *(iv)* avoids unnecessary reconfigurations, and *(v)* facilitates FPGA application development and deployment with high-level APIs. As an end-to-end solution, *microkernels* [4, 68, 72, 81, 89] inspire us to adapt their principles to the FPGA world. Similar to microkernels that manage applications as *a group of processes* connected through *inter-process communication (IPC)*, we propose to manage FPGA accelerators as *a combination of composable and shareable hardware modules* and connect them with *hardware-level IPC*, while *enforcing isolation*.

To this end, this paper introduces **μShell**, a hardware-OS

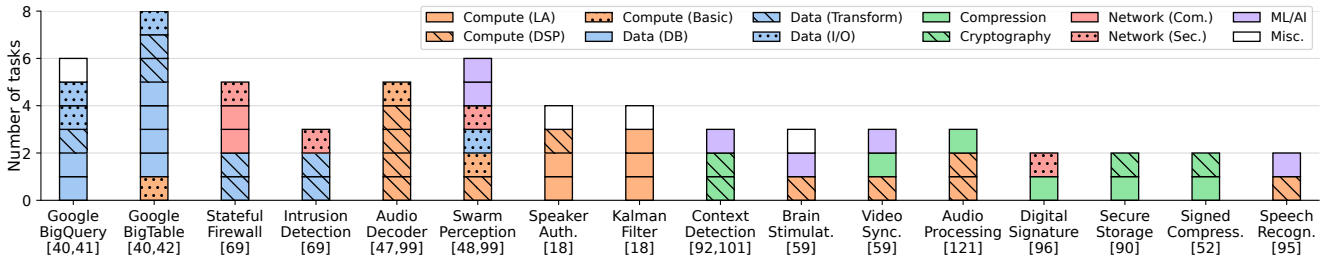

Figure 1: **Modularity analysis** for real-world applications: big data analysis [43–45], networking [79], extended reality [53,115], autonomous vehicles [54,115], wearable devices [20,108,117], cross-domain workloads [67], security [59,105,112], and audio intelligence [111,138]. Classification of their tasks is detailed in Table 1.

Classification	Description & Representative Tasks
Compute (LA)	**Linear algebra**: GEMM, GEMV, LU decomposition.
Compute (DSP)	**Digital signal processing**: FFT/IFFT, rotate order, FIR.
Compute (Basic)	**Basic computations**: Fused Multiply-Add (FMA), etc.
Data (DB)	**Database**: SQL query, hash/sort aggregation/join, etc.
Data (Transform)	**Data transformation**: parsing, filtering, compaction.
Data (I/O)	**I/O tasks**: memory reads/writes, sensing, etc.
Compression	**Data compression/encoding**: GZIP, RLE, Huffman decoding, MPEG encoding/decoding.
Cryptography	**Encryption/decryption**: RSA, AES-GCM, AES-CTR.
Network (Com.)	**Network communication**: TCP/IP, packet switching, connection tracking.
Network (Sec.)	**Network security**: SHA256, IP packet filtering, packet classifier, data descrambling.
ML/AI	**ML and predictive ops**: SVM, Viterbi sensing/decoding, logistic regression, dynamic time warping.

Table 1: Task classifications in Figure 1.

co-design for modular accelerator deployment and execution. Inspired by the microkernel principle, μShell enables *dynamic accelerator composition*, deploying individual hardware modules into distinct vFPGAs and dynamically chaining them together to compose the entire accelerator. To achieve this, μShell adapts microkernel features: *capability-enforced isolation* for secure resource sharing, *component-aware task scheduling* for minimizing reconfiguration overheads, and *IPC* for peer-to-peer data transfers between vFPGAs. μShell provides these features through *a high-level API*, enabling FPGA accelerator composition and deployment in a flexible and dynamic manner. The μShell ecosystem is constructed with three key system components:

(1) **μShell hardware (§4.1).** We design μShell, a microkernel-based shell architecture for dynamic accelerator composition. μShell provides *Capability Enforcement Units (CEUs)* for each vFPGA, which bridges distinct vFPGAs through the IPC mechanism while enforcing capability-based isolation, enabling secure, dynamic accelerator composition.

(2) **μShell OS (§4.2).** We design the μShell OS, privileged software responsible for managing the μShell hardware upon user requests. It provides microkernel features essential for FPGA accelerator composition: capability, address space management, task scheduling, and IPC.

(3) **μShell programming API (§4.3).** We design a high-level API that allows guest applications to compose and deploy FPGA accelerators in a hardware-agnostic manner. The user-space API library transparently communicates with the μShell OS and abstracts complex capability details and hardware architectures from developers.

We implement a μShell prototype on AMD Alveo U280 cards [126]. We build the entire μShell hardware by extending Coyote v2 [103], the state-of-the-art FPGA shell for monolithic accelerators. We also port five real-world applications [59,105,111,112,138] with our μShell prototype. To compose these applications, we leverage pre-built IP cores from FPGA vendors [129] and open-source projects [27,71].

We comprehensively evaluate μShell's performance, scheduling effectiveness, programmability, and FPGA resource overheads using five real-world applications. We highlight that μShell's modular accelerator deployment incurs only 3.3% throughput degradation compared to Coyote v2, the monolithic approach's baseline that achieves optimal performance. In addition, μShell's task scheduler reduces vFPGA reconfigurations by up to 79% compared to Coyote v2, by sharing hardware components across applications.

2 Background and Motivation

2.1 FPGA Shell Architectures

Commercial FPGA products adopted in the cloud [8,31,90] serve as PCIe-connected devices [18,19,126–128], which consist of an FPGA chip and off-chip peripherals for external I/Os such as memory and network ports. The FPGA chip is split into two regions: a static region or *shell*, which is statically configured at system boot and contains I/O modules (e.g., DMA and memory controllers) and common features (e.g., interrupts), and a dynamic region, where custom user logic can be dynamically reconfigured. While vendor-provided shells [2,7,55] often provide a single dynamic region, the state-of-the-art shells in academic studies [27,64,71,76,87,103] use partial reconfiguration (PR) to split it into multiple, isolated *virtual FPGAs (vFPGAs)*, enabling spatial sharing of the FPGA.

Although these state-of-the-art shells promise an efficient use of limited FPGA resources, they assume that applications are ***monolithic***, where user logic is designed as an independent, single accelerator dedicated to its target application and instantiated on a single vFPGA. While this design choice

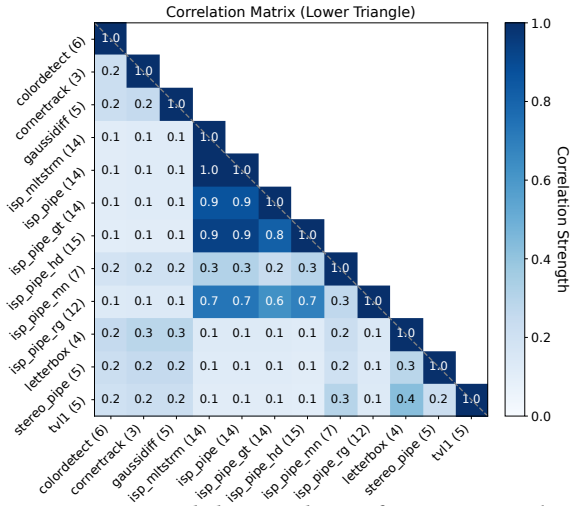

Figure 2: **Composability analysis** of Vitis Vision Library applications [130] based on overlap in library function usage (parentheses indicate call counts).

simplifies an isolation mechanism across vFPGAs, in reality, applications are ***modular*** (§2.2); deploying them on these existing shells poses several challenges (§2.3).

2.2 FPGA Application Requirements

In contrast to the state-of-the-art shells designed for monolithic applications, real-world applications are ***modular and composable***, highlighted by our two empirical studies. First, Figure 1 illustrates the ***modularity*** of real-world applications from prior studies spanning across multiple domains. Each section of bars represents an independent task deployed and executed on any compute device, such as a CPU core, ASIC accelerator, or custom logic on the FPGA. As seen here, modern workloads are not monolithic but composed of *diverse, modular tasks*. Second, Figure 2 shows the ***composability*** study of HLS applications developed with the Vitis Vision library [130], where we analyze the library functions called by each application code and visualize matches of the same function calls between two applications as the correlation strength. We observe that up to 93% of application pairs have shared functions and more than 20% of them have high correlation (more than 0.5), indicating that applications are deployed as a combination of *sharable and composable functions*.

These applications are typically designed and built on FPGAs as a combination of multiple *hardware modules*, each dedicated to a specific task. To maximize acceleration effectiveness, establishing data paths between modules is essential for enabling ***direct communication***, thereby significantly increasing throughput [43, 67, 115, 121]. Figure 3 demonstrates the effectiveness of direct communications, compared to a CPU-driven synchronization, where a host CPU sequentially invokes FPGA accelerators that comprise each application. The results highlight that direct communication achieves up to 3.7× by avoiding unnecessary CPU-FPGA communications.

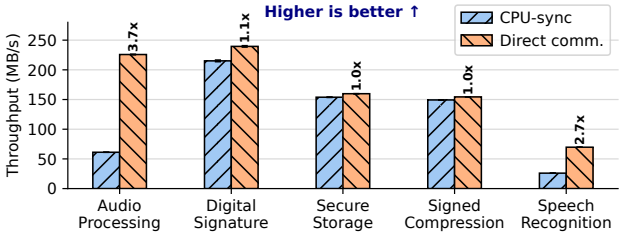

Figure 3: **Direct communication effectiveness** for our target applications [59, 105, 111, 112, 138] (§6).

2.3 State-of-the-art FPGA Shells

Due to the fundamental mismatch between state-of-the-art shells and real-world applications, existing FPGA platforms deploy applications as *monolithic* accelerators that combine all submodules into a single static accelerator on a single vFPGA, imposing five fundamental challenges. We have a detailed comparison with the state-of-the-art FPGA shells and platforms in §7.

(1) Limited flexibility. First, the monolithic design loses the flexibility of FPGA applications. Real-world applications are composed of multiple tasks, as shown in Figure 1, while they are developed as a single-purpose, static accelerator on the FPGA. Although this design fully optimizes performance, it increases the logic's size and complexity, making it error-prone and hard to debug. Hardware bugs are mostly caused at certain execution stages and intersections between submodules [75]. Moreover, minor changes to a specific submodule (e.g., applying different ML algorithms for speech recognition [111]) affect the entire accelerator design, forcing users to recompile and resynthesize the entire design. It substantially increases development efforts.

(2) Limited scalability. Second, existing shells leveraging partial reconfiguration (PR) limit the scalability of FPGA accelerators. Although multiple vFPGAs can increase the concurrency of FPGA applications, more vFPGAs reduce the available resources. Existing shells, which allow user logic to be deployed to a single vFPGA, limit the deployable logic size to the capacity of that vFPGA. Figure 4 analyzes available FPGA resources per vFPGA on Coyote v2 [103] deployed on the U280 FPGA with different numbers of vFPGAs, highlighting that available resources are severely restricted, i.e., only 10.8% to 12.5% of the U280 capacity when we have 8 vFPGAs.

(3) Resource inefficiency. Third, the monolithic accelerator deployment leads to resource inefficiency. As demonstrated in Figure 2, FPGA applications likely contain the same modules, which can be shared. In a monolithic design, these

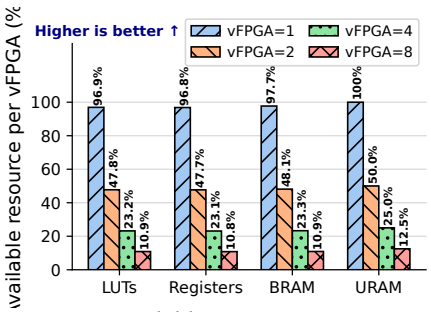

Figure 4: Available FPGA resources per vFPGA.

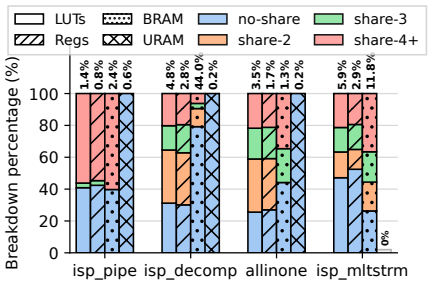

Figure 5: Resource usage analysis. Bar labels show relatives to U280 capacity.

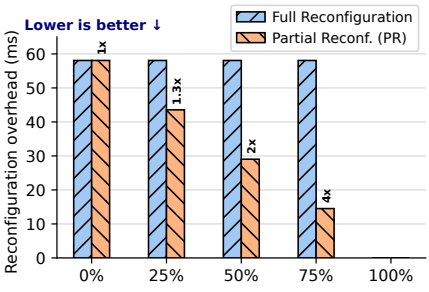

Figure 6: Reconfiguration overhead. The x-axis shows the shared logic ratio.

shareable components are unnecessarily duplicated because each application is deployed as an independent module, leading to wasted FPGA resources. Figure 5 visualizes FPGA resource usage of non-shared and shared modules of four representative applications from the Vitis Vision Library [130] (share-X indicates modules shared by X applications from the library). It highlights that shared components can account for up to 80% of the application's total resource usage.

(4) Scheduling overheads. Fourth, monolithic accelerators induce significant scheduling overheads when switching tasks deployed on the same vFPGA (temporal sharing). This process invokes reconfiguration of the entire accelerator logic, leading to substantial (ms-order) performance penalties [71]. While some shells support accelerator reuse to avoid reconfiguration [71], this feature is only available when the accelerators used by two applications are identical. Figure 6 demonstrates expected task switching (reconfiguration) overheads, comparing two cases: the baseline that reconfigures the entire vFPGA, and the ideal case that only reconfigures non-shared components. The result indicates that we can potentially mitigate the switching overheads if the FPGA platform allows us to reconfigure only an independent portion of the logic.

(5) Limited programmability. Fifth, existing shells and programming APIs are primarily designed for monolithic accelerators and offer limited programmability for dynamic I/O configurations between hardware modules. Table 2 compares existing FPGA systems in terms of I/O functions and their programmability. HLS compiler-based approaches [29, 125] ease the description of inter-module communication, but are limited to a single accelerator design. FPGA APIs [41, 46] support dynamic I/O switching between modules but not direct communication across vFPGAs. Some shells, such as Coyote [71], enable inter-vFPGA communication, while they are statically configured as a function of the shell.

2.4 Our Proposal and Design Goals

To overcome these challenges, we propose μShell, a microkernel-based FPGA shell architecture. Inspired by the microkernel concept [4, 68, 81, 89], μShell enables *the modular deployment and execution of FPGA accelerators*. Unlike the monolithic approach, μShell deploys an application across separate vFPGAs as hardware modules and dynamically chains them to compose the entire application. μShell realizes this by offering microkernels' core system properties: capability management, address space isolation, task management/scheduling, and IPC. We design our μShell architecture to meet the following design goals:

(1) **Capability-enforced isolation.** μShell leverages capabilities [16, 37, 74, 78] to ensure robust isolation across shared and non-shared accelerator modules and memory buffers in a multi-tenant environment.

(2) **Inter-process communication (IPC).** μShell allows applications to establish peer-to-peer communication channels between accelerators deployed on vFPGAs, enabling fast I/O communications while improving flexibility.

(3) **Component-aware task scheduling.** μShell schedules tasks deployed on FPGAs while accounting for hardware modules shared across multiple applications and minimizing the number of reconfigurations.

(4) **API for dynamic accelerator composition.** μShell provides a high-level API that allows developers to describe application dataflow across components and dynamically deploy them in a modular and flexible manner.

The μShell design comprehensively addresses the challenges outlined above. ***First,*** it ensures flexibility, because applications can be updated without involving unchanged components. ***Second,*** it ensures scalability because μShell can chain any number of vFPGAs to construct applications, thereby fully utilizing all available FPGA resources. ***Third,*** it improves resource efficiency by allowing multiple applications to share components deployed on the same FPGA. ***Fourth,*** μShell induces less task switching overhead because only non-shared components need to be reconfigured. ***Fifth,*** μShell provides an easy-to-use API that enables developers to design and deploy their modular, composable applications within the μShell ecosystem.

3 Overview

3.1 System Overview

Figure 7 shows the overview of μShell, comprised of guest applications using the *μShell API*, privileged *μShell OS*, and

the μShell substrate offering multiple vFPGAs. At the core of each vFPGA is a *Capability Enforcement Unit* (CEU), which acts as a hardware gatekeeper, regulating data transfers, connection setup, access control, and memory allocation for the associated accelerator module.

Hardware components. *μShell* (§4.1) is deployed as a privileged component at system boot and provides multiple vFPGAs. Besides common shell components such as a PCIe bridge IP, it offers dedicated CEUs that connect each vFPGA to streaming data paths via the data interconnect. Each CEU enforces capabilities, allowing only authorized data transfers between vFPGAs, while the μShell OS restricts guest application access to prevent tampering with shell components and capabilities.

Software components. *μShell OS* (§4.2) and *μShell API library* (§4.3) are two key software components. The privileged μShell OS offers four microkernel-based features for secure accelerator composition: (1) *capabilities* [50, 123] to restrict access to accelerator components like user logic on vFPGAs and memory buffers; (2) *address space management* to ensure that a group of accelerator components sees the same virtual address space; (3) *task scheduling* to enable temporal and spatial sharing of vFPGAs between applications; (4) *IPC* to enable communication between the components. The μShell API library provides a hardware-agnostic interface for applications to interact with the OS and to deploy and execute accelerators. Since many real-world FPGA applications [51, 57, 93, 97, 107] are composed of modular hardware components and designed as pipelined streaming dataflows, the μShell API aligns with this programming model and does not limit the generality of applications.

System workflow. During initialization, guest applications use μShell APIs to construct dataflow graphs (DFGs) by defining computational tasks, memory buffers, and their data dependencies. These are sent to the μShell OS, which verifies DFG correctness and consistency with capability constraints. Based on programmed logic on vFPGAs and other running tasks, the μShell OS performs task scheduling, task mapping to vFPGA, reconfiguration, memory allocation, and capability initialization. At runtime, the μShell OS enforces capability-based access control and orchestrates data transfers. The system ensures secure resource cleanup through automatic capability reclamation, eliminating manual resource management overhead while maintaining strict security boundaries.

3.2 Technical Challenges and Key Ideas

While the microkernel concept is the key to deploy and execute modular, composable FPGA applications (§2.4), the nature of FPGAs and their toolchains pose several challenges to adapting microkernel principles [37, 68, 81]. We tackle this challenge with a hardware-OS co-design approach. Specifically, we build the μShell ecosystem to address four key design challenges:

#1: Isolation and sharing for accelerator components. In contrast to existing shells for monolithic applications [64, 71, 76, 103], which dedicate each vFPGA to a single application and ensure per-vFPGA isolation, μShell deploys applications as a set of accelerator components (*hardware tasks*) distributed across vFPGAs, similar to microkernel applications comprising multiple services [25]. This design introduces two unique challenges. First, existing shells, including Coyote [71, 104], enforce isolation at the vFPGA granularity, assuming that each vFPGA runs a single monolithic application (detailed in Table 7). As a result, they lack mechanisms to safely compose or share independently deployed hardware components across vFPGAs, since there is no fine-grained control over inter-component communication or memory access. Second, the non-preemptive nature of FPGAs [69] complicates the management of internal state when hardware components are reused across applications, making secure sharing difficult without explicit isolation support.

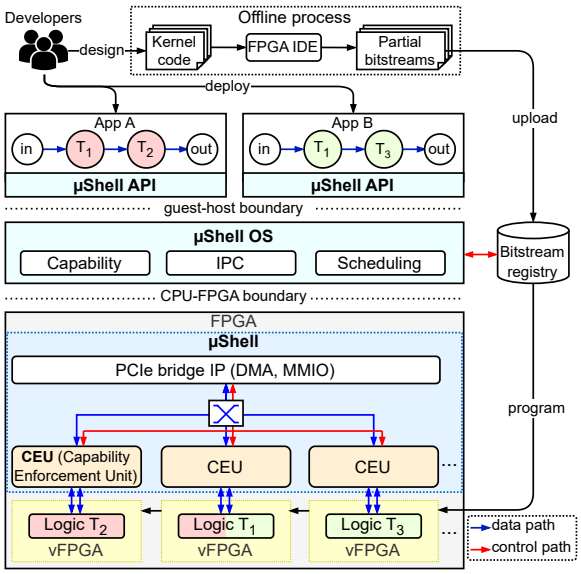

Figure 7: Overview of the μShell system.

Key idea. We design a unique capability-based, hardware-enforced isolation mechanism that restricts IPC channel establishment and memory accesses, achieved by μShell CEUs (§4.1) and OS (§4.2). μShell ensures that internal states of shared hardware components are clearly flushed before switching applications.

#2: Secure IPC establishment across vFPGAs. Constructing secure chains of user logic and memory buffers requires robust resource isolation. μShell adapts the microkernel's IPC mechanism to dynamically establish data paths between accelerator components. To achieve this, we require a reconfigurable I/O switching mechanism that establishes streaming channels between vFPGAs and memory buffers on demand, while maintaining isolation. Such cross-vFPGA communications are restricted in existing shells; they either do not provide any interconnects and rely on static data paths in monolithic designs [5, 64, 80, 113, 119, 135] or require recompiling the entire shell to bridge vFPGAs [71, 79, 104]. As

a result, they cannot dynamically establish communication channels between independently deployed components. Other designs [65, 91] support flexible data movement but lack fine-grained access control, making it difficult to securely connect components across application boundaries.

Key idea. We introduce a fast, flexible IPC mechanism using CEUs and a centralized interconnect (§4.1). μShell OS's IPC module (§4.2) dynamically and securely configures IPC channels by enforcing capabilities with minimal overhead. μShell is the first FPGA shell that functions IPC between components with secure isolation properties.

#3: Hardware task scheduling and deployment. Scheduling and deploying a set of hardware tasks across a limited number of vFPGAs is challenging. While this approach enables component sharing across applications, current PR technologies on FPGAs [12, 56] limit deployment flexibility because PR regions (vFPGAs) are not interchangeable; each vFPGA requires a dedicated bitstream. Moreover, although component sharing potentially improves utilization and reduces reconfiguration overhead (§2.3), it may lower throughput compared to the exclusive use of the entire FPGA, especially when reconfiguration occurs frequently. Prior hardware schedulers either overlook this trade-off [71, 91] or disable PR at the cost of flexibility [64].

Key idea. μShell OS's component-aware task scheduler (§4.2) allows applications to share accelerator components while retaining isolation and throughput. μShell OS also enables flexible hardware task deployment on any system-provided vFPGAs by managing multiple bitstreams.

#4: Programming APIs for dynamic accelerator composition. The lack of FPGA shells that support dynamic accelerator chaining limits software libraries from providing easy ways to pipeline multiple applications. As a result, existing frameworks [41, 46, 76, 131] do not natively support connecting and orchestrating multiple pipelined applications.

Key idea. We present a user-space API library (§4.3) that enables composing dataflows and deploying them without manual communication or resource management.

4 Design

We introduce design details of the core system components: μShell, μShell OS, and μShell API library.

4.1 μShell Hardware

We first introduce the μShell hardware architecture, illustrated in Figure 8. μShell comprises components for common shell functionalities, i.e., a PCIe bridge IP, a PR controller, and a DMA request scheduler, and μShell-specific components for capability enforcement and IPC, i.e., a data interconnect and per-vFPGA CEUs. The PCIe bridge IP provides two host-FPGA communication interfaces: a memory-mapped interface for control paths (e.g., AXI4-Lite [13]) and a

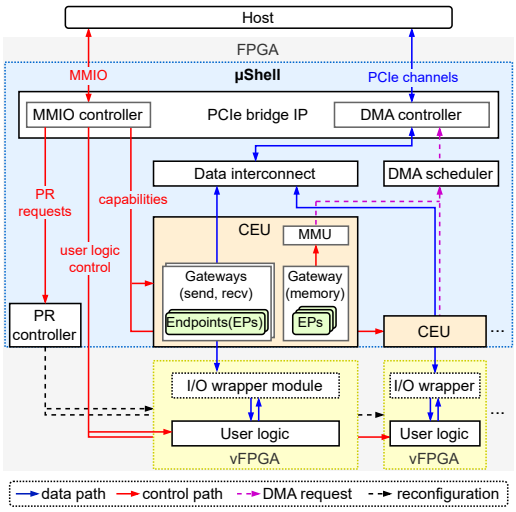

Figure 8: μShell hardware architecture.

streaming interface for data paths (e.g., AXI4-Stream [14]). The PR controller reconfigures a selected vFPGA through the ICAP interface [1] without interrupting other hardware components. The data interconnect provides a configurable peer-to-peer link between vFPGAs and host memory. Through the interconnect, the CEUs establish capability-enforced channels by configuring *endpoints* depending on I/O types (send, receive, or memory). For memory accesses from vFPGAs, the CEUs issue DMA requests, which are handled by the DMA scheduler in a round-robin fashion. For vFPGAs, μShell provides an I/O wrapper module that abstracts multiple input and output ports of user logic.

Capabilities. The μShell framework employs capability-based isolation as its fundamental access control mechanism for accelerator composition on the FPGA. Capabilities are unforgeable tokens that grant specific permissions to access system resources, providing both authentication and authorization in a single primitive [16, 49, 68, 123]. This approach ensures that user logic can only access resources for which they hold valid capabilities, enabling fine-grained access control.

μShell uses capability-based isolation to protect IPC between vFPGAs and memory access. *Object capabilities* authorize access to specific user logic instances and communication endpoints, and *memory capabilities* constrain accesses to approved address ranges and include permissions (read/write). Capabilities are created and managed per application by the μShell OS and enforced at runtime by the CEUs, preventing cross-application interference.

Capability Enforcement Unit (CEU). The CEU enables IPC and capability enforcement and is designed to offer three key functions: handling multiple connections for user logic, safely invalidating unauthorized accesses, and enabling time-sharing of user logic. To achieve this, the CEU includes configurable *gateways* for each communication channel, which act as verification checkpoints for IPC. There are three gateways for different I/O types: *send gateway* to manage

data transfers from the hosted vFPGA, *a receive gateway* to validate incoming data streams, and *a memory gateway* to validate memory accesses and issue DMA requests.

Figure 9 illustrates the CEU architecture. Each gateway consists of *endpoints* and *validators*. Endpoints are registers that store capabilities granted to the associated user logic. Send/receive, and memory endpoints are created from object and memory capabilities, respectively. Creating memory endpoints also involves the MMU registering a page table entry. The gateway establishes communication channels only with authorized vFPGAs or memory spaces whose capabilities are configured as endpoints, and rejects unauthorized requests. Endpoints of these gateways are initialized or updated only once per application execution at the deployment phase. During execution, incoming/outgoing data is seamlessly validated by its gateways without capability updates.

Given that user logic can have multiple input/output ports, a single gateway can configure multiple endpoints to establish multiple channels. The send and receive endpoints use *port IDs* to identify specific ports of user logic. The port IDs are transferred as part of execution requests from applications via the μShell API (§4.3) and enable gateways to internally manage port mappings across different channels.

Validation. The validators detect unauthorized requests and stop them. When sending requests, the send gateway's validator receives a port ID from the user logic and checks whether the associated send endpoint has been created. The gateway then generates *a route ID* containing the port ID, the sender's, and receiver's vFPGA IDs. The route ID is propagated to the data interconnect and the receiver, along with data streams, to guide routing and enable the receiver's capability checks. When receiving requests, the receiver's validator uses the route ID to identify the sender's vFPGA and verify whether the receiver has the associated capability. It then extracts a port ID from the route ID and transfers the data to the associated user-logic port. For memory requests, the validator checks whether the memory capability covers the specified address range.

On failure, the validator drops the request and interrupts μShell OS. It safely suspends the execution without affecting other components: incoming streams are drained to avoid hangs or data leakage, and invalid memory requests are rejected without issuing DMA, ensuring no transaction occurs.

Component sharing. The CEU enables temporal sharing of user logic between applications. While custom IPs can deliver higher performance, standardized reusable modules (e.g., AFI [9]) reduce development cost and improve composability. μShell currently supports sharing of stateless accelerators across applications, as reliably resetting internal hardware state is challenging. For non-shared stateful applications, on-chip memories (e.g., LUTRAMs and BRAMs) can be used to maintain their internal states. μShell also supports off-chip memory such as HBM and DRAM, which are treated similarly to the host memory. These off-chip memory regions are used as data buffers for communication between the host and accelerators, e.g., input/output buffers for data transfer, rather than as persistent, application-private state tied to a specific accelerator instance across invocations. The shell maintains only two types of application-specific contexts: CEU endpoints and MMU page tables, which are cleared upon application switches. Since FPGAs are non-preemptive, μShell waits for the current execution to finish before updating capability mappings of the associated CEUs. It then applies new routing capabilities before switching applications, without saving or restoring the accelerator state. μShell additionally resets the residual state in the accelerators to mitigate potential data leakage. While a full hardware reset of all components is non-trivial, as states can be distributed across many elements (BRAMs, flip-flops, etc.), μShell relies on the fact that HLS provides easy-to-use reset mechanisms to clear internal states (e.g., reset pragma, dedicated reset port [11]).

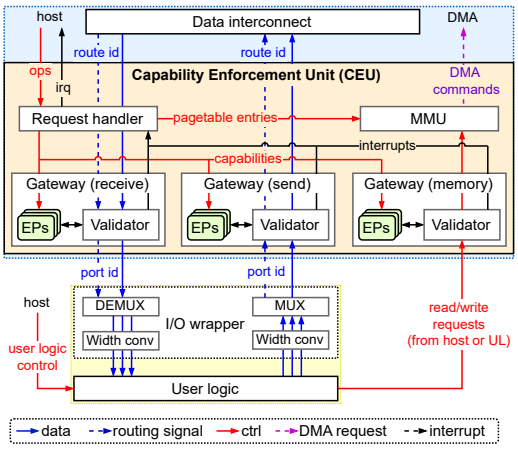

Figure 9: Capability Enforcement Unit (CEU).

Data interconnect. The data interconnect acts as a central switch, routing data streams between vFPGAs and host memory. It maintains static connections to all sources and destinations, while actual routing is dynamically configured via route IDs attached to incoming data streams. The interconnect uses the route ID to identify the correct destination and forwards data and accompanying signals that mark the start and the end of data streams. It provides independent data paths between source and destination pairs and supports multiple concurrent streams without interference. The interconnect uses a round-robin scheduling algorithm for streams that go to or come from the same vFPGA.

I/O wrapper module. The I/O wrapper module abstracts μShell's unified data stream interfaces from user logic. It contains a multiplexer (MUX) and a demultiplexer (DEMUX) to route I/O streams from and to a single shell-side data channel. It includes a width converter to reconcile mismatches between the data widths of the user logic ports and the μShell interface. As a result, user logic can be deployed on μShell without requiring any modification.

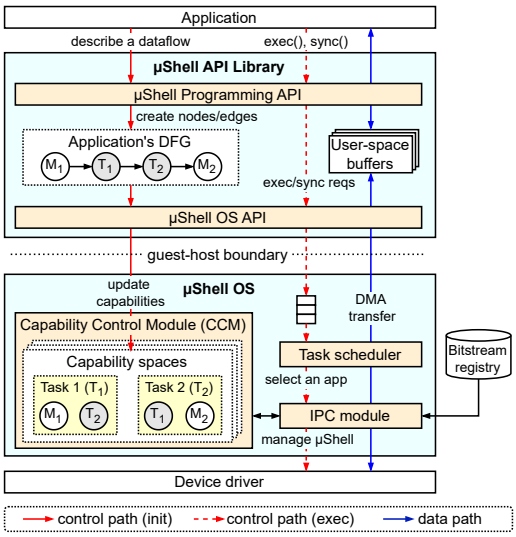

Figure 10: μShell API library and OS architecture.

4.2 μShell OS

We propose μShell OS, a privileged software designed to adapt the microkernel principle to resource management for modular, composable FPGA applications. Unlike traditional microkernels for CPU programs [4, 39, 68, 81], μShell repurposes microkernel features for FPGA applications, accounting for the fundamental limitations of modern FPGA architectures and toolchains.

Figure 10 shows the architecture of the software components. μShell OS consists of three key components: the *capability control module (CCM)* for managing capabilities, the *dataflow task scheduler* for scheduling hardware tasks, and the *IPC module* for deploying and invoking tasks on vFPGAs and enabling IPC. μShell OS provides the microkernel's fundamental features: *capability management*, *address space management*, *task (thread) management*, and *IPC*.

Capability management. The CCM is responsible for maintaining a lifecycle of application capabilities with fine-grained control. Similar to seL4 [68] and M^3 [16], the μShell OS manages all application objects (tasks and memory) using capabilities for robust isolation, while it is tuned for building and executing accelerator chains on the FPGA.

The CCM creates *capability spaces* for individual applications to guarantee multi-tenant isolation. The CCM ensures that capabilities remain unforgeable, as guest applications can only access their own capability spaces via μShell APIs. Unlike existing microkernels that manage capabilities for CPU processes [4, 37, 68], the CCM adapts capabilities to define strict data flows between hardware tasks and memory buffers for secure accelerator composition. The CCM treats a guest CPU application as a *parent* and allows it to manage capabilities for these accelerator components as children or *dataflow nodes* through three primary operations: *create*, *delegate*, and *revoke*.

An application begins by creating object/memory capabilities for dataflow nodes, which allows the application to possess a parent capability with delegation rights and request a new, subordinate capability for nodes through the delegation. Created/delegated capabilities are securely maintained through a tree structure: child capabilities never have more privileges than their parent, preventing privilege escalation. The revocation process verifies every access to capabilities and safely retires capabilities with zero usage count. Once an application is complete, its capabilities are immediately removed.

Delegated capabilities enable nodes to communicate via IPC or memory accesses. For example, as shown in Figure 10, when a task (T_1) sends data to another (T_2), T_1 must have T_2's capability with a write permission, while T_2 owns T_1's capability with a read permission.

Address spaces. μShell OS maintains and exposes virtual memory address spaces not for CPU programs but hardware tasks running on the FPGA. It allows applications to allocate FPGA-accessible memory buffers while enforcing isolation. In μShell, applications do not share page tables; each application maintains its own address space within a dedicated MMU with its TLB, managed by the CCM. The CCM is responsible for memory allocation and mapping, ensuring that all access permissions are maintained per-application and that isolation is enforced across vFPGAs. Since μShell guarantees that each application has exclusive access to its assigned vFPGAs during execution, TLB operations (e.g., flushing) remain localized and do not impact other applications.

Tasks and threads. Instead of CPU tasks and threads, μShell manages *hardware tasks* that execute on specific user logic. Unlike task execution on CPUs, hardware task deployment and execution require FPGA reconfiguration by loading a bitstream into a PR region (vFPGA) to initialize user logic, posing two challenges. First, vFPGAs are not interchangeable and their capacity cannot be changed dynamically due to limitations of existing FPGA toolchains. Current PR technologies [12, 56] require bitstreams dedicated to each vFPGA, which complicates the deployment and switching of user logic across vFPGAs. Second, FPGA reconfiguration is known to be a time-consuming process, which induces performance overheads of hundreds of milliseconds [71].

We address these limitations with two approaches. First, the μShell ecosystem requires developers to provide multiple bitstreams for each pair of user logic and vFPGA, so that the μShell OS can seamlessly select the bitstream associated with the target vFPGA. This constraint follows state-of-the-art PR-enabled FPGA shells [64, 71, 103] (§8). μShell OS maintains multiple bitstreams per user logic in the bitstream registry. Specifically, it classifies bitstreams by assigning unique IDs to user logic and vFPGAs. These IDs are attached to each bitstream depending on its associated logic and vFPGA.

Second, we propose the dataflow task scheduler, which mitigates the reconfiguration overhead by promoting component reuse, i.e., deploying tasks using user logic that has already been programmed on vFPGAs. Algorithm 1 details our scheduling algorithm. The scheduler employs a non-

Algorithm 1: The component-aware scheduler.

```
1  schedule_app(priority_array, vFPGAs)
2  begin
       /* Select apps with highest priority */
3      foreach priority in priority_array do
4          if priority_array[priority] != null then
5              candidate_array ← priority_array[priority];
6              break;
7          priority ← priority - 1;
8      end
       /* Select app with the highest overlap with free vFPGAs */
9      foreach app in candidate_array do
10         app.overlap ← overlap_with_free_vFPGAs(app, vFPGAs);
11     end
12     candidate_app ← max_overlap(candidate_array);
       /* Check if there are enough vFPGAs to schedule the app */
13     if candidate_app.size > free_vFPGAs.size() then
14         return null;
15     foreach priority in priority_array do
16         foreach app in priority_array[priority] do
17             app.time ← app.time + 1;
18         end
           /* Promote long-waited app priority */
19         if app.time > threshhold then
20             app.priority ← app.priority + 1;
21             app.time ← 0;
22         priority ← priority - 1;
23     end
24     return candidate_app
25 end
```

preemptive policy to avoid expensive context switches on FPGAs [17]. It continuously monitors all vFPGAs, tracking programmed user logic and execution status. Any system event (e.g., a request arrival or completion) triggers the scheduling of a new task. The scheduler first considers applications with the highest priority (L3-8). For those with the same priority, it selects an application with the greatest overlap between the requested user logic and the logic programmed on vFPGAs (L9-11). To prevent starvation, an application that has waited longer than a threshold has its priority promoted (L19-22). Once the application is selected, the scheduler forwards the execution request to the IPC module, which is responsible for the μShell configuration and execution invocation. When components have imbalanced execution times that may lead to pipeline stalls, this reflects a common challenge in streaming and pipeline-based accelerator design. It is the developer's responsibility to partition the application such that the processing latency of each stage is balanced to maximize throughput.

Inter-Process Communication (IPC). IPC in a hardware context differs fundamentally from that for CPU processes [68, 81]. CPU-based IPC relies on blocking remote procedure calls (RPC), which require context switches to the OS kernel. In contrast, IPC between hardware tasks is implemented as non-blocking, direct data transfers via streaming protocols (e.g., AXI4-Stream [14]) across multiple hardware modules, i.e., sender/receiver logic and μShell. This hardware-level IPC is faster and more efficient than CPU-based IPC because all components run in parallel and all operations occur without interruption. However, due to the lack of context-switch mechanisms in FPGAs [86, 109, 120], IPC initialization on FPGAs is less flexible than on CPUs. Before launching the entire execution, all hardware components must be instantiated on vFPGAs and IPC channels established between them.

The IPC module of μShell OS is responsible for IPC management and for invoking hardware tasks. The module handles low-level hardware management to trigger the entire dataflow execution on the FPGA, such as vFPGA reconfiguration, CEU and MMU configuration, and DMA invocation. It receives execution requests from the scheduler and reconfigures vFPGAs if necessary. It then refers to the corresponding capability space maintained by the CCM and configures endpoints on the associated CEUs and MMU page tables to establish IPC channels, ensuring all communication between hardware tasks occurs without involving the μShell OS.

High-level API	Description
create_task(*name*)	Create a task node.
create_buffer(*data*)	Create a host data buffer.
dataflow()	Instantiate a dataflow graph.
dataflow::connect(*src, dst*)	Connect two tasks.
dataflow::execute()	Execute the dataflow.

Table 3: μShell API for building host-side control logic.

```
// Create tasks and data buffers as DFG nodes
sha = ushell::create_task("sha");
rsa = ushell::create_task("rsa");
in  = ushell::create_buffer(host_in);
out = ushell::create_buffer(host_out);
// Describe a dataflow
df = ushell::dataflow();
df.connect(in, sha.in);
df.connect(sha.out, rsa.in);
df.connect(rsa.out, out);
// Validate and execute the dataflow
df.execute();
```

Listing 1: An example written by μShell API.

4.3 μShell API and Programming Model

The μShell programming API and library are designed to improve programmability, illustrated in Figure 10. The API lets developers describe only an accelerator's DFG, and the library transparently handles μShell's low-level management, e.g., capability enforcement, via the primitive OS API.

Programming API. Table 3 shows μShell APIs. Applications initialize a dataflow graph (DFG) via the *dataflow()* function. The DFG consists of three components: *tasks*, representing computational nodes on vFPGAs and created with *create_task()*; *buffers*, representing input/output memory and created with *create_buffer()*; and *edges*, representing data dependencies between tasks and buffers and created with *connect()*. Once the complete DFG is constructed, it can be validated and executed using *execute()*. These APIs abstract low-level FPGA management from developers, while the underlying μShell OS transparently orchestrates end-to-end execution.

Example code. Listing 1 presents a code example of a digital signature accelerator composed of two logics: SHA and RSA.

First, the application creates tasks and buffers as dataflow nodes (L2-5). Upon creating these nodes, the μShell library transparently communicates with the CCM and creates their capabilities. Next, the application instantiates a DFG and describes edges between the nodes (L8-11). These edge creations invoke capability delegation, e.g., the input buffer *in* connects to the SHA logic *sha*, delegating the in's memory capability to SHA with a read permission, granting read access. Lastly, it submits the DFG as an execution request (L14). The μShell library then validates the completeness and correctness of the DFG and forwards it to the task scheduler.

5 Implementation

We implement μShell by redesigning and extending Coyote v2 [35] in both hardware and software. We choose Coyote v2 as the base for our implementation because it provides a mature, open-source FPGA shell with a well-defined hardware-software stack on the Xilinx Alveo U280. This allows us to focus on designing and evaluating our proposed mechanisms without requiring significant engineering effort. Our extensions include the AXI4-Stream Switch as the data interconnect (supporting up to 15 vFPGAs), per-vFPGA CEUs, the μShell OS, and the μShell API library.

5.1 μShell Hardware Shell

To support IPC and capability-based isolation, we extend Coyote's hardware shell with two components.

Data interconnect. We use Xilinx's AXI Stream Switch IP [10] to route data between vFPGAs and the host. Since the AXI Stream Switch supports up to 16 master-slave interface pairs, μShell can support up to 15 vFPGAs, with one pair reserved for communication with host memory. The interconnect supports custom-length destination (TDEST) signals for flexible routing configurations and is configured to accommodate varying numbers of vFPGAs in the shell.

Capability Enforcement Unit. We implement one CEU per vFPGA in the static shell region. Each CEU augments Coyote's per-vFPGA MMU with: (1) a memory gateway that stores capabilities as registers (base/bound addresses, access permissions, validity flags) and performs bounds checks on all DMA requests, and (2) send/receive gateways that manage object capabilities using vFPGA IDs for destination lookup and verification. Placing these components in the static region prevents tampering via partial reconfiguration. The CEU also generates signals to notify the host OS of capability violations.

5.2 μShell OS

To support communication between the host application and FPGA driver, we extend Coyote's userspace system software service with μShell OS features for capability management. We implement the dataflow scheduler within this service.

Capability Control Manager (CCM). The CCM manages capabilities through three core operations: allocation, delegation, and revocation. In software, the CCM is implemented as a kernel module that maintains a capability table indexed by capability IDs. When allocating a new capability, it creates an entry with memory bounds and permissions, then programs the corresponding CEU registers via MMIO. For delegation, it creates a new derived capability with restricted permissions and updates both its internal table and the CEU hardware state. Revocation traverses the capability tree to invalidate all derived capabilities before clearing the hardware registers. The CCM tracks process ownership to automatically revoke capabilities when processes terminate, preventing resource leaks.

Task scheduler. We implement μShell's component-aware policy in its dataflow scheduler. The scheduler receives execution requests from host applications and deploys the application logic through the FPGA driver. This design overcomes a limitation in Coyote's server-client model, where per-vFPGA reconfiguration servers have their own local run queues, preventing global visibility into waiting applications.

5.3 μShell API Library

We implement a two-tier C++ library that provides both high-level APIs for FPGA-accelerator composition and low-level APIs for μShell OS control. The high-level API allows users to construct dataflow graphs through node creation and edge connection calls. When users invoke these APIs, the library builds an internal graph representation and automatically determines the required capabilities for each connection. Upon graph execution, the runtime evaluates the dataflow topology and issues corresponding requests to the kernel driver: node creation triggers vFPGA allocation and configuration, while edge creation establishes data paths between components with appropriate capabilities. The primitive OS API provides direct access to these kernel operations for advanced users who need fine-grained control. The library ensures each component receives only the minimum required capabilities based on its connections in the dataflow graph.

6 Evaluation

We evaluate μShell from the following dimensions: performance (§6.1), scheduling (§6.2), deployment overheads (§6.3), programmability (§6.4), and resource overheads (§6.5).

Experimental setup. We perform the experiments on a server equipped with an AMD U280 FPGA [126]. The server has an AMD EPYC 7413 processor operating at 2.65 GHz and running NixOS 23.0 with Linux kernel 6.9. We configure μShell with up to eight vFPGAs, which is equivalent to state-of-the-art shells [64, 103]. We do not support inter-vFPGA communication through HBM [91], but applications can use it as a scratchpad memory to store data for execution. Since other open-source FPGA systems [64, 76] do not support our

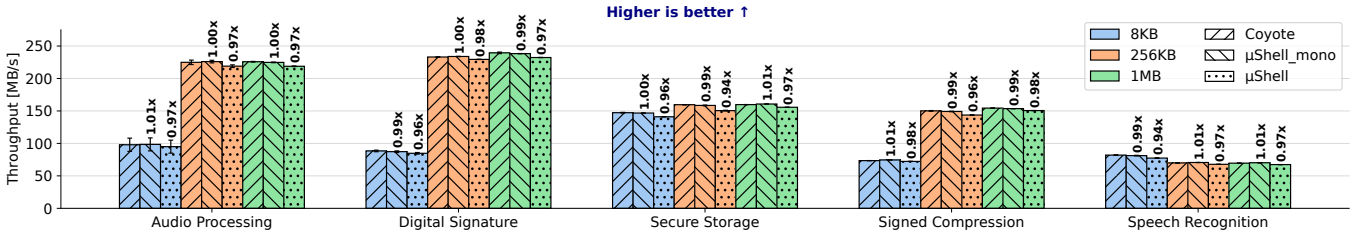

Figure 11: µShell's end-to-end performance against Coyote v2 (*Coyote*) and the monolithic implementation (*µShell_mono*).

Application	Components		
Audio Processing [138]	FFT	Quantize	RLE
Digital Signature [112]	SHA256	RSA	
Secure Storage [105]	RLE	AES-CTR	
Signed Compression [59]	RLE	RSA	
Speech Recognition [111]	FFT	SVM	

Table 4: Applications and their components used in the evaluation: signal processing (FFT, quantization), cryptography (AES-CTR, SHA256, RSA), compression (RLE).

target hardware platform, and porting them would require substantial engineering effort beyond the scope of this work, we use Coyote v2 as the primary baseline for comparison. We note that µShell is not tied to this platform and can be ported to smaller FPGAs that support partial reconfiguration.

Application benchmarks. Our evaluation uses five applications (Table 4) that comprise realistic kernel-level workloads from open-source libraries [129]. While we do not include full end-to-end applications, these benchmarks consist of representative dataflow components commonly found in real-world FPGA workloads (e.g., streaming pipelines and multi-stage processing). This design allows us to effectively demonstrate µShell's capabilities in real-world scenarios.

6.1 Performance

First, we evaluate the end-to-end performance of applications to show the overheads introduced by µShell. We measure the I/O throughput of the five applications listed in Table 4 and run them on Coyote v2 and µShell by varying data sizes (8 KiB, 256 KiB, and 1 MiB), reporting the average across 10 runs.

For µShell, we evaluate two variants: µShell, which allocates vFPGAs per component and composes accelerators from multiple vFPGAs, and µShell_mono, which deploys monolithic accelerators on a single vFPGA, as Coyote v2 does. For all setups, we use host DRAM as data storage and transfer data directly between the memory and the FPGA.

Results. Figure 11 shows the I/O throughput across different data sizes. µShell delivers performance comparable to Coyote v2 for all applications, averaging 3.3% lower throughput. Audio processing and speech recognition applications incur 2.9% and 3.9% overhead, respectively, while digital signature, secure storage, and signed compression incur 2.9%, 4.2%, and 2.8% overhead, respectively. We observe standard deviations below 10.2 MB/s across all experiments, and most measurements exhibit standard deviations under 3.4 MB/s. Results from µShell_mono indicate that monolithic applications perform almost identically to the baseline (within ±1.4%), confirming that the memory gateway adds negligible overhead. The µShell's throughput overheads occur due to additional latency introduced by the CEU's endpoint validation and dynamic routing between vFPGAs. In summary, µShell achieves near-identical throughput to Coyote v2 with minimal overhead.

6.2 Scheduling Improvements

Next, we evaluate µShell's component-aware scheduling policy with Coyote v2's FIFO policy. We measure five metrics: end-to-end latency, reconfiguration count, average response time, tail (95%) response time, and deadline miss rate, using three component-shared applications: digital signature (SHA256, RSA), signed compression (RLE, RSA), and audio processing (FFT, RLE). These metrics are chosen to capture system throughput, reconfiguration overhead, and quality of service for the two scheduling algorithms.

In each experiment, we periodically deploy 8, 12, or 16 application instances every 20ms, which is shorter than the execution time, forcing applications to induce queuing in the scheduler. Each instance is randomly assigned one of three priority levels. Both policies enable component sharing, i.e., if an idle vFPGA has a matching component for a new application, µShell reuses it to avoid reconfiguration.

While Coyote advertises PR support, we encountered technical issues that prevent its activation across multiple vFPGAs, stemming from the complexity of interrupt handling. Instead, we emulate the PR behavior by provisioning all application components in advance. Specifically, we emulate four PR-enabled vFPGAs to ensure that at least two applications can run simultaneously. To do this, we configure two copies of each application component (SHA256, RSA, RLE, and FFT) on the FPGA and use only four of them as 'active' components, while the others remain 'idle'. When an idle component is selected to deploy a new instance, we inject the pre-measured reconfiguration delay, preserving PR's functional behavior.

End-to-end latency. This metric captures the total time to complete all applications, from the arrival of the first instance to the completion of the last. As shown in Figure 12 (a), µShell reduces end-to-end latency by approximately 24-35% across all scenarios, consistently outperforming Coyote v2's FIFO policy. These results highlight µShell's component-aware scheduling's ability to improve overall efficiency.

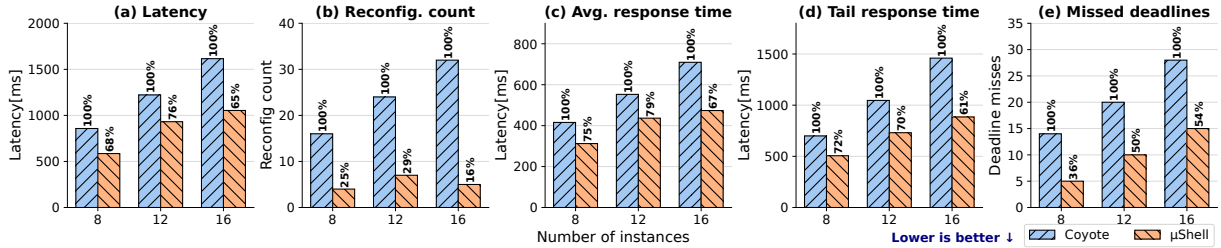

Figure 12: μShell's component-aware scheduling comparing against Coyote's FIFO scheduling algorithm using five metrics: (a) end-to-end latency; (b) reconfiguration count; (c) average response time; (d) tail response time (95%); (e) deadline misses.

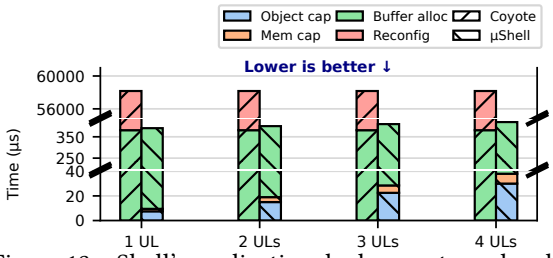

Figure 13: μShell's application deployment overheads.

Applications	SLoC		CC	
	Coyote	μShell	Coyote	μShell
Audio Processing	254	270 (+6.3)	26	14 (-46.2)
Digital Signature	247	251 (+1.6)	24	14 (-41.7)
Secure Storage	302	296 (-2.0)	43	21 (-51.2)
Signed Compression	328	323 (-1.5)	44	32 (-27.3)
Speech Recognition	244	301 (+23.4)	24	18 (-25.0)

Table 5: μShell's programmability, showing Source Lines of Code (SLoC) and Cyclomatic Complexity (CC) of CPU application code. Parentheses show changes from Coyote v2.

Reconfiguration count. To explain μShell's performance gains, we analyze the number of partial reconfiguration operations for both schedulers. Figure 12(b) shows μShell keeps reconfiguration counts stable (5-7), even as application instances grow. In contrast, Coyote v2 requires approximately 3-5× more reconfigurations for the same workload. To conclude, μShell's component-aware scheduling effectively eliminates unnecessary reconfigurations and improves the throughput, especially under heavy queueing.

Average response time. We measure response time, the interval from application instance deployment to completion. Figure 12(c) shows its geometric mean across all instances. As shown here, μShell reduces the response time by 21–33% compared to Coyote, led by fewer vFPGA reconfigurations.

Tail response time. We measure the 95th percentile tail response time to assess the impact on the slowest applications. In Figure 12(d), μShell improves tail response time by 28–39% over Coyote. This gain stems from priority promotion in μShell's component-aware scheduling, which favors long-waiting instances. Thus, μShell improves response time without sacrificing tail latencies.

Deadline miss rate. We measure deadline misses that occur when a component's response time exceeds its deadline under both scheduling policies. Deadlines are assigned per component rather than per application, so a two-component application incurs two deadline misses if both components exceed their individual deadlines due to queuing delays. To ensure that higher-priority applications have shorter deadlines compared to lower-priority applications that can tolerate longer wait times, deadlines are assigned using the formula: $(100\% + x) * (1 + priority)$ of its average response time, where x is a random number between 40 and 80. Figure 12(e) shows the results, highlighting that μShell reduces deadline misses by 46–64% against Coyote v2. The number of missed deadlines increases with more applications because some misses are inevitable when applications arrive at a rate exceeding the vFPGA's execution capability. In summary, μShell's component sharing and priority promotion are effective to mitigate deadline misses.

6.3 Application Deployment Overheads

We next compare the overheads for deploying multi-component applications on μShell and Coyote v2. For μShell, we measure the latency of host-initiated capability updates and memory buffer allocation, assuming an ideal case where all application components are already deployed on the vFPGAs, thus avoiding PR. For Coyote, all user logic (UL) is packaged into a single bitstream, and a monolithic accelerator containing all components is deployed within a single vFPGA, requiring PR and memory buffer allocation. We evaluate four accelerator configurations, each consisting of 1, 2, 3, and 4 ULs, respectively, along with a pair of input/output buffers.

Results. Figure 13 compares deployment overhead between μShell and Coyote v2. For Coyote, the PR time (Reconfig) dominates the overhead, at around 58 ms. Since Coyote v2 does not support component sharing, application deployment always involves a single PR regardless of the number of modules. Consequently, the overhead remains constant for applications with 1–4 ULs. In contrast, μShell avoids PR in this scenario, where all required components already exist on vFPGAs; PR is performed only for missing components. To reuse the shared components, μShell only needs to update memory buffer allocation and capability configuration, with the latter scaling with the number of components. These capability updates (2-3 us per object/memory update) are orders of magnitude faster than PR. Consequently, μShell achieves significantly lower deployment overhead when application components are shareable.

Entity	LUT (%)		Register (%)		BRAM (%)		URAM (%)

Table 6: μShell's resource usage on U280 FPGA. The components in bold are unique to μShell.

6.4 Programmability

Next, we assess the programmability benefits of μShell for host (CPU) code managing FPGA user logic. We compare equivalent host applications using Coyote v2's custom API for monolithic designs versus μShell's programming API. To quantify development effort and complexity, we measure source lines of code (SLOC) and cyclomatic complexity (CC) with *scc* [110].

Results. Table 5 compares SLOC and CC metrics for both approaches. μShell consistently reduces CC by 25.0-51.2% while SLOC changes modestly (-2.0% to +23.4%). The slight SLOC changes result from μShell's API, which adds calls for dynamic accelerator composition, unlike Coyote's static model that manages a single vFPGA with a monolithic accelerator. The CC reduction results from eliminating complex control flow, improving maintainability. In summary, μShell's modular, declarative API enables dynamic composition of FPGA accelerators at a small cost in code size.

6.5 Resource Overheads

Lastly, we measure the resource overhead of μShell using the Vivado IDE, recording the required LUTs, registers, BRAM, and URAM. We configure μShell and Coyote v2 with three vFPGAs and report both total and per-component resource usage. Since the number of vFPGAs affects resource usage, we also measure the resource usage of the data interconnect with 3, 4, 6, and 8 vFPGAs, respectively (Inter 3, 4, 6, 8 in Table 6).

Results. Table 6 shows the resource usage of two shells (μShell and Coyote v2) along with their key components and each accelerator logic for applications. The MMU and CEU rows show resource usage of a single module for one vFPGA, which scales linearly with the number of vFPGAs. We highlight that μShell components (the CEUs and interconnect) consume only 1.4% of LUTs and 0.9% of registers for three vFPGAs.

For scalability, each additional vFPGA requires dedicated CEU and MMU instances, as well as expanded interconnect. While the CEU and MMU's usage scales linearly with the number of vFPGAs, the interconnect's usage scales approximately quadratically, since μShell requires a mesh connection to all vFPGAs so that any vFPGA can establish IPC with any other. Nevertheless, even with eight vFPGAs, the CEUs and interconnect account for 6.6% of the total FPGA resources.

7 Related Work

We first compare μShell with the state-of-the-art shells and FPGA frameworks (Table 7), highlighting our unique contributions across four key dimensions: (1) modularity, (2) composability, (3) communication, and (4) isolation.

FPGA platforms and comparison with μShell. For (1) modularity, ReconOS [83] and Hthreads [98] treat hardware logic as OS threads, yet they target monolithic applications. FOS [119], DrawerPipe [79], Harmonia [80], and Coyote [71, 104] apply modularity to their shells with reusable building blocks. However, application designs remain monolithic, limiting fine-grained reuse and independent updates of hardware modules for FPGA applications.

For (2) composability, most systems support PR to enable spatial or temporal multiplexing, but they do not allow user logic to be flexibly shared or composed across applications. DrawerPipe [79] enables component sharing but is constrained by its static pipeline architecture, which requires the entire shell to be reconfigured. As a result, general-purpose, dynamic composition remains unsupported.

For (3) communication, cross-component communication is constrained by static interconnects (e.g., Coyote's FIFOs and DrawerPipe's linked-list connections) or indirect off-chip paths (e.g., Nyx's [91] memory FIFOs). Rosebud [65] provides dynamically configurable direct I/Os but is specialized for network-processing pipelines.

Lastly, for (4) isolation, existing systems provide either coarse-grained per-application isolation [79], memory isolation via MMUs [113], or both [64,71,91,104,119,135]. However, there are no systems that enforce fine-grained control over inter-component communication distributed across vFPGAs.

In summary, μShell is the first framework to provide the full system properties required for modular FPGA application deployment. By integrating cross-vFPGA IPC control, capability-based isolation, and component sharing support, it enables secure, controlled interaction between independently deployed and shared components on FPGAs.

FPGA OSes. FPGA OSes adopt OS abstractions for custom logic, spanning spatial/temporal sharing, memory management, and scheduling [40, 62, 76, 83, 84, 98, 100, 113, 135]. μShell is the first work to adapt microkernel principles to enable modular, composable FPGA application deployment.

Accelerator chaining and data movement. Prior work has optimized data movement between heterogeneous accelerators [61, 92, 94, 99, 101, 136, 137], often through costly host-mediated point-to-point transfers. Recent efforts enable host-free, composable chains of single-purpose accelerators

Platform	(1) Modularity		(2) Composability		(3) Communication		(4) Isolation

Table 7: Comprehensive analysis of PR–based and component-based FPGA shells.

(e.g., ASIC) via data restructuring and interconnect-based isolation [15, 16, 43, 121]. μShell's CEUs provide functionality similar to M³'s DTUs [16], but differ fundamentally: CEUs are designed for FPGA streaming architectures, whereas M³ targets NoC-based many-core processors.

FPGA virtualization and isolation. FPGA virtualization supports spatial sharing [21, 24, 95], temporal sharing [73, 106, 122], memory virtualization [30, 47, 83, 124], and context switching [60, 77]. Cloud virtualization systems such as Optimus [84], AvA [132], and others [85, 118] extend guest OSes or hypervisors to isolate FPGA resources across VMs. However, they expose vFPGAs as individual resources, limiting accelerator composition. In contrast, μShell presents all vFPGAs as a unified workspace while preserving multi-tenant isolation.

FPGA programming model. Dataflow programming models describe inter-/intra-accelerator communications [28, 29, 70, 116, 125]. Compiler-based approaches such as HeteroFlow [125], TAPA [29], and SODA [28] are actively studied, while they build static, monolithic accelerators. Runtime libraries support kernel chaining via OpenCL pipes [46] and XRT native API [66], but are also limited to monolithic designs. In contrast, the μShell API enables dynamically chaining accelerators across vFPGAs without compromising isolation.

FPGA task scheduling. FPGA task scheduling balances resource utilization, performance, and isolation [33, 36, 38, 88, 91]. Nimblock [88] provides fine-grained sharing through overlay virtualization, while Nyx [91] virtualizes dataflow execution using virtual FIFOs. However, existing schedulers lack awareness of cross-application component reuse, leading to frequent reconfiguration overhead. μShell's component-aware scheduling prioritizes applications based on user logic overlap, maximizing reuse while minimizing reconfiguration costs.

8 Conclusion and Discussion

We present μShell, a hardware-OS co-design for modular accelerator deployment on FPGAs, delivering three key contributions: (1) a shell architecture for building secure, direct communications between distinct vFPGAs, (2) an OS providing microkernel features to manage FPGA tasks, and (3) a high-level dataflow API for dynamic accelerator composition. We implement and evaluate the μShell prototype on Alveo U280 FPGA, highlighting μShell's performance, flexibility, scheduling effectiveness, programmability, and resource efficiency.

Interchangeability among PR regions. Consistent with modern FPGA shells (e.g., Coyote [71, 103], AmorphOS [64]), μShell generates a separate partial bitstream for each logic-vFPGA pair. For instance, deploying two distinct logic kernels across two vFPGAs requires four unique bitstreams. This limitation arises from current toolchains, which require each kernel to be synthesized for every target vFPGA. Recent studies [96, 133] mitigate these constraints by decoupling compilation from physical placement and flexibly sizing PR regions. μShell can leverage these advances to further enhance deployment flexibility and interchangeability.

vFPGA resource usage. μShell supports variable-size vFPGA partitions through PR. However, due to limitations in current PR toolchains, vFPGA sizes must be manually defined, and bitstreams must be generated for predefined vFPGAs. In the current prototype, we adopt uniform vFPGA partitioning to simplify bitstream management and deployment.

Multi-FPGA deployments. Exploring multi-FPGA deployments (e.g., Catapult [102]) is beyond our current scope and planned as future work. This paper demonstrates the benefits of intra-FPGA chaining for realistic, kernel-level workloads, showing how μShell components efficiently share and compose resources within a single FPGA. For these use cases, efficient chaining of user logic is crucial, as it improves resource utilization and reduces deployment costs, making cloud FPGAs more accessible and economically viable.

Artifact. We release μShell as an open-source project [3].

A Artifact Appendix

A.1 Abstract

This artifact contains the implementation and evaluation framework used in the USENIX OSDI 2026 paper, "μShell: A Microkernel-based FPGA Shell Architecture" by J. Chen, A. Panda, H. Unnibhavi, A. Koshiba, and P. Bhatotia. μShell is a hardware-OS co-design for modular accelerator deployment and execution. It provides capability-enforced isolation for secure resource sharing, component-aware task scheduling to reduce FPGA reconfiguration overheads, and inter-process communication (IPC) for peer-to-peer data transfers between vFPGAs.

A.2 Scope

The artifact reproduces all experimental results presented in the paper. It includes the hardware and software source code required to build the FPGA shell and host applications, as well as scripts for running the evaluation. To simplify deployment and reduce build times, we also provide precompiled FPGA bitstreams for both the shell and benchmark applications.

A.3 Contents

The artifact is published in our GitHub repository and contains the following items:

- `bitstreams/`: Precompiled FPGA bitstreams.
- `driver/`: Source code for the Linux kernel driver.
- `hw/`: Source code for the μShell shell.
- `examples_hw/`: Source code for benchmark application accelerators.
- `sw/`: Source code for the host-side runtime and infrastructure.
- `examples_sw/`: Source code for benchmark host applications.
- `evaluation/`: Scripts and supporting files for reproducing the evaluation results.

The repository root also contains scripts and configuration files required for FPGA programming and system setup.

A.4 Hosting

All the project source code, including the instructions for evaluating and building the software, is available in the following git repository: https://github.com/TUM-DSE/microShell. Please follow the instructions on the `master` branch to reproduce the results.

A.5 Requirements

We require the following software and hardware configurations to reproduce our experimental results.

A.5.1 Hardware Dependencies

- Machine with AMD EPYC 7413 CPU connected to public network.
- Xilinx (AMD) Alveo U280 FPGA cards.

A.5.2 Software Dependencies

- Operating system: NixOS 25.11 with Linux kernel 6.9.0-rc7.
- Nix: we use the Nix package manager to download all build dependencies for reproducibility. We use nix-shell to provide a consistent runtime environment.
- Python 3.10 or newer for the script that reproduces the evaluation.
- Vivado v2022.1 to compile the FPGA bitstreams and program the FPGA.

A.6 Methodology

- Figure 11 (§ 6.1): Throughput comparison across three deployment setups and varying data sizes, demonstrating the performance overhead of μShell.
- Figure 12 (§ 6.2): Comparison of scheduling metrics between μShell and Coyote, highlighting the benefits of the proposed scheduling algorithm.
- Figure 13 (§ 6.3): Reconfiguration latency comparison between μShell and Coyote for deploying multi-component applications.
- Table 5 (§ 6.4): Comparison of Source Lines of Code (SLoC) and Cyclomatic Complexity (CC) for host applications and user logic, illustrating the programmability improvements of μShell over Coyote.
- Table 6 (§ 6.5): FPGA resource utilization of μShell.

A.6.1 End-to-end performance (§ 6.1)

First, run the following commands to measure the benchmark throughput for different setups:

```
$ cd evaluation/scripts/
$ bash e2e_6.1/run_e2e.sh
 ↪  ~/microShell_base ~/microShell
```

To generate Figure 11, run the following command:

```
$ python3 e2e_6.1/plot_e2e.py
```

A.6.2 Scheduling improvements (§ 6.2)

First program the FPGA with the provided bitstream:

```
$ bash ./program_fpga.sh 6_2_sched
```

Build the software application:

```
$ cd ~/microShell
$ nix-shell shell.nix # this can be
 ↪  skipped if you are already in the nix-shell
$ mkdir build_sched_sw && cd build_sched_sw
$ cmake
 ↪  ../examples_sw/ -DEXAMPLE=scheduler_client
$ make
```

Copy some bash scripts that help to run the application from evaluation/scripts, then run the following commands to perform the experiments:

```
$ cp ../evaluation/scripts/scheduling_6.2/*.sh
 ↪  .
$ bash ./init_csv.sh
$ bash ./run_coyote.sh
$ bash ./run_ushell.sh
```

Copy the generated data back to the evaluation folder and create the plots:

```
$ cp *.csv ../evaluation/data/scheduling_6.2/
$ cd ~/microShell/evaluation/scripts
$ python3 scheduling_6.2/plot_sched.py
```

A.6.3 Application-deployment overheads (§ 6.3)

Open two terminals connected to our machine, in one for the server terminal:

```
$ cd ~\microShell
$ bash ./program_fpga.sh 6_3_pr
$ mkdir build_perf_server_sw/
 ↪  && cd build_perf_server_sw/
$
 ↪  cp
 ↪  ../bitstreams/cyt_top_pr_time_3_0807/config_*/*
 ↪  .
$ cmake ../examples_sw/ -DEXAMPLE=perf_server
$ make
$ sudo ./bin/test
```

In the second terminal for the client:

```
$ cd ~\microShell
$ nix-shell shell.nix # this can be
 ↪  skipped if you are already in the nix-shell
$ mkdir build_perf_client_sw/
 ↪  && cd build_perf_client_sw/
$ cmake ../examples_sw/ -DEXAMPLE=perf_client
$ make
$ sudo ./bin/test -1 true
```

Save the log into a file and copy it into the data folder, kill the server thread, and generate the plots:

```
$ journalctl -n 200 > reconfig_pr.log
$ cp reconfig_pr.log
 ↪  ../evaluation/data/deployment_6.3/
$ ps -aux | grep test
$ sudo kill -9 pid_of_test
$ cd ../evaluation/scripts
$ python3 deployment_6.3/extract_reconfig.py
$ python3
 ↪  deployment_6.3/plot_reconfig_overhead.py
```

A.6.4 Programmability (§ 6.4)

First, install the tools and run the measurements:

```
$ cd ~/microShell
$ nix-shell -p scc jq
$ cd evaluation/scripts/
$
 ↪  bash
 ↪  complexity_6.4/measure_complexity_baseline.sh
 ↪  ~/microShell_base
$
 ↪  bash
 ↪  complexity_6.4/measure_complexity_ushell.sh
 ↪  ~/microShell
```

The two CSV files are located at the path *evaluation/data/complexity_6.4*. To generate the data for the table, run the following commands:

```
$ python3
 ↪  complexity_6.4/extract_complexity.py \

    ↪  --baseline-csv
    ↪  path_to/complexity_baseline_results.csv
    ↪  \
   --ushell-csv
    ↪  path_to/complexity_ushell_results.csv
```

A.6.5 Resource Overheads (§ 6.5)

Run the following commands to extract the resource utilization of each component:

```
$ cd ~/microShell
$ nix-shell shell.nix # this can be
 ↪  skipped if you are already in the nix-shell
$ cd evaluation/scripts
$ python3 resource_usage_6.5/extract_util.py
$ python3
 ↪  resource_usage_6.5/extract_modules.py
$ python3
 ↪  resource_usage_6.5/plot_resource_usage.py
$ python3 scalability_2/plot_scalability.py
 ↪  --baseline ~/microShell_base
```

Abstract

While eBPF has become the de facto standard for kernel customization in cloud-native systems, its design implicitly assumes a single trust domain. Allowing multiple tenants to deploy their own eBPF programs breaks this assumption, making the system both insecure and inefficient. We identify the root cause as eBPF's *static-binding model*, which rigidly couples logical eBPF programs to physical kernel hooks, forcing tenants to contend for shared execution contexts.

We propose ▽BPF, a virtualization layer that shifts to a *late-binding model*. By repurposing physical hooks as generic interposition points and deferring the binding until the event is attributed at runtime, ▽BPF decouples tenant context from the underlying kernel. ▽BPF achieves this via three key mechanisms: (1) a *Sniffer* that accurately attributes interrupt-driven events to tenants, (2) a *Dispatcher* that replaces linear traversal with scalable $O(1)$ program lookup, and (3) a compiler-assisted framework for state isolation. Implemented on Linux 6.12, ▽BPF enables the secure coexistence of multi-tenant workloads. Our evaluation shows that ▽BPF reduces latency by up to 3.9× (lmbench) and improves throughput by 29% (PostgreSQL) compared to native contention.

1 Introduction

In modern cloud and data center systems, the ability to securely customize kernel behavior is critical to ensuring the performance [8,21,27,66], security [14,19,30], and observability [14,38] guarantees required in multi-tenant environments. eBPF has emerged as the de facto standard technology for achieving this goal, giving rise to a new class of powerful infrastructure software. Platform providers such as Meta, Google, and Netflix [53, 57] routinely deploy trusted eBPF programs to implement core services, while projects like Cilium [8] and Falco [14] leverage this technology to deliver efficient network connectivity and security monitoring for all containerized workloads.

At the same time, a new frontier is emerging: enabling tenants to deploy their own eBPF programs. This unlocks fine-grained, application-specific optimizations that platform-level tooling cannot achieve. Recent studies demonstrate the value of tenant-defined eBPF in areas such as storage and I/O [47, 50, 87, 104, 105, 107, 111], scheduling [31, 33, 52, 71, 74, 110], networking [25, 43, 61, 108, 109], concurrency control [88, 89], profiling [54, 90] and AI [97].

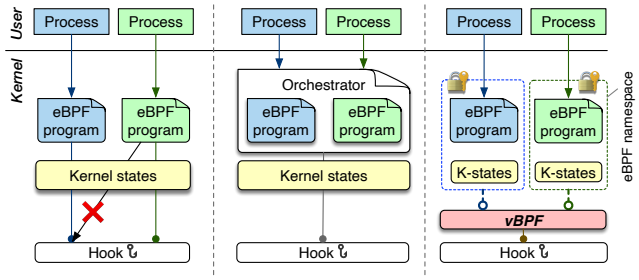
Beyond expanding customization, the use of tenant eBPF is becoming more frequent and more dynamic. Modern cloud workloads run in short-lived containerized environments [29, 53] and increasingly use eBPF for dedicated requirements. This trend is being further accelerated by automation (e.g., via AI agents [10, 17, 40, 51]), which can assist in generating or updating eBPF programs. As a result, tenant eBPF shifts from occasional operator-managed customization toward more frequent runtime adaptation.

However, allowing tenants to load their own programs into a kernel already managed by platform-level eBPF introduces architectural conflicts. The eBPF subsystem is designed under the assumption of a single trust domain, which may break when tenant and platform programs are forced to coexist.

This is not a hypothetical concern. For example, hooks based on `struct_ops` replace global function pointers. Customizing TCP behavior, such as pacing, therefore allows only one implementation to be attached system-wide, forcing a binary choice between the platform policy and a tenant policy. In addition, when multiple tenants use kprobes to trace the same kernel function, they may interfere with one another [54, 69]: a program from one tenant that alters a function's return value can silently corrupt the observation results of others [65, 92], leading to anomalous behavior.

These problems stem from a fundamental architectural flaw: *eBPF's reliance on a static-binding model*. During deployment, eBPF programs are verified, loaded, and bound to physical hooks. Subsequent hook events are broadcast to the fixed attached set, sharing the same execution context. This static coupling between a logical program and physical kernel resources is the root cause of multi-tenancy conflicts. Although the kernel permits multiple attachments to a single hook, it forces them to contend for the same execution context and shared kernel objects, creating unavoidable channels for performance interference and state corruption.

Existing mechanisms are merely workarounds that struggle against the limitations of this static model (Figure 1-a/b). First, *in-program filtering* [54] allows tenants to bypass irrelevant events via conditional checks, but these checks are



(a) Native Static Binding (b) Orchestrator Static Binding (c) Late Binding (Ours)

Figure 1: **eBPF for multi-tenancy.**

neither enforceable nor free, since every program must still be invoked. Second, *cgroup-based dispatch* [89,111] efficiently isolates workloads by scoping programs to specific cgroups, but it relies strictly on process context, leaving interrupt-driven events (e.g., packet processing) completely uncovered. Third, *centralized orchestrators* [7,22,45] can resolve attachment conflicts through global policies, but this rigidity sacrifices eBPF's inherent flexibility and consolidates logic into monolithic binaries that increase the verifier's burden, raising the risk of rejection. Most critically, all these approaches fail to provide state isolation, as tenants continue to contend for shared kernel objects, leaving the system vulnerable to cross-tenant semantic pollution.

Our key insight is that resolving these conflicts requires *decoupling the logical program from the physical hook through a late-binding execution model.* We argue that physical hooks should serve as generic interposition points rather than fixed execution destinations. Much like dynamic dispatch in polymorphic programming languages [1,2,41,94], the binding of an event to its program set and state view should be deferred until the event is attributed at runtime. By intercepting the event first and resolving its semantic context (i.e., the tenant), the system replaces the blind, indiscriminate execution of the static model with a context-aware dispatch.

However, realizing this late-binding model introduces three technical challenges. First, *it requires precise event attribution to identify the target tenant before execution.* This is difficult in interrupt-driven contexts where the execution context is detached from the logical tenant. Second, *it requires high-performance dynamic dispatch that conflicts with the existing kernel's linear organization.* Since current hooks are designed for sequential execution, selective dispatch would degrade to $O(N)$ complexity, whereas critical paths usually demand $O(1)$ latency for better scalability. Third, while late-binding enables state isolation by resolving tenant context, *achieving both high performance and maintainability is difficult.* Naive solutions must either rely on heavyweight hardware switching [54] or enforce invasive software constraints that break existing applications.

Based on our insight, we propose vBPF, a virtualization layer that implements this *late-binding model* (Figure 1-c). vBPF creates eBPF namespaces for each tenant and, upon an event, dynamically resolves the target program and virtual context. To realize this, vBPF introduces three key designs to overcome those challenges.

First, we introduce the vBPF *Sniffer*, which resolves tenant attribution for kernel events in interrupt contexts using a two-phase mechanism. The *context-aware phase* captures the mapping between interrupt-visible resources and namespaces during operations with process context, such as system calls. The *context-free phase* then efficiently determines the targeted tenant from interrupt-driven events, such as XDP packets, by querying this pre-recorded mapping that manages the complex and dynamic lifecycle of these mappings. Rather than attributing all interrupts, we target tenant-bearing resources (e.g., network flows) that cover the key interrupt-driven eBPF use cases in our scope.

Second, to resolve the conflict between linear organization and high-performance dispatch, we introduce the vBPF *Dispatcher*. It redesigns the multi-program architecture by replacing the kernel's existing linear structures with a hierarchical, hash-based index that mirrors the tenant namespace structure. This allows vBPF to locate a tenant's entry point in $O(1)$ time. To efficiently execute the resulting parent-child program chains (e.g., pod-level tracing over container logic), we introduce an optional path flattening: vBPF pre-compiles the entire chain into a single array, trading a small amount of memory for near-zero dispatch latency.

Third, we achieve state isolation without the performance-maintainability trade-off by leveraging a key observation: *eBPF programs interact with shared kernel state exclusively through specific entry points.* So we propose a *compiler-enforced state isolation framework.* At the base, a *static analyzer* audits these helpers, rejecting unsafe global state access by default. To resolve conflicts without changing the tenant code, we provide a *variable library* for kernel developers. This library automatically transforms stateful operations by delegating static variables to tenant-private instances and patching dynamic state accesses. This design ensures strict isolation with minimal runtime cost while preserving the original eBPF programming model.

We implement a prototype of vBPF on Linux kernel 6.12 and evaluate it on a series of microbenchmarks and real-world applications. Our results demonstrate that vBPF effectively resolves multi-tenancy conflicts while delivering superior performance isolation. For example, vBPF enables the coexistence of singleton hooks and allows distinct containers to deploy independent eBPF programs without interference. In multi-tenant scenarios, vBPF reduces latency by up to 3.9× (`lmbench`) and improves application throughput by 29% (`PostgreSQL`) compared to native eBPF, primarily by eliminating redundant execution.

vBPF is available at `https://github.com/vbpf-osdi-2026`.

2 The Case for eBPF Virtualization

2.1 eBPF Explained

eBPF has emerged as the main mechanism for safe kernel programmability in Linux. Its verifier [13] statically enforces strict safety properties before execution, and its JIT compiler [9] translates verified bytecode [5] into efficient native code. The Linux community has widely embraced this model, continuously adding new eBPF features [59] and making kernel customization practical for modern applications.

The architecture of eBPF is illustrated in Figure 2. eBPF programs are attached to predefined *hooks* within the kernel. They retrieve eBPF-specific data via *eBPF maps* and interact with global kernel states through *helper functions* or *kernel functions (kfuncs)*. The following presents three core components of eBPF.

Event-Driven Execution. Developers can write *eBPF programs* using tools like `bcc` [18] and `libbpf` [24], each of which serves as a specific user-defined kernel extension. Numerous *hooks* are distributed across various kernel subsystems, including system call entry/exit, tracepoints, traffic control, and more. eBPF programs are attached to these hooks, which are triggered by *events* like syscall invocations. When execution reaches a hook point, the kernel sequentially invokes the attached eBPF programs.

eBPF Map. The eBPF program is distinct from the map, and these two elements can be linked through system calls, enabling the eBPF program to access the specified map. Conversely, given that the maps are globally shared data structures, the userspace program only needs to get the corresponding `fd` to have access to the map. The eBPF map provides a variety of ways to access the map, such as the file system and the eBPF map ID. *The BPF file system* is a pseudo-file system, and userspace programs can access the map through the file system operation. Furthermore, the eBPF subsystem maintains a global ID table for the map, which enables the user to obtain the map's `fd` directly from the ID.

Global Kernel States and Access Interfaces. Although eBPF was designed to restrict access to arbitrary kernel memory, there are still limited interfaces to interact with specific kernel data structures. For example, eBPF *helper functions* provide safe operations on data structures such as `task_struct` and `sk_buff`, ensuring that arguments and pointers are strictly checked by the verifier. To further enhance accessibility, the eBPF *kernel function (KFunc)* mechanism introduces a whitelist of custom functions through BTF-based metadata [6]. Unlike helper functions, which rely on strict prototypes and stable APIs, KFuncs are verified mostly against BTF types and annotations. As a result, they can expose richer kernel-internal functionality, including functions that inspect or modify kernel state. However, KFuncs do not provide stability or availability guarantees across kernel versions and configurations.

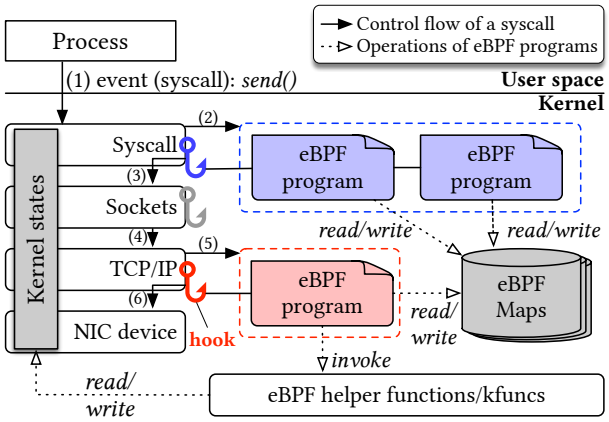


Figure 2: **eBPF in the Linux kernel.**

2.2 From Platform to Tenant eBPF

eBPF has become the standard for programmable cloud infrastructure, enabling providers to enforce policies and manage resources transparently. In this *platform-defined* model, trusted infrastructure components attach eBPF programs to manage all workloads in a shared kernel. For example, CNIs like Cilium [8] and Calico [27] use `XDP` and `TC` hooks for high-performance packet processing and load balancing; security systems like KubeArmor [30] enforce container-aware runtime constraints via LSM hooks; and observability tools like Pixie [19] and NetObserv [26] provide deep visibility into cluster health. These programs are typically managed by the platform administrator or a global eBPF manager [7, 22, 45], and therefore operate within a single trust domain.

However, restricting eBPF to this platform layer leaves a semantic gap: the platform controls kernel resources, but often lacks the application-specific context needed for optimal execution. A *tenant-defined* model closes this gap by allowing tenants to deploy eBPF logic tailored to their own workloads. For example, with the advent of `sched_ext` [31, 33], a latency-sensitive tenant can replace the generic CFS scheduler with a custom FIFO policy to minimize tail latency. Similarly, data-intensive applications (e.g., databases) can optimize page cache replacement policies based on query patterns [50, 104, 111]. Tenants can also deploy tracing programs to debug complex logic such as tracking specific lock contention or transaction latency. This shift transforms the kernel from a static resource manager into a programmable accelerator tailored to each tenant's specific workload.

Beyond enabling richer customization, the tenant-defined model also changes how eBPF programs are deployed and managed. Modern cloud workloads increasingly run in short-lived containerized environments, where requirements may evolve as applications scale, migrate, or change execution phases. Automation can further accelerate this trend (e.g., via AI agents [10, 17, 40, 51]), which can assist in generating or updating eBPF programs. As tenant eBPF shifts from occasional hand-written customization to more frequent runtime

```c
// container-A redirect to egress
SEC("tc/ingress")
int tc_ingress(struct __sk_buff *ctx) {
    if (iph.saddr == 0x9c3ca8c0) {
        iph.saddr = 0x0A0A0A01;
        return bpf_redirect(2, 0);
    }
    return TC_ACT_PIPE;
}

// container-B redirect back
SEC("tc/egress")
int tc_egress(struct __sk_buff *ctx) {
    if (iph.saddr == 0x0A0A0A01)
        return bpf_redirect(2, 1);
    return TC_ACT_PIPE;
}
```

Listing 1: **Infinite forwarding loop caused by functionality conflicts**. *Two tenants in TC redirect the same packets.*

adaptation, multi-tenant platforms must allow independently developed tenant programs, as well as platform-managed programs, to coexist in the same kernel.

2.3 The Challenges for Tenant-Defined eBPF

We observe three limitations of the existing eBPF design for tenant-defined eBPF in cloud-native platforms.

The Singleton Conflict. Certain powerful kernel hooks are designed as singletons, allowing only one eBPF program to govern a hook globally. This is particularly evident in hooks based on `struct_ops`, which function by replacing global function pointers. For example, customizing TCP behavior, such as overriding loss recovery, RTT sampling, or pacing, requires overwriting these global callbacks. So the first successful registration continues to own the singleton resource, and later conflicting registrations fail at load or attach time, preventing tenants from deploying distinct TCP policies. Similarly, the extensible scheduler (i.e., `sched_ext` [31]) operates by replacing the global scheduling class, ruling out the coexistence of multiple scheduling policies. Furthermore, eBPF iterators (e.g., `bpf_iter_task`) allow only a single `seq_ops` implementation to define iteration behavior, preventing multiple tenants from simultaneously customizing how they traverse system resources.

> **Limitation 1:** The singleton design of global eBPF hooks enforces a "winner-takes-all" model.

Functionality Conflicts. The global nature of the eBPF subsystem allows programs from different tenants to destructively interfere with one another. This manifests primarily as *control flow interference*. As illustrated in Listing 1, consider two benign tenants (A and B) attaching redirection logic to interconnected interfaces. Tenant A redirects packets to Interface-2, while Tenant B redirects them back. This creates an *infinite forwarding loop*, where a single packet circulates indefinitely, saturating the CPU and collapsing the network stack. While both programs are valid in isolation, their uncoordinated composition leads to catastrophic failure. Beyond control flow, *data dependency conflicts* occur when programs share mutable context. If a tenant modifies a packet header or overrides a kernel function return value (via kprobe), they silently corrupt the input state for subsequent programs.

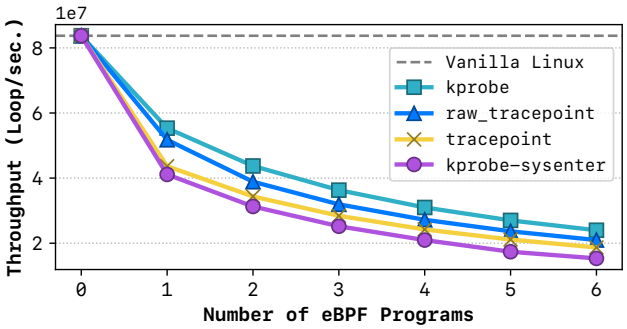

Figure 3: ***Performance interference on UnixBench [96].*** *The Y-axis represents syscall throughput (loops/second). Performance degraded when attaching eBPF programs to the getpid syscall. kprobe-sysenter attaches to* `sys_enter` *and relies on in-program conditional checks to filter for getpid, similar to tracepoint and raw_tracepoint.*

> **Limitation 2:** Shared execution context creates implicit dependencies between tenants, allowing side effects to corrupt correctness.

Performance Degradation. The lack of execution isolation forces a global broadcast model, where unrelated eBPF programs indiscriminately consume CPU cycles on critical paths. We quantified this "noisy neighbor" effect by measuring `getpid` throughput under unrelated eBPF attachments (Figure 3). The results reveal three key findings: (1) *Severe "zero-to-one" penalty*: attaching a single unrelated program causes a sharp throughput drop due to the overhead of enabling the indirect call to the eBPF program. (2) *Consistent runtime cost*: the degradation magnitude remains consistent across different hook types. (3) *Magnified impact on static tracing*: Unlike kprobes which trigger only on specific functions, (raw) tracepoints attach to the global `sys_enter` path, forcing the program to execute on every system call and significantly increasing unnecessary invocations.

> **Limitation 3:** The lack of scope-aware dispatching forces unrelated programs to execute on every event, imposing unavoidable overhead on all tenants.

2.4 Approaches to eBPF Multi-Tenancy

In-Program Filtering. The most rudimentary approach relies on tenants embedding filtering logic directly into their programs [54] (e.g., filtering by `PID`). However, this mechanism is neither mandatory nor enforceable, leaving the platform vulnerable to malicious or buggy tenants who may omit these checks to snoop on neighbors or interfere with system-wide operations. Furthermore, this approach incurs a prohibitive execution tax: *the kernel must invoke every attached program to evaluate these conditions on every event.* This results in unavoidable invocation overhead that scales linearly with the number of programs.

Cgroup-Based Dispatch. Linux cgroups [12] provide a kernel-native mechanism to attach eBPF programs to specific process hierarchies [89, 111]. While effective for cgroup-aware events (e.g., socket operations), this mechanism relies on specialized attachment types that are distinct from the standard hooks (e.g., tracepoints) used by many tools. Crucially, *it fails for interrupt contexts.* Hooks like `XDP` operate at the driver level without access to process information, rendering cgroup identification impossible. Moreover, cgroups only partition the attachment scope, not the underlying hook. Singleton hooks, such as `struct_ops` or specific LSM hooks, cannot be partitioned by cgroups, so only one tenant can attach at a time. Finally, cgroup-based dispatch does not isolate the kernel state observed or mutated by dispatched programs, making it insufficient to handle multi-tenancy.

Orchestrators Provided by Platforms. Platform orchestrators [7, 8, 45] attempt to resolve conflicts by merging multiple tenant programs into a single monolithic executable or a static `tail_call` chain. This centralization shifts the burden to the kernel verifier: *merging logic from multiple tenants increases complexity and instruction counts*, causing the combined program to exceed the verifier's strict limits [42] and potentially resulting in rejection. *Furthermore, dynamic updates incur significant latency.* Inserting or removing a single tenant's program often requires recompiling and atomically replacing the entire monolithic chain within the kernel. *Finally, this approach compromises portability.* Tenants must rewrite standard eBPF programs to fit rigid orchestrator APIs, sacrificing eBPF's inherent flexibility and tool compatibility.

Verification-Based Admission Control. Concurrent with our work, KrakenGuard [91] proposes a trusted user-space eBPF manager that uses symbolic execution to enforce fine-grained policies at load time. It provides policy-based admission control rather than a runtime virtualization layer, rejecting programs that violate policies or conflict with already loaded programs instead of enabling coexistence. KrakenGuard is therefore complementary to ▽BPF. It strengthens safety at load-time, while ▽BPF allows tenant programs to coexist transparently at runtime, including when they use singleton hooks or shared kernel state.

Approaches	Enforced Isolation	State Isolation	Global Scope	Verifier Scalability	Trans-parency
Conditional Checks [54]	✗	✗	✓	✓	✗
Cgroups BPF [89, 111]	✓	✗	✗	✓	✓
Orchestrators [7, 8, 45]	✓	✗	✓	✗	✗
KrakenGuard [91]	✓	▲	✓	▲	✓
▽BPF *(Our work)*	✓	✓	✓	✓	✓

Table 1: ***Existing approaches to eBPF multi-tenancy.***

Summary. As Table 1 shows, no existing mechanism satisfies the requirements for secure, scalable multi-tenancy. They either rely on tenant-provided checks, restrict only certain attachment scopes, compose programs ahead of time, or reject unsafe programs at admission time. Although these approaches can enforce useful restrictions, they lack architectural support needed for general multi-tenancy. The core challenge, therefore, is the absence of a virtualization layer that decouples the tenant's logical view of the kernel from the physical execution environment.

2.5 Threat Model and Assumptions

We target a multi-tenant shared-kernel platform where the host kernel, eBPF verifier, JIT compiler, container runtime, and platform administrator are trusted. Conversely, tenants and their eBPF programs are untrusted. Even if accepted by the verifier, a buggy or malicious tenant program could attempt to observe peer tenants, induce unnecessary execution on unrelated workloads, corrupt shared execution contexts, or manipulate helper-accessible kernel state beyond its authorized scope. Here, we consider the kernel state to include both internal data structures (e.g., `task_struct`) and eBPF-specific structures (e.g., eBPF maps).

The goal of ▽BPF is to confine tenant-defined eBPF execution and state updates to the tenant's scope, while preserving explicitly authorized hierarchical visibility for platform monitoring. ▽BPF does not protect against malicious host administrators, compromised kernel, verifier or JIT bugs, hardware faults, microarchitectural side channels, or resource-exhaustion attacks that should be handled by existing kernel mechanisms.

3 The Late-Binding Architecture

3.1 The Abstraction Gap of Static Binding

The core limitation of eBPF multi-tenancy is its reliance on a *static-binding model.* Currently, tenant programs are bound to physical hooks during deployment. Once a hook is triggered, the kernel dispatches the event to the hook's fixed attached program set, independent of tenant relevance. *This static coupling hardwires tenant code to a specific kernel hook and makes programs operate within a global memory space.* While the kernel permits multiple attachments, it forces tenants

to contend for the same execution context and global states, leading to state corruption and performance interference. Consequently, mechanisms built on today's eBPF model can only mitigate conflicts indirectly, for example through in-program filtering or external coordination of attachments. Because the underlying hooks and kernel state remain shared, these approaches still fall short of the isolation guarantees expected in multi-tenant environments.

3.2 Insight: Decoupling via Late-Binding

We propose that secure multi-tenancy requires a *late-binding architecture*. Rather than statically mapping logical programs to physical resources, ▽BPF introduces a layer of indirection. In this model, physical kernel hooks serve merely as interposition points. The binding of an event to its program set and virtual state view is deferred until the event is attributed at runtime. Upon an event, the ▽BPF runtime dynamically resolves which logical program to execute and which context to map based on the active tenant. By decoupling logical operations from physical realization, late binding transforms eBPF from a shared kernel extension facility into a virtualized runtime, enabling selective execution, precise attribution, and independent state management.

3.3 Design Overview

Inspired by the concept of late binding, we present ▽BPF, a novel eBPF execution model that achieves virtualization through three key techniques.

eBPF Namespaces. To isolate tenants, we introduce a new, hierarchical eBPF namespace bound to processes. A new namespace is essential for orthogonal policy composition, allowing security controls via ▽BPF to be decoupled from resource management like cgroups. This composable design enables fine-grained policies impossible with existing namespaces, such as applying different tracing rules to a sidecar and an application that share the same network. Moreover, its hierarchical structure allows parent namespaces (e.g., the host) to transparently audit child tenants. Following Linux namespace conventions, ▽BPF supports standard operations: creating new namespaces via `clone` [11] and `unshare` [39], and joining existing ones via `setns` [36]. This design enables seamless integration with container runtimes like runc [29] and orchestration platforms like Kubernetes [20].

Execution Context. The OS kernel operates in two distinct states [93]: *process context* and *interrupt context*. Process context handles synchronous user-space transitions (e.g., system calls), where the kernel can reliably identify the initiating tenant by inspecting the `current` task structure. In contrast, interrupt context handles asynchronous events like timer interrupts or packet arrivals that preempt the running task. When an interrupt occurs, the `current` task only represents the process that was interrupted (or the idle task), which is usually unrelated to the event's owner. Consequently, it is unsafe to rely on `current` to identify the target namespace.

▽BPF ***Sniffer.*** The first challenge for late-binding is to identify the tenant namespace accurately, particularly during interrupt-driven events (e.g., `XDP` packet arrival) where process context is absent. The ▽BPF *Sniffer* bridges this semantic gap using a *two-phase attribution mechanism*. During process-context operations (e.g., system calls), the sniffer captures the association between physical resources (e.g., sockets or block I/O requests) and tenant namespaces, storing this mapping in a global registry. When an interrupt fires, the sniffer queries this registry to resolve tenant attribution. This design enables ▽BPF to dynamically determine the tenant attribution for programs and events at runtime.

▽BPF ***Dispatcher.*** Once tenant attribution is resolved, the ▽BPF *Dispatcher* resolves the logical program to execute. Unlike the flat, linear traversal of native eBPF, the dispatcher organizes programs into tenant-scoped domains that mirror the namespace hierarchy. Furthermore, ▽BPF introduces two key optimizations. First, the dispatcher replaces existing linear scans with a hash-based lookup, locating the tenant's entry point in $O(1)$ time regardless of system scale. Second, to support parent-child relationships (e.g., global monitoring), the dispatcher offers a configurable trade-off: a memory-efficient recursive lookup or a path flattening optimization that pre-compiles the execution chain into a single array, trading memory for minimal dispatch latency.

▽BPF ***State Isolation Framework.*** Finally, ▽BPF achieves state isolation through a *compiler-enforced, multi-layered mechanism*. We leverage the observation that eBPF programs interact with shared kernel state exclusively through helper functions. At compile time, ▽BPF deploys a static analyzer to audit these interfaces and reject helper functions that modify global state unless explicitly allowlisted. At runtime, our *variable library* virtualizes state access for eBPF programs: it delegates static variables from global definitions to tenant-private instances and manages kernel structures via fine-grained dynamic patching. This allows eBPF developers to write standard eBPF code without modification, as the ▽BPF automatically redirects "global" writes to shadowed local copies to prevent cross-tenant pollution.

4 Detailed Design

4.1 ▽BPF Sniffer

The initial step of ▽BPF is to identify the correct eBPF namespace for triggered events. While this identification is straightforward in process contexts by inspecting the initiating task, it is non-trivial in interrupt-driven scenarios. As noted in §3, when a packet arrives, the *current* task only represents the interrupted process, which is typically unrelated to the packet's owner. ▽BPF *Sniffer* is designed to resolve this challenge.

Component	API	Description
Sniffer	`insert(writer)`	Extracts a stable key from *writer* and maps it to the current namespace. Called in process context.
	`resolve(reader)`	Looks up the target namespace using a key derived from *reader*. Called in interrupt context.
	`remove(key)`	Deletes the mapping associated with *key* to release resources. Called in process context.
Dispatcher	`get_namespace()`	Identifies the tenant namespace by inspecting the current process context or querying the Sniffer.
	`dispatch(ns)`	Locates the program set for namespace *ns* and invokes the appropriate tenant eBPF programs.
	`attach/detach(ns, prog)`	Registers or unregisters *prog* for namespace *ns*. Updates reference counts to trigger `enable/disable`.
	`enable/disable(ns)`	Lazily initializes the Dispatcher hook on the first attachment, or tears down on the last detach.

Table 2: Core abstractions of ▽BPF *Sniffer* and ▽BPF *Dispatcher*.

Observation. Our design is based on a key observation: *an interrupt event is linked to a resource that was previously set up in a process context.* E.g., a network packet arrives only after a process has established a connection. Thus, instead of relying on the unreliable execution context, we track the resource itself. *Sniffer* records the eBPF namespace for resources (e.g., network IP and port) during their initialization. Later, when an interrupt occurs, the system simply looks up this pre-recorded mapping to identify the target namespace.

Importantly, this resource-based attribution does not assume a strict one-to-one relationship between interrupt event and a task. Multiple interrupt events may resolve to the same namespace (e.g., packets from the same flow share a 5-tuple). Conversely, the resource visible at an interrupt may aggregate work from multiple tasks or namespaces, such as merged `bio/request` objects in the block layer. In such cases, the *Sniffer* records a namespace set as the mapped value and propagates it when requests are split or merged.

General Procedures. As Figure 4 shows, the *Sniffer* implements this logic through a two-phase lifecycle. In the *context-aware phase*, we instrument specific kernel resource allocation paths, such as `bind()` or `connect()` system calls. Since the process context is valid at these points, we capture the resource identifier (e.g., the socket's 5-tuple) and register a `{resource-ns}` entry in the resource-based mapping. In the *context-free phase*, which occurs during interrupts, we extract the identifier from the raw context. We then query mapping to retrieve the associated namespace, enabling precise dispatch without relying on the execution context.

Unified Key Interface. A major challenge is that the two phases see different data structures: the first phase sees high-level kernel objects (e.g., `sock`), while the second sees raw event metadata (e.g., `xdp_md`). To solve this, we *separate the matching mechanism from the data extraction policy (Table 2)*. We define the process-side context as a *writer* and the interrupt-side context as a *reader*. These interfaces serve as adapters that extract the same identity information from their different sources. This *unified key* enables `insert()` and `resolve()` to match resources across the boundary, independent of the data format.

Use Cases. We instantiate ▽BPF *Sniffer* for three main classes of resources. For networking (`TC/XDP`), a `network_sniffer` derives keys from packet headers (e.g., 5-tuples in `sk_buff/xdp_md`) and supports multi-stage matching across connection setup, binding, and acceptance, refining the *{resource-ns}* entry as more information becomes available. For storage, a `request_sniffer` keys on kernel I/O request objects (e.g., bio/request) so that completion interrupts can be resolved back to the namespace that submitted the operation. Finally, we use a `task_sniffer` to handle teardown corner cases: before a task's namespace is destroyed, it records a stable task-namespace mapping, allowing late process-context events in the exit path to identify the correct tenant even after the namespace reference in the task has been reclaimed.

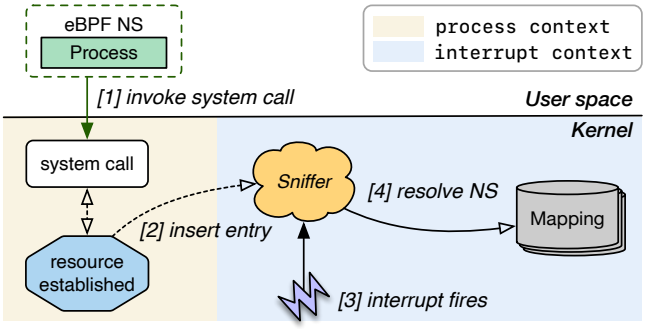

Figure 4: ▽BPF **Sniffer workflow.** *First, a process invokes a system call ([1]), triggering the Sniffer to record the mapping between the established resource and the namespace ([2]). Later, when a interrupt fires ([3]), the Sniffer uses this pre-recorded mapping to resolve the associated namespace ([4]).*

Scope. ▽BPF *Sniffer* targets kernel events whose handling spans both process and interrupt contexts. However, platform-level interrupts such as IPIs, device hotplug, and other hardware management events have no meaningful tenant owner and remain confined to the host namespace. This partition is deliberate: we only pay the cost of *Sniffer* where namespace identification is useful, and fall back to simpler, semantically correct mechanisms elsewhere.

4.2 ▽BPF Dispatcher

Once a tenant's eBPF namespace is identified, ▽BPF should dispatch the event to the correct eBPF programs. However,

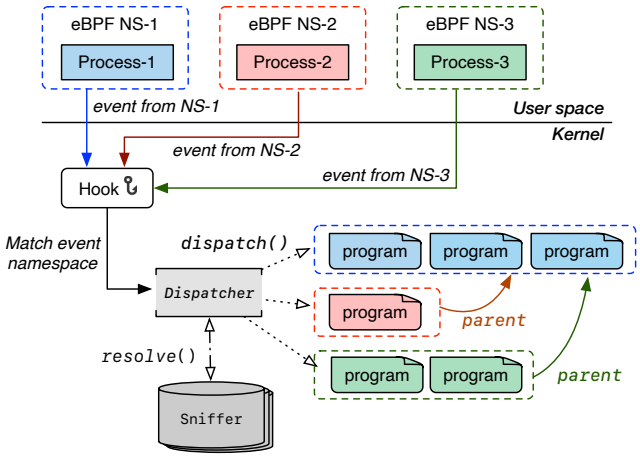

Figure 5: vBPF ***Dispatcher.*** *The Dispatcher sits at each hook, receives the namespace resolved by the Sniffer, and dispatches the event only to the matching tenant programs and eligible parent programs.*

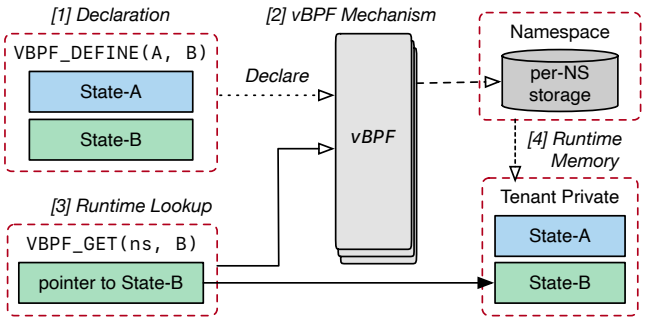

Figure 6: vBPF **tenant-private states.** *Developers declare multiple states using* `VBPF_DEFINE` *([1]), and then* vBPF *automatically maps them into a cohesive per-namespace storage layout ([2]). At runtime,* `VBPF_GET` *efficiently resolves ([3]) the specific state instance from the tenant-private memory ([4]).*

the native eBPF execution model is mismatched with the nature of multi-tenant environments. First, specific attachment points enforce exclusivity. For example, hooks based on `struct_ops` or LSM often accept only a single global program. Second, even for hooks that support multiple programs, the kernel relies on linear data structures (Figure 2). Concretely, kprobes utilize linked lists while tracepoints employ arrays to manage attached programs. A naive implementation might perform filtering at runtime, but this approach degrades performance by sequentially traversing unrelated programs. As shown in Figure 5, vBPF *Dispatcher* redesigns the program organization to address these challenges.

Virtual Hook Multiplexer. To implement the late-binding execution model, vBPF introduces a lightweight multiplexer attached to the physical hook. This component functions as a global indirection layer, similar to a virtual method table in object-oriented languages. Instead of binding tenant programs directly to kernel attachment points, the system installs this multiplexer as the sole occupant of the physical hook. Upon event triggering, the multiplexer acts as an entry point and queries the *Sniffer* to identify the corresponding tenant namespace. It then dynamically routes the event to logical programs registered by that tenant.

Hash-Based Tenant Indexing. Although subsystems like kprobes natively support multi-program attachment, they rely on a linear organization. These programs are then executed in a sequential manner, which is reasonable in today's Linux since all programs need to be executed. However, with vBPF, we need to check each program to ensure that only the targeted programs are executed, bringing a significant runtime overhead. vBPF replaces this linear scan with an O(1) dispatch mechanism based on tenant indexing. The *Dispatcher* uses a hash map, keyed by eBPF namespace, to directly locate a tenant's programs, which are themselves organized into a contiguous array. This design combines an efficient tenant lookup with a cache-friendly intra-tenant program traversal, ensuring that dispatch latency remains constant and isolated from the activities of other tenants.

Flattened Hierarchical Execution. For certain use cases, such as tracing, a hierarchical approach is necessary where parent namespaces should observe events in child namespaces. vBPF supports this via a bottom-up execution order, propagating events from the specific tenant up to the root. This allows platforms to audit, modify, or veto tenant actions, as context modifications are visible up the chain, and parents can override children's return codes. However, recursively walking the namespace tree on the critical path is inefficient. To address this, we introduce a *path flattening* optimization. During the program attachment, vBPF pre-computes the call chain from tenant to root as a static array. At runtime, dispatch becomes a simple iteration over this flattened path. Flattened path consistency is maintained atomically during parent program updates to prevent race conditions.

4.3 The vBPF State Isolation Framework

To deliver a virtualized environment, vBPF must enforce strict boundaries on state modification. The main goal is to ensure that tenants operate on independent state instances. For example, if two tenants attempt to modify the same `sk_buff`, the system must ensure they operate on separate local copies to avoid conflicts. However, achieving this is non-trivial. On the one hand, coarse-grained methods like page-table switching provide strong isolation but incur high overhead and lack the granularity to isolate small kernel objects efficiently. On the other hand, fine-grained methods that manually rewrite kernel logic are efficient but too invasive and hard to maintain across a large, changing codebase.

To address these challenges, vBPF proposes a multi-layered state isolation framework. At its foundation is a static analyzer that prevents access to unverified eBPF ker-

nel interfaces (e.g., eBPF helper functions). Building on this guarantee, a variables library provides high-level, transparent abstractions for managing both simple per-tenant state and complex, shared kernel objects.

The Static Analyzer. The core of vBPF's state isolation is a static analyzer built upon a key observation: *eBPF programs access kernel state exclusively through a bounded set of verifier-visible kernel interfaces, including eBPF helper functions and kfuncs.* This provides a natural checkpoint for enforcing isolation. Our analyzer, integrated into the kernel's compilation toolchain as a compiler frontend plugin, enforces a default-deny policy: *it rejects any eBPF kernel interface that can modify global kernel state unless it is explicitly annotated as safe.* This ensures tenant programs only use interfaces audited for multi-tenant environments, drastically reducing the attack surface for cross-tenant interference.

Analysis Procedure. Our static analyzer's design relies on two compiler attributes. `vbpf_helper` is integrated with the kernel's `BPF_CALL_*` macros to automatically identify the complete API surface of all functions exposed to eBPF. The second, `vbpf_safe`, is a manual annotation applied by kernel developers, serving as a formal assertion of state safety. It then employs a taint analysis to automatically verify the state safety of these helpers. If a side effect is detected, it then requires the `vbpf_safe` annotation as an explicit developer sign-off. To ensure soundness, we define rigorous propagation rules for complex control flows such as static branches, loops, and indirect calls. Any violation of these rules results in a compile-time error, preventing the creation of an insecure vBPF-enabled kernel.

Pointer Analysis. By default, the analyzer treats all argument pointers as tainted (unsafe). However, a naive rejection of all pointers yields excessive false positives. To resolve this, we leverage the eBPF verifier's existing type constraints. Our key observation is that the *verifier strictly defines the argument pointer types and memory regions a pointer can access.* For each analyzed interface, the analyzer reads its verifier-visible prototype (e.g., `bpf_func_proto` for helpers and BTF prototypes for kfuncs) and lifts each pointer argument into a safety category. Pointers that are guaranteed to access tenant-private memory (e.g., the eBPF stack, local maps) or read-only regions (e.g., string constants) are classified as safe. This verifier-assisted pointer classification allows vBPF to accept common interfaces that only write to tenant-owned buffers while still rejecting hidden mutations to shared kernel state.

The vBPF Variables Library. Our static analyzer provides a strong safety foundation, but shifts the burden of state management to developers. To automate this complex and error-prone task, we introduce the vBPF *variables library.* The design is guided by a key insight: *kernel state consists of two distinct categories requiring different management.* The first is *tenant-private state*, which can be safely instantiated per tenant. The second is *shared state*, which cannot be replicated and whose access must be virtualized. Our library provides two distinct mechanisms tailored to these categories: a highly-efficient, declarative API for tenant-private state, and a general state overlay engine for virtualizing shared state. eBPF kernel interfaces can use these mechanisms to redirect accesses to namespace-private instances or to record tenant-specific updates to shared objects.

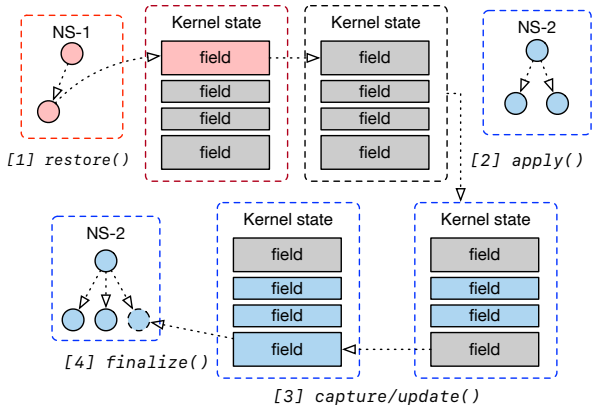

Figure 7: vBPF **semantic state overlay.** *Upon a context switch from NS-1 to NS-2,* vBPF *restores the kernel to a clean state ([1]) before applying NS-2's specific patches ([2]). During eBPF program execution, helper functions capture modifications ([3]), which are finalized and appended to the namespace's patch set ([4]) after the program exits.*

Declarative API. Manually converting a global variable into a per-tenant instance is a complex task. It requires defining a new type, managing memory allocation, and implementing lookup logic, which forces invasive changes across the kernel code. As Figure 6 shows, to minimize this complexity, vBPF introduces a declarative API that abstracts away these details. Instead of writing extensive boilerplate, developers simply use `VBPF_VARS_DEFINE` to declare a variable and `VBPF_FIELD_INIT` to register custom initialization logic. At runtime, accessing the tenant-specific instance requires only a single call to `VBPF_VARS_GET(ns, ...)`. Using this API, vBPF provides per-namespace pointers that allow exclusive access to the states. Fields in the same group are resolved cohesively from a single namespace instance, ensuring auxiliary objects like locks remain consistent with the state they protect. This abstraction handles the storage and mapping automatically, reducing hundreds of lines of code to just a few declarations.

Semantic State Overlay. Virtualizing shared state requires a way to inspect and understand kernel data structures at runtime. A simple memory snapshot is not enough because it cannot handle complex structures like dynamic arrays and does not understand the difference between pointers and data. To solve this, we use the BPF Type Format (BTF), which is embedded within the kernel image. *Although BTF was*

```c
// Precompute the context
struct overlay_ctx ctx;
overlay_ctx_init(&ctx, "sk_buff", skb);
// Hot path: record the patches
struct patch_builder *pb;
pb = overlay_begin(&ctx);
{ skb->priority++; }
overlay_capture(pb, skb);
/* Or use update */
overlay_update(pb, skb, struct sk_buff, tstamp);
overlay_finalize(&ctx, pb);
```

Listing 2: **Primitive usage in helper function.** *The helper initializes an overlay context for the target kernel object, records modifications through either full-object capture or field-level update, and finalizes them into the namespace's patch set.*

originally designed for debugging, we found that its detailed descriptions of data types and memory layouts make it perfect for reflections. As Figure 7 shows, we use BTF to implement a form of reflection that allows vBPF to understand the structure of kernel objects. This enables us to create a semantic overlay: instead of blindly copying memory, our engine calculates the exact size and layout of an object to generate a precise, safe patch that applies tenant-specific changes.

State Overlay in Practice. As presented in Listing 2, the state overlay workflow of vBPF begins by registering an overlay context based on the current object state. When an eBPF helper function executes, it initializes a builder to track the modification process. After the state is modified, the engine generates patches using one of two methods: a `capture` mode that automatically detects changes by comparing snapshots, or an `update` mode that allows manual recording of specific fields. These patches are then committed to the current namespace's patch set via a `finalize` operation. These patches are atomically applied when a tenant context switches in and reverted when they switch out.

5 Implementation

We have implemented a vBPF prototype based on Linux kernel 6.12 and LLVM 20, with 12k LoC for the kernel and 1k for the Clang frontend plugin.

Concurrency. Performance and correctness of vBPF under concurrency are paramount. To achieve this, we employ a hash table protected by Read-Copy-Update (RCU), enabling the query operations, such as *Sniffer* `resolve` and *Dispatcher* `get_namespace`, to proceed in a lock-free manner with minimal synchronization overhead. The insertion and removal operations in the hash table oversee object lifecycle management, with removals processed asynchronously. For scenarios with extremely large key sets where lookup misses are common, we offer an optional bloom filter to preemptively reject lookups for non-existent keys, further reducing cache pollution and lookup latency.

Preallocation and Lazy Allocation. vBPF paradoxically boosts performance using two opposing allocation strategies: eager preallocation and deferred lazy allocation. First, to guarantee the performance of our lock-free data structures, we employ aggressive preallocation. By using the kernel's `kmem_cache` and custom memory pools, we pre-provision objects to prevent runtime allocation failures and latency fluctuation within critical sections. Conversely, to minimize memory footprint and startup latency, a tenant-private state is not created with its namespace but is deferred until its first access. We adapt the *LazyCell* [23] concept for this: a program must first `VBPF_VARS_GET` a variable, which triggers a one-time initialization on the first call, thereby lowering cache pollution and improving data locality at scale.

Pre-Computation for Runtime Efficiency. A core design principle in vBPF is to aggressively shift computational work from hot runtime paths to the less frequent setup phase. We apply this in two critical components. First, for the *Dispatcher*'s hierarchical execution, we implement path flattening. At program load time, we pre-compute the entire call chain from a tenant to the root and cache it in an array. At runtime, this transforms a recursive traversal of the namespace hierarchy into a highly efficient iteration, achieving near-constant-time dispatch. Second, for the *state overlay engine*, we pre-parse BPF Type Format (BTF) metadata at initialization. We cache the layouts of kernel objects into a simple array of field offsets and sizes. This allows the runtime *capture* operation to bypass expensive BTF parsing entirely.

6 Evaluation

Hardware and Software. We use an x86-64 machine with Intel(R) Xeon(R) Gold 6330 CPU @ 2.00GHz, 28x2x2 cores, 512GB DRAM to evaluate microbenchmark and performance breakdown. To deploy our prototype system, we adopted the Linux 6.12 kernel and Ubuntu 24.04 LTS as the base system and built our implementation on top of it. eBPF programs and other components of vBPF are built on LLVM 20 with our customized Clang frontend plugin. In addition, all eBPF programs are jitted in our evaluation. For all benchmarks, we set the machine to run in performance mode and bound dedicated CPU cores for single-thread microbenchmarks.

Benchmarks. We evaluate vBPF on microbenchmarks and real-world applications. The microbenchmarks include `lmbench` [78, 98] and `UNIX Bench` [96]. We use real-world eBPF applications, `sysdig` [35] and `netobserv` [26], as monitor programs and applications like `PostgreSQL` [62] and `Apache` [37] as workload programs, and compare standard eBPF and vBPF in terms of performance degradation relative to vanilla Linux. We run `Postgres` [62] through Phoronix Test Suite and use the official benchmark tool `ab` [4] to eval-

uate Apache. Finally, we use `sched_ext` [31] as a use case to demonstrate the performance improvement of `redis` [28] and `7z` [3] decompression using vBPF.

6.1 Microbenchmarks

We use microbenchmarks to evaluate the runtime characteristics of vBPF. By comparing vanilla Linux, native eBPF, and vBPF, we aim to verify two key properties: (1) the low overhead of the *Sniffer/Dispatcher* mechanism, and (2) the performance isolation benefits for cross-tenant scenarios.

Methodology. We use lmbench [78, 98] to generate system workloads covering syscalls, I/O, process creation, and networking. To simulate a realistic eBPF workload, we run sysdig [35], a comprehensive system visibility tool, to trace system events. We evaluate three configurations: (1) *Native eBPF*, where sysdig is attached globally using the standard kernel mechanism, (2) vBPF *(Co-located)*, which runs lmbench workload and sysdig in the same tenant namespace, (3) vBPF *(Cross-Tenant)*, which runs lmbench workload and sysdig in different tenant namespaces.

Results. Figure 8 shows the latency results of lmbench [78, 98] and Figure 9 shows the bandwidth results. We quantify baseline cost by comparing vBPF (*Co-Located*) against *Native eBPF*. vBPF introduces acceptable overhead: up to 4.81% for syscall, 5.18% for select, 3.39% for process creation and 2.51% for networking. Performance remains comparable to *Native eBPF*, indicating efficient *Sniffer* and *Dispatcher* designs.

In cross-tenant scenarios, vBPF demonstrates significant advantages over *Native eBPF*. While *Native eBPF* imposes overhead on all processes through global hooks, vBPF bypasses execution for unmonitored tenants. For high-frequency operations, vBPF reports 0.258, 0.319, and 0.288 us for `NULL call`, `read`, and `write`, reducing latency by 3.7×, 3.8×, and 3.9× over *Native eBPF*. For network workloads, vBPF reports 17.55, 21.31, and 13.89 us for `RPC/UDP`, `RPC/TCP`, and `TCP/IP`, improving latency by 1.4×, 1.4×, and 1.5× over *Native eBPF*, restoring throughput for non-monitored tenants and approaching *Vanilla Linux* baseline performance.

6.2 Breakdown

We collect the latency of the `tcx` network packets tracing program to analyze the breakdown of the eBPF program execution time. We insert `tcx` to `lo` and use iperf3 to trigger packet transmissions. *Co-Loc(vBPF)* and *Co-Loc(+Sniffer)* both denote that `iperf3` and eBPF programs run in the same eBPF namespace. *+Sniffer* indicates employing a sniffer within the interrupt context, whereas *vBPF* signifies operation in the process context. *X-Tenant(vBPF)* and *X-Tenant(+Sniffer)* follow a similar pattern but with `iperf3` and the eBPF program in different eBPF namespaces.

The results are shown in Figure 10. A basic `tcx` program takes 1135 ns, covering core parsing and statistics function-

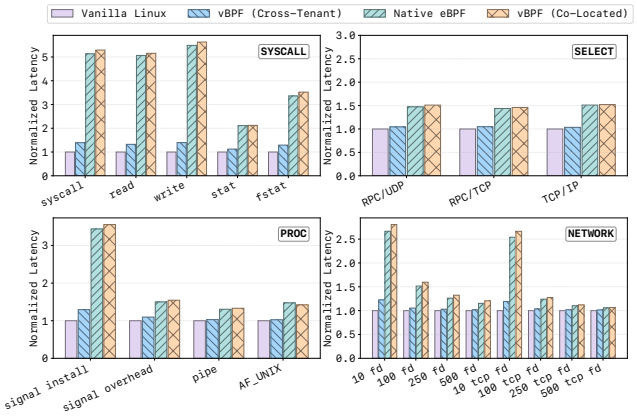

Figure 8: **Latency comparison of lmbench**

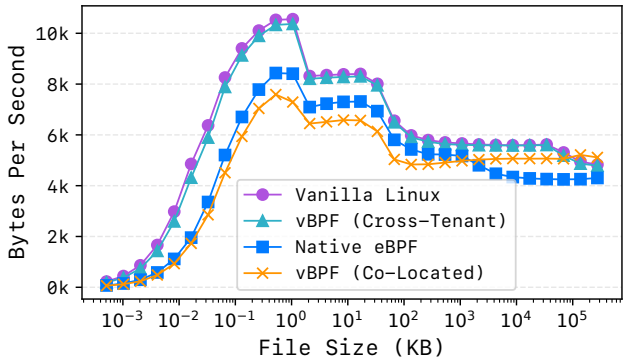

Figure 9: **Bandwidth comparison of file reading**

alities typical of eBPF overhead. In comparison, vBPF adds *sniffer resolve* at 134 to 136 ns, *namespace lookup* at 32 to 33 ns, and *program lookup* at 60 to 74 ns. The largest vBPF overhead accounts for only 2.1% of total eBPF execution, confirming minimal cost in co-located scenarios with substantial gains in cross-tenant settings.

6.3 Scalability Analysis

We further evaluate the scalability of vBPF using the same `tcx` program in §6.2, specifically focusing on the dispatch overhead as tenant density increases. Figure 11a depicts the latency of the *Sniffer* and *Dispatcher* as the number of active eBPF namespaces scales from 10 to 100. The results demonstrate that as the number of namespaces increases, the *sniffer resolve* latency stabilizes at the range of 131.7–136.6 ns and 58.3–60.7 ns for *program lookup*. This confirms our hash-based lookup maintains consistent low-latency performance in high-density, multi-tenant environments.

Figure 11b evaluates the dispatch efficiency when multiple kprobe programs contend for the same kernel function (`sys_read`). We compare vBPF against *Native eBPF* (sequential execution) and *vBPF (Co-located)* (manual conditional

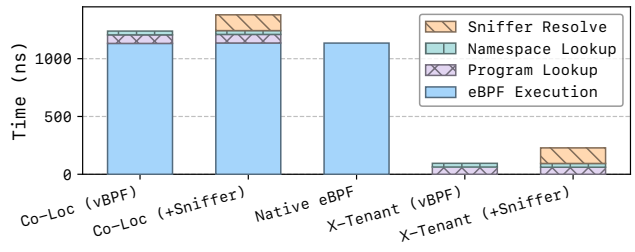

Figure 10: **Breakdown of tcx tracing program**

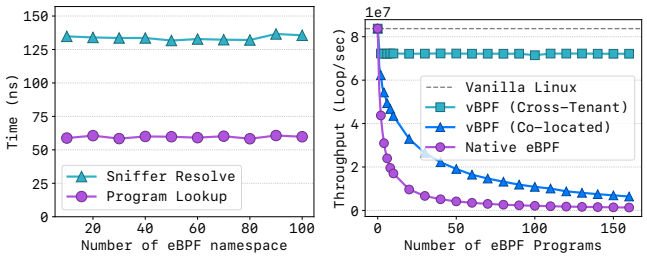

(a) **Sniffer/Dispatcher latency** (b) **kprobe performance**

Figure 11: **Scalability comparison**

checks). The results highlight a fundamental scalability gap. While both baselines exhibit linear performance degradation ($O(N)$) due to accumulated execution costs, *vBPF (Cross-Tenant)* maintains a flat throughput profile ($O(1)$). By efficiently bypassing unrelated programs, vBPF achieves a speedup of up to 54× compared to *Native eBPF* and 11.4× compared to the manual inner filter approach when inserting 160 kprobe programs, proving its ability to handle high-density multi-tenancy without performance degradation.

6.4 End-to-End Performance under Tracing

We use two real-world workloads and two real-world eBPF tracing applications to evaluate the end-to-end vBPF performance in cross-tenant scenarios.

PostgreSQL. PostgreSQL [62] is an open-source object-relational database system. We evaluate throughput (transactions per second) and latency with different scales, client numbers, and access modes (read-only or read-write). We use `sysdig` [35] as a background eBPF program to monitor system data. As Figure 12 shows, vBPF can offer 29% higher throughput and 23.6% lower latency compared to *Native eBPF*.

Apache. Apache `httpd` [37] is a widely used web server. We analyze the throughput (requests per second) of `httpd` with the `ab` [4] benchmark tool in different concurrent connection settings. Besides, we choose `netobserv-ebpf-agent` [26] as the background network monitor, which utilizes different types of eBPF programs, including kprobe, tracepoint, and traffic control (TC), etc., to collect network data. As Figure 13 shows, compared to the *Native eBPF*, vBPF can achieve up to 2.8× throughput speedup, and is close to *vanilla Linux*.

6.5 Use Cases: sched_ext

In this section, we demonstrate a use case of vBPF. The extensible scheduler class (`sched_ext`) [31] enables customized scheduling policies through eBPF programs. While `sched_ext` can improve performance for specific workloads, it lacks fine-grained isolation beyond cgroup boundaries, which can lead to global interference and performance degradation for unrelated workloads.

To demonstrate this capability, we evaluate two distinct workloads with contrasting characteristics: Redis [28], a key-value database optimized for low-latency operations, and `7z` [3], a file archiver performing CPU-intensive decompression. We employ `scx_central` [33], a scheduler that maximizes time slice allocation, making it particularly well-suited for CPU-bound workloads but potentially detrimental to latency-sensitive applications. We compare three configurations: (1) *Vanilla Linux* using the standard CFS scheduler, (2) *Native eBPF* using `scx_central` to schedule both `redis` and `7z`, and (3) vBPF using `scx_central` exclusively for `7z` while keeping `redis` under the default scheduler, where each scheduler manages a disjoint set of CPU cores.

As Figure 14 shows, *Native eBPF* improves `7z` [3] decompression performance by 10% compared to *Vanilla Linux*, but causes an 18% degradation in `redis` [28] throughput. In contrast, vBPF achieves the same 10% improvement for `7z` while keeping `redis` performance close to vanilla Linux.

6.6 State Overlay Overhead

We evaluate the overhead of the vBPF state overlay using three representative kernel data structures (`sk_buff`, `file` and `task_struct`) alongside a simplified `sk_buff_fake`. We measure the latency of the four critical operations: *capture / update* (calculate or manually create the state overlay), *apply* (switch-in), and *restore* (switch-out). In addition, we compare the optimized implementation against a naive baseline to quantify the benefits of precomputed layout strategy.

Results. In Linux 6.12, `sk_buff` is 232 bytes, `task_struct` is 10,112 bytes, and `file` is 184 bytes. `sk_buff_fake` simplifies `sk_buff` with reduced type complexity. In the test, we modify only one field in these data structures, which is common for a specific helper function. Figure 15 presents the results: the latency of *apply*, *restore*, and *update* remains stable, with the first two in the range of 42–44 ns and the latter at 52–56 ns. The latency of *capture* is influenced by the size of the type. In common cases (e.g., `sk_buff` and `file`), the overhead is 118.8 and 100.9 ns, respectively. In addition, our optimization can reduce the overhead up to 31.4×.

6.7 Memory Overhead

We measure the peak additional memory consumed by vBPF under representative workloads and attribute it to its major

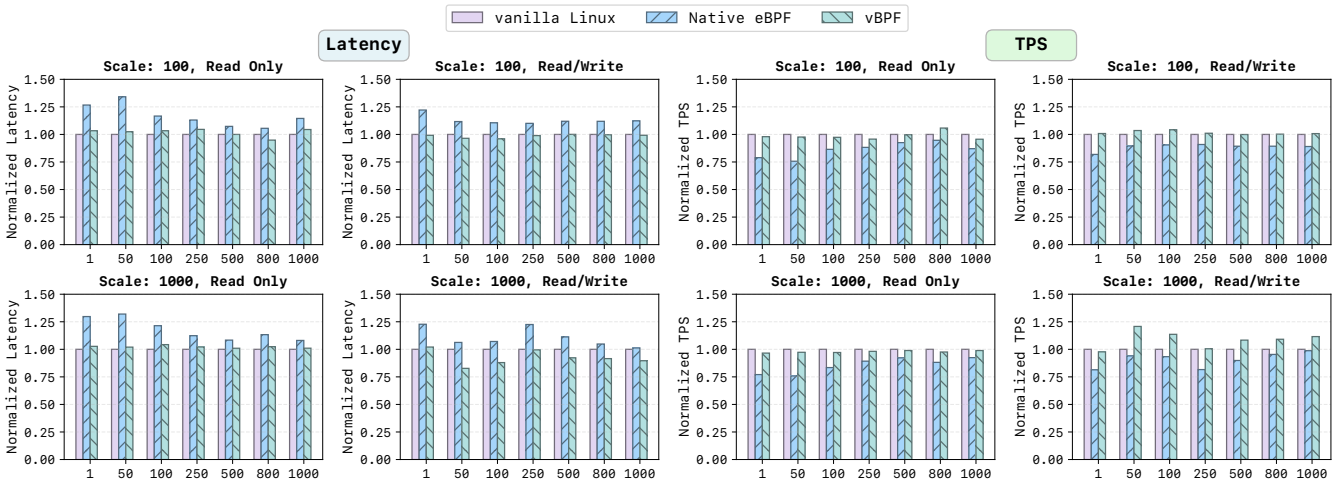

Figure 12: **Performance comparison of PostgreSQL benchmark under different workloads**

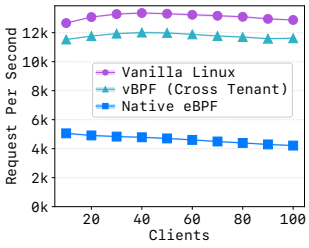

Figure 13: **Apache benchmark**

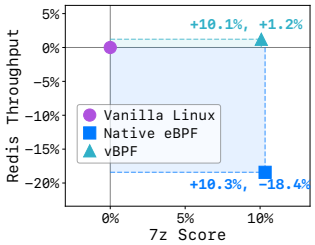

Figure 14: **Scheduler results**

Application	Peak Memory Overhead (KiB)				
	Dispatcher	Sniffer	State	Other	Total
Apache	19.3	39,334.1	0.2	16.4	39,370.0
PostgreSQL	1.8	3.4	0.2	6.2	11.6
`fio`	0.4	38,961.3	0.2	1.6	38,963.5

Table 3: **Peak memory overhead of vBPF by component**

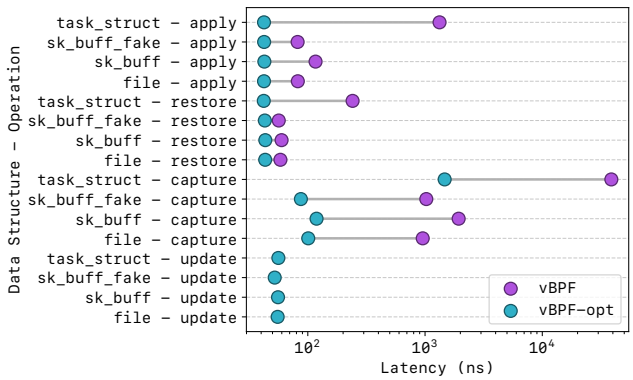

Figure 15: **Latency of vBPF state overlay.** *Capture latency depends on data-structure complexity, while apply and restore remain nearly constant. The optimized version uses precomputed layouts to avoid the runtime analysis.*

components. We use `netobserv`, sysdig, and a simple bio monitor program as the eBPF workload, respectively. Table 3 shows that the fixed metadata remains small: the dispatcher uses at most 19.3 KiB, state bookkeeping uses 0.2 KiB, and other metadata stays below 16.4 KiB. The dominant factor is the *Sniffer* registry, whose footprint depends on the number of live resource-to-namespace mappings. PostgreSQL creates few such mappings and adds only 11.6 KiB in total. In contrast, Apache and `fio` keep many network or I/O resources active at peak, increasing *Sniffer* memory to 39,334.1 KiB and 38,961.3 KiB, respectively.

The state component remains minimal because modifications are rare, and ID-based eBPF state (e.g., eBPF maps use `idr`) adds only constant per-namespace metadata. For workloads that frequently modify shared kernel objects, overlay state grows with the modified objects but remains a demand-driven cost for strict isolation. Thus, vBPF incurs negligible fixed metadata cost, while total memory usage mainly tracks the active *Sniffer* registry and state modifications.

7 Related Work

Kernel Isolation. There is a long line of research works introducing isolation to OS kernels [46, 55, 68, 70, 75, 80, 81, 85, 95]. Some of them [46, 68, 70, 75, 80, 81] use safe languages to extend the type system of the kernel. While others [95] utilize runtime checks to provide a sandbox execution environment. Besides, there are also a lot of works [55, 85] that leverage static verification, which has become a standard method of eBPF nowadays. Additionally, leveraging hardware-based isolation mechanisms [49, 63, 67, 84] has proven to be an effective approach for kernel isolation.

eBPF and Its Applications. eBPF has been used in many scenarios for optimizations. For instance, some works [8, 25, 48, 56, 61, 66, 103, 107, 109] focus on improving the I/O performance. Others are customizing the kernel components with eBPF, including memory management [50, 82, 102], locking [89], scheduling [31–34, 71, 74], file system [72], process management [106], page fault handling [110], etc.

eBPF Enhancements. eBPF enhancements have been a hot topic in recent years. There are a few works [76, 86, 99–101] that improve the verifier. Others are proposed to improve the code generation of eBPF. For example, Merlin [77] is a recent system that utilizes customized IR to optimize generated eBPF bytecodes. Morpheus [79] leverages traffic patterns to optimize datapath binaries, including eBPF bytecodes.

Mitigation of Tracing Overhead. [60] provides a comprehensive survey of tracing, while [83] reduces the unnecessary overhead for fuzzing. As for eBPF, KFuse [72] improves performance by merging multiple eBPF programs without failing the verifier. [54] provides isolated eBPF programs for each process. [69] eliminates the exception of kprobe, and improves the tracing performance. Most of them are orthogonal to vBPF and can be integrated with vBPF.

Multiple Kernel Views. Barrelfish [44] is an early work that splits the kernel into multiple independent components. FACE-CHANGE [64] and MultiK [73] propose per-process kernel view in one kernel. These efforts are too heavy to virtualize the eBPF programs and kernel states.

8 Discussion

Memory Costs. While memory overhead may increase with the number of state overlays over time, we believe that it is acceptable in practice for three reasons. First, most dynamic kernel states like `sk_buff` are short-lived, allowing immediate reclamation of allocated memory. Second, using copy-on-write strategy can make sure that it only stores the specific fields modified rather than the full objects. Third, writes are sparse since they occur solely through helper functions. As most eBPF programs are read-only for inspection, they incur zero additional memory cost.

Maintainability. As the kernel evolves, the number of modifiable states will increase naturally. Although vBPF introduces some maintenance overhead, it mitigates this challenge by leveraging the fact that eBPF programs modify state exclusively through well-defined entry points. Rather than manually rewriting arbitrary kernel code, maintainers need only inspect verifier-visible helper and kfunc boundaries to explicitly mark or virtualize stateful interfaces. Consequently, our static analyzer can seamlessly evolve alongside the kernel, requiring only a one-time annotation effort for each newly introduced function. While our current prototype focuses on helper functions due to their API stability, the underlying isolation mechanism is generic and can be readily extended to kfuncs given their semantic similarity.

State Consistency. vBPF ensures concurrency safety by leveraging synchronization mechanisms like RCU for atomic updates. Our current design assumes exclusive access (e.g., via locking) and does not explicitly account for RCU readers. However, this could be addressed by first reading the base variable and then independently applying per-tenant patches. We agree that virtualizing some kernel states is impractical, but this limitation is intentional. For example, global resources like timers should remain immutable to tenants. Working with our static analyzer, vBPF empowers kernel developers to define strict safety boundaries.

vBPF ***vs. MicroVMs.*** Hardware isolation [15, 16, 58] enforces strict binary isolation. vBPF addresses its limitations in two ways. First, efficiency: MicroVMs incur significant memory and startup overheads, while vBPF provides process-level agility where VM costs are prohibitive. Second, controlled sharing: patterns like sidecars require safe introspection, not total isolation. Unlike MicroVMs, which block visibility, vBPF enables selective virtualization with hierarchical auditing while preventing interference.

Generality of the Sniffer. The *Sniffer* is designed to capture the relationship between synchronous resource allocation and asynchronous event execution. By tracking stable logical resources instead of volatile packet headers, vBPF can handle complex scenarios like network tunnels and connection migration. Furthermore, this mapping mechanism can be offloaded to hardware to eliminate runtime overhead.

9 Conclusion

We present vBPF, a virtualization layer that adopts a late-binding execution model. Guided by the insight of dynamic dispatch in polymorphic languages, vBPF resolves the fundamental architectural conflicts of the static-binding model through a context-aware *Sniffer*, a hierarchical *Dispatcher*, and a state isolation framework. This work opens new directions for building safe, multi-tenant eBPF ecosystems.

A Artifact Evaluation

This appendix describes the artifact for vBPF and how reviewers can build and exercise it. The artifact entry point is the `.github` repository under the GitHub organization:

https://github.com/vbpf-osdi-2026/

The profile README in that repository gives the full command-by-command guide. The artifact is split into four sibling repositories, which should be checked out under the same parent directory.

Repository	Contents
`llvm-vbpf`	LLVM, Clang, LLD, the vBPF compiler support, and the `VBPFAttribute` Clang plugin.
`linux-vbpf`	Linux 6.12 kernel tree with vBPF support and an evaluation-ready kernel configuration.
`vm`	QEMU/KVM virtual-machine scripts for booting and testing the vBPF kernel.
`ebpf-bootstrap`	Example eBPF programs, helper tools, `bpftool`, and test scripts used to exercise BPF namespaces.

Table 4: vBPF ***artifact repositories.***

A.1 Supported Claims

The artifact is designed to support the main functional claims of the paper. First, it builds the modified LLVM/Clang toolchain and the `VBPFAttribute` plugin used to check vBPF-related annotations during the kernel build. Second, it builds a Linux 6.12 kernel with the vBPF core, Sniffer, benchmark interface, and sample code enabled. Third, it boots that kernel in a QEMU/KVM VM and runs example eBPF programs in ordinary and isolated BPF namespaces. Fourth, it provides scripts to inspect namespace-local programs and maps and to run repeated loaders in one or more BPF namespaces.

The full performance study in §6 used an x86-64 machine with Intel Xeon Gold 6330 CPUs and 512 GB DRAM, Ubuntu 24.04 LTS, Linux 6.12, and an LLVM 20 based toolchain. The artifact VM is intended as a reviewer-friendly environment for build and functionality validation. The benchmark workloads in §6, including `lmbench`, UNIX Bench, PostgreSQL, Apache, `sysdig`, `netobserv-ebpf-agent`, and `sched_ext`, can be run on comparable hardware for performance reproduction.

A.2 Host Requirements

The artifact expects a Linux host with KVM support. On Ubuntu or Debian, the host-side dependencies are standard compiler, kernel-build, and QEMU packages:

```
sudo apt update
sudo apt install -y \
  git cmake ninja-build make clang lld llvm \
  build-essential pkg-config libelf-dev zlib1g-dev \
  libbfd-dev libcap-dev openssl libssl-dev binutils \
  qemu-system-x86 genisoimage bridge-utils
```

The VM launcher uses `uv` and Python 3.12 or newer. Reviewers should install `uv` if it is not already available on the host.

A.3 Checkout

The repositories should be placed under one artifact root so that scripts can refer to them consistently through `AE_ROOT`:

```
mkdir -p ~/vbpf-ae
cd ~/vbpf-ae

git clone https://github.com/vbpf-osdi-2026/llvm-vbpf.git
git clone https://github.com/vbpf-osdi-2026/linux-vbpf.git
git clone https://github.com/vbpf-osdi-2026/vm.git
git clone https://github.com/vbpf-osdi-2026/ebpf-bootstrap.git

export AE_ROOT="$PWD"
```

A.4 Build LLVM and the Static Analyzer

Reviewers first build the modified LLVM tree. This produces the Clang toolchain used by the kernel build and the `VBPFAttribute.so` plugin.

```
cd "$AE_ROOT/llvm-vbpf"

cmake -S llvm -B build -G Ninja \
  -DCMAKE_BUILD_TYPE=Release \
  -DLLVM_ENABLE_PROJECTS="clang;lld" \
  -DLLVM_TARGETS_TO_BUILD="X86;BPF" \
  -DCMAKE_INSTALL_PREFIX="$PWD/install"

cmake --build build
cmake --build build --target VBPFAttribute
sudo cmake --install build

export LLVM_HOME="$AE_ROOT/llvm-vbpf/build"
export PATH="$LLVM_HOME/bin:$PATH"
export LD_LIBRARY_PATH="$LLVM_HOME/lib:$LD_LIBRARY_PATH"
```

The expected sanity checks are that `clang –version` uses the newly built toolchain and that `$LLVM_HOME/lib/VBPFAttribute.so` exists. The LLVM repository also includes a standalone analyzer test at `clang/examples/VBPF/tests/test.c`. It intentionally contains both accepted and rejected helper patterns, so a non-zero exit status is expected when the analyzer reports unsafe global-state writes or unresolved unsafe calls.

A.5 Build the vBPF Kernel

The kernel is built after LLVM because the build loads the `VBPFAttribute` plugin. The provided configuration enables baseline BPF support, BPF JIT, BPF LSM instrumentation, `CONFIG_BPF_VBPF`, `CONFIG_VBPF_SNIFFER`, `CONFIG_VBPF_BENCH`, and the sample vBPF programs.

```
cd "$AE_ROOT/linux-vbpf"

make LLVM=1 -j"$(nproc)" \
  KCFLAGS="-fplugin=$LLVM_HOME/lib/VBPFAttribute.so \
  -Xclang -add-plugin -Xclang vbpf_attrs -ferror-limit=1000"
```

The kernel image used by the VM is:

```
$AE_ROOT/linux-vbpf/arch/x86/boot/bzImage
```

A.6 Prepare and Boot the VM

The `vm` repository prepares an Ubuntu guest image and boots it with the ▽BPF kernel. The first step initializes the image and cloud-init seed:

```
cd "$AE_ROOT/vm"
uv sync
uv run vm.py --prepare
```

The QEMU bridge helper should allow `virbr0`, and the bridge should be available before the first installation boot:

```
sudo mkdir -p /etc/qemu
echo "allow virbr0" | sudo tee /etc/qemu/bridge.conf
sudo chmod 0644 /etc/qemu/bridge.conf

sudo ip link add name virbr0 type bridge
sudo ip addr add 192.168.122.1/24 dev virbr0
sudo ip link set virbr0 up
```

If `virbr0` already exists, reviewers can keep the existing bridge. The first boot installs and initializes the guest:

```
uv run vm.py --install
```

After shutting down the initialized guest, reviewers set `kernel.path` in `$AE_ROOT/vm/config.json` to the absolute path of `linux-vbpf/arch/x86/boot/bzImage`. The VM can then be started with:

```
cd "$AE_ROOT/vm"
uv run vm.py
```

The default guest login is `ubuntu`/`ubuntu`, and the expected SSH address is `192.168.122.10`.

A.7 Build and Run the Examples

After the VM boots the ▽BPF kernel, reviewers copy the examples into the guest, install guest-side build dependencies, and build the loaders:

```
scp -r "$AE_ROOT/ebpf-bootstrap" ubuntu@192.168.122.10:~
ssh ubuntu@192.168.122.10
cd ~/ebpf-bootstrap

sudo apt update
sudo apt install -y \
  clang cmake make pkg-config libelf-dev zlib1g-dev git \
  libbfd-dev libcap-dev llvm-dev openssl libssl-dev \
  ninja-build g++-14

git submodule update --init --recursive
CXX=g++-14 cmake -S . -B build -G Ninja
cmake --build build
```

Before running loaders, reviewers should confirm that the ▽BPF kernel exposes BTF metadata:

```
ls /sys/kernel/btf/vmlinux
```

A basic end-to-end check starts the `kprobe` loader, observes trace output, and triggers events:

```
sudo ./build/kprobe
sudo mount -t debugfs none /sys/kernel/debug
sudo cat /sys/kernel/debug/tracing/trace_pipe
./trigger_kprobe.sh
```

The examples also provide a wrapper test:

```
sudo ./test.sh ./build/kprobe
```

A.8 Namespace Checks

Reviewers can inspect programs and maps in the current BPF namespace with the artifact-built `bpftool`:

```
sudo ./build/bpftool/bpftool prog show
sudo ./build/bpftool/bpftool map show
```

To exercise namespace isolation, the artifact provides an `unshare` helper that starts a loader inside a fresh BPF namespace:

```
sudo ./build/unshare -b ./build/kprobe
sudo ./build/unshare -b ./build/bpftool/bpftool prog show
sudo ./build/unshare -b ./build/bpftool/bpftool map show
```

For repeated loaders in one namespace or across nested BPF namespaces, use:

```
sudo ./multi.sh 4 -- ./build/kprobe
sudo ./ns_multi.sh ./build/kprobe 4 2
```

Successful runs show that eBPF programs and maps can be loaded, inspected, and isolated by BPF namespace under the ▽BPF kernel. These checks exercise the same mechanisms used by the paper's Sniffer and Dispatcher evaluation, while the larger performance experiments can be run with the benchmark workloads described in §6.

DVLA: Dynamic VM Lifetime Aware Scheduling for Drifting Lifetime Distributions and Long-Lived VM Placement Debt (Operational Systems)

Zhengtong Zhang, Zihan Xu, Zhidong Hu, Yanbo Shan, Fei Peng, Suhong Chen,
Kaiyuan Shen, Xiangyun Kong, Handu Ding, Bing He, Binda Ma

Alibaba Cloud Computing

Abstract

Efficient Virtual Machine (VM) scheduling is critical for maximizing resource utilization in cloud computing. However, state-of-the-art lifetime-aware schedulers face two critical issues in real-world deployments. First, their static policies are brittle against the significant *spatial and temporal drifts of VM lifetime distributions*. Second, and more insidiously, their placement strategies inadvertently scatter long-lived VMs, creating a persistent *long-lived VM placement debt*. This debt, compounded by inevitable prediction errors, pins down machines and cripples cluster-wide resource reclamation, and cannot be repaid by online scheduling alone.

To address these challenges, we present *Dynamic VM Lifetime Aware scheduling (DVLA)*, an end-to-end system that synergistically combines online scheduling with offline rectification. DVLA comprises four key components: (1) a Hierarchical Lifetime Prediction Model that delivers multi-horizon predictions to inform both initial placement and offline optimization; (2) a Dynamic Affinity Grouping strategy that adapts to workload distribution drifts in real time; (3) a Debt-Aware Placement Policy (DAPP) that proactively consolidates long-lived VMs to minimize debt creation at the source; and (4) a Placement Debt Rectification Engine (PDRE) that employs strategic live migrations to amortize accumulated debt offline. Extensive trace-driven simulations and a large-scale production deployment at Alibaba Cloud demonstrate that DVLA consistently outperforms state-of-the-art methods, achieving an additional 0.6 percentage points in packing density. This translates to saving thousands of machines in production, delivering substantial cost reductions.

1 Introduction

In large-scale cloud infrastructure, the physical footprint required to host VMs is governed by Packing Density (PD, Eq. 1). Because infrastructure capital and operational costs scale directly with the physical machine count, even a one percentage point (pp) increase in PD can translate into hundreds of millions of dollars in annual savings [8]. Production schedulers at major cloud providers [5, 13, 14, 46] therefore strive to maximize PD by casting VM placement as a large-scale dynamic bin-packing problem, and a leading approach leverages VM lifetime predictions to guide placement and improve utilization [8, 16, 33, 42]. Promising as they are, we find that these lifetime-aware schedulers break down in large-scale, real-world deployments.

Through a systematic analysis of production workloads, we identify two fundamental issues that undermine existing methods. First, their static policies are brittle. Lifetime-aware schedulers rely on fixed, hard-coded lifetime categories, yet VM lifetime distributions exhibit significant *spatial and temporal drift* across clusters and over time, rendering any fixed strategy ineffective. Second, and more insidiously, their placement strategies accumulate what we term *long-lived VM placement debt*—a persistent, cluster-wide inefficiency that directly inflates the number of machines a cluster must maintain to serve the same workload. As we formalize in Section 2.4, a suboptimal long-lived VM packing density (PD_L) translates into L_{debt} additional machines that could otherwise be reclaimed (Eq. 3), a concrete and measurable cost.

This debt arises from a flawed placement philosophy. Strategies such as LAVA [33], which co-locate short-lived VMs with long-lived ones, optimize for single-machine packing at the expense of scattering long-lived VMs across the cluster. Compounded by inevitable lifetime-prediction errors, this dispersion strands many machines for extended periods: our production data show that even a single suboptimally placed long-lived VM dramatically prolongs machine occupancy and reduces recycling frequency (Figure 4a). The result is fragmentation that cripples cluster-wide reclamation and accumulates a persistent debt that online scheduling alone cannot resolve.

To address these challenges, we present *Dynamic VM Lifetime Aware scheduling (DVLA)*, an end-to-end system that synergistically combines online and offline scheduling. DVLA includes four key components. To provide the foundational lifetime estimates, (1) a Hierarchical Lifetime Prediction

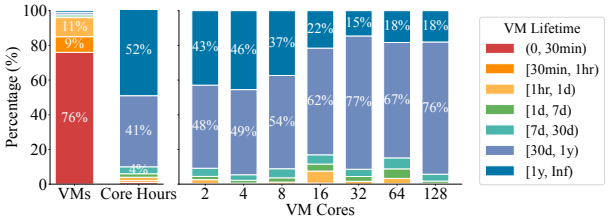

Figure 1: VM lifetime distribution. Left: Request volume vs. core-hours consumption. Right: Lifetime distribution by cores. Long-lived VMs dominate resource footprint.

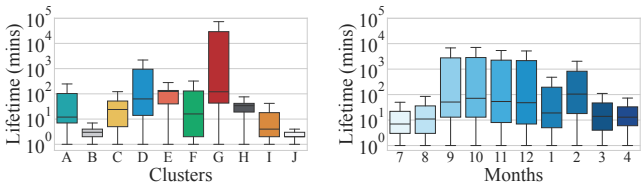


(a) Cross-cluster heterogeneity. (b) Intra-cluster temporal drift.

Figure 2: The spatial and temporal volatility of VM lifetimes.

Model delivers multi-horizon predictions informing both online placement decisions and offline optimization. To counter distribution drifts, (2) a Dynamic Affinity Grouping strategy with a lightweight change-point detector adapts scheduling policies in real time. To mitigate placement debt at the source, (3) a Debt-Aware Placement Policy (DAPP) guides the online scheduler to proactively consolidate long-lived VMs. Finally, to handle the unavoidable accumulated debt, (4) a Placement Debt Rectification Engine (PDRE) employs strategic live migrations to amortize this debt offline.

In summary, the primary contributions of this paper are:

- We perform the first systematic study that identifies and quantifies the dual challenges of distribution drifts and long-lived VM placement debt, revealing the fundamental limitations of static, online-only schedulers.
- We design and implement DVLA, an end-to-end system that uniquely synergizes a dynamic online strategy to adapt to distribution drifts and prevent debt creation with a targeted offline mechanism to amortize placement debt.
- We demonstrate DVLA's effectiveness through both extensive trace-driven simulations and a large-scale production deployment at Alibaba Cloud, confirming substantial resource savings with manageable overhead.

2 Background

2.1 The Nature of VM Lifetimes in Cloud

Analysis of our production environment, spanning millions of daily allocations, reveals a significant long-tail distribution in VM lifetimes. As shown in the left panel of Figure 1, while short-lived VMs (<1 day) account for 96% of total requests, they contribute less than 2% to total core-hours. In contrast, long-lived VMs (>1 month) dominate resource consumption, representing 93% of core-hours despite comprising only 2.5% of requests. The right panel further breaks down this lifetime distribution by VM cores using data from active production VMs, revealing that long-lived VMs consistently command the majority of resources across all configurations. Notably, this concentration is even more pronounced in smaller VMs (e.g., $\leq$8 cores). These findings underscore that optimizing for long-lived VMs is critical for resource efficiency.

In our infrastructure, a zone comprises multiple clusters. Within a cluster, machines are homogeneous, yet significant heterogeneity exists across clusters within the same zone. Consequently, VM lifetime distributions across clusters are neither uniform nor static. As Figure 2a demonstrates, lifetime profiles exhibit significant spatial heterogeneity across clusters at a single point in time. In some clusters (e.g., B, J), the vast majority of VMs are short-lived, while in others (e.g., E, G), they are predominantly long-running. Furthermore, Figure 2b illustrates substantial temporal drift within individual clusters over months. This spatial and temporal volatility renders static scheduling policies suboptimal, a critical challenge we quantify in Section 3.

2.2 Online and Offline Schedulers

Online Scheduler. The online scheduler handles VM placement when a new VM is being created. Following a common *filter-and-score* paradigm [8, 24, 25, 53], it first filters for candidate machines that meet a VM's resource and constraint requirements. It then scores these candidates to optimize for objectives like packing efficiency and service stability. Strict latency requirements force online decisions to be fast and greedy, causing resource fragmentation over time.

Offline Scheduler. The offline scheduler complements its online counterpart by periodically correcting the fragmentation and suboptimal placements that inevitably accumulate. By performing global analysis and orchestrating live migrations, it consolidates target VMs to reclaim underutilized machines. However, this process is slow and resource-intensive, making it an insufficient remedy on its own for the relentless accumulation of placement errors. This fundamental limitation motivates our synergistic design, which combines proactive online prevention with reactive offline correction.

2.3 VM Lifetime Prediction in Scheduling

Schedulers leverage VM lifetime information to improve resource utilization and accelerate machine reclamation, employing strategies that fall into two main categories. Homogeneous placement, exemplified by LA [8] and NILAS [33],

aims to co-locate VMs with similar predicted lifetimes for synchronized machine reclamation. Heterogeneous placement, adopted by LAVA [33], intentionally co-locates short-lived VMs with long-lived ones to fill resource fragments without further extending the machine's reclamation timeline.

The effective implementation of any lifetime-aware strategy hinges on accurate prediction. This requires two models to suit different operational needs: (1) a low-latency *Initial Lifetime Prediction* at VM creation for the online scheduler, using static request features; and (2) a more accurate *Remaining Lifetime Prediction* for running VMs, which leverages rich runtime data. To manage the inherent uncertainty in lifetime prediction, prior works employ two methodologies: regression and classification. Regression models [31, 33], while predicting exact durations, exhibit high variance in long-tailed environments. They struggle to maintain precision across diverse lifetime ranges, and their sensitivity to extreme values leads to significant numerical deviations, ultimately causing poor co-location and increased resource fragmentation.

In contrast, classification models [8, 10, 16] map lifetimes into discrete categories (e.g., [1d, 7d)) and are more robust. By quantizing lifetime uncertainty into limited buckets, classification mitigates the impact of extreme-value errors. This approach trades overly fine-grained estimates for robustness, ensuring that scheduling decisions remain resilient to the inherent noise and volatility of cloud workloads.

2.4 Metric Definitions

To quantitatively assess the impact of VM placement strategies on cluster-wide resource efficiency, we define three foundational metrics. These metrics enable us to differentiate between overall packing density and the infrastructure overhead incurred by dispersion of long-lived VMs.

Packing Density (PD). A standard metric for overall packing efficiency in [8], defined as the ratio of total allocated cores to the total cores on all non-empty machines, computed as:

$$PD = \frac{\sum_{i=1}^{V} C_{vm,i}}{\sum_{j=1}^{M} C_{pm,j}} \tag{1}$$

where V is the number of VMs, M is the number of non-empty machines, $C_{vm,i}$ is the number of cores for VM i, $C_{pm,j}$ is the number of cores for physical machine j.

Long-Lived VM Packing Density (PD_L). Since long-lived VMs dominate core-hour consumption, we isolate their packing efficiency using PD_L:

$$PD_L = \frac{\sum_{i=1}^{V_{long}} C_{vm,i}}{\sum_{j=1}^{M_{long}} C_{pm,j}} \tag{2}$$

where V_{long} is the number of long-lived VMs, M_{long} is the number of machines hosting at least one long-lived VM. This metric specifically targets the consolidation of high-value, long-lived VMs, making a higher PD_L an indicator of more effective debt reduction and machine reclamation potential.

Long-lived VM Placement Debt (L_{debt}). We quantify the infrastructure overhead induced by long-lived VM dispersion as *Long-lived Placement Debt* (L_{debt}). It represents the number of machines that could be reclaimed if the current PD_L were improved to a target operational density ρ_{target}, which represents the achievable packing limit in production. We define L_{debt} as:

$$L_{debt} \approx M_{long} - \frac{\sum_{i=1}^{V_{long}} C_{vm,i}}{\frac{\sum_{j=1}^{M_{long}} C_{pm,j}}{M_{long}} \cdot \rho_{target}} = M_{long} \cdot \left(1 - \frac{PD_L}{\rho_{target}}\right) \tag{3}$$

L_{debt} bridges the gap between long-lived VM placement quality and machine wastage. A sub-optimal PD_L translates directly into a positive L_{debt}, forcing the cluster to maintain an unnecessarily large M_{long}. While L_{debt} quantifies the theoretical infrastructure overhead at the cluster level, *Stranded Machines* provide an operational measure at the individual machine level. Specifically, a machine is considered stranded when it hosts one or more long-lived VMs, but their core utilization remains below 50%. In the following section, we use Stranded Machines as the measurable manifestation of placement debt to evaluate standalone and synergistic strategies.

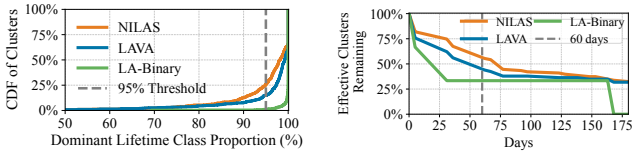
3 Motivation

Achieving high resource efficiency through lifetime-aware scheduling is deceptively complex. State-of-the-art schedulers are undermined by two fundamental challenges in real-world cloud environments: the brittleness of static policies against distribution drifts, and a flawed placement philosophy that creates compounding, long-lived VM placement debt.

3.1 Static Policies are Brittle

Prevailing lifetime-aware schedulers, such as LA-Binary [8], NILAS [33], and LAVA [33], rely on rigid, hard-coded categorization. LA-Binary uses {≤1h,>1h}, NILAS uses a 12-interval grid {0m,...,168h}, and LAVA uses {<1h,1-10h,10-100h,100-1000h}. These methods apply fixed categories uniformly across all clusters, ignoring the significant spatial and temporal drifts in VM lifetime.

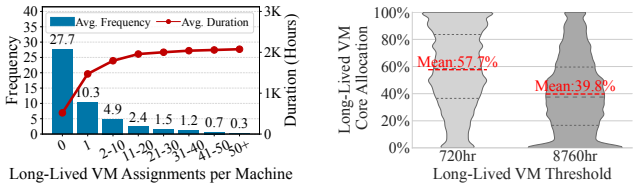
Ineffectiveness Against Spatial Diversity. To evaluate these categorization policies, we define a policy as *applicable* to a cluster if the VM lifetime distribution provides sufficient diversity (i.e., no single lifetime category contains ≥95% of the VMs). When a policy concentrates most of the VMs into a single category, it loses the ability to differentiate workloads, collapsing into random placement. Figure 3a reveals that these policies are inapplicable: for LA-Binary, nearly all clusters fail this diversity criterion; for NILAS and LAVA,



(a) High homogeneity (>95% in one category) renders static policies ineffective across clusters.

(b) Temporal decay showing that policy applicability drops as lifetime distributions drift over time.

Figure 3: Static categorization is ineffective against the spatial diversity and temporal dynamics of real-world workloads.



(a) Machine recycle frequency and occupied duration relative to the number of long-lived VMs.

(b) Per-Machine core allocation of long-lived VMs, revealing suboptimal consolidation.

Figure 4: Long-lived VMs drive machine occupancy and remain poorly consolidated.

85% and 74% of clusters, respectively, exhibit this lack of differentiation.

Decay Under Temporal Drifts. Even if a policy is initially applicable, it inevitably degrades as VM lifetime distributions evolve. Figure 3b tracks the fraction of clusters where policies remain applicable. As VM lifetime distributions drift, the applicability of NILAS and LAVA drops to 55% and 44% within 60 days, while LA-Binary's applicability collapses even faster.

This spatial and temporal volatility demonstrates that static categorizations are fundamentally inadequate for real-world workloads, motivating our DVLA design: a dynamic grouping mechanism that continuously adapts to lifetime distribution drifts within each cluster.

3.2 Long-Lived VM Placement Debt

Beyond the brittleness of static policies, a more insidious problem undermines state-of-the-art schedulers: their placement philosophies inevitably create a compounding, cluster-wide inefficiency we term long-lived VM placement debt. This debt stems directly from a flawed understanding of how to manage the most resource-dominant long-lived VMs.

The Flawed Philosophies of Prior Work. Existing lifetime-aware strategies fall into two camps, both of which inadvertently create placement debt. On one side, schedulers like LA [8] and NILAS [33] champion homogeneous placement, aiming to co-locate VMs with similar lifetimes. However, their design exhibits a narrow definition of long-lived. By focusing their finest-grained categories on VMs lasting up to only three or seven days, they overlook the truly resource-dominant VMs that persist for weeks or even months. Consequently, these schedulers fail to prioritize the aggregation of these critical long-lived VMs, leading to their gradual dispersion and the accumulation of placement debt.

On the other side, schedulers like LAVA [33] advocate for the opposite: heterogeneous placement. They intentionally co-locate short-lived VMs with long-lived ones to maximize single-machine packing density. While this provides local packing benefits, the strategy is counterproductive at the cluster level. It systematically scatters long-lived VMs across the fleet, directly creating placement debt, crippling global resource reclamation efforts.

The Enormous Cost of Placement Debt. Long-lived VMs dictate machine reclamation timelines because they dominate long-term resource consumption (Figure 1). Figure 4a shows that as the number of allocated long-lived VMs increases, machines experience longer occupancy and fewer recycles. The drastic gap between 0 and 1 allocation identifies the first long-lived VM as the primary driver of machine pinning, with diminishing marginal impact thereafter. This confirms that consolidating long-lived VMs effectively limits their footprint, maximizing cluster-wide reclamation.

Despite the necessity for consolidation, Figure 4b exposes a significant inefficiency in current production placement. We analyzed the core allocation of VMs with remaining lifetimes exceeding 720h (1 month) and 8760h (1 year). Their average utilization remains strikingly low at 57.7% and 39.8%, respectively. This reveals that long-lived VMs are rarely densely co-located in practice. Such poor consolidation creates a substantial opportunity for smarter, lifetime-aware strategies to improve cluster-wide resource utilization.

The Inevitable Accumulation of Debt. This placement debt, originating from flawed scheduling philosophies, is further compounded by an unavoidable operational reality: imperfect predictions. Even with a highly accurate model, prediction errors guarantee a continuous stream of misplacements.

For instance, consider a modest 5% error rate of misclassifying a long-lived VM as short-lived. Assuming independent errors, placing just 14 such presumed-short VMs onto a single machine yields an over-50% probability that the machine hosts at least one true long-lived VM, blocking its timely reclamation. When scaled across millions of daily allocations, this compounding effect ensures a relentless increase in the placement debt of the cluster.

3.3 Limitations of Standalone Strategies

Given the persistent accumulation of placement debt, a natural question arises: can this debt be managed by employing either aggressive offline correction or refined online prevention?

We argue that both standalone approaches are fundamentally insufficient, making a synergistic strategy essential.

As illustrated in Figure 5, we evaluate three placement strategies via trace-driven simulations on empty clusters using production workloads. *Online-Only* enforces lifetime affinity during initial placement for long-lived VMs, incorporating a 5% prediction error rate that occasionally disrupts affinity by placing long-lived VMs on non-affine machines. In contrast, *Offline-Only* disregards affinity during initial allocation, relying instead on limited daily offline rebalancing to consolidate long-lived VMs. Finally, *Online+Offline* hybridizes these approaches by combining online lifetime-aware placement with periodic offline consolidation.

Why Offline-Only Correction Fails. Relying solely on offline migration to repay placement debt is a losing battle for two reasons. First, the operational scope is heavily constrained. Our production analysis (Table 1) reveals that 40% of VMs are structurally non-migratable due to hardware dependencies, workload constraints, or policy restrictions. Second, even for the migratable subset, the rate of new debt creation far outpaces feasible correction capacity. As shown in Figure 5, an offline-only strategy, even with more migration budget, fails to curb the growth of debt.

Why Online-Only Prevention is Insufficient. Conversely, a purely proactive, online-only strategy can slow the creation of debt but cannot eliminate it. Inevitable prediction errors will always introduce new misplacements. Furthermore, an online scheduler makes greedy, largely irrevocable decisions and is powerless to fix the debt that has already accumulated from past mistakes. Figure 5 quantifies this limitation: under an online-only policy, the number of misplaced long-lived VMs grows unabated, demonstrating that prevention alone cannot solve a cumulative problem.

This analysis leads to a crucial insight: an effective system must address placement debt on two fronts simultaneously. It requires an online scheduler that minimizes debt creation at the source, coupled with a targeted offline mechanism that strategically amortizes the accumulated debt. This synergistic philosophy is the core motivation for DVLA's design.

Table 1: Breakdown of VM migration constraints.

Constraint Type	Proportion (%)
Migratable	60
Workload Constraints	20
Hardware Dependencies	14
Policy & SLA Restrictions	5
Other	1

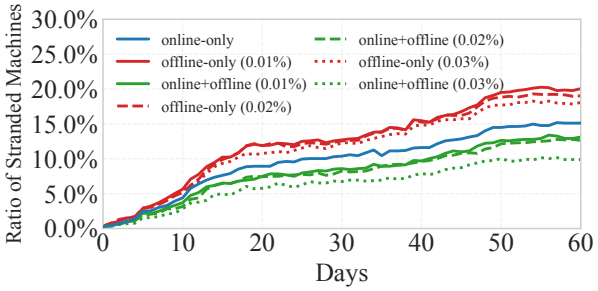


Figure 5: Proportion of stranded machines under three allocation strategies, varying by migration budget (ratio of migrated to total VMs).

4 DVLA Design

Section 3 demonstrated that static lifetime-aware policies are brittle against distribution drifts and inadvertently create long-lived VM placement debt. To overcome these challenges, we designed DVLA, a system that synergistically combines online prevention with offline correction. This section details DVLA's core design components: (1) A Hierarchical Lifetime Prediction Model delivering multi-horizon predictions for both initial placement and offline optimization (Section 4.1); (2) A Dynamic Affinity Grouping strategy that detects and adapts to distribution drifts in real-time (Section 4.2); (3) A Debt-Aware Placement Policy (DAPP) for the online scheduler to proactively consolidate long-lived VMs and prevent debt creation (Section 4.3); (4) A Placement Debt Rectification Engine (PDRE) that employs live migrations to amortize accumulated debt (Section 4.4).

4.1 VM Lifetime Prediction Model

Accurate lifetime prediction is the cornerstone of DVLA. To address the rigidity of static categorization, we implement a two-tiered, extensible prediction framework that decouples lifetime threshold definition from scheduling policy.

Extensible OvR Architecture. We employ a One-vs-Rest (OvR) binary classification design where each lifetime threshold is handled by an independent model. This modularity allows us to refine or extend granularity (e.g., a 15-minute granularity for bursty microservices) by training specific binary classifiers without retraining the entire system. While we utilize the set [0–1hr, 1hr–1d, 1d–7d, 7d–30d, 30d-1y, >1y] in production, these remain environment-specific parameters rather than hard-coded constraints.

Hierarchical Prediction Architecture. The system consists of two specialized models: (1) Initial Lifetime Prediction, which provides low-latency inference at VM creation using static request features; and (2) Remaining Lifetime Prediction, which executes offline to provide more accurate estimates for running VMs by incorporating rich dynamic runtime metrics.

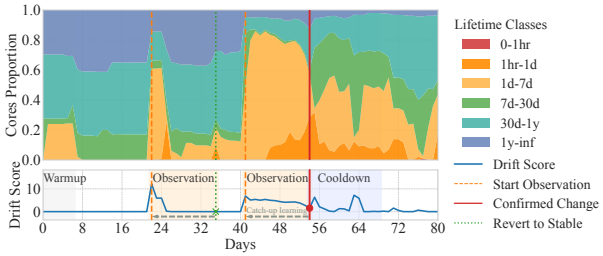

Figure 6: An illustrative dynamic affinity grouping process handles workload changes by first dismissing a transient spike (day 22) as noise, then correctly identifying and adapting to a persistent shift (day 41) by triggering a policy update.

As detailed in Appendix A, our feature importance analysis confirms that while the Initial prediction model captures application semantics, the Remaining prediction model extracts essential insights from survival history, providing a robust signal for our subsequent Dynamic Affinity Grouping mechanism.

4.2 Dynamic Affinity Grouping

As demonstrated in Section 3.1, any static lifetime categorization policy is brittle against the spatial and temporal drifts of real-world workloads. To overcome this, DVLA introduces a dynamic affinity grouping strategy. This mechanism continuously monitors cluster-wide workload to dynamically recalibrate affinity groups, ensuring that scheduling decisions remain aligned with the distribution of VM lifetimes. The entire process is detailed in Algorithm 1. The strategy operates as a robust daily cycle driven by state-machines, distinguishing persistent structural shifts from transient workload noise to prevent policy instability. Figure 6 presents an illustrative example of the mechanism operating on a real-world trace. The key stages of this mechanism are detailed below.

Workload Vectorization and Drift Scoring. Each day, we compute a cores distribution vector for the cluster, representing the proportion of total CPU cores consumed by running VMs in each global lifetime class. We monitor running VMs, not just incoming requests, as this reflects the actual resource landscape the scheduler must manage. This time series of vectors is fed into a lightweight change-point detector. The detector maintains an Exponentially Weighted Moving Average (EWMA) of historical vectors as a dynamic baseline of the cluster's normal state. A daily drift score is calculated as the cosine distance between the current day's vector and this baseline (line 7), flagging significant deviations in the distribution's shape. We use cosine distance as it is effective at capturing changes in the shape of the distribution, independent of the overall core volume.

State-Machine-Based Drift Confirmation. To distinguish persistent shifts from transient noise, a finite state machine (FSM) interprets the stream of drift scores. The FSM transitions between *Warmup, Stable, Observation*, and *Cooldown* states. When the policy is first applied to a new cluster, it enters a *Warmup* phase for an initial period. During this phase, the system exclusively collects data to establish the initial EWMA baseline (lines 9-12), without triggering any alarms. Once initialized, the system transitions to the *Stable* state (line 12), where it continuously updates the baseline with new daily vectors as long as the drift score remains below a predefined alarm threshold θ_{alarm} (lines 13-15).

A high drift score moves the system from *Stable* to *Observation* (lines 15-17), where it collects data for a fixed window W_{obs} (line 19) without updating the baseline. If the drift is confirmed as persistent, a policy update is triggered (lines 23-26). Otherwise, the event is dismissed as noise, and the system performs catch-up learning by retrospectively incorporating the data from the observation window into the baseline, ensuring that it accurately reflects the new normal (line 30).

Adaptive Affinity Group Generation. Upon a confirmed change, a new affinity group $G_{affinity}$ is generated (line 24). The algorithm sorts the global lifetime classes in descending order of their average core consumption during the observation window and greedily selects the top-ranked classes until their cumulative consumption exceeds a 95% threshold. For instance, if classes representing 0-1hr, 1d-7d, and 30d-1y are the most resource-intensive, the new affinity group becomes $\{$0-1hr, 1d-7d, 30d-1y$\}$. After an update, the system enters a *Cooldown* period to prevent oscillatory changes (line 27).

This mechanism counters policy decay by keeping affinity groups aligned with workload dynamics. While Algorithm 1 provides the overall control flow, the detailed formulations for its key functions are consolidated in Appendix B.

4.3 Proactive Debt Mitigation with DAPP

While Dynamic Affinity Grouping (Section 4.2) determines which lifetime categories are significant, it does not specify how to use them to prevent placement debt. To address this, we introduce the Debt-Aware Placement Policy (DAPP), a two-part mechanism designed to proactively mitigate debt at the source. DAPP advances the homogeneous placement principle [8, 33] by first, robustly classifying machines using a core-weighted method that is resilient to existing fragmentation, and second, applying an asymmetric affinity score that heavily penalizes debt-creating placements. We detail these two components below.

Robust Machine Lifetime Classification. To determine a machine's lifetime category, we first need to represent VM lifetimes numerically. Our system predefines a set of fine-grained lifetime classes (e.g., 0-1h, 1h-1d, 1d-7d, etc.), which are then mapped to ascending integer indices (e.g., 1, 2, 3, ...). This mapping provides a standardized numerical representation, L(vm), for a VM's lifetime class, which is essential for

Algorithm 1 Workload Drift Detection and Policy Adaptation

Input: Workload trace $T = \{v_1, v_2, ..., v_N\}$, Config C
Initialize:
  $State \leftarrow$ WARMUP
  $Detector \leftarrow$ DriftDetector(C)
  $t_{obs_start} \leftarrow -1$, $t_{update} \leftarrow -1$
for each day t with workload vector v_t in T **do**
  $score_t \leftarrow Detector$.Score($v_t$)
  switch $State$ **do**
    case WARMUP:
      $Detector$.Learn(v_t)
      if $t \geq C.P_{\text{warmup}}$ **then**
        $State \leftarrow$ STABLE
    case STABLE:
      $Detector$.Learn(v_t)
      if $score_t > C.\theta_{alarm}$ **then**
        $State \leftarrow$ OBSERVATION
        $t_{obs_start} \leftarrow t$
    case OBSERVATION:
      if $t - t_{obs_start} + 1 \geq C.W_{obs}$ **then**
        $V_{obs} \leftarrow$ GetVectorsInWindow(T, t_{obs_start}, t)
        $S_{obs} \leftarrow \{$Detector.Score(v) $\mid v \in V_{obs}\}$
        avg_score $\leftarrow$ Mean(S_{obs})
      if avg_score $\geq C.\theta_{confirm}$ **then**
        $G_{affinity} \leftarrow$ GenerateAffinityGroup(V_{obs}, C)
        UpdateSystemPolicy($G_{affinity}$)
        $t_{update} \leftarrow t$
        $Detector$.CatchUpLearn(V_{obs})
        $State \leftarrow$ COOLDOWN
      else
        $State \leftarrow$ STABLE
        $Detector$.CatchUpLearn(V_{obs})
    case COOLDOWN:
      if $t \geq t_{update} + C.P_{cooldown}$ **then**
        $State \leftarrow$ STABLE
  end switch

the calculations in both Eq. 4 and Algorithm 2.

A common approach in prior work is to use the lifetime of the longest-running VM (a MAX rule) to define a machine's category. However, our analysis revealed this is brittle in production clusters where long-lived VMs are already scattered. In such scenarios, where many machines host at least one long-lived VM (as suggested by Figure 4a), a MAX rule would classify nearly all of them as long-lived, rendering any subsequent affinity scoring ineffective. To address this, we compute a more robust, core-weighted average lifetime index for the machine, $L_{raw}(pm)$, as defined in Eq. 4. This method is less sensitive to the presence of a single long-lived VM and better reflects the machine's overall lifetime character.

$$L_{raw}(pm) = \sum_{i=1}^{n} \left(\frac{C_{vm,i}}{\sum_{j=1}^{n} C_{vm,j}} \times L(vm_i) \right) \tag{4}$$

Algorithm 2 Machine Lifetime Category Calculation

Input: A machine pm; the affinity group $G_{affinity}$
Initialize:
  Calculate $L_{raw}(pm)$ using Eq. (4)
  $min_dist \leftarrow \infty$
  $L_{pm} \leftarrow -1$
Output: The machine's lifetime category L_{pm}
for each lifetime category c in $G_{affinity}$ **do**
  $dist \leftarrow |c - L_{raw}(pm)|$
  if $dist < min_dist$ **then**
    $min_dist \leftarrow dist$
    $L_{pm} \leftarrow c$
  else if $dist = min_dist$ **then**
    $L_{pm} \leftarrow \max(L_{pm}, c)$
return L_{pm}

where vm_i denotes the i-th VM among n VMs running on the machine, $L(vm_i)$ is the numerical index of the lifetime class for vm_i, $C_{vm,i}$ represents the core allocation of vm_i.

This continuous L_{raw} value is then mapped to a discrete category. Crucially, the set of possible categories for a machine is not globally fixed, it is constrained by the cluster's current affinity group $G_{affinity}$, as determined by Dynamic Affinity Grouping (Section 4.2). This ensures a machine's category is always relevant to the prevailing workload. Algorithm 2 performs this mapping by finding the category index c within $G_{affinity}$ that has the minimum distance to L_{raw}. In case of a tie, we conservatively select the larger category index, ensuring a machine on the boundary is treated as the longer-lived one to further mitigate placement debt risk.

Asymmetric Affinity Scoring. With the VM and machine categories determined, DAPP's affinity score calculates their placement compatibility. The score is defined in Eq. 5 and is designed to aggressively penalize debt-creating placements while remaining flexible for others.

$$\text{Score}(vm, pm) = \begin{cases} 1, & \text{if } L_{vm} = L_{pm} \\ \dfrac{K - |L_{vm} - L_{pm}|}{K}, & \text{if } L_{vm} < L_{pm} \\ \dfrac{K - |L_{vm} - L_{pm}|}{K} \times \omega, & \text{if } L_{vm} > L_{pm} \end{cases} \tag{5}$$

where L_{vm} and L_{pm} are the lifetime category indices for the VM and machine. K is the total number of global lifetime classes. The key lies in the adaptive penalty factor ω, which is applied only when placing a longer-lived VM onto a shorter-lived machine ($L_{vm} > L_{pm}$).

The core mechanism is an asymmetric penalty designed to prevent placement debt. It exclusively penalizes placing a longer-lived VM on a shorter-lived machine. The penalty is twofold: a standard one (e.g.,$\omega = 0.8$) for general mismatches, and a harsher one (e.g.,$\omega = 0.2$) for placing a VM with a life-

time over one month. This severe penalty effectively blocks debt-creating placements and forces the consolidation of these critical VMs.

4.4 Amortizing Placement Debt with PDRE

While DAPP proactively minimizes debt creation, prediction errors make some accumulation of placement debt inevitable. To address this residual debt, we designed the Placement Debt Rectification Engine (PDRE), a targeted offline mechanism. Unlike generic defragmenters, PDRE is not focused on overall cluster packing. Instead, it is focused on amortizing the most costly placement debt. PDRE operates in a three-stage process: identifying targets, prioritizing migrations, and executing placements under strict constraints.

Identifying Stranded VMs. PDRE's first task is to locate *stranded VMs*, i.e., long-lived VMs that reside on stranded machines. To do this with high confidence, it leverages the more accurate Remaining Lifetime Prediction model, allowing PDRE to identify VMs with over one month of expected remaining lifetime. Crucially, non-migratable long-lived VMs are excluded from this set.

Migration Prioritization. To maximize the return on a limited migration budget, PDRE prioritizes candidates using a two-tiered strategy. It first targets machines that are easiest to reclaim (i.e., those with the fewest *stranded* VMs). Machines hosting any non-migratable long-lived VM are strictly excluded from consideration. Within this group, it then prioritizes migrating the VMs with the greatest remaining lifetime. This deterministic sorting ensures that each migration delivers the maximum impact towards machine reclamation.

Constrained Placement Execution. The prioritized list of VMs is not migrated blindly. Instead, it is passed to a unified offline scheduler that finds optimal destinations to colocate them with other long-lived VMs. The entire process is governed by production-safe constraints, including migration budgets to limit system disruption and net-positive gain requirements to ensure every action is beneficial. By strategically amortizing placement debt, PDRE acts as the indispensable offline counterpart to our proactive online scheduler, completing DVLA's synergistic approach.

5 System Architecture and Implementation

This section details the production-grade architecture of DVLA, bridging the design principles to a robust implementation. As shown in Figure 7, our system integrates three key components: (1) an online scheduling pipeline for real-time, debt-aware VM allocation; (2) a Placement Debt Rectification Engine (PDRE) for offline debt amortization; and (3) a set of core services for state management and policy adaptation. We will first detail the architecture (Section 5.1), then discuss the key engineering solutions for production deployment (Section 5.2) and operational monitoring (Section 5.3).

5.1 System Architecture

Online Scheduling for Proactive Debt Mitigation. The online scheduler is the first line of defense against placement debt. It handles real-time VM allocation requests with stringent latency constraints ($< 100\,ms$) and is engineered to proactively consolidate long-lived VMs.

Low-Latency Lifetime Prediction. When a scheduling request arrives, the control service injects an initial lifetime prediction. To meet the tight latency budget, we designed a multi-tiered prediction strategy. First, an in-memory prediction cache serves predictions for recurring request features (e.g., user ID, cores), achieving more than 90% hit rate. For a cache miss, the request is sent to a fleet of auto-scaling inference servers. This remote inference is designed to complete within a few tens of milliseconds of latency budget, including network overhead, preventing it from becoming the critical path.

DAPP-based VM Allocation. The allocation process is critically enhanced by DAPP. To compute the score efficiently, the lifetime category of the incoming VM is obtained from the prediction service, while the category of each candidate machine is pre-calculated and retrieved from a low-latency, distributed Machine Tag Cache. This design trades slightly stale machine state for low scoring latency. The state is kept fresh via the Tag Update Service (Section 5.2), which ensures that tag staleness rarely impacts placement quality.

Dynamic Affinity Grouping Engine. To combat the policy decay caused by lifetime distribution drifts (Section 3.1), DVLA incorporates a Dynamic Affinity Grouping Engine. This engine implements the adaptive policy mechanism detailed in Section 4.2 and Algorithm 1.

Orchestration. It operates as a daily scheduled task that analyzes the cores distribution vector of each cluster, using up-to-date data from the Remaining Lifetime Prediction model.

Stateful Drift Detection. The engine feeds this data into the change-point detector, which uses a state machine to distinguish persistent distributional shifts. The engine's state machine for each cluster is persisted to ensure robustness.

Policy Deployment. Upon confirming a persistent drift, the engine generates a new, optimized set of affinity groups for the cluster. This updated policy is then propagated to the online scheduling servers and the Tag Update Service, ensuring that subsequent placement decisions and machine state calculations are based on the most relevant lifetime categorization.

PDRE for Amortizing Accumulated Debt. The Placement Debt Rectification Engine (PDRE) is our offline component designed to amortize accumulated placement debt. It operates as a periodic task, leveraging the high-fidelity Remaining Lifetime Prediction model to identify and execute strategic live migrations. In our production implementation, PDRE

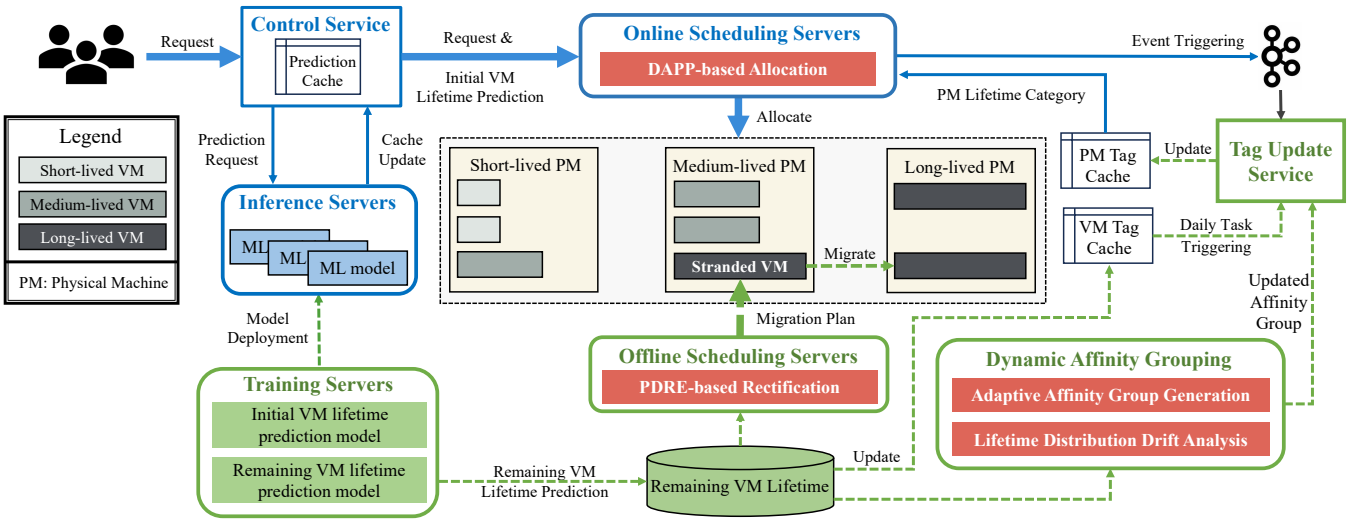

Figure 7: Overview of the online and offline scheduling architecture with DVLA.

is integrated with the cluster's maintenance workflow and focuses on two high-impact scenarios.

Consolidating Stranded Long-Lived VMs. PDRE scans for machines pinned by only a few migratable long-lived VMs. It then generates migration tasks to move these stranded VMs to existing long-lived consolidated machines, maximizing the potential for machine reclamation.

Efficient Machine Evacuation. When a machine is scheduled for maintenance, PDRE provides an optimized evacuation plan. It prioritizes migrating VMs with the longest remaining lifetimes first, while leaving short-lived VMs to terminate naturally. This strategy, similar to LARS [33], minimizes migration volume and accelerates the machine draining process.

Core State Management and Synchronization. The accuracy of DVLA's decisions hinges on up-to-date lifetime state, managed by a dedicated Tag Update Service. This service must provide fresh data without overwhelming the system, a challenge we address with a dual-mechanism design and performance optimizations.

Dual-Mechanism Update for Freshness. To balance accuracy and overhead, the service employs a dual update strategy. Event-triggered updates occur in real-time in response to critical events like VM allocation or release, ensuring immediate state consistency. Complementing this, a daily periodic task recalibrates the lifetime categories of all machines using the latest predictions from the Remaining Lifetime Prediction model. This accounts for the natural aging of VMs and corrects any potential state drift over time.

Selective Updates for Scalability. Naive event-triggered updates would be prohibitively expensive. We implement a selective policy that dramatically reduces update frequency, ensuring the scalability of state management (Section 5.2).

5.2 Addressing Deployment Challenges

To ensure DVLA's robust and efficient operation in a complex production environment, we designed and implemented several mechanisms to address key practical challenges.

ML Service Availability and Fault Tolerance. Online scheduling demands extremely low latency, yet the ML inference service can experience disruptions from network timeouts or node failures. To ensure system resilience, we implement a multi-tiered fallback strategy.

Primary Model. Under normal conditions, the system uses the live inference service for high-accuracy predictions.

Profile Matching. If the service is unavailable or times out, the system falls back to a lightweight profile-matching mechanism. This mechanism leverages a local cache of precomputed profiles, which map common VM request features (e.g., user ID, image type) to lifetime categories. Each profile is a tuple $(\mathbf{F}, c)$ where $\mathbf{F}$ is the feature vector $(f_1, f_2, ..., f_n)$ that are matched against incoming requests and c is the corresponding lifetime category. Our analysis shows that the profile-matching achieves 75% of the primary model's accuracy, which is significantly better than a random or static default, ensuring graceful degradation.

Safe Default. In the rare event that both the primary model and profile matching fail (e.g., for a new customer's first request), the system assigns a default lifetime category (e.g., 1m-1y). This default is conservatively chosen to align with our core principle of debt avoidance. Misclassifying a truly long-lived VM as short-lived creates significant placement debt, whereas the reverse error is far less costly. This *safe default* thus acts as a final guardrail against debt creation during system faults.

To combat concept drift over the long term, we have also established a model retraining pipeline that periodically re-evaluates and updates the classifiers. The frequency and over-

head of this process are detailed in Section 6.4.

Optimizing Machine Category Update Overhead. The machine's lifetime category is critical to DVLA. In a large-scale cluster with thousands of events per second, recomputing this tag upon every VM allocation or release would impose prohibitive overhead, risking system instability.

Our analysis revealed that the vast majority of these events do not actually alter a machine's lifetime category. We therefore designed a selective update policy that triggers recalculation only for three critical events: (1) the last VM on a machine is released; (2) the first VM is allocated to an empty machine; (3) the last long-lived VM (e.g., remaining lifetime more than one month) is migrated off a machine. By implementing this fine-grained strategy, we reduced the frequency of tag updates by an order of magnitude, significantly enhancing system stability and efficiency while maintaining the necessary accuracy of machine lifetime categories.

5.3 Operational Monitoring and Diagnostics

To ensure the long-term health and debuggability of DVLA in production, we have built a comprehensive monitoring dashboard that tracks key metrics across the entire system pipeline. This framework is structured around three stages.

Predictor Health and State Integrity. We assess the quality of the input signals, which includes monitoring the prediction accuracy and service performance of our ML models, tracking not only accuracy but also inference latency and cache hit rates. We also ensure label integrity by tracking the coverage rates of VM and machine lifetime categories.

Policy Dynamics and Enforcement. We evaluate the effectiveness of the core policy execution. This involves tracking the placement affinity achieved by the online scheduler, monitoring the adaptive policy dynamics by logging the frequency of change-point detections and affinity group updates, and measuring the volume and success rate of PDRE.

Consolidation Effectiveness. The ultimate measure of DVLA's success is its ability to reduce placement debt, which we quantify by tracking the packing density of long-lived VMs (formally defined in Section 2.4). This metric directly reflects the end-to-end impact of our DVLA.

This multi-faceted monitoring framework enables operators to perform root-cause analysis. For example, a decline in the consolidation of long-lived VMs can be traced back to poor placement affinity, which might be caused by prediction errors or outdated machine tags, allowing for targeted intervention.

6 Evaluation

6.1 Experimental Setup

Methodology and Workloads. We evaluate DVLA using a high-fidelity, event-driven simulator that precisely models our production scheduling environment. Crucially, the simulator shares its core scheduling logic with our production system, ensuring our findings are directly applicable to real-world scenarios. Our evaluation uses extensive operational traces collected over two months from 23 production clusters. These traces capture a diverse range of real-world workloads, varying in scale (from 200 to 2,200 machines), intensity (from 12k to 800k VM events), and VM lifetime distributions, providing a robust testbed for our system.

Baseline. We compare DVLA against three schedulers: (1) production baseline, our provider's non-lifetime-aware scheduler; (2) LA-Binary [8]; and (3) LAVA [33]. While NILAS [33] is also a relevant lifetime-aware scheduler, the paper reports LAVA's superior performance over NILAS, making LAVA a state-of-the-art baseline for our comparison.

LA-Binary Configuration. We implement the binary Lifetime Alignment algorithm with a 2-hour threshold to distinguish short and long classifications [8]. Machines are dynamically classified using a MAX rule, by the maximum predicted lifetime of resident VMs. Placement prioritizes machines of the same class using Best-Fit. If no suitable machine exists, the VM is placed on any available machine via Best-Fit, or a new machine is allocated.

LAVA Configuration. Following [33], we employ a regression model that leverages VM uptime to dynamically refine remaining lifetime estimates, thereby mitigating initial prediction errors. Both VMs and machines are mapped to four lifetime classes (<1h, 1-10h, 10-100h, 100-1000h). LAVA adopts a recycling strategy: machines exceeding 90% utilization exclusively accept VMs from strictly lower lifetime classes. Machine classifications are dynamically updated upon deadline violations or VM departures.

Prediction Model Fairness. To isolate the impact of scheduling algorithms from prediction quality, all schedulers utilize the same production-grade VM lifetime prediction models. For LAVA, which requires a regression model, we trained a dedicated predictor that achieves 99% precision and 90% recall on a 7-day lifetime threshold, significantly outperforming the 70% recall reported in the original LAVA paper. This ensures we are comparing DVLA against a powerful, state-of-the-art implementation.

Metrics. We assess performance using three key metrics that directly map to our design goals. Beyond the Packing Density and Long-lived VM Packing Density metrics defined in Section 2.4, we also evaluate the VRAR metric.

VM Risk Aggregation Ratio (VRAR). This metric quantifies the trade-off with service stability, defined as the fraction of a customer's VMs co-located on a machine beyond a soft threshold θ (Eq. 6). While our scheduler strictly enforces all explicit anti-affinity constraints, this internal metric helps us monitor fault isolation for customers without such explicit requirements. A modest increase in VRAR is acceptable if

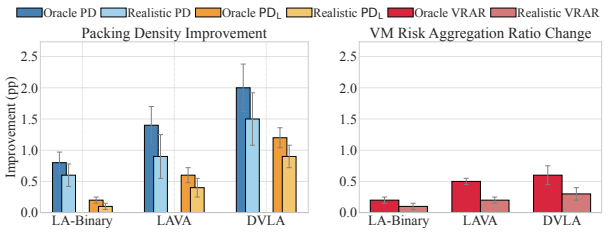

Figure 8: End-to-end performance comparison. DVLA significantly outperforms LA-Binary and LAVA in both overall PD and PD_L, while the VRAR change remains modest.

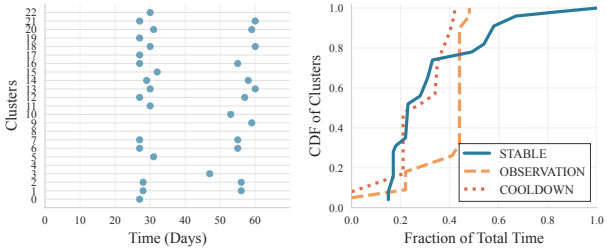

Figure 9: Effectiveness and Stability of Dynamic Policy Adaptation. (Left) Confirmed events (dots) identified via affinity grouping across 23 production clusters over 60 days. (Right) CDF of policy state durations.

accompanied by significant packing gains.

$$VRAR = \frac{\sum_{i=1}^{n} \sum_{u \in U} m_{i,u} \cdot \mathbb{I}(m_{i,u} > \theta)}{\sum_{i=1}^{n} \sum_{u \in U} m_{i,u}} \quad (6)$$

where n is the number of machines, U is the set of all customers, and $m_{i,u}$ represents the number of VMs belonging to customer u on machine i. The parameter θ is the predefined threshold. The indicator function $\mathbb{I}(m_{i,u} > \theta)$ equals 1 if $m_{i,u} > \theta$, and 0 otherwise.

6.2 End-to-End Performance

We evaluate the end-to-end performance of DVLA against the baseline and state-of-the-art schedulers. The results, averaged across 23 production clusters and weighted by size, are presented in Figure 8. We report performance under two settings: a *Realistic* scenario using our production prediction models and an *Oracle* scenario with perfect lifetime predictions to isolate the performance of the scheduling strategy itself.

Packing Density Improvement. Figure 8 demonstrates DVLA's superiority relative to the production baseline. In the Realistic setting, DVLA increases the overall packing density (PD) by 1.5 percentage points (pp), significantly outperforming LAVA (0.9 pp) and LA-Binary (0.6 pp). To understand the source of this improvement, we specifically analyze the packing of resource-dominant long-lived VMs. The results show that DVLA boosts the long-lived VM packing density (PDL) by 0.9 pp, an improvement more than double that of LAVA (0.4 pp) and 9x that of LA-Binary (0.1 pp). This finding confirms that the substantial overall gain is primarily driven by DVLA's effectiveness in consolidating long-lived VMs, directly validating our central hypothesis that tackling placement debt is key to maximizing cluster-level efficiency.

Crucially, DVLA with realistic predictions (1.5 pp) surpasses LAVA's oracle upper bound (1.4 pp), demonstrating that our algorithmic design outweighs the benefit of perfect lifetime information. This lead is consistent across the 23 diverse clusters, where DVLA delivered an additional 0.2 to 4.3 pp in packing density gain over LAVA. Importantly, the average 0.6 pp improvement over this strong baseline translates to saving thousands of machines at cloud scale, highlighting the substantial economic impact of our approach.

Trade-off with Service Stability. As shown in Figure 8, achieving higher density involves a trade-off with risk aggregation. DVLA increases the VRAR by 0.3 pp in the *Realistic* setting. This modest increase, only 0.1 pp higher than LAVA's, remains well within operational tolerance and is a small price to pay for the substantial efficiency gains. This demonstrates that DVLA strikes a favorable balance between maximizing resource savings and maintaining service stability.

The significant improvements observed in simulation motivated its deployment into our production environment. The real-world impact and costs are detailed in Section 6.4.

6.3 Analysis of DVLA's Key Designs

We now dissect DVLA's performance to validate the efficacy of its core design components.

The Efficacy of Dynamic Affinity Grouping. To validate that our dynamic approach overcomes the brittleness of static policies (Section 3.1), we analyzed its adaptation behavior across 23 production clusters over 60 days. Figure 9 confirms that adaptation is both necessary and stable.

The necessity is stark: 91% (21 of 23) of clusters exhibited workload drifts requiring at least one policy update. The CDF in Figure 9 reveals why: clusters spend a median of only 23.3% of time in STABLE, with OBSERVATION and COOLDOWN occupying 43.3% and 33.3%, respectively. This indicates that production workload distributions exhibit continuous drift, with clusters in non-STABLE phases for over 75% of the period.

Crucially, this pervasive drift does not induce instability. The update cadence remains consistent, with a median interval of 28 days and a tight interquartile range of 28–29 days. The substantial OBSERVATION time acts as an effective filter: despite continuous drift detection, most observation windows do not trigger confirmed updates (Figure 9). This demonstrates that our change-point detector effectively distinguishes persistent structural shifts from transient noise, preventing policy

thrashing and validating its robustness for production.

The Impact of Machine Lifetime Classification. As justified in our design (Section 4.3), we opted for a core-weighted average (WAVG) method for machine lifetime classification due to its superior robustness over a simple MAX rule in mature, fragmented clusters. We empirically compared the performance of WAVG against MAX under the Oracle setting. Figure 10 reveals a context-dependent trade-off. In existing populated clusters, the robust WAVG method achieves a 0.5 pp higher PD gain, as it is more resilient to the pinning effect of pre-existing scattered long-lived VMs. Conversely, in empty clusters where placements can be optimized from scratch, the more aggressive MAX rule yields a 0.2 pp higher PD gain by establishing dense long-lived machines early. This insight led to a hybrid, two-phase strategy in our production implementation. DVLA bootstraps empty clusters with the MAX method and automatically transitions to the more robust WAVG method after the first affinity group update, optimizing for both initial packing and long-term stability.

Quantifying Component Contributions via Ablation. To quantify the individual contribution of each component in DVLA's design, we conducted an ablation study. Figure 11 shows a waterfall chart illustrating the drop in PD gain as we sequentially remove key components from the full DVLA. All ablation experiments are conducted under the Oracle prediction setting to isolate the algorithmic contribution from prediction noise. Removing *Dynamic Affinity Grouping* causes the largest single drop (0.34 pp), confirming the high cost of using brittle, static policies. Removing *PDRE* as a whole results in a significant 0.31 pp loss, unequivocally proving the necessity of an offline mechanism to amortize the placement debt that online scheduling alone cannot fix. Within the dual-mechanism of state management, disabling the periodic *Tagging Task* (0.21 pp loss) is more detrimental than disabling reactive *Event-Triggered updates* (0.14 pp loss), highlighting the importance of periodic, global state recalibration over just real-time updates. This study validates our end-to-end design, demonstrating that each component provides a significant, measurable contribution. The synergy between proactive online debt prevention and reactive offline debt correction is what enables DVLA to achieve its superior performance.

Robustness and Parameter Tuning. To ensure DVLA operates robustly in production, we carefully selected its key hyperparameters. For the Dynamic Affinity Grouping mechanism, we performed a comprehensive sensitivity analysis on its three parameters: θ_{alarm}, W_{obs}, and $\theta_{confirm}$. Our analysis, detailed in Appendix C.1, evaluated numerous combinations against a cost function prioritizing system stability over hyper-responsiveness. The results clearly indicated that a conservative strategy (e.g., an observation window of 20 days with high confirmation thresholds) optimally balances adaptability with stability by effectively filtering transient noise. This data-driven approach led to the stable and effective policy

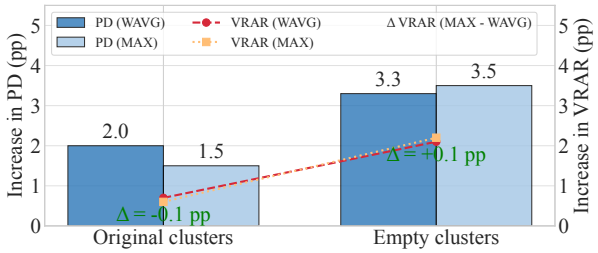

Figure 10: Performance of WAVG and MAX categorization strategies on PD and VRAR in original and empty clusters.

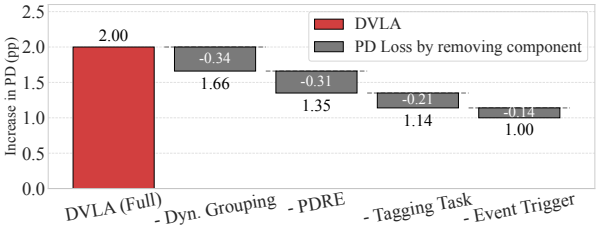

Figure 11: Ablation study on DVLA components. The waterfall chart shows the PD gain loss from removing each component sequentially, quantifying its contribution.

adaptation achieved by our mechanism (Figure 6).

Beyond parameter sensitivity, we also evaluated DVLA's robustness to the accuracy of lifetime predictions, a critical factor for real-world deployment. A detailed sensitivity analysis, presented in Appendix C.2, confirms DVLA's resilience. While its performance naturally scales with prediction accuracy, DVLA still delivers 1.02 pp packing density gain even when the recall for long-lived VMs drops to a low 40%. This demonstrates that DVLA is not brittle and can provide significant benefits even with imperfect prediction models.

6.4 Production Impact and Overhead Analysis

Beyond simulation, we deployed DVLA in Alibaba Cloud for over seven months. This section presents a comprehensive analysis of its real-world performance: (1) operational health and system overhead; (2) sustained end-to-end efficacy in improving packing density; and (3) enhanced robustness against fluctuations in workload demand.

Operational Monitoring. DVLA maintained high fidelity and coverage throughout the deployment. The remaining lifetime prediction model achieved 92% accuracy, with the initial lifetime model at 82%. This high accuracy enabled a near-total lifetime category coverage of 99% for VMs and 98% for machines. Consequently, over 98% of new VMs were placed on machines with a higher or equal lifetime category, effectively preventing long-lived VMs from occupying short-lived machine capacity. To maintain this high affinity, corrective ac-

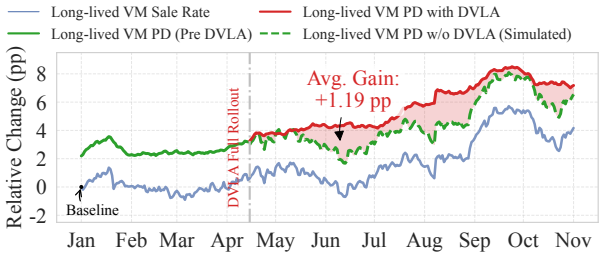

Figure 12: Comparison of long-lived VM packing density with and without DVLA, shown against the sale rate.

tions were opportunistically integrated into daily maintenance tasks, which migrated an average of 810 VMs per day. This process included correcting 39 misplaced long-lived VMs and yielded an average 0.3 pp PD_L increase per task.

System Overhead. The overhead introduced by DVLA is minimal and well-managed. Model training is an offline process, representing a trivial cost for a cloud provider managing hundreds of thousands of machines. The initial lifetime model trains weekly (40 mins on a 16-core, 64 GB instance), and the five remaining lifetime models train daily in parallel (1 hour on five 16-core, 32 GB instances). Since PDRE is piggybacked onto existing maintenance tasks rather than actively triggered, it incurs no extra scheduling overhead. The online scheduling path is also highly efficient, with a 90% cache hit rate for initial lifetime predictions, cache misses result in a negligible 99^{th} percentile inference latency of only 5 ms. The service has maintained 100% availability since its launch.

End-to-End Efficacy. As illustrated in Figure 12, DVLA delivers substantial and sustained improvements. After its full roll-out, the packing density of long-lived VMs consistently outperformed a baseline simulating performance without DVLA. To create this realistic counterfactual, we introduce the long-lived VM sale rate, a metric representing the underlying demand for long-lived resources. We define it as the ratio of total cores allocated by long-lived VMs to the total available core capacity in the cluster. By modeling the historical correlation between this sale rate and packing density from the pre-DVLA period, we project what the PD_L would have likely been without our system. Over the evaluation period, DVLA achieved an average PD_L gain of 1.19 pp against this demand-aware baseline. This significant efficiency gain was achieved with remarkable stability, the VRAR metric saw an average increase of only 0.28 pp, and no user complaints related to performance degradation were reported.

To quantify the impact of DVLA on mitigating placement debt, we analyzed the distribution of *stranded machines*. Figure 13 illustrates a reduction in stranded machines following the full rollout of DVLA, with the average proportion dropping from 25.3% to 21.3%. Notably, the subset of machines hosting only a single long-lived VM decreased from 4.3% to 3.5%. These results confirm that DVLA effectively mitigates

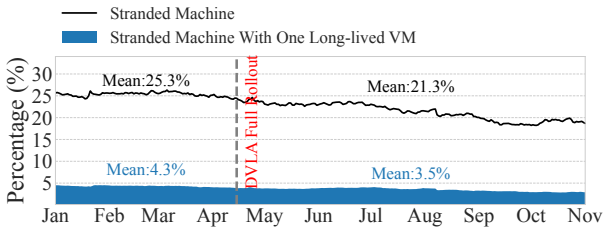

Figure 13: Proportion of stranded machines (out of all non-empty machines) before and after DVLA's full rollout.

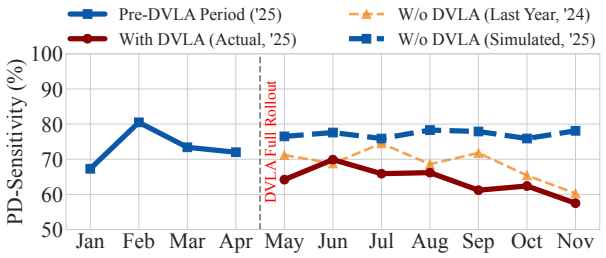

Figure 14: Impact of DVLA on cluster robustness, measured by PD-Sensitivity, where a lower value is better.

the pinning effect of long-lived VMs.

Robustness Against Demand Fluctuation. Beyond static efficiency gains, a critical measure of a scheduler's quality is its robustness to workload demand fluctuations. To quantify this, we propose a novel metric called *Packing Density Sensitivity (PD-Sensitivity)*. It measures how much packing density drops for every one percentage point drop in resource demand (i.e., sale rate). A lower PD-Sensitivity is highly desirable, as it signifies that the cluster's packing efficiency is less perturbed by drops in resource demand.

Formally, for a given time interval defined by a drop in demand, we first define the change in Packing Density (ΔPD) and the change in Sale Rate (ΔSR)

$$\Delta PD = PD_{before} - PD_{after} \tag{7}$$

$$\Delta SR = SR_{before} - SR_{after} \tag{8}$$

The PD-Sensitivity for that event is then the ratio:

$$PD - Sensitivity = \frac{\Delta PD}{\Delta SR}, \; where \; \Delta SR > 0 \tag{9}$$

In a well-consolidated cluster, a drop in demand (e.g., from termination of short-lived VMs) allows the scheduler to reclaim entire machines, preserving high PD on the remaining active machines. In a fragmented cluster, long-lived VMs are scattered, pinning down many machines. A drop in demand here leads to lower utilization across a wide footprint without enabling machine reclamation, causing a sharp decline in overall PD. PD-Sensitivity thus provides a dynamic measure

of the cluster's structural health, directly reflecting the quality of lifetime-aware affinity placement.

Figure 14 plots this metric over time. After DVLA's rollout, the actual PD-Sensitivity (blue line) established a new, more resilient operational baseline, consistently outperforming both the pre-DVLA period and the same period from the previous year (orange dashed line). Critically, the persistent gap between the actual performance and the simulated performance without DVLA baseline (blue dotted line) demonstrates DVLA's direct and continuous causal impact. On average, DVLA reduced PD-Sensitivity by 7.1 pp, showcasing its sustained effectiveness in a dynamic production environment.

7 Related Work

Online Scheduling. Online VM scheduling is a cluster scheduling problem [24, 30, 45, 49, 53]. There are algorithms based on resource allocation [2, 6, 9, 12, 15, 17, 22, 26, 40, 47, 56, 58], bin packing [3, 4, 7, 27, 32, 39, 48], and prediction of future requests [19, 31, 35, 36, 44]. [28] and [34, 43, 55] use SelfTune and LLM to optimize the system. There are also many studies using lifetime to optimize scheduling strategies [21, 51, 52, 54]. According to [16], long-lived VMs consume more than 95% of the total CPU workload, and those with similar lifespans can be grouped. [10] proposed to predict the lifetime and load of VMs in scheduling. [8] designed a VM lifetime-aware scheduling algorithm using a binary classification model. However, due to different payment types and VM lifetime distributions, these algorithms struggle to achieve the best bin-packing effect in our system.

Offline Scheduling. Offline VM rescheduling can improve the scheduling result of online VM allocation [1, 11, 18, 20, 23, 37, 38, 41, 50, 57]. It can use more complex methods to achieve better results than online VM scheduling. [23, 38] discussed the optimal packing rate that can be achieved when offline migration times are less than or more than VMs. [11] used divide-and-conquer idea, graph neural network, and combinatorial optimization solver in VM clustering to improve the customer experience. [50] proposed a VM migration algorithm based on the Markov decision process and the Q-learning algorithm. [18] rescheduled VM with reinforcement learning to achieve an effect close to mixed integer programming at a higher speed. However, no previous work has applied features related to lifetime prediction to VM rescheduling.

VM Lifetime Prediction. In recent years, many works have studied VM lifetime in cloud computing. [16, 42] pointed out that most VMs in public clouds are short-lived, but long-lived VMs take up most of the core hours. [8] considered VM features, customer features, and timing features, and used LightGBM [29] for binary classification prediction. The authors argue that it is difficult to use deep learning models to predict while ensuring millisecond-level scheduling delays.

8 Conclusion

State-of-the-art lifetime-aware schedulers are undermined by two critical, real-world challenges: the brittleness of static policies against drifting lifetime distributions and the insidious accumulation of long-lived VM placement debt. We presented DVLA, an end-to-end system that conquers these issues through a synergistic design combining proactive online prevention with reactive offline correction. Online, DVLA uses dynamic affinity grouping to adapt to workload drifts and a Debt-Aware Placement Policy (DAPP) to prevent debt at the source. Offline, a Placement Debt Rectification Engine (PDRE) employs strategic migrations to amortize the unavoidable residual debt. Our large-scale production deployment at Alibaba Cloud demonstrates DVLA's superiority, achieving an additional 0.6 percentage points higher packing density than state-of-the-art methods. This directly translates to saving thousands of physical machines and significantly enhances cluster robustness.

Appendix

A VM Lifetime Prediction Model

A.1 Initial Lifetime Prediction

This model provides low-latency predictions at VM creation time for the online scheduler, using static features available in the VM request. The 19 features used are listed in Table 2.

Feature Importance Analysis. As shown in Figure 15, feature importance analysis reveals that *image_id* , *user_id*, and *operator* are substantially more predictive than all other static features. This indicates that a VM's lifetime is primarily determined by its intended application (proxied by the image) and the historical usage patterns of its owner (user/operator). A secondary tier of features, including *inst_type_name* and *min_of_day*, also provide significant predictive value.

A.2 Remaining Lifetime Prediction

This model provides higher-accuracy predictions for running VMs, designed for offline optimization tasks and state updates. It augments the 19 static features (Table 2) with dynamic runtime information, historical user statistics, and performance metrics. Key additional features are listed in Table 3.

Table 2: Features for the Initial Lifetime Prediction model.

Feature	Type	Description
min_of_day	Int	Minute of day (0-1439)
day_of_week	Int	Day of week (0-6)
user_id	String	Unique user identifier
biz_id	String	Business unit identifier
channel	String	Request source (API, Console)
operator	String	Operator identity
cpu_cores	Int	Number of CPU cores
mem_size	Int	Memory size (GB)
inst_type_name	String	Full instance type name
inst_family	String	Instance family
sysdisk_cat	String	System disk category
sysdisk_perf	String	System disk performance level
sysdisk_size	Int	System disk size (GB)
region_id	String	Deployment region ID
avail_zone	String	Deployment availability zone
pay_type	String	Payment model
is_spot	Boolean	Is a Spot Instance
image_id	String	VM image ID
use_default_vpc	Boolean	Uses the default VPC

Table 3: Key additional features for the Remaining Lifetime Prediction model.

Feature	Type	Description
survival_hrs	Int	Current runtime (hours)
is_container	Boolean	Is Container Instance
avg_life_1mo	Float	User avg. lifetime (last mo.)
avg_buys_1mo	Float	User avg. daily buys (last mo.)
cpu_p95_1wk	Float	P95 CPU util. (last week)
mem_p95_1wk	Float	P95 memory util. (last week)

Feature Engineering. Beyond the basic features in Table 3, we engineer a comprehensive set of features. (1) *Historical Statistical Features*: we compute statistical aggregates (e.g., avg, std, p75, p90) of user-level metrics like lifetime and *vm_num* over various time windows (e.g., past 0.5, 1, and 2 months); (2) *Offline Performance Metrics*: we collect recent performance profiles, such as the 95th percentile of cpu utilization, mem utilization over the past day or week.

Feature Importance Analysis. As shown in Figure 16, the feature importance for this model shifts significantly. It is dominated by historical user behavior and the VM's current runtime. This confirms that a user's past behavior and a VM's survival history are the strongest predictors of its remaining lifetime, validating our two-model approach where the offline model gains its power from rich, dynamic information.

B Details of Dynamic Affinity Grouping

This appendix provides the detailed algorithms for the key functions within DVLA's Dynamic Affinity Grouping mechanism, as referenced in the main paper.

B.1 Online Drift Detector

Our change detection is powered by an online detector that maintains Exponentially Weighted Moving Averages (EWMAs) of the workload vector, the drift error, and the error's standard deviation. This enables an adaptive drift scoring mechanism. Algorithm 3 presents the core logic.

Algorithm 3 Online Drift Detector Internals

State Variables:
  `ewma_vector`: EWMA of workload vectors (the baseline).
  `ewma_error`: EWMA of drift errors.
  `ewma_stddev_error`: EWMA of the standard deviation of drift errors.
  α, β: Smoothing factors for vector and error updates.
  t: Internal day counter.
  P_{warmup}: Number of warmup days.

function SCORE(v_t)
  if $t \leq P_{\text{warmup}}$ **or** `ewma_vector` is **null then**
    return 0.0
  $error \leftarrow 1.0 - \text{COSINESIMILARITY}(v_t, \texttt{ewma_vector})$
  $score \leftarrow \max\left(0, \frac{error - \texttt{ewma_error}}{\texttt{ewma_stddev_error} + \varepsilon}\right)$
  return *score*

function LEARN(v_t)
  $t \leftarrow t + 1$
  if `ewma_vector` is **null then**
    `ewma_vector` $\leftarrow v_t$
    return
  $error \leftarrow 1.0 - \text{COSINESIMILARITY}(v_t, \texttt{ewma_vector})$
  if `ewma_error` is **null then**
    `ewma_error` $\leftarrow error$
    `ewma_stddev_error` $\leftarrow 0.0$
  else
    $std_dev \leftarrow |error - \texttt{ewma_error}|$
    `ewma_error` $\leftarrow \beta \cdot error + (1-\beta) \cdot \texttt{ewma_error}$
    `ewma_stddev_error` $\leftarrow \beta \cdot std_dev + (1-\beta) \cdot$ `ewma_stddev_error`
  `ewma_vector` $\leftarrow \alpha \cdot v_t + (1-\alpha) \cdot$ `ewma_vector`

B.2 Adaptive Affinity Group Generation

When a persistent drift is confirmed, this function (Algorithm 4) generates a new, optimized affinity group by identifying the most resource-dominant lifetime classes from the observed workload.

C Sensitivity Analysis

This section analyzes DVLA's sensitivity to its key hyperparameters and the accuracy of its underlying prediction models, providing a principled basis for our production configuration.

C.1 Parameters of Dynamic Affinity Grouping

The Dynamic Affinity Grouping mechanism's key hyperparameters θ_{alarm}, W_{obs}, and $\theta_{confirm}$ must balance responsiveness against stability. We conducted a sensitivity analysis by

Algorithm 4 GenerateAffinityGroup

Input:
  `avg_workload`: Average workload vector.
  `GlobalClasses`: List of all global lifetime classes.
  θ_{coverage}: Cumulative threshold.
  N_{min}: Minimum number of classes to keep.
Output:
  `AffinityGroup`: The new set of lifetime classes.

function GENERATEAFFINITYGROUP(`avg_workload`, `GlobalClasses`, θ_{coverage}, N_{min})
  `Pairs` $\leftarrow$ ZIP(`GlobalClasses`, `avg_workload`)
  `SortedPairs` $\leftarrow$ SORT(`Pairs`, descending = True)
  `AffinityGroup` $\leftarrow \emptyset$
  cum_coverage $\leftarrow 0.0$
  for each $(label, val)$ in `SortedPairs` **do**
    if *cum_coverage* $< \theta_{\text{coverage}}$ **or** $|\texttt{AffinityGroup}| < N_{\text{min}}$ **then**
      `AffinityGroup` $\leftarrow$ `AffinityGroup` $\cup \{label\}$
      cum_coverage $\leftarrow$ *cum_coverage* $+ val$
    else
      break
  return `AffinityGroup`

evaluating parameter combinations against simulated workloads, using a unified cost function that penalizes false positives more heavily than detection latency (70% weight), reflecting our operational priority for system stability.

Figure 17 shows that a conservative strategy yields the lowest cost. Short observation windows proved overly sensitive to transient noise. A moderate window of 20 days, combined with higher alarm and confirmation thresholds, consistently minimized cost by ensuring the system reacts only to significant, persistent changes. This data-driven analysis led us to select the optimal, stability-focused parameter set ($W_{obs} = 20$, $\theta_{alarm} = 2.0$, $\theta_{confirm} = 3.0$) for our production deployment.

C.2 Robustness to Prediction Errors

DVLA's effectiveness is linked to the quality of its VM lifetime predictions. To quantify this relationship, we evaluated its performance under varying synthetic prediction accuracies. Our primary metric is the PD improvement over the production baseline.

The analysis, shown in Figure 18, yields two key insights. First, DVLA's performance scales directly with prediction quality, particularly for long-lived VMs. Under a realistic accuracy model, increasing the recall of long-lived VMs from 40% to 100% boosts the PD gain from 1.02 pp to 1.66 pp. This confirms that correctly identifying these resource-intensive VMs is a primary driver of efficiency.

Second, and more importantly, DVLA demonstrates strong

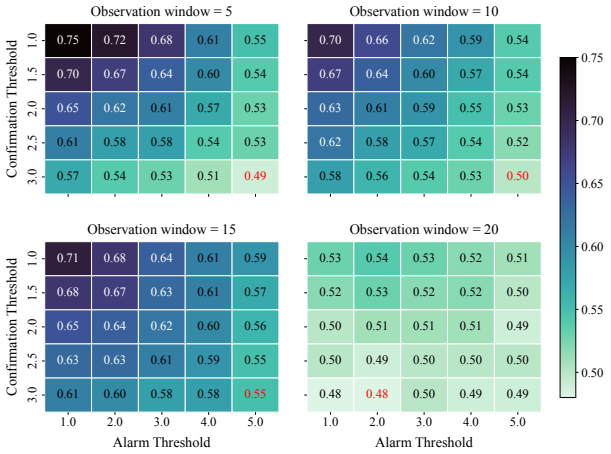

Figure 17: Sensitivity analysis of DVLA's change detection parameters. Each heatmap shows the average cost (lower is better) for a given `observation_window`.

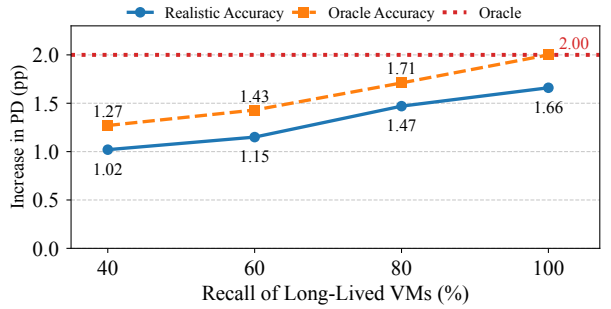

Figure 18: Sensitivity analysis of DVLA's performance with respect to VM lifetime prediction accuracy. The plot shows the Packing Density improvement as a function of the recall rate for long-lived VMs.

robustness to prediction errors. Even with a low 40% recall for long-lived VMs, the system still achieves a significant 1.02 pp PD improvement. This resilience highlights that DVLA's synergistic design can extract substantial value even from noisy signals, making it well-suited for real-world deployment where perfect prediction is unattainable.

PIMS: Fleet-wide Datacenter Maintenance with Minimal Capacity Buffer and Predictable Latency (Operational System)

Abstract

Maintenance is a fundamental operation in datacenters to ensure that hardware and software operate correctly, efficiently and use up-to-date versions. We present Meta's maintenance system in production over the last five years that provides continuous support to tens of thousands of services running on our fleet of millions of servers and seamlessly orchestrates this process. To our knowledge, this is the first paper to discuss predictable maintenance at scale.

The key challenge is how to minimize the capacity buffer—servers reserved to absorb capacity loss caused by maintenance—while providing a predictable latency to maintenance operations. This paper presents a series of strategies and techniques we use to accomplish this goal, such as aligning maintenance with fault domains, placing hardware evenly across fault domains, a maintenance contract among participating parties, etc. Indicatively, we observe that these techniques have helped us reduce the size of the capacity buffer by about 15% in one quarter of 2025 and allowed us to perform a fleet-wide deployment under targeted SLOs (e.g., 45 days for a new OS, 90 days for a new firmware).

1 Introduction

This paper presents Predictive Integrated Maintenance at Scale (PIMS), Meta's approach to fleet-wide planned maintenance that includes software upgrades and physical maintenance of devices such as servers, network switches, and power components. Meta operates a hyperscale private cloud of millions of servers running tens of thousands of services and serving billions of users. Orchestrating maintenance at this scale is challenging as it has several conflicting goals.

To prevent service interruption due to loss of servers, Meta reserves additional servers, called a capacity buffer [11,27,31]. If a service loses servers due to maintenance or failures, it can use servers in the capacity buffer to continue its operation. PIMS considers three different types of events that require capacity buffers: a) a loss of servers due to scheduled maintenance; b) a loss of a fault domain (i.e., a group of servers sharing a single point of failure like a switch or a power supply) due to unexpected failures of the shared component; c) a loss of a fault domain due to scheduled physical maintenance of the shared component.

Intuitively, the bigger the buffers allocated to maintenance the more machines can be maintained in parallel and so maintenance can be completed faster. However, considering Meta is operating a hyperscale fleet with millions of servers, these buffers could represent a significant resource usage of the entire fleet. Therefore, the key challenge PIMS faces is **how to minimize capacity buffers while keeping a predictable latency for maintenance operations.**

Minimal capacity buffer. PIMS performs maintenance in each region (i.e., several datacenters close to each other) independently. This enforces us to define capacity buffers per region and so we allocate a capacity buffer at the size of a fault domain within a single region. Below, we explain the reasons for this and describe how a single capacity buffer can be efficiently used to cover for all three types of events described above towards minimizing its size.

First, since servers in a fault domain share either the power supply or the network switch, when the shared device is maintained, all servers in its domain become unavailable. This inevitably drives us to align maintenance with fault domains (i.e., maintain one fault domain at a time), which makes it possible to use a single buffer for events a) and c).

Second, we further use the same buffer to handle events b), i.e., the loss of a fault domain due to a shared device unexpected failure. The risk here is that if a domain fails during the maintenance of another domain, then we are losing two domains and the service may not have enough buffer. However,

we can do this due to the following: for physical maintenance, which cannot be paused easily, due to its low frequency (9% of all maintenance operations), it is very unlikely for a domain failure and a physical maintenance to happen at the same time. Automated maintenance, such as kernel or firmware upgrades, is much more frequent, so the chance of both happening together is non-negligible. To address this problem, our strategy is to pause the automated maintenance quickly when another domain fails and gives back the capacity.

Third, naturally, smaller fault domains lead to a smaller capacity buffer. By applying redundancy to the shared components, we can shrink or even eliminate fault domains, but that would increase the resource usage and the complexity of our infrastructure. Meta takes a middle ground by applying redundancy to the top-level shared components and leave the lower-level components unreplicated. In this way, each of our fault domains contains about 20K servers. However, note that, shrinking fault domains does not automatically lead to smaller capacity buffer. Assuming that a service allocates servers from multiple fault domains, it needs a capacity buffer to account for the loss of the fault domain that holds the greatest number of its servers. Therefore, to minimize the capacity buffer, it's better for a service to allocate servers evenly from different fault domains.

Accomplishing this goal requires both an even distribution of each type of hardware across different fault domains and an algorithm to evenly distribute the machines allocated to a service across different fault domains. While the latter is well studied [1, 12, 21], we are not aware of practical solutions to achieve the former. In Meta, we have introduced a hardware placement algorithm that aims to minimize the uneven distribution of hardware across fault domains via rack movements. We use these outputs as suggestions and as appropriate we regularly relocate racks of machines across different positions. Concretely, the rack relocation moves suggested by the hardware placement algorithm has helped us reduce the size of our buffers by 15% in 2025 Q2 alone, which yields a saving of tens of thousands of servers.

Predictable end-to-end maintenance latency. Maintenance operations can have constraints about conflicts, dependencies, priorities, etc. To handle them, PIMS incorporates a centralized scheduler to schedule maintenance operations, with the following techniques.

First, maintenance latency involves the latency in PIMS to schedule a maintenance operation, the latency in the affected services to switch to the capacity buffer, and the latency of the maintenance operation itself. Achieving a predictable end-to-end latency inevitably requires collaboration among three parties The core of PIMS is a *maintenance contract*, which clearly defines the expectation for each party. Second, to meet its expectation, PIMS incorporates a layered design. Each layer operates with its own service-level objective (SLO) such that collectively all layers contribute to comply with the maintenance contract. Third, PIMS makes a balance between maintenance latency and throughput by combining batching, which executes multiple maintenance operations within a domain, and prioritized scheduling within a batch.

To the best of our knowledge, this is the first work to present fleet-wide datacenter maintenance operations. The contributions of this paper are as follows: 1. We present a holistic approach of planned maintenance covering hardware, software and data placement. The core is a maintenance contract to define the expectations for each participating party. 2. We present methods to minimize capacity buffers, by multiplexing the same buffers across different event types and minimizing their sizes through even hardware spread. 3. We present a maintenance stack to centrally manage shared capacity buffers and to carefully orchestrate fleet-wide predictable rollouts. 4. We present performance results of our system in production over the last five years.

2 Background

2.1 Maintenance operations

Maintenance operations, or maintenances, encapsulate a large and diverse set of required actions on our assets, i.e., all devices including compute and storage servers, network and power components, to keep an up-to-date and secure fleet for our services. We identify four categories of operations, shown in Figure 1, based on how they are initiated and whether they are executed by datacenter (DC) engineers or software workflows. We also distinguish between *planned* and *unplanned* maintenance. The latter is usually corrective. This paper is on planned maintenance shown with green in the figure.

First, planned automated maintenance involves software upgrades managed as rollouts. These operations keep our servers up-to-date and secure and some of these upgrades are required by law. Installation of all types of non application-specific software (e.g., kernels, drivers, etc) and firmware belongs in this category. Note that application-level software maintenance is managed differently, with Conveyor [15], and is not the focus of this paper.

Second, planned physical maintenance refers to periodic operations to support hardware health. For example, some hardware components have to be periodically shut down, taken apart and tested.

Third and fourth unplanned physical and automated operations refer to those executed when an unexpected problem is detected on a server or rack that requires urgent action. Depending on the nature of the problem and its trigger, e.g. automated alert or a ticket from a DC engineer, maintenance operation can be performed either automatically or manually.

For completion, there are also additional important DC maintenance operations which are not the focus of this paper. These include physical operations of large scope (e.g., busway replacement due to overheating); operations resulting

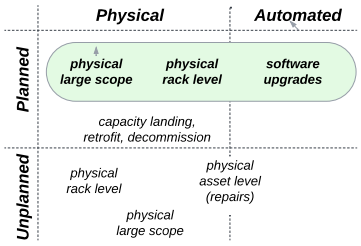

Figure 1: Maintenance operations. The focus of this paper is on planned maintenance operations shown in green.

in changes to fleet composition, at physical or logical levels, such as turning up new hardware and decommissioning old hardware or changing configuration of existing servers to run different kinds of service workloads; and even datacenter outages [32].

To summarize, PIMS is responsible for scheduling the first two categories of planned automated and physical maintenance. The last two categories are more on-demand in nature, relying on a different set of expectations, and are therefore served differently. However, scheduling the first two categories requires PIMS to consider all categories of maintenance coherently, and we will illustrate this in later sections.

To provide context, about 91% of maintenance operations are automated maintenance and 9% are physical maintenance.

2.2 Fault domains

In Meta, a *fault domain* refers to the set of servers connected to the same power supply or network switch. In this case, if the shared device is down, all servers in the domain becomes unavailable. We continue to elaborate on the size of fault domains related to a power supply or a network switch.

Power distributions in DCs are composed of high, medium and low voltage equipment. An equipment with a higher voltage usually supports multiple equipments with a lower voltage, which means the unavailability of the former has a larger impact than the latter. As a result, Meta applies full redundancy to medium and high voltage equipments to avoid to take down too many servers. Natural disasters, like tornadoes or wildefires, can still take down those equipments, but such events are rare, and Meta has incorporated a separate buffer to absorb such loss. As a result, PIMS's capacity buffer does not consider the loss of servers due to such rare major disasters. A Main Switch Board (MSB) is the low voltage component which supports the largest number of servers. It has partial redundancy (there are usually two reserve MSBs per DC; each DC has 36 to 72 MSBs) and this could power around O(10,000) servers. We observed high frequency of MSB faults which led us to the need of a capacity buffer to handle MSB faults.

We designed our network topology so that a switch and its associated servers use the same power supply. In this way, a network fault domain is always within a power fault domain, so that PIMS only needs to consider the power fault domain.

2.3 Maintenance buffer and others

As discussed in Section 1, PIMS uses one buffer, defined as b_{PIMS}, to absorb loss caused by both unexpected domain faults and planned maintenance operations. In other words, PIMS *aligns maintenance domains (MDs) with fault domains.* The requirement to maintain the shared devices, e.g., MSBs and switches, is the primary reason to align maintenance domains with fault domains. In the rest of the paper, we will use MD to refer to a fault or maintenance domain.

Physically, PIMS maintains one b_{PIMS} for each region and it includes servers spanning different MDs of the corresponding region. b_{PIMS} should be able to absorb the loss of any MD. Since there are different types of hardware, which may be distributed unevenly across MDs, the size of b_{PIMS} is typically larger than the size of the largest MD. Concretely, for each server type, its required buffer size is equal to the maximal number of this server type across all MDs. Then the size of b_{PIMS} is equal to the sum of the required buffer size of each server type. For simplicity, we normalize different server types using their power consumptions. The size of b_{PIMS} varies over time. As of May 2026, its size is about 3% of our fleet.

Meta internally maintains multiple kinds of buffers for different purposes. We present a few examples to clarify the scope of b_{PIMS}. First, Meta maintains a buffer to absorb loss caused by random server failures, whose size is about 2% of our fleet. Second, Meta maintains a buffer to absorb loss caused by major disasters like a tornado disabling a whole region. Its size changes over time due to the addition of new regions. Third, as discussed above, each application maintains its own buffer for application-level maintenance. As a result, b_{PIMS} does not need to consider loss caused by these events.

We have been considering the possibility to merge b_{PIMS} and disaster recovery buffer to further reduce buffer size: to accomplish this, we will need to do maintenance region by region. This is possible since services in Meta are designed to be able to tolerate a region failure [32]. However, there are many complexities with HW and services affinity, services expectations, capacity tracking, traffic redirection, reliability expectations, etc, which are under discussion.

3 Design of PIMS

Figure 2 shows an overview of our system on Predictable Integrated Maintenance at Scale (PIMS). There are two independent streams of work, namely maintenance and placement, both targeting all Maintenance Domains (MDs) in a region and across all regions. The placement stream targets to make similar MDs of *even spread* of their hardware assets, services running and data stored. The maintenance stream is responsible to apply all maintenance requests from clients

(i.e., Meta employee who submit maintenance requests), resolve conflicts and adhere to upgrades priorities. It operates on the assumption of even MDs as these are created by the placement stream.

3.1 Maintenance contract

In the maintenance stream we introduce the *maintenance contract* that describes important system guarantees for predictability. The maintenance contract has the following core four expectations among all parties involved including maintenance clients, components of the maintenance stack and services running on machines in our private cloud:

1. All services are expected to tolerate the loss of one MD at any given point in time so that services and data should be spread across different MDs, if necessary.
2. All services have to drain their hosted machines within one MD according to the agreed SLOs, e.g, within three hours. This is to ensure that the maintenance stack can safely schedule maintenance events on clean-state machines for predictability.
3. The buffer (b_{PIMS}) supports a maximum unplanned fault domain of servers powered by a single MSB in the common case. Following the discussion on the selection of MDs in Section 2.2, this ensure that b_{PIMS} occupies the minimum capacity buffer in our fleet that can support our maintenance contract.
4. In the event of an unplanned fault, any software upgrade operations using b_{PIMS} will relinquish capacity within an SLO of 35 minutes so that the buffer can be used to mitigate the capacity loss due to the fault. This is a consequence of multiplexing buffers for maintenance and failures.

This simple but powerful contract allows us to design and build a system with the following characteristics on maintenance, services and failures: It offers a predictable maintenance cycle time for the entire region, reducing the variability of a software rollout duration; where previously some rollouts were very quick and others were very slow. It offers predictable start times for maintenance events and a predictable schedule of operations for DC technicians so they can plan corrective maintenances. Services don't have to be aware of physical maintenances as long as the maintenances are contained within the MD. Exceptional cases can be handled with a regional disaster recovery strategy. Services can choose how to handle the loss of one MD. For example, stateful services can factor that into their state management control plane and quorum-based services can decide to ensure there is no loss of quorum. Service placement can be balanced across MDs. It allows us to support the failure of MSBs on the power path, which is our largest component without full physical redundancy. It enables DC designers to make decisions within the expectation of a maximum supported number of MDs. Finally, we can tolerate physical faults gracefully such that services remain unaware of them. As far as we know, this is the first system to provide these characteristics.

3.2 Scheduling in Maintenance Stream

The input to PIMS includes a list of maintenance requests, either submitted by clients or generated automatically. Each request asks for a software update or physical maintenance on all or a subset of servers in a region. Since preparing for a maintenance can take a long time (i.e., three hours to drain the traffic of an MD) and many types of maintenance requests themselves take shorter (e.g., tens of minutes to upgrade the OS), it is very inefficient to execute one maintenance request after each preparation. Instead, PIMS executes those requests in a batched manner at a single MD at a time: after it drains the traffic for one MD, it executes a batch of maintenance requests in that MD and then moves to the next MD.

We use the railroad metaphor to name the components of this workflow. The *maintenance train* is the overarching approach: a continuous cycle that visits MDs one at a time. A *train cycle* is one full pass through all MDs in a region. A *boxcar* is the atomic unit of maintenance work: a concrete, time-bounded plan for a specific MD, comprising a drain window followed by a work window. In the drain window all services of the selected MD are migrated to b_{PIMS}. In the work window all required upgrades are installed in the MD's assets and at the end of it services are un-drained back from the buffer to this MD.

In such a design, the scheduling algorithm of PIMS needs to answer two questions: 1. Which MD shall PIMS visit next? 2. Which maintenance requests shall PIMS execute in that MD? PIMS employs a two-step approach of first scheduling an MD and then the maintenance operations within the selected MD. However, all scheduling decisions are made in a way to align towards fleet-wide SLOs. This section provides a high-level description as follows. Section 4 provides more details about implementation and corner cases.

Ordering MDs. PIMS selects the next MD for maintenance according to the least recently visited (LRV) order, naturally due to the consideration that we do not want to leave some MDs unmaintained for long. It therefore determines the order within and the duration of the train cycle depending on the number of MDs per region and the time to spend per MD visit. Note that although a train cycle primarily determines the order of the scheduled MDs, in practice we also refer to the duration of a train cycle as the total time needed to maintain all MDs in region. For example, for regions with 72 MDs and MD visits of 12h, we need 36 days to visit each MD once. We also need to account time for revisits in case of failures. Our experiences have shown that an additional 9 days are sufficient to capture our needs. In this case, the SLO

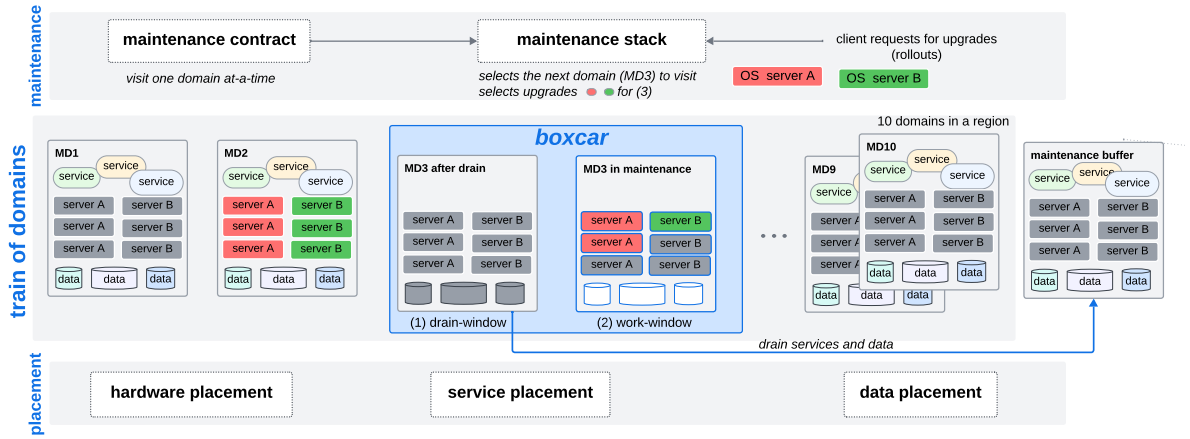

Figure 2: PIMS overview. Figure shows an example of a region of 10 MDs where hardware, service and data are evenly spread across MDs. At any point a single MD is in maintenance leaving 9 MDs to run services. This figure shows a train of 10 MDs and a rollout example in progress of two new OS versions (red and green) to be installed on server types A and B. The figure shows a snapshot in time when MD2 has already been updated and MD3 is being maintained. First, during drain-window, MD3's services have been drained to the maintenance buffer. Then, at the work-window MD3's servers are being updated while MD3's services run from the maintenance buffer.

of this layer is *to guarantee at least one visit for every MD in this region every 45 days*. Over the years we have worked with different train cycles of like 30 or 45 days. Nowadays, we keep a train cycle of 45 days, 90 days, and so on regardless of how machines are located in the region.

There are additional constraints to consider when ordering MDs in a train. For example, there is a constraint on working hours to capture that manual maintenance of small scope, such as of several racks, must be performed within working hours and this is normally scheduled as part of a scheduled MD visit in a train cycle. To address this, we create time slots for up to 90 days with fixed start and end times aligned with the region's timezone which is necessary to enable manual operations alongside automated/planned operations. 90 days allows us to schedule MDs beyond the SLO of 45-days in cases where any time slots cannot be used. Then, we iterate over all slots in a chronological order starting from the earliest until all MDs are scheduled using the LRV order and other constraints. To accommodate preventative physical maintenances we periodically recalculate the order of MDs in the 90 days time slots although we fix the order of MDs for the next 3 working days for stability and predictability.

Note that LRV is not different from round robin scheduling if there is no constraint on when PIMS can maintain an MD. However, the additional constraints for manual maintenance as mentioned above and the occasional emergency maintenance (§4.2.3) may disrupt the round robin order and that's why PIMS adopts LRV.

Planning within an MD. Typically, due to high demand, the time to run all requests for all assets in an MD exceeds the work-window time of its boxcar. Here we describe how PIMS prioritizes the requests in the boxcar plan such that all rollouts will finish according to their SLOs.

tier	description	examples	SLO
gold	important, time-critical	kernel, driver version upgrade	100%, 45 days
silver	important, not urgent	firmware upgrade new OS	95%, 180 days 95%, 90 days
bronze	best-effort	non-critical firmware	n/a

Table 1: Tiers of upgrades. In the first quarter of 2026, about 65% of the rollouts are gold tier, 35% are silver tier, and the number for bronze tier is negligible.

Our goal is to rank all requests and so we define three priority tiers shown in Table 1. The *gold tier* is for time-critical important maintenance workflows like kernel and driver upgrades that need to be scheduled as soon as possible. The *silver tier* is for less time-critical workflows that though still require frequent and deterministic rollout convergence such as firmware version upgrades. The *bronze tier* is for workflows that are not time-sensitive and include deep health checks and other housekeeping. We then fill the boxcar plan with as many maintenance operations as possible starting from the most important ones until we reach the duration of the MD visit for all servers.

A boxcar plan has a fixed duration: e.g., 6h out of which 3h for drain and 3h for effective maintenance work. Our goal is *to allow equitable progress of rollouts based on their importance and their workflow expected duration*. A rollout's expected duration is typically estimated from its historical

data. We split the 3h work window into a set of *budgets* where each budget has a target percent of hosts to represent the minimum set of hosts required to be successfully upgraded with a specific type of upgrade. For example, for gold-tier workflows we set the target budget percent to 100% since they typically take 15 to 30 min in total to execute so all such upgrades can easily fit in a single boxcar. Silver-tier workflows are often slower as they take one to two hours to execute and they are less critical, and so their budgets are proportional to their expected workflow duration. Bronze-tier upgrades are executed on a best-effort once gold- and silver-tier finish execution.

Using budgets, we define SLOs with clients. For example, the SLO with the kernel team is to upgrade every asset in the fleet within 45-days of the rollout creation. The SLO with the firmware team is to upgrade every asset in the fleet within 90-days of the rollout creation (50% budget). We further use the request creation timestamp as a second key of prioritization within the same upgrade type to prioritize new request over older ones. We then create the boxcar plan with scope, duration and priority per request.

3.3 Placement Stream

The goal of the placement stream is to create similar MDs of even spread of their hardware assets, services running, and data stored. As discussed in Section 1, this is fundamental to minimize the capacity buffer b_{PIMS}.

Hardware placement. We formulate the placement problem as a mixed-integer linear programming problem (MILP) to minimize an objective function, which includes the spread of assets across MDs and some other factors. Although our formulations conform to traditional MILP representations that could be solved by known solvers, our problem size makes this approach hard to maintain and with scalability problems [8, 20]. Instead, we use a brute force greedy search algorithm for scalability and low latency reasons. This algorithm works in multiple iterations. In every iteration, it searches for one movement (i.e., move a rack of servers from one location to another) to minimize the objective value, and it repeats this process for multiple iterations until either it cannot find a beneficial movement or a limit is reached. This approach does not guarantee to find the global optimum, but it's fast and can provide a reasonably good plan in our experience. We next describe the objective function and our greedy algorithm in more details. We begin by providing necessary terminology.

A *rack* holds a group of servers of the same type. There are a number of *rack_type*, represented by the type and number of servers in a rack. A *position* is a physical location in a datacenter that can hold a rack. The goal of the placement algorithm is to determine which position should hold which rack. Our placement algorithm considers three types of *resources*: power supply, network bandwidth, and cooling capability. A *scope* is a group of positions that share a resource limit. For example, positions that are connected to the same MSB become a scope; positions that are connected to the same network switch also become a scope. A *period* is a time period (e.g., a week).

Figure 3 presents the detailed definition of our objective function, which is a weighted sum of multiple terms. For most of the terms, we represent decision variables and other inputs as tensors in PyTorch and define the objective terms as certain computations on those tensors. The benefit of this approach is that we can then use PyTorch to compute the gradient of those terms, which represent how the values of those terms would change if we moved a rack into or out of a position. There are a few terms we found challenging to represent as tensors and thus we use a different representation.

Concretely, on the left side of this figure, the layout tensor, which maps a rack_type to a position, is the decision tensor. There are four input tensors: 1. The position_by_scope tensor records which positions each scope includes. Note that a position may be included in multiple scopes. 2. The scope_resource_limit tensor records the resource limit of each scope. 3. The racktype_by_resource tensor records the resource consumption of each rack_type. 4. The resource_scale factor records the max value for each resource across all rack_types, used for normalization purpose.

On the right side, the objective function includes three groups of terms. The first group tries to encourage each scope to have enough unused resource (i.e., "headroom") to accommodate future rack placement. This group considers power of MSB and network bandwidth of switches at this moment. The second group tries to penalize resource over-utilization. Note that we allow oversubscription of power and cooling but want to discourage that. The third group encourages an even distribution of different types of servers across different scopes. The other nodes in the middle represent intermediate tensors that are used to compute the objective terms from the input and decision tensors and how to compute them.

There are two additional terms: the network compatibility score determines how well a rack_type fits with the position's network configuration. There are generally three types: if it's totally incompatible (e.g., a rack_type requires Infiniband but that position does not have Infiniband), the score will be infinite; if it's a perfect match (e.g., a rack_type requires Infiniband and that position has Infiniband), the score will be 0; if it's OK but not preferred (e.g., a rack_type does not need Infiniband and that position has Infiniband), the score will be a positive value. The tapbox score determines the usage of tapbox, a power unit shared between adjacent positions.

Tuning the weight of each term has been a challenge. To this end, we set different values and we rely on feedback from the different clients to adjust accordingly. In practice and over the years, this approach has worked well for our cases.

Our placement algorithm executes iteratively. In each iteration, it enumerates all the possibilities of moving one rack out

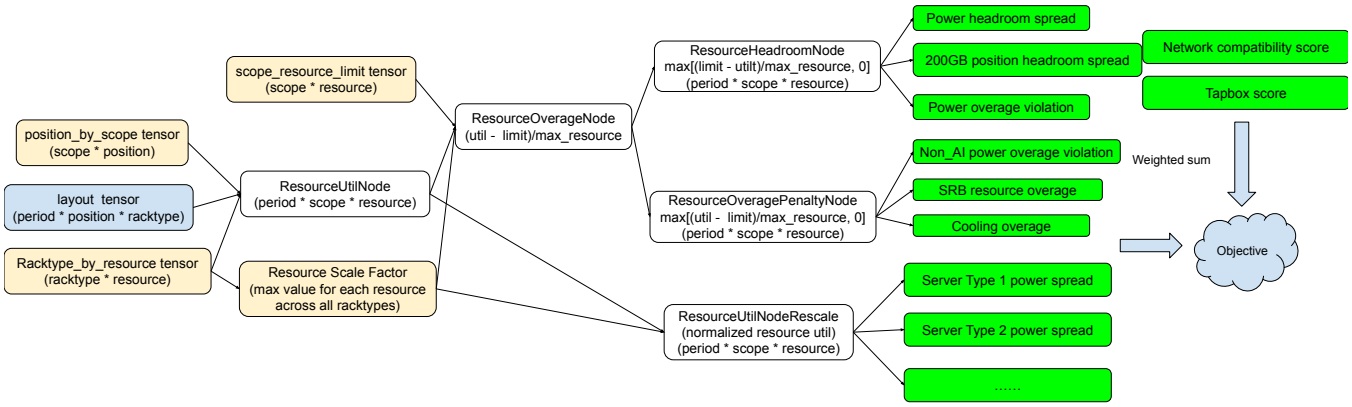

Figure 3: Objective function of hardware placement.

of its current position and into a different position; it adopts the pair of (source position, destination position) which yields the lowest value of the objective function. The algorithm terminates when the benefit is smaller than a threshold.

PIMS runs the placement algorithm monthly to optimize hardware placement. Every run takes about 25 minutes, including data preparation, running the placement algorithm mentioned above, and postprocessing. One run typically performs a few to a few hundred iterations before it hits the termination condition. Each iteration takes about one second. Relocation is executed independently with software maintenance, since the relocation team reserves a small buffer independent of b_{PIMS}. However, it needs to coordinate with hardware maintenance or decommission to avoid conflicts.

Note that reducing the buffer size is only one goal of this algorithm, represented by the third group of its objective terms (i.e., Server Type X power spread). It needs to consider many other factors, as expected in complex production systems.

In order for this whole idea to work efficiently, a fundamental assumption we make here is that different MDs within a region are balanced with similar power supply, network bandwidth, etc. Historically, Meta has incorporated new MD designs over time, but it only applies a new MD design in a new region to avoid unbalanced MDs within a region.

Service and Data Placement. Even when we distribute hardware evenly across the physical infrastructure in a DC, a software engineer could unknowingly deploy all instances of a service in a single MD, not only negating the benefits of balanced spread but also putting service availability under risk. Therefore, we provide placement libraries within our scheduler's capacity management system to ensure that all deployments are spread across MDs. These libraries have been presented in prior papers like Twine [27] and RAS [27] and thus are not the focus of this paper. Additionally, we operate ShardMananger [21], an advanced data management system which may run many shard replicas in a region. It is important to spread shards across all MDs in a region to avoid the case that all replicas of a shard are placed on a given MD, making that MD skewed.

When we move a rack to a new MD due to hardware placement, there is a potential for heterogeneous software configurations to exist within an MD, which may be a problem for certain services. To eliminate such risk, we re-image the servers in the rack to be moved to match those in the destination MD.

3.4 Multiplexing Domain Failure Buffer and Maintenance Buffer

PIMS uses one buffer b_{PIMS}, which has the size of an MD, to absorb loss caused by both domain failures and maintenance operations. To accomplish this, PIMS does not schedule new maintenance operations when an MD fails in the same region. However, the challenging case is that an MD fails *after* a maintenance operation already starts to run in the same region. In this case, we are losing two MDs, which exceed the capacity of b_{PIMS}. This section discusses our analysis and strategy about such risks.

In 2025, Meta has experienced four MD failures in total. They spread across three different regions and the longest aggregated MD failure time in one region is five hours. Considering Meta has tens of regions, many do not experience any MD failures. It should be noted that such failure rate is not going to grow as our fleet grows: PIMS manages maintenance in each region independently. Meta mainly grows its fleet by adding new regions, not by adding machines or MDs within a region. As a result, the MD failure rate per region is not going to grow as our fleet grows. In fact, the failure rate has been dropping over the years due to improved hardware and software reliability.

For physical maintenance, since it accounts for about 9% of the total operations, the chance for it to happen together with a MD failure is low. For a simple analysis, if maintenance happens during X% of the time and MD failure happens during Y% of the time, then they happen together during

$X\% \times Y\%$ of the time, assuming that they are independent. Following this calculation, physical maintenance and MD failure will happen together during $9\% \times \frac{5}{24\times365} = 0.005\%$ of the time, which translates to about 0.45 hours in one year. The actual number should be lower as 5 hours is the longest MD failure time among all regions, and PIMS will not schedule new maintenance operations when an MD failure happens.

For automated maintenance, which accounts for 91% of the total operations, the chance of a concurrent MD failure is not negligible (4.6 hours in one year using the above computation). To address this problem, when a MD fails during the automated maintenance, PIMS pauses maintenance and gives back the capacity back to this affected service as fast as possible. That is why PIMS sets an SLO in its contract that it should be able to return all capacity within 35 minutes, which strike a balance between effectiveness and feasibility. First, empirically, we find the 35-minute delay in returning capacity is generally acceptable in most cases. Second, we find the 35-minute delay is feasible: PIMS can naturally pause maintenance after one upgrade finishes. Many types of upgrades do not take long, but a few types can take significantly longer than average, often requiring multiple rounds of rebooting. For such long upgrades, we require the client who submits the request to split a long upgrade into multiple smaller ones. In addition, PIMS has a monitoring system, which will notify an on-call developer promptly if an upgrade gets stuck for unexpected reasons, and the developer can manually relinquish the capacity. Due to these optimizations, we have not seen a violation of the 35-minute SLO in the last five years.

Despite these strategies, the risk of concurrent failure still exists. In practice, a service may not be running at peak load when this happens, so it may be able to absorb such loss by itself. When the service is not able to absorb the loss, it can still turn to other capacity buffers (e.g., the buffer for major disasters) for temporary help, but this is very rare in our experience: in 2025, for each of the four MD failures mentioned above, we were able to relinquish capacity under 20 minutes and did not need the help of other buffers.

4 Implementation of Maintenance Stack

The overarching goal of PIMS is to implement fleet-wide maintenance in a *scalable* and *predictable* manner. To handle scalability, our system is region-based and operates maintenance decisions in parallel and independently across all regions. To be predictable, we employ a layered design composed of the Intent, Sequencing, Budgeting, Orchestration, and Execution layers. Each layer is expected to complete its goals according to its own SLOs towards the other layers. Collectively the layers handle the complexities of maintenance and provide rollout guarantees. Ultimately, maintenance decisions are performed in a region-based coordinated manner. Next, using Figure 4 we describe the steps taken by each layer to safely execute a maintenance request, referred to as the *maintenance workflow*.

First, maintenance clients (1) submit their requests referred to as *rollouts* to the appropriate rollout configuration systems (1)[1]. Clients include different teams and systems generating maintenance requests. For example, teams like the Kernel Team periodically release new versions of the kernel.

Rollout requests contain different attributes including the request type, such as kernel, firmware version upgrades, and the rollout scope specifying the set of machines to execute the rollout request at, such as an entire region, or machines matching a certain host prefix. Figure 4 shows two example rollout requests. The Rollout Service monitors the status of the rollout progress on a server basis for all rollouts. At any given time we have thousands of rollouts in progress across our fleet.

The Intent layer continuously checks new rollouts and produces a list of *intents* to declare the upgrade that is needed for every machine matching the scope criteria (3). It also maintains a list of all machines in the fleet with the state of their upgrades. The SLO of the Intent layer is to timely gather client rollout requests and to timely update the machine list with upgrade states within a few hours at the latest.

The Sequencing layer selects the next MD to schedule for maintenance and its SLO is to ensure at least one visit per MD in a cycle of a fixed number of days such as 30 or 45 (4). This layer also takes into account additional needs such as time constraints for physical maintenance, revisits due to failed upgrades, and more.

Given the next MD for maintenance, the Budgeting layer populates the list of intents to be executed during the visit of the next selected MD (5). This layer operates on a single MD visit at-a-time. Its SLO is that required upgrades for the assets of this MD are given enough time to complete at the next boxcar according to their tiers as in Table 1.

The Orchestration layer coordinates execution of individual maintenance operations in a way that is safe for the fleet and predictable for the maintenance stack (6). This involves creating a *clean execution environment* for every individual operation - ensuring that service workloads are migrated away (i.e. drained) from affected servers, and ordering execution to avoid interference between operations. The SLOs of this layer is about creating such an environment on time (e.g. 3h) to maintain predictable throughput. This is the only layer in the stack that is shared between planned, corrective, and fleet topology change maintenances, as it requires coherent view of all work in the DC to achieve its objective.

The Execution layer handles the execution of maintenances (7). The SLO of this layer is based on three metrics: success rate of the upgrader, duration of it and host health rate after upgrades, e.g., for kernel it's 99%, O(minutes) and 98% correspondingly. It is also responsible for identifying bad actors - maintenances that do not comply with the above requirements

[1] In this section, all (*) refer to Figure 4.

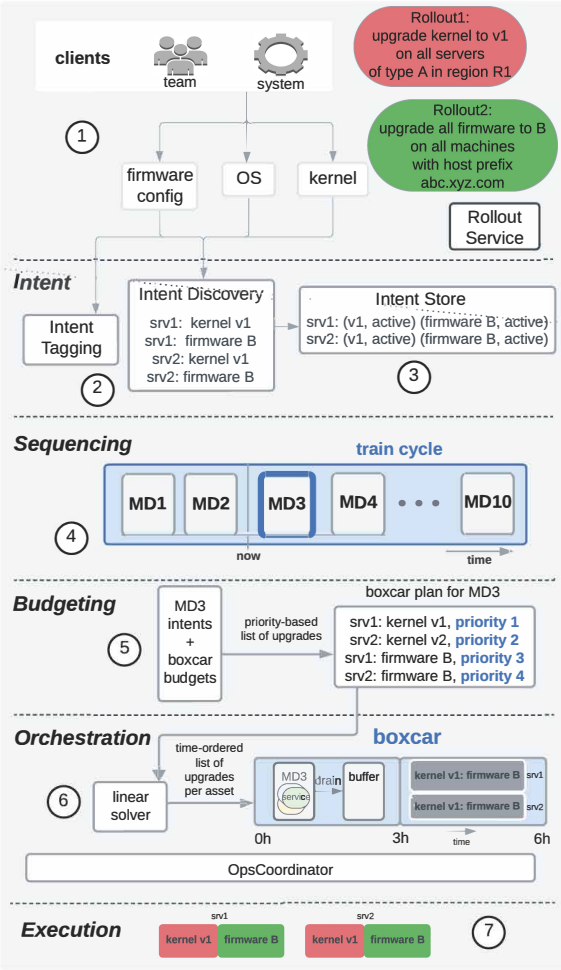

Figure 4: Maintenance stack overview.

- and providing a signal to remove them from the system to maximize utilization of available maintenance time.

Note that our system is not triggered by new rollout requests. Rather we keep two parallel threads of execution. The first keeps an up-to-date list of all upgrades per machine. The second is to pick the next MD for which the requested upgrades for all its assets are to be installed. These two threads run continuously. Despite the two asynchronous threads, our system relies on strict SLOs and performs efficiently and predictable as evaluation shows.

PIMS is backed up by a fault tolerant database to store incoming requests, intents, boxcar plans, etc. As a result, if PIMS process crashes for some reason, we just need to restart it, which will resume based on the information stored in the database.

4.1 Intent Layer

The Intent layer is composed of the *Intent Store*, the *Intent Discovery* and the *Intent Tagging* services to capture clients' rollout requests and to generate upgrade intents per machines.

The Intent Discovery service operates continuously to collect all *intents* from services (2) where an intent denotes the desired maintenance action to be performed on assets. Intents are stored in the Intent Store (3) which keeps the up-to-date state of all clients' intents. When an intent is published at the Intent Store, it is augmented with additional properties including *state*, *priority*, and more. An intent's state can be either *active* or *fulfilled*. All intents are initially active and remain so until fulfilled. An intent priority represents the urgency of an intent and can be used by Budgeting to onboard upgrades to boxcars created in emergency situations. Once an active intent is in the Intent Store, it signifies that its upgrade should be installed. Scheduling and running the upgrade of an active intent is done asynchronously by the layers below described in the next sections.

There are *gradual rollouts* deployed in a stepwise fashion (i.e., after the pre-production testing, production rollouts are deployed first to 5% and then to 25% and 100% of servers of the global scope) to ensure safe and controlled upgrades similar to rolling upgrades [15, 26]. For such upgrades it is challenging to find the specific servers to upgrade to meet rollout scope quotas when we upgrade an MD at-a-time. To this end, the Intent Tagging service aims to find specific assets in the fleet across MDs for gradual rollouts. For this, it greedily assigns assets at the upcoming MDs with the target version to ensure that the rollout will happen in the shortest time possible while ensuring efficiency without compromising safety.

The Intent layer monitors upgrade reattempts so that when an upgrade fails, an intent is kept in the active state until the corresponding upgrade successfully puts the server in its desired state. This also allows us to count the number of upgrade retries and so we can identify problems in cases of many unsuccessful attempts.

4.2 Sequencing Layer

The Sequencing layer determines the order to visit MDs in a train. As described in Section 3.2, it mostly follows the Least Recently Visited (LRV) order. This section discusses more details.

4.2.1 Failed maintenance domain visits

Every MD visit contains upgrades that belong to multiple rollouts and some of them might fail to execute. We need to measure upgrade failures in a boxcar to decide whether the MD should be rescheduled again with the remaining failed and other non-completed upgrades, referred to as a *MD revisit*. For this we define the success rate of a boxcar as the ratio between successful completed upgrades and the total number

of upgrades in the MD visit. If the success rate is below a threshold we schedule the MD to be revisited to retry failed upgrades. We can set this threshold with different values. According to our experience, an 80% threshold works well for our cases, because it achieves a good balance between success of individual rollouts versus the majority of rollouts that are executed in parallel in the same region.

Further, the Sequencing layer reschedules an MD after a failed visit. However, as a revisit requires an additional time slot there could be cases with not enough slots left to meet the 45-days SLO. To minimize this risk, the Sequencing layer monitors MD failures and in cases of subsequent failures of the same MD, it reschedules a visit after a configurable number of days in the future, which is similar to the exponential back-off mechanism. This enables us to continue to other MDs while issues in the problematic MD are being addressed.

4.2.2 Large-scale manual maintenance

In addition to running boxcars with automated upgrades, there is a need to schedule large-scale manual maintenance. Their scope is defined by power and network constraints, which can impact capacity maintained by different trains.

As discussed before, one of the scheduling constraints is that each capacity type under maintenance aggregated should not exceed an MD at-a-time. Because of this, once there is manual maintenance on a specific capacity type, we cannot perform any other maintenances on the scope of the same type. To solve this we place manual maintenances in a separate schedule called *manual train*. Trains are placed in order of priority, with the manual train being placed first so it does not face any conflicts and can schedule a boxcar on any day. When we place other trains, we search for conflicts with already placed boxcars. If any of the constraints are violated, the time slot of the boxcar of the train of less priority is skipped. In this way, automated trains are scheduled around manual trains.

The existence of manual trains could increase the chances of SLO violation, due to manual trains' high priority and restricted scheduling constraints (e.g., a human engineer typically only works during of a workday). Historically, we have alleviated this problem by careful planning. Today, we observe that manual trains have no big impact in PIMS.

4.2.3 Emergency rollouts

There are cases when a specific upgrade needs to be rolled out faster than the usual 45 or 30 days. For instance, assume that a new GPU driver has been rolled out to 50% of machines across MDs in a region when we observe significant performance degradation in the already upgraded machines. Instead of waiting for 45 days to recover the cluster we introduce *emergency rollouts* to roll back to the latest stable version.

There are two different cases: a) requiring upgrades are located in a few MDs; and b) a small number of machines require upgrades spread evenly across the region, for example only when a specific model is affected by buggy software. In the first case we use *emergency trains* that have the highest priority and are configured on demand. By placing emergency trains first, we can achieve automatic conflict resolution without manual intervention. The speed of the rollout by the emergency train is restricted by the number of MDs, drain time, and required work window. In the second case, for some capacity types that depend only on the number of machines available in the region (GPU training capacity), we can make a single visit that covers a few MDs and controls the number of machines on-boarded for maintenance. This approach can reduce the mitigation time from weeks to 1-2 days.

4.3 Budgeting Layer

Following the algorithm described in Section 3.2, The Budgeting layer takes all intents for every asset in an MD from the Intent Store and produces the *boxcar plan* which contains a priority list of upgrades for all assets that can run in the next visit of that MD.

This section reports on issues of safeguarding, fine-grain duration prediction and supercession. First, safeguarding ensures that all systems involved in upgrade operate correctly. To this end, we continuously monitor the reliability of workflows by checking for example whether an intent is successfully applied and the host is in a healthy and production-ready state after the upgrade. Once we detect an unreliable workflow, we stop its execution to investigate the problem. After the problem is fixed we then allow back the intent to boxcars.

Second, accurate workflow duration is important for the boxcar plan and to ensure workflow execution only when there is enough time left in the boxcar. We have developed an ML model to predict workflow duration based on historical data for workflows with high duration variation such as firmware upgrades [10].

Finally, there are cases where some of the workflows in higher priority tiers are applied out-of-the-box by other workflows in the lower priority tiers referred to as *supercession*. For example, OS reinstalling would automatically fetch and install the desired kernel version. To reduce duplication in boxcar plans, this layer further applies a step that detects and deduplicates supercession.

4.4 Orchestration and Execution Layers

The Orchestration layer coordinates the execution of all maintenance operations in the fleet, across categories, in a safe way for service workloads and predictable for maintenance operations. In the context of planned maintenances every train visit should start at a specific time and should finish within its predetermined duration for next MD visit. The OpsCoordinator system in Orchestration is responsible for guaranteeing that

timeline: services drain on time and that a batch of operations in a boxcar can reach one of the terminal states on time.

This layer achieves its objectives by combining fleet-wide safety invariants, service workload drains, time-order and topology awareness, and coordination between maintenances under a single user-facing abstraction. It is guaranteed that once OpsCoordinator makes a decision to start execution, maintenance will operate in a clean execution environment - service workloads are migrated away and no other concurrent maintenances are being executed on the same hardware.

Safety Invariants. In context of planned maintenances OpsCoordinator assesses safety across three dimensions to ensure that the maintenance contract is upheld at all times. First, it ensures that not more than one MD of the same type is taken down for maintenance in a region. Then, it verifies that there's enough buffer capacity to sustain the outage of the chosen MD. And finally, in case of a large sub-region failure event or buildup of organic failures, it will pause planned maintenance execution, and facilitate return of maintained capacity back to production so it can be used to absorb the impact.

Cross maintenance coordination. The main objective at this stage is to order incoming maintenance operations to avoid conflicts such that no two maintenances execute concurrently on the same device, as well as ensure that their execution is not impacted by utility loss. This stage coordinates across different categories of maintenances (software upgrades, unplanned operations, retrofits, etc). In context of planned maintenances this means that execution of software upgrades on devices with ongoing corrective work will be avoided, as well as some ongoing planned maintenances may be cancelled to facilitate cleanup across execution call stack to make room for higher-priority work.

Drain. The main goal at this stage is to gracefully migrate service workloads on all affected servers into buffers. Fully bootstrapping a workload on a new machine can take anywhere between a few seconds (for compute) to a few days (for storage). To avoid disruption all affected service workloads should be migrated to buffer capacity ahead of time. OpsCoordinator initiates and monitors the drain process. Our cloud manager Twine [31] provides a mechanism to ask services to vacate their host machines and also drives workload reallocation. OpsCoordinator is responsible for interfacing with this mechanism on time, and provides the required metadata about the drain. OpsCoordinator further resolves any conflicts due to hardware topologies.

In context of planned maintenances, maintaining predefined schedule of boxcar execution is important for rollout SLOs. This is a secondary goal during this stage, as it favours service availability first. According to the maintenance contract, all service workloads have to be able to migrate within 3h to maintain predictable schedule. OpsCoordinator is responsible for enforcing this expectation by forcefully preempting service workloads if they do not drain on time, apart from the scenarios when a large-scale infrastructure failure is observed.

For stateful services, due to the need to replicate or rebuild data, 3h drain may not be enough to gracefully migrate their workload. Therefore, they also receive an 24h advance notice prior to the maintenance train visit, and can utilize this signal to kick off data replication or rebuild.

Execution. Once the previous stages complete upgrades are ready for execution. OpsCoordinator requires all maintenance executors to implement a standardized service interface that is used to dispatch callbacks, monitor progress of the work, and inject control signals such as preemption. Once the executor reports on completed work, OpsCoordinator handles transparent return of the maintained hardware back to production. For planned maintenances, it is possible that not all operations from the boxcar finish by the end of the predefined work-window. As trains need to follow the schedule from Sequencing to maintain the rollout SLO, PIMS will release those servers that have finished maintenance, keep doing maintenance on those unfinished ones, and move to the next MD. Our statistics show that about 0.5% servers cannot finish maintenance by the end of the window, and we assume that the buffer to absorb random failures can handle such 0.5% capacity loss, since many unfinished maintenances are indeed caused by random failures.

5 Evaluation

In this section we report performance results of PIMS in production to maintain millions of servers in Meta's private cloud and thousands of rollouts. Section 5.1 reports the effectiveness of hardware placement on reducing buffer size. Section 5.2 evaluates predictability. In Section 5.3, we evaluate important SLOs of the maintenance stack. Section 5.4 evaluates the utilization of MDs and discusses related tradeoffs.

5.1 Buffer size reduction

As discussed in this paper, PIMS reduces buffer size in two ways. First, it uses one buffer to absorb the capacity loss caused by server maintenance, MD maintenance, and MD failures. If PIMS did not perform such multiplexing, the required buffer size may be trippled.

Second, PIMS applies the hardware placement algorithm to make MDs within a region balanced, because its buffer needs to accommodate the loss of the largest MD and thus balanced MDs help to reduce buffer size. Meta started to apply the hardware placement algorithm to reduce buffer size since 2022. We quantify its benefit with the size of b_{PMIS}, estimated using the approach described in Section 2.2.

Typically, there are more movement activities following either a significant change to the algorithm or an installation or decommission of many servers, and there are fewer movement activities when the situation gets stable. During the second quarter of 2025, which is a rather active period, we moved a total of 15,716 racks under the suggestion of the hardware

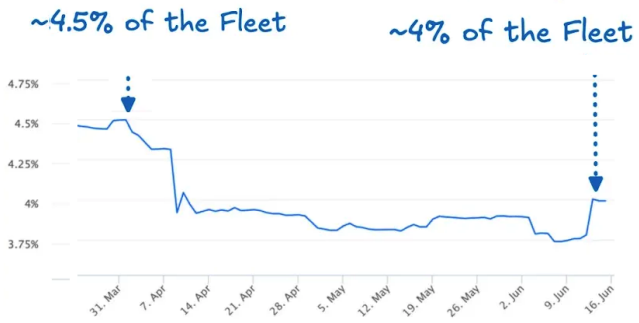

Figure 5: Reduction of buffer size due to hardware placement algorithm in 2025 Q2.

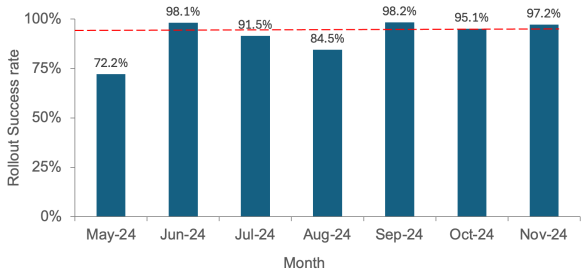

Figure 6: Rollout success rate.

placement algorithm. As shown in Figure 5, such activities have helped Meta to reduce the size of b_{PIMS} from about 4.5% of the fleet capacity to about 4%. Note that since the total fleet capacity was growing during this period, the actual reduction (15%) is larger than $\frac{4.5\%-4\%}{4.5\%}$. This can help us save tens of thousands of servers every year. As of May 2026, the size of b_{PIMS} has been reduced to about 3% of our fleet capacity.

Also note that, since Meta has been running the placement algorithm since 2022, 2025 Q2 already started with a reasonably optimized placement. If we applied this algorithm on a random placement plan, it is likely for this algorithm to achieve more reduction.

The problem of hardware placement is NP hard, so we do not know the optimal buffer size, but we can estimate its lower bound in the following way: if a region has n MDs, then the lower bound of the buffer size is $\frac{1}{n}$ of the region capacity, assuming that MDs are perfectly balanced. Most Meta regions have 36 to 72 MDs, which means that the lower bound is about 1.4% to 2.8%. However, due to different server types, different resources to consider, and different goals to optimize (Figure 3), it is unlikely that we can reach this lower bound. Our speculation is that there might be some room for further reduction, but probably not a significant one.

5.2 Maintenance predictability

Planned software and firmware upgrades. First, we evaluate maintenance predictability for planned software and firmware upgrades. We measure the *rollout success* defined as the ratio of rollouts completed according to their SLOs (see Table 1) on a monthly basis. The rollout success rate is weighted by the number of assets in the rollout scope to align with our goal to get as many assets as possible upgraded to the desired software or firmware version. In six months in 2024, we rolled out more than 300 different versions in Kernel, Firmware and OS categories through 52 upgrade types totaling to an average of 2-3K rollouts globally every month.

Figure 6 illustrates the rollout success rate over six months. Results show 90% or higher rollout success rates for four months. Success rate only drops for May (72%) and Aug (84%) because of failures in upgrade logging caused by a configuration update and a system bug in discovering intents. Once discovered, these issues were immediately addressed and rollout success rate was back again to very high values in the next months. Very high rollout success rates show that PIMS works in a predictable manner according to the SLOs.

To provide context on the importance to consistently meet SLOs consider *OS freshness*: 95% of our millions of servers have their OS provisioned every 45 days. In the past, before the current centralized maintenance system, we needed about 3 years for a fleet-wide OS upgrade. This corresponds to a 23x reduction in rollout time and the current 45-days SLO for OS provision ensures that we can maintain the latest OS version for fleet safety and compatibility.

Planned physical maintenance. Second, we evaluate predictability for planned physical maintenance in two cases. First, *fixed-date* maintenance is scheduled by DC engineers who provide the date and time to run such boxcars in the maintenance stack, which means the date is fixed for PIMS. Second, the *flexi-date* maintenance is scheduled by PIMS, which means the date is flexible for PIMS, and then DC engineers are given the date and time to run these boxcars. Depending on these two types of boxcars, we have two different contracts to ensure that we can start on time, and to limit the wait time.

First, we support the "start-on-time" SLO declared as *95% of both fixed- and flexi-date maintenance should start within 30 minutes of their scheduled time*. Figure 7 shows the percent of both boxcar types in the six months that successfully start within 30 min of their scheduled time. Results show that we are above 95% in most cases. Second, we support the "limit-the-wait-time" SLO as *99% of flexi-date manual maintenance operations should start within 90 days of request creation*. Figure 8 shows the percent of boxcars in the six months that successfully start within 90 days of request creation. Results show that we are compliant in 5 out of the past 6 months with this SLO. The two SLOs above were breached only to support the necessary hardware retrofit of network equipment in a flexible way which accounted for the delivery of parts and resources to fit them.

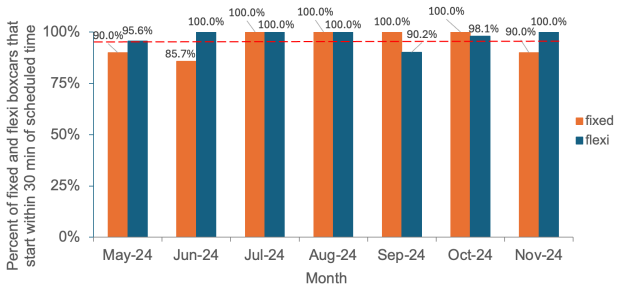

Figure 7: Percent of fixed- and flexi-date maintenances that start within 30 min of their scheduled time.

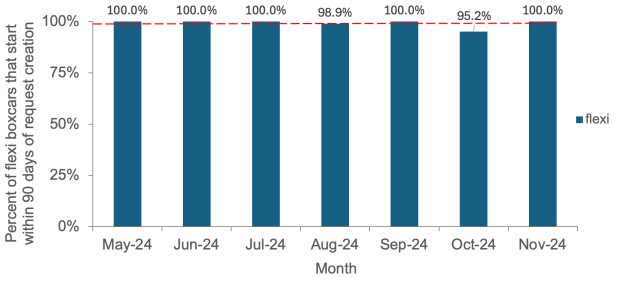

Figure 8: Percent of flexi-date maintenances that start within 90 days of request creation.

5.3 Maintenance layers SLOs

Maintenance predictability depends on how well each layer in the stack meets its own SLOs. Here, we show results on how well the Sequencing and Orchestration layers meet their SLOs in Table 2. The performance of these two layers is instrumental for the maintenance contract to ensure the 45-days train cycle and the total boxcar duration of 6h respectively.

First, Table 2 shows that over the six months, the compliance rate of the 45-days SLO is very high and consistently above 95%. Second, we evaluate the SLO compliance in boxcar for both the drain- and work-window. Table 2 shows that the enforcement rate which is defined as percent of drains that fail to finish in 3h and so enforced by OpsCoordinator is very low at 0.6%. Drain enforcement impact depends on the asset type and service and thus is processed differently; it is either automated or an oncall engineer is notified to handle this.

Third, Table 2 shows the number of breaches of the upgrade success rate, upgrade duration and host failure rate SLOs per million of upgrades in one month for the work-window. Note that SLOs differ across upgrade types. For example, the OsRefresh upgrade has a critical threshold of P80 duration of 50 min per boxcar. A violation of this SLO is a critical breach and requires immediate action, intervention and investigation. Results show that for most upgrade types breaches to these SLOs are rare with the exception of RDMAFirmware upgrades. Although RDMAFirmware has the smallest number of upgrades, it has the highest ratio of breaches likely due to a bug where a different, longer duration upgrade was incorrectly performed under the name of RDMAFirmware.

Sequencing 45 days SLO						
May	June	July	Aug.	Sept.	Oct.	Nov.
99.9%	99.1%	98.6%	98.2%	98.6%	98.9%	98.4%

Orchestration 3h drain SLO			
boxcar drain	P95 duration	P99 duration	enforcement
	77 min	175 min	0.6%

Boxcar 3h execution SLO				
upgrade type	total upgrades per month	no of breaches/1M upgrades in		
		success rate	duration	host failure
RDMAFirmware	46,174	22	282	0
FbossForwardingStack	1,117,445	7	4	1
GenericPWMProvision	260,461	4	0	0
OsMclassicaRefresh	4,579,434	1	0	0
OsRefresh	70,201,856	0	1	0
LemonaidChecker	51,527,866	0	0	0
HostProfilePWM	90,061,861	0	0	0
Firmware	23,945,836	0	0	0

Table 2: Results on meeting maintenance SLOs.

5.4 Maintenance overhead and efficiency

The overall efficiency of our system is reflected at the speed at which we can execute rollouts while maintaining predictability. Rollout speed depends on how fast the train schedule can visit all MDs in a region which depends on the duration of a boxcar visit. We have used different drain-window and work-window durations from 1 to 2 and now to 4 boxcars/day.

To explore whether we can further reduce boxcar duration, we measure the drain- and work-window utilization in one month across all boxcars and regions. The drain-window utilization is 7% on average and 23% for the work-window. This data shows that most drain and upgrades finish early and their assets wait idle until the end of the windows. However, as shown in Table 2 the P95 duration of drains is 77min and the P99 duration is 175min (almost 3h) indicative of a long tail. Similar distributions are observed in the work-window. Further reducing the boxcar duration will increase the enforcement rate and the number of unfinished upgrades which will adversely impact rollout success. Beginning upgrade as soon as a drain completes is possible for automated upgrades, but not possible for those requiring manual effort, since engineer time must be scheduled in advance.

6 History, lesson, and future

In early days, maintenance was performed in isolation by different service teams, which fully managed the allocation and usage of their own buffers. It became challenging with our fleet growth, as we often needed to coordinate multiple maintenances due to resource and reliability reasons. This led to the development of PIMS as a centralized maintenance system in 2019 and the first major deployment in 2021.

As for the major components or ideas of PIMS, we have decided to use a single buffer since the beginning and incorporated the hardware placement algorithm to reduce buffer size in 2022. We created a maintenance contract at the beginning, but it only included the expectations that maintenance

will take down one MD and we will reserve a buffer for that. We added the SLO expectations for different components and teams (i.e., 3 hours for draining and 35 minutes for relinquishing capacity during unplanned faults) in December 2021. Through the years, we have tested different boxcar durations and settled with our current setting.

Our most important lesson is that the maintenance contract is important to the success of PIMS, especially in a hyper-scale environment like Meta. Maintenance is a typical example of tasks that require close collaboration among multiple teams. By clearly defining the responsibility of each team, the contract allows each team to focus on its own goal and achieve the maintenance SLOs with a collective effort.

The recent development of AI clusters, especially the training clusters, has created new challenges to maintenance but it has also simplified maintenance in several other aspects.

1. Training clusters are mostly homogeneous, with the same type of servers and GPUs, so we do not need the hardware placement algorithm to balance MDs.
2. Training is not servicing user traffic, so it can tolerate capacity adjustment, as long as it is planned carefully.
3. Training systems provide fault tolerance capability through mechanisms like checkpoint, so PIMS could interrupt them for maintenance, though the interruption is costly for large-scale training like LLM pre-training [29].
4. The new generations of GPUs allow direct memory access from GPU to GPU across different hosts, which introduces a new kind of network domain. These network domains do not necessarily align with power domains.

In general, smaller maintenance domain means smaller buffer and thus more capacity for training in the common case, but it also means more frequent maintenances and interruptions, which lead to a higher interruption cost. Considering 3 and 4, we currently settle with performing maintenance at the granularity of the new network domains, which are smaller than power domains, for automated upgrades. For physical maintenances that need to take down power domains, we perform them less frequently and take out additional capacity, which is acceptable due to 2. We also try to avoid a physical maintenance during large-scale LLM pre-training. However, due to the fast evolvement of both training software and hardware, our design is subject to changes in the future.

7 Related work

To our best knowledge, this paper is the first to discuss fleet-wide physical maintenance and software upgrades. More broadly, many works discuss the upgrades and maintenance of specific systems, such as ML Supercomputer [34], network devices [2, 3, 14, 23, 25], confidential virtual machines [7], and application-level software [9, 15, 17, 26, 33]. While PIMS shares some of their challenges and design principles, PIMS faces a unique challenge that it has to consider and optimize hardware placement to achieve its goal of minimizing capacity buffer, which leads to our design choices to align maintenance with failure domains and to physically relocate machines to achieve even spread. In addition, as a centralized scheduler, PIMS can schedule many upgrades at the same time, creating opportunities for improving efficiency, while most prior work consider one upgrade at a time.

There are works targeting specific problems during upgrades. For example, Azure's Gandalf focuses on early capturing bad rollouts to prevent widespread outages [22]. Other works focus on classifying upgrades as sources of failures [14, 16, 18, 33]. We also find related work on reducing downtime during upgrade even without migrating running services [5, 6, 13, 19, 26, 28, 30] and tailored approaches to reduce drain time [4]. Finally, Hyrax [24] allows partially-failed servers to be used while waiting for maintenance. These works are largely orthogonal to our work, since our work may apply similar approaches to reduce the chance of failures or reduce down time, though in our experience, these works often work only for specific systems.

8 Conclusions

PIMS achieves small capacity buffer and predictable maintenance at the scale of millions of servers, with a collective effort of clear contract to define the expectation for each participant, optimized hardware placement, SLO-aware prioritized scheduling, and buffer sharing motivated by failure statistics. PIMS has been in production over the last five years in Meta's hyperscale private cloud managing planned maintenance such as kernel and firmware updates. Production data shows that it can significantly reduce capacity buffer size, which yields an annual saving of tens of thousands of servers, and can achieve a reasonable SLO for regular maintenance tasks.

Acknowledgments

This work would not have been possible without the sustained collaboration across many teams at Meta, including Capacity, Core Infra, Datacenter Operations, Network, Production Engineering, Site Operations, and many others. We thank those who have contributed to PIMS: Justin Boseant, Philip Harries, Scott Michelson, David Steere, Ivan Santa Maria Filho, Brian Spaulding, Grigory Turunov, Usman Sharif, Sajal Jain, Yang Xia, Ivan Cikic, Alexander Opeykin, Igor Tufanov, Richa Kala, Victoria Puscas, Maxim Kuthorenko, Andrei Darabanov, Artemiy Kolesnikov, Catherine Sweeney, Aileen McCabe, Konstantin Startsev, Cedric Van Goethem, Sahil Deshpande, Max Khodak, Michal Sedlak, Saranyan A Vigraham, Sudheer Vaddi, Surupa Biswas, and CQ Tang. We also thank all reviewers for their insightful comments.

Abstract

The rapid scaling of generative AI (GenAI), alongside the continued reliance on classical deep neural networks (DNNs), has pushed production AI infrastructure toward massive, heterogeneous GPU fleets. We present a comprehensive characterization of Alibaba Serverless Infrastructure (ASI), a hyperscale production cluster, based on a six-month trace covering 155,410 GPUs of multiple vendors and generations and jobs from 81 departments, spanning ad-hoc development, training, and online and offline inference. Our central finding is that high GPU demand does not yield high effective utilization: idle GPUs frequently become unallocatable because free capacity is stranded across nodes, lacks matching CPUs, or violates network-locality constraints, and because users reserve ample headroom for production safety. Notably, fractional-GPU fragmentation, a focus of prior work, is now negligible, as GPU sharing is rarely used. We detail deployed solutions that recover this capacity: a practical GPU defragmentation algorithm that cuts the number of nodes with slack resources by 20.2%, and SpotGPU, a preemption-cost-aware scheduling framework that safely harvests idle resources and raises the GPU allocation ratio from 68% to 93%. We further surface open challenges in skewed multi-vendor GPU adoption, bandwidth bottlenecks between heterogeneous GPUs, and interference among colocated workloads. We release the ASI trace, the most comprehensive to date in workload diversity and cluster scale, to support future research.

1 Introduction

Production AI clusters are no longer built for a single class of ML workload. Large generative AI models have driven rapid growth in GPU demand, especially for LLMs and image/video generation [1, 7, 12, 57, 58, 62]. At the same time, classical DNNs and recommendation models remain central to latency-critical business services [5,51,59,66]. These workloads differ in model size, execution time, priority, resource shape, and sensitivity to communication and interference. As a result, modern production clusters must manage large GPU fleets as high-value shared infrastructure for heterogeneous workloads that are *first-class* citizens in production.

This paper studies Alibaba Serverless Infrastructure (ASI), a hyperscale shared production GPU cluster. We analyze a six-month trace from ASI that covers 155,410 GPUs and jobs submitted by 81 internal departments. The trace spans ad-hoc development, training, online inference, and offline inference, and includes LLMs [12,57,58], generative image/video models [1,6,7,25,41], DNNs [5,51], and recommendation models [59,66]. Each job specifies the GPUs, CPUs, memory, and replicas it needs, which the cluster uses for allocation and billing. Unlike prior traces that mainly study homogeneous GPU fleets [16] or dated hardware generations [15,51], our trace captures a recent heterogeneous fleet with multiple GPU generations and vendors (Table 1).

The central lesson from ASI is that high demand does not by itself imply high effective utilization. Our ASI cluster represents a large financial investment, so even a 1% utilization change has substantial operational impact. Yet idle GPUs can remain *unutilizable* because free resources are split across the wrong nodes, lack matching CPU capacity, violate network-locality requirements, or are held as headroom for time-varying production demand. Thus, the main resource-management problem is not simply to fill idle GPUs, but to match heterogeneous workload demands to heterogeneous hardware under topology, priority, and interference constraints. Our study follows this problem from measurement to practice: we first characterize why resources become unusable (*fragmentation*), then describe deployed mechanisms that recover part of the lost capacity, and finally identify remaining challenges that still require new system support.

Diagnosing GPU fragmentation. We first show that GPU fragmentation is a primary reason that idle GPUs become unallocatable in ASI [9,43,52]. Fragmentation arises from several sources: fractional GPU allocations, stranded GPUs left on multi-GPU nodes, insufficient CPU capacity on otherwise available GPU nodes, and network topology constraints. Although prior work has discussed the first three sources [52],

[*]Equal contributions.

our trace shows that fractional GPU fragmentation is now a minor contributor in ASI because GPU sharing is rarely used. Instead, stranded GPUs, CPU bottlenecks, and topology constraints dominate. The topology effect is especially important for large GenAI training and serving jobs, which rely on parallelism strategies [34] and therefore need high-bandwidth placement across multiple GPU nodes.

To mitigate fragmentation, we developed IPC (iterative partitioned consolidation), a practical defragmentation algorithm for hyperscale GPU clusters. IPC uses fast partitioned search and ejection-chain scheduling to generate migration decisions that respect affinity rules and locked tasks. We also introduce an entropy-based metric for topology-aware allocation, which prefers placements concentrated within fewer access switches when possible (§4.1). In replay experiments, IPC makes migration decisions within minutes and reduces the number of nodes with slack resources by 20.2%.

Mitigating resource underutilization. We next show that production reservations create a second source of lost capacity. Users reserve capacity for diurnal traffic, failover redundancy, and peak-event headroom, leaving many GPUs idle during off-peak periods. Our trace shows that the peak amount of idle standby capacity can reach 10,000 GPU hours around midnight. This problem cannot be solved by ordinary best-effort packing alone: production jobs must retain guaranteed availability, while flexible jobs should use the idle capacity only when doing so does not endanger high-priority workloads.

ASI addresses this tension through two priority classes and a deployed preemptive scheduling framework called *SpotGPU*. High-Priority (HP) jobs receive guaranteed resources and can reclaim them from Low-Priority (LP) spot jobs, which run at a discounted rate on flexible capacity. Unlike prior workload characterizations, our trace includes job priority metadata, allowing us to study this policy directly. SpotGPU combines a "*Standby*" mechanism, through which HP users explicitly release temporarily idle resources, with a preemption-cost-aware scheduler that places LP jobs while minimizing wasted work when HP jobs reclaim capacity. Together, these mechanisms harvest idle resources while preserving HP resource availability (§4.2).

Understanding remaining heterogeneity challenges. Even with deployed mechanisms for fragmentation and underutilization, several problems remain open because they stem from deeper heterogeneity in hardware, network topology, and workload behavior.

First, ASI uses GPUs from multiple vendors to reduce supply-chain risk, but users initially adopted XPU-A more slowly than NVIDIA GPUs. Although XPU-A has stronger theoretical specifications than NVIDIA H20, its out-of-the-box GenAI performance was only 80% of H20 because key kernels did not yet match the hardware's execution patterns. Our preliminary XPU-A optimizations for LLM serving improve performance by up to 43% and increase HP demand for XPU-A by 2.5×, but supporting diverse model architectures across heterogeneous accelerators remains an open problem.

Second, hardware heterogeneity interacts poorly with network locality. Systems can use heterogeneous GPUs to match different phases of a workload to different hardware capabilities [14, 18, 33, 39, 61, 65]. In ASI, however, heterogeneous GPUs are often located under different access switches (ASW); in our benchmark, same-ASW placement improves `allreduce` bandwidth by 27% relative to cross-ASW placement. For communication-sensitive workloads such as Prefill-Decode (PD) disaggregation [14, 39, 65], the scheduler must balance hardware specialization against the cost of placing communicating instances further apart.

Third, online inference leaves substantial room for co-location, but current isolation mechanisms do not yet make this opportunity easy to exploit. Online inference has a median GPU SM utilization of only 6%. GenAI serving often exhausts GPU memory while leaving compute resources idle, whereas classical DNN serving tends to underutilize both memory and compute. Although co-locating these workloads could improve efficiency, existing GPU sharing techniques such as static partitioning [36] and time-sharing [2, 53, 56, 60] either partition resources too rigidly or fail to provide the latency isolation needed by online services. Similarly, ASI co-locates CPU-only jobs with GPU jobs to harvest idle CPU cycles, but this can reduce the P90 SM utilization of GPU training workloads by 18%.

We believe the observations from ASI are useful beyond our deployment because they expose resource-management problems that arise when large-scale AI infrastructure combines heterogeneous workloads, accelerators, priorities, and topologies. By releasing the sanitized ASI trace[1] and sharing the mechanisms and open challenges from our production experience, we hope to support follow-up research on more efficient GPU cluster management.

2 Background

ASI cluster. ASI is a shared, multi-tenant GPU cluster that provides infrastructure services to dozens of internal departments whose businesses span e-commerce, advertising, local services, logistics, fintech, and content platforms. These departments rent compute resources from ASI to develop and deploy ML services without operating separate GPU clusters. To ensure fairness in resource allocation, ASI allocates resources *on a quota basis*: a tenant cannot request more resources than its assigned quota. Since its inception in 2022, ASI has supported critical business operations across these departments.

Fig. 1 shows the cluster organization. ASI adopts a fat-tree network [26, 40] in which 8-GPU nodes attach to access

[1] https://github.com/alibaba/clusterdata/tree/master/cluster-trace-gpu-v2026

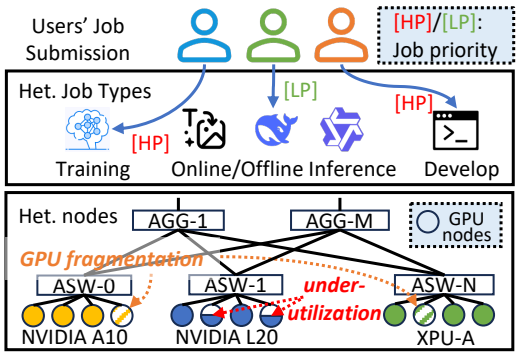

Figure 1: Overview of ASI as a shared GPU infrastructure service. **ASW**: access switch; **AGG**: aggregation switch.

switches (ASW) that are in turn interconnected through aggregation switches (AGG). Each ASW aggregates 32–64 nodes, so a single ASW domain spans roughly 256–512 GPUs, and the GPUs under one ASW are homogeneous. Because the network is not fully non-blocking, a job placed within one ASW communicates at full bandwidth, whereas a job spread across ASWs traverses additional switch layers and loses effective bandwidth. This topology directly shapes placement: communication-sensitive jobs request ASW-local allocations, which in turn constrains how freely the scheduler can pack the cluster. We quantify this effect on fragmentation in §4.1.

Workload scope. ASI must serve two workload classes at once: rapidly growing GenAI models and mature classical DNNs. GenAI models such as LLMs and diffusion-based image/video generation [1, 12, 48, 57, 58] can claim very large allocations; the largest single GenAI job in our trace used over 2,000 high-end GPUs simultaneously and consumed more than 800,000 GPU hours. Classical DNNs remain central to high-throughput production services such as Click-Through Rate (CTR) prediction, recommendation, and optical character recognition (OCR) [51, 59, 66]: they still account for roughly 70% of online-inference GPU hours in our trace (Fig. 3). Co-locating these classes forces ASI to manage workloads with sharply different resource shapes, execution times, priorities, and placement constraints. The trace covers large-scale training and inference in this shared cluster, but *excludes the pre-training of hyperscale foundation models*, which typically runs on dedicated clusters with cutting-edge hardware [47].

Trace. ASI records the metadata needed to study these production resource-management problems, including job types, priorities, model information, hardware types, utilization metrics, and network topology that prior public traces do not expose together. As shown in Table 1, the ASI trace surpasses prior studies by up to two orders of magnitude in both job volume and cluster size, while spanning a far more heterogeneous GPU fleet. These fields connect the workload characterization in §3.1 to the later analyses of fragmentation (§4.1), priority-based resource harvesting (§4.2), and hardware/topology heterogeneity (§5).

3 Workload Characterization

This section characterizes the ASI workload. We first give an overview of the trace—the units of work it records, along with job types, priorities, models, and hardware—and then analyze the temporal and spatial patterns of resource demand and usage.

3.1 Trace Overview

Trace information. The ASI trace records a mix of training, inference, and development jobs running diverse ML models across mainstream frameworks [10, 24, 45, 64]. For each job, it details resource requests, execution durations, scheduling delays, and utilization of GPUs, CPUs, GPU memory, and main memory at job, task, and instance granularity. We further enrich the trace with user-provided application metadata, such as job and model types, and with machine-level telemetry—GPU specifications, node capacities, and time-varying utilization—collected by daemon agents that periodically query the Linux kernel and GPU drivers (e.g., NVML [35]).

Jobs, tasks, and instances. Similar to prior studies [16, 51], users submit jobs as the primary unit of work. Each job consists of one or more tasks that perform distinct computational roles, and each task runs as one or more instances, each encapsulated in a Kubernetes pod (one or more co-scheduled containers). We manage these pods with a customized Kubernetes that lets users specify fine-grained resource requests and limits [21, 22].

Job types. Jobs in ASI span the entire lifecycle of ML model development and deployment, and fall into four broad types:

[2]We use XPU as a desensitized name for non-NVIDIA GPUs.

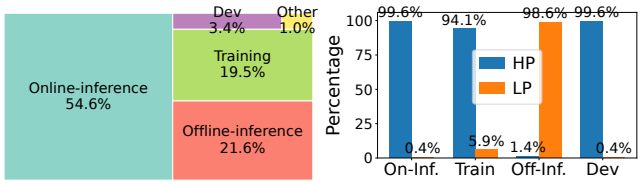

Figure 2: **Left:** Job type distribution. **Right:** Distribution of job priority within each job type.

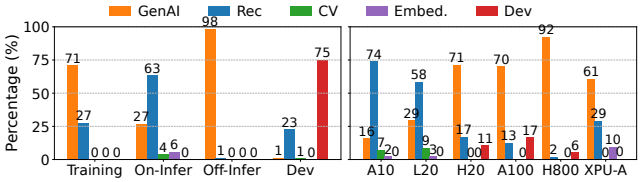

Figure 3: Model type distribution grouped by job types (left) and GPUs (right).

- **Dev** jobs are typically interactive, ad-hoc sessions used for model prototyping and debugging via coding interfaces.
- **Training** jobs execute iterative optimization algorithms to update model parameters. The duration of these jobs varies from thousands of hours when training from scratch to much shorter periods for fine-tuning tasks.
- **Offline-inference** jobs perform batch model inference tasks, such as model evaluation and data generation [50]. These jobs are generally not latency-sensitive.
- **Online-inference** jobs support user-facing or latency-critical model serving applications.

Fig. 2-Left illustrates the distribution of these job types within our cluster. Online-inference constitutes the largest proportion, accounting for over 50% of the workload.

Job priorities. We allow users to specify job priorities, enabling the scheduler to differentiate between workloads. In our trace, we coarsely classify jobs into high-priority (HP) jobs and low-priority (LP) spot jobs for desensitization purposes. HP resources command higher prices but provide guaranteed availability without preemption. Conversely, LP jobs are cheaper but may be preempted by HP jobs.

As shown in Fig. 2-Right, Online-inference and Training jobs are predominantly HP: Online-inference requires high availability for latency-critical services, while training needs long, stable allocations to support iterative optimization. Offline-inference jobs, by contrast, are typically LP, since they are latency-insensitive and well-suited to lower-priority execution that maximizes economic efficiency. Notably, Dev jobs are almost exclusively HP: developers need stable environments and must avoid sudden termination so that intermediate state can be checkpointed.

Various models are deployed. Models executing in ASI can be broadly classified into five categories: *GenAI* (generative AI, including text, image, and video generation), *Rec* (recommendation models, such as CTR prediction [66]), *CV* (computer vision models, e.g., OCR), *Embedding models*, and *Dev* (models under development). We observe several popular model families, including Qwen [57,58], TBStars [1,7], WanX [48], DeepSeek [12], and BERT [5].

Fig. 3-Left shows the model type distribution within each job type. GenAI workloads dominate both Training (71%) and Offline-inference (98%), reflecting heavy demand for large-scale training, model evaluation, and data generation. Online-inference, by contrast, is primarily Rec models (63%), matching the low-latency demands of user-facing services.

Fig. 3-Right breaks down workloads across GPU types. Older or mid-tier GPUs such as the A10 and L20 mostly run classical DNN models, including recommendation and CV models, whereas newer high-end accelerators such as the H800 are dedicated almost entirely to GenAI. This pronounced specialization suggests that users deliberately match hardware capability to workload requirements to control cost.

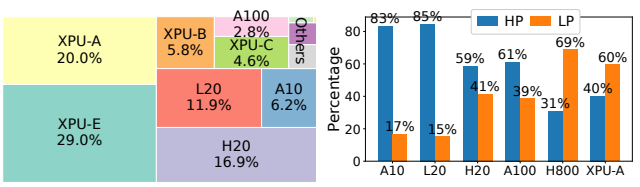

Figure 4: **Left**: Distribution of GPUs. **Right:** Job priority distribution in terms of the GPU hours they run.

Various GPU types to choose from. We offer a heterogeneous set of GPUs (Table 1) and let users request a specific GPU type for their tasks. Strikingly, over 99% of jobs explicitly pin a required GPU model, in sharp contrast to the 6% reported by an earlier study [51].

Fig. 4-Left shows the distribution of GPU types in our inventory, which spans hardware from NVIDIA and other vendors. Fig. 4-Right then shows how HP and LP jobs adopt these types, revealing that job priority correlates with an accelerator's compute capability. Earlier-generation or mid-tier accelerators such as the A10 (83% HP) and L20 (85% HP) are dominated by HP production-critical workloads, partly because they mainly serve mature traditional DNN models that have anchored our businesses for years (see Fig. 3-Right).

Conversely, LP jobs favor newer, more powerful hardware such as the H800, since most of them run GenAI models (Fig. 3-Left), and offline-inference, being latency-insensitive, is cost-effective to run at low priority. Finally, the vast majority of jobs request homogeneous GPUs; fewer than 1% use heterogeneous GPUs.

3.2 Temporal Pattern

Diurnal request and utilization patterns. GPU demand in ASI follows strong diurnal cycles. Fig. 5-Top shows the

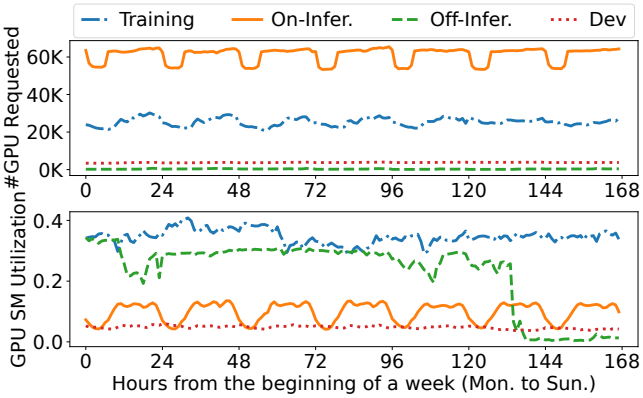

Figure 5: **Top:** number of requested GPUs over one week; **Bottom:** GPU SM utilization over the same week.

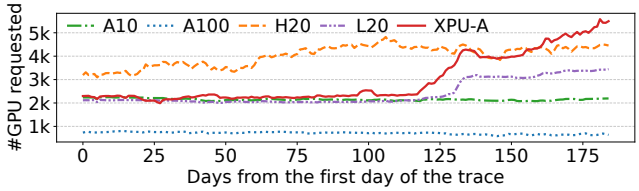

Figure 6: #GPUs requested for different GPU types.

volume of GPUs requested over a representative week: both Training and Online-inference jobs request substantially more GPUs during the day than late at night.

GPU SM utilization, however, tells a more nuanced story (Fig. 5-Bottom). Online-inference utilization stays diurnal because it tracks immediate user demand, whereas Training utilization does not, since long-running iterations keep GPUs busy around the clock. Offline-inference instead exhibits a weekly cycle, with SM utilization dropping sharply over the weekend.

GPU adoption. GPU adoption in ASI has shifted as we diversified our hardware supply. NVIDIA GPUs have been deployed for years and see relatively stable demand. To ease supply-chain constraints and build a more sustainable infrastructure, we recently began sourcing GPUs from other vendors; these non-NVIDIA devices, which we call XPUs, now make up a significant portion of our fleet (see Fig. 4-Left). Users were initially reluctant to adopt XPU-A because its out-of-the-box performance fell short of their expectations. Starting around Day 120, however, XPU-A adoption rises sharply (Fig. 6), following our release of a dedicated optimization suite that markedly improves model performance on XPU-A (§5.1).

Task instance run-time. Fig. 7 shows the CDF of task execution time, grouped by job type and by model type. Dev tasks run the longest, since developers keep long-lived interactive coding sessions open. Excluding Dev, Online-inference and Training tasks have comparable execution times, both longer than Offline-inference tasks. By model type, Rec and CV

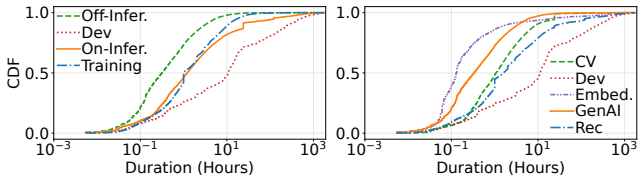

Figure 7: Task execution time grouped by job type (**Left**) and by model type (**Right**).

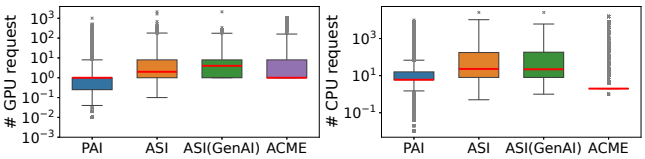

Figure 8: Jobs' #GPU and #CPU requested in different traces.

models accordingly run the longest, as they are dominated by Online-inference workloads, whereas GenAI models, which dominate Offline-inference, run shorter than CV and Rec models.

Overall, the median job execution time in ASI is 5 hours—far longer than the 23 minutes in PAI [51] and the 2 minutes in Acme [16]. We attribute this to ASI's mix of long-running online serving and large-scale training: PAI covers only DNN jobs, while Acme is dominated by short-running evaluation jobs (93%). Scheduling latency, in contrast, is low: the median is just 1 second, and even the P90 for HP tasks is 101 seconds—negligible against their P90 execution time of 24 hours.

3.3 Spatial Pattern

We now turn to spatial patterns—how tasks request and use resources across the cluster. ASI samples telemetry for every running task at 20-second intervals.

GPU and CPU request. Jobs in ASI request markedly more GPUs per job than in older traces. Fig. 8 compares the distribution of requested GPUs and CPUs against PAI [51] and Acme [16] using boxplots; for ASI, we report both the full dataset (ASI) and the GenAI-only subset (ASI(GenAI)). The median and mean GPU request grow from 1 and 2.6 in PAI to 2 and 11.0 in ASI, and to 4 and 11.0 in ASI(GenAI), driven in part by GenAI models that PAI predates. Acme, which targets LLM training, has a median and mean of 1 and 5.0; its low values arise because short-running evaluation jobs dominate its job count yet consume few resources [16], which also explains the outliers in the CPU plot. CPU requests show a similar PAI-to-ASI trend.

GPU allocation. We measure the GPU allocation ratio—the fraction of total GPU capacity claimed by jobs—which reflects how effectively resources are claimed and directly affects revenue. We further differentiate the allocation ratio attributed to HP jobs from that of combined HP and LP jobs

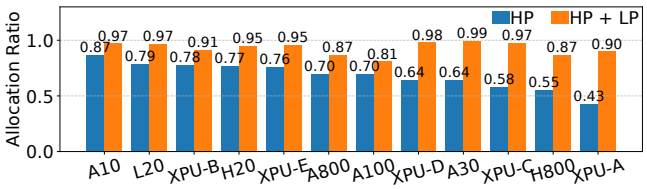

Figure 9: GPU allocation ratio by GPU type. **HP:** HP jobs only. **HP+LP:** HP and LP jobs combined.

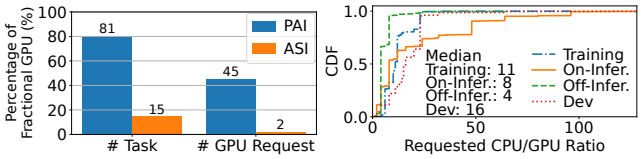

Figure 10: **Left**: Percentage of GPU sharing (fractional GPU) usage. **Right:** Ratio of #CPU/#GPU requested for tasks.

(HP+LP) to illustrate the effectiveness of LP workloads in boosting utilization. As Fig. 9 shows, LP jobs raise the allocation ratio for all GPU types, and especially for high-end GPUs: the cluster average rises from 68% with HP jobs alone to 93% with HP and LP combined. We detail how we enable LP spot jobs in §4.2.

Rare GPU sharing. GPU sharing lets multiple jobs that request fractional GPUs (< 1.0) multiplex a single device, and prior systems treat it as a key efficiency lever [51–53]. In ASI, however, GPU sharing is now rarely used, for reasons we discuss in §4.2. Fig. 10-Left reports both the share of tasks that claim fractional GPUs and the share of total GPUs they request; compared with PAI, both are negligible in ASI.

CPU/GPU ratio. Although ML workloads train and run inference on GPUs, much of their data processing—fetching and sampling, for example—runs on CPUs, which can become a bottleneck [51]. Fig. 10-Right shows the ratio of requested CPUs to requested GPUs per task, the CPU/GPU ratio. Most tasks have moderate ratios, but some are extreme, because ASI's GPU servers span a wide range of CPU/GPU configurations: an 8-GPU H20 server may have 192 CPU cores, whereas a 1-GPU A10 server may have 128. To keep requests feasible, we cap each request's CPU/GPU ratio according to its target server type.

Resource utilization. Fig. 11 shows task-level resource utilization by job type. Dev tasks have the lowest utilization across all metrics, reflecting their ad-hoc nature, while Training tasks have the highest, reflecting their compute intensity. Online-inference and Offline-inference use host memory similarly but differ sharply in CPU and GPU SM utilization, because Online-inference is driven by interactive user requests whereas offline-inference runs as batch jobs. Online-inference also uses less GPU memory than offline-inference, as it mainly runs standard DNN models while offline-inference predominantly runs GenAI models.

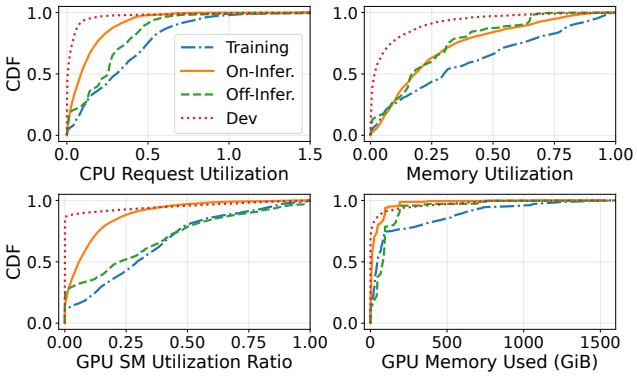

Figure 11: Task-level resource utilization.

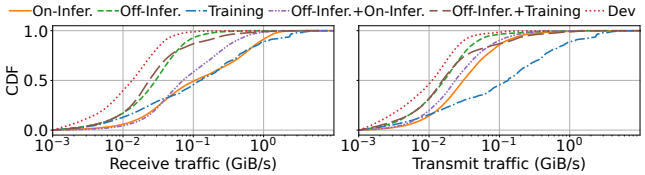

Figure 12: Node-level network utilization.

We next examine node-level network utilization (receive and transmit bandwidth). Because tasks of different job types can share a node, we group nodes by the mix of tasks they host and show the six most common mixes. As Fig. 12 shows, nodes running only training tasks have the highest network utilization, since most ASI training uses GenAI models that rely on parallelism and thus heavy inter-node communication.

3.4 Case Study

We close the characterization with three case studies of online LLM serving in ASI.

PD-disaggregated LLM serving. Adoption of prefill-decode (PD) disaggregation [14, 39, 65] for LLM serving has surged in ASI: the daily average GPU count for these workloads grew 3.7× over the trace period, from 1,041 to 3,841. Yet, contrary to strategies that pair heterogeneous GPUs with the distinct compute profiles of prefill and decode [65], our users request homogeneous GPUs, citing deployment complexity and network degradation when spanning heterogeneous GPU types (see §5.2).

Smaller LLMs are favored. Among one month of online-inference tasks running Qwen-family LLMs [57, 58], smaller models dominate usage. Grouped by parameter count, the *0–30B*, *30–100B*, and *100B+* tiers consume 60.9%, 35.0%, and 4.1% of GPU hours, respectively. Users favor smaller models because they cost less and, after fine-tuning, perform well enough in their target domains.

Comparison between representative LLMs and DNNs. We compare the three most popular models in online-

inference tasks: BERT [5], Qwen [57, 58], and CTR prediction [66]. CTR, BERT, and Qwen request a median of 24, 8, and 4 CPU cores, respectively—consistent with prior reports that recommendation models are more CPU-heavy [51, 59]. As for GPU compute, Qwen's median GPU SM utilization of 26% is 2.7× that of CTR and 9.6× that of BERT.

4 Improving Resource Utilization

In this section, we describe two resource-management challenges observed in the ASI cluster, GPU fragmentation and resource underutilization, and present the production mechanisms we deploy to address them.

4.1 Tackling GPU Fragmentation

GPU fragmentation breaks idle GPU resources into pieces that cannot be allocated as a whole to satisfy a resource request [43, 52], shrinking the effective capacity of the cluster. We first diagnose the causes of fragmentation in ASI and then present two mechanisms that address its dominant causes: *IPC defragmentation*, which consolidates jobs to recover stranded GPUs and relieve CPU bottlenecks, and *topology-aware allocation*, which mitigates the fragmentation induced by network-topology requirements.

Causes of GPU fragmentation. Prior work [52] identifies three common causes of GPU fragmentation:

1) Fractional GPU fragmentation. ML models in production can be small. For example, a ResNet-152 model only has 60 million parameters, which cannot occupy a whole GPU. Therefore, we allow users to request a fractional GPU, e.g., 0.25 GPU, such that multiple small ML models can collocate in a single GPU for resource-efficient GPU sharing [51]. Despite the benefits, fractional GPU can cause intra-GPU fragmentation, as fractional allocations can leave unusable residual capacity on individual GPUs, especially preventing the placement of jobs that require whole GPU cards.

2) Stranded GPU fragmentation. For multi-GPU nodes, GPU fragmentation can appear when a job does not request all GPUs in the node, making the remaining GPU cards stranded. For example, assigning a 2-GPU task to an 8-GPU node results in intra-node fragmentation, leaving the remaining six GPUs as stranded resources that cannot satisfy a subsequent request for a full-node (8-GPU) allocation.

3) Insufficient CPUs. While GenAI models heavily use GPUs, we observe CPUs can be the bottleneck for GPU allocation. This happens when a node can satisfy the GPU requests but fails to meet associated CPU requests, typically due to extreme CPU/GPU ratios (see Fig. 10-Right). Exhausting CPUs in a node can cause GPU fragmentation.

In ASI, fragmentation is rarely caused by fractional GPUs but is instead driven by two bottlenecks: stranded GPUs and insufficient CPUs. Fig. 13 diagnoses this by measuring fragmentation, in unallocatable idle GPUs, under varying resource request configurations. That fractional GPUs barely contribute echoes Fig. 10-Left, where GPU sharing is rare. For requests with high CPU/GPU ratios (e.g., 1G8C and 8G128C), the dominant bottleneck is "Insufficient CPU": GPUs cannot be allocated because CPUs are exhausted. For mid-sized configurations (e.g., 4G32C through 8G64C), "Stranded GPUs" (orange bars) dominate: aggregate GPU capacity exists but is fragmented across nodes, preventing the scheduling of jobs that require contiguous multi-GPU allocations.

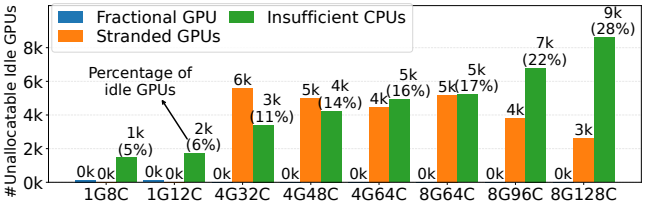

Figure 13: GPU fragmentation with varying resource requests. **8G128C**: request 8 GPUs and 128 CPUs.

Beyond these three known causes, we observe a new cause of GPU fragmentation when users submit a multi-GPU request with network-topology requirements.

4) Network topology. Very large ML models, such as LLMs, often demand aggregate GPU memory exceeding that of a single GPU server, so the standard practice is to partition the model into chunks distributed across multiple GPU nodes [34]. Both training and inference of such models entail intensive cross-node communication. To reduce this communication bottleneck, users often request *topology-aware placement*; for example, requiring all allocated GPUs to reside under the same ASW. As described in §2, the ASI fat-tree network is not fully non-blocking, so a job placed across multiple ASWs traverses additional switch layers and loses effective bandwidth; our benchmark shows that colocating all GPUs under a single ASW improves `allreduce` bandwidth by 27% relative to cross-ASW placement.

However, strictly enforcing such topology requirements introduces a new form of fragmentation: GPUs scattered across different switches become ineligible for a single job, substantially shrinking the effective pool of available resources. To illustrate its severity within ASI, we constructed two large-scale configurations—jobs requesting 128 and 256 GPUs, respectively, each GPU requiring 12 CPUs—and measured how many such requests ASI could fulfill. Fig. 14 reports the impact of these ASW constraints on allocation.

The comparison between the baseline (across ASW) and the ASW-enforced configuration (within ASW) shows that enforcing ASW constraints significantly reduces the number of fulfillable jobs. This reduction is particularly severe when requesting large sets of homogeneous NVIDIA GPUs, where capacity drops to near zero, indicating that strict topological requirements disproportionately impact these high-demand

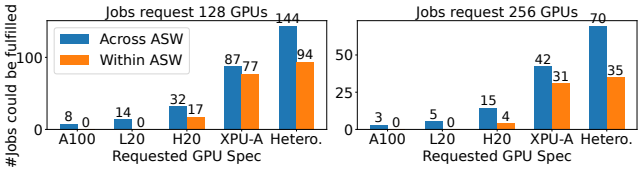

Figure 14: Impact of network topology on GPU allocation.

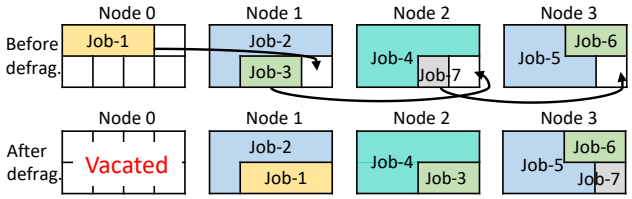

Figure 15: Illustration of the ejection chain in IPC. To evacuate Node 0, Job-1 must first be migrated off the node. Before defragmentation, none of Nodes 1–3 individually has sufficient GPU slots to host Job-1, even though they collectively provide three idle GPU slots. With an ejection chain: Job-3 is moved from Node 1 to Node 2, which first requires shifting Job-7 to Node 3; Job-1 is then moved from Node 0 to Node 1, vacating Node 0 after defragmentation. CPUs are omitted for clarity.

resources. Conversely, for less popular XPU-A, the impact is less pronounced. Furthermore, when heterogeneous GPU allocations are permitted, the cluster retains higher capacity for large-scale requests. Therefore, promoting the use of less popular GPUs alongside heterogeneous GPUs can effectively alleviate the bottlenecks caused by topology requirements.

GPU defragmentation. To recover stranded GPUs and relieve CPU bottlenecks, ASI runs GPU defragmentation as a routine maintenance task that consolidates jobs occupying only a fraction of a server, freeing whole-machine GPU capacity for incoming workloads that demand both multiple GPUs and substantial CPUs.

Challenges. Such consolidation is achieved by migrating running jobs to pack them onto fewer servers, yet performing these migrations in a live production cluster raises three challenges. First, new jobs can be submitted to the cluster at any time, which dynamically alters resource availability and allocation. As a result, the decision-making of GPU job migration must be fast, ensuring that migration and scheduling decisions can be completed within a few minutes, which poses a challenge given the large scale of our cluster. Second, migrating workloads across nodes must satisfy practical cluster-level constraints [28], including adhering to existing affinity and anti-affinity rules [20], which define if tasks can run on a certain node or if a set of tasks can be colocated. Besides, 40% of tasks in ASI are labeled as "locked", indicating that they are business critical and cannot be moved. Third, GPU job migration and defragmentation must remain transparent to users. This means we cannot impose constraints on the underlying machine learning frameworks used by the jobs, nor can these operations introduce any service downtime [29].

IPC Algorithm. We design and deploy IPC (iterative partitioned consolidation), a practical defragmentation algorithm that takes a snapshot of the current node and task states and generates a set of task migration decisions whose objective is to vacate as many nodes as possible. Each of the three challenges above maps to a design choice in IPC: *divide-and-conquer* keeps decision-making fast at cluster scale, *ejection-chain scheduling* respects affinity, anti-affinity, and locked-task constraints during migration, and an *iterative* process drives the number of vacated nodes higher across rounds. To keep migration transparent to users, IPC adopts a make-before-break approach: it brings up a new instance on the target node before terminating the old one, eliminating service downtime.

1) Divide-and-conquer. To generate migration decisions quickly, IPC randomly partitions the cluster's nodes into disjoint groups, each an independent subproblem within which IPC tries to vacate as many nodes as possible. These subproblems run embarrassingly in parallel, accelerating decision-making at cluster scale.

2) Ejection chain scheduling. Within each group, IPC scores every node by priority and heuristics, e.g., the number of pods it hosts, and selects higher-priority (fewer-pod) nodes first as they are easier to vacate; Algorithm 1 gives the pseudocode for a partition. As illustrated in Fig. 15, IPC builds an ejection chain recursively (`Eject`$(\cdot)$ at line 6): if a destination node cannot accommodate a task, it recursively moves tasks off that destination node until all pods are placed or the recursion-depth limit K (line 6) is reached. In practice, we set K to 3.

Algorithm 1: Ejection Chain Scheduling

Input: Node partition $\mathcal{N}$, Max depth K
Output: Set of migration actions $\mathcal{M}$

1 $\mathcal{M} \leftarrow \emptyset$; $\mathcal{L} \leftarrow$ Sort$(\mathcal{N})$ `// sort nodes in the partition`
2
3 **foreach** $n \in \mathcal{L}$ **do**
4 $\quad \mathcal{M}_n \leftarrow \emptyset$; *feasible* $\leftarrow$ **true**
5 $\quad$ **foreach** $\tau \in n.tasks$ **do**
$\quad\quad$ `// Eject() recursively searches a feasible ejection chain C that satisfies the practical constraints and resource requests and is shorter than K`
6 $\quad\quad C \leftarrow$ Eject(τ, K)
7 $\quad\quad$ **if** $C \neq \emptyset$ **then**
8 $\quad\quad\quad \mathcal{M}_n \leftarrow \mathcal{M}_n \cup C$
9 $\quad\quad$ **else**
10 $\quad\quad\quad$ *feasible* $\leftarrow$ **false**; **break**
11 $\quad$ **if** *feasible* **then**
12 $\quad\quad \mathcal{M} \leftarrow \mathcal{M} \cup \mathcal{M}_n$
13 $\quad$ **else**
14 $\quad\quad$ Mark n as non-migratable
15 **return** $\mathcal{M}$

3) Iteration. To vacate as many nodes as possible, the IPC algorithm iteratively runs the process of divide-and-conquer and ejection chain scheduling for several rounds, attempting to vacate nodes in each round. We empirically observe that the marginal benefit becomes small after the third round, so we cap the maximum number of rounds at five.

Effectiveness of IPC. IPC has run stably in our scheduler for years, making a migration decision in under 2 minutes; on a two-month trace replay, it reduces the number of not-fully-occupied nodes by 20.2%. It replaced our earlier reliance on Kubernetes [21] eviction, which redistributes evicted jobs randomly across the cluster. We use a heuristic rather than an optimal plan because optimal defragmentation is impractical online: the optimization is expensive to solve, and an optimal plan may demand large-scale pod migrations that production cannot absorb. Formulating defragmentation as an integer linear program (ILP), a 25-node cluster yields 4,000 binary variables and 800 constraints that Gurobi [13] solves to optimality in roughly 5 minutes on a 16-CPU node, whereas a 100-node cluster takes two days—yet in practice each IPC partition holds 500 nodes.

Topology-aware GPU allocation. To address the topology-induced fragmentation of Fig. 14, ASI deploys an allocation policy that consolidates the GPUs of a large-scale request into as few ASWs as possible. We describe the deployed single-job policy here; its optimal multi-job generalization remains an open challenge (§5), so we report no aggregate benefit number for it. We introduce *entropy* to quantify the distribution of the allocated GPUs of a job. Suppose that the GPUs requested by a job are distributed across n ASWs. Let $g_1, g_2, \ldots, g_n$ denote the number of GPUs in each ASW, and let G denote the total number of GPUs ($G = \sum_{i=1}^{n} g_i$). The GPU entropy of the job is defined as

$$H = -\sum_{i=1}^{n} p_i \log p_i, \text{ where } p_i = \frac{g_i}{G}, \tag{1}$$

where higher entropy indicates a more uniform distribution, whereas lower entropy indicates concentration within a small number of ASWs. Our allocation policy seeks to consolidate the GPUs assigned to the job within as few ASWs as possible; accordingly, lower entropy is preferred.

The process of generating a GPU allocation plan for a large-scale job is shown in Algorithm 2. For each iteration, we decide which ASW to use by iterating over all ASWs, and for each ASW, we calculate the GPU-topology distribution if we allocate as many of its GPUs to the job as possible. Then we select one that yields the minimum entropy, allocate that ASW's idle GPUs to the job, and proceed to the next iteration.

This greedy algorithm is optimal for a single job, but not across multiple jobs, where the scheduling order matters and the problem becomes combinatorial. In practice, we sort jobs by size in descending order and schedule the largest first; cross-ASW migration reuses IPC, with network topology added as a practical constraint. We leave large-scale topology-aware allocation as an open challenge in §5.

Algorithm 2: Topology-aware GPU allocation

Input: Number of requested GPUs G; available ASWs $\mathcal{N}$
Output: Allocation Plan $\mathcal{P}$

$\mathcal{P} \leftarrow \emptyset$; $G_{rem} \leftarrow G$
while $G_{rem} > 0$ ***and*** $\mathcal{N} \neq \emptyset$ **do**
  `// Find ASW s that minimizes entropy if added`
  $s^* \leftarrow$ $\arg\min_{s \in \mathcal{N}} \text{Entropy}(\mathcal{P} \cup \{\min(\text{Cap}(s), G_{rem}) \text{ GPUs of } s\})$
  $n \leftarrow \min(\text{Cap}(s^*), G_{rem})$
  $\mathcal{P} \leftarrow \mathcal{P} \cup \{(s^*, n)\}$; $G_{rem} \leftarrow G_{rem} - n$
  $\mathcal{N} \leftarrow \mathcal{N} \setminus \{s^*\}$
end
return $\mathcal{P}$

4.2 Addressing Resource Underutilization

Our characterization reveals substantial temporal and spatial resource underutilization in the cluster (Fig. 5 and Fig. 11). Discussions with our users trace this primarily to a common practice: users over-provision GPU capacity to absorb diurnal traffic peaks, maintain failover redundancy, and reserve headroom for peak events. Such defensive reservation leaves a sizable fraction of resources idle for long periods, degrading cluster-wide efficiency.

GPU sharing as a strawman solution. A natural way to reclaim underutilized resources is *GPU sharing*: co-locating multiple jobs on one GPU so they time-multiplex it and fill idle cycles [51, 52, 55]. Although ASI supports GPU sharing, adoption remains low (Fig. 10-Left), for two reasons. First, GPUs offer weaker isolation than CPUs, so co-located jobs interfere; even virtualization mechanisms such as MPS (Multi-Process Service) [37] and MIG (Multi-Instance GPU) [36] provide only coarse-grained, inflexible partitioning. Second, emerging GenAI models consume large amounts of GPU memory for parameters and intermediate state (e.g., KV-Cache) [24], making it infeasible to share a single GPU across jobs. Consequently, in ASI fractional GPU requests come almost exclusively from classical CV and recommendation models, which reserve GPUs with MPS enabled to serve small models. GPU sharing therefore reclaims idle capacity only within a single device; to reclaim the much larger pool of reserved-but-idle capacity across jobs, we instead operate at job granularity through SpotGPU.

SpotGPU. SpotGPU is designed to achieve two objectives. First, it reclaims reserved-but-idle GPU capacity and returns it to productive use, raising cluster-level utilization. Second, it offers this reclaimed capacity, together with other idle resources, to users with flexible workloads at a discounted spot rate. Concretely, SpotGPU safely oversubscribes the reserved capacity of HP jobs and allocates the resulting idle capacity to LP spot jobs. Because resources granted to LP jobs are not guaranteed, they are priced lower; when HP jobs reclaim their

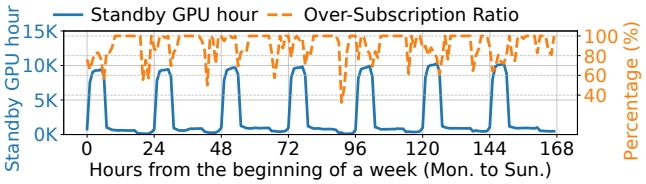

Figure 16: Temporal pattern of GPU hours of "Standby" tasks and the over-subscription ratio of the "Standby" GPU hours.

reserved resources, SpotGPU preempts the running LP jobs in near real-time.

"Standby" HP tasks. To reclaim reserved capacity from HP jobs without disrupting them, SpotGPU offers a "Standby" mechanism and incentivizes participation with financial rebates. Through an API, a user labels an HP task as "Standby" for a chosen window, e.g., by updating the labels of its Kubernetes pods [23], signaling willingness to temporarily release the task's allocated resources to LP spot jobs. Fig. 16 shows that "Standby" GPU hours follow a pronounced diurnal pattern, surging at midnight to as much as 10,000 hours.

A Standby task must reactivate quickly, so SpotGPU does not tear down its container. Instead, it detaches the task's request traffic and replaces the container's main service process with a `sleep` command, releasing the CPUs and GPUs while keeping the container warm; reactivation then skips the costly steps of rescheduling and image pulls. When an HP task must resume, SpotGPU first triggers a graceful eviction of the co-located spot job and then signals the HP task to resume, preserving HP SLOs. The eviction proceeds as follows: (i) the node agent observes the HP pod arriving on its node, (ii) it sends `SIGTERM` to the co-located spot pod, (iii) the in-container graceful shutdown runs, executing user-defined logic, bounded by a 60-second termination period, and (iv) the container exits and the GPU is reclaimed. Steps (i), (ii), and (iv) are platform-side and complete quickly and deterministically, so eviction latency is dominated by the user-defined step (iii). In our deployment, the average eviction time is 13 seconds (P95 of 48 seconds), well within the 60-second window; containers that do not exit within this window are forcibly terminated via `SIGKILL`, affecting fewer than 5% of evictions. To resume the HP task, SpotGPU restores its original command in place of the `sleep`. As shown in Fig. 16, on average, 90% of "Standby" GPU hours are harvested.

Preemptive task scheduling. For newly submitted jobs, ASI uses a preemptive scheduling policy that prefers non-preemptive allocation for stability but, when it must reclaim resources from LP spot jobs, accounts for the resulting preemption cost. Since GPU tasks commonly checkpoint during execution [31,46], a preempted task can resume from its last checkpoint rather than restart. ASI lets users specify a checkpoint interval, and we define the preemption cost of a task as its wasted computation, i.e., the work performed since its last successful checkpoint.

We formulate the preemptive scheduling decision as a mixed-integer linear program (MILP), detailed in Appendix A. Because the MILP is intractable for online scheduling, we instead use an efficient heuristic. The algorithm first attempts non-preemptive allocation for an HP task on available GPUs. If this fails, it switches to preemptive mode and evicts selected LP spot tasks to reclaim their resources for the HP task. New spot tasks, in contrast, are scheduled strictly non-preemptively.

1) Non-preemptive scheduling. For an HP or spot task, the scheduler first filters nodes that meet the task's GPU requirements to form a candidate set. It then ranks the node candidates by three criteria applied in order, each breaking ties left by the previous one:

- *Task packing:* prioritize nodes with the least idle GPU capacity, packing tasks onto fewer nodes to limit fragmentation.
- *Homogeneous co-location*: place HP tasks on nodes hosting other HP tasks, and assign spot tasks to spot-dedicated nodes. This strategy insulates and prioritizes HP tasks, allowing for efficient future scheduling via preempting spot tasks when necessary.
- *Eviction history*: assign a new spot task to the node with the *lowest* historical eviction count so it is less likely to be preempted, and a new HP task to the node with the *highest* eviction count. This strategy concentrates future preemptions on already-volatile nodes and leaves stable nodes for long-running spot tasks, reducing repeated evictions of the same spot tasks.

2) Preemptive scheduling. When a new HP task cannot be placed non-preemptively, the scheduler preempts spot tasks. Because preemption disrupts a spot task's progress, the scheduler chooses victims so as to minimize wasted computation: it identifies the nodes that could host the HP task if their spot tasks were removed, scores each by its preemption cost, and selects the node with the lowest cost.

Concretely, consider an HP task arriving at time τ_{now} that requires G_{hp} GPUs. For a running spot task t using G_t GPUs with its last checkpoint at τ_{ck}, we define its preemption cost as the lost work weighted by resource usage, $C_t = G_t \cdot (\tau_{now} - \tau_{ck})$. To score a node, the scheduler sorts its spot tasks by ascending preemption cost and takes the smallest prefix $\{t_1, \ldots, t_k\}$ such that their combined resources meet the HP task's demand, i.e., $\sum_{j=1}^{k} G_{t_j} \geq G_{hp}$. The node's total preemption cost is hence given by $\sum_{j=1}^{k} C_{t_j}$. Having all nodes scored, the scheduler then places the HP task on the one with the minimum preemption cost and evicts the selected spot tasks there. For heterogeneous GPUs, G_{hp} and G_t become resource vectors whose elements give the required quantity of each GPU type.

	#GPUs per node	Memory per card	HBM BW (TBps)	Inter–GPU BW (GBps)	FP16 Tensor Core Compute Spec.
H20	8	96	4.0	900	148 TFLOPS
XPU-A	8	192	5.2	896	203 TFLOPS

Table 2: Hardware specifications of H20 and XPU-A.

Benefits of SpotGPU. SpotGPU raises the average GPU allocation ratio from 68% to 93% (Fig. 9), meaning a substantially larger fraction of resources is put to productive use, and Fig. 16 shows that users actively release reserved capacity through "Standby", shortening idle periods. To isolate the preemptive scheduler's contribution, we compare it against a baseline that disables co-location and eviction awareness in non-preemptive scheduling and replaces preemptive scheduling with random victim selection. Our scheduler reduces LP task completion time by 24% without affecting HP task performance, a gain that stems from accounting for preemption cost to avoid discarding spot tasks' near-complete work.

5 Open Challenges

The mechanisms in §4 address resource-management problems that we have largely brought under control in production. We now turn to problems that remain open. We first examine the imbalanced adoption of heterogeneous GPUs, an increasingly pressing issue as we diversify beyond a single vendor, together with our preliminary efforts to close the resulting performance gap (§5.1). We then discuss three further challenges in allocation and colocation that we have yet to fully resolve (§5.2).

5.1 Imbalanced Adoption of Heterogeneous GPUs

The adoption gap. Meeting the growing demand for high-end GPUs while avoiding the risks of single-vendor dependency has led us to diversify our hardware. We recently integrated XPU-A from another vendor as a primary alternative, attracted by its large memory capacity and competitive compute. Adoption, however, is heavily skewed: we observe an *imbalanced adoption of heterogeneous GPUs*, in which HP jobs request NVIDIA GPUs and other XPUs far more than XPU-A (Fig. 9). Closing this gap would do more than load balancing. Because most XPU-As can satisfy strict network-topology requirements that NVIDIA GPUs often cannot (Fig. 14), broader XPU-A adoption would also relieve the topology-induced fragmentation of §4.1.

This imbalance stems from performance, not capacity. On paper, XPU-A surpasses the NVIDIA H20, its closest counterpart in FP16 compute, offering larger memory and higher bandwidth (Table 2). In practice, however, it underdelivers on GenAI models: Fig. 17-Left shows XPU-A trailing H20 when serving DeepSeek-R1. Profiling and discussions with

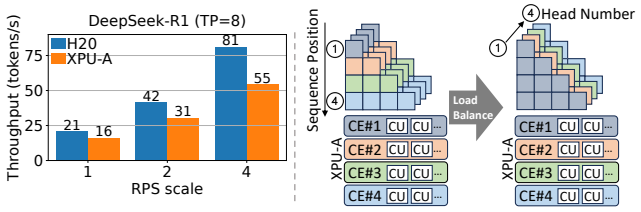

Figure 17: **Left:** Throughput of Deepseek-R1 [12]. **Right:** Optimized prefill. **CE**: Compute Engine. **CU**: Compute Unit.

the XPU team trace this to a single root cause—standard kernel implementations are mismatched to XPU-A's hardware-specific features—which motivates the optimizations below.

Optimizing XPU-A for LLMs. Guided by this diagnosis, we have benchmarked and optimized XPU-A for Qwen-family LLMs on vLLM [24] and RTP-LLM [10], a production-grade inference engine developed by Alibaba. For brevity, we describe two representative optimizations, one for the prefill phase and one for decoding.

Prefill. In the prefill phase, the Flash Attention kernel in XPU-A's official library distributes work poorly under the *causal mask*, the mechanism that lets each token attend only to preceding tokens. The mask imposes a triangular computation in which per-token load grows linearly with a token's position in the sequence (Fig. 17-Right). The existing kernel maps thread blocks to the logical grid along the sequence-length dimension and dispatches them to Compute Engines (CEs) of XPU-A in rigid round-robin order, causing severe load imbalance: the CE handling the tail of the sequence becomes a bottleneck while the others finish early and idle. We instead parallelize CE assignment along the attention-head dimension, which evens out the load across CEs. Simple as it is, this change yields a 1.58× speedup in prefill computation for a 4k-token sequence with 64 heads.

Decoding. During decoding, most serving engines use Paged Attention (PA) kernels [24], which are memory-bound because decoding each token requires reading the entire KV-cache history from GPU memory. To saturate Compute Units (CUs) of an XPU, PA adopts a SplitKV strategy that partitions the KV-cache into chunks processed in parallel across CUs. When we port PA to XPU-A with Triton [38], however, the compiler inverts the thread-block layout, so every thread subgroup redundantly recomputes the full matrix instead of dividing the work, wasting most of the compute. We fix this by injecting custom compiler passes into Triton that enforce the correct parallelism, and have contributed the fix back to the Triton ecosystem.

Effectiveness. We have integrated these and further optimizations into RTP-LLM [10], with two effects. First, user demand for XPU-A has risen sharply: HP jobs request 2.5× more XPU-A GPUs after the optimizations (Fig. 6). Second, the optimizations close the performance gap: on Qwen LLMs

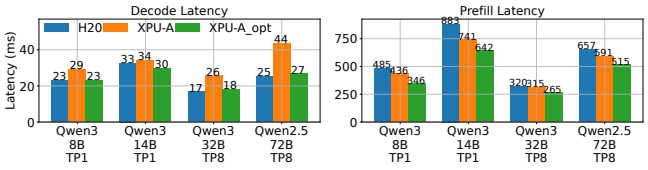

Figure 18: Performance of Qwen LLMs on varying GPUs with tensor parallelism (TP). XPU-A_opt: XPU-A with optimization. **Left:** Decoding performance at batch size=64. **Right:** Prefill performance (batch size=1).

```
# Original FlashAttention import
import flash_attn

# Replace it with our drop-in optimized implementation
import asi.api.flash_attn as flash_attn
```

Figure 19: An example of integrating our optimizations.

of varying sizes [57, 58], optimized XPU-A matches H20 and far outperforms the unoptimized baseline (Fig. 18). Benchmarking the same suite on vLLM [24, 44], optimized XPU-A improves request latency by 33% and 43% at one and two requests per second (RPS) over unoptimized XPU-A, surpassing H20 by 2% and 21%; the larger margin at RPS=2 comes from XPU-A's larger memory, which holds a bigger KV-cache and reduces queuing delay.

Programming interface. To make these optimizations easy to adopt, we expose them through drop-in APIs. In PyTorch, a user enables an optimization by changing a single `import` (Fig. 19); the frontend API preserves compatibility with existing code, and the API layer handles all remaining adaptation transparently.

Beyond LLMs. Our broader goal is to deliver high-performance services across heterogeneous GPUs, so that balanced GPU usage improves resource management and widens the range of viable hardware choices. The optimizations above target LLMs; substantial challenges remain for multimodal models, e.g., Qwen Next [42], and generative image/video models, whose distinct architectures and attention mechanisms demand separate hardware-specific tuning [30].

5.2 Additional Resource-Management Challenges

Topology-aware allocation under heterogeneity. In §4.1, we showed how network-topology constraints limit GPU allocation; these constraints also collide with hardware heterogeneity. In ASI, GPUs under the same ASW are homogeneous, so enforcing ASW-level locality precludes mixing heterogeneous GPUs within a single job—precisely when heterogeneity is becoming a key GenAI optimization [39]. The PD-disaggregation paradigm, for instance, is now widely used in LLM serving and accounts for up to 12,000 GPUs per day in ASI: prefill is compute-bound and favors high-performance GPUs, whereas decoding is memory-bound and needs high bandwidth [65]. Such heterogeneous matching is more cost-effective, but it places the KV-cache transfer between disaggregated nodes on the critical path—decoding cannot begin until the KV cache arrives—making network performance the bottleneck. Cost-efficiency therefore hinges on balancing hardware specialization against topology constraints, a tension that extends beyond LLM serving to any system built on heterogeneous GPUs [8, 18, 33, 49, 61].

Underutilization of online-inference jobs. Online-inference jobs dominate ASI yet run highly inefficiently: aggregated across all such jobs, median SM utilization is only 6% and median GPU-memory utilization only 30%. This low overall utilization masks two distinct workload patterns. GenAI inference is memory-bound, consuming 94% of GPU memory but only 5% of SM, so it exhausts memory while leaving compute idle. Conventional DNN inference, in contrast, is light on both resources, using just 20% of memory and 6% of SM. The two patterns are complementary: a DNN job needs little memory and could run on the compute that a memory-bound GenAI job leaves idle, raising SM utilization without contending for memory. Realizing this colocation in practice, however, is difficult. GPU sharing falls short under latency-sensitive online inference and lacks large-scale support [56]; hardware partitioning such as MIG [36] is too static for dynamic workloads; and GPU time-sharing violates strict latency SLOs because of weak isolation [51, 53].

Interference between colocated CPU and GPU jobs. Like Acme [16], ASI nodes show low CPU utilization (median 31%). We mitigate this by colocating pure-CPU jobs with GPU workloads, which makes 80% of nodes *CPU-job-dominant*, i.e., their CPU-job core usage exceeds that of GPU jobs. This colocation, however, interferes with GPU training: median and P90 SM utilization fall by 10% and 18% on *CPU-job-dominant* nodes relative to *GPU-job-dominant* ones, showing that our naive colocation is suboptimal. Prior approaches that exploit idle CPUs on GPU nodes [4, 27] target specific model architectures (e.g., LoRA adapters) and require high-end CPUs, limiting their applications. Closing this gap calls for a multi-resource scheduler that jointly accounts for GPUs and associated resources such as CPUs, together with new isolation techniques to contain interference.

6 Limitations and Related Work

We close by clarifying the scope of the ASI trace and situating it among prior workload-characterization studies. Our goal is not to cover every AI cluster workload, but to expose the resource-management issues that arise in a large shared production cluster with heterogeneous workloads, priorities, accelerators, and topology constraints.

Limitations. The ASI trace does not cover large-scale

foundation-model pretraining, which typically runs on dedicated clusters with the most advanced GPUs. It also does not distinguish fine-grained subcategories within each job type; for example, training jobs may include both supervised fine-tuning and LoRA fine-tuning, but the trace does not separate them. Finally, although we collect utilization data across CPU, memory, network, and GPU resources, space constraints lead us to focus mainly on GPU workloads and leave CPU-only jobs to future analysis.

Related work. Workload characterization has long informed cluster management, but existing public traces capture only part of the setting faced by modern production AI clusters. Table 1 compares ASI with the closest public GPU-cluster traces, Acme [16] and PAI [51]. Other recent studies focus on narrower slices of the AI infrastructure stack: ServeGen [54] provides granular request-level data for LLM serving, while ByteRobust and Megascale [19, 47] study stability issues in foundation-model training on tens of thousands of NVIDIA GPUs. In contrast, ASI exposes a shared production infrastructure that combines heterogeneous workloads, priorities, GPU types, and topology constraints in one cluster. Earlier DNN workload studies [3, 11, 15, 17, 32, 55, 63] remain useful references, but their reliance on older GPU generations makes them less representative of today's GPU cluster management problems.

7 Conclusion

We have characterized six months of production workloads in ASI, a shared AI cluster with 155,410 GPUs and 81 internal departments. The trace showed that modern AI clusters must manage heterogeneity in both workloads and hardware: classical DNN services, GenAI training, and GenAI serving coexist on GPU fleets spanning multiple generations and vendors. Our key lesson was that high GPU demand did not imply high effective utilization. Idle GPUs often remained unusable because capacity was stranded across nodes, blocked by CPU shortages, constrained by network locality, or reserved as production headroom. We also showed how these observations shaped production mechanisms. The remaining challenges point beyond simple packing: heterogeneous accelerators required software optimization before users adopted them, online inference left substantial compute idle, and CPU/GPU colocation recovered CPU cycles but interfered with GPU training. By releasing the sanitized ASI trace, we hope to support future work on GPU cluster management under coupled workload, hardware, topology, and priority heterogeneity.

Acknowledgments

We thank our shepherd and the anonymous reviewers of OSDI 2026 for their invaluable comments that help improve the quality of this work. We are also grateful to Dongqing Bao, Yujie Deng, Zhiwei Han, Wenhu Hu, and Zhuo Yuan at Alibaba Group for their helpful discussions. This work was supported in part by the HKUST-Alibaba Joint Laboratory on Big Data and AI, RGC CRF Grant (Ref. #C6015-23G), RGC GRF Grant (Ref. #16217124), and NSFC/RGC CRS Grant (Ref. #CRS_HKUST601/24).

A MILP Formulation

Here, we present the MILP formulation of the preemptive scheduling problem described in §4.2.

Consider a set of tasks $\mathcal{T} = \{\tau_1, \tau_2, \cdots, \tau_{|\mathcal{T}|}\}$ submitted to a cluster of M nodes $\mathcal{G} = \{n_1, n_2, \cdots, n_M\}$, where each node n_j possesses S_j GPUs. Each task is defined as a tuple $\tau_i = \langle w_i, g_i, \zeta_i, \psi_i, \iota_i \rangle$, requesting w_i pods with g_i GPUs each. The task type is denoted by $\zeta_i \in \{0,1\}$ (representing LP/spot and HP, respectively), and the task includes D checkpoint milestones $\psi_i = \{c_{i,1}, \cdots, c_{i,D}\}$.

Additionally, let $\iota_i = \{\langle t^s_{i,1}, t^e_{i,1}, f_{i,1} \rangle, \cdots, \langle t^s_{i,E_i}, t^e_{i,E_i}, f_{i,E_i} \rangle\}$ represent the set of E_i runtime logs for task τ_i. Each log corresponds to the k-th execution run, starting at $t^s_{i,k}$, ending at $t^e_{i,k}$, and achieving the $f_{i,k}$-th checkpoint. The scheduler aims to optimize the following dual objectives, formulated as a mixed-integer linear programming problem over a discrete time horizon $t \in \{1, \ldots, T\}$:

$$\min \quad \frac{\sum_{i=1}^{|\mathcal{T}|} \sum_{j=1}^{M} \sum_{t=1}^{T} x_{i,j,t}(E_i - 1)}{\sum_{i=1}^{|\mathcal{T}|} \sum_{j=1}^{M} \sum_{t=1}^{T} x_{i,j,t} E_i} - \alpha \cdot \frac{\sum_{i=1}^{|\mathcal{T}|} \sum_{j=1}^{M} \sum_{t=1}^{T} x_{i,j,t} w_i g_i c_{i,f_{i,E_i}}}{\sum_{j=1}^{M} S_j T} \tag{2a}$$

$$\text{s.t.} \quad \sum_{i=1}^{|\mathcal{T}|} x_{i,j,t} g_i \le S_j, \quad \forall j,t \tag{2b}$$

$$\sum_{j=1}^{M} x_{i,j,t} = w_i, \quad \forall i,k, \forall t \in [t^s_{i,k}, t^e_{i,k}) \tag{2c}$$

$$(E_i - 1)\zeta_i = 0, \quad \forall i \tag{2d}$$

$$\sum_{j=1}^{M} x_{i,j,t^e_{i,k}} = 0, \quad \forall i,k \tag{2e}$$

$$c_{i,f_{i,k}} - c_{i,f_{i,k-1}} \le t^e_{i,k} - t^s_{i,k} < c_{i,f_{i,k}+1} - c_{i,f_{i,k-1}}, \quad \forall i,k \tag{2f}$$

$$x_{i,j,t} \in \mathbb{Z}_{\ge 0}, \quad \forall i,j,t \tag{2g}$$

where $x_{i,j,t}$ is a decision variable representing the number of pods assigned to task τ_i on node n_j at time t, and α is a weighting factor. Constraint (2b) enforces physical GPU limits per node. Constraint (2c) ensures gang-scheduling requirements during each active run. Constraints (2d) and (2e) enforce strict priority, restricting evictions and interruptions to spot tasks only. Constraint (2f) correlates task duration with completed checkpoints; by convention we set $f_{i,0} \triangleq 0$ and $c_{i,0} \triangleq 0$ so that the constraint is well-defined for $k = 1$. Finally, Constraint (2g) restricts the decision variables to non-negative integers.

MIMESYS: Generating Realistic Executable Testing Environments from Resource Usage Traces

Donghyun Kim Zichao Hu Joydeep Biswas Aditya Akella Daehyeok Kim
The University of Texas at Austin

Abstract

Testing applications under realistic resource contention is challenging because production workloads are often inaccessible due to privacy and proprietary concerns. Existing approaches either use simplistic resource stressors that fail to capture temporal dynamics and multi-resource interactions, rely on limited benchmark suites, or require exhaustive per-application profiling. This paper explores an alternative direction: Synthesizing executable workloads from resource usage traces to reproduce realistic colocation scenarios.

We present MIMESYS, a system that transforms time-series resource usage traces into executable workloads that emulate resource contention patterns. MIMESYS represents emulated workloads as compositions of resource stressors and employs a diffusion-based generative model to learn the inverse mapping from traces to stressor compositions. We introduce two key ideas: state-aware conditioning that conditions generation on both target traces and prior system state to capture temporal dependencies, and execution-driven alignment that adapts the model to real application patterns using direct execution feedback without requiring ground-truth labels. Our evaluation shows that MIMESYS achieves up to 5.5× higher trace similarity and reproduces application performance under contention 2.6× more accurately than baselines.

1 Introduction

Access to real-world production applications is essential for many research and engineering tasks. Researchers need realistic workloads to evaluate system designs, architectures, and optimizations. Developers require representative applications to test their software under production-like conditions. Cluster operators need diverse workloads to benchmark hardware configurations and inform capacity planning decisions.

Unfortunately, obtaining access to production applications is often impractical. Privacy regulations prevent organizations from sharing applications that process sensitive user data, while proprietary concerns make companies reluctant to disclose intellectual property. Even when sharing is permitted, applications often have complex dependencies on internal infrastructure that make them difficult to package and distribute.

As a result, the community today relies on imperfect alternatives. Public resource usage traces from production systems [29,54] capture metrics such as CPU utilization, memory bandwidth, cache usage, and I/O throughput, but they provide only aggregate system behavior without executable workloads.

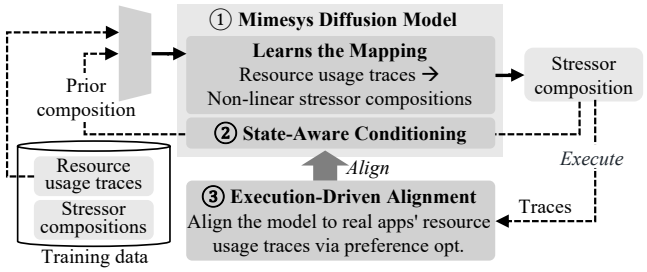

Figure 1: *Overview of* MIMESYS *with its key ideas.*

Benchmark suites [8,47,48] offer reproducibility but are difficult to generalize beyond their limited coverage and lack diversity. Testing directly in production is resource-intensive, difficult to scale, and fails to provide reproducible conditions as workload contention evolves over time. Synthetic workload generation offers a more promising path [44], but existing approaches fall short: resource stressors [3,26] are typically used in simplistic ways that poorly capture temporal variations and multi-resource interactions, while application cloning techniques [27,28] require exhaustive per-application profiling and primarily reproduce coarse-grained statistical patterns rather than fine-grained temporal dynamics.

This paper asks: *Can we reverse-engineer executable workloads from resource usage traces?* Cluster operators routinely collect such traces from production environments, capturing resource usage patterns over time. If we could synthesize executable workloads that reproduce these patterns, we could enable realistic testing and experimentation without requiring access to actual production applications. This would provide controlled, reproducible environments while preserving privacy and protecting proprietary information.

We explore this question in a concrete context: reproducing realistic environments for testing applications under resource contention from co-resident workloads. In production deployments, colocated workloads compete for shared resources such as CPU, memory bandwidth, cache, and I/O, creating contention that can degrade application performance. This contention remains hidden when testing in isolation, leading developers to deploy applications that perform poorly or violate service-level objectives under real deployment conditions. An ideal solution would synthesize workloads at the application-logic level, reproducing not only system-level resource usage but also fine-grained characteristics such as memory access patterns and microarchitectural behaviors.

We present MIMESYS, a system that takes a practical first step toward this vision by transforming resource usage traces into executable workloads that emulate realistic colocation scenarios (Figure 1). While synthesizing application logic from traces remains infeasible, we observe that for reproducing resource contention, emulating resource usage patterns suffices without recovering the underlying application logic. MIMESYS represents emulated workloads as *compositions of parameterized resource stressors* and learns the complex, nonlinear mapping from resource usage traces to stressor compositions. By using stressors as expressive building blocks rather than simple, pre-configured tools, MIMESYS can approximate diverse, realistic resource usage patterns in a practical and scalable manner. We employ a *diffusion model* to learn this mapping because it can capture complex, multimodal distributions over stressor compositions (① in Figure 1).

Realizing this approach entails two challenges. First, stressor compositions exhibit complex temporal and cross-resource dependencies, where a stressor's impact depends on concurrent execution and prior system state. Second, real applications exhibit structured behaviors driven by their computational logic that differ from arbitrary stressor combinations, requiring explicit alignment beyond synthetic training data.

We address these challenges with two key ideas. First, we introduce *state-aware conditioning* (②) that conditions generation not just on target traces but also on prior system state. Unlike conventional diffusion models, our approach incorporates previously generated stressor compositions and their resulting resource usage into the conditioning mechanism, enabling the model to capture temporal dependencies. Second, we devise *execution-driven alignment* (③), a training approach that adapts the model to real application behaviors without requiring ground-truth stressor labels. Inspired by preference optimization [11, 24, 37] in generative models, this approach learns from unlabeled real application traces through direct execution feedback, bridging the gap between synthetic training data and real application traces.

We implement MIMESYS in Python for model training and inference and C++ for the executable generator. The diffusion model uses a U-Net architecture [42] with 8.9M parameters and trains in ≈4 hours on one NVIDIA A100 GPU. The executable generator extends Fleetbench [8] with stress-ng [26] stressors, supporting diverse resource usage patterns across CPU, memory, cache, and I/O. We open-source MIMESYS at https://github.com/ldos-project/mimesys.

Our evaluation shows that MIMESYS generates emulated workloads that closely reproduce multi-resource usage patterns of diverse workload mixes. Using the Dynamic Time Warping distance metric [10], MIMESYS achieves up to 5.5× higher similarity compared to stressor-based baselines. We further demonstrate that MIMESYS accurately emulates application performance under contention across multiple benchmarks. For example, MIMESYS reproduces throughput degradation in database workloads with an average error of 8.3% points, outperforming baselines by 2.6×.

2 Background and Motivation

2.1 Need for Realistic Testing Environments

To evaluate whether an application will perform well in practice, application developers need to test it in realistic environments. An environment can be defined by two components: (1) the hardware configuration (*e.g.,* CPU, memory, storage, network bandwidth) and (2) the collocated workloads that run alongside the target application. For a given hardware configuration, realistic colocated workloads are essential because they share computing resources with the target application, creating resource contention that can affect performance in ways that remain hidden when testing in isolation. This resource contention, arising from competition for CPU, memory bandwidth, cache, and I/O devices, is a defining characteristic of production deployments where applications are colocated with other workloads on shared infrastructure.

The need for such realistic testing environments is particularly pronounced in cloud settings, where providers colocate multiple tenant applications on shared physical hosts to improve resource utilization. This colocation creates resource contention that makes performance unpredictable [39, 52, 57], where colocated workloads unintentionally interfere with one another as noisy neighbors. Application developers need to test their applications against these realistic contention patterns before deployment to ensure their applications will perform acceptably under production conditions. For example, TUNA [19] demonstrates the value of testing under realistic noise by modeling resource contention from noisy neighbors during database configuration tuning, enabling it to identify configurations that remain robust when deployed.

Beyond simply exposing applications to realistic contention, developers also need these testing environments to be reproducible. Reproducibility enables developers to systematically evaluate different application configurations, conduct fair performance comparisons, and validate optimizations under consistent conditions. However, prior studies [18, 21, 51] highlight the difficulty of achieving such reproducibility in shared environments where resource contention varies unpredictably. Without reproducible testing conditions, developers struggle to isolate the effects of their changes from environmental noise, making it difficult to draw reliable conclusions from their experiments.

Difficulties in obtaining realistic colocated workloads. Unfortunately, obtaining realistic colocated workloads is challenging. One straightforward approach would be to use actual workloads from production deployments. However, actual tenant workloads cannot be shared due to privacy and proprietary concerns. Even when developers have access to production environments for testing, they face two critical limitations.

First, it is resource-intensive and difficult to scale. Developers must deploy their applications into production-like infrastructure to experience realistic contention. For instance, TUNA requires actual deployment to measure performance impact from noisy neighbors, demanding substantial infrastructure (10 nodes over 8 hours per run) that becomes impractical when many developers need to test diverse applications.

Second, production environments evolve continuously as workloads change, making it difficult to achieve reproducible testing conditions. The contention patterns observed in production represent specific deployment states that may change over time, preventing developers from conducting consistent experiments across different configurations or optimizations.

2.2 Limitations of Existing Approaches

Given the difficulties in obtaining realistic workloads from production environments, synthetic approaches offer an attractive alternative. Rather than using actual production workloads, these approaches generate controlled workloads or inject artificial interference to mimic resource contention effects. Developers can use synthetic workloads to reproduce stress conditions in a controlled manner while avoiding the infrastructure costs and privacy concerns of real-world testing.

However, existing approaches exhibit limitations in accurately reproducing realistic deployment conditions.

Resource stressors. Resource stressors such as stress-ng [26] and Intel MLC [3] are commonly used to inject resource contention. These tools intentionally stress specific resources (*e.g.,* CPU or memory) for a given duration, enabling researchers to study how systems behave under abnormal conditions [35, 46, 57]. However, stressors are typically used in simple ways: practitioners manually select a few stressors to run continuously at maximum intensity for fixed duration. As shown in §7, this naïve usage poorly captures the realistic conditions operators observe, where applications exhibit temporal variations in resource usage (*e.g.,* periodic bursts, gradual ramps) and complex multi-resource interactions (*e.g.,* memory access patterns that depend on CPU load).

Application benchmarks. Standard benchmarks such as SPEC [47], DCPerf [48], and Fleetbench [8] are carefully designed by domain experts to represent realistic workloads. While benchmarks offer better realism than stressors, they cover only a limited subset of real-world application behaviors. Furthermore, diversifying benchmarks to cover new workload types is challenging: each new benchmark requires manual effort to implement applications that reflect evolving workload characteristics, making it difficult to keep pace with the diversity of modern applications.

Application cloning. Application cloning techniques [27, 28] generate synthetic programs that replicate the performance and resource usage profiles of complex or proprietary applications without exposing their internal logic. They profile target applications across the system stack (*e.g.,* I/O operations, kernel activities) to capture their statistical resource usage properties, then construct synthetic programs that exhibit similar characteristics. However, achieving such fidelity requires exhaustive profiling for each application, making it costly to extend cloning to a diverse set of applications. Furthermore, cloning methods primarily reproduce coarse-grained statistical patterns (*e.g.,* mean or median resource utilization) rather than fine-grained temporal dynamics. This focus on statistical characteristics means cloned applications cannot effectively capture the dynamic, time-varying resource usage that characterizes real workloads.

3 Design Overview

To address the limitations of existing synthetic approaches while avoiding the costs of real-world deployments, we propose MIMESYS, a system that transforms *resource usage traces* into *executable workloads* that run alongside a developer's target application to emulate realistic collocated workloads. Resource usage traces capture system resource consumption over time, recording metrics such as CPU utilization, memory bandwidth, cache usage, and I/O throughput. Our key insight is that while recovering individual application logic from traces is infeasible, we can synthesize executables that reproduce similar time-series resource usage patterns when executed on the same or similar hardware. Unlike application cloning, which targets individual applications and requires exhaustive per-application profiling, MIMESYS synthesizes *environment-level* workloads from aggregate resource usage traces. This enables realistic synthetic test environments without requiring access to actual production workloads.

3.1 Our Approach

MIMESYS is built on two key ideas.

Stressor composition. We represent emulated workloads as *compositions* of parameterized resource stressors. As discussed in §2, resource stressors generate workloads designed to exercise specific system resources (*e.g.,* CPU, memory, cache, I/O). We choose stressors as building blocks because they are already in an executable form and can be mixed and combined to create diverse stress conditions, making them practical for generating many different emulated workloads.

Learning trace-to-stressor composition mapping. However, mapping resource usage traces to stressor compositions is challenging because the relationship between stressor parameters and observed system behavior is complex and nonlinear. Simple approaches, such as linearly scaling stressor intensities and concurrency to match target utilization, fail for most resources. For example, our measurements show that interleaving a memory stressor with sleep periods to reduce its average intensity does not produce proportional memory bandwidth reductions; the actual bandwidth usage differs from the target by more than 3× due to caching effects and memory controller policies. Concurrency further complicates this relationship: running a memory stressor with an 8 MiB

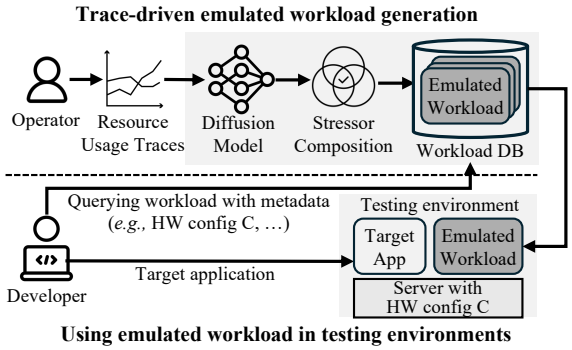

Figure 2: MIMESYS *workflow. Operators use* MIMESYS *to generate emulated workloads from resource usage traces collected in production environments. Developers retrieve emulated workloads matching their target hardware configuration and execute them alongside their applications to test under realistic colocated workloads.*

working set across eight threads increases memory bandwidth usage by 1800× compared to a single thread. These emergent behaviors make it difficult to analytically derive stressor parameters from target resource usage patterns.

To address this complexity, MIMESYS employs a *diffusion-based generative model* [22] that learns the mapping from traces to stressor compositions. Diffusion models can capture complex, multimodal distributions over each stressor's parameters and support conditioning on high-dimensional, long-horizon time-series resource usage traces, enabling trace-driven synthesis of emulated workloads. Our model divides resource usage traces into fixed-duration time windows and generates a stressor composition for each window.

Workflow. Figure 2 illustrates how MIMESYS can be used. Cloud operators (*e.g.,* Azure, AWS, or CloudLab) capture resource usage traces from their production environments and feed them into MIMESYS, which generates a set of emulated workloads as executables. Each workload is labeled with metadata such as hardware configuration and the time period when the traces were collected. The operator can then release these emulated workloads publicly. Application developers retrieve emulated workloads that match the desired deployment characteristics they want to test against. They run these workloads on a hardware environment that is the same or similar to the one described in the metadata, alongside their target application in the testing environment.

This model is analogous to how operators release various forms of traces today (*e.g.,* packet traces [1], flow-level traces [43], microservice call graph traces [29]). By sharing emulated workloads instead of raw traces, operators provide developers with directly executable artifacts that reproduce realistic resource contention while preserving the privacy and proprietary nature of the actual production workloads. Specifically, MIMESYS preserves tenant-sensitive information such as application logic, proprietary algorithms, and business data.

3.2 Challenges

While the diffusion-based stressor composition approach is promising, realizing it entails two main challenges:

C1: Capturing temporal and cross-resource usage dependencies. As mentioned in §3.1, the relationship between stressor compositions and resulting resource usage is inherently nonlinear and context-dependent. A stressor's impact on resources depends not only on its own composition but also on what other stressors are running concurrently and what execution has occurred previously. For example, prior memory accesses can warm the cache hierarchy, drastically reducing subsequent memory bandwidth utilization for the same stressor composition. Similarly, CPU contention from co-running stressors alters thread scheduling patterns, which in turn affects cache miss rates and memory access patterns. To synthesize realistic workloads, the model must learn these system-level dependencies and generate stressor compositions that produce target resource patterns while accounting for temporal execution context.

C2: Aligning with real applications. MIMESYS collects synthetic training data by executing diverse stressor combinations. However, the space of possible stressor combinations is enormous, making it challenging to ensure that the training data covers resource usage patterns exhibited by real applications. Real applications exhibit structured behaviors driven by their computational logic (*e.g.,* periodic memory access in databases, bursty compute phases in scientific workloads) that differ from arbitrary stressor mixes. Although stressor compositions capable of reproducing these patterns may exist, synthetic training data alone provides insufficient supervision for the model to discover them. Without explicit alignment with real application traces, the model will learn only the resource usage distribution of synthetic stressor combinations rather than the patterns exhibited by real applications.

3.3 Key Ideas

To address these challenges, MIMESYS incorporates two key ideas for training the diffusion model.

I1: State-aware conditioning (§4.2). To capture temporal and cross-resource dependencies, we propose a novel adaptation of diffusion models that conditions generation not just on target traces but also on *prior system state*. Unlike typical diffusion models that condition on static inputs (*e.g.,* static text inputs in image generation), our approach makes the model *state-aware* by incorporating prior system state directly into the conditioning mechanism. Rather than generating stressor compositions for all time windows independently, the model generates them sequentially, conditioning each window on: (1) target resource usage traces across multiple metrics, capturing cross-resource dependencies, and (2) a previously generated stressor composition, reflecting execution temporal dependencies. This enables the model to account for state-dependent system effects such as cache warming and resource

contention, generating stressor compositions that adapt to how the system state evolves over time.

I2: Execution-driven alignment (§4.3). Inspired by preference optimization in generative models [11,24,37], we devise *execution-driven alignment*, a training approach that adapts diffusion models to match real application behaviors without requiring ground-truth stressor labels. This approach bridges the distribution gap between synthetic training data and real deployment patterns through direct execution feedback. We treat the diffusion model as a policy and apply reinforcement learning to optimize it based on actual system execution. The model iteratively generates stressor compositions from unlabeled real application traces, executes them on hardware, and receives rewards based on how closely the resulting traces match target patterns. Policy gradient methods then update the model to prefer compositions that better reproduce real application behaviors.

3.4 Training and Inference Pipeline

Model training. For training, operators specify the target resource metrics (*e.g.,* CPU utilization, memory bandwidth, last-level cache (LLC) traffic) and candidate stressors. MIMESYS collects training data by executing diverse stressor combinations using novelty-guided data collection (§4.2.3) and profiling their resource usage traces. The diffusion model learns the mapping from resource usage traces to stressor compositions. To capture temporal and cross-resource dependencies, the model conditions generation on both the target trace and prior stressor compositions (§4.2). MIMESYS then adapts the model to real application traces through execution-driven alignment (§4.3), which optimizes the model based on how closely the generated workloads reproduce target resource patterns when executed.

Emulated workload generation. During inference, operators provide target resource usage traces as input. For each time window, the diffusion model generates a stressor composition conditioned on the target resource usage for that window and the previously generated composition. The workload generator then translates the composition sequence into an executable program that orchestrates the stressors across threads and time windows (§5).

4 Training MIMESYS Model

This section formalizes the emulated workload generation problem (§4.1), presents our diffusion model with state-aware conditioning and training data collection (§4.2), and explains how we adapt the model to real application traces using preference optimization (§4.3).

4.1 Problem Formulation

Consider a workload mix P executed on a system that produces multivariate time-series resource usage traces $o_{1:T} = \{o_1, \ldots, o_T\}$, where each $o_t \in \mathbb{R}^N$ represents N resource metrics (*e.g.,* CPU utilization, memory bandwidth, LLC traffic) measured over a fixed time window of size W seconds. In our setting, we do not have access to the original workload P itself. Our goal is to generate an emulated workload $P' = \{a_1, \ldots, a_T\}$ that, when executed on the same hardware, produces resource usage traces similar to those of P.

Stressor composition representation. We represent each emulated workload as a sequence of stressor compositions, where $a_t \in \mathbb{R}^{M \times K}$ denotes the composition of M stressors across K CPU threads for the t^{th} time window. Each entry $a_t[m,k]$ specifies the fraction of W during which stressor m executes on thread k, with values ranging from 0 to 1. For example, $a_t[m,k] = 0.4$ means stressor m runs for $0.4 \cdot W$ seconds on thread k within the t^{th} window. The duration allocated to all stressors on a single thread sum to at most W. The aggregate intensity of a stressor type across the system is determined by how many threads execute it concurrently.

Objective. We say that an emulated workload P' is δ-trace-equivalent to P under a distance metric $\ominus$ (*e.g.,* mean-squared error, Dynamic Time Warping [10]) if the trace produced by executing P', denoted $o'_{1:T}$, satisfies $\|o_{1:T} \ominus o'_{1:T}\| \leq \delta$. The emulated workload generation problem is to learn a function $f_\theta : o_{1:T} \mapsto P' = \{a_1, \ldots, a_T\}$ such that samples $P' \sim f_\theta(o_{1:T})$ produce traces that are δ-trace-equivalent to the observed traces $o_{1:T}$ with high probability. The objective of MIMESYS training is to learn such a mapping that yields δ-trace-equivalent emulated workloads across diverse resource usage patterns.

4.2 MIMESYS Diffusion Model

Straightforward approaches such as regressing stressor compositions directly from traces or linearly interpolating stressor intensities treat each time step in isolation and assume a deterministic, one-to-one mapping. As discussed in §3.2, these fail due to temporal dependencies, cross-resource interactions, and nonlinear resource behavior.

Our approach. We extend *diffusion* models [11,24] to be *state-aware* by conditioning generation not just on target traces but also on prior system state. We call this technique *state-aware conditioning*. Unlike conventional diffusion models that generate outputs based solely on input conditions, our approach incorporates a prior stressor composition directly into the conditioning mechanism. Concretely, instead of learning a direct mapping $o \mapsto a$, we model the conditional distribution $p(a_t \mid o_t, a_{t-1})$, where o_t represents the target trace for the t^{th} time window and a_{t-1} is a stressor composition generated at the $(t-1)^{th}$ window. This enables sequential generation across time windows, where each window's stressor composition is conditioned on both the target resource usage and the system state affected by the prior composition.

4.2.1 Why Use a Diffusion Model?

Several properties of the workload generation problem guide our choice to use diffusion models. The mapping from traces

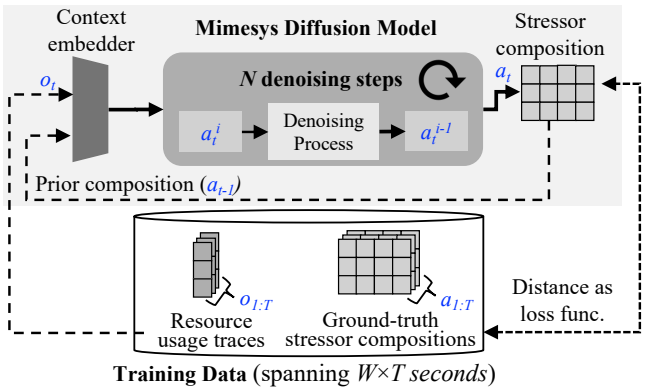

Figure 3: MIMESYS *diffusion modeling. The model is conditioned on input traces and prior stressor compositions to capture temporal and cross-resource dependencies. Each trace and stressor composition corresponds to a time window.*

to stressor compositions is *one-to-many*: many distinct stressor compositions can produce similar resource usage patterns. Diffusion models are well suited to handle such one-to-many mappings through their iterative denoising process [23]. Starting from noise, the model progressively refines samples while exploring multiple feasible stressor compositions before converging to a final output. This iterative refinement naturally captures the complex multimodal conditional distributions that arise from the one-to-many mapping. Furthermore, while traditional search and optimization methods struggle to generalize as the metric space grows (*e.g.,* across dozens of resource metrics), diffusion models efficiently learn the underlying mapping to safely interpolate across workload traces not seen during training.

Importantly, diffusion models support flexible conditioning mechanisms through learned context embeddings [32, 36]. This allows us to realize our state-aware conditioning by incorporating a prior stressor composition directly into the generation process, as we discuss next.

4.2.2 Model Architecture and Training

We now formalize how to extend a diffusion model with state-aware conditioning. The key is to define a conditioning context that captures both the target trace and system state affected by the prior stressor composition, then use this context to guide the iterative denoising process. Figure 3 illustrates our model architecture and training process.

Model interface. To make the diffusion model state-aware, we construct a conditioning context that captures both the target trace and system state. MIMESYS employs a learnable embedder $g(\cdot)$ that encodes the target trace o_t and a prior stressor composition a_{t-1} into a compact context representation: $c = g(o_t, a_{t-1})$. This context embedding summarizes two key components: (1) the target resource usage patterns across multiple metrics, capturing cross-resource dependencies, and (2) how the prior stressor composition has shaped the current system state.

With this conditioning, the model approximates the distribution $\pi_\theta(a_t \mid c)$, where a_t is the stressor composition for the t^{th} time window. Because c incorporates both target traces and the prior stressor composition, the diffusion model generates a_t that accounts for state-dependent effects such as cache warming and resource contention. This formulation enables iterative generation across time windows: after generating a_t, this composition becomes part of the conditioning context c for generating the next window's composition a_{t+1}.

Training objective. The training objective is to align the model's predictions with the ground-truth stressor compositions observed in the training data. At a high level, this corresponds to minimizing the expected discrepancy between predicted and ground-truth stressor compositions:

$$\arg\min_{\theta} \mathbb{E}_{a' \sim \pi_\theta(a|c)} \left[D(a', a^{\text{gt}}) \right],$$

where a^{gt} denotes the ground-truth stressor composition and $D(\cdot,\cdot)$ is a distance metric (*e.g.,* mean-squared error).

In diffusion modeling, we realize this objective by instantiating the general diffusion loss, where the model predicts noise for each denoising step [22]. The clean sample a_t^0 is obtained by denoising N steps from a random noise a_t^N, where a_t^0 corresponds to the ground-truth stressor composition a_t. The training objective aims to minimize the mean-squared error (*i.e.,* distance) between the true noise ε and the predicted noise ε_θ. The resulting training loss for the composition generation is:

$$\mathcal{L} = \mathbb{E}_{a_t^0, \varepsilon, i} \left[\|\varepsilon - \varepsilon_\theta(a_t^i, i, c)\|^2 \right],$$

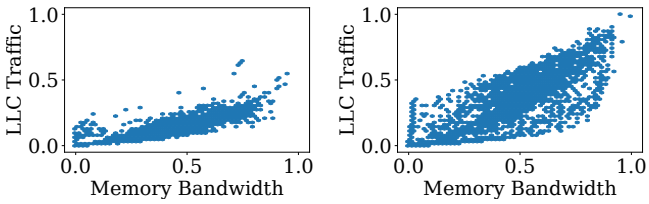
where $\varepsilon_\theta(a_t^i, i, c)$ is the model's noise prediction conditioned on the context embedding c at i^{th} denoising step. By minimizing this loss, the model learns to reverse the noising process: each denoising step refines a stressor composition toward the ground-truth stressor composition paired with the context embedding c. The context embedder $g(\cdot)$ is jointly trained with the diffusion model, so its representations are optimized end-to-end for guiding the denoising process.

During generation, the trained model synthesizes stressor compositions by starting from Gaussian noise and iteratively applying the learned reverse transitions, conditioned on the context embedding (see §5 for details).

4.2.3 Novelty-Guided Training Data Collection

Training our model requires a diverse dataset of traces that spans a wide range of resource-usage patterns across CPU utilization, memory bandwidth, LLC traffic, and disk I/O. Without sufficient coverage of the resource space, the model cannot learn to generate stressor compositions that reproduce diverse or extreme resource behaviors observed in real applications.

Challenge. A straightforward approach is to randomly sample stressor compositions, execute them to collect traces, and construct a dataset of (composition, trace) pairs. However, random sampling produces highly skewed data. As shown in the



(a) *Random sampling* (b) *Novelty-guided collection*

Figure 4: *Joint distribution of memory bandwidth and LLC traffic for 5K training samples. (a) Random sampling produces clustered, skewed coverage. (b) Novelty-guided collection achieves more balanced resource-space coverage.*

left plot of Figure 4, random combinations cluster in narrow regions of the resource space, with many compositions producing similar resource-usage behaviors. This occurs because random composition draws rarely trigger extreme or asymmetric resource patterns (*e.g.,* CPU-intensive but memory-light), causing most samples to collapse into moderate, balanced behaviors. The resulting dataset leaves large portions of the resource space underrepresented, limiting the model's ability to learn mappings for diverse or high-intensity patterns. Because profiling stressor compositions is time-consuming, simply collecting more random samples is impractical.

Our approach. We address this challenge through *novelty-guided training data collection*, which prioritizes profiling stressor compositions likely to produce underexplored resource-usage patterns. The approach collects training data iteratively. At each round, MIMESYS trains a lightweight prediction model (*e.g.,* Random Forest [13] in our implementation) on the current dataset, which consists of all traces collected from previously profiled compositions. This predictor estimates the resource usage that candidate stressor compositions would produce. MIMESYS then assigns each candidate a novelty score based on two complementary factors: (1) how rare its predicted trace is under the current data distribution, measuring underrepresentation, and (2) how uncertain the predictor is about that composition, measured via prediction variance, indicating low-confidence regions where the model needs more data. Compositions with high novelty scores either produce underrepresented behaviors or expose gaps in the predictor's knowledge. MIMESYS selectively profiles the highest-scoring compositions and adds their traces to the training set, iteratively expanding coverage toward underexplored regions.

As shown in the right plot of Figure 4, this approach produces a dataset with substantially better coverage of the joint distribution of memory bandwidth and LLC traffic. The improved diversity enables our model to learn mappings across a more representative range of system behaviors.

4.3 Execution-Driven Alignment

Our diffusion model trained on synthetic stressor combinations learns to map resource-usage traces to stressor compositions across a diverse range of patterns. However, as discussed in §3.2, real applications produce resource-usage patterns shaped by their algorithmic structure that often diverge from those induced by arbitrary synthetic stressor combinations. While the training data may span a broad range of resource-usage values, the temporal structure and cross-resource correlations characteristic of real applications are difficult to capture through synthetic combinations alone. As a result, the pre-trained model may fail to generate stressor sequences that faithfully reproduce real-world application traces, even if it performs well on synthetic test data, as shown in §7.3.

Our approach. To address this gap, we employ *execution-driven alignment*, an approach inspired by preference optimization in large language models [11,24]. The key challenge is that real traces do not come with ground-truth stressor compositions, making standard supervised learning infeasible. Instead of learning from labeled pairs, execution-driven alignment learns from unlabeled real application traces through direct interaction with the system. We treat the diffusion model as a policy π_θ and optimize it to prefer stressor compositions that, when executed, produce traces similar to real applications. The model iteratively generates stressor compositions conditioned on real application traces, executes them on actual hardware to observe their resource usage, and receives rewards based on trace similarity. Policy-gradient methods [30] then update the model weights to maximize these rewards, shifting the distribution toward compositions that better reproduce real application behaviors. This approach bridges the distribution gap between synthetic training data and real deployment patterns without requiring ground-truth labels.

Optimization objective. The goal is to optimize the policy π_θ such that generated stressor compositions, when executed, produce resource-usage traces that closely match those observed in real applications. For each real trace $o \in \mathcal{T}_{\text{real}}$, the policy generates a stressor composition $a' \sim \pi_\theta(a \mid o, a_{\text{prev}})$ conditioned on the target trace o and prior composition a_{prev}, and obtain the corresponding trace o' by profiling. We define a reward function $R(a') = -D(o', o)$ based on the distance between the executed trace o' and the target trace o. For the distance metric D, we use weighted L1 distance, where weights reflect the relative importance of each metric to operators. The optimization objective maximizes the expected reward over the policy distribution:

$$\arg\max_{\theta} \mathbb{E}_{a' \sim \pi_\theta(a|o,a_{\text{prev}})}[R(a')].$$

This objective guides policy updates toward stressor compositions that, under actual execution, produce traces that more closely align with real application behaviors.

Optimization procedure. We realize execution-driven alignment through a reinforcement learning algorithm that updates the policy based on execution-derived rewards. MIMESYS adopts the denoising diffusion policy optimization (DDPO) framework [11, 24], which treats each denoising step in the

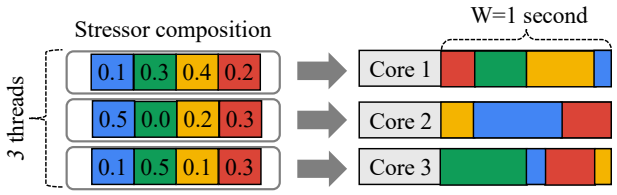


Figure 5: *Converting a stressor composition into an executable workload for a system with three CPU cores. Different colors represent different stressor types. Values specify the fraction of W, allocated to each stressor.*

diffusion model as an action and optimizes the policy via policy-gradient methods [45] to maximize expected rewards.

The adaptation process begins with the pre-trained policy π_θ and a set of real-world traces $\mathcal{T}_{\text{real}}$ provided by the operator. In each iteration, the policy generates a stressor composition $a' \sim \pi_\theta(a \mid o, a_{\text{prev}})$ for a trace o sampled from $\mathcal{T}_{\text{real}}$. The stressor compositions $[a_{\text{prev}}, a']$ are then executed on a system (*i.e.,* server) to collect the resulting trace o' produced by a'. The reward $R(a')$ is computed by measuring the distance (D) between the executed trace o' and the target trace o. The policy gradient method [40, 45] then updates the model parameters to increase the expected reward. This process iterates until convergence or for a fixed number of iterations, producing an adapted model π'_θ that better aligns with real application patterns.

5 Executable Workload Generation

Once the MIMESYS model is trained, operators can use it to generate emulated workloads that reproduce target resource-usage patterns. The generation process operates on time-series resource traces divided into fixed-duration windows, where the window size W is a training hyperparameter determined during model training. For example, given $L_{trace} = 30$ seconds of resource traces and $W = 1$ second, the model produces $T = \frac{L_{trace}}{W} = 30$ time windows. As described in §4.2.2, the model generates a stressor composition a_t for each window t through an iterative diffusion process conditioned on the target trace segment o_t and a prior composition a_{t-1}. This produces a sequence of stressor compositions $a_{1:T}$ that must be translated into an executable workload.

From compositions to executables. Figure 5 illustrates how MIMESYS converts stressor compositions into executables. The left side shows a generated composition a_t represented as a matrix with three rows (one per CPU thread) and four columns (one per stressor type, shown as different colors). Each matrix entry specifies the fraction of the time window allocated to that stressor on that thread. For example, the first row shows $[0.1, 0.3, 0.4, 0.2]$, indicating that thread 1 should execute stressor types 1 through 4 for 10%, 30%, 40%, and 20% of the window duration, respectively.

The executable generator maps each matrix row to a physical CPU core, as shown on the right side of the figure. Within each window (1 second in this example), each core executes its assigned stressors for the specified duration. The colored segments on the right visualize these execution schedules: Core 1 runs the red stressor for 0.2 seconds, the green stressor for 0.3 seconds, and so on. To avoid introducing systematic temporal bias, MIMESYS randomizes the execution order of stressors within each window while preserving their allocated duration. For instance, Core 2 might execute the orange stressor first, then blue, then red, rather than in a fixed order.

MIMESYS generates the final executable as a standalone C++ program that orchestrates stressor execution according to these schedules, as we describe next.

6 Implementation

We implement MIMESYS in approximately 1.8K lines of Python for model training and inference, and 800 lines of C++ for the emulated workload generator. We release MIMESYS at `https://github.com/ldos-project/mimesys`.

Training data collection. For novelty-guided data collection (§4.2), we implement a Random Forest predictor [13] with 100 trees that estimates resource usage from stressor compositions. The novelty score combines prediction uncertainty (measured via variance across trees) and rarity (measured via distance to the nearest training sample in the predicted metric space). We collect training data iteratively, profiling 128 high-novelty compositions per round for 100 rounds, yielding 12K diverse training samples. We profile each data sample multiple times for accurate measurements. Collecting the full training dataset takes 8 hours on 8 machines, though this time varies with the number of samples, window size, and the number of machines used. The profiling infrastructure collects CPU utilization, memory bandwidth, LLC traffic (via hardware performance counters), and disk I/O throughput (via `/proc/diskstats`) at 1000ms granularity using TACC cluster's HPC monitoring tools [49]. The stressor library is fixed during data collection and training; consequently, adding or replacing stressors requires re-profiling and retraining MIMESYS.

Diffusion model. The diffusion model uses a U-Net architecture [42] with 8.9M parameters, where the encoder downsamples the input and the decoder upsamples it to capture how per-thread stressors jointly shape resource usage. For state-aware conditioning (§4.2.2), we employ two MLP-based encoders: a trace encoder that transforms target resource usage vectors into a 256-dimensional embedding via 4 fully-connected layers, and a state encoder that similarly processes prior stressor compositions. These embeddings are concatenated and injected into each U-Net layer to guide the denoising process.

We train the model in PyTorch [31] using the standard noise prediction objective from DDPM [22]. Pretraining runs on one NVIDIA A100 GPU with a learning rate of 1×10^{-4} for 2000 epochs using 25 denoising steps, taking approxi-

mately 2 hours. For execution-driven alignment, we apply DDPO [11] with a learning rate of 3×10^{-6} and the advantage clipping threshold of 3, requiring an additional 2 hours with 8 machines for profiling. We assign equal weights to each resource type in the reward function and use a 1-second time window (W) for both training and inference (see Appendix B for detailed setup). The 1-second window length was selected as a trade-off between data reliability and temporal resolution. Smaller windows resulted in higher variance in collected measurements, whereas larger windows masked fine-grained resource dynamics and increased training data collection time.

From the trained model, generating stressor compositions simply incurs the diffusion model's inference cost. In our setup, it processes roughly 190 time windows per second with a batch size of 128 on an A100 GPU.

Executable generator. We build the executable generator by extending Fleetbench [8] with additional stressors from stress-ng [26], supporting stressor types spanning CPU (integer arithmetic, floating-point operations), memory (sequential/random access with varying working set sizes), cache (LLC-focused access patterns), disk I/O (sequential/random reads and writes), and a `sleep` stressor for idle periods. Each stressor is implemented as a parameterized C++ function. To translate model-generated compositions into executable workloads, we implement a code generation module that produces standalone C++ programs. For each time window, the generator maps stressor parameters to thread-level execution schedules and randomizes stressor execution order within each window to avoid temporal bias.

7 Evaluation

We evaluate MIMESYS to answer four key questions:

- Can MIMESYS reproduce performance degradation caused by noisy neighbor effects (§7.1)?
- How closely do MIMESYS-generated workloads' resource usage patterns match those of real applications (§7.2)?
- How effective are MIMESYS's techniques (§7.3)?
- How sensitive is MIMESYS to input trace variations (§7.4)?

Experimental setup. We evaluate MIMESYS on CloudLab [17] c220g2 machines (Intel Haswell, 20 cores) running Ubuntu 22.04 with Linux kernel 5.15. Input traces consist of per-core CPU utilization, memory bandwidth, LLC traffic, and disk I/O (23 dimensions). We use 14 stressors spanning CPU, memory, cache, and disk I/O resources chosen based on their distinct resource-usage patterns to ensure diversity (see Appendix A for the complete list). To construct this stressor set, we first profiled approximately 600 candidate stressors from Fleetbench and stress-ng, then selected representative stressors based on their resource-usage characteristics to maximize coverage of the resource-usage space while avoiding redundant behaviors.

Category	Workloads	Distributions
Web Serving	DaCapo [12], Renaissance [34]	31%
Big Data	HiBench [2] on Spark [56]	32%
KV Store	YCSB [15] on Redis [5], memcached [4], FASTER [14]	14%
ML Inference	MLPerf Inference [38] (ResNet50 [20], StableDiffusion [41])	11%
Database	TPC-C [6] on Silo [50], TPC-H [7] on PostgreSQL [33]	7%
Graph	GAP Benchmark [9]	5%

Table 1: *Workloads used in the evaluation.*

Workloads. We construct realistic contention scenarios by colocating multiple workloads, each running in a separate VM on Linux/KVM on shared physical machines. We create workload mixes by colocating up to 6 workloads sampled from popular benchmarks (Table 1) according to Azure's workload distribution [16, 53] for realism. To ensure broad coverage of contention scenarios, we balance the mixes by selecting an equal number for each colocation level, controlling the average total load. For each mix, we run workloads for 5 minutes and collect traces across CPU utilization, memory bandwidth, LLC traffic, and disk I/O, totaling 10 hours of diverse workload patterns.

Baselines. We compare MIMESYS against three baselines:
***Search-based*:** For each time window, it selects the stressor composition from the training data with minimum Euclidean distance to the target trace in resource usage space.
***Linear interpolation*:** For each time window, it identifies the 100 nearest training samples in resource usage space and linearly interpolates their stressor compositions to approximate the target trace.
***Single stressor*:** Uses a single resource-targeting stressor with calibrated sleep intervals to match per-core CPU utilization. We use Fleetbench (swissmap) for cache and memory bandwidth, and stress-ng (readahead) for disk I/O.

Metrics. We evaluate fidelity using two metrics. First, *trace similarity* measures how closely synthetic traces match real ones using the Dynamic Time Warping (DTW) distance metric [10], which captures temporal alignment and shape similarity. DTW distances are normalized to [0,1], where 0 indicates identical traces (a value of 0.1 indicates roughly 10% difference). Second, *application performance degradation* compares the impact on colocated applications (throughput drop or latency increase) when running alongside synthetic *vs.* real workloads. We report the %-point difference in degradation.

7.1 Reproducing Noisy Neighbor Effects

To serve as useful test environments, MIMESYS-generated workloads must induce similar performance impacts on colocated applications as real workloads. We measure application performance (throughput or latency) when colocated with MIMESYS-generated workloads *vs.* real workloads. To clearly

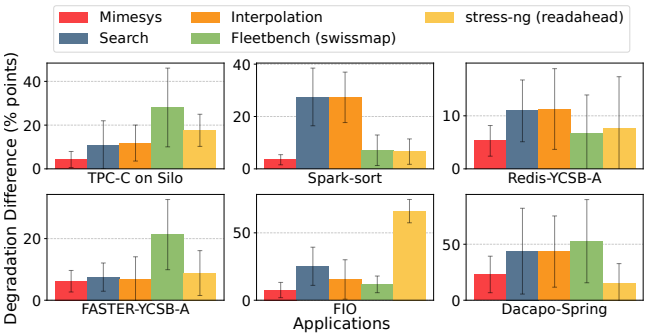

Figure 6: *Differences in application performance degradation when colocated with synthetic workloads generated by* MIMESYS *or baselines.*

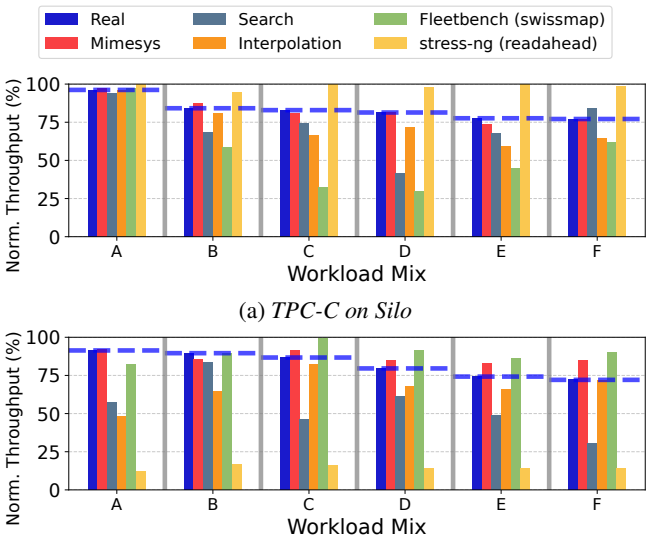
expose contention effects, we configure colocated workloads to use more than 50% of available CPU cores, ensuring measurable performance degradation on the target application.

Overall results. We evaluate 6 target applications spanning databases (TPC-C on Silo), key-value stores (YCSB on FASTER and Redis), file I/O (FIO), big data (Spark Sort), and web serving (DaCapo). Figure 6 shows the difference in performance degradation when colocating these applications with MIMESYS-generated *vs.* real workloads.

MIMESYS achieves an average degradation difference of 8.3% points across all applications, compared to 19.4% points for the next best baseline (Interpolation). This shows that MIMESYS captures the resource contention dynamics more accurately than baselines. The baselines perform inconsistently across applications. For example, the Fleetbench baseline, one of single stressor baselines, achieves 11.8% points for FIO but 28.1% points for TPC-C, as it focuses on cache and memory bandwidth stress without capturing cross-resource interactions. For certain applications like DaCapo, MIMESYS exhibits higher degradation differences (15% points), where we use p90 latency as the performance metric. Capturing tail latency effects is more challenging due to their sensitivity to request-level dynamics and data access patterns. For example, for Redis, the throughput degradation predicted by MIMESYS differs by only 5.3% points, whereas the corresponding p99 latency degradation can vary by as much as 9×. This effect arises because, for some cases, small differences in request-level behavior can amplify into large tail-latency changes, making tail latency hard to reproduce with aggregate stressors.

Figure 7 shows a detailed view for TPC-C and FIO. We plot normalized throughput compared to isolated runs, varying the colocated workloads from real workload mixes (blue) and synthetic workloads generated by MIMESYS (red) or the baselines. Different workload mixes (labeled on the x-axis) induce varying contention levels, causing throughput drops from 3% to 23% (blue horizontal lines). MIMESYS-generated workloads closely track the degradation caused by real workloads across all mixes, while baselines show larger



(a) *TPC-C on Silo*

(b) *FIO benchmark*

Figure 7: *Application performance degradation while varying colocated workload mixes for (a) TPC-C on Silo and (b) FIO.*

deviations. In TPC-C (Figure 7a), Mix A (two web servers and one ResNet50 inference) causes a minimal throughput drop of 3%, which most synthetic workloads capture well. However, for mixes B to F with KV and Spark workloads that induce higher contention, MIMESYS maintains close alignment with real workload degradation, while baselines do not consistently track the patterns. For FIO (Figure 7b), running sequential read/write operations alongside colocated workloads causes throughput drops from 5% to 25%. MIMESYS reproduces these drops across all workload mixes, while baselines show deviations in several mixes (*e.g.,* Mix A and D).

Case study: TPC-C on Silo. The ability to reproduce time-varying performance impacts is crucial for evaluating applications under realistic contention. We examine a case where TPC-C on Silo is colocated with two applications (Spark running SVD and a Renaissance web server), each running in separate VMs. Figure 8 shows TPC-C throughput and resource usage over time when colocated with real workloads (blue) *vs.* MIMESYS-generated workloads (red). For the application throughput, we report the difference from the isolated run (no colocation) in percentage to highlight performance degradation due to contention.

As shown in the first plot, when colocated with a real workload mix, TPC-C throughput drops up to 37% after 30 seconds. The resource usage plots below reveal the contention sources: spikes in memory bandwidth, LLC traffic, and CPU utilization (we show per-core utilization for CPU 0 of the web server and CPU 8 of Spark for brevity). Y-axis ranges are normalized by the maximum values from training data.

MIMESYS-generated workloads reproduce this behavior with 4% average throughput deviation and 8% DTW distance in resource usage patterns. Both the timing and magnitude of performance degradation closely match the real

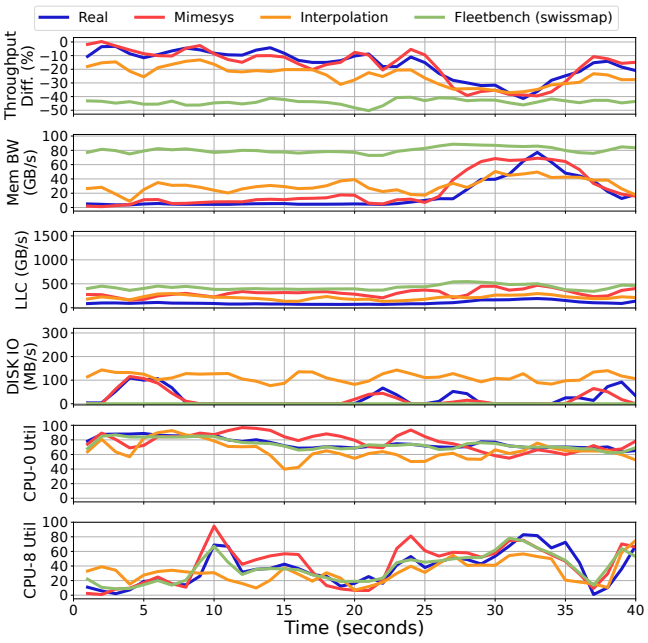


Figure 8: *TPC-C throughput and resource-usage over time when colocated with real (Spark & Renaissance web server workload mix) vs.* MIMESYS*-generated workloads.*

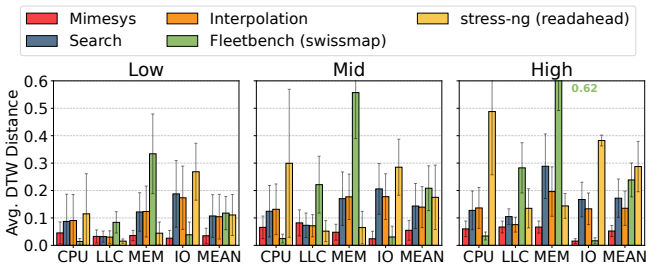

Figure 9: *DTW distances between real and synthetic traces for different metrics and workload mixes. "MEAN" reports the average DTW error over all metrics.*

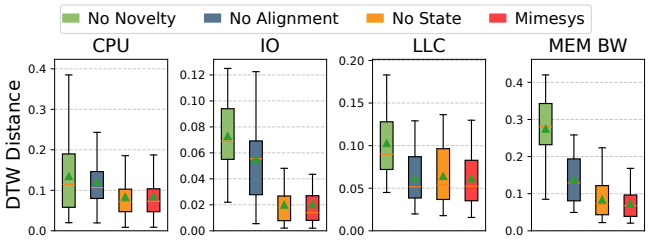

Figure 10: *Effectiveness of the proposed techniques.*

workload scenario. The alignment between memory bandwidth spikes and throughput drops suggests that memory contention from Spark is the primary cause of TPC-C degradation, which MIMESYS successfully captures. While other baselines closely match CPU utilization, they fail to match other resource usage patterns, leading to larger throughput deviations (9% for interpolation and 30% for stressor baselines).

7.2 Trace Similarities

We evaluate how closely MIMESYS-generated workloads' resource usage traces match those of real workloads. We report similarity using DTW distance, which accounts for temporal misalignment and variations in time-series traces. We classify workloads into three load levels based on CPU core allocation: low (0-30%), mid (30-60%), and high (60% and above).

Figure 9 illustrates the overall similarity between the generated and real traces for different metrics (CPU Utilization per core, memory bandwidth, LLC traffic, and disk I/O) and workload mixes (low, mid, and high load). For simplicity, we report the average CPU utilization across all cores instead of reporting per-core utilization separately. The results show that MIMESYS achieves low DTW distances across all metrics, indicating that the generated traces closely match the real ones. In terms of overall performance, MIMESYS outperforms all baseline methods, achieving an average DTW distance improvement up to 5.5× compared to our baselines.

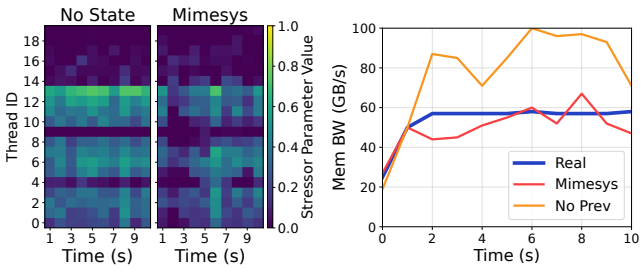
The gaps grow with load level, demonstrating MIMESYS's ability to emulate complex resource patterns. Heuristic baselines (search-based and linear interpolation) fail to capture multi-resource interactions under contention, resulting in high usage deviations. While the memory stressor baseline (Fleetbench) matches CPU utilization via sleep intervals, it fails to capture other resources, yielding higher DTW distances in memory bandwidth and LLC traffic. The IO stressor baseline (stress-ng) performs poorly across all metrics due to its sole focus on disk I/O.

7.3 Effectiveness of MIMESYS Techniques

In this section, we study how MIMESYS's key techniques contribute to its effectiveness. We ablate novelty-guided data collection, state-aware conditioning, and execution-driven alignment to measure their individual impacts on trace similarity between MIMESYS-generated workloads and real ones.

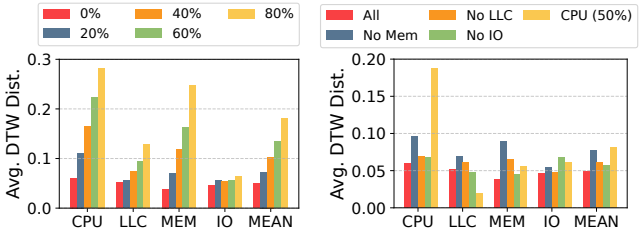
Novelty-guided training data collection. We evaluate the impact of novelty-guided data collection by comparing MIMESYS trained with and without this technique. Without novelty guidance, MIMESYS collects the training data through random sampling of stressor compositions. As shown by the green bars in Figure 10 ("No Novelty"), random sampling yields substantially higher DTW distances. Novelty-guided data collection expands coverage of the resource-usage space (Figure 4), reducing average DTW error by 2.5×.

State-aware conditioning. We evaluate state-aware conditioning by comparing MIMESYS with a variant that does not condition on prior stressor compositions. The yellow bars in Figure 10 ("No State") show DTW distances without state-aware conditioning. While the average difference is small (7% higher), certain cases show larger deviations. Relative to



(a) *Memory stressor intensity* (b) *Memory bandwidth usage*

Figure 11: *Effectiveness of state-aware conditioning.*



(a) *Varying trace dropping rate* (b) *Varying dropped metric*

Figure 12: *Sensitivity to input trace variations.*

the same stressor composition profiled after an idle window, the 90th-percentile change in LLC and memory bandwidth is 135.7% and 95.0%, respectively. State-aware conditioning is beneficial in tail cases where the preceding stressor shifts the observed metric by more than 2×.

In particular, Figure 11 presents a case study where state-aware conditioning substantially improves fidelity. Figure 11a shows how the memory bandwidth stressor is activated across threads over time, where each heatmap cell represents the fraction of time window allocated to this stressor on a particular thread. Without state-aware conditioning (left), the model generates uniformly high activations across most threads with little temporal variation, as shown by the bright green regions. This uniform high intensity creates excessive memory contention that drives bandwidth usage above target levels in subsequent windows. In contrast, with state-aware conditioning (right), the model generates more varied activation patterns, reducing memory-stressor intensity when prior execution has already created high memory load. As shown in Figure 11b, this adaptive behavior produces memory bandwidth traces that align more closely with the target.

Execution-driven alignment. We evaluate the impact of execution-driven alignment by comparing trace similarity before and after this training stage. The blue bars in Figure 10 ("No Alignment") show DTW distances for the model without alignment. Without alignment, DTW errors are 59% higher on average, demonstrating that execution-driven alignment substantially improves fidelity to real application behaviors. The improvement is particularly pronounced for memory bandwidth and I/O metrics. However, for some metrics such as LLC, improvements are less apparent. This likely occurs because the reward function may not fully capture all dimensions of trace similarity, causing the alignment process to prioritize certain metrics over others. While adjusting metric-specific weights can help, exploring more expressive reward formulations remains important future work.

7.4 Sensitivity to Input Traces

We study MIMESYS's sensitivity to variations in input traces through two experiments.

Random trace dropping. We randomly drop portions of input traces during inference to evaluate robustness to incomplete data. Figure 12a shows DTW distances when varying the dropping rate from 0% to 80%. As the dropping rate increases, similarity degrades gradually: 1.4× higher DTW distance at 20% and up to 3.7× at 80%. Missing trace segments challenge the model's ability to infer accurate stressor compositions. Despite expected degradation, MIMESYS maintains reasonable fidelity, demonstrating robustness to incomplete traces.

Metric-specific dropping. We evaluate the impact of dropping specific metric types during inference. Among the 23 input dimensions, we drop one metric type at a time and measure the resulting DTW distances. For CPU utilization, we drop 50% of per-core measurements; for other metrics (memory bandwidth, LLC traffic, disk I/O), we drop the entire metric during inference. Figure 12b shows the results. As expected, dropping specific metrics increases DTW distances for the corresponding metrics. MIMESYS maintains reasonable fidelity across other metrics (less than 1.7× degradation), showing it can infer stressor compositions that approximate overall resource patterns despite missing metrics.

8 Other Related Work

Synthetic trace generation. Prior works have explored synthetic trace generation for system evaluation. NetShare [55], and NetDiffusion [25] generate synthetic network traffic that mimics real-world patterns using machine learning models such as GANs and diffusion models. These approaches produce network packet traces (*e.g.,* packet sequences, flow statistics) as data artifacts for purposes such as privacy-preserving data sharing or network simulation. In contrast, MIMESYS generates executable programs that produce resource usage traces across multiple dimensions (*e.g.,* CPU, memory bandwidth, cache), enabling active experimentation under realistic contention conditions.

Synthetic workload generation. Other works have explored generating synthetic workloads to replicate the behavior of real applications without exposing proprietary code or data. Datamime [27] and Pbench [58] generate synthetic workloads for specific domains by using Bayesian optimization to match application performance characteristics or by combining database queries based on workload statistics. These

approaches focus on reproducing coarse-grained performance metrics for specific application types. MIMESYS differs by generating general-purpose workloads from system-level traces that reproduce fine-grained, multi-resource usage patterns over time across diverse application types.

9 Discussion

Portability across hardware platforms. MIMESYS currently targets a specific hardware platform, as the stressor library and generative model are trained for a known environment. Synthetic workloads generated for one platform may not reproduce the same resource usage patterns on systems with different hardware characteristics. For example, when synthetic workloads generated on a Haswell system are executed on a Skylake platform, we observe 190% higher prediction errors than using synthetic workloads generated by a model trained and deployed on Skylake.

The degradation is primarily caused by architectural differences that change how stressors consume system resources. While the stressors are designed for specific working-set sizes, variations in their per-iteration execution characteristics across architectures result in different LLC utilization and memory bandwidth behaviors. As future work, the generative model could be conditioned on hardware descriptors (*e.g.,* CPU architecture, cache hierarchy, memory topology) to automatically adapt stressor compositions and improve cross-platform generalization.

Other use cases. MIMESYS could be extended to enable operators to evaluate resource management policies under realistic conditions. For example, operators could assess policy changes (*e.g.,* new scheduling algorithms and NUMA balancing strategies). This would require extending MIMESYS to emulate fine-grained resource usage patterns, such as memory access patterns and cache behaviors, that influence how resource policies interact with workloads.

More broadly, realizing these use cases will require richer telemetry than the CPU, LLC, memory bandwidth, and I/O metrics considered in this work. Access to additional signals, such as memory-access locality, NUMA traffic, network activity, and accelerator utilization, together with a richer library of stressors and microbenchmarks that exercise these resources, could enable more faithful workload emulation. Such telemetry and workload primitives would allow MIMESYS to capture resource behaviors beyond those exposed in this work, supporting a broader range of tasks including resource management, and performance debugging.

10 Conclusions

We presented MIMESYS, a system that generates executable workloads from resource usage traces to enable realistic testing environments. MIMESYS represents workloads as stressor compositions and employs a diffusion model to learn the complex mapping from traces to stressor compositions. Two innovations enable this: state-aware conditioning, which captures temporal dependencies by conditioning on a prior stressor composition that affects system state; and execution-driven alignment, which adapts the model to real application behaviors using direct execution feedback. Our evaluation shows that MIMESYS achieves up to 5.5× higher trace similarity than baselines and reproduces application performance under contention 2.6× more accurately. By enabling reproducible testing without proprietary access, MIMESYS opens new possibilities for systems research and practical development.

A List of Stressors Used in MIMESYS

MIMESYS uses 14 stressors spanning CPU, memory, cache, and disk I/O resources, selected to ensure diverse resource usage patterns. We select these stressors by profiling approximately 600 candidates from stress-ng [26] and Fleetbench [8], choosing those with distinct resource usage characteristics. Table 2 lists the selected stressors along with their resource types: Computation (Comp), Memory (Mem), Cache, I/O (IO), and No-op (Sleep). The library column indicates the source of each stressor (either stress-ng or a specific Fleetbench benchmark), while the stressor name specifies the particular function used. For brevity, we omit detailed configuration parameters such as boolean flags or other default settings.

Library	Stressor Name	Type
Compression	ZSTD_decompress_Fleet	Comp
Hashing	Extendcrc32cinternal_Fleet_cold	Mem
Hashing	Computecrc32c_Fleet_cold	Mem
Libc	Memcpy_Fleet_L1	Cache
Simd	SerialDistanceComputation:256	Comp
Simd	SerialDistanceComputation:512	Comp
Swissmap	InsertMiss/density:0	Mem
Swissmap	InsertManyOrdered/density:0	Mem
Swissmap	InsertManyOrdered/density:1	Mem
Swissmap	InsertManyUnordered/density:1	Mem
Stress_ng	Readahead	IO
Stress_ng	Fallocate	IO
Stress_ng	Sendfile	IO
Sleep	-	No-op

Table 2: *Stressors used in* MIMESYS *with their library sources and resource types.*

B Hyperparameters Used for Execution-Driven Alignment

We use denoising diffusion policy optimization (DDPO) [11] to fine-tune the diffusion model during execution-driven alignment (§4.3). DDPO is a reinforcement learning algorithm that adapts the pretrained diffusion model to maximize reward signals based on actual execution feedback. The training process involves several key hyperparameters that affect both training stability and the quality of the aligned model.

We set the learning rate to 3×10^{-6}, which is lower than the pretraining learning rate to ensure stable fine-tuning without destroying the knowledge acquired during pretraining. To normalize rewards and reduce variance during training, we estimate advantages using a running mean baseline. The running mean is computed over a buffer of 512 samples, providing a stable estimate of expected rewards. For training stability, we clip the advantage ratio to 3, which limits the magnitude of policy updates and prevents large, destabilizing changes to the model during alignment.

C Artifact Appendix

C.1 Abstract

This artifact provides the implementation of MIMESYS, including the pipeline for training data collection, diffusion-model training, and execution-driven alignment. It also includes the scripts used to run and profile the workload mixes in the evaluation. The artifact enables users to generate synthetic workloads from resource usage traces and evaluate their fidelity using the profiling methodology described in the paper.

C.2 Scope

The artifact is intended to support the reproducibility of the key results in the paper. Specifically, it allows users to:

- Collect training data from stressor executions.
- Train the diffusion model used by MIMESYS.
- Perform execution-driven alignment.
- Run the evaluation pipeline in the paper.

C.3 Contents

The artifact includes the source code for all major components of MIMESYS, including training data collection, diffusion-model training, and execution-driven alignment. In addition, it provides the scripts, configurations, and profiling infrastructure used to generate, execute, and evaluate the workload mixes presented in the paper.

C.4 Hosting

The artifact is available at `https://github.com/ldos-project/mimesys`. The `artifact-eval` branch contains the version prepared for artifact evaluation.

C.5 Requirements

The artifact is designed to run on Linux systems capable of executing stressors (*e.g.,* Fleetbench and stress-ng) and collecting resource-utilization profiles using TACC's HPC monitoring infrastructure. Training requires NVIDIA GPUs with CUDA 12.x support. Detailed hardware and software dependencies, installation instructions, and environment specifications are provided in the artifact repository.

Abstract

The diverse and complex modern workloads pose a major challenge for cache to remain effective across all scenarios, degrading the performance of critical systems such as web caches. Adaptive cache eviction algorithms promise to address this challenge by observing access patterns and adjusting their behavior accordingly. However, existing ones fail this promise, even underperforming static policies. Our analysis shows that this is because they adapt only to a few typical patterns, incurring poor performance on others. Moreover, they adapt by switching between supposedly complementary algorithms, which turn out to interfere with each other.

We present MERLIN, an efficient adaptive algorithm that robustly handles diverse access patterns while maintaining low overhead and high multicore scalability. The efficiency of MERLIN stems from a principled pattern characterization method that can express a wide spectrum of access patterns rather than a few typical ones. This is achieved by characterizing at the level of individual objects while accounting for both access locality and cache size. Furthermore, MERLIN cleanly decouples responsibilities among its components, with each component performing a single task, thereby eliminating the costly interference between base algorithms. Our evaluation across 11 datasets with 5423 traces shows that MERLIN achieves robust improvements in hit rate over existing algorithms, increasing throughput by 1.4× to 7.8×.

1 Introduction

To improve performance, modern computing systems widely employ software caches, such as in-memory key-value stores in data centers [3,8,9,13,30,58,59,68], edge caches in content delivery networks [3,7,12,16,33,43,52,61,68], and page caches in operating systems [14,15,27,35,42,46,48,78]. The efficiency of such caching systems largely depends on their eviction algorithms, which manage limited cache space to exploit access locality in the workload. The effectiveness of eviction algorithms, in turn, hinges on how well their underlying assumptions match the workload access patterns.

However, prior studies [12, 35, 45, 48, 67, 69, 70, 77] show that modern workloads exhibit diverse and varying access patterns. We confirm the above conclusion through an analysis of 11 real-world datasets (§3.1). To express workload diversity, prior work [48] classifies access patterns into four primitive types: 1) `LFU-friendly` (high-frequency access), 2) `LRU-friendly` (high-recency access), 3) `Churn` (objects accessed periodically), and 4) `Scan` (objects accessed only once). The workload's access pattern is often a varied combination of these primitives, while also shifting rapidly over time.

The complex access patterns are a key challenge to eviction algorithms, as they must remain effective across all patterns. Nevertheless, decades of advancements in the field have mainly focused on static algorithms [8, 13, 17, 27, 35, 40, 71, 72, 78], which use fixed policies to manage cache regardless of access patterns. Despite many elegant proposals, the inherent rigidity of static algorithms limits their ability to deliver the best performance across diverse workloads, as our evaluation shows in §3.

To tame workload diversity, a general system design principle is to introduce *adaptivity*, which has seen great success across multiple domains, such as scheduling, resource allocation [23,24,75] and fuzzing [26,29,66]. In the context of cache eviction, an adaptive algorithm involves two key aspects: 1) *Pattern characterization*, *i.e.*, observing and characterizing workload access patterns; and 2) *Policy adjustment*, dynamically changing its policy to suit the observed patterns. Such adaptivity promises an effective way to treat the diverse access patterns in modern workloads.

However, existing adaptive algorithms [6, 45, 48, 55] fail to fulfill this promise, to a degree that they often underperform their static counterparts across real-world workloads, as we measure in §3.2. Indeed, designing effective adaptive algorithms is challenging. Prior work [71] shows that a simple yet effective static algorithm already performs well on common workloads, while making itself adaptive only offers marginal gains in the rare adversarial workloads. This suggests that the complexity cost of adaptivity may outweigh its benefits. Our work revisits this problem by studying how to design an effective adaptive algorithm with low complexity.

This paper presents MERLIN[1], a cache eviction algorithm that adapts to a broad spectrum of access patterns with low management overhead and high multicore scalability. To design MERLIN, we begin with an in-depth analysis of the typical patterns where existing adaptive algorithms fail (§3.3).

Through the analysis, our key observation is that existing adaptive algorithms are designed to be effective for a few typical patterns, thereby incurring poor performance in many

[1]The Arthurian wizard, who shape-shifts to navigate different scenarios.

other cases. Algorithms like ARC [45] and CAR [6] adapt cache space for accesses dominated by 1) objects accessed only once recently, or 2) objects accessed multiple times recently. As both categories represent short-term accesses, they do not effectively capture long-term access patterns. Cacheus [48] adapts by switching between two complementary base algorithms, each effective for two of the four aforementioned primitive patterns. Thus, Cacheus fails to adapt when accesses deviate from these typical patterns.

To overcome the above limitations, Merlin advances in both key aspects of adaptivity. In *pattern characterization*, state-of-the-art mechanisms classify access sequences into only a few typical patterns, failing to extract the characteristics of many access traces. This is due to a failure to meet the challenge of devising an approach for accurately expressing the full spectrum of access patterns.

To address the above challenge, we identify three key requirements. The characterization must 1) be flexible, *i.e.*, not limited to a small fixed set of access patterns, 2) reflect the degree of locality, the key to caching effectiveness, and 3) account for cache size, since the same access sequence can behave differently under different cache sizes. Prior characterization approaches do not meet all these requirements, explaining their ineffectiveness across diverse patterns.

Merlin's principled characterization approach meets all the above requirements. Merlin characterizes by classifying objects based on two dimensions: *hotness* and *popularity* into four types: hot-popular, hot-rare, cold-popular, and cold-rare. *Hotness* and *popularity* denote short-term and long-term access counts, respectively, capturing both recency and frequency aspects of locality, therefore meeting the second requirement. To meet the third requirement, Merlin sets the total number of hot and popular objects to fit the cache, with an intuition that only the hottest and most popular items are stored. With this object-level classification, Merlin accurately captures a wide range of access patterns using counts of the four object types, satisfying the first requirement.

Regarding *policy adjustment*, prior work uses complementary base algorithms or data structures that turn out to interfere with each other when neither is particularly effective, leading to poor performance (§3.3). Thanks to its principled characterization, Merlin adapts using a simple policy that avoids such interference: prioritize hot-popular objects, then hot or popular objects, and filter out cold-rare objects, as the object type counts reflect the access pattern.

Merlin's design is based on a unified and cohesive architecture that embraces recent advances in multi-queue FIFO-based algorithms [71]. It consists of multiple components with cleanly decoupled responsibilities, each performing a single task. Merlin uses 1) a small FIFO queue to filter cold-rare objects, 2) a core queue and a staging queue, two large FIFO queues to prioritize hot-popular objects, followed by hot or popular objects, 3) a ghost queue [6, 36, 45, 48, 71] to accurately identify hot-rare objects, and 4) a count-min sketch [21, 22, 27, 31] to spot cold-popular objects.

We evaluated Merlin with 16 algorithms on 5423 real-world traces from 11 datasets across various domains, including CDN, KV stores, and VM management/storage caching. Our evaluation shows that Merlin achieves robust improvements in hit rate over prior work, while incurring low management overhead and offering high multicore scalability, improving throughput by 1.4× to 7.8×.

In summary, this paper makes the following contributions:

- **Analysis.** We show that prior adaptive algorithms fail to cover the wide spectrum of access patterns, mainly because of their overly simple pattern characterization.
- **Pattern characterization.** We identify the key requirements for access characterization and contribute a principled approach that expresses diverse patterns.
- **Merlin.** We design Merlin, an adaptive cache eviction algorithm with a unified, cohesive architecture. Merlin delivers robust performance across diverse patterns, while offering low overhead and high scalability.

2 Cache Eviction Algorithms

A cache system's efficiency hinges on its eviction algorithm, since it decides which objects[2] utilize the scarce cache space. This section briefly reviews state-of-the-art cache eviction algorithms, covering both static (§2.1) and dynamic ones (§2.2).

2.1 Static Eviction Algorithms

A static algorithm always applies the same fixed set of rules for eviction, no matter the workload characteristics. Research over the past few decades has primarily focused on static algorithms. Early static algorithms, such as LFU, FIFO [10, 53], and LRU [10, 25], use simple heuristics that perform well only for a narrow set of access patterns. For example, LRU favors accesses with high recency, but performs poorly for objects repeatedly accessed in a round-robin fashion.

Follow-up work aims to be more robust across diverse access patterns by using better ranking metrics [8, 12, 13, 18, 40] and/or combining multiple components (*i.e.*, LRU lists, and FIFO queues) [6, 27, 34–36, 45, 71, 78]. Two notable examples are LIRS [35] and S3-FIFO [71], performing best on the datasets we evaluated (§7). As explained in §5, Merlin inherits the FIFO-based design from S3-FIFO, but generalizes it to: 1) be adaptive, 2) account for both recency and frequency, and 3) use a better characterization of one-hit wonders (§5.4).

2.2 Adaptive Eviction Algorithms

An adaptive eviction algorithm involves: 1) observing and characterizing workload access patterns, and 2) adjusting its policy (behavior) accordingly (by, *e.g.*, automatically tuning internal parameters) to maximize performance.

Adaptive algorithms fall into two categories: 1) size-adaptive and 2) policy-adaptive.

A size-adaptive algorithm partitions cache into multiple

[2] We use the term "object" to collectively refer to various types of data (*e.g.*, pages, blocks, key-value pairs) stored in a cache.

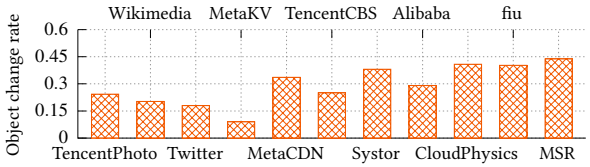

Figure 1: The object change rate of 11 real-world datasets.

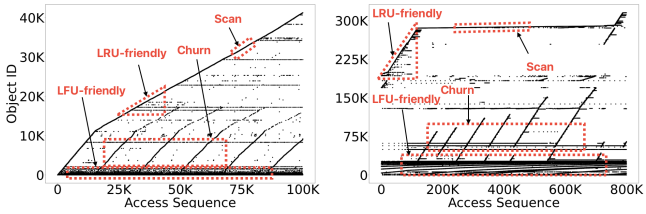

Figure 2: Two examples of real-world access patterns. The *x*-axis is the access sequence number, and the *y*-axis is the object ID. Each point means that the object is accessed at that moment.

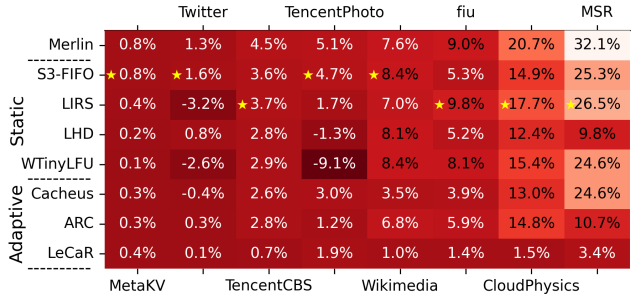

Figure 3: The average hit rate improvement over LRU for 8 representative eviction algorithms on 8 real-world datasets. The cache size is 3% of the working set size. The larger the value, the higher the hit rate, with a star showing the best algorithm (excluding Merlin). Merlin achieves the highest hit rate in 5 datasets, with close to the best performance in 3 datasets.

parts and adapts by adjusting each part's size based on access patterns. The state-of-the-art is ARC [45] and CAR [6].

ARC divides cache into two lists: a one-hit list and a multi-hit list. A new object is first placed in the one-hit list and added to the multi-hit list on a second access. On a cache miss, ARC checks whether it has previously evicted the requested object by looking for it in the eviction history of both lists. If so, ARC expands that list's size and correspondingly reduces the size of the other list. In this way, ARC adapts by dynamically adjusting the cache space partition to favor either 1) objects accessed only once recently (by expanding the one-hit list), or 2) objects accessed multiple times recently (by expanding the multi-hit list). CAR follows a similar design but notably replaces the LRU lists with FIFO queues.

A policy-adaptive algorithm adapts by switching between multiple base eviction algorithms depending on their effectiveness under observed access patterns [55].

Cacheus [48] is state-of-the-art, working by classifying access into four primitive patterns: 1) *LFU-friendly*: a small portion of objects are frequently accessed. 2) *LRU-friendly*: recently accessed objects are likely to be accessed again soon 3) *Churn*: all objects are repeatedly accessed with equal probability, and 4) *Scan*: all objects are accessed only once.

To adapt, Cacheus uses two complementary base algorithms: a *scan-resistant* LRU variant and a *churn-resistant* LFU variant, to cover all four primitive access patterns. Cacheus maintains a weight for each base algorithm. Upon a cache miss, Cacheus selects a base algorithm to perform eviction using probabilities proportional to the weights of the algorithms. Next, Cacheus checks whether it mistakenly evicted the requested object, and, if so, penalizes the responsible base algorithm by reducing its weight. Cacheus uses machine learning to control the rate at which weights change.

3 How Modern Algorithms Perform

This section analyzes the characteristics of modern cache workloads (§3.1), evaluates existing eviction algorithms on them (§3.2), and identifies remaining deficiencies (§3.3)

3.1 Characteristics of Modern Cache Workloads

It is well known that modern cache workloads 1) exhibit diverse access patterns and 2) that their access patterns change over time [48, 49, 56, 57, 70]. We confirm this by analyzing 11 real-world datasets with a total of 5423 traces (Table 2)

Figure 1 summarizes our analysis. As we have not found a prior metric to quantify the diversity and variability of access patterns, we propose a new metric[3], the object change rate, which measures the fraction of change in uniquely accessed objects between consecutive time windows. As shown in the figure, using a time window of 1% of the trace length, all datasets exhibit a high object change rate, up to ~45% (*i.e.*, nearly half of the accessed objects change in each window).

Figure 2 visualizes two examples of diverse and varying access patterns. Following the classification in Cacheus (§2.2), all four patterns appear in two traces with frequent switches.

3.2 Performance of Existing Algorithms

We evaluate 16 state-of-the-art cache eviction algorithms on 11 real-world datasets. Figure 3 shows a subset of the results (full results in §7.2), including the top-performing algorithms in both the static and adaptive categories (§2).

We draw two conclusions. First, for static algorithms, there is no "silver bullet" that consistently outperforms others. S3-FIFO achieves the highest hit rate across 4 datasets (excluding Merlin), in some cases by a significant margin over the runner-up. In the remaining 4 datasets, LIRS is the best.

We analyze a few typical traces where LIRS and S3-FIFO underperform and find that their deficiencies stem from their static nature; a fixed set of rules is a poor match for the diverse and varying access patterns. Introducing adaptiveness enables the two algorithms to perform better on such traces. For example, LIRS may benefit from adjusting its promotion

[3] While this metric is not perfect, it is still useful to quantify accesses.

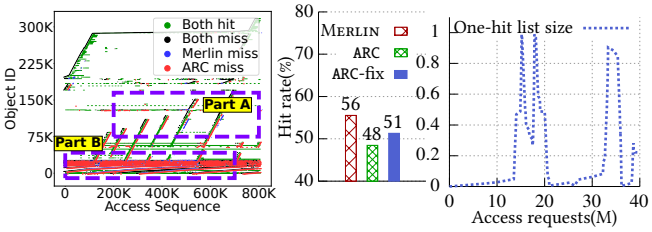

Figure 4: The Alibaba [1] 742 trace. ARC-fix only caches objects in the two-hit list. Assuming the cache is in DRAM with 100ns access time and the backend is SSD with 10μs access time, MERLIN improves performance by 8× over ARC. MERLIN excels by caching both short- and long-term locality objects.

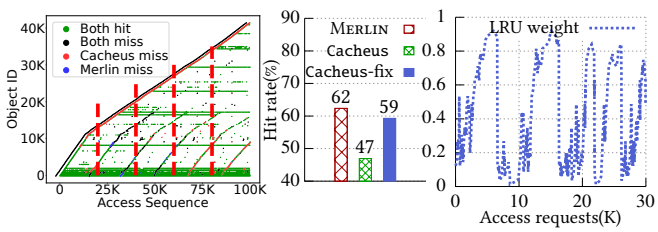

Figure 5: The Alibaba 269 trace. As shown in the left-most figure, given a time window (data between vertical red lines), the access patterns do not fall into any one of the primitive patterns; LRU weight is the activation probability of the LRU variant. Cacheus-fix only uses the LFU variant. MERLIN improves by identifying the high-frequency objects in the churn pattern.

policy or the small FIFO queue's size, and S3-FIFO could improve by adapting its reinsertion policy.

Second, adaptive algorithms consistently underperform the static ones. None of the adaptive algorithms 1) achieves the highest hit rate in any dataset; nor 2) matches the performance of the best static algorithms (*i.e.*, S3-FIFO) and arguably the second-best one (*i.e.*, LIRS) across all datasets.

This result is surprising, as adaptiveness should better match diverse and varying access patterns (§3.1), expectedly. Indeed, we view this as an anomaly in systems research, as adaptiveness succeeds widely in other domains (*e.g.*, scheduling and resource allocation [23,24,75] and fuzzing [26,29,66]), often resulting in significant performance gains over static counterparts. This provides strong motivation for MERLIN, which advances the design of adaptive eviction algorithms.

3.3 Remaining Deficiencies in Adaptive Algorithms

We analyze several representative traces to reveal three limitations of existing adaptive algorithms.

Limitation #1: Failure to adapt to real-world patterns. An inherent limitation of prior mechanisms is that they only adapt to a small subset of access patterns. This is because their design assumes that a given access sequence will always conform to a few fixed patterns. This assumption is explicitly made in Cacheus (§2.2), which uses base algorithms to cover all primitive patterns. The assumption is also made implicitly in ARC and CAR, which model access sequences as dominated only by short-term locality. They thus forgo long-term locality, as we explained next. However, the diverse access patterns in real-world workloads often deviate from these fixed patterns. Therefore, in those cases, existing adaptive algorithms fail. As detailed in §4, the root cause of this limitation is their inaccurate characterization approach.

Figure 4 shows a trace where ARC fails. This trace exhibits a mix of accesses with high long-term locality (Part A) and high short-term locality (Part B). Specifically, Part A contains objects accessed repeatedly but often with long intervals (that exceed the cache size) between two accesses. Such objects are good candidates for caching. However, with ARC, they are often first placed in the one-hit list and then evicted before the second access. Thus, regardless of how ARC partitions the cache between the two lists, it fails to cache these objects, leading to poor performance.

Figure 5 shows a trace where Cacheus fails. In this trace, for most of the time, the access sequences do not fall into any one of the primitive patterns (§2.2); rather, all four of them exist simultaneously. This renders both base algorithms ineffective, and thus, no matter how Cacheus adjusts their weights, it cannot deliver good performance. We further analyze this trace in §5.4.

Limitation #2: Adversarial base algorithms/data structures. Related to the first limitation, another key limitation lies in the adaptiveness approach: if the access patterns do not fall within the assumed ones, due to the nature of their policy- or space-adaptive design, the supposedly complementary base algorithms or data structures end up working against each other, further reducing performance.

For space-adaptive algorithms, like ARC, with a mixed access pattern, accesses to objects in both partitions suffer excessive cache misses. In this case, we find that the algorithm blindly adjusts partition sizes (the right most in Figure 4), leading to thrashing that actually evicts useful objects. Similarly, in such a case, policy-adaptive algorithms like Cacheus, blindly adjust weights (the right most in Figure 5), causing one algorithm to evict useful objects cached by the other. Indeed, as shown in Figures 4 and 5, for these two traces, using a single base data structure (ARC-fix) or algorithm (Cacheus-fix) actually outperforms the full algorithm.

Limitation #3: Poor robustness across cache sizes. Existing adaptive algorithms fail to deliver robust performance across different cache sizes, as shown in Figure 11. Their design does not consider the impact of cache sizes on access patterns (§2.2). This is less inherent, as one can likely enhance these algorithms to overcome it. Nonetheless, MERLIN also overcomes this limitation.

4 Characterizing Workload Access Patterns

We next show how MERLIN addresses the inherent limitations of prior adaptive algorithms (§3.3) through its characterization approach. Later sections present MERLIN's design (§5) and implementation (§6), both enabled by this new way of

	Fine-grained	Flexibility	Short-/long-term Locality	Cache-size Awareness
Cacheus	✗	✗	✓	✗
ARC	✓	✓	✗	✗
Merlin	✓	✓	✓	✓

Table 1: A summary of the characterization approach in state-of-the-art adaptive algorithms. ✗: not considered; ✓: considered.

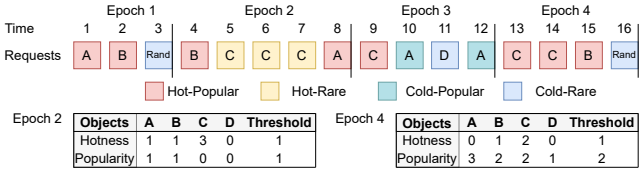

Figure 6: An example of how Merlin characterizes access patterns. Rand denotes an access to an irrelevant object.

characterizing access patterns.

Challenge. Our key observation is that the inherent limitation of prior work (*i.e.*, the inability to adapt to diverse access patterns) lies in their characterization approach. Their mechanism cannot accurately characterize the full spectrum of diverse and complex patterns.

Merlin overcomes this challenge by 1) identifying four key requirements, following general design principles in caching literature, and 2) introducing a new characterization approach that meets all these requirements (Table 1).

Requirements. The first requirement is fine granularity; characterization should not be at the level of access sequences, since a sequence may involve multiple patterns (Figure 5). The second requirement is flexibility, *i.e.*, not assuming a fixed set of access patterns, since such a fixed set is unlikely to match the diversity of real-world access patterns.

The third requirement is that the characterization should capture both short-term access locality (commonly referred to as recency) and long-term access locality (commonly referred to as frequency); as evident in much prior work [8, 13, 36], missing either one leads to high inefficiency.

The final requirement is a cache-size-aware characterization, since the same access sequence may require different handling under different cache sizes [48, 71]. For example, consider a sequence that repeatedly accesses five objects.[4] With a cache size of less than five, an LRU policy does not work, as it thrashes the cache, leading to a zero hit rate. Yet, if the cache size is larger than five, an LRU policy works well.

Object-level characterization. To meet the first requirement, Merlin characterizes at the object-level, the finest granularity possible. For an access sequence, Merlin characterizes by evaluating each accessed object using specific metrics (specifically, hotness and popularity, as detailed next).

Flexible characterization. For the second requirement, Merlin characterizes by using metric distributions (*i.e.*, the number of objects falling into different ranges of the metrics). The continuous nature of metric distributions captures patterns that a fixed set cannot express.

Reflecting short and long-term locality. To meet the third requirement, Merlin first divides an access sequence into *epochs*, each containing as many unique object accesses as the cache size. Merlin measures the short-term locality of an object using *hotness* [5], the number of times an object is accessed in the current epoch. It measures long-term locality through *popularity*, the number of past epochs in which the object was accessed, excluding the current epoch.

Using cache size to decide thresholds. For the last requirement, Merlin accounts for cache size with two steps. First, Merlin introduces a threshold for both hotness and popularity to classify objects. In the hotness dimension, an object is marked as hot or cold based on whether its hotness is above or below the hotness threshold. Likewise, in the popularity dimension, an object is marked as popular or rare by comparing its popularity with the popularity threshold.

Next, Merlin dynamically adjusts the thresholds by considering cache sizes. Suppose that the cache size is S, the hotness (and popularity) threshold is the hotness (and popularity) count of the current S-th hottest (and the most popular) object. The reason is intuitive: the cache should hold the hottest and the most popular objects to maximize hit rate.

Putting it together. With the above design rationale, Merlin's characterization approach is perhaps surprisingly simple. Merlin characterizes workload access pattern by classifying each accessed object into one of the four access types based on its hotness and popularity: hot-popular, hot-rare, cold-popular, and cold-rare. The cache size decides the thresholds for hotness and popularity, and the number of objects in each type reflects the access patterns.

Figure 6 shows an example with the cache size of 3. The access patterns change from *LFU-friendly* at the end of Epoch 2 to *LRU-friendly* at the end of Epoch 4. The change in access type for objects A and C captures this pattern change. Object A is hot-popular at the end of Epoch 2; its hotness is 1, due to an access in Epoch 2, and its popularity is 1, due to that Epoch 1 accesses it. However, at the end of Epoch 4, object A becomes cold-popular with a hotness of 0 (no access in Epoch 4) and a popularity of 3 (accessed in Epochs 1, 2, and 3). Object C changes from hot-rare to hot-popular, due to its frequent accesses in Epochs 3 and 4.

Discussion. In essence, the effectiveness of Merlin's characterization approach lies in meeting all four requirements (Table 1). Among them, the first two are implicitly

[4] For clarity, §4 and §5 assume all objects have a size of one. Our implementation and evaluation consider variable-size objects; see §6

[5] To avoid confusion, we use the terms hotness and popularity rather than the more common, often overloaded terms recency and frequency. For example, ARC uses these terms to distinguish objects accessed once from those accessed multiple times in the recent past. In contrast, we use them to represent short- and long-term locality, respectively.

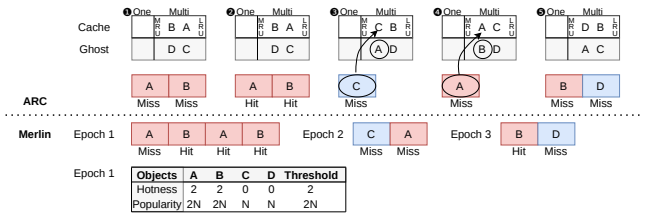

Figure 7: An example of Merlin characterizing access patterns more accurately than ARC. The cache size is 2, with the access sequence repeating ABABCABD. With ARC, the initial cache state in Step ❶ is identical to that in Step 5 (because the access sequence repeats). Thus, accessing A misses and evicts B, and accessing B misses and evicts D. In Step ❸, accessing C misses and evicts A. In Step ❹, accessing A misses and evicts B. In Step ❺, both accesses miss. For Merlin, the table shows the characterization at the end of Epoch 1. In Epoch 1, accessing A misses and evicts D. In Epoch 2, accessing C misses and evicts A, and accessing A misses and evicts C. In Epoch 3, accessing B hits, and accessing D misses and evicts A.

adopted by ARC. We make them explicit here as potentially useful guidelines for future algorithms. The last two are general caching design principles, but prior designs such as ARC and Cacheus do not fully incorporate them.

For the third requirement, there exist other metrics for short- and long-term locality, such as reuse distance for the former and total access count (with a decay factor) for the latter. Merlin uses count-based metrics mainly for their efficiency, as detailed in §5 and §6.

For the fourth requirement, Merlin contributes a new adaptive approach that dynamically adjusts the thresholds based on cache size. Adapting by changing thresholds departs from the prior approach that adapts by 1) changing component sizes (as in ARC) or 2) changing algorithm weights (as in Cacheus). As further explained in §5.1, this new approach is the key for Merlin to avoid the adversarial effect of base algorithms/data structures.

To complement the explanation with real-world traces in Figures 4 and 5, Figure 7 provides an illustrative example of why Merlin characterizes access patterns more accurately than ARC. In this example, as ARC does not consider long-term locality, it cannot distinguish poor-locality objects C and D and good-locality objects A and B. As a result, ARC is effectively reduced to LRU, leading to a 25% hit rate. In contrast, Merlin correctly finds that objects A and B have better locality than objects C and D. Hence, Merlin will keep one of the objects A and B in the cache for the subsequent accesses (object B in this example), leading to a 50% hit rate.

5 Merlin Design

This section presents the design of Merlin, an efficient eviction algorithm that adapts to a broad spectrum of patterns. We present the design overview (§5.1), its components (§5.2) and workflow (§5.3), concluding with examples of how Merlin adapts to various access patterns (§5.4).

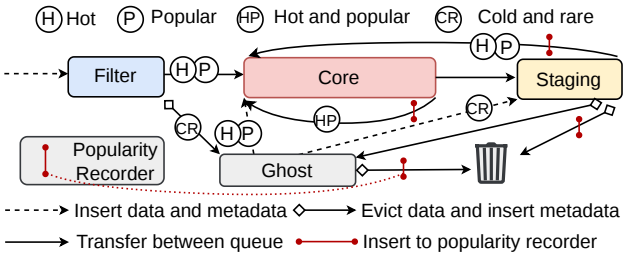

Figure 8: An overview of Merlin's key components and workflow.

5.1 Merlin Design Overview

With its principled characterization method (§4), Merlin's design accomplishes two tasks: 1) track each object's hotness and popularity over time to classify it into one of the four access types; and 2) prioritize keeping hot-popular objects (since they have the best locality), followed by hot-rare and cold-popular objects, while evicting cold-rare objects.

How Merlin adapts. As patterns vary over time, Merlin adapts by dynamically adjusting the hotness and popularity thresholds, which, in turn, changes the number of objects in each access type. As shown in Figure 6, when the pattern shifts from *LRU-friendly* to *LFU-friendly*, Merlin adjusts its thresholds, leading to more popular and fewer hot objects in Epoch 4 than in Epoch 2. In this way, Merlin correctly captures the shift from recency to frequency. Section 5.4 provides more examples of how Merlin adapts.

A cohesive architecture. As dynamic thresholds enable adaptiveness, Merlin's caching architecture forgoes the use of complementary base algorithms/data structures. Merlin thus overcomes the limitation in the adaptiveness approach of prior works (*i.e.*, Limitation #2 in §3.3).

Merlin achieves this cohesive architecture by embracing recent advances in FIFO-queue-based designs, as exemplified by S3-FIFO [71]. Specifically, as S3-FIFO, Merlin uses a small queue to filter out objects with poor locality (*i.e.*, cold-rare objects), and a large queue to store main objects. Moreover, as S3-FIFO and other works [8, 35, 36, 45, 48, 55, 72], Merlin uses a ghost queue to signal and act upon poor evictions.

As detailed next, unlike S3-FIFO, Merlin is adaptive with the following key differences: 1) Merlin admits objects to different caching components based on their access types (rather than fixed access counts); 2) Merlin tracks objects' hotness and popularity, where the latter requires a new component, the popularity recorder, implemented as a count-min sketch (§6); and 3) Merlin adds a staging queue to prioritize hot-popular objects over hot-rare and cold-popular objects.

5.2 Merlin Components

Figure 8 shows Merlin's components and workflow. The main part of Merlin consists of three FIFO queues: a filter queue, a core queue, and a staging queue. In addition, Merlin maintains a FIFO ghost queue and a popularity recorder.

The filter, core, and staging queues store objects and their

metadata, which includes their hotness count and access type. The ghost queue stores only metadata, while the popularity recorder only stores the objects' popularity count.

Task division. The filter queue is a small queue that quickly evicts likely cold-rare objects. The core queue consumes most of the cache space to store hot and/or popular objects. The ghost queue stores metadata for objects evicted by the filter queue, providing a second chance to correctly identify access types. This is necessary since the small filter queue may falsely filter out objects that are hot or popular. The staging queue verifies the object types before the final eviction. The filter, core, ghost, and staging queues also work together to track objects' hotness; these four FIFO queues ensure an invariant that an object is observed for at least one epoch (§4).

The popularity recorder tracks the popularity of objects. Conceptually, it is a two-dimensional counter recording each object's access numbers for past epochs. The actual realization of the popularity recorder is a count-min sketch (§6).

Space allocation. The filter queue, core queue, and the staging queue use 10%, 85%, 5% of the cache space, respectively. The ghost queue stores the metadata of one epoch, while the popularity recorder stores the popularity of all objects accessed in the past 16 epochs. We identify these values through sensitivity analysis (§7.5) and found that they work well across a wide range of real-world workloads.

5.3 Merlin Workflow

Overview. As shown in Figure 8, when an object is accessed for the first time, Merlin places it on the filter queue and starts observing its access type. Upon leaving the filter queue, if its access type is cold-rare, Merlin evicts its data and places its metadata in the ghost queue. Otherwise, Merlin promotes the object to the core queue.

As the core queue is FIFO, the oldest object leaves it when the queue becomes full. If the object is hot-popular, Merlin reinserts it to the core queue, since it has the best locality. Objects of other types are placed in the staging queue, which may lead to eviction.

For an object in the ghost queue, upon access, Merlin must bring it back into the cache. Merlin examines the object's access type and promotes it to the core queue if it is hot or popular. Otherwise, Merlin promotes it to the staging queue. In the latter case, if the staging queue later evicts the object, Merlin places it back in the ghost queue to complete a full epoch of hotness observation.

As discussed earlier, the staging queue stores objects from the core and ghost queues. Upon object eviction, the staging queue verifies its access patterns and reinserts it into the core queue if its access pattern is not cold-rare.

The staging queue thus serves two purposes. For objects from the core queue, the staging queue maximizes the hit rate by retaining objects with good locality, following the spirit of FIFO-reinsertion [20]. For objects from the ghost queue, the staging queue provides yet another chance to verify their access types before eviction.

The popularity recorder tracks, for each object, its access count in the recent epochs. It operates when an object is reinserted into the core queue from 1) the core queue itself, 2) the staging queue, or 3) upon eviction from the ghost queue. On these events, the popularity recorder checks if the object was accessed in the last epoch and, if so, increments its access count for the last epoch.

Finally, with hotness counts tracked in the FIFO queues and popularity counts maintained by the popularity recorder, Merlin updates both thresholds based on their distributions.

Figure 9 shows the detailed algorithm of Merlin.

Cache hits. On a cache hit (L2), Merlin simply updates the hotness of the object (L3) and the hotness distribution (L4).

Cache misses. Upon a cache miss (L5), Merlin first checks if the cache is full, and if so, evicts an object (L12-13). Next, Merlin checks if the object has been previously encountered and resides in the ghost queue (L14). If so, Merlin updates its hotness (L15-16), checks the object's access type (L17), and inserts it into either the core queue (L18) or the staging queue (L20). If not, Merlin treats the object as a new object and inserts it into the filter queue (L23-24).

Object eviction. When the cache is full, Merlin first tries to evict from the filter queue (L28-34). If no object is evicted (*i.e.*, all of them go to the core queue), Merlin evicts from the staging queue (L36). For this, Merlin first reinserts hot-popular objects to the core queue (L44-48) while moving the rest to the staging queue (L50). Upon reinsertion, Merlin updates the object's hotness and popularity for a new epoch (L45-47). Merlin does not directly set hotness to zero, since in practice such a drastic demotion can lead to thrashing. Next, Merlin evicts objects from the staging queue (L51-63). If an evicted object is from the ghost queue, Merlin inserts it back (L57-58). Otherwise, Merlin evicts it completely (L62).

The eviction guarantees to succeed, as objects reinserted to the core queue reduce their hotness and popularity, and thus eventually become cold-rare ones. In practice, we found that the eviction loop rarely iterates more than a few times.

Updating thresholds. Merlin amortizes the overhead of updating the hotness and popularity thresholds (L7-9) by every `ADJUST_INTERVAL` (64 in our implementation) accesses.

Recording objects' popularity. As discussed, Merlin updates popularity upon three events, as shown in L39, L46, L54. Merlin sets the access flag `x.acc` to `True` upon an access (L4, L6) and clears it after updating the popularity (L46, L54).

Deciding thresholds. Figure 10 presents Merlin's remaining algorithm. To decide the thresholds, Merlin maintains the distribution of hotness and popularity counters (*i.e.*, how many objects fall under each specific counter value) (L1-11). Afterward, Merlin scans the distributions from high to low, sums the counts until the total exceeds the cache size, and uses this value as the thresholds (L24–36). This threshold is the minimum hotness or popularity for an object to rank

```
1  def access(x):

63             return True
```

Figure 9: The core algorithm of Merlin.

among the top S objects, where S is the cache size. Merlin uses the thresholds to classify objects (L38-44).

Progressing epochs. Merlin maintains a global counter, and when the number of inserted objects reaches the cache size (L20), Merlin enters a new epoch (L21-22) by clearing the popularity records of the oldest epoch. This is accurate because the rest of Merlin is FIFO queues, and thus each invocation of `recordpop` entails a new object access.

5.4 How Merlin Adapts to Access Patterns

With the design in place, this subsection demonstrates how Merlin adapts to diverse access patterns.

The primitive access patterns (§2.2). With an *LRU-friendly* pattern, Merlin tracks hotness and identifies that most objects are hot (hot-popular or hot-rare). The reinsertion behavior of the core and staging queues retains hot objects in the cache, similar to LRU. With an *LFU-friendly* pattern, most objects are popular (hot-popular or cold-popular), and the popularity recorder behaves like LFU by tracking objects' popularity. A *Scan* pattern comprises mostly cold-rare objects, which the filter queue evicts.

The *Churn* pattern is interesting because Merlin behaves differently depending on the cache size. When the cache is large enough to hold all repeatedly accessed objects, they become hot-popular, which Merlin caches to maximize performance. However, if the cache is too small to store all of them, some become cold-popular while the rest remain hot-popular; Merlin caches the latter to prevent thrashing.

Access patterns in prior work. S3-FIFO [71] evicts those objects that are accessed only once, *i.e.*, one-hit wonders. Merlin more accurately characterizes one-hit wonders by

classifying them as either 1) cold-rare objects that are never accessed again, or 2) cold-popular objects that are accessed again after the current epoch. For the former, as in S3-FIFO, Merlin quickly evicts them using the filter queue. For the latter, unlike S3-FIFO, Merlin keeps them due to their good frequency, thereby improving efficiency over S3-FIFO.

LIRS caches objects with low Inter-Reference Recency (IRR), *i.e.*, a small number of requests between consecutive accesses and evicts those with high IRR. However, this policy is suboptimal, since some high IRR objects may still be frequently accessed and therefore good candidates for caching. Merlin identifies these objects as cold-popular and caches them, thereby improving over LIRS.

Complex access patterns. For more complex access patterns, such as those in Figures 4 and 5, Merlin identifies and caches objects with the highest hotness and/or popularity, thereby maximizing performance.

Next, we further explain how Merlin effectively handles the trace in Figure 5. Initially, Merlin sets the hotness threshold to 1, allowing objects hit once (or hit in the ghost-queue) to enter the core queue. This behavior filters out *Scan* (cold) objects. As the workload evolves and more reusable objects appear, Merlin increases the hotness threshold to 2, preventing objects hit once from entering the core queue. This adjustment filters out relatively cold objects, that are part of *LRU-friendly* or *Churn* patterns. Then, the threshold changes from 2 to 5 according to the pattern. Merlin preserves cache capacity for hot objects, thereby improving the hit rate.

In contrast, Cacheus faces a dilemma when workloads contain mixed patterns. It first inserts incoming objects into the cache and later evicts them using a weighted combination of *scan-resistant* LRU and *churn-resistant* LFU policies. For *LRU-friendly* objects, the *churn-resistant* LFU policy makes false eviction decisions, and Cacheus reduces its weight. Then, when the *Churn* pattern emerges, the *scan-resistant* LRU policy performs poorly, causing Cacheus to reduce its weight instead. As a result, Cacheus continuously shifts between policies and cannot adapt effectively to the full mixture of access patterns, resulting in lower hit rates.

6 Realizing Merlin

We implemented Merlin in both CacheLib [11], a development library for caching systems deployed at Facebook, and libCacheSim [2], an efficient cache simulator. We choose these two frameworks because many eviction algorithms (§7) are already implemented on them. We also contributed implementations of ARC and CAR to CacheLib, and an implementation of CAR to libCacheSim.

Realizing the popularity recorder. A challenge Merlin overcomes is minimizing the popularity recorder's space overhead. A naive approach that records object names (*e.g.*, block/page addresses, key values) and popularity counts would incur significant overhead.

Following W-TinyLFU [27], Merlin minimizes such overhead using a count-min sketch [21, 22, 31] with a sliding window. A count-min sketch operates similarly to a counting bloom filter [32, 54] with $\mathcal{H}$ hash functions. It also has $\mathcal{H}$ arrays of counters. Each hash function maps an object to one counter in a row. When an object arrives, the sketch increments all mapped counters. Upon query, the minimum counter value is used as the estimated count. Therefore, a count-min sketch forgoes the need to store an object's name.

In addition, rather than using a count-min sketch for each epoch, Merlin uses a single sketch to reduce space and performance overhead. To approximate access counts in past epochs, Merlin maintains a global counter and increments it when an object arrives. Once the global counter reaches 16 (the number of epochs Merlin tracks) times the cache size, Merlin clears it and halves all counters in the sketch. W-TinyLFU [27] shows this approach is accurate, supported by both theoretical error bounds and evaluation results.

Common optimizations. Merlin applies several common performance and space optimizations in prior work. First, following CacheLib's implementation, Merlin uses a hash table to index all cached objects, minimizing the lookup time.

Second, following [71], Merlin implements the ghost queue with a hash table. For each ghost object, Merlin stores its fingerprint, hotness counter, and a sequence number in the hash table, for a total of 8 bytes. Merlin uses the sequence number to identify if an object is still in the ghost queue, facilitating lazy object deletion. Merlin increments a global sequence number upon each insertion to the ghost queue. Thus, any object with a sequence number less than the global sequence number minus the ghost queue's size has already been evicted from the ghost queue. Thanks to the sequence number, Merlin lazily removes an evicted ghost object from the hash table only upon its access.

Accounting for object sizes. For clarity, the discussion thus far assumes that all objects have a unit size of one. The actual implementation of Merlin handles variable-sized objects. For example, it counts epochs by the total size of unique objects accessed, not their count. It sets the hotness and popularity thresholds for the counts of the hottest and most popular objects whose total size matches the cache size.

Other optimization/implementation. Merlin's current implementation uses a linked list to implement FIFO queues, while one can also implement them with ring buffers. Merlin performs an optimization to avoid deleting the object from the ghost queue upon its promotion to the staging queue (L20 in Figure 9). Therefore, Merlin does not need to record each object's position in the ghost queue. This is possible since a stale object in the ghost queue does not affect the correctness of Merlin; Merlin only checks whether the object is in the ghost queue upon a cache miss (L6) in which case the object must not be in the staging queue.

Tradeoff between cache hit rates and overhead. The count-min sketch and a hash table for the ghost queue may

reduce the hit rates of Merlin. For the former, multiple objects may map to the same counter, and the reset operation is an estimation. For the latter, Merlin may falsely believe that an object is in the ghost queue due to fingerprint collisions. However, our evaluation shows that the impact is negligible.

6.1 Overhead Analysis

This section presents a qualitative analysis of Merlin's overheads with quantitative analysis in §7.3.

Space overhead. The space overhead of Merlin mainly comes from 1) per-object metadata, 2) the ghost queue, and 3) the popularity recorder. Each metadata is 5 bits, consisting of a hotness counter (3 bits), a 1-bit flag recording if the object is from the ghost queue (L14 in §5.3), and a 1-bit access flag (L4). The ghost queue stores the same number of objects as the main cache, and each object consumes an additional 8 bytes. The count-min sketch uses, on average, one byte for each object with a false positive error rate of 1% [21, 22, 31, 32, 54]. Consider a typical object size of 4KB; the space overhead of Merlin is 0.31% of the cache size.

Management overhead. The ultimate goal of a cache is to deliver low latency and high throughput. However, a high hit rate does not guarantee either, since an algorithm may incur high management overhead, *e.g.*, in metadata maintenance.

The management overhead in Merlin is low. Upon a cache access, Merlin searches the object in the hash table. A cache hit only requires updating the hotness counter (L3-4 in §5.3), the access flag, and the hotness map, incurring minimal overhead. On a cache miss, most of the processing time comes from evicting items from the filter or staging queues, involving reinsertion to the core queue. However, as discussed in §5.3, such reinsertion is rare. The rest of the operations (*e.g.*, updates hotness distribution) incur minimal overhead.

Multicore scalability. Multicore scalability is increasingly important for modern caches, which rely on many CPUs to handle the large volumes of requests they receive [6, 8, 71, 72].

Indeed, the design of Merlin is scalable. Following `S3-FIFO` [71] and `SIEVE` [72], Merlin builds on FIFO queues, which are scalable; unlike `LRU` lists, FIFO queues avoid locking the entire queue on every access. The rest of Merlin's design also avoids coarse-grained locks; Merlin uses atomic operations for metadata updates, while the indexing hash table and the count-min sketch deliver good scalability.

Complexity. The complexity of Merlin is modest. While Merlin is more complex than algorithms like `LRU`, `LFU`, and `SIEVE` [72] for it uses multiple components, we argue that Merlin is simpler than machine-learning-based algorithms such as LRB [51] and HALP [52]. In addition, the complexity does not translate to high space or management overhead, as discussed earlier. We found that Merlin's behavior is easy to reason about (§7.6) thanks to its intuitive pattern characterization and clean task division among components.

Self-tuning. Tuning parameters is notoriously difficult for eviction algorithms [6, 45, 48, 55, 71]; Merlin adjusts the hotness and popularity thresholds with complete automation.

Table 2: The datasets evaluated in this work.

6.2 Discussion

Dynamically adjusting component sizes further improves Merlin's adaptiveness. The filter queue size decides how long a new object stays in the cache: a larger queue increases the chance of retaining objects with good locality, thereby improving performance, but it wastes space if the objects' locality is poor. The staging queue reflects a similar tradeoff for previously accessed objects that remain classified as cold-rare in the ghost queue, since they are promoted to the staging queue on access (§5.3).

However, how to adapt size remains an open challenge, as shown by the poor performance of existing size-adaptive algorithms (§3.3). Our view on the poor performance is that they lack a theoretical model to guide the adaptation. As future work, we plan to follow prior performance analysis work (§8) to develop a theoretical model for size adaptation.

Extremely small or large caches may degrade performance for Merlin. For extremely small caches, Merlin cannot rely on short-term access behavior as objects are evicted quickly. With extremely large caches, as a single epoch may span multiple phases with different access patterns, hotness may not accurately reflect the current phase's access pattern.

Despite the above, with the configuration in §7.2, Merlin ranks first in 5 datasets under an extremely large cache (20% of WSS), and ranks first or second in 7 datasets under an extremely small cache (0.3% of WSS). Figures are not shown.

Dynamic memory budgets. Merlin assumes a fixed cache size, but in multi-tenant or elastic environments, cache capacity may change dynamically. Such changes can invalidate the hotness and popularity thresholds, since they depend on cache capacity. It requires Merlin to re-adjust these thresholds, which we left as future work.

7 Evaluation

Our evaluation answers the following questions:

- Does Merlin adapt to various real-world workloads across different cache sizes (§7.2)?
- Does Merlin achieve high throughput and scale with thread counts (§7.3)?

- Is Merlin friendly to flash-based cache systems (§7.4)?
- How sensitive is Merlin to different parameters (§7.5)?
- Why is Merlin robust and effective (§7.6)?

7.1 Evaluation Setup

Environment. Our evaluation platform is a 2-socket machine equipped with a 192-core AMD EPYC 9965 Processor. The system runs Debian 12 and Linux kernel 6.13.8. We disable hyperthreading, turbo boost to obtain stable results.

Workload. We used 11 open-source datasets with 5423 traces to evaluate Merlin, as shown in Table 2. These traces are diverse in both application domains, including key-value, object CDN, and block caches, and time periods, spanning from 2008 to 2023. In total, these datasets contain 338 billion requests, 33 billion objects, and 11 PB of traffic for a total of 1837.2 TB of data. The object size varies from 1 B to 4 GB across workloads. Following prior work [71], we split Tencent CBS [73] and Alibaba [1] into per-tenant traces.

To demonstrate the effectiveness of Merlin on different cache types, we evaluate both scenarios: fixed-size objects and variable-size objects. In total, we ran 38.5 trillion requests, using a million CPU hours.

Baseline. Merlin is compared with 16 eviction algorithms, including 1) classical algorithms: `LRU`, `LFU`, `FIFO` and `2Q` [36], 2) recent static algorithms: `S3-FIFO` [71], `LIRS` [35], `LHD` [8], `W-TinyLFU` [27], GDSF [18], Hyperbolic [13], SIEVE [72], 3) existing adaptive algorithms: `ARC` [45], `CAR` [6], `Cacheus` [48], `LeCaR` [55]. and 4) a machine-learning-based algorithm: GL-Cache [68]. We follow the default configurations of these algorithms. Given the large number of baseline algorithms, presented figures show only the best performers for clarity.

Configuration. We evaluate for three aspects: hit rate, throughput (for management overhead and multicore scalability), and flash-friendliness (for applicability in flash caches). For hit rates, given the thousands of traces, we follow the conventional approach [8, 48, 68, 71, 72] to evaluate with a cache simulator: `libCacheSim` [2]. We evaluate throughput with Cachelib (§6). For flash-friendliness, we evaluate Merlin on an extension of `libCacheSim`.

7.2 Hit rate

Hit rate improvement. Figure 11 shows the hit rate of evaluated algorithms. Following [6, 27, 35, 45, 48], we report the improvement over `LRU` (*i.e.*, $\frac{HR_{algo}-HR_{lru}}{HR_{lru}}$), since hit rate ranges widely given many traces and baselines. Merlin significantly outperforms others. On average, Merlin improves the hit rate over LRU by 10.4% when cache size is 10% of the working set size (WWS). In contrast, `S3-FIFO`, `Cacheus`, and `ARC` achieve 7.1%, 6.8%, and 6.1%, respectively. In terms of robustness, Merlin ranks first in 6 out of 11 datasets. As a comparison, `S3-FIFO` is the best runner-up, ranking first in 3 datasets. Merlin ranks second in another 3 datasets, closely matching the best performance with only 0.5% difference.

Furthermore, as shown in the figure, the performance of Merlin remains robust across different cache sizes; Merlin is always the best in 6 out of 11 datasets and ranks second in another 3 datasets for all cache sizes. The performance of `ARC` and `Cacheus` varies significantly with cache size. (See Cloudphysics, Systor, FIU, and TencentPhoto datasets.)

Comparison to dominant algorithms. To further evaluate robustness, we compare Merlin to a dominant algorithm, defined as the best-performing algorithm for each trace under a given cache size.

Figure 13 shows the results of datasets with more than 100 traces, illustrating the robustness of Merlin. For example, in Tencent CBS dataset with a 10% WSS cache size, Merlin's value at the 1% CDF point (P1) is roughly 88%. This means that, for 99% of traces, Merlin achieves at least 88% of the dominant algorithm's hit rate (note that the dominant algorithm may vary across traces). In contrast, `S3-FIFO`, `Cacheus`, and `ARC` achieve only about 83%, 76%, and 76%, respectively. Among the 4,611 Tencent CBS traces, `Cacheus` and `ARC` have about 138 traces (P3) whose performance falls below 87% of the dominant algorithm, while Merlin achieves 92.5%.

Adversarial workloads for Merlin. To understand the limitations of Merlin, we analyze the traces where Merlin underperforms the best-performing algorithm by more than 5%. These adversarial traces account for 2.9% of all traces. Among them, we identify two representative classes.

The first class is unpredictable workloads, where the past access history does not reflect future reuse behavior. This breaks an inherent assumption of adaptive algorithms, making Merlin, other adaptive algorithms, as well as most static algorithms, underperform.

In particular, we observe three main patterns in this class of objects. First, the trace repeatedly accesses a small set of objects for a long period, but accesses these objects only rarely afterward. Second, the trace accesses a set of objects for a certain amount of time, and then accesses a mostly different set of objects. Third, the trace repeatedly alternates between two phases: (a) a scan phase that touches many objects once, and (b) a phase that repeatedly accesses a small set of hot objects, with the hot set changing in every iteration. In the above cases, Merlin may cache the wrong objects for a certain period of time (due to their hotness or popularity in the past), leading to a lower hit rate.

Another class is workloads that cause high false positives in the count-min sketch (§6), therefore making Merlin misclassify unpopular objects as popular. These workloads account for 1.1% of the total traces.

The small amount of adversarial workloads may potentially include correlated workloads, where objects that are semantically related are accessed together. For example, when a user visits a profile page, it may access a set of objects semantically related to that page, *e.g.*, the user's profile picture, recent posts, and friend list.

Merlin (and many prior algorithms) do not consider the semantics of objects, and thus cannot handle such workloads

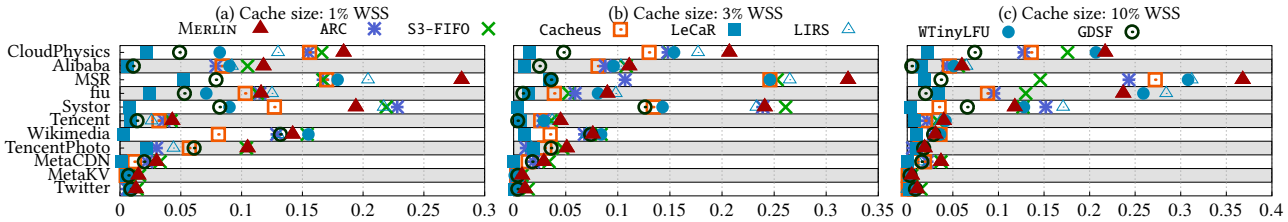

Figure 11: Hit rate of evaluated algorithms. The x-axis shows hit rate improvement over LRU. Only the best-performing baselines are shown.

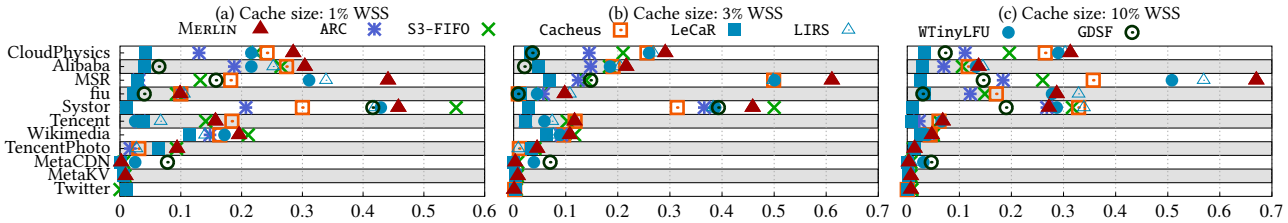

Figure 12: Byte hit rate of evaluated algorithms The x-axis shows improvement over LRU. Only the best-performing baselines are shown.

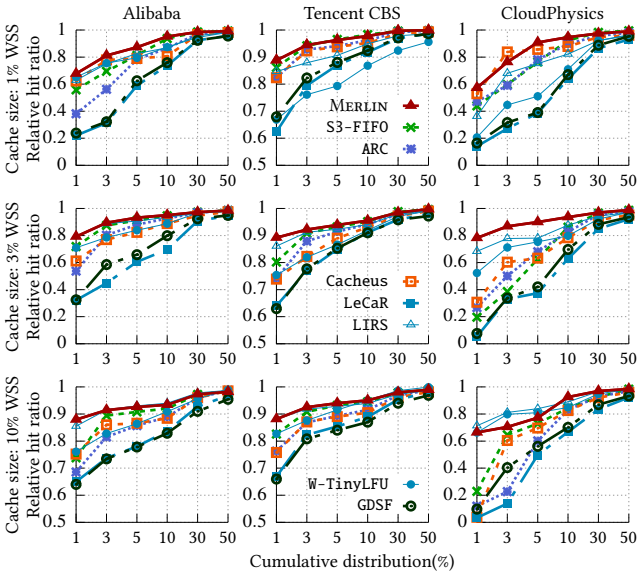

Figure 13: Relative hit rate compared to the dominant algorithm. The y-axis reports the relative hit rate, and the x-axis presents the ascending-sorted cumulative distribution of traces.

well. We did not report the portion of these correlated workloads, as it is difficult to manually identify them without a semantic-aware caching algorithm.

Byte hit rate improvement. The hit rate measures the fraction of requests served from the cache, while another metric is the byte hit rate, *i.e.*, the fraction of requested bytes served from the cache (or $\frac{\sum(ObjSize_{hit})}{\sum(ObjSize_{acc})}$) This metric considers object sizes, and is important for CDN, which cares about bandwidth savings. Figure 12 shows the results, where MERLIN exhibits trends similar to Figure 11.

7.3 Throughput

To evaluate the throughput and management overhead in complex scenarios, we identify typical diverse and shifting access patterns and generate a representative mixed trace, following prior work [8, 71]. We analyze thousands of traces across all datasets and find that most exhibit four primitive access patterns at scale (millions of requests).

We use four distributions to represent four primitive access patterns and randomly shuffle them. They are 1) a Zipfian distribution, 2) a uniform distribution, 3) repeated sequential accesses, and 4) scan accesses. Then we randomly shuffle them to approach the mixed access patterns in real traces, generating a 200M-request trace with 2M objects. We simulate a 10 μs backend latency when there are cache misses.

Multicore scalability. Figure 14 (a) shows the throughput of evaluated algorithms under thread counts from 1 to 32. MERLIN outperforms others significantly, achieving 1.4× to 7.8× higher throughput than others at 32 threads. The reasons are twofold. First, MERLIN achieves a high hit rate, reducing backend accesses. For this reason, MERLIN outperforms S3-FIFO by around 1.4× across different thread counts. Second, MERLIN demonstrates strong scalability due to its multi-FIFO queue design (§6.1), while LRU and ARC suffer from lock contention on the LRU list.

Management overhead. Figure 14 (b) removes backend latency to evaluate management overhead (§6.1). MERLIN incurs low overhead, thanks to the optimizations in §6, and delivers 16% higher throughput than S3-FIFO. Both MERLIN and S3-FIFO achieve 2-3× higher throughput compared to them with backend latency, showing that cache operations are not the bottleneck in real systems. In contrast, LRU and ARC continue to suffer from lock contention.

7.4 Flash-friendliness

Modern datacenters use both DRAM and flash devices for caching [28, 44, 50]. In this setup, a key metric is how much data is written to flash, since excessive writes reduce device lifetime. This subsection evaluates this scenario.

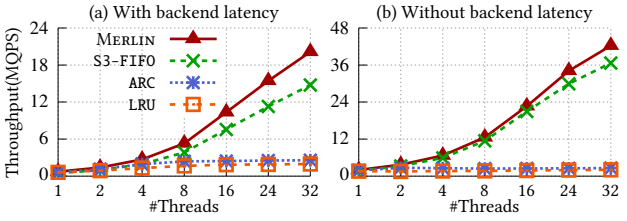

Figure 14: Throughput of the evaluated algorithms.

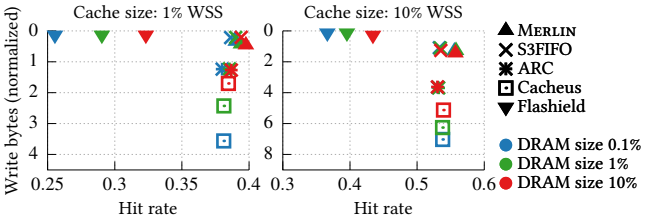

Figure 15: Write bytes (normalized to trace size) and hit rate in Cloudphysics. The upper-right corner is the best.

Setup. MERLIN naturally fits this setup due to its modular design (§5.2): its small filter queue and metadata sit in DRAM, while the staging and core queues reside in flash. We also evaluate several representative baselines. For `Flashield` [28] and `S3-FIFO` [71], we use their original designs. For `ARC`, we set its one-hit list into DRAM and frequency list in flash. For `Cacheus`, we split the SR-LRU list, keeping the SR portion in DRAM and the R portion in flash.

Adaptiveness in flash-friendliness. Figure 15 shows the flash-friendliness of evaluated algorithms, where we vary 1) the cache size from 1% to 10% of the WSS and 2) the DRAM size from 0.1% to 10% of the cache size. MERLIN achieves the highest hit rate with low write bytes. Compared to adaptive algorithms, `ARC` and `Cacheus`, MERLIN reduces write bytes by 70% and improves absolute hit rate by 1–2%. Compared with `S3-FIFO`, MERLIN produces nearly the same write volume but has 1% absolute hit rate improvement. `Flashield` reduces write bytes but at the cost of a substantial drop in hit rate.

MERLIN performs well in DRAM–Flash hierarchical caching due to both its task-division design (§5.2) and its accurate access-pattern characterization (§4). Compared to `Cacheus` and `ARC`, MERLIN's component separation avoids unnecessary flash writes. Compared to `S3-FIFO`, more accurate access-pattern identification further improves the hit rate.

7.5 Sensitivity Analysis

This subsection evaluates the sensitivity of MERLIN's tunable parameters, including 1) the sizes of the filter, staging, and ghost queue; 2) the length of epoch to decide popularity (§5.2); and 3) the size of the count-min sketch (§6).

Queue sizes. Figure 16 shows, across all datasets, how different queue sizes affect MERLIN's hit rates. We find that for the evaluated ranges of the filter (5% - 15%), staging (1% - 10%) queues, and ghost (50% - 200% of the cached objects) queues, the hit rate of MERLIN is stable; only a few traces

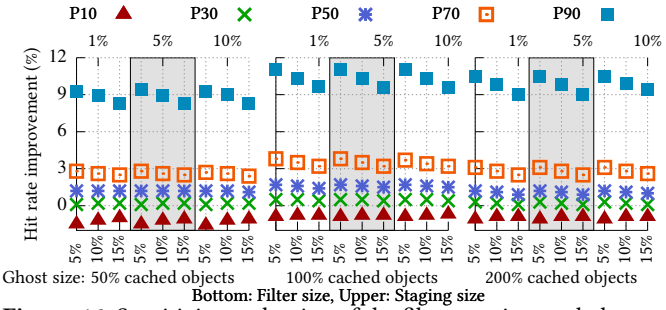

Figure 16: Sensitivity evaluation of the filter, staging, and ghost queue sizes (%). The filter queue ranges 5%, 10%, and 15%; the staging queue is set to 1%, 5%, and 10%; and the ghost queue varies across 50%, 100%, and 200% of the cache size. Cache size is 10% of WSS

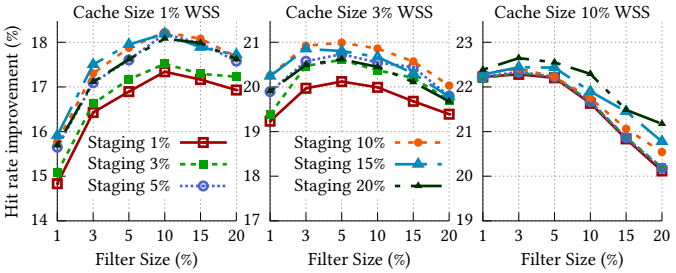

Figure 17: Sensitivity evaluation of the filter and staging queue sizes (%) in Cloudphysics dataset. The queue sizes range from 1% to 20% of the cache size. Cache size ranges from 1% to 10% of WSS.

show more than 1% hit-rate variation. Among these configurations, the 10% filter, 5% staging, and 100% ghost queues achieve the best overall performance.

Sensitivity across different datasets. To further understand the impact of queue sizes, we evaluate 1) a wider range of queue sizes; and 2) the hit rates across different datasets.

Figure 17 shows the results of CloundPhysics, which represents the behavior of most datasets. MERLIN's hit rate is stable in a wide range of filter and staging queue sizes (5%-15%) with all cache sizes. MERLIN only underperforms in two extreme cases: 1) a small filter queue (<5%) under a small cache size (1% of WSS); and 2) a large filter or staging queue (>15%) under a large cache size (10% of WSS).

A few datasets show a slightly different behavior. Specifically, for Meta CDN and Tencent Photo with a 10% WSS cache size, a large filter queue increases the hit-rate improvement over LRU by up to 3%. For Wikimedia with a 1% WSS cache size, a small filter queue, and a large staging queue achieves up to 5% improvement.

The length of recorded epochs and the size of the count-min sketch. We evaluate the sensitivity of MERLIN to the recorded epoch length (Figure 18) and the count-min sketch size (Figure 19) across all datasets. In summary, MERLIN achieves robust performance across a wide range of configurations. For the recorded epoch length ranging from 4 to 128, the hit rate of MERLIN is stable in most traces. For a wide range of count-min sketch sizes, corresponding to false positive rates from 0.1% to 5%, MERLIN achieves a robust

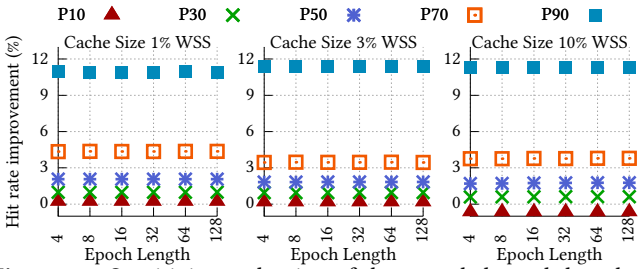

Figure 18: Sensitivity evaluation of the recorded epoch length, which ranges from 4 to 128.

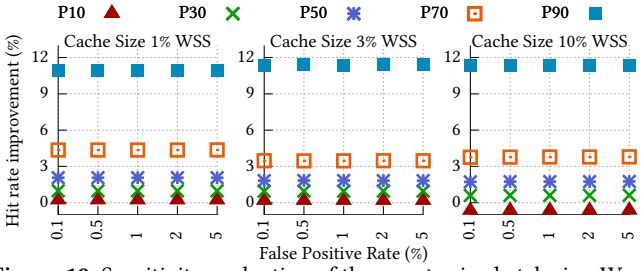

Figure 19: Sensitivity evaluation of the count-min sketch size. We vary the false positive rate (FP) from 0.1% to 5%.

performance, with a few traces benefiting from larger sizes.

In a subset of workloads (8% of the total traces), the recorded epoch length and the count-min sketch cause more than 1% variation in hit rate improvement over LRU (figures not shown). This includes around 25% of CloudPhysics traces, 17% of Alibaba traces, 5% of Tencent CBS traces.

Epoch length. With Merlin, the epoch length is set to the cache size. We note that this is not a tunable parameter, as Merlin uses the properties of FIFO queues to track objects within an epoch (for hotness), as discussed in §5.2.

Therefore, to understand the sensitivity of epoch length, we use the ghost queue size to approximate it. Specifically, a small ghost queue approximates a shorter epoch, as Merlin observes hotness for a smaller amount of time. Vice versa, a large ghost queue approximates a longer epoch. As shown in Figure 16, varying ghost queue sizes has little impact, suggesting that Merlin is robust to different epoch lengths.

7.6 Why is Merlin effective?

To evaluate why Merlin is effective, we measure the precision and average hit count of objects promoted from ghost queues across different adaptive algorithms. The precision is the fraction of promoted objects that are later accessed again, indicating the decision accuracy. The average hit count captures how valuable these promoted objects actually are.

Figure 20 reports precision and average hit counts across Twitter and FIU traces. Merlin performs well on both metrics, demonstrating its accurate identification of hot and/or popular objects. In comparison, ARC and Cacheus show much lower precision and hit counts, demonstrating that they do not make good caching decisions.

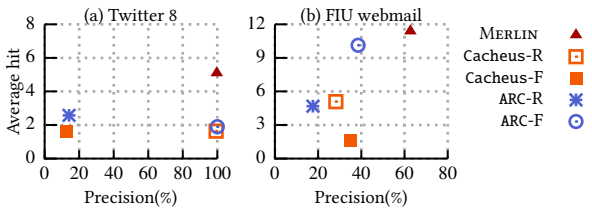

Figure 20: Precision of access pattern identification.

8 Other Related Work

The most important related work (*e.g.*, Cacheus and ARC) has been discussed throughout the paper.

Machine learning based algorithms. LRB [51] and HALP [52] model access sequences and feed object features (*e.g.*, timestamps, gaps, and frequencies) into machine learning predictors to select eviction candidates. These approaches incur high management overhead due to their online training and inference costs.

Performance analysis. HOTL [65], Counter stack [62], and Footprint sampling [63, 64] provide theoretical analysis and approximation methods to predict the hit rate. SHARDS [57], Miniature [56], and Kosmo [49] build small-scale models to estimate cache performance for different configurations. Such work complements Merlin.

Cliff removal. Ideal eviction policies yield convex hit-rate growth as cache size increases, but real-world policies often show non-convex "cliffs." Talus [9] and Cliffhanger [19] mitigate this by segmenting the cache without modifying the underlying algorithm. This work is orthogonal to Merlin.

9 Conclusion

This paper presents Merlin, an adaptive cache eviction algorithm that achieves high hit rates across diverse real-world workloads. Merlin's effectiveness stems from two key designs. First, Merlin proposes a principled fine-grained access characterization method that also accounts for locality and cache size. Specifically, Merlin classifies objects into four types based on hotness and popularity, where the cache size determines the thresholds, and the distribution of types reflects the access patterns. Such a classification allows Merlin to accurately capture a wide spectrum of access patterns beyond a few typical ones. Second, Merlin employs a unified and cohesive architecture that cleanly separates component responsibilities, thereby eliminating the interference seen in prior designs. Evaluations on 11 datasets and 5,423 traces show that Merlin achieves high efficiency, scalability, and low management overhead.

10 Acknowledgment

We thank our shepherd and the anonymous reviewers for their insightful comments. The work is supported by the National Key R&D Program of China under Grant No. 2023YFB4502303, and by the National Science Foundation of China (Nos. 62372011, 92582118, 62032001). Abstract

Caching is widely used across the system stack to improve performance and efficiency, with eviction algorithms at its core. Existing cache eviction policies fall into two broad categories: static heuristics (e.g., 2Q, S3-FIFO) and smart algorithms (e.g., ARC, LRB). Smart caches can adapt to workloads and have the potential to achieve higher efficiency and robustness than static heuristics. However, we find that existing smart caches suffer from objective mismatches and instability.

We introduce Learning-Augmented Heuristics (LAH), a framework that learns the cache-level parameters of static heuristics. By decoupling the data and control planes, LAH supports simple, high-speed data reads and writes on the data plane, while performing occasional asynchronous learning on the control plane using cache-level features.

We demonstrate the effectiveness of LAH through S4-FIFO, a Smart S3-FIFO cache eviction algorithm. We pre-train a single model on 4,140 production traces and embed it in S4-FIFO to learn optimal cache parameters. On 1,035 evaluation traces, S4-FIFO improves the mean efficiency by 26% compared to S3-FIFO and by 8% compared to 3L-Cache, the best state-of-the-art algorithm. S4-FIFO is also robust—increasing miss ratio over FIFO by 0.8% on the worst trace, whereas 3L-Cache increases FIFO's miss ratio by 8.8%. Finally, S4-FIFO's decisions are also interpretable: a language model can provide a rationale for why a particular configuration was chosen.

1 Introduction

Caching underpins performance across modern systems—from storage stacks [11, 64, 67, 75] and databases [35, 57] to large web services [7,9,12,14,25,27,47,50,54,61,69,72]—by absorbing repeated access and reducing backend load. At the heart of every cache is an eviction algorithm that decides which objects to retain under tight memory budgets. Today's production systems overwhelmingly rely on static heuristics such as LRU, 2Q [35], S3-FIFO [74], and SIEVE [77] because they are simple, fast, and easy to deploy. In parallel, a growing body of work has proposed "smart" caches—adaptive and learned policies such as ARC [46], LeCaR [63], LRB [58], LHD [10], GL-Cache [70], and 3L-Cache [83]—that aim to tailor eviction decisions to each workload.

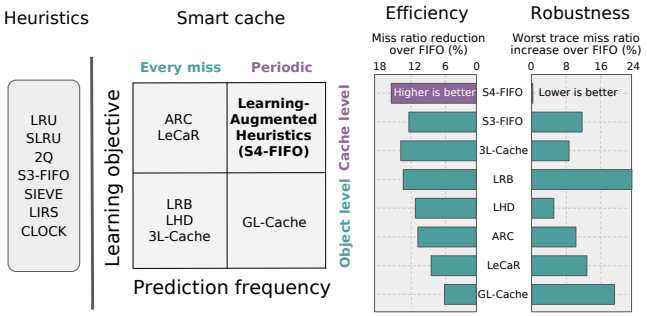

Figure 1: A classification of eviction algorithms (Section 2.2) indicates that periodic cache-level learning is highly effective, yet it has not been explored. We bridge this gap with learning-augmented heuristics, exemplified by a new algorithm, S4-FIFO, which achieves both high efficiency and strong robustness.

In principle, smart caches should dominate hand-crafted heuristics. In practice, very few of them (if any) have been adopted. Many of the smart caches learn at the granularity of individual objects and make predictions on *every miss*, optimizing surrogate objectives such as reuse-distance regression loss or per-object utility scores rather than the cache's true objective, the miss ratio. These object-level, per-miss learning schemes suffer from four recurring problems: (1) **objective mismatch**, where improvements in prediction metrics do not translate into fewer misses; (2) **instability and noise sensitivity**, as these schemes react to highly variable request-level signals; (3) **overheads**, due to per-object metadata, frequent inference on the critical path, and additional runtime complexity; and (4) **limited robustness and interpretability**, as eviction decisions are opaque, difficult to interpret, and may yield miss ratios higher than FIFO on some workloads.

At the same time, recent work shows that static heuristics can achieve surprisingly strong performance. S3-FIFO [74], for example, uses a small FIFO queue, a main FIFO queue,

and a metadata-only ghost queue with simple promotion rules to filter one-hit wonders and retain popular objects. While it is strong on the mean and median trace, our analysis reveals that its static configuration leaves substantial headroom for the tail traces.

We classify smart eviction algorithms along two axes—*learning granularity* (object vs. cache level) and *prediction frequency* (per-miss vs. periodic)—and observe that existing approaches occupy three of the four quadrants (Figure 1). The remaining quadrant, periodic cache-level learning, remains unexplored, despite offering an appealing opportunity: directly learning cache parameters that optimize miss ratio.

This observation motivates a fundamentally different approach to incorporating learning into caching: instead of learning a new, complex eviction policy, we propose learning to configure a simple, expressive heuristic. We introduce **L**earning-**A**ugmented **H**euristics (LAH), a framework that cleanly separates the cache's data and control planes. The data plane implements a deterministic heuristic with a small number of explicit knobs. The control plane runs asynchronously and infrequently, using cache-level features to select a configuration that directly targets miss-ratio reduction. A single model, pre-trained offline on a large corpus of traces, acts as a reusable "foundation model" for caches: it performs zero-shot prediction without per-deployment retraining.

We realize LAH in S4-FIFO, a "Smart S3-FIFO" eviction algorithm that augments S3-FIFO with an additional FIFO region and exposes its internal control knobs for learning. S4-FIFO discretizes the configuration space into a small set of representative parameter combinations and trains a gradient-boosted decision tree [18, 28] to choose among them using a cost-sensitive objective that explicitly anchors robustness to FIFO. Trained once on 4,140 production traces spanning block, key–value, and CDN caches, this model is embedded into the algorithm as lightweight, dependency-free code. When evaluated on 1,035 held-out production traces, S4-FIFO improves mean miss-ratio reduction by 26% over S3-FIFO and by 8% over 3L-Cache, the best prior algorithm, while never exceeding FIFO's miss ratio by more than 0.8% on the worst trace. For comparison, the next-best algorithm, 3L-Cache, increases FIFO's miss ratio by 8.8% in the worst case. Because of the separation of the control and data planes, S4-FIFO achieves throughput on par with other heuristics, such as LRU and 2Q. Because both its inputs and outputs are cache-level quantities with clear semantics, S4-FIFO's decisions are also relatively interpretable: a language model can reason about the factors behind a particular configuration choice.

This paper makes the following contributions:

- We introduce a cache classification and demonstrate that *periodic cache-level* learning is the most effective approach.
- We propose learning-augmented heuristics (LAH), a framework that augments static heuristics with parameters and uses a foundation model to learn them.
- We design and implement S4-FIFO, an example of LAH. We pre-train a gradient boosting tree model for S4-FIFO on 4,140 production traces and provide a dependency-free library for users [1].
- We evaluate S4-FIFO on 1,035 production traces and show that it is both more efficient and more robust than state-of-the-art algorithms, while matching the throughput of heuristics. Moreover, S4-FIFO's decisions are interpretable.

2 Background and Motivations

2.1 Evolution of Cache Eviction Algorithms

A central component of cache performance is the eviction algorithm, deciding which object(s) to remove when space runs out. Over the years, researchers and practitioners have designed a wide spectrum of eviction strategies, from simple heuristics to learning-based policies.

2.1.1 Heuristics-Based Algorithms

Most (if not all) production systems use heuristics-based eviction algorithms today. Traditional heuristics, such as 2Q [35] and LIRS [33], and modern heuristics, such as S3-FIFO [74] and SIEVE [77], operate based on *manually* curated rules that exploit recency and frequency patterns in a workload. These heuristics are valued for their simplicity, high throughput, and ease of implementation. However, they often fall short in efficiency compared to adaptive algorithms.

2.1.2 Smart Cache Eviction Algorithms

Adaptive algorithms. For example, ARC [46] maintains four LRU queues: two for data and two for ghost. It dynamically resizes recency and frequency data queues based on observed hits on the corresponding ghost queues. Similarly, DLIRS [41] extends LIRS by introducing an adaptive partition between low-reuse (HIR) and high-reuse (LIR) regions, which is dynamically resized based on its reuse distance. Although adaptive cache eviction algorithms do not employ machine learning models, we classify them as smart cache eviction algorithms because they can adapt to workloads by observing dynamic features.

Learning-based algorithms. More recent work builds prediction models to guide eviction decisions. Algorithms such as LRB [58], 3L-Cache [83], and GL-Cache [70] use supervised learning at the object level to estimate reuse distance and then evict the object predicted to have the least future value. Other approaches like LHD [10] model eviction using conditional hit-density, while LeCaR [63] adaptively reweights LFU and LRU weights with regret minimization. Although these complex policies may outperform heuristics, deploying them adds practical challenges, mainly: (1) online model training and inference add overheads, reducing cache throughput, and (2) their decision-making logic is opaque, from their features to their outputs. As a result, it is hard to interpret, tune, or debug why they behaved the way they did.

[1] https://libcachesim.com

Table 1: Classifying smart caches based on learning granularity and prediction frequency.

Learning granularity	Prediction frequency	Example	Problems
Object-level	Every miss	LRB [58], LHD [10], 3L-Cache [83]	Objective mismatch, unpredictability, overheads
	Periodic	GL-Cache [70]	Stale prediction
Cache-level	Every miss	ARC [46], LeCaR [63]	Instability, delayed reward
	Periodic	S4-FIFO (this work)	None of the above

Figure 2: Object-level learning has an objective mismatch issue. A smaller loss on object-level metrics, e.g., reuse distance, does not guarantee fewer cache misses.

2.2 Classifying Smart Eviction Algorithms

We classify existing smart cache eviction algorithms along two dimensions: the *granularity of learning* and the *frequency of prediction or adaptation* (Table 1).

Learning granularity. A smart cache eviction algorithm adapts to workloads by making predictions about the workload. These predictions can be either at the object level or the cache level. *Object-level algorithms*, such as 3L-Cache [83], LRB [58], and LHD [10] assign utility score or eviction probability to every individual object in the cache. For example, LRB and 3L-Cache learn the reuse distance for objects in the cache to predict the next access. Note that we also classify GL-Cache [70] as an object-level algorithm because it makes predictions for object groups similar to objects.

In contrast, *cache-level algorithms* learn by optimizing the internal cache parameters rather than evaluating individual objects. A classic example is ARC [46], which dynamically tunes the target sizes of its recency and frequency queues based on workload patterns, without assigning scores to cached objects. Similarly, LeCaR [63] dynamically adjusts the expert weights based on hits on the ghost queues.

Prediction frequency. Besides granularity, the frequency at which an algorithm predicts or adapts is also critical. Most prior algorithms (e.g., LRB, ARC, LeCaR) make a prediction *every miss*. For example, LRB samples 64 objects and predicts their reuse distance at each eviction; ARC updates the queue sizes upon each hit on the ghost queue (cache miss).

GL-Cache is the only algorithm that makes predictions *periodically* by ranking all object groups and evicting the top 10%. It does not trigger another prediction before all the top 10% object groups are evicted.

2.3 Learning Granularity: Object vs Cache

2.3.1 Object-level Learning

Several recent approaches operate at the granularity of individual objects, typically by predicting reuse distance or popularity. While this formulation appears natural, object-level learning faces inherent challenges regarding *objective alignment*, *predictability*, and *robustness and interpretability*.

Objective mismatch. The first challenge with object-level learning is objective mismatch, a phenomenon akin to Goodhart's Law: when a proxy becomes the target, it ceases to be a good measure. Many learned caches optimize for object-level metrics (e.g., minimizing L2 loss on reuse distance) rather than the actual miss ratio objective. For example, Figure 2 shows an example where model A achieves a lower L2 loss than model B, yet it fails to evict the correct object.

Unpredictability. Object-level metrics often cannot be predicted accurately. First, metrics, such as object reuse distance, are not intrinsic to an object and are heavily influenced by the workload, such as burstiness. Furthermore, cache workloads often exhibit a large number of one-hit wonders [74], for which no information (e.g., past N reuse distance, frequency) is available for learning. Some object-level metrics, such as popularity, are intrinsic properties of an object; however, they change quickly over time and cannot be used directly for eviction.

Robustness and interpretability. As object-level learning is driven by the unpredictable metrics described above, it becomes highly sensitive. Variations in workload can produce wrong eviction decisions. This volatility directly translates into poor robustness; models may perform well on average yet fail badly on certain workloads. Moreover, the outputs of object-level learning are fundamentally opaque. The model assigns per-object scores with little to no operational semantics, leaving operators unable to explain when the miss ratio increases. This combination of unpredictable inputs and opaque outputs makes object-level learning risky to deploy at scale.

2.3.2 Cache-level Learning

Cache-level learning avoids the aforementioned problems by tuning a small set of global cache parameters. For example,

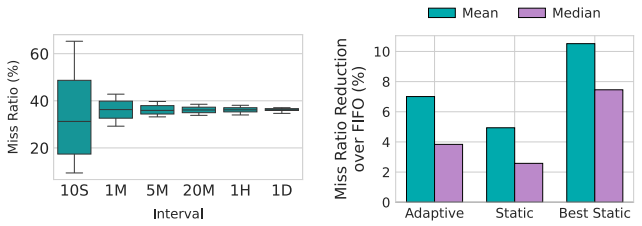

Figure 3: (a) Cache metrics, such as miss ratio, exhibit greater variance at finer time granularity. (b) Choosing the correct parameters can outperform LeCaR's per-miss adaptivity.

ARC [46] maintains two data queues and two ghost queues. Data queues store data, while ghost queues only keep metadata of recently evicted objects. ARC dynamically adjusts the queue size based on ghost hits. Intuitively, the more hits on the ghost queue, the more space is needed for the corresponding data queue. As another example, LeCaR [63] uses two eviction algorithms as experts and randomly chooses one expert to pick an eviction candidate based on its weight. The expert (algorithm) with a larger weight is more likely to be used for eviction. Similar to ARC, LeCaR adjusts experts' weights based on ghost hits using reinforcement learning.

Direct optimization. *Cache-level learning often directly optimizes for the miss ratio*. For example, a ghost hit means that if the data queue is larger, it will be a cache hit, so increasing the data queue size directly reduces misses. Similarly, if an expert has many ghost hits in LeCaR, indicating it is not suitable for the workloads, then reducing its weight would reduce the number of wrong evictions. Direct optimization not only helps reduce the miss ratio but also improves interpretability, enabling operators to reason about specific actions.

Magic parameters. Although cache-level learning is intuitive and avoids the objective-mismatch problem, it often has magic parameters. For example, how much and how often the parameters should be updated. Previous work has shown that the default move *one* slot *per ghost hit* approach in ARC has pathological failure cases [74].

2.4 Prediction Frequency: Per-miss vs Periodic

While the learning objective is critical for the effectiveness of a smart cache, how often a cache makes a prediction or adaptation is equally important.

2.4.1 Per-miss Prediction and Adaptation

Most algorithms make predictions at the request granularity, e.g., every miss. For example, LRB estimates object reuse distance on each cache miss, while ARC and LeCaR update queue sizes or weights on every hit to their ghost queues. Although such per-miss adaptation can appear highly responsive, it suffers from three key limitations: *instability and noise overfitting*, *delayed reward*, and *inference overhead*.

Instability and overfitting to noise. Observations on each request and object might not reflect the overall patterns in the workload. By reacting to every miss, the algorithms will instead "chase" this noise. We find that real-world workloads often exhibit significant variance at fine time granularity, and request-level signals are often very noisy. Figure 3 left shows the miss ratio measured at different time granularities on a CloudPhysics trace. We observe that at smaller time intervals, the miss ratio over time tends to have a very large variance.

We further measured the impact of per-miss adaptivity using 106 traces from the CloudPhysics dataset. Figure 3 right shows that, although per-miss adaptivity improves over using a single static parameter for *all* traces (static), it is significantly worse than choosing the best static parameter for each trace. This suggests that choosing the right parameter is much more important than per-miss adaptivity.

Delayed Reward for Cache-level Learning. Besides overfitting, per-miss learning also suffers from the delayed reward problem. Because a cache miss may happen *long* after an object is evicted, and parameter changes take time to become effective, we find that the change often lags behind the need. This lag makes the feedback signal slow and ambiguous.

Overheads for Object-level Learning. When pairing per-miss prediction with object-level learning, another drawback is the overhead. Performing a model inference on each miss significantly reduces the throughput. Besides, object-level learning also incurs significant per-object metadata storage overhead. For example, LRB adds over 200 bytes of features to each object, which eats into DRAM capacity.

2.4.2 Periodic Prediction

To the best of our knowledge, GL-Cache [70] is the only cache eviction algorithm that uses periodic prediction. Similar to other object-level learned caches, GL-Cache predicts a score for each object group. However, instead of predicting on the critical path, GL-Cache makes one prediction *periodically* and reuses the scores until 10% of the object groups are evicted. However, because the usefulness of objects and groups changes over time, their predictions quickly become stale, and periodic prediction often leads to lower efficiency when used with object-level learning.

Our analysis of existing algorithms reveals a dichotomy in the design space. Object-level algorithms suffer from objective mismatch, unpredictability, and huge overheads. Moreover, per-miss learning algorithms are prone to instability and delayed rewards. Table 1 highlights a distinct gap in the design space—we need smart cache eviction algorithms that *learn and adapt at the cache level, with the learning objective aligned with miss ratio reduction*; meanwhile, we need *periodic learning* to avoid unnecessary overfitting to noise and magic parameters.

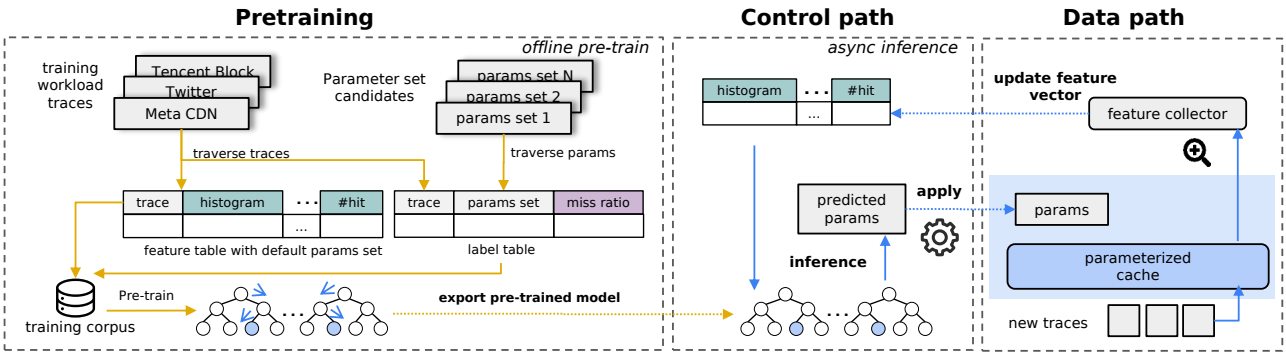

Figure 4: Illustration of learning-augmented heuristics. (1) Offline pretraining (left): A foundation model is trained on a massive corpus of trace features and optimal parameter labels to learn universal caching rules. (2) Online operation (right): The system decouples the critical *data path* from the *control path*. The data path collects lightweight workload-level features, while the control path asynchronously queries the pre-trained model to adapt the cache parameters to the current workload trace.

3 Learning-Augmented Heuristics (LAH)

In this section, we introduce a *learning-to-configure* paradigm that fundamentally rethinks how machine learning interacts with caching systems. Instead of embedding complex learning logic (e.g., neural networks) directly into the critical path, we propose a clean separation of concerns: *the cache data path executes a simple, parameterized heuristic, while the control plane utilizes a pre-trained "foundation model" to choose the heuristic's parameters*, an approach we call Learning-Augmented Heuristics (*LAH*).

Existing learning-based caches (e.g., GL-Cache, LeCaR) often treat learning as an online, instance-specific task and train from scratch for each new or even the same workload. This approach suffers from "catastrophic forgetting" and high retraining costs. In contrast, our approach builds upon the well-established insight that cache access patterns are governed by universal characteristics: phenomena like scanning, looping, and thrashing are structural behaviors that transcend specific datasets [21, 33]. By extracting *content-oblivious* features rather than tracking specific object IDs, we can train a single global model that generalizes across diverse workloads. This effectively builds a foundation model for caching: knowledge learned from thousands of offline traces is preserved and transferred to new, unseen environments. The model does not need to relearn but recognizes the pattern and applies the optimal configurations. This decoupled architecture offers five critical advantages over tightly coupled learned caches.

Simplicity. The data path logic remains simple and deterministic. It requires almost no metadata overhead (unlike LRB or 3L-Cache, which track extensive ghost histories per object) and avoids complex data structures. This "stateless" nature drastically reduces code complexity and bug surface area, making the system easier to verify and deploy in production.

Performance. By offloading the inference to an asynchronous control plane, the critical path for GET and PUT operations remains extremely lightweight, ensuring high throughput and low tail latency.

Efficiency. Simple static heuristics, such as 2Q, cannot achieve high efficiency compared to state-of-the-art algorithms. LAH can automatically optimize for different workloads. During the cache warm-up period, LAH identifies the "golden configurations" and updates its parameters to match the workload's patterns.

Robustness. When evaluating state-of-the-art eviction algorithms on thousands of production workloads, we find that most of them exhibit poor robustness—some traces exhibit a miss ratio significantly higher than a simple baseline such as FIFO. This hinders adoption because users do not know whether these algorithms will work on their workloads. LAH learns the configuration from high-level workload features, which are less susceptible to perturbations and noise. Moreover, LAH selects parameters from a validated set of safe configurations. These enable LAH to achieve robustness.

Interpretability. LAH operates on aggregated metrics such as hit distributions, which align naturally with how operators already think about and understand cache behavior. These high-level signals are then mapped to a small set of heuristic parameters, so each prediction corresponds to a knob with a clear operational meaning and existing tuning intuition. Because both the inputs and outputs live in this shared, cache-centric space, the resulting configurations are much more interpretable than existing learned caches.

While LAH can be designed on top of different parameterized algorithms, we use S3-FIFO [74] as an example because it is simple, performant, and scalable. In the next section, we describe S4-FIFO, a new cache eviction algorithm that is Simple, Scalable, Smart, and only uses Static FIFO queues. S4-FIFO exposes and augments S3-FIFO's internal parameters to our foundation model for learning, transforming a static heuristic into an efficient, robust, and interpretable learning-augmented heuristic.

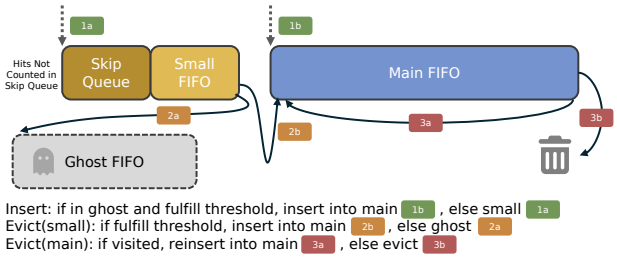

Figure 5: An illustration of the data path in S4-FIFO.

4 S4-FIFO Design and Implementation

In this section, we describe the design of S4-FIFO, detailing the heuristic data path, feature engineering, configuration quantization, and model training.

4.1 Overview

We illustrate the high-level overview as shown in Figure 4.

Heuristic Augmentation. We first augment S3-FIFO with a burst-aware parameter that virtually partitions the small queue into an additional FIFO queue, giving the parameterized heuristic greater flexibility to minimize the miss ratio.

Dataset Preparation. We randomly split the 5,175 traces used in this study into training and test sets to avoid data leakage. Then we perform a grid search to determine the best parameters (labels for training) for each trace. Next, we collect cache and workload-level features by running S4-FIFO using the default parameter on each trace, yielding the samples used to train the model.

Model Pretraining. We use features and labels from the previous step to train a classification model that predicts the best parameters for an unseen workload.

4.2 Augmenting the Parameters

Parameter prediction and request serving. The previous steps only need to be performed once offline. Once the model is trained, it will be used in different settings without retraining. When a cache starts, S4-FIFO collects features online and then asynchronously makes a single prediction. Then S4-FIFO switches from the default parameters to the predicted parameters. Queue resizing is lazy: when the predicted configuration reduces a queue's target size, S4-FIFO does not immediately move or evict objects. Instead, future evictions preferentially come from queues that exceed their new limits until the queue sizes converge. This allows parameter updates without pausing the cache or adding extra work to the request critical path. For simplicity, our evaluation makes a single prediction per trace. We found that substantial shifts requiring a new prediction are uncommon. In practice, S4-FIFO could be made to periodically re-predict its parameters if needed, for example on a weekly basis. We leave the choice of refresh policy and interval outside the scope of this work.

Table 2: Hyperparameters of the S4-FIFO.

Symbol	Physical Meaning	Default	Learning range
ρ_S	Small queue size ratio	0.10	$[0.05, 0.90]$
ρ_G	Ghost queue size ratio	0.90	$[0.90, 6.00]$
κ	Small skip ratio	0.00	$\{0.00, 0.25\}$
τ_S	Small-to-Main promotion threshold	2	$\{1, 2\}$
τ_G	Ghost-to-Main promotion threshold	0	$\{0, 1\}$

S3-FIFO maintains three FIFO queues. A small queue, occupying 10% of the cache, filters out one-hit wonders; a main queue retains popular objects via reinsertion; and a metadata-only ghost queue identifies moderately popular objects that were mistakenly evicted from the small queue. Each cached object is associated with a 2-bit saturated frequency counter that is incremented on every cache hit, and a threshold on this counter governs movement between the queues. S4-FIFO preserves the same three physical FIFO queues, but parameterizes their behavior, as shown in Figure 5. The parameters are shown in Table 2.

Queue size. While S3-FIFO sets the small queue at 10% of the cache, S4-FIFO treats the queue sizes as tunable parameters. This allows the system to select the optimal ratio between the small and protected regions based on workload characteristics. In addition, S4-FIFO also makes the ghost queue size tunable to collect more information about the workload.

Promotion threshold. S3-FIFO moves an object evicted from the small queue to the main queue if the object's frequency is greater than 1. S4-FIFO makes the frequency threshold learnable, allowing control over how strictly the small queue filters new insertions. Similarly, to handle cyclic scan patterns [33, 51], S4-FIFO learns the frequency threshold for promoting an object from the ghost queue to the main queue.

Skip ratio. To mitigate correlated references (bursty "one-hit wonders") [35, 76], S4-FIFO does not increment the frequency counter for objects in the first κ fraction of the small queue. This creates a virtual probationary region inside the small queue, adding an extra filtering stage without introducing a fourth physical FIFO queue.

Parameter discretization. The parameter space of S4-FIFO is continuous and high-dimensional, and its exponentially growing combinations make it impossible to perform a grid search to find the best parameters. Therefore, we discretize the parameter ranges and choose a few values for each based on domain knowledge. Specifically, the small queue size can take up 5%, 10%, 20%, 30%, 50%, 70%, or 90% of cache capacity; the ghost queue can store the same number of objects, $3\times$ or $6\times$ that of the main queue; the small-to-main promotion threshold can be either 1 or 2; the ghost-to-main threshold can be either 0 or 1; and the skip ratio can be either 0 or 0.25.

Table 3: Features used by S4-FIFO.

Features	Dimension	Meaning
Small histogram	20	Hit-position distribution ratio in $\mathcal{S}$
Main histogram	20	Hit-position distribution ratio in $\mathcal{M}$
Ghost histogram	20	Hit-position distribution ratio in $\mathcal{G}$
Small hits ratio	1	Proportion of hits happening in $\mathcal{S}$
Main hits ratio	1	Proportion of hits happening in $\mathcal{M}$
Ghost hits ratio	1	Proportion of hits happening in $\mathcal{G}$
Log cache size	1	log(cache size)
Utility gap	1	Utility divergence between $\mathcal{S}$ and $\mathcal{M}$
Filtering efficiency	1	Relative hit density of $\mathcal{S}$ vs. $\mathcal{M}$
Ghost pressure	1	Intensity of miss-on-eviction events
Tail heaviness	1	Hit concentration at the deep end of $\mathcal{M}$
Decay rate	1	Recency decay slope at the head of $\mathcal{S}$
One-hit ratio	1	Estimated fraction of one-hit wonders
Unique ratio	1	Workload churn rate (unique objects ratio)
Scan intensity	1	Effective scan pressure under capacity limits
Thrashing risk	1	Signal for working set exceeding capacity

4.3 Learning the Parameters

4.3.1 Learning Objective

To enable efficient learning, we formulate the parameter learning as a probabilistic classification task over a finite set of candidate parameter configurations $\mathcal{C}$. We learn a conditional probability distribution $P(y = c_j|\mathbf{x};\phi)$ over these candidates $c_j \in \mathcal{C}$ given the workload features $\mathbf{x}$.

Standard classification objectives (e.g., cross-entropy) treat all misclassifications symmetrically. However, in caching, error costs are highly *asymmetric and pairwise*: mistaking a scan-heavy workload for a recency-friendly one causes catastrophic thrashing, whereas the reverse error often yields only marginal degradation. To capture these varying penalties, we employ a data-driven cost matrix $\mathbf{L} \in \mathbb{R}^{K\times K}$, where K is the number of candidate parameter configurations. Each entry L_{kj} quantifies the pairwise "regret" of selecting configuration c_k when the true optimal is c_j, normalized by the miss ratio of a baseline anchor $\mathcal{M}_{\text{anchor}}$,

$$L_{kj} = \mathbb{E}_{\text{train}}\left[\frac{\text{MR}(c_k) - \text{MR}(c_j)}{\mathcal{M}_{\text{anchor}}}\right].$$

Choice of Anchor. While the anchor can theoretically be any baseline (e.g., LRU, FIFO), we select $\mathcal{M}_{\text{anchor}} = \text{MR}_{\text{FIFO}}$. This choice is motivated by the structural nature of our system: (1) S4-FIFO is fundamentally built upon FIFO queues, therefore FIFO serves as the natural lower bound for robustness, and (2) normalizing by FIFO makes the cost metric invariant to the cacheability of the trace, allowing the model to learn effectively across workloads with vastly different miss ratios.

During inference, we minimize the expected risk,

$$\hat{c} = \arg\min_{c_k\in\mathcal{C}} \sum_j P_\phi(c_j|\mathbf{x}) \cdot L_{kj}.$$

4.3.2 Features

To enable lightweight yet effective learning, we model the cache states and workload characteristics s_t using a compact feature vector (73 dimensions). The list of features used can be found in Table 3, where $\mathcal{S}$, $\mathcal{M}$, and $\mathcal{G}$ are the small queue, the main queue, and the ghost queue, respectively.

Cache metrics and workload characteristics. Cache size is critical for scale-invariant learning: the effectiveness of the small queue depends on its *absolute* capacity to absorb bursts, not just its relative share of the cache. For example, a 10% partition in a 100 GB cache provides ample buffer space, whereas 10% of a 100 MB cache may be insufficient for the same workload. Therefore, we track cache size using the log-transformed capacity. To capture the "shape" of locality beyond simple scalar averages, we maintain lightweight histograms (20 equally-sized bins each) for the small, main, and ghost queues. These histograms capture the distribution of hit position within each queue. For instance, the first bin stores the number of hits in the first 5% of the queue. Intuitively, the histograms enable the cache to learn the queue usage. For example, many ghost hits suggest the small queue might be too small. Besides the histogram, we also include the number of hits per queue and the total number of requests.

Composite features. To avoid complex models, we use feature crossing to capture non-linear relationships between features, following common practice in traditional recommendation systems that rely on simple models [19, 52].

- *Utility gap* measures the utility divergence between the small and main queues and is defined as the absolute hit difference between them divided by total hits, $\frac{H_{\text{main}} - H_{\text{small}}}{H_{totql}}$. A positive gap indicates that the main queue is effectively retaining hotter items than the small queue.
- *Filtering efficiency* quantifies how well the small queue filters one-hit, computed as the ratio of hits in the small queue to those in the main queue, $\frac{H_{\text{small}}}{H_{\text{main}}}$.
- *Ghost pressure* measures the fraction of hits served by the ghost queue, $\frac{H_{\text{ghost}}}{H_{\text{ghost}}+H_{\text{total}}}$. A high ghost pressure suggests that the small queue is undersized or that the promotion threshold is too conservative.
- *Tail heaviness* measures the dependence of the workload on long-term retention and is computed as the sum of hits in the last 10 bins of the main queue's histogram, with larger values indicating that a substantial fraction of hits comes from long-resident objects.
- *Decay rate* measures how quickly items lose utility in the probationary small queue and is computed as the slope between the first two bins of the small queue's histogram, where a steep negative slope indicates that most objects become cold quickly.
- *Unique object ratio* estimates cacheability and is computed as $\frac{\#\text{ insertions to small}}{\#\text{ requests}}$.
- *One-hit ratio* estimates the fraction of one-hit wonders in the workload and is computed as $\rho_{\text{onehit}} = \frac{N_{\text{onehit}}}{N_{\text{unique}}}$, where N_{onehit} is the number of objects evicted from the small queue without reaching the promotion threshold, and N_{unique} is the number of unique objects observed during the window.
- *Scan intensity* and *thrashing risk* are derived by normalizing *unique object ratio* and *one-hit ratio* by the request rate, providing the model with explicit signals to distinguish

between benign scans and destructive thrashing.

4.3.3 Model and learning

Inference Model. We employ a Gradient Boosting Decision Tree ensemble as the predictive model ϕ. It accepts the 73-dimensional feature vector $\mathbf{x}$ and outputs a probability distribution over the 18 classes. We choose GBDT over deep neural networks (DNNs) for two reasons. First, it can be easily packaged into a few portable headers for distribution, allowing users to use the pre-trained model in other programming languages without installing any new libraries. For example, our Cachelib [11] prototype employs the same model we trained using the libCacheSim [1] simulator. Second, GBDT excels at handling heterogeneous, nonlinear features (e.g., histograms mixed with scalar ratios) and needs no complex normalization.

Parameter search space reduction. Although we have discretized each parameter into a few options, the number of possible parameter combinations remains huge, which reduces learning effectiveness. We employ a clustering-based strategy to reduce the search space. We use the offline grid search results to identify the most common parameter combinations and identify 18 representative parameter sets out of 168 candidates via greedy set cover algorithm [55].

4.4 Implementation

We implement S4-FIFO in both libCacheSim for simulation-based evaluation and Meta Cachelib for prototype evaluation and production deployment. Both implementations extend S3-FIFO and employ the same pre-trained model, trained on features and labels collected in the simulator. In each system, a hash table is used for indexing, and linked lists are used to implement the queues.

4.4.1 Model implementation

We use LightGBM for our model implementation in the simulator. Because tree-based models can be compiled into sequences of conditional branches, we export the pre-trained model into simple, *dependency-free* libraries using m2cgen [2], targeting several common programming languages, including C/C++, Go, Rust, Java, and JavaScript. This enables users to use our model directly without relying on LightGBM or other machine learning libraries. For example, our Cachelib implementation uses the C++ header files.

4.4.2 Feature collection

Most of the features are simple counters and straightforward to maintain, so we focus on the histogram features.

Small and Main FIFO queues. We use insertion time (i.e., the insertion index) to calculate the histogram bin for each object as $\lceil \frac{T_{obj}-T_{tail}}{w} \rceil$ where T denotes the insertion time and w is the bin width. For example, suppose the queue has a capacity of 1000, and we divide it into 20 bins, each with a width of 50. If the tail object was inserted at time $T_{tail} = 20$ and the current object at $T_{obj} = 80$, then the object should be incrementing the counter at the $\lceil \frac{80-20}{50} \rceil = 2^{nd}$ bin.

Ghost queue. Computing histogram bin indices in the ghost queue is more involved because a hit in the ghost queue removes the corresponding metadata entry and shifts all subsequent entries forward. As a result, using insertion time alone to determine the bin index yields incorrect positions. To compensate, we maintain an additional *deletion-count* histogram alongside the hit-position histogram for the ghost queue. Concretely, let i be the bin index obtained from the insertion-time-based formula. We sum the deletions recorded in bins 1 through $i-1$, divide this sum by the bin width w to calculate the number of shifted bins s, and then correct the bin index as $i' = i - s$. This adjusted index is used as the hit-position bin in the ghost-queue histogram. Even with the adjustment, the calculated bin is still approximate because we do not consider the deleted objects in bin i. However, the approximation has bounded error and is at most off by 1.

4.4.3 Overhead Analysis

We analyze the runtime complexity of S4-FIFO to demonstrate that it incurs almost no overhead compared to heuristics.

Inference. All cache operations, i.e., read, write (including eviction), are $O(1)$. S4-FIFO adds two components. On the data path, it needs to collect features. However, many of the features it collects, such as the number of requests and hits, are already tracked in most production caches. The primary additional overhead introduced by S4-FIFO is the hit-position distribution histogram. This histogram is maintained as an array of counters, with exactly one counter incremented per access, yielding a strict $O(1)$ time complexity. In Section 5.4, we show that the feature collection has a negligible impact on throughput. In deployments that are very sensitive to computational overhead, the feature collection can use sampled requests. On the control path, S4-FIFO performs inference, which has a time complexity of $O(T \cdot D)$, where T is the number of trees (20 in our model) and D is the maximum depth (9 in our model). Since the inference happens rarely and asynchronously, and each inference call takes less than 2 ms, there is no impact on request serving.

Training. The training cost of S4-FIFO is entirely offline and consists of two stages: label generation and model fitting. Label generation is the dominant cost. For each training trace

and cache-size ratio, we run S4-FIFO over a fixed grid of candidate configurations and select the configuration with the lowest miss ratio as the label. Given N training traces, R cache-size ratios, G candidate configurations, and L requests per trace, label generation costs $O(N \cdot R \cdot G \cdot L)$. In our evaluation, G is a small constant determined by the parameter grid. Moreover, the grid search is embarrassingly parallel across traces, cache sizes, and configurations. Model fitting is substantially cheaper. Once the labels have been generated, we train a small GBDT using one compact feature vector per trace/cache-size pair. The model contains 20 trees with a maximum depth of 9 and predicts over 18 representative parameter sets. Thus, retraining is a one-time offline cost and does not affect the request-serving path. Deployments can directly use the pre-trained model. Retraining is only needed when operators want to incorporate additional training data. Further details can be found in Appendix Section A.1.

Storage. Unlike object-level learning, which requires maintaining feature vectors per object, S4-FIFO uses only 73 global features in total. Beyond the 2-bit counter inherited from S3-FIFO, no additional per-object metadata is needed. Including model parameters, the total storage overhead introduced by learning is on the order of only tens of kilobytes. The dominant storage overhead in S4-FIFO arises from the ghost queue. Each ghost entry requires 8 bytes to record the object ID (or fingerprint) and its insertion timestamp. For a cache holding 1 million objects, the ghost queue can therefore consume several megabytes of memory. Nonetheless, as long as objects are relatively large (e.g., larger than 200 bytes), this overhead remains small compared to the total data volume.

5 Evaluation

In this section, we use S4-FIFO as a case study to answer the following questions:

- Do augmented heuristics expose sufficient headroom for efficiency improvement?
- Can we accurately learn the optimal parameters of augmented heuristics to realize these efficiency gains?
- Do learning-augmented heuristics improve robustness?
- Do learning-augmented heuristics reduce throughput?
- Is a single pre-trained model sufficient across workloads, and why?

5.1 Methodology

Workloads. We evaluate S4-FIFO using 5,175 production traces collected from 14 sources (Table 4). We exclude very small traces with fewer than 100,000 objects, as these typically correspond to low-priority workloads (e.g., development traffic). Notably, many learned caches, such as LRB and 3L-Cache, perform extremely poorly on these short traces, which skews both average efficiency and robustness metrics. In contrast, S4-FIFO is insensitive to trace length because it relies on aggregated cache-level features. Consequently, including all traces would make S4-FIFO's results even stronger.

Table 4: Summary of datasets used in our evaluation. We filtered out traces with fewer than 100,000 objects.

Dataset	Approx time	Cache type	# Traces
MSR [48, 49]	2007	Block	14
FIU [37]	2008-11	Block	7
CloudPhysics [64]	2015	Block	104

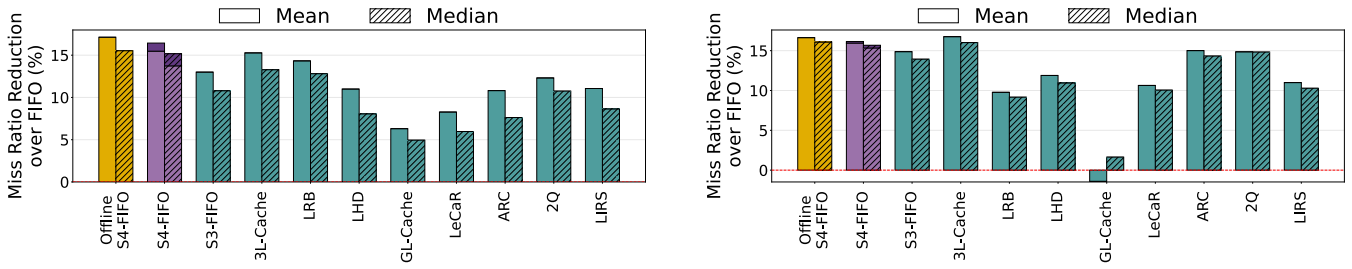
Meta KV [15]	2022	KV	5
Meta CDN [15]	2023	Object	3

Experiment setup. We randomly split the traces into two sets: 4140 for training and 1035 for evaluation. For each trace in the training set, we run S4-FIFO with the default parameter combinations to collect training samples of (features, label) pairs. For each trace in the test set, we start the cache using S4-FIFO with the default parameter combinations, run for 20% of the trace to collect features, then make one prediction and apply the predicted parameters to the rest of the trace. To ensure a fair comparison with the offline optimum obtained via grid search, we restrict ourselves to one prediction per trace, since the offline optimum also uses a single parameter setting for the entire trace.

We compare S4-FIFO with S3-FIFO [74], LIRS [33], ARC [46], LRB [58], 3L-Cache [83], LHD [10], GL-Cache [70], and LeCaR [63]. Besides, we have also evaluated SIEVE [77], GDSF [20], and TinyLFU [24]; however, their results are worse than the ones in the figure. Due to space limits and for ease of plotting, we omit them in the figure. We evaluate each algorithm at three cache sizes—0.1%, 1%, and 10% of the trace's working-set size—but, for space reasons, we only present results for the smallest (0.1%) and largest (10%) caches. The results for the medium size (1%) consistently fall between these two.

All miss ratio results are from libCacheSim because most state-of-the-art eviction algorithms are not available in open-source caches such as Cachelib. Because our Cachelib implementation uses the same model as the simulator, S4-FIFO shows almost identical miss ratios in the simulator and prototype. We report throughput results by comparing S4-FIFO with highly optimized LRU, 2Q, S3-FIFO, and TinyLFU us-



(a) Large cache (10% of working set)

(b) Small cache (0.1% of working set)

Figure 6: Mean and median miss ratio reduction from FIFO of different algorithms using the large and small cache sizes. S4-FIFO is significantly better than all state-of-the-art algorithms at the large cache size, while on par with the best of all algorithms at the small cache size.

ing CacheBench from Meta. The experiments were performed on a 20-node cluster with 32 cores and 192GB of memory. All experiments are repeated three times, and we report the mean result.

Metrics. We evaluate using the following metrics.
(i) *Efficiency*: Following prior work [74], we report the miss ratio reduction over FIFO, computed as $\frac{MR_{\text{FIFO}} - MR_{\text{algo}}}{MR_{\text{FIFO}}}$. We present the mean reduction in miss ratio across the 1,035 traces in the test set.
(ii) *Robustness*: We report miss ratio reduction for the worst-case workload and for the 10^{th}-percentile workload.
(iii) *Overhead*: We use Cachelib throughput as our primary overhead metric.

5.2 Efficiency

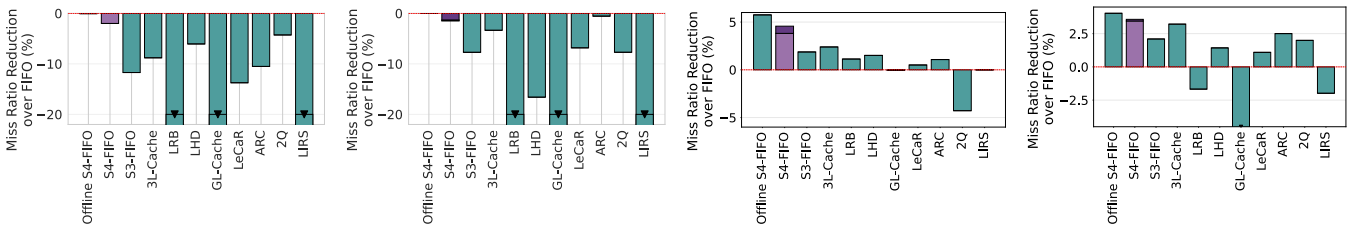
Efficiency is the primary performance metric for cache eviction. Figure 6 reports the mean and median miss-ratio reduction over FIFO for both small and large caches. Since S4-FIFO uses the first 20% of each trace to collect features before making a prediction, we evaluate two variants. In the online variant (v1, light purple), the first 20% of requests are served using the default parameters, and the remaining 80% are served using the predicted parameters. In the retrospective variant (v2, dark purple), the predicted parameters are applied to the entire trace; this isolates the quality of the learned configuration from the cost of the observation window. Across both cache sizes, v2 consistently outperforms v1, indicating that the predicted parameters improve efficiency and that the observation window accounts for the gap between the two variants.

Offline S4-FIFO. Unlike many learned caches, such as 3L-Cache, LRB, and LHD, which use sampling to select eviction candidates and can evict any object in the cache, learning-augmented heuristics like S4-FIFO are constrained by their underlying data structures: objects must pass through at least one queue before they can be evicted. Nevertheless, Figure 6 shows that offline S4-FIFO, which selects parameters via grid search, consistently achieves the highest efficiency. This suggests that the data structures used in S4-FIFO do not prevent it from attaining high efficiency. When comparing S4-FIFO with offline S4-FIFO, we find that the second variant, which runs the full trace using predicted parameters (same as offline S4-FIFO), achieves very similar miss ratio reduction as offline S4-FIFO with at most 0.2% difference in mean and median miss ratio reduction. This demonstrates the effectiveness of learning in S4-FIFO. In Section 5.5, we will show that S4-FIFO learns the best parameters most of the time, and even when it does not, the learned parameters are close to the best.

Comparison with state-of-the-art algorithms. S4-FIFO is built on top of S3-FIFO; compared to S3-FIFO, it achieves a 26% higher miss ratio reduction at the large cache size and an 8% higher reduction at the small cache size. Across all state-of-the-art algorithms, 3L-Cache consistently delivers the best performance. Relative to 3L-Cache, S4-FIFO attains slightly higher or comparable miss ratio reductions. For instance, at the large cache size, S4-FIFO achieves an 8% higher reduction. Compared with ARC, S4-FIFO nearly doubles ARC's improvement over FIFO at the large cache size. Relative to the large-cache setting, S4-FIFO's performance at the small cache size is less impressive: it is slightly worse than 3L-Cache, though still substantially better than the other state-of-the-art algorithms. For instance, S4-FIFO improves LRB's mean reduction ratio from 9.8% to 16.2%. The slight advantage of 3L-Cache at small cache sizes stems from the fact that the cached objects are all highly popular, providing rich signals for object-level learning. However, object-level learning incurs high overhead and low throughput. In our simulator, 3L-Cache is 17.3× slower than S4-FIFO on average (max 274×). In summary, S4-FIFO achieves a high efficiency via its superior learning methods and the pre-trained model.

5.3 Robustness

Historically, work on designing new cache eviction algorithms has focused on reducing miss ratio on a small set of traces or improving average performance. Far less attention has been given to the robustness of these algorithms. Yet robust-



(a) Worst case, large cache **(b)** Worst case, small cache **(c)** 10^{th}-percentile, large cache **(d)** 10^{th}-percentile, small cache

Figure 7: Efficiency on the worst case and 10^{th}-percentile trace. A negative value indicates the algorithm has a miss ratio higher than FIFO. S4-FIFO is more robust than all state-of-the-art algorithms.

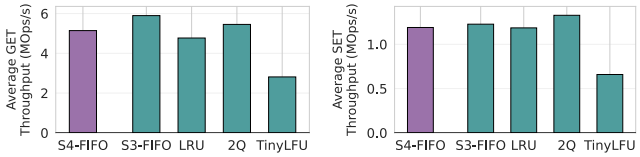


Figure 8: Set and Get throughput evaluated in Cachelib.

ness is crucial, because an algorithm can severely degrade performance when the workload is out of distribution relative to its design assumptions. In this section, we evaluate the robustness of state-of-the-art algorithms using the worst trace and 10^{th}-percentile trace. Note that we do not consider the competitive ratio because the arbitrary workload used in competitive-ratio analysis rarely occurs in the real world, so we focus on the worst-case production trace.

Figure 7a and Figure 7b show the miss ratio change relative to FIFO on the worst trace for each algorithm. We observe that all state-of-the-art eviction algorithms incur a higher miss ratio than FIFO on their worst-case trace. In particular, LRB and LIRS perform substantially worse than the others, increasing FIFO's miss ratio by 20% to 72%. In contrast, S4-FIFO increases FIFO's miss ratio by only 0.8% and 0.2% at large and small cache sizes, respectively. For comparison, the next-best algorithm at the large cache size is 2Q, which raises FIFO's miss ratio by 4.3%.

Although the single worst-case trace may be unrepresentative, Figure 7c and Figure 7d show results on the 10th-percentile trace. On this metric, S4-FIFO widens its lead over state-of-the-art algorithms. While some schemes, such as LRB and LIRS, still exhibit miss ratios higher than FIFO, S4-FIFO reduces FIFO's miss ratio by 4.2% and 3.6% at large and small cache sizes, respectively.

The robustness of S4-FIFO arises from three core design choices. First, S4-FIFO employs static FIFO queues and therefore avoids the pathological behaviors that can arise in adaptive algorithms [74]. Second, S4-FIFO leverages learning to select its parameters, enabling it to sidestep the adversarial workloads that often degrade the performance of fixed, heuristic-based schemes. Third, S4-FIFO's learning objective uses FIFO as an anchor to directly optimize for robustness.

5.4 Throughput

To assess whether S4-FIFO preserves the high throughput of lightweight heuristic policies, we measure its throughput using CacheBench and compare it against highly optimized Cachelib implementations of S3-FIFO, LRU, LRU2Q (a modified 2Q without a ghost queue), and TinyLFU. In this experiment, S4-FIFO collects features continuously for every request throughout the benchmark. This deliberately conservative configuration provides an upper bound on the overhead of feature collection. In practice, periodic or sampled feature collection could further reduce this overhead; exploring these optimizations is left to future work. We use CacheBench's CDN workload and four Graph Cache workloads, run each benchmark with 48 threads, and report the average throughput across all five workloads in Figure 8.

Even under this deliberately heavy configuration, S4-FIFO sustains throughput comparable to conventional heuristics, with only a modest slowdown from continuous feature extraction. Achieving heuristic-level throughput is challenging for typical learned caches, which often require critical-path inference or online training. S4-FIFO avoids these costs by collecting features outside the critical section and performing inference infrequently and asynchronously using an offline-trained model. As a result, its critical path remains lightweight, preserving throughput and simplifying deployment. By contrast, TinyLFU incurs additional overhead because its count-min sketch must be updated within the critical section to ensure correctness, resulting in significant throughput degradation.

5.5 Why does Learning Work?

As a simple algorithm with static queue sizes, S4-FIFO achieves both higher efficiency and robustness compared to state-of-the-art algorithms. This section deep dives into how learning helps S4-FIFO achieve this and why one pre-trained model is sufficient.

Miss ratio over time. Figure 12 illustrates the effect of how learned parameters affect miss ratio over time for a representative trace. The vertical dashed line marks the point at which S4-FIFO switches to the predicted parameters, which shrink the small-queue size to 5% of the cache and skip frequency-counter increments for 25% of the items at the front of the small queue. After this parameter change, S4-FIFO (solid

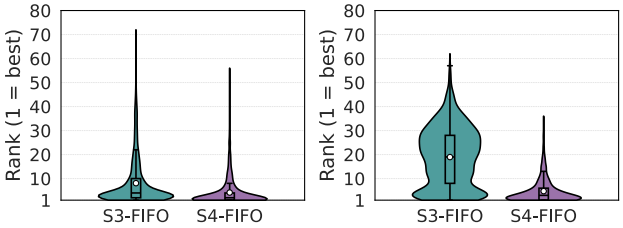
(a) Cumulative miss ratio **(b)** Interval miss ratio

Figure 12: Miss ratio over time where the learned parameters significantly reduce the miss ratio.



(a) Large cache **(b)** Small cache

Figure 13: Rank distribution of the default (S3-FIFO) and predicted parameters (S4-FIFO) from optimal grid search configuration.

line) quickly diverges from the baseline (dashed line): the interval miss ratio drops substantially and remains consistently lower for the remainder of the trace, and the cumulative miss ratio curve steadily widens its gap relative to the baseline. This example shows that although parameters remain static (i.e., not updated per-miss), learning a set of parameters for each workload can deliver a substantial reduction in miss ratio compared to using a fixed set of parameters.

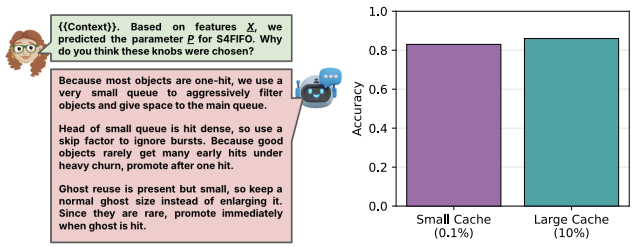
Rank of predicted parameters. Figure 13 compares the grid-search rank distributions of the default S4-FIFO parameters (most are inherited from S3-FIFO) with the learned parameters, where a lower rank indicates better performance (rank 1 is the best). In both small and large cache sizes, the predicted parameters from S4-FIFO are consistently close to the best configuration across traces. In contrast, the default parameters have a substantially wider distribution that extends to much worse ranks, indicating that using the same parameters across traces leaves significant headroom for improvement.

Feature importance. We compute the feature-importance scores from the trained decision tree. As shown in Figure 9, the histograms of all three queues (ghost, main, and small) are the most important. Together, these histogram features account for 75% of the total importance, indicating that the shape of hit distributions within each queue (workload locality) is the strongest signal for predicting good configurations. The remaining composite features, such as thrashing risk (working set size estimate) and ghost pressure (hits found on the ghost), account for 25% of the importance.

Training data size. To understand why a single pre-trained model works, we measure how prediction accuracy changes with the number of training traces. For each training dataset size, we pre-train a new model and evaluate on the same test dataset. We measure top-1, top-2, and top-3 accuracy, which are the fractions of traces in which the predicted parameters are ranked top-1, top-2, or top-3, respectively. Figure 10 shows that all three metrics monotonically increase with more training data. With several thousand traces, top-1 approaches 60%, top-2 approaches 70%, and top-3 approaches 80%. Although performance starts to plateau, increasing the training dataset size further is likely to make the pre-trained model increasingly accurate.

Cross-dataset generalization. The training and test traces we have been using so far are generated using a random split, without considering the dataset (source). This is acceptable because each dataset contains many diverse traces, and traces within a single dataset can be more diverse than those across datasets. To verify whether pre-trained models can generalize across datasets, we train a model on the CDN2 dataset (object cache) and evaluate on the Twitter dataset (key-value cache). Figure 11 shows that the model pre-trained on one dataset can be directly used on a different one, and the knowledge learned is generalizable as long as the training dataset is large and diverse enough.

Generality across eviction algorithms. The principles of LAH can be applied to other policies that expose a small set of configuration knobs. For example, CacheLib's LRU exposes configurable behaviors such as node-promotion frequency, whether metadata is updated on reads, writes, or contention,



(a) Explaining predicted parameters **(b)** Selecting suitable parameters

Figure 14: LLM-based interpretability evaluation. S4-FIFO's cache-level features and semantic parameters allow an LLM to explain predicted configurations and distinguish suitable parameter choices.

and the insertion position of new objects in the LRU queue. 2Q [35] exposes the relative sizes of its hot and cold queues, ARC [46] exposes the balance between its recency and frequency regions, and LeCaR [63] exposes the weights assigned to its eviction experts. Extending LAH to these policies requires policy-specific feature engineering. For example, an LRU-based instantiation could additionally track hit positions in the queue and their reuse distances. These extensions are beyond the scope of this work.

5.6 Is the Learned Decision Interpretable?

S4-FIFO learns from high-level cache features and predicts high-level knobs. Because both the inputs and outputs operate at the cache level, the decisions it produces are far more interpretable than those of prior smart-cache designs. Unlike approaches that make opaque predictions (e.g., ranking objects or estimating reuse densities), S4-FIFO expresses its decisions using knobs that operators already understand, such as queue sizes and promotion thresholds. The features S4-FIFO used characterize workload, capturing burstiness, one-hit ratios, and reuse-distance patterns, making the mapping from features to knobs easier to interpret.

We use LLM-based evaluation as a proxy for semantic interpretability: if an external reasoning model can connect workload-level features to the selected cache knobs, then the learned decisions are likely expressed in a form that operators can reason about. We evaluate this with two language-model-based experiments, shown in Figure 14. First, given workload features and a predicted S4-FIFO configuration, LLMs are able to explain why the selected knobs match the workload behavior. Second, we provide an LLM with the workload features and two configurations with distinctly different miss ratios and ask it to identify the better configuration. Across 100 traces for each cache size, the LLM performs substantially above chance, achieving 83% and 86% accuracy in the small-cache and large-cache setting. While these results do not establish the correctness of the learned policy, they suggest that S4-FIFO's feature and parameter spaces are semantically meaningful enough to support external reasoning, making the selected configurations easier to explain, justify, and debug. We provide further details in Appendix Section A.2.

6 Related Work

Optimizing cache efficiency. Many studies have examined the design of eviction algorithms to improve efficiency. These include static heuristics such as S3-FIFO [74], SIEVE [77], QDLP [71], LIRS [33,80], clock variants [16,32,42], 2Q [35], S4LRU [31], LRFU [22], LFU variants [5, 6, 36], greedy-dual variants [20, 34], MQ [84], Clock2Q+ [76], Hyperbolic [13]; per-miss cache-level adaptive algorithms, such as ARC [46], CAR [8], SEQ [29], EELRU [56], Clock-Pro+ [42], LeCaR [63], CACHEUS [53], TinyLFU [24]; and object-level learning algorithms, such as LRB [58], 3L-Cache [83], LHD [10], PA-Cache [26], RL-Belady [68], Raven [30], HALP [59], Darwin [17]. Compared with these algorithms, to the best of our knowledge, this is the first work to propose learning-augmented heuristics that separate the control and data-serving planes to achieve both high efficiency and performance. S4-FIFO demonstrates this idea by using a pre-trained model to learn the parameters of S3-FIFO.

Machine learning for systems. Prior works integrate ML into systems at three distinct levels of the stack, ranging from replacing internal mechanisms to tuning external knobs. (1) Structural replacement: Works such as learned indexes [38,60] and learned bloom filters [62] aim to *replace* data structures with neural networks. (2) Policy optimization: ML replaces specific heuristics (policies) while keeping the underlying mechanism intact. Examples include RL-based flash admission [75], and language-model-based C++ memory manager [44,45]. (3) Black-box autotuning: Systems like OtterTune [3] treat the database as a black box, optimizing configuration knobs via Bayesian optimization. S4-FIFO occupies a distinct point in this design space: unlike structural replacement, it preserves the mechanism's deterministic safety (the S4-FIFO data path); unlike per-instance policy optimization, it leverages a pre-trained foundation model to generalize to unseen workloads; and unlike black-box autotuning with slow iterative search, it performs zero-shot inference, quickly selecting an optimal configuration after a brief observation window and avoiding costly online exploration.

7 Conclusion

We introduce Learning-Augmented Heuristics (LAH), which keeps the data path simple while using a pre-trained model to configure a few semantic knobs. Our S4-FIFO instantiation extends S3-FIFO with tunable parameters and selects configurations based on cache-level features. Evaluated on 1,035 production traces, S4-FIFO achieves higher average miss-ratio reduction and stronger robustness than state-of-the-art algorithms, while matching the throughput of heuristics. These results indicate that learning to configure expressive heuristics is an effective and interpretable way to bring ML into core caching systems.

Acknowledgments

We thank the anonymous reviewers for their valuable feedback and our shepherd for the constructive suggestions. We also would like to thank the people and organizations that have open-sourced and shared production traces. We thank Cloudlab [23] for providing infrastructure support to run experiments.

Abstract

This paper presents a set of in-process and remote distributed caches for datacenter environments, CLINK and CRINK respectively, that provide linearizable reads entirely from memory without contacting storage. These caches remain loosely coupled to the storage layer and achieve high performance, scale, and availability by cooperating with auto-sharders and by tracking consistency metadata at the granularity of key ranges rather than individual keys. To our knowledge, CLINK is the first distributed linked cache that delivers scalable, linearizable reads from memory while remaining loosely coupled with storage.

At the heart of these caches is a lightweight storage primitive called *WriteGuards* that can be easily added to a distributed store. WriteGuards prevent a subtle race we call the *delayed-writes anomaly* arising during changes in ownership of key ranges. Each write carries a small fencing value tied to the current owner, and the storage system checks this value to reject delayed writes. WriteGuards apply to key ranges instead of individual keys for scalability, add only a conditional check on the write path, and require no coordination on reads.

We implemented our cache designs on TiDB. The in-process cache CLINK cuts tail read latency by three orders of magnitude, and the remote cache CRINK reduces it by $2.2 - 2.4\times$ relative to direct storage access and existing strongly consistent remote caches.

1 Introduction

Many large-scale cloud services in datacenter environments require low-latency access to the latest state on the critical path. For example, a data governance service at Databricks must retrieve current permissions before every request, and a query coordination service must track up-to-date session state to ensure correct SQL execution. These requirements are widespread: major companies such as Dropbox [81], Google [20], and Meta [39] report similar needs. Furthermore, recent work [64] highlights the necessity of linearizable reads in latency-critical domains like financial trading [17, 29] and online ad bidding [96].

While distributed storage systems provide strong consistency, they incur high overheads. Each read involves network round trips, serialization, and transaction processing [31, 44, 79], resulting in multi-millisecond tail latencies [34]. To avoid this cost, large-scale services rely on distributed lookaside caches to serve frequently accessed data from memory. These caches are particularly effective for *serving* workloads, where reads dominate and writes are relatively infrequent [18, 67]. However, these caches generally provide only eventual consistency and cannot guarantee that reads reflect the latest committed state.

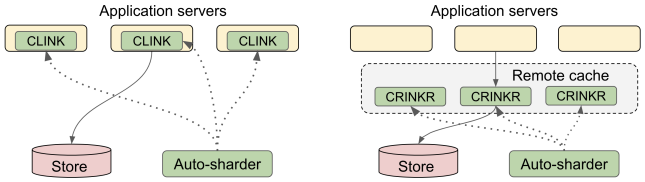

Figure 1: CLINK (in-process) and CRINK-R (remote) architectures.

A distributed write-through cache can provide linearizable reads, but several challenges must be addressed. First, to be usable as a general solution it must remain loosely coupled with storage so each layer can evolve independently. Second, it must scale to hundreds of millions or billions of keys. Third, for high performance and availability, the cache must handle dynamic resharding of keys, e.g. to move keys from unhealthy to healthy pods or for load balancing purposes.

Finally, the most significant challenge, which serves as the primary focus of this paper, is a subtle race condition we term the *delayed-writes problem*. When resharding occurs and a key is reassigned, the previous owner may still have writes in flight to storage. If the new owner reads and caches values before those writes arrive, the late writes can update storage and render the new owner's cache stale. This puts the new owner at risk of serving stale data. The delayed-writes problem is not a hypothetical possibility. Write operations have been observed in production systems [18, 67] to stall for extended periods, with GitHub reporting packets remaining in flight for approximately ninety seconds during an outage [82]. Such slowdowns can cause writes to arrive at the storage layer long after key ownership has changed in the application. Preventing delayed writes from committing after ownership changes is therefore essential for serving linearizable reads.

To address the delayed-writes problem, we introduce *WriteGuards*, a scalable and lightweight fencing mechanism that also enables loose coupling. Storage maintains WriteGuards as soft state: a small map from key ranges to opaque tokens checked on each write. On cache key ownership changes, the new cache pod owner installs WriteGuards over key ranges in storage to block delayed writes from prior owners. Write-

Guards enable decoupling of ownership logic in the cache layer from storage, allowing both systems to evolve independently. Because WriteGuards are simple, efficient, and broadly applicable, we recommend that providers of distributed storage systems expose them as a standard write-fencing primitive.

We leverage WriteGuards to construct in-process and remote caches that serve linearizable reads directly from memory. In these designs, new owners install guards in storage to block delayed writes. Our in-process solution, CLINK (Consistent Linked In-memory Key-value cache, Figure 1), keeps data in the application address space. A read from CLINK is equivalent to a linearizable read from storage, making it a transparent cache over the underlying store. For shared or multi-tenant scenarios, we present a remote strongly consistent cache, CRINK (Consistent Remote In-memory Key-value cache), with two architectures: CRINK-R (Figures 1 and 9) stores versions and values in a remote tier, whereas CRINK-L (Figure 10) stores only versions, allowing it to be paired with any lookaside cache (e.g., Redis). In all our designs, the cache is write-through; all writes flow through it to storage. The write throughput remains bounded by the storage system, ensuring the cache adds no new write bottleneck.

Like other modern cache systems, we address the third challenge of high performance and availability via an auto-sharder [7, 9, 53]. Improving over static placement schemes such as consistent hashing, auto-sharders dynamically reshard key ranges to handle autoscaling, pod failures, rolling upgrades, and load imbalance. They scale by tracking sharding metadata at the range rather than key level and can ensure that all pods agree on the key-to-pod assignment, which CLINK and CRINK rely on to support linearizable cached reads.

Both caches handle hot keys by letting the auto-sharder isolate a key and create replicas, with one acting as primary. Reads for a key can be served from storage by any pod, or directly from the in-memory cache of the pod currently assigned that key. All writes flow through the primary and follow a two-phased invalidation protocol. This could suggest reduced write availability during pod restarts. However, because unplanned failures are rare and the auto-sharder performs proactive resharding during planned restarts, the observed write unavailability remains extremely low (below 0.001%, see §2.3.2). Hence, CLINK and CRINK provide scalable, low latency linearizable reads across replicas while preserving high write availability.

Our approach extends to cross-datacenter environments, where caching offers significant benefits for geo-distributed applications using global stores like Spanner [30] by reducing expensive WAN traffic. However, we limit the scope of this paper to single-datacenter environments.

We implemented WriteGuards in TiDB [44] and built CLINK and CRINK in C++. Using production traces from Meta [5, 15], Twitter [88], and an internal workload from Unity Catalog at Databricks, we show CLINK reduces P_{90} read latency by orders of magnitude relative to accessing storage (from 10.3ms to 4.2μs). For shared data access or multi-tenant deployments, our remote caches CRINK-R/CRINK-L achieve up to $3.6-5.2\times$ lower P_{90} read latency than direct storage access, and $2.2-2.4\times$ lower latency compared to alternative consistent remote caches.

This paper makes three contributions:

- **WriteGuards:** a lightweight storage-level fencing mechanism that operates on dynamic ranges to prevent delayed writes from previous owners after resharding, and which can be easily added to a distributed store.
- **Strongly consistent caches:** CLINK, the first strongly consistent distributed cache that serves scalable, linearizable reads directly from application memory while remaining independent of storage, and its variants CRINK-R and CRINK-L which can be deployed remotely.
- **Implementation & evaluation:** we have integrated WriteGuards in TiDB and demonstrated their use in building performant linked and remote caches.

2 Background

In this section, we introduce the application, storage, caching, and auto-sharding model that motivates our design choices, providing the architectural context needed for the later sections on supporting linearizable cached reads.

2.1 Application and storage model

Many large-scale datacenter services process requests keyed by logical identifiers across billions of keys. Each request issues reads and writes for a specific identifier, such as a *CustomerID*. Underlying systems like DynamoDB [76], FoundationDB [100], and TiKV [44] support these per-key operations. The identifier often prefixes the full storage key (e.g., *CustomerID* in <*CustomerID, WorkspaceID*>); we denote this key as *C*.

2.2 Distributed caching for latency and scale

Remote lookaside caches (Figure 3) like Memcached or Redis offload storage but incur network latencies, serialization, and queuing costs [8]. In contrast, linked in-process caches like CLINK (Figure 1) store objects in native formats, avoiding remote lookups for significantly lower latency [8, 9].

This efficiency is critical for services storing large values (MBs–GBs). Remote caches struggle with partial reads of these values: returning the entire object causes overreads [8], while partial fetching often amplifies one API call into 10–30 network requests. Linked caches eliminate this overhead, turning expensive network operations into cheap local function calls.

2.3 Auto-sharders

To scale caches, modern systems partition keys across pods using auto-sharders [9, 53] rather than using static schemes like consistent hashing. At Databricks, auto-sharding serves more than half of all services and nearly all critical ones. These systems dynamically split, merge, and reassign contiguous key ranges, or *slices*, to handle load imbalance, hot keys, crashes, and to support high performance and availability. Auto-sharders also coordinate with cluster managers for

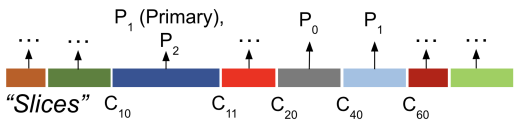

Figure 2: An example assignment of slices to pods. Each slice is assigned to one or more replicas, with one as primary for writes.

planned restarts and migrate state during reassignment [53] to avoid storage reads. Figure 2 illustrates a sample mapping.

Auto-sharding is also integral to storage systems. For example, Bigtable's master and TiDB's Placement Driver place and rebalance *tablets*, which are key ranges with associated records, across storage servers, also called *tablet servers*.

Figure 3 shows how auto-sharders route requests across the cache and storage layers. A request for customer C_{45} is directed to cache pod P_1, which owns slice $[C_{40}, C_{60})$. A cache hit returns immediately. On a miss, the pod issues a lookup to tablet server S_1, which hosts tablet $[C_{30}, C_{50})$, retrieves the value, populates the cache, and responds to the client. Linked caches follow the same routing logic except that the request goes directly to the application pod that owns the slice and stores the cached data locally. The caching layer and the storage layer are loosely coupled and sharded differently based on their respective load.

2.3.1 Features for scalability and strong consistency

Modern auto-sharders provide mechanisms that help services handle skewed workloads, scale under heavy demand, and achieve exclusive ownership over keys.

Hot key detection and replication: Many large-scale systems experience load imbalance driven by hot keys, which attract far more traffic than others in domains such as social media, ML serving, and content platforms [9, 43, 55, 59, 66, 67, 90]. Auto-sharders detect these hotspots and isolate the hot key onto its own slice and pod [9, 53]. When even a dedicated pod cannot meet demand for the hot key, the auto-sharder employs *asymmetric replication*, creating multiple replicas of only the hot key and assigning one to be the primary to handle writes. This approach scales throughput in proportion to key popularity. For example, Figure 2 shows key C_{10} isolated and replicated across P_1 and P_2, with P_1 acting as the primary.

Strong ownership guarantees: Auto-sharders [7, 9, 53]

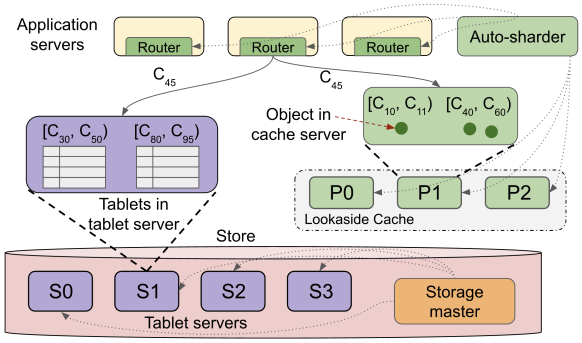

Figure 3: Auto-sharders assign and rebalance key ranges across cache or tablet servers to maintain performance and high availability.

support ensuring that at most one pod holds authoritative ownership of a key at any time. Our auto-sharder generalizes this model by producing assignments that all pods agree on, including which pods act as primaries when replicas exist, a property we call *Assignment Consistency*. To implement this efficiently at scale, the auto-sharder grants leases over key ranges rather than individual keys, amortizing coordination overhead across many keys while preserving consistent ownership semantics. The server library exposes the following API:

```
GetSliceHandle(KeyRange) → SliceHandle
IsStillAssigned(SliceHandle) → Bool
IsPrimary(SliceHandle) → Bool
```

The *GetSliceHandle* API returns a *SliceHandle* for a key range $[lowInclusive, highExclusive)$ where a single key is simply a singleton range. The *IsStillAssigned* API verifies that the *GetSliceHandle*'s range has remained continuously assigned to the pod since the handle was acquired, acting as a lightweight lease check implemented internally by the auto-sharder. When the auto-sharder assigns key K to pod P, the time interval until K is reassigned defines P's *period of ownership*. If a key is replicated, *IsPrimary* says whether the pod is the primary replica for that SliceHandle's range.

2.3.2 Availability impact of restarts and crashes

Strong ownership allows a cache implementation such as CLINK to let the pod that owns a key K serve linearizable reads directly from memory, since all writes on K are guaranteed to route through that pod. Ensuring strong ownership, however, necessarily introduces an availability tradeoff when ownership must move, for example during pod restarts or crashes.

In the common case of planned restarts, auto-sharders integrate with the cluster manager to receive advance notice and proactively migrate affected key ranges before the restart occurs. In systems enforcing strong ownership, this involves transferring leases for those key ranges from the restarting pod to other pods. In the common case, these transfers complete within milliseconds, resulting in minimal availability impact.

In rare cases, however, restarts are unplanned, for example due to a segfault or OOM. In these situations, the old owner's lease must expire before another pod can safely assume

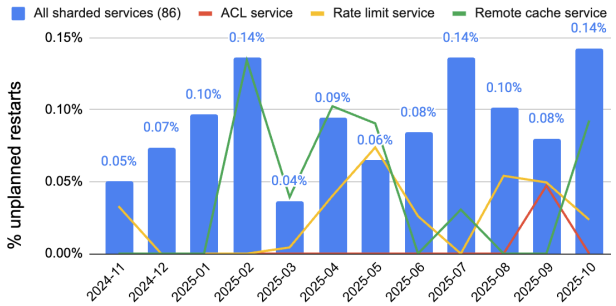

Figure 4: Global % of unplanned restarts across 86 sharded services in production by month. Critical path services for caching, ACLs, and rate limiting generally have few to no crashes in a given month.

ownership, which in practice results in order tens of seconds of unavailability for the key range. Though this may seem disastrous for availability, Figure 4 shows that such unplanned failures in production occur only once in roughly 750 to 2000 restarts, consistent with industry observations that critical services are engineered for robustness [80,84]. In a 100 pod service, this corresponds to roughly one crash every two months. Even if a single pod becomes unavailable for 30 seconds and temporarily affects 1% of keys, overall daily availability still exceeds 99.999%, making the practical impact negligible.

3 Motivation

Large scale services increasingly need both low latency and strong consistency, yet existing storage and caching layers struggle to provide both efficiently.

3.1 Low-latency reads are critical

Low tail latency is essential in serving scenarios [18, 67] as well as for interactive and data-intensive services. In practice, reads often suffer 1–5 ms tails due to queuing and concurrency, despite sub-millisecond network RTTs. Because requests fan out into many key-value RPCs, small delays compound into tail amplification [34, 35, 41, 51], impacting systems like Facebook's web search [18, 67], Google Search [34], Zanzibar [46], Presto [38], Michelangelo [1], and TFX [14]. This forces substantial overprovisioning to meet strict SLOs (e.g., DynamoDB [4], Cosmos DB [3], TAO [2]). Research systems [37, 50, 57] report tens of microseconds, but rely on dedicated hardware and limited multi-tenancy rather than production environments.

3.2 The need for linearizable reads

Many large-scale services require that reads reflect the latest committed value. Systems such as Spanner [31], CosmosDB [3], and Dropbox [81] provide linearizable reads. Such guarantees are also essential in domains like financial trading [19] and ad bidding [72]. Stale reads introduce subtle, hard-to-diagnose anomalies, such as stale permissions in Zanzibar [46], outdated metadata in Presto [38], or inconsistent features in TFX [14]. Similarly, our internal governance and query routing systems require these guarantees to prevent incorrect permission checks and session-dependent execution.

3.3 Storage is slow and costly for reads

Transactional stores (e.g., Spanner [31], CockroachDB [79], TiDB [44]) provide strong semantics but incur protocol overheads and serialization costs. This results in multi-millisecond tail latency and high variability, making them unsuitable for latency-critical paths. Storage is also costly at high request rates, offering limited throughput and requiring significantly more compute than in-memory caches [62]. Consequently, services offload read-heavy workloads: Facebook's Memcache fleet handles massive latency-sensitive volumes [67], and TAO [18] optimizes for social graph lookups. Serving such traffic directly from storage would impose prohibitive operational costs.

3.4 Caches are fast but typically not consistent

Distributed caches reduce latency and cost by serving hot data with sub-millisecond performance and high throughput [18, 67]. However, they provide only eventual consistency: values become stale immediately after a write and are later refreshed via timeout (TTLs), polling, or explicit invalidation. This occurs because remote lookaside caches (e.g., Memcached) sit off the write path, while linked caches see only local writes unless ownership is coordinated across pods. As a result, achieving low latency, linearizable reads, and high availability together remains difficult.

4 The Delayed-Writes Anomaly

To achieve low-latency linearizable reads, we consider a write-through in-process cache, loosely coupled with the storage system, in which applications issue both reads and writes through the cache. An auto-sharder provides ownership over keys (§2.3.1). However, despite this exclusive ownership, a subtle but important anomaly can still occur, causing the pod to serve stale reads:

> **Delayed-write anomaly.** A delayed write for key K is a write that commits in the storage system after a new owner has already assumed ownership of K *in storage*.

Ownership at the caching layer is not enough. A pod must also become the owner in the storage layer before assuming that no other writes can succeed. Otherwise, a write from a previous owner may commit after ownership has changed at the caching layer, and cause the cache to return stale values. Preventing delayed writes is therefore essential for any strongly consistent cache.

4.1 Example: Delayed writes

We now show a resharding scenario in Figure 5 where the delayed-writes problem can occur. The sequence unfolds in the following steps:

1. Pod P_1, which has exclusive ownership over slice $[C_{40}, C_{60})$ issues a write with an OCC check: "Write key C_{45} with version V_2 if its current version is V_1."
2. The auto-sharder reshards $[C_{40}, C_{60})$, assigning $[C_{40}, C_{50})$ to pod P_0 and $[C_{50}, C_{60})$ to P_2 .
3. Pod P_0 reads C_{45} from the database and observes the latest committed version V_1.

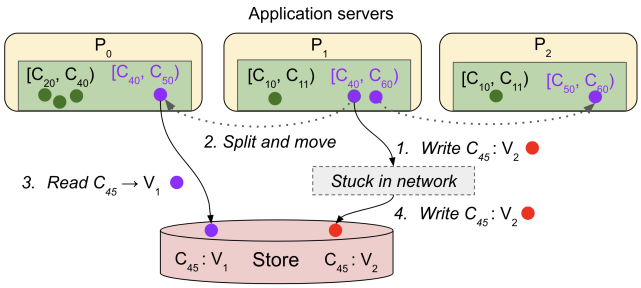

Figure 5: A delayed write of Write(C_{45},V_2) that comes in after P_0 has read version V_1 of C_{45} and cached it in memory.

4. The delayed write from P_1 arrives, passes the version check, and commits version V_2 for C_{45}.

The store now contains V_2, yet P_0 may still cache and serve V_1, violating linearizability. P_0 assumes exclusive ownership of key C_{45} when caching V_1, but this is incorrect because it never established ownership in storage, allowing a delayed write from P_1 to commit. The same issue can occur after a pod restart in a statically sharded cache (e.g., via consistent caching), where a new instance rebuilds its cache but an old in-flight write later commits and leaves the cache stale.

Although seemingly rare, long in-flight delays are well documented. Large systems suffer network anomalies where packets linger for minutes due to corrupted NICs or aggressive TCP retransmission backoffs [12]; GitHub similarly reported packets delayed for ninety seconds [82]. Delays need not be network-related: stop-the-world GC pauses and runtime stalls [49, 77] can last minutes in production workloads [58], and a buffered write may be released only after ownership has moved. In comparison, key reassignment is fast (e.g. 20ms). These real-world anomalies confirm that strongly consistent caches must explicitly guard against delayed writes.

4.2 Existing delayed-write prevention methods

Delayed writes can be prevented, but current mechanisms are slow, inefficient, or unscalable.

4.2.1 Version check on every read

One option is verifying each read against storage before serving, e.g., in Figure 5, the pod will not return C_{45}'s stale value if V_2 is already committed in storage. This ensures correctness but forces a remote version check on every read, adding latency and load which significantly reduces caching benefits [63].

4.2.2 Convert reads into metadata-writes

Alternatively, the first read for each key after ownership transfer can perform a write to advance the version (e.g., P_0 bumps C_{45} to V_1'), ensuring prior delayed writes fail their OCC check. However, this places a write on the critical read path, increasing latency and storage load.

4.2.3 Sequencer-based fencing in Chubby

Another approach to preventing delayed writes uses a lease management system such as Chubby [20] in conjunction with a storage system such as Bigtable [26]. Chubby provides a mechanism called sequencers. At any time, an application holding a lease can request the lease's sequencer, an opaque byte string that captures the state of the lock immediately after acquisition.

When an application performs a Bigtable write, it can attach a sequencer. Bigtable can then use the sequencer to verify that the application still holds the lease or that the sequencer is newer than the most recent one observed by the server. However, this approach requires application servers to acquire leases for every key they cache and requires the storage system to maintain per-key lease or sequencer state. In large multi-tenant deployments, applications may cache tens or hundreds of millions of keys, making this approach prohibitively expensive for the lease service, application servers, and storage backend. Consequently, sequencer-based fencing does not scale well for fine-grained caching systems. In our experience, this usage pattern was uncommon in production and discouraged by Chubby SREs because of the operational overhead it imposed. Additionally, it tightly couples the storage system and lease service by introducing an external dependency on the write path.

4.2.4 Synchronized clocks (e.g., TrueTime)

One possible solution to the delayed writes problem is to leverage synchronized clocks such as TrueTime in Spanner [31]. In this design, the storage system must provide timestamp-based write fencing, rejecting writes whose timestamps exceed a configured threshold T. When ownership of a key changes, the new owner waits for T seconds before serving requests, ensuring that delayed writes from the previous owner can no longer be accepted.

In this approach, choosing T involves a tradeoff. A value that is too small may reject legitimate writes under transient delays, while a value that is too large increases the unavailability period during ownership transitions. Moreover, the approach depends on specialized clock synchronization hardware that is often unavailable in public cloud environments, making it unsuitable for many general-purpose deployments.

4.2.5 Approximate correctness via timeouts

Given the rarity of unplanned pod failures, one might consider coordinating ownership transfer directly with the source pod. Under this approach, a slice is not reassigned until the source pod has drained all outstanding writes and explicitly acknowledges that ownership can be transferred.

While appealing in the common case, this design tightly couples the autosharder to application-specific logic and requires additional mechanisms to ensure liveness when the source pod crashes, becomes unreachable, or fails to respond. One possible approach is to assume bounded write delays and delay ownership transfer until the worst-case write latency has elapsed. Unlike leases, however, which derive their correctness from hardware-based bounds on local clock rates, this approach relies on a bound on write latency as measured across machines. Since no such bound exists in an asynchronous distributed system, the approach cannot provide formal correctness guarantees and instead only decreases the likelihood of stale writes.

5 The WriteGuard Primitive

We now present WriteGuards, which enable a loosely coupled cache to support linearizable cached reads. It does so by allowing the owning pod upon assignment of a new slice to establish ownership of the corresponding key range in storage. Unlike per-key approaches, WriteGuards scale to handle applications with millions to billions of keys efficiently by operating on key ranges. This requires only two storage operations: installing a guard and checking incoming writes against it.

5.1 WriteGuard installation

The storage system exposes a *SetGuard(range, guardValue)* call that associates an opaque guard value (denoted by *WG*) with a key range. If a newly assigned slice spans multiple tablets, the caller must split it into subranges and issue the SetGuard call to the appropriate tablet servers either through the client library or a higher-level layer. Figure 6 shows a case where CLINK splits the range $[C_{40},C_{60})$ into two calls to the relevant two tablets since C_{50} is a splitpoint: SetGuard($[C_{40},C_{50})$, WG_5) and SetGuard($[C_{50},C_{60})$, WG_6). *Splitpoints* or tablet boundaries can be discovered by periodically probing the storage layer using standard APIs available in existing systems [31,44]. An up-to-date view improves efficiency but is not required for correctness: if the tablet layout changes, servers return a status code indicating the change, and the caller can then obtain the new boundaries and retry the SetGuard calls.

Tablet servers maintain an in-memory interval map that associates non-overlapping key ranges with their guard values. This metadata is soft state and not persisted. On startup, a tablet initializes its full key range with an empty guard (lazy initialization is possible, but we assume eager initialization for clarity). When a SetGuard(*R*, *WG*) request arrives, the tablet intersects *R* with its owned ranges and updates the corresponding entries in the interval map, overwriting any existing guards in that region. In Figure 6, the two tablets install WG_5 on $[C_{40},C_{50})$ and WG_6 on $[C_{50},C_{60})$, while $[C_{30},C_{40})$ and $[C_{60},C_{80})$ keep their previous guards. Each tablet then acknowledges the request.

Stale splitpoint maps cause SetGuard calls to hit the wrong tablet server and return a *TabletLayoutChanged* error. CLINK catches this error to refresh the map and retry the call.

5.2 WriteGuards and tablet resharding

Storage-layer reshardings are relatively infrequent and typically triggered only under sustained load over minutes, since splitting or migrating tablets is expensive in systems such as Bigtable, Spanner, and HBase [21, 25, 31]. WriteGuards must be updated correctly during these operations.

When a tablet is split, each resulting tablet inherits the guard values of the original tablet. After a merge, the new tablet keeps the distinct guard values for the subranges contributed by each source tablet. (In practice, systems may need to bound the number of retained guards to avoid excessive metadata, though we did not explore this in our prototype.) For simplicity, our prototype drops guard metadata during tablet migrations rather than transferring it. This does not affect correctness, and we found that retaining guards across migrations offers negligible benefit relative to the complexity of moving guard state between tablet servers.

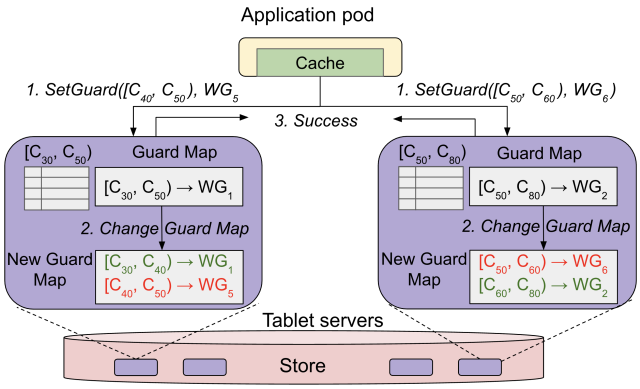

Figure 6: Installing a WriteGuard across two tablets. Upon receiving two slices, $[C_{40},C_{50})$ and $[C_{50},C_{60})$, the application pod generates two guard values (WG_5, WG_6) for each slice, and issues SetGuard to two tablets based on the cached splitpoints of tablets at the tablet servers.

5.3 Checking writes with WriteGuards

The storage system is also extended to validate a write's supplied WriteGuard against the installed WriteGuard for the key's corresponding range. A tablet server accepts writes only if the guards match, thereby rejecting delayed requests from previous owners. For example, in Figure 6, the tablet server would reject a delayed write for C_{45} carrying WG_1 because the WriteGuard in storage has been updated to WG_5. This design also ensures backward compatibility. Applications not using WriteGuards omit guard values, resulting in matching empty guards that trivially pass validation. This allows the storage system to enforce checks uniformly without requiring application changes.

5.4 Example: Preventing delayed writes

We now revisit the example from Section 4.1 to illustrate how WriteGuards prevent delayed writes. In that scenario (Figure 5), pod P_1 issued a write that updated key C_{45} from version V_1 to V_2. The write became delayed in the network while the slice $[C_{40},C_{60})$ was resharded, causing the subrange $[C_{40},C_{50})$ to be reassigned to pod P_0.

Under our approach, P_0 first installs a new WriteGuard, W_{new}, on the tablet server(s) responsible for the reassigned range and then reads key C_{45}, observing version V_1. Later, when the delayed write carrying version V_2 arrives at the tablet server, the write is rejected because its WriteGuard, W_{old}, does not match the currently installed WriteGuard, W_{new}. As a result, the stale write cannot overwrite data owned by the new pod.

6 CLINK: Serving linearizable cached reads

In this section we present CLINK, an auto-sharded cache linked directly into application pods that scales to handle millions to billions of keys. It provides linearizable reads while remaining loosely coupled to storage. CLINK allows reads to access storage from any pod to preserve high availability, but only pods assigned the key may serve reads directly from their local cache. CLINK uses WriteGuards to avoid delayed writes and scales by operating on key ranges rather than individual keys. To ensure linearizable cached reads, CLINK maintains the following invariant:

> **Latest State Invariant (LSI).** A key *K* may be served from the cache only if it equals the latest committed value of *K* in storage.

This invariant makes the cache transparent to applications,

since serving from memory is indistinguishable from serving from storage. A direct consequence is: when a pod issues a write on K, its cached value cannot be returned until that write has fully committed.

Note that we focus solely on LSI and linearizable reads. All other aspects of storage correctness are handled by the storage system's own transactional or consistency model, which operates independently of the mechanisms we introduce. For clarity, we defer optimizations such as buffering repeated reads and rejecting writes during a SetGuard call to §6.6. The remote variants of CLINK is discussed in §7. Detailed steps for various aspects of ownership, reads and writes are presented in Algorithms 1, 2 and 3.

6.1 Types and data structures

Each CLINK pod uses two main types. The first, *GuardHandle*, tracks a WriteGuard, the key range it covers, and the SliceHandle for that range. The second, *OpHandle*, captures the GuardHandle in effect when a request was issued to the store, the operation type (*RD* or *WR*), and a boolean flag *writeOverlap* indicating if any write overlapped with that operation.

```
GuardHandle = (KeyRange, WriteGuardID, SliceHandle)
OpHandle = (opType, writeOverlap, GuardHandle)
```

Each CLINK pod maintains three data structures. The *CacheMap* stores cached values. The *GuardMap* maps WriteGuard ranges to their associated GuardHandles and supports lookups by key or by range. The *OpMap* tracks all pending operations to storage. Together, these structures enable CLINK to serve linearizable reads while being auto-sharded. We write GuardMap[K] to denote a lookup of the GuardHandle for key K.

```
GuardMap : KeyRange → GuardHandle
CacheMap : Key → (GuardHandle, Value)
OpMap : Key → Array[OpHandle]
```

6.2 Preventing delayed writes via WriteGuards

We now describe how WriteGuards are installed on ownership changes via Algorithm 1 and how they prevent delayed writes.

6.2.1 Handling ownership change

Upon receiving a new assignment, CLINK acquires a SliceHandle for each newly assigned slice S, intersects S with the tablet ranges, and generates a unique WriteGuard value (e.g., a UUID) for each intersected sub-interval R_i (lines 7–9). These sub-ranges are precisely the key ranges in the storage layer that must be protected from delayed writes before CLINK can assume ownership of S. CLINK periodically refreshes tablet split points from the store to keep this mapping current. For each R_i, the pod issues a SetGuard call and installs the resulting GuardHandle in the GuardMap if the call succeeds and ownership has remained continuous (lines 11–13) – checking whether the slice S has been assigned to the current pod since the SliceHandle's creation. Figure 8 illustrates this process for a newly assigned slice $[C_{40}, C_{60})$, resulting in two SetGuard calls for the tablet ranges $[C_{40}, C_{50})$ and $[C_{45}, C_{60})$.

If the store reports a tablet-layout change, CLINK refreshes its cached split points and restarts the procedure (lines 14–15). If a SetGuard call times out, it is retried with a fresh unique WriteGuard value (lines 16–17). If ownership has been lost, CLINK aborts creation of the GuardHandle for R_i.

Algorithm 1 Assignment Handling (Red means critical section)

```
 1: procedure HandleNewAssignment(Asn)
 2:   for each new/removed slice X in Asn do
 3:     Clear GuardMap[X]
 4:   for each new slice S in Asn do
 5:     HandleNewSlice(S)
 6: end procedure

 7: procedure HandleNewSlice(S)
 8:   for each range R_i in intersection of S and store splitpoints do
 9:     Obtain SliceHandle SH_i
10:     Create unique WriteGuard WG_i
11:     status ← SetGuard(R_i, WG_i)
12:     if IsStillAssigned(SH_i) then
13:       if status == Success then
14:         GuardMap[R_i] ← GuardHandle(WG_i, R_i, SH_i)
15:       else if status == TabletLayoutChanged then
16:         Refetch store splitpoints and retry from line 8
17:       else                          ▷ SetGuard call had a timeout
18:         Retry from line 10 with a new WriteGuard
19: end procedure
```

6.2.2 WriteGuard ordering

CLINK enforces the following rules on SetGuard calls:

1. **Ownership-contained.** CLINK creates GuardHandles only for WriteGuards whose SetGuard calls both started and finished within a single ownership period.
2. **Non-overlapping.** Within any ownership period and for any key K, CLINK allows at most one outstanding SetGuard call whose range covers K.
3. **Unique-valued.** Every SetGuard call issued by CLINK (including retries) uses a fresh WriteGuard value.

Figure 7 illustrates these rules with four GuardHandles, G_1 through G_4, created across three exclusive ownership periods E_1, E_2, and E_3 established by leveraging the strong ownership

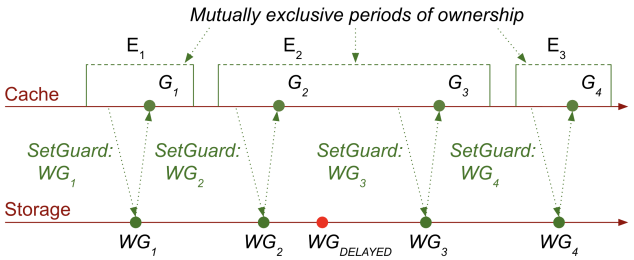

Figure 7: Relevant WriteGuards (green) are ownership-contained and non-overlapping.

guarantees of the auto-sharder (§2.3). Each SetGuard call installs a unique WriteGuard value (WG_1, WG_2, WG_3, WG_4, and the delayed $WG_{DELAYED}$ described later). The GuardHandles are created only when the corresponding SetGuard call both begins and ends within the same ownership interval. In ownership interval E_2, the calls that produce G_2 and G_3 are non-overlapping. In contrast, $WG_{DELAYED}$ comes from a SetGuard call that either timed out or returned so late that it violated the ownership containment rule and thus has no GuardHandle.

We next show how the first two rules induce, for each key, a total order on GuardHandles that aligns with the per key installation order of their WriteGuards in storage. The importance of the last rule is discussed in the next section.

First, because ownership periods are totally ordered by the auto-sharder, the *ownership-contained* rule ensures that any GuardHandle created in a later ownership period follows all GuardHandles from earlier ones. Further, each WriteGuard is installed between the start and end of its SetGuard call, and that call lies entirely within a single ownership period, so the WriteGuards inherit the same total order. In the figure, WG_2 and WG_3 (for G_2 and G_3) follow WG_1 (for G_1).

Second, within a single ownership period, the *non-overlapping* rule ensures that each SetGuard call must finish (or time out) before the next one begins. Again because each WriteGuard is installed at some moment during its SetGuard call, the WriteGuards appear in storage in the exact order of those calls. The corresponding GuardHandles are created in the same order (for example, WG_3 appears after WG_2).

Therefore, we have the following property:

WriteGuard Ordering. All GuardHandles form a total order, and their corresponding WriteGuards in storage follow the same order. We call the WriteGuards associated with these handles *relevant*. All others are *irrelevant*.

6.2.3 Why relevant WriteGuards prevent delayed writes

Relevant WriteGuards prevent delayed writes since once a new owner creates a GuardHandle, its relevant WriteGuard is installed strictly after all relevant WriteGuards from prior owners. Furthermore by the *unique-valued* rule for WriteGuard values (rule 3), all WriteGuards in storage (relevant or not) are unique. Thus any delayed write from a previous owner has a WriteGuard that cannot match the new owner's relevant WriteGuard, so such writes are rejected. This guarantees that all future reads by the new owner are protected.

6.3 Handling writes and reads

We now present the handling of write (Algorithm 2) and read operations (Algorithm 3).

6.3.1 Write operations

Upon a write to K, CLINK rejects the request if the WriteGuard is missing or ownership is lost (lines 2–6). The latter is an optimization, as the write would likely fail anyway due to the new owner's WriteGuard. CLINK then evicts K to preserve LSI, as the pending write renders the storage value unknown. Finally, it flags pending operations as overlapping (lines 8–9) and sets the request's *writeOverlap* bit if another write is in flight (line 10). Figure 8 phase (b) shows the case of a write for C_{43} which overlaps for a read for the same key and thus sets the read operation's *writeOverlap* bit, causing the result of the read to be uncacheable (see §6.3.3).

Algorithm 2 Write Operation (Red means critical section)

```
1:  procedure WRITE(K, V)
2:    if GuardMap[K] is empty then
3:      return error              ▷ Reject: no WriteGuard protection
4:    guardHandle ← GuardMap[K]
5:    if not ISSTILLASSIGNED(guardHandle.SliceHandle) then
6:      return error              ▷ Reject: lost continuous ownership
7:    Evict CacheMap[K]           ▷ Writes invalidate the cache
8:    for each op X in OpMap[K] do
9:      X.writeOverlap ← true     ▷ Prior ops overlap w/ write
10:   writeOverlap ← (OpMap[K] contains write?)
11:   opHandle ← OpHandle(WR, writeOverlap, guardHandle)
12:   Add opHandle to OpMap[K]
13:   status, result ← SENDWRITE(K, V)
14:   if status == Success then
15:     CacheMap[K] ← (guardHandle, result)
16:     if not SATISFIESLSI(opHandle) then
17:       Evict CacheMap[K]  ▷ Unsafe value, LSI not guaranteed
18:     return result
19:   else if status == Timeout || WriteGuardMismatch then
20:     if not ISSTILLASSIGNED(guardHandle.SliceHandle) then
21:       return error            ▷ Reject: lost continuous ownership
22:     Clear GuardMap[K]
23:     Install new GuardHandle
24:     Restart at step 1                ▷ retry with fresh guard
25:   else
26:     return error
27: end procedure
```

CLINK then executes the storage write. Successful results are cached only if they satisfy the LSI (lines 15–17). A timeout (line 19) signals a potential self-inflicted delayed write. To resolve this, or if a delayed WriteGuard error occurs, CLINK clears the GuardHandle, installs a fresh guard, and retries if it still owns K (lines 20–24).

6.3.2 Read operations

Read handling differs from writes because reads may be handled by any pod. When a pod owns K and the key is present in the cache, it may serve the cached value as long as ownership has been continuous since the entry was installed (lines 2–5 of the READ procedure). Figure 8 shows a case where C_{45} was read by a pod from storage and later served from the cache since it has continuous ownership and no writes have invalidated the cached value.

If a continuously owned value was not found, CLINK proceeds by evicting any entry if present (line 6) and reads from storage, setting *writeOverlap* if needed (lines 7–11). The result is returned to the caller and cached if it satisfies LSI.

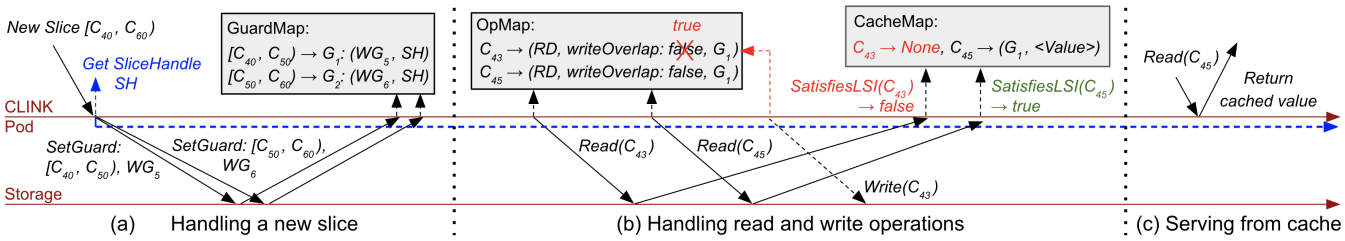

Figure 8: Life of a slice assignment and serving reads and writes in CLINK. Details described in the text.

Algorithm 3 Read Operation (Red means critical section)

```
1:  procedure READ(K)
2:    if CacheMap[K] not empty then
3:      value ← CacheMap[K].value
4:      sliceHandle ← CacheMap[K].GuardHandle.SliceHandle
5:      if ISSTILLASSIGNED(sliceHandle) then return value
6:    Evict CacheMap[K]        ▷ invalidate any stale cached value
7:    writeOverlap ← (OpMap[K] contains write?)
8:    guardHandle ← GuardMap[K] or null
9:    opHandle ← OpHandle(RD, writeOverlap, guardHandle)
10:   Add opHandle to OpMap[K]
11:   result ← SENDREAD(K)
12:   CacheMap[K] ← (guardHandle, result)
13:   if not SATISFIESLSI(opHandle) then
14:     Evict CacheMap[K]      ▷ Unsafe value, LSI not guaranteed
15:   return result
16: end procedure
```

6.3.3 Cacheability

CLINK caches results only if they satisfy LSI. It does this by ensuring no storage mutations occurred during execution. SATISFIESLSI (Algorithm 4) uses the OpHandle to rule out three mutation sources: (1) *previous owners*, by checking for WriteGuard protection (line 3); (2) the *current owner*, by ensuring no writes overlapped (line 4) which is checked with *writeOverlap* and (3) *future owners*, by verifying continuous ownership since WriteGuard installation (line 6). If these conditions hold, the value matches storage and is safe to cache.

Figure 8 phase (b) shows SATISFIESLSI returns false for the read of C_{43} since it was concurrently mutated by the current owner, but SATISFIESLSI returns true for the read of C_{45} (in phase (c)) as it was free of mutations from previous, current, or future owners (was continuously owned).

Algorithm 4 Check for cacheability (Red is critical section)

```
1: procedure SATISFIESLSI(opHandle)
2:   guardHandle ← opHandle.GuardHandle
3:   if guardHandle == null then return false      ▷ prev owner
4:   if opHandle.writeOverlap then return false    ▷ current owner
5:   sliceHandle ← guardHandle.SliceHandle
6:   return ISSTILLASSIGNED(sliceHandle)           ▷ future owner
7: end procedure
```

6.4 Why CLINK serves linearizable reads

In this section, we demonstrate that CLINK guarantees linearizability. Since direct storage reads inherit storage guarantees, we focus on proving that cached reads satisfy LSI. CLINK achieves this by enforcing two invariants:

1. **LSI-at-entry:** The value satisfies LSI upon insertion into the cache.
2. **LSI-at-serve:** The value remains unchanged in storage between insertion and serving.

Algorithms 2 and 3 enforce LSI-at-entry by caching the operation's return value and immediately checking LSI (with `SatisfiesLSI`, Algorithm 4), evicting the entry if the check fails.

To guarantee LSI-at-serve, CLINK employs two mechanisms. First, it evicts cached values on every local write (Algorithm 2, line 7), ruling out mutations by the *current owner*. Second, it verifies continuous ownership before returning a cache hit, ruling out mutations by *future owners* (if the ownership is temporarily transferred to a different owner after the read initiates, the key will not be continuously owned when it returns). Mutations by *previous owners* are already precluded by LSI-at-entry (via WriteGuards). Consequently, any value returned from the cache matches storage, ensuring linearizability.

6.5 Serving reads from multiple pods for scale

To support high-traffic keys, CLINK employs asymmetric replication (§2.3.1). A designated primary handles all writes and maintains the WriteGuard; upon leadership change, a new WriteGuard is installed to reject delayed writes.

Initialization and Ownership: Replicas initialize ranges as *uncacheable*. Once the primary installs an ownership-aligned WriteGuard, it notifies replicas to mark ranges *cacheable* and provides identifiers for the current ownership epoch so they can acquire the correct SliceHandles. Serving reads requires *continuous group ownership*: all pods in the replica set must remain assigned without interruption. Any membership change (notified by the autosharder and detected via SliceHandles) breaks this invariant, forcing replicas to evict cached entries, though reads may proceed directly to storage.

Write Protocol: Writes utilize a two-phase invalidation process. (1) The primary sends invalidation messages; replicas evict the key K and mark it uncacheable. (2) Upon receiving all acknowledgments, the primary writes to storage. (3) The primary sends a finish message (optionally piggybacking the new value), allowing replicas to restore K's cacheability.

Failure Handling: If a write fails, the finish message restores cacheability. Timeouts trigger a new WriteGuard installation and retry (§6.3.1). If membership changes mid-protocol, Assignment Consistency (§2.3.1) ensures replicas detect the loss of group ownership and drop the corresponding ranges and mark the range uncacheable. Because resharding is infrequent, this simple rule is sufficient.

This design significantly increases read throughput and availability. While invalidating replicas adds slight write latency (§9.5), the impact on write availability is negligible due to the rarity of crashes (§2.3.2) and the auto-sharder's rapid removal of unhealthy pods (§2.3.1).

6.6 Potential Optimizations

CLINK admits several future optimizations. First, request gating can buffer repeated reads on the same key so that only one storage fetch is issued. Second, storing value versions in the cache would enable finer cachability decisions. For example, if concurrent writes produce v_8 and v_9 while the cache holds v_7, CLINK currently caches neither; checking versions would allow safely caching v_9. Third, when a write fails, CLINK could install a new WriteGuard for only the affected key instead of the entire key range, though this risks creating many entries in the GuardMap. Finally, tagging reads with their WriteGuard would allow early detection of guard changes in storage (e.g., after a delayed SetGuard call), enabling timely refreshes.

7 CRINK: Strongly consistent remote caches

While CLINK provides linearizable reads at local memory latency, there are cases where a remote cache is the better fit. First, some environments cannot host stateful components because of serverless or stateless runtimes, memory limits, or operational restrictions. Second, service owners generally avoid exposing internal schemas, which means any shared dataset must be served through the owning service's API, forcing that service to scale just to proxy reads. Third, some workloads do not shard cleanly. A single request may touch multiple keys, and forwarding these fanout RPCs through the owning service is undesirable [83].

A remote cache sidesteps these issues. The owning service retains exclusive control of writes and schema evolution while the cache absorbs read traffic, improving latency, increasing read throughput, and reducing demand on storage. A platform team can even operate this tier as shared infrastructure, though the owning service must grant it controlled read/write access.

We present a remote cache CRINK (Consistent Remote In-memory Key-value cache) with two possible architectures, CRINK-R and CRINK-L. Like other remote caches they cannot match CLINK's performance because each access incurs network transfer, serialization overheads, and overreads [8]. They do, however, provide strong consistency, which traditional lookaside caches do not.

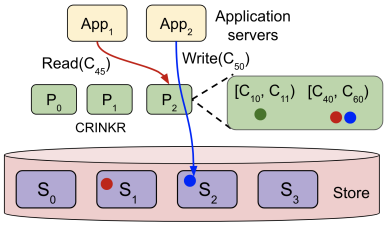

Figure 9: CRINK-R: Remote deployment of CLINK. CRINK-R is a sharded strongly consistent remote write-through cache.

7.1 CRINK-R

CRINK-R (CRINK - Regular) deploys the CLINK architecture as a standalone caching service using a write-through pattern. It retains the auto-sharder and WriteGuard mechanisms to enforce ownership and consistency. Writes flow through CRINK-R to storage, and subsequent reads are served from memory. This setup runs CLINK out-of-process and allows downstream services to share a strongly consistent cache. Figure 9 shows an application writing key C_{50} through CRINK-R and reading C_{45} from the cache.

7.2 CRINK-L

CRINK-L (CRINK - Layered) decouples consistency metadata from value storage (Figure 10). A lightweight *version service* maintains auto-sharded assignment consistency while values reside in a generic lookaside cache like Redis that need not be consistent.

For reads the client queries both the version service and the cache in parallel. Once both fetches complete, if the versions match then it returns the cached value, as with C_{45} in Figure 10. If they differ it falls back to storage and may refresh the cache. For writes the client commits through the version service and pushes the value to the cache asynchronously, as with C_{50} in Figure 10. Any delay in this propagation is harmless because a version mismatch always triggers a storage read. A small client library can hide these details from applications.

CRINK-L improves on the monolithic CRINK-R design by enabling *independent scaling*, *layered consistency*, and *flexible consistency*. Independent scaling lets the value cache (e.g., Redis) replicate for scale while a separate service supplies small consistent versions. Because the approach is layered, it can add linearizability to existing eventually consistent caches. It is flexible since it allows applications to read from the cache for eventual consistency or consult the version service for

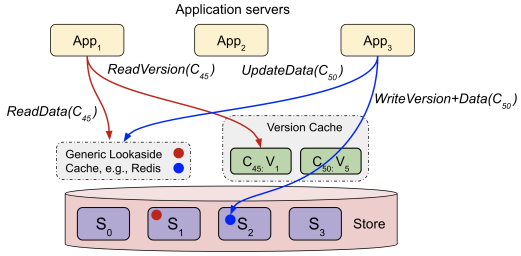

Figure 10: CRINK-L: The version service maintains consistent versions, while values reside in an ordinary lookaside cache.

linearizability. Note that Chrono offers similar capabilities but has several issues including temporary blocking of cached reads after each write (§4.2).

8 System implementation

Auto-sharder with strong ownership: We implemented an auto-sharder with strong ownership, inspired by Centrifuge [7]. When an assignment changes, the previous owner explicitly relinquishes its lease to ensure consistent transitions. The auto-sharder supports asymmetric replication as discussed in §2.3.1. It guarantees that all pods agree on the assignments; it supports the API to check continuous assignment of a key at the application pod without coordination with the auto-sharder. The assigner logic is implemented in about 12000 lines of Scala.

Cache: The cache is implemented in approximately 6000 lines of C++. We implemented the protocols and the data structures described in §6, i.e., GuardMap, CacheMap and OpMap. Storage splitpoints are obtained by periodically probing the underlying storage system (TiDB). We implement CLINK, CRINK-R, and CRINK-L as described above.

Storage: We used TiDB [44] as a representative distributed database. TiKV is the storage engine that TiDB uses. We add a new API (SetGuard) to TiDB (Version 7.5.1). The TiDB placement driver (PD) is responsible for splitting and migrating key ranges that are stored on TiKV. We modified TiDB (↑ 717 lines of Rust for TiKV, ↑ 229 lines of Go for TiDB SQL layer, and ↑ 57 lines of Go for PD) to add the support for WriteGuard installation and checking. WriteGuards are implemented as in-memory state, and are cleared upon storage pod restart or failure without affecting correctness. The entire TiDB modification took roughly 1 person-month, showing that changes are fast and lightweight.

9 Evaluation

Our evaluation addresses four questions:

- **Per-core throughput:** Does CLINK scale per-pod? *Our unoptimized prototype reaches about 1M ops per core.*
- **WriteGuard overhead:** What latency and throughput cost do WriteGuards introduce? *WriteGuards add negligible overhead.*
- **Read performance:** How do CLINK and CRINK compare to other strongly consistent caches? CLINK *reduces read tail latency by three orders of magnitude, and* CRINK *improves tail latency by* 2.2–2.4×.
- **Multi-replica writes:** What is the cost of serving a hot key from multiple pods? *Additional replicas introduce modest coordination overhead on writes.*

9.1 Methodology

Experimental setup All experiments run on production clusters. For storage, we use 9 TiKV pods, 6 TiDB pods, and 3 PD pods. Each TiKV pod is provisioned with 15GB of memory and 30 vCPUs. We use 6 pods for application servers, each is provisioned with 16 vCPUs and 16GB of memory. As is the case in most prior work [10, 36, 37, 47, 54, 60, 67, 68, 85, 91, 98–100], we measure latency from the application server's perspective which is using the cache. The internal cluster runs on cloud networks with single-digit-millisecond latency.

Workloads We evaluate CLINK and CRINK using public Meta [5, 15] and Twitter [88] traces, plus an internal Unity Catalog (UC) production trace. While Meta and Twitter are simple key-value workloads, Unity Catalog reflects a complex serving workload where each request requires 6–8 storage fetches to compose the value. The traces differ significantly in read-write ratios and object sizes: Meta is ≈70% reads with ≈ 10B median values; Twitter varies from read-heavy (82–99%) to write-heavy (31–50%) with 230B values; and Unity Catalog is read-heavy (99.4%) with large ≈ 23KB values. We present performance comparisons across all three traces in §9.4.1. Due to space constraints, the remaining focused evaluations use only Unity Catalog and synthetic workloads.

Baselines We compare our linked (CLINK) and remote (CRINK-R, CRINK-L) caches against several baselines. Chrono [81] (§4.2) uses the 5s attempt timestamp given in [81]. *Version* performs a storage version check on every read, while *Storage* accesses the underlying store directly.

9.2 CLINK throughput

We measured CLINK's throughput as we increased the number of cores. Figure 11a shows that CLINK scales near linearly, sustaining approximately one million read operations per second per core, reaching 22.8 million QPS at 24 cores. Because all reads come directly from memory and require no cross-machine coordination, throughput grows proportionally with available CPUs.

Our throughput results are not intended to represent state-of-the-art cache performance. The prototype focuses on validating the WriteGuard primitive rather than maximizing raw efficiency, so it omits optimizations such as lock-free indexing, advanced eviction strategies, CPU-cache-optimized data layouts, and kernel-bypass or co-designed network stacks [10,24,57,60,61,91]. Even without these techniques, CLINK achieves reasonable CPU performance, and the experiments below show that caches using WriteGuards can provide practical and efficient linearizable reads without the penalties of prior approaches.

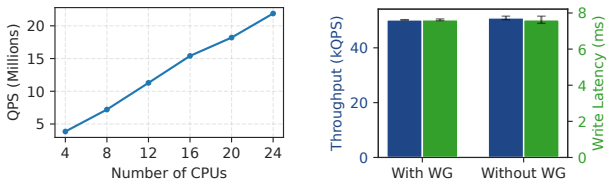

Figure 11: (a) Throughput scalability of CLINK over increasing number of CPU cores (b) Overhead of WriteGuards (WG) on the storage layer, comparing both the throughput (kQPS) and the write latency (ms).

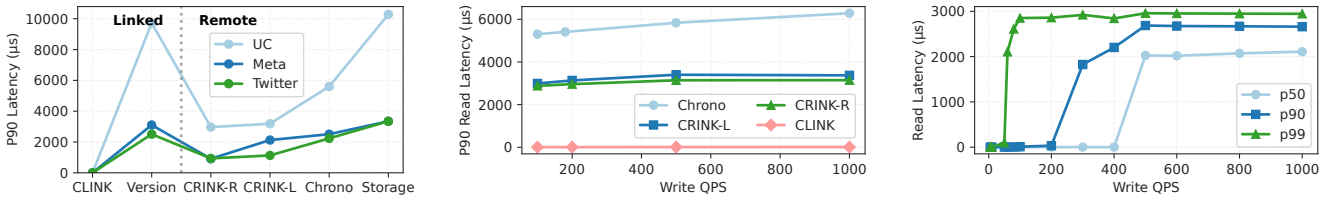

Figure 12: Read latency analysis. (a) P90 read latency comparison across Unity Catalog (UC), Meta, and Twitter traces, comparing both the linked and remote deployments. (b) Performance comparison of CLINK against baselines with increasing write QPS over Unity Catalog traces. We adjust the write QPS by converting reads to writes in the trace. (c) CLINK read latency over a synthetic workload of increasing write QPS on *a single key* to stress test the impact on read latency.

9.3 Overhead of WriteGuards

To quantify the overhead of WriteGuards in the storage layer, we measured throughput and latency under a write-only workload designed to maximally stress the WriteGuard mechanism. Figure 11b presents the throughput and latency results at 75% storage layer CPU utilization. We observe that neither throughput nor latency is adversely affected by WriteGuards, as they introduce only a lightweight conditional check. Furthermore, SetGuard operations occur per *assignment* change (which is infrequent, as shown in Figure 14) rather than per write, thereby imposing minimal overhead on the storage layer.

9.4 Read latency evaluation

We now compare CLINK and CRINK against existing solutions, and analyze how write traffic and resharding affect read latency.

9.4.1 Performance on production traces

Figure 12a summarizes steady-state read latency. We omit P_{50} latency, as it follows a similar trend, and P_{99} latency, which primarily reflects cache misses. Across all systems and percentiles, CLINK demonstrates the lowest latency (P_{90} of 0.5μs–4.2μs), remaining well below remote caches and significantly outperforming Storage (P_{90} of 4.8ms–10.3ms). Version (P_{90} of 3.3 ms-9.0 ms) offers only marginal improvement over Storage, as the latency is dominated by the overhead of accessing storage. By storing values in the application address space and leveraging WriteGuards to bypass coordination on the read path, CLINK achieves latencies orders of magnitude lower than the alternatives.

For remote caching architectures, Figure 12a demonstrates that CRINK-R/CRINK-L (P_{90} of 0.65ms–3.2ms) outperform Chrono (P_{90} of 2.3ms–5.5ms) across all workloads. This performance gap arises because Chrono writes use an attempt timestamp 5s in the future (the default recommended in [81]), preventing reads from being served from the cache for that duration after every write. Our measurements show that Chrono has a lower hit rate due to this; consequently, its P_{90} latency partially reflects storage access times. Chrono also adds additional latency on every read and write path, by requiring a concurrent timestamp check to the remote Chrono service that tracks timestamp bound per-key, adding some variability to read latency.

9.4.2 Sensitivity to write traffic

We next measure read latency sensitivity to write traffic. Figure 12b varies write QPS for the Unity Catalog trace (by converting reads to writes in the trace), comparing CLINK against CRINK-R, CRINK-L, and Chrono. Latency remains stable as in-flight writes increase, except for Chrono, where frequent timestamp updates narrow the cacheable read window. Since writes are distributed and few keys see high write QPS, the overall impact on read latency is minor.

Figure 12c shows an adversarial microbenchmark for CLINK varying concurrent write QPS on a single key. Since CLINK prevents cache population during writes, latencies rise to storage levels (2ms–2.8ms) when hit rates drop below the target percentile. Specifically, P_{99} spikes at 80 write QPS, while P_{90} and P_{50} spike at 200 and 400 QPS. These thresholds significantly exceed observed production rates for write QPS on a single key.

9.4.3 Sensitivity to resharding

Figure 13a shows that even during resharding events (with 0.5% traffic churn), CLINK maintains 100% availability and low latency. This is because key assignment is adjusted quickly (< 20 ms, small enough for retries to succeed), which results in negligible impact on read latency and availability. Figure 14 shows the percentage of load moved per minute for load balancing purposes for three production services, indicating that churn is typically < 0.2%. This means that resharding and the subsequent SetGuard operations triggered for the newly assigned slices have negligible impact on read latency.

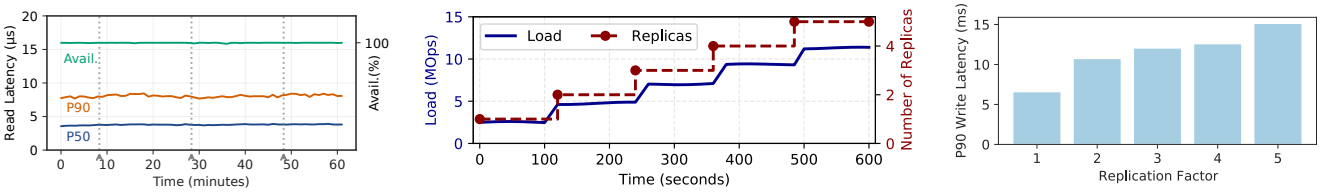

Figure 13: CLINK characteristics. (a) CLINK maintains high availability and low latency during resharding events. (b) the auto-sharder increases replicas as load increases. (c) more replicas increases write tail latency by a small amount.

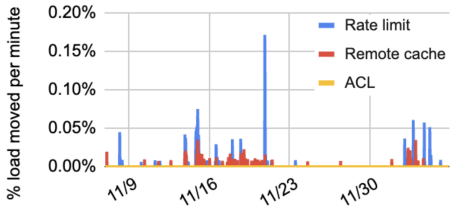

Figure 14: Minimal churn observed in practice. Figure shows the percentage of load moved per minute for load balancing over 30 days for 3 critical services.

Similarly, upon rolling restart, the auto-sharder can proactively migrate the slices to the new pod with state transfer between old and new pod [53], ensuring minimal impact on latency.

Depending on the workload, the storage layer (e.g., TiDB) may also undergo resharding (Figure 15). However, the impact on service availability and write latency is negligible, as WriteGuards are preserved across ownership changes (§6.2.1).

9.5 Asymmetric replication

CLINK manages hot keys by first *isolating* the target key on a single pod, then asymmetrically replicating it across additional pods when load exceeds the capacity of a single pod. Figure 13b demonstrates the auto-sharder dynamically adding replicas as the read QPS increases. Figure 13c shows that write latency increases only modestly with additional replicas due to coordination overhead. We artificially lowered pod capacity for this experiment, as triggering 5 replicas on standard 16-core pods normally requires 80M+ QPS on a single key. Note that though 5 replicas incurs some overhead for writes, in our experience such workloads are dominated almost entirely by reads.

10 Related Work

To the best of our knowledge, loosely coupled caches that provide linearizable reads of state in storage remain largely unexplored. We summarize the most relevant approaches below.

10.1 Strongly consistent caches

The primary systems that support linearizable cached reads are Chrono [81] and Chubby [20]. Chubby introduces tight coupling, and per-key leases limit scalability. Chrono is remote, requires an additional round trip on each operation, and blocks cached reads for a period after every write.

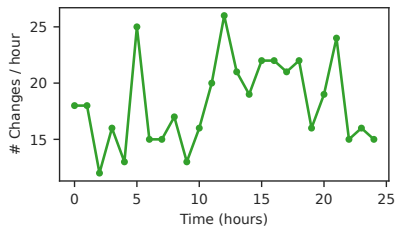

Figure 15: Frequency of resharding events in the TiDB storage layer. The changes capture either the addition or removal of at least one shard. This shows resharding happens over tens of minutes of granularity.

10.1.1 Chrono

Chrono [81] provides linearizable reads from a remote cache by tracking, for each key, an upper bound on the commit timestamps that could have been assigned by the storage system, and then using storage-provided read timestamps to determine whether a cached value is guaranteed to reflect the latest possible write. Chrono assumes an underlying storage system with two properties. First, the storage system must support specifying maximum commit timestamp bounds on writes. Second, it must return read timestamps on reads that respect transaction ordering and that track current time.

More specifically, to perform a write, a client first proposes a new maximum commit timestamp bound for the key to Chrono. If the proposed bound is greater than the current bound, Chrono accepts it and the client issues the write to storage tagged with that bound. The storage system processes the write only if it can assign the write a commit timestamp less than the provided bound.

The cache stores values read from storage together with their corresponding read timestamps. On a cache lookup, clients read both the cached value and the latest timestamp bound for the key from Chrono in parallel. If the cached value's read timestamp is greater than the latest bound returned by Chrono, the cached value is guaranteed to reflect all writes that completed before the read began, and is therefore linearizable. Otherwise, linearizability cannot be guaranteed from the cache and the read must be served by the storage layer.

This design has several drawbacks. First, unlike CLINK, the cache is remote, so all accesses incur remote cache latency. Second, clients must choose write timestamp bounds far enough into the future for writes to succeed, but larger bounds delay when storage reads become cacheable. For example, with the recommended threshold of 5 seconds, a write on a key K prevents cached reads of K for the next 5 seconds; any write rate higher than one every 50 seconds on a key yields a hit rate under 90%. Third, both reads and writes require an extra round trip to Chrono, adding latency and creating an additional availability dependency. Finally, the storage layer must support rejecting writes that exceed a maximum timestamp and must return read timestamps that are guaranteed to be greater than the last committed write. We believe these requirements are more invasive than our WriteGuard approach.

10.1.2 Synchronous invalidation (e.g. Chubby)

Another approach to strong consistency relies on reader leases and synchronous invalidation such as those provided by Chubby [20]. In such systems, a cache pod may serve a cached value only while it holds a lease for the corresponding key or object. Before committing a write, the storage system must synchronously revoke or invalidate all outstanding reader leases to ensure that no cache can subsequently serve stale data.

This approach tightly couples the cache and storage layers because the storage system must track cache ownership and coordinate invalidations across cache instances. It also scales

poorly for distributed caches serving millions to billions of keys, as the storage system must maintain lease state for every cached key. In discussions with Chubby production engineers, we learned that synchronous invalidations increased load on the service because writes were forced to wait for lease recalls and invalidation acknowledgements. Slow, stalled, or crashed clients could delay writes until lease expiration, leading to high write tail latency and reduced throughput. To the best of our knowledge, no modern *general-purpose* scalable storage system exposes distributed reader leases or synchronous invalidation as a client-facing primitive.

Note that CLINK also uses synchronous invalidation when a hot key is replicated across multiple pods (§6.5). However, unlike lease-recall schemes that apply broadly across all keys, this mechanism is used only for the small subset of hot keys that require replication, substantially reducing the amount of coordination required in practice. In addition, invalidations are exchanged directly between application pods, rather than requiring the storage system to participate in lease recall from application servers.

10.2 Storage-layer caches

Many storage systems natively support automatic block or row caching of popular tables and rows for fast lookups [32, 45, 56, 69, 73–75, 86]. While such caches provide linearizable reads, the storage layer quickly becomes a performance bottleneck [88, 92, 93], causing practitioners to explore solutions based on external caches.

10.3 Caches with weak read consistency

Many caches [11, 13, 16, 18, 23, 27, 28, 33, 40, 42, 48, 65, 71, 78, 87, 89, 92, 94] are based on TTLs, providing eventually-consistent and not linearizable reads. Cache invalidation [6, 22, 52, 67, 95, 97] has been explored. However, none of these caches provide linearizable reads. TxCache [70] provides transactional consistency for in process caches by validating cached objects against a central database, but it differs from our approach in several key aspects. First, it does not guarantee that reads return the latest committed value. Second, it is not designed for auto-sharded or dynamically rebalanced systems and therefore does not address correctness under shifting key ownership. Third, it targets a single relational database rather than a distributed, sharded storage layer.

11 Conclusion

This work introduced WriteGuards, a lightweight storage mechanism that prevents delayed writes from previous owners and enables loosely coupled caches to serve linearizable reads from memory. Using this primitive, we presented CLINK, the first in-process datacenter cache that provides linearizable cached reads with low latency, and CRINK-R and CRINK-L, two remote variants that offer the same guarantees for shared and multi-tenant deployments. Our caches are performant: CLINK reduces tail latency of reads by up to three orders of magnitude. CRINK-R and CRINK-L also significantly cut tail latency compared to direct storage access. These results show that linearizable reads at low latency are achievable in large-scale, auto-sharded datacenter services through a simple write-fencing abstraction. We argue that distributed stores should adopt WriteGuards to allow loosely coupled caches such as CLINK and CRINK to serve linearizable reads directly from memory. More broadly, supporting WriteGuards would open the door to a general ecosystem of strongly consistent caches layered on top of these stores.

Acknowledgement

We sincerely thank the anonymous reviewers and our shepherd for their insightful feedback. We also thank Ray Matharu for his assistance in obtaining production workload traces for Unity Catalog, and Ge Gao for his help with TiDB. Abstract. CXL allows multiple hosts to share memory. However, the hardware is expected to provide cache coherence only for a small region of CXL memory and it is difficult for hosts to share data in the non-coherent region. Recent work proposes using the small coherent region (SCR) to track coherence metadata and enables coherent and correct sharing of data in the software. We find that this approach suffers from poor performance for large datasets as it cannot fit the metadata in SCR. We propose MEGALON, a new data-sharing approach for CXL that uses a novel split approach, where big but infrequently updated metadata is logically shared via replication, and only small and heavily updated metadata is shared via SCR. This enables MEGALON to support much larger datasets with high performance. MEGALON augments the split approach with novel techniques enabled by a CXL shared log that unlock high performance under many workloads.

1 Introduction

Recent interconnect technologies, like Compute Express Link (CXL) [27, 33, 59, 64], enable *memory sharing* across a group of hosts. This offers an opportunity to build more efficient databases, key-value stores, and object stores that span many hosts and efficiently share data by keeping it in CXL memory and accessing it via CPU loads and stores [10, 18, 19].

Unfortunately, today it is hard for hosts to coherently share data in CXL. This is because, even with the latest CXL versions [18, 19], hardware is expected to provide coherence only for a small part of the CXL memory. Vendors like AMD, Micron, and practitioners alike posit that hardware coherence will be limited to a few hundred MBs of CXL memory, while total CXL memory will span several TBs [10, 26–28, 47, 60]. We call this model the *partly coherent* CXL model, where the CXL memory has a *small coherent region* (SCR) and a *large non-coherent region* (LNR). This coherence model creates a problem for applications: because LNR is not kept cache coherent by the hardware, host processor caches may hold stale values when accessing data, leading to correctness problems.

*Equal contribution.

A natural way to address this problem is to use SCR to provide coherence in software for data in LNR. The actual data objects can be kept in LNR, and their coherence can be ensured in software by tracking a per-object coherence record in SCR. Software coherence is feasible because coherence needs to be tracked only for coarse-granular application objects (e.g., database rows), not cachelines [27]. To enable hosts to locate data objects and coherence records, a sharing approach must also share an index that maps an object identifier to its location in LNR and its coherence record in SCR. This index can itself be shared via SCR. We refer to the coherence records and index together as metadata, and we call the scheme of relying on the hardware-coherent region to share this metadata across hosts to enable CXL data sharing *hardware-coherent metadata-based sharing*, or HCMeta for short.

HCMeta is the approach used by Tigon [26], a recent CXL database. Tigon is a partitioned database that uses CXL to share data accessed in cross-host transactions. By using CXL instead of message passing, Tigon makes cross-host transactions faster than RDMA-based databases [26]. Tigon keeps the shared database tuples in LNR and provides coherence via a per-tuple coherence record in SCR, with each record also pointing to the tuple's location in LNR. Tigon stores an index in SCR that maps a row key to its coherence record.

A downside of the HCMeta approach is that, with a large number of objects, the metadata (which is essential for correctly sharing data) would not fit in SCR. For example, with a large dataset, the metadata would be two orders of magnitude bigger than the expected SCR capacity (§2.2).

Tigon handles this by limiting the number of CXL-resident objects so that their metadata fits in SCR. When this limit is hit, Tigon *unshares* objects, moving them from CXL to local-DRAM partitions to which those objects belong, and reclaims their SCR metadata space for newly shared objects. When the shared working set is small, Tigon can fit the metadata in SCR, yielding good performance. However, with larger datasets, even low fractions of cross-host transactions increases the total amount of shared data over the course of the workload. This causes churn, where objects are repeatedly unshared and

reshared, which degrades performance. For example, with 20% cross-host transactions, increasing the dataset from 2.4M to 24M objects reduces Tigon's throughput by 10× due to churn and data movement between CXL and DRAM. We also implement HCMeta in a key-value store that keeps partitions in CXL (instead of host-local DRAM). Even when avoiding data movement, HCMeta suffers from poor performance due to churn (§2). Overall, enabling CXL data sharing by relying entirely on hardware coherence for metadata leads to repeated unsharing and resharing, and ultimately poor performance.

This paper thus asks a fundamental question: *How can one share a large number of objects in CXL without unsharing some of them when even the metadata is too big to fit in the hardware-coherent memory?* We answer this with MEGALON, a new data-sharing approach for partly coherent CXL.

MEGALON, like HCMeta, shares data objects via some shared metadata. The metadata in MEGALON consists of an index that maps an object identifier to its coherence record and its location within LNR. The coherence record consists of a lock bit and a counter. At a high level, writes to an object are serialized by the lock and writes increment the counter; reads check the counter to catch intervening writes and detect (and flush) stale processor caches at the host.

The key novelty in MEGALON is its ability to share a large number of objects in CXL without being constrained by SCR capacity. Unlike HCMeta, which relies *entirely* on SCR to share *all* metadata, MEGALON adopts a *split* approach. It observes that the index is large (as it contains object identifiers) but is updated infrequently; in contrast, coherence records are tiny (a lock bit and a counter) but are updated on every object write. Based on this asymmetry, MEGALON splits the metadata: it *logically* shares the index by *replicating* it in each host's local DRAM, while relying on SCR only for keeping the small coherence records, maintaining pointers to them from the replicated index. Because each host has significant DRAM capacity, it can easily fit index replicas even for large datasets. Although replication increases local DRAM usage, each index entry is still small compared to a data object. Since the index changes infrequently, keeping the replicas consistent adds minimal overhead. Meanwhile, placing the frequently updated coherence records in SCR keeps sharing efficient. Overall, by storing only the small, frequently updated parts of metadata in SCR and replicating the rest, the split approach dramatically increases the number of objects that can be shared.

While the split approach enables sharing many objects, MEGALON still needs to solve two big challenges. First, how to maintain the consistency of index replicas? Second, because a coherence record is maintained for every object in SCR, there is still a limit on the number of shared objects. How can MEGALON tackle this limit? The answer to both these challenges is a *shared log* in CXL. The shared log is also central to other optimizations in MEGALON. The shared log is an ordered sequence of entries that hosts can append to and read from. To conserve SCR, MEGALON maintains the log entries in LNR and only the shared-log tail pointer in SCR.

The shared log keeps the index replicas across hosts consistent by ordering all operations to the index. To update the index, a host sequences the update by incrementing the tail and appending the update to the log. To read the index, a host synchronizes its replica with the shared log by checking if the tail has advanced and applying any new entries. It then performs the index read, ensuring consistency.

The shared log also enables MEGALON to increase the number of objects that can be shared by allowing it to *dynamically* allocate and deallocate coherence records. MEGALON first observes that coherence records are unnecessary for objects that are only read (read-shared), and so it *dynamically* allocates them only for objects that are both read and written (read-write-shared). Readers perform coherence checks only if a coherence record exists. Thus, the number of read-shared objects is not bounded by SCR capacity. The number of read-write-shared objects, however, remains limited by SCR. When this limit is hit, MEGALON converts some objects to read-shared by deallocating their coherence records and reallocating them to other objects. These dynamic allocations and deallocations are enabled by the shared log which helps update the pointers to the coherence records consistently in the index replicas.

With dynamic coherence records, coherence records can be allocated and deallocated at any time and MEGALON must still correctly ensure coherence. To solve this, MEGALON uses a novel *dual-path coherence* technique, where it uses the shared log to provide coherence when the coherence records themselves alone cannot. In the first path, when the coherence record's allocation status of an object does not change, the coherence record itself ensures coherence. In the second path, when the allocation status changes, the shared log provides the required coherence. Specifically, hosts detect allocation status changes from the (de)allocation events in the shared log and take necessary actions to ensure coherence (e.g., by flushing CPU caches).

Like HCMeta, MEGALON *does* experience churn to deallocate and allocate coherence records. In fact, any sharing approach that maintains metadata in SCR that is linear in the number of the objects in CXL will incur churns. However, MEGALON pushes the point at which churn happens significantly further than HCMeta. It does so by keeping the index out of SCR and allocating coherence records only for read-write-shared objects. Further, a churn in MEGALON is far cheaper. In HCMeta, when SCR runs out, objects must be unshared. To reshare an unshared object, a host must contact and wait for the owner to share the object. In contrast, MEGALON need not unshare an object but only deallocate the coherence record. Further, the shared log enables efficiently resharing an object in read-write mode: any host can allocate a coherence record without synchronously waiting for other hosts.

The shared log also enables many optimizations. First, it allows shrinking coherence-record counters to just a few bits; when the counter wraps around, MEGALON records the event in

the shared log so that hosts can use them to flush caches and avoid stale reads. Second, the shared log allows MEGALON to support local DRAM partitions, letting hosts store exclusively accessed data in local DRAM and keep only shared objects in CXL. Specifically, MEGALON uses the index to point to local-DRAM locations and moves objects between CXL and host-local DRAM by modifying the index via the shared log.

Results. We have built MEGALON in a CXL-based key-value store and file-system page cache. In read-only workloads, MEGALON improves throughput by 15× over HCMeta for large datasets. Under read-write workloads, MEGALON supports up to 12× larger datasets without churns, improving performance by 4×–10×. Even when MEGALON experiences churns, it improves performance by 2.5×–14.9× as it reduces the number of churns and each churn is 8× cheaper. HCMeta's performance drastically drops with larger keys, whereas MEGALON is unaffected by key size. The shared log allows MEGALON to use smaller coherence records, improving performance by 6.3× over the default coherence-record size. It also enables MEGALON to use host-local DRAM, offering high performance in partitioned workloads. Under YCSB, MEGALON performs 3×–14× better than HCMeta. MEGALON can share a larger page cache, improving performance by 1.9×–5.7×.

Contributions. This paper makes four contributions.

- We propose MEGALON, the first sharing approach for partly coherent CXL that can share a large number of objects.
- MEGALON introduces a novel *split* approach for sharing the metadata, logically sharing the index and relying on hardware coherence only for coherence records.
- MEGALON uses many novel techniques centered around a *shared log*. The shared log keeps the index replicas consistent; it also allows MEGALON to dynamically allocate and deallocate coherence records and do so without synchronously waiting for other hosts; it also enables *dual-path coherence*, where coherence is ensured by the shared log when the coherence records themselves alone cannot.
- We experimentally show MEGALON's benefits.

MEGALON is open-sourced at https://github.com/dassl-uiuc/MEGALON-artifact.

2 Background and Motivation

We describe the partly coherent CXL model and explain the drawbacks of the current approach to sharing in this model.

2.1 Partly Coherent CXL Memory

CXL is an emerging interconnect standard built atop PCIe, using which hosts can access a CXL memory device. With CXL 1.1, a single host can use CXL for memory expansion and access the memory in a cache-coherent manner. With recent CXL 3.0 and CXL 3.2 specifications, *multiple hosts* can share memory on an external CXL device, allowing processors in hosts to issue loads and stores directly on the shared memory. Like any other memory, accesses to CXL memory are optimized through several levels of processor caches. In addition to the shared CXL memory, each host has a local memory not accessible by other hosts. Local memory has substantial capacity (a few 100GBs per host [27]), and it has lower latency and higher bandwidth than CXL memory [27, 33, 56, 64].

While CXL 3.0 and later specifications [18, 19] provide cache coherence in hardware, it is expected that this support will be limited to a small region, while the rest of CXL memory is non-coherent without support for speculative prefetching. Indeed, hardware vendors such as AMD, Micron, and Samsung indicate that hardware-based coherence is practical only for a few hundred MBs, while CXL memory can span several TBs [10, 25–28]. The reason for this limit is that the cache coherence mechanisms (snoop filters and back invalidation) do not scale with increasing memory sizes [10, 25, 26].

We call this model the *partly coherent* model, and refer to the small hardware cache-coherent region as SCR and the large non-coherent region as LNR. This model creates a problem for applications. If an application spanning across hosts shares data in the LNR, the processor caches may hold stale values, resulting in correctness problems. For example, in an object store, one host could update an object, but another host that had previously read that object may read an old value from its processor cache, resulting in a stale object being returned.

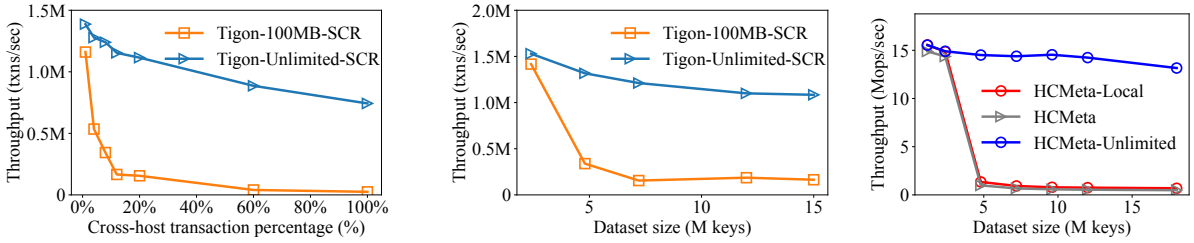
2.2 Sharing Approaches for the Partly Coherent Model

One way to completely sidestep the incoherence problem is to restrict sharing only to the SCR. However, this is impractical given SCR's tiny capacity: applications cannot coherently share more than a few hundred MBs of data simultaneously, which severely limits the utility of shared CXL memory.

Another approach is to allow sharing data in LNR and realize correct and coherent sharing in software by tracking some metadata in the hardware-coherent region. We refer to this general scheme of sharing data in CXL as *hardware-coherent metadata-based sharing* (or HCMeta).

In fact, this is the approach used by Tigon [26]. Tigon is a partitioned database system, where each host has its own partition of the data in the host-local DRAM. A host cannot access the data present in another host's local DRAM. If a transaction at a host accesses a tuple from other partitions (i.e., it is a cross-host transaction), Tigon moves those tuples to CXL memory for sharing across hosts. Thus, cross-host transactions can complete without any network coordination, but with just memory accesses. While Tigon is an ACID compliant database, we focus on its approach to share data in CXL because our goal is to build an efficient data-sharing approach for CXL, and not a specific application like a database.

Tigon realizes correct sharing by keeping the shared tuples in LNR and providing coherence for these tuples via per-tuple coherence information (called HWcc record in Tigon [26, §3.2]) that it stores in SCR. The HWcc record contains a lock and bitmap (one bit per host) that ensures coherence.



(a) Tigon Artifact: Varying Cross-Partition Txns (b) Tigon Artifact: Varying Dataset Size (c) HCMeta in a KV Store

Figure 1: **Drawback of HCMeta** *(a) and (b) show Tigon artifact's performance and (c) shows the performance of HCMeta in a key-value store.*

Specifically, the lock serializes accesses to a tuple. Writers, when updating a tuple, reset the bitmap entries for other hosts. When reading, a reader checks if its bit is set. If so, it can rely on its processor caches to read that tuple; otherwise, its caches are out of date and thus the host flushes the corresponding cachelines and reads the data from CXL and sets its bit in the bitmap. The HWcc record also helps hosts locate the shared tuple in LNR. To allow hosts to locate the HWcc record for a tuple, Tigon maintains an index in SCR, which maps a row key to its HWcc record in SCR. Thus, Tigon, by maintaining metadata (i.e., per-object HWcc record and the index) in SCR, enables correct sharing of data tuples in LNR.

Since systems using the HCMeta approach maintain per-object metadata, with a large number of objects, the metadata would not fit in SCR. For example, in Tigon, with 24-byte keys and 8-byte HWcc records [26, §3.2], metadata would be at least 8GB for a 1TB dataset with 4KB objects, which is roughly two orders of magnitude more than the SCR, which is expected to be a few 100 MBs [10, 27, 28]. HCMeta thus has a limit on the number of objects that can be shared in CXL.

When the SCR limit is hit and no more metadata can be kept in there, HCMeta *unshares* some objects, so that the metadata space can be used for other objects. For example, Tigon moves some objects from CXL to their local partitions in the host-local DRAM. To share an unshared object, a host that wants to access that object contacts the host that owns the partition that the object belongs to. The owner moves the object to CXL and creates a HWcc record and index entry in SCR for it (unsharing other objects in its partition if it needs to make space). After this, other hosts can access the object.

2.3 Drawbacks of HCMeta

When many data objects are shared in a workload, HCMeta incurs a lot of churn to share and unshare objects. Note that the data that needs to be shared at a particular point may be small. For example, in Tigon, only those tuples that are currently being accessed by cross-host transactions need to be present in CXL, which is small [26]. Thus, the metadata to share data at a particular point would fit in SCR. However, over the course of the workload, different data objects need to be shared at different points and the metadata for all of them will not fit in SCR. Thus, some objects need to be unshared so that some other ones can be shared and this happens repeatedly. This churn resulting from unsharing and sharing can significantly degrade performance.

We measure this impact in the publicly available Tigon artifact [58]. Figure 1(a) and (b) show the results. In 1(a), we fix the dataset size to 12M rows. We run the YCSB-based read-only transaction workload from the Tigon paper, where each transaction accesses 10 rows with a skewness factor of 0.7. A transaction can be local (all 10 rows from the local partition) or cross-host (5 from local partition and 5 from remote). We vary the percentage of cross-host transactions and plot Tigon's throughput with an SCR size of 100MB (realistic) or an unlimited SCR (unrealistic). As shown, with few cross-host transactions, both the 100MB-SCR and unlimited-SCR versions perform well. This is because only a small amount of data is shared via CXL and thus there is little churn. However, with a higher percentage of cross-host transactions, there is more data shared over the course of the workload. Thus, the metadata does not fit in the 100MB-SCR, causing churn and reducing its performance compared to an unlimited SCR. Figure 1(b) shows a similar result when varying the dataset size with a fixed cross-host transaction percentage (20%). With small datasets, the metadata fits in SCR and thus Tigon performs well. However, as dataset size increases, the metadata does not fit, causing churns and a steep drop in performance.

Since Tigon is a transactional database, to measure the impact of HCMeta in isolation, we implement the HCMeta scheme in a non-transactional key-value store. We build three variants of this store: (i) where the partition resides on host-local DRAM similar to Tigon (called HCMeta-local), (ii) where partitions reside entirely on CXL, so that only metadata (not data) moves between local DRAM and CXL memory as part of the churn (HCMeta), (iii) a variant of HCMeta with unlimited SCR (HCMeta-Unlimited). Figure 1(c) shows the results for a read-only workload with varying dataset sizes.

First, if the SCR space is unlimited, all metadata fits and thus no churn happens. Thus, the HCMeta-Unlimited variant performs well even as the dataset keeps increasing. However, in HCMeta-local, the metadata does not fit, leading to churn and data movement, which degrades performance. Although HCMeta incurs only metadata movement and performs slightly better than HCMeta-local, as the dataset increases, its performance still drops significantly due to churn.

Summary. Although metadata is critical to enable coherent and correct sharing of CXL data, relying entirely on SCR for sharing metadata leads to churn and poor performance.

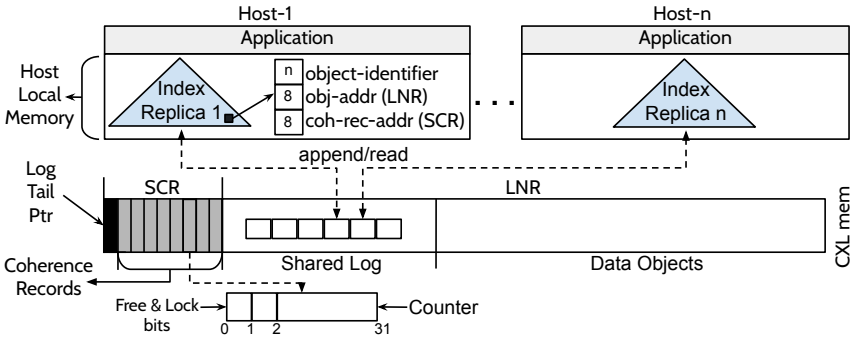


Figure 2: **Split Sharing.** *Each host has a replica of the index in local DRAM; each index entry maps an n-byte object identifier to the object in* LNR *and the object's coherence record in* SCR. *The index replicas are kept consistent via a shared log in CXL (§3.3).*

3 MEGALON Design

MEGALON is a new data-sharing approach for partly coherent CXL memory. It can share many objects without being limited by SCR. We first describe what metadata MEGALON maintains to let hosts coherently share objects and locate them (§3.1). We then explain its novel split approach, which shares only coherence records via SCR and the index via replication (§3.2). Next, we describe how a shared log enables consistency of index replicas (§3.3). We then explain how shared-log-enabled dynamic coherence records allow sharing more objects and how dual-path coherence ensures coherence via either coherence records or the shared log (§3.4). Finally, we discuss how the shared log enables optimizations like compressing coherence records and local-DRAM partitions (§3.5).

3.1 Shared Metadata

Like HCMeta, MEGALON also shares metadata across hosts to enable correct, coherent sharing of data objects. Like HCMeta, MEGALON tracks coherence for coarse-grained (1KB – 4KB) data objects like database rows, key-value pairs, object-store blobs, and file pages (and not cachelines). To ensure coherence of data objects in LNR, MEGALON maintains a *coherence record* per object, that consists of a lock bit, a free bit, and a counter. It also maintains an index that maps each object identifier to its location in LNR and its coherence record.

For coherence of data objects, one must ensure the *single writer or multiple readers (SWMR)* and *data-value* invariants [54, §2.4]. SWMR requires that for each data object, at any time, either a single writer may write it, or some number of readers may read it. The data-value invariant requires that the latest write to an object is visible to subsequent readers.

MEGALON ensures SWMR as follows. When a write to an object starts, the host performing the write sets the lock bit, increments the counter, and performs the write to LNR. It then increments the counter again and clears the lock bit. For a read, the host first notes the counter value as $c1$, reads the data from LNR, then notes the counter value again as $c2$. If $c2$ is odd or $c1$ and $c2$ are not equal, the reader detects an intervening write and retries the read (after flushing the CPU cache lines of the data object). Since writes are serialized by the lock bit and reads cannot succeed with intervening writes, the coherence record ensures SWMR. This mechanism is similar to how sequence locks work [52].

To maintain the data-value invariant, MEGALON keeps a *host-side* counter for each object a host has successfully read. To ensure that reads do not see stale data in CXL memory, upon every write, a host flushes its CPU caches; the host does so after the write to the object but before incrementing the counter the second time. Before reading from LNR, a reader checks whether its host-side counter matches $c1$ (from above). If they match, it proceeds with the read; otherwise, its CPU cache is stale, so it flushes the object's cache lines and then reads. If both the SWMR and the data-value invariant checks pass, the read succeeds. The reader then updates its host-side counter of the object to the post-read counter value $c2$.

A host performing a read or a write first looks up the index to locate the object in LNR and access its coherence record. It then performs the read or write as described above.

3.2 Split Metadata Sharing Approach

The previous subsection explained how the shared metadata across hosts enables MEGALON to coherently share data objects and correctly locate them. We now discuss how MEGALON consistently shares the metadata itself across hosts. Relying purely on SCR limits the number of data objects that can shared in CXL, leading to churn and low performance (§2.3).

To enable sharing a large number of objects, MEGALON proposes a novel *split metadata sharing* approach that is not constrained by SCR. The key insight is to split the metadata into two parts: (1) a small but frequently updated part, which is shared using hardware coherence, and (2) a large but infrequently updated part, which is shared using other means. MEGALON *physically* shares only coherence records via SCR and *logically* shares the index by *replicating* it in each host's local-DRAM. The index maps object identifiers to their data locations in LNR and their coherence-record locations in SCR. Figure 2 shows the split-sharing idea.

The rationale behind the split approach is as follows. First, since the coherence records are small (just lock and free bits and a counter per record), they can be maintained in SCR even for a large number of objects. Further, because they are fre-

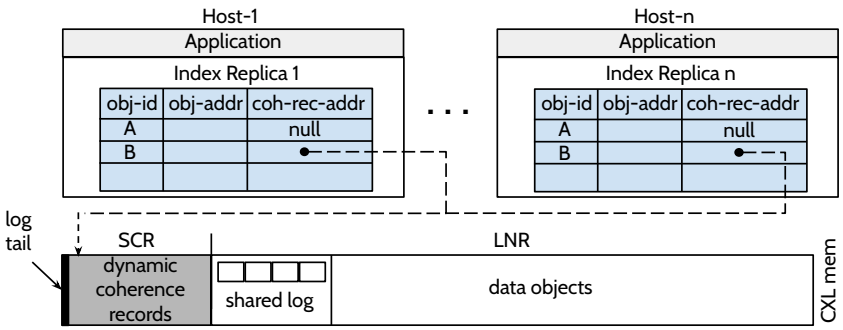

Figure 3: **Dynamic Coherence Records.** *B is read-write shared and thus has a coherence record allocated, while A does not.*

quently updated (on every object write), sharing them via the hardware-provided cache-coherent region is more efficient. Second, the index is large because it contains object identifiers as keys, which can be much larger compared to coherence records. For example, keys can be as large as 50 bytes [14], whereas coherence records are just 4 bytes. Thus, the index cannot be contained in SCR. While SCR is too small (a few 100 MBs) to fit the index, each host locally has considerable amounts of DRAM (a few 100 GBs), which is 1000× bigger than the SCR. This allows the index to fit within every host's local-DRAM even with large datasets. While replication increases local-memory footprint, each index entry is still much smaller compared to the coarse-granular data object. For example, a 50-byte index entry is 80× smaller than 4KB objects. Further, compared to coherence records that are updated on every write, the index is modified less frequently (e.g., when a new object is inserted). Thus, maintaining the consistency of index replicas can be done with little overhead.

Overall, by keeping only coherence records (not the index) in SCR, the split approach significantly increases the number of objects that be shared. Consider a 100MB SCR, 40-byte keys, and 4-byte coherence records. The split approach can share ∼25M objects. The HCMeta approach requires 52 bytes (as it also stores two 4-byte pointers, one to point to coherence record and the other to the object in LNR) in SCR per object. Thus, it can share only 1.9M objects, an order of magnitude less than the split approach. As a result, with large datasets, MEGALON offers much higher performance than HCMeta. Although MEGALON adds local-DRAM memory overhead for replicating the index, it is a small cost to pay for the outsized performance improvements it brings, as we show later (§6.6).

In addition to reducing SCR usage, the replicated index also offers two benefits over keeping the index in SCR. First, it improves latency because index accesses are in local memory. Second, it offers better scalability because each host has its own copy of the index and thus leads to less contention than synchronizing on a shared index in SCR.

Why not logically replicate all metadata? One might consider logically replicating all metadata, including coherence records, so as to not be limited by SCR capacity. Unfortunately, this approach requires synchronizing the replicas for coherence records across hosts, which is expensive because they are frequently updated. The split approach avoids this overhead by physically sharing coherence records via SCR and thus taking advantage of hardware cache coherence for them. We showcase the benefits of the split approach over pure logical replication in our evaluation (§6.10).

Challenges. Although the split approach pushes the limit on how many objects can be shared, MEGALON still faces two major challenges. First, MEGALON must keep the index replicas consistent across hosts. Second, because split sharing requires a coherence record for every object, the total number of shareable objects remains constrained by SCR capacity. The solution to both challenges is a *shared log* in CXL. This shared log also underpins several optimizations in MEGALON.

3.3 Index Consistency atop Shared Log

One way to realize consistency of index replicas across hosts is to use state-machine replication [50] via consensus [31, 37]. However, this incurs significant overhead as it requires software coordination via message passing. MEGALON, instead, takes inspiration from Node Replication [13] and shared logs [6, 7], which consistently replicate data structures using a log. MEGALON adapts this idea to ensure consistency of index replicas via a shared log in CXL that orders all operations on the index.

The log consists of an array of entries and a *log tail*. When a host intends to update the index (e.g., to insert an object), the host performs the update through the shared log. It first reserves a new entry in the log by advancing the log tail via a compare-and-swap operation; it then logs the operation in the new entry. The host then applies all entries up to the tail to its local index replica, after which the update completes. Local reads of index at replicas are guaranteed to be consistent because, before a local read, the host does a *tail check*: it checks if it has applied all entries up to the current tail; if not, it replays all entries up to the current tail to bring the local replica up-to-date. The shared log avoids message passing across hosts to agree on the index. The shared log also eschews synchronous cross-host software coordination, as hosts can independently append to and synchronize with the log.

To minimize SCR use, MEGALON stores log entries in LNR

and keeps only the log tail in SCR (see Figure 2). MEGALON bypasses CPU caches when reading log entries, so coherence is not a concern. CPU caches anyway offer little benefit because log entries are read sequentially. When writing a log entry, hosts flush it to CXL. Hardware guarantees coherence for the log tail (as it is in SCR), ensuring hosts see the changed tail during tail checks. This prompts them to apply new log updates, keeping index replicas consistent across hosts.

3.4 Dynamic Coherence Records, Dual-Path Coherence

The split approach increases the number of objects that can be shared. However, because it maintains a coherence record for every object, the SCR space still limits the the number of shared objects. To address this problem, MEGALON uses the shared log to *dynamically* allocate and deallocate coherence records. It then uses a novel *dual-path coherence* mechanism, where MEGALON leverages the shared log to enforce coherence when coherence records cannot alone do so.

3.4.1 Dynamic Coherence Records

MEGALON first realizes that if a shared object is only read (read-shared), it does not need a coherence record. Thus, MEGALON does not allocate a coherence record for such an object and the object's index entry does not point to a coherence record. For such objects, a host performing a read skips coherence checks. For example, in Figure 3, when reading object *A*, hosts would skip the coherence checks. MEGALON only maintains coherence records for objects that are being both written and read (read-write-shared); a host performing a read for such objects (e.g., object *B* in Figure 3) will locate the coherence record from the replicated index, and perform coherence checks.

Since MEGALON does not spend any memory in SCR for read-shared objects, the number of read-shared objects is not bound by the SCR. However, SCR space still limits how many objects MEGALON can share in the read-write-shared mode. When this limit is hit, because MEGALON does not require coherence records for read-shared objects, MEGALON *dynamically* converts some read-write-shared objects into read-shared objects. Whenever a write occurs to a read-shared object, MEGALON dynamically allocates the coherence record for it. Thus, by dynamically converting between read-write-shared and read-shared modes, MEGALON can avoid unsharing the object when it hits the SCR space limit (unlike HCMeta).

3.4.2 (De)allocating Coherence Records via Shared Log

All hosts must correctly know whether or not an object has a coherence record. MEGALON ensures this by using the shared log to update the coherence-record pointer in the index.

When an object is created, MEGALON does not allocate a coherence record. A host performing a write first checks the index to see if the coherence record is allocated for the object. If not, the host allocates the coherence record in SCR; it uses the free bit (see Figure 2) to find an unoccupied coherence record and clears the free bit. It then updates the pointer in the index to point to the allocated record via the shared log.

If two hosts race to update the pointer in index, only the first one in log order will succeed. Although both hosts can allocate coherence records independently and both can append their request to the log, only the first request can be successfully applied to the replicated index. This is because, all hosts apply the two operations in the same order from the log. Thus, all hosts will know that the pointer is already set in the index by the first request and thus ignore the second request. When this happens at the host that created the second request, it frees the coherence record it allocated. Note that only the first write transitioning an object to read-write sharing needs to assign a new coherence record for the object, requiring log updates. Subsequent writes are efficient; they simply use the coherence record in SCR without log updates.

Deallocations also happen via the log. Such deallocations happen to make space for allocating coherence records for different objects. Any host can deallocate a coherence record by clearing the pointer in the index through the shared log and then deallocating the corresponding coherence record (setting the free bit) in SCR. This can happen either in the synchronous path when a host cannot find space for allocating a new coherence record or in the background as MEGALON proactively tries to keep some free coherence records.

3.4.3 Dual-Path Coherence

So far, we discussed how MEGALON ensures coherence via coherence records. If coherence records were never deallocated, this mechanism would suffice. However, because coherence records are dynamic, they can be deallocated anytime. To solve this problem, MEGALON uses a scheme for coherence with two paths: one provided by the coherence record (discussed so far) and another enabled by the shared log (discussed below). We first explain why coherence records alone are insufficient. We then explain how the shared log helps.

Why coherence records alone are insufficient? Dynamic coherence records do not pose a problem for writes because a coherence record cannot be deallocated when a write is in progress as the writer holds the lock. However, this is not true for reads. When a read starts, a coherence record may exist for the object but may be deallocated before the read finishes. Conversely, a coherence record may not exist at the beginning of the read but may be allocated before the read completes.

One might handle these cases by checking that the index entry is the same before and after the data read. However, this check is insufficient, because reading the index tells only the current allocation status of the coherence record and not the transitions. For example, suppose an object *A* is in read-shared mode (i.e., coherence record does not exist). A host *i* first checks the index and skips the coherence check and performs the read. During the read from LNR by *i*, another host *j* switches *A* to read-write mode, writes to it, and then switches it back to read-shared mode. If host *i* again checks index after the read, it sees that the object does not have a coherence record and incorrectly skips the coherence check.

Such a transition could also happen after a host reads an object and before the host reads the object again. For example, suppose host *i* reads object *A*, then *A* is switched to read-write mode, written to, and then switched to read-shared mode. If host *i* reads *A* again and skips coherence checks because it does not find the coherence record in the index, it incorrectly reads the object from its (stale) CPU caches.

Thus, a host cannot rely only on the current coherence-record state. It must know if there were any allocation status changes for the coherence record since the host began the current read or the host previously read an object.

Shared-log enabled coherence path. One option to realize this is to synchronously notify all hosts of such events. Specifically, a host that changes the coherence-record status of an object notifies and waits for all other hosts to acknowledge before it changes the status. The other hosts can take necessary actions like flushing their caches before they acknowledge. However, this would significantly increase the overhead to switch between read-shared and read-write-shared modes.

MEGALON's shared log enables a better solution, where the host that switches the sharing mode simply records the event in the shared log. Each host independently detects these events when they replay the shared log. This reduces overhead to switch between modes. This mode switch in MEGALON is akin to the churn in HCMeta. However, the cost of the churn in MEGALON is much lower because the log decouples the hosts.

Thus, the shared-log coherence path works as follows. While replaying the log, if a host finds an allocation or deallocation event, it flushes the CPU caches for the affected objects. Reads after this point do not see stale caches. This mechanism also handles cases where the coherence-record allocation status for an object changes while a read is in progress; hosts simply check if there was a coherence-record status change for that object between the first and second coherence checks. If so, the host retries the read after flushing the cache.

3.4.4 Handling Object Deletions

When an object is deleted, its index entry is removed via the shared log and the LNR memory used by the object is reclaimed. Object deletions, however, introduce challenges to coherence that MEGALON must handle. One challenge is that hosts may be caching the old contents of the memory location of the deleted object. Suppose a reader reads object *A* at some location in LNR, storing its contents in its CPU cache. Then suppose *A* is deleted and another object *B* is allocated at the same location by another host. If the first host tries to read *B*, the host will see *A*'s contents (from its cache), which is incorrect. Similarly, consistency can be violated if such deletions happen while the read is in progress. When a write is in progress, MEGALON prevents changes to the index entry of an object because writers set the lock bit. However, because reads are optimistic, an object can be deleted while the read is in progress. So, MEGALON must detect any changes to the index entry of the object while the read was in progress.

MEGALON handles both these challenges via the shared-log-enabled coherence path. Specifically, since object creations and deletions happen via the shared log, hosts can use those events and correctly flush the caches during replay.

3.4.5 Putting It Altogether: MEGALON Reads and Writes

We now describe how the different pieces of MEGALON work together in the read and write of an object.

Read. To read an object *A*, a host synchronizes the index with the shared log, and reads its local index to find *A*'s LNR location. At this point all new log entries have already been applied on the replica, thus flushing potentially stale cachelines of *A*. If *A* is read-write-shared, the host obtains the counter *c* from the coherence record and compares it with the host-side counter *l*. If they are not equal or *c* is odd, the host flushes the cachelines of *A* and retries the read. This is the *pre-read* check. Pre-read check is not needed if *A* is read-shared. The host then accesses the actual data from LNR. The host then performs *post-read* checks: it checks if there were any log updates concerning *A* or if *A* is read-write-shared and the current counter *c'* is different from the previous value of *c*. If either is true, the host flushes cachelines of *A* and retries the read. After a successful read, the host updates *l* to *c'*.

Write. To write an object *A*, a host synchronizes the index and consults the index entry of *A*. If *A* is read-shared, the host allocates a coherence record for *A* by finding a free coherence record and updates the pointer in the index. If the index update fails, it retries the write. It then acquires the lock bit in the coherence record, and checks if there were any log updates since it initially got the index entry; this is because the index might have been updated after acquiring the entry and before acquiring the lock bit. The host then increments the counter in coherence record *c*. This is the *pre-write* step. The host then updates *A* in LNR. It then performs the *post-write* steps. It flushes the relevant cachelines, pushing the update to CXL memory. The host then increments the counter *c* again and sets host-side counter to *l*. It then finally resets the lock bit.

3.5 Shared-Log-Enabled Optimizations

The shared log also enables other optimizations in MEGALON.

3.5.1 Smaller Coherence Records

The counter in the coherence record is 30 bits. If fewer bits are used, then coherence records for more objects can fit in SCR, which increases the number of objects that can be shared in read-write mode. This improves performance by reducing churn. However, with fewer bits, counters may wrap around and threaten coherence: a host could think that its counter in the host-side metadata is the same as the one in the coherence record, but in reality, the counter has wrapped around; in such cases, the host may incorrectly read its stale CPU caches. The shared log provides a way to handle this issue. When the counter wraps around, MEGALON logs the wrap-around event in the shared log. When hosts replay the log, they see such

events and flush their caches, avoiding stale reads.

3.5.2 Supporting Local Partitions

Another optimization that the shared log enables is local DRAM partitions. Partitioned applications store data in host-local DRAMs and move data to CXL only for sharing across hosts (e.g., Tigon). Such applications perform well under workloads where hosts mostly access data from their own partitions. MEGALON can also support local partitions; it uses the index to point to local-DRAM locations and moves objects between CXL and local DRAM of hosts by modifying the index appropriately via the shared log. Thus, MEGALON can also realize high performance for partitioned workloads. MEGALON decides to move an object to local when n consecutive accesses are from the same host (n is configurable). MEGALON performs the movement by making a copy of the object on local DRAM and updating the index to point to the local copy. The correctness of the movement is also guaranteed by the dual-path coherence mechanism. Consistency of local objects are managed by local reader-writer locks. When a host tries to access an object that is moved to a remote host, it sends a message to the remote host. The remote host brings the object back to CXL by performing the data copy and index update.

3.5.3 Supporting Local Data Copies

MEGALON can also consistently maintain local copies of data, where hosts store copies of an object in the host-local DRAM to avoid CXL accesses. MEGALON supports local data copies by having the index of an object in read-shared mode to point to multiple locations for the same object, one in LNR and others in local DRAM of hosts. MEGALON ensures coherence in the presence of data copies via the shared log. Specifically, when a host writes to an object that has multiple copies, it updates the index to point only to the CXL copy and changes the object to read-write-shared mode through the shared log. This logically invalidates the local copies because MEGALON synchronizes the index with the log tail on any host upon a subsequent read. This allows MEGALON to invalidate the local copies asynchronously without waiting for all hosts to acknowledge the invalidation. We call the variant of MEGALON that replicates objects locally MEGALON-DATA-COPY. MEGALON-DATA-COPY currently uses a simple policy to create local copies: it creates a local copy of an object at a host when the number of read accesses for that object from the host crosses a threshold. HCMeta cannot support local data copies because the index in SCR only tracks one location for each object.

4 Implementation

MEGALON is implemented as a C++ library in ~8K LOC. An application runs across hosts, and on each host, the application links against the MEGALON library. To ease application development, MEGALON library implements the *pre-read* and *post-read* checks and *pre-write* and *post-write* steps in read_start, read_end, write_start, and write_end calls. Applications invoke them before and after the actual read or write operation. It also exposes calls to create and delete objects.

The replicated index on each host is a hashmap with object-id as the key that maps to locations of the object in LNR and coherence record in SCR. MEGALON manages the space where the objects are stored as fixed-size slots. The entry of an object in the index points to the slot where the object lives. MEGALON currently takes the slot size as a compile-time parameter. MEGALON can be easily extended to support variable-sized objects at object creation time by keeping the object size as a field in the logically shared metadata. To support objects that can change size during their lifetime, MEGALON could treat them as delete-then-insert. A better approach to support dynamic object sizes with more efficient memory management is an avenue for future work.

To manage index replicas, MEGALON builds on the open-source Node Replication (NR) implementation [48]. NR can replicate any datastructure across NUMA nodes via a shared log, which occupies 32 MB by default; we treat the index hashmap as the NR datastructure. NR stores the shared log as a circular buffer. Updates to the replicated index are flat-combined [24] within a host and appended by a single thread per host to reduce contention on log tail. On each replica, NR protects the index with a reader-writer lock [13]. Before reading the index, a thread replays the log to bring its replica up to date, applying only fully-written entries and ignoring incomplete ones from concurrent writers. After all the replicas have replayed up to a certain log entry, the log head is safely incremented to recycle the log space. NR does not perform checkpointing since the log is used only for replication not recovery. This aligns well with MEGALON's failure model.

We make several modifications to NR. First, we allocate the log on CXL, with only the log tail and head in SCR, and perform non-temporal accesses to log entries. Second, we modify it to support the shared-log enabled coherence path. Specifically, when a replica replays the log, it flushes the CXL memory addresses of the slot contained in the log entries. Further, we add notifications from the log about events that modify the object (i.e., create, delete, coherence-record (de)allocations). For example, when MEGALON starts a read, it subscribes to such changes to the object; upon read end, MEGALON checks if there was an event, if so, retries the read.

The space for coherence records is fixed at initialization. MEGALON runs a background thread periodically to deallocate coherence records to keep the used ratio below a watermark. We use random sampling and recycle coherence records with the lowest counter (indicating objects with least writes).

As described in §3.5.2, MEGALON's policy to move an object to local DRAM is n consecutive accesses to an object. MEGALON does this by keeping the last access host to an object in LNR and keeps a per-object counter locally for tracking consecutive accesses. Keeping the last access host information

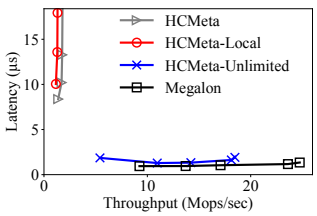

Figure 4: **Read-only Workload**

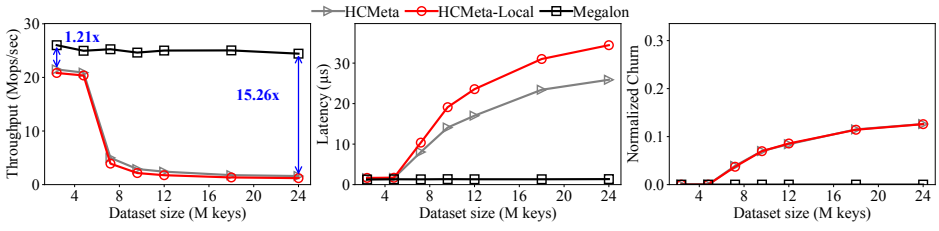


(a) Throughput (b) Latency (c) Churn

Figure 5: **Read-only performance: Growing Dataset Sizes**

in LNR is acceptable because the policy does not need to be precise. False positives can be limited by setting a reasonable *n*. Also, objects can be always brought back to CXL.

We adopt an open-source shared-memory RPC implementation [16] for general communications between hosts, such as requesting a partitioned object to be moved back to CXL. Underneath the RPC implementation, it uses a small pairwise multi-producer multi-consumer (MPMC) queue. Note that the communication method is orthogonal to the design of MEGALON, thus barely optimized. We can easily reduce the memory footprint of the MPMC queue by moving the queue entries to LNR and only keeping the head and tail in SCR. More extremely, we can even use the shared log for communication, which is already on CXL. We leave these optimizations for future work.

Currently, MEGALON is targeted to a system with 8–16 nodes as MEGALON's local memory footprint grows linearly with the number of nodes. To scale to a larger number of nodes, one could explore techniques such as rendering a partial view of the shared metadata to each node, or sharding the shared metadata by adopting multiple shared logs.

5 Applications

KV Store. The KV store exposes a linearizable put-get interface. Each KV pair is a MEGALON object, with the key serving as the object identifier. Put creates or updates the object via create, or write_start and write_end. Get reads the object and returns the value when read_end finishes without errors.

File-system Page Cache. This application treats each file page ([inode, block-number]) as a 4KB-sized MEGALON object. Here, not all data fits in CXL memory and so the application must evict pages to make space for new pages from disk. The application admits a page into the cache by reading it from disk and then calling MEGALON's create. If two threads admit a page, the second create fails. To evict a page, the application calls delete. The application chooses a victim using a per-object count, which is incremented by application threads upon accesses. Access counts need not be accurate, so the application keeps them in LNR. It runs a clock-like algorithm over the pages. The application writes back dirty pages to disk. The application maintains a dirty bit for each object in SCR, which it sets before it calls write_end. A background thread writes back dirty pages. It calls write_start on the dirty page (preventing other writes), flushes the page, clears the dirty bit, and calls write_end. Before a page is switched to read-shared mode, the application flushes the page to disk and clears the dirty bit, ensuring that the page is clean in read-shared mode.

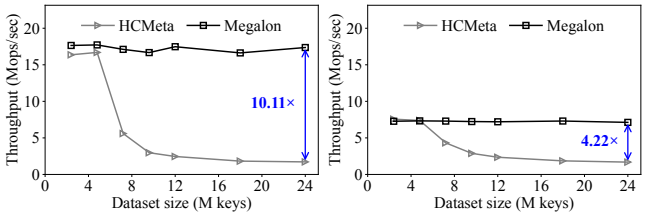
Failure Model. Like Tigon [26, §2], both KV store and page cache assume a fail-stop model. A failure of any host or CXL memory causes the entire system to fail. KV store is in-memory; our current implementation does not implement disk-based checkpointing. Our file-system page cache is disk-based and the file system can recover the state from the disk. Our page cache provides the same guarantees as existing file systems: all fsync-ed writes are guaranteed to be recovered.

6 Evaluation

We ask the following questions in our evaluation:

- How does MEGALON perform in read-only workload? (§6.1)
- How do dataset sizes impact read-only performance? (§6.2)
- How does MEGALON perform in read-write workload? (§6.3)
- How does MEGALON perform in cases where its coherence records do not fit in SCR? (§6.4)
- How does object identifier size affect performance? (§6.5)
- What does MEGALON pay for the higher performance? (§6.6)
- Do smaller coherence records improve performance? (§6.7)
- How do local-DRAM partitions enabled by the shared log help under partitioned workloads? (§6.8)
- How do local data copies enabled by the shared log improve performance? (§6.9)
- How does an approch that logically shares all metadata via replication perform compared to MEGALON's split-sharing approach? (§6.10)
- How does MEGALON perform in YCSB workloads? (§6.11)
- Does MEGALON help the page-cache application? (§6.12)

Setup. CXL 3.0 hardware is not commercially available, so we emulate CXL and hosts on a 4-socket server with Intel Xeon Gold 6418H processors. We designate NUMA node 0 as CXL memory and nodes 1-3 as hosts. Each emulated host has 24 physical cores with hyperthreading disabled and 64GB local DRAM. To approximate CXL latencies, we throttle the uncore frequency of node 0, as in prior work [3]. We distribute threads equally across hosts. We compare against three baselines: HCMeta, HCMeta-local, and HCMeta-Unlimited



(a) 5% write (b) 50% write

Figure 6: **Read-write performance: MEGALON vs. HCMeta**

(described in §2.3). All experiments by default runs on the KV Store application with 1KB objects. Unless stated otherwise, we use 200MB for the SCR (like in Tigon [26]).

6.1 Performance under Read-Only Workload

We first evaluate under a read-only workload with Zipfian access pattern (Zipf parameter 0.99), where most accesses are to some popular objects. We use a dataset of 18M objects. We vary the number of threads and plot throughput and average latency for MEGALON and baselines. Figure 4 shows the result.

As shown, HCMeta and HCMeta-Local do not scale because metadata doesn't fit in SCR at this dataset size, causing excessive churns. HCMeta-Local performs worse than HCMeta due to additional data-copy overhead during churns, but both are ultimately bottlenecked by churn. The performance of HCMeta-Unlimited, which has unlimited SCR, confirms that churn is the bottleneck; with unlimited SCR, it has no churns and achieves high throughput and low latency.

MEGALON's split design keeps the index out of SCR; further, since this is a read-only workload, it does not allocate any coherence records. Thus, MEGALON avoids churn entirely, achieving high performance. MEGALON's throughput exceeds that of HCMeta-Unlimited because accessing the physically shared metadata in HCMeta-Unlimited incurs higher overhead than accessing the local index replicas in MEGALON.

6.2 Read-only Performance with Growing Dataset Sizes

We next examine how dataset size affects performance under read-only workloads. We vary dataset size and measure throughput, latency, and normalized churn (the fraction of operations that incur churn). HCMeta variants churn when they share an unshared object; a churn in HCMeta-local additionally copies the data. In MEGALON, churn occurs when a read-shared object is converted to read-write-shared mode.

As shown in Figure 5, for small datasets, all three systems deliver high throughput and low latency, as seen in the two leftmost points of 5(a) and (b). This is because none of the systems incurs churn, as shown by the two leftmost points in 5(c). MEGALON has a small throughput advantage (about 1.2×) due to lower contention from its locally replicated indexes.

For large datasets, HCMeta and HCMeta-Local suffer from poor throughput and high latency because their churn rises with dataset size. HCMeta-Local has even higher latency due to data-copy overhead. MEGALON is unaffected by dataset size and offers 15× higher throughput because it does not allocate any coherence records in this workload, incurring no churn. Since HCMeta-Local is strictly worse than HCMeta, we omit it from future experiments (except §6.8).

6.3 Performance under Read-Write Workloads

We next compare performance under read-write Zipfian workloads with 5% and 50% writes. In these workloads, MEGALON must convert objects to read-write-shared mode by allocating coherence records. Figure 6 shows the result.

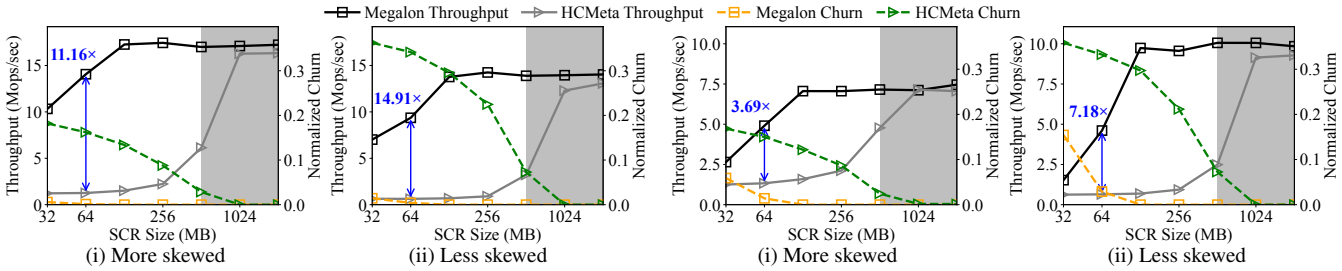
As shown in 6(a), with 5% writes, MEGALON sustains high throughput, while HCMeta's throughput drops significantly due to churn as the dataset grows. MEGALON avoids this drop because its split design uses SCR only for small coherence records, not the index (unlike HCMeta). Thus, even with 24M objects, MEGALON still has ample space left in SCR and incurs no churn, achieving 10× higher throughput than HCMeta. In fact, with a 200MB SCR, MEGALON can hold coherence records for up to 50M objects, which is 12× more than what HCMeta can support without churn. We later examine the case where MEGALON's coherence records no longer fit in SCR (§6.4).

With 50% writes (Figure 6(b)), both systems have lower absolute throughput because more writes cause additional lock contention and cache-line invalidations, reducing performance for both MEGALON and HCMeta. However, MEGALON still offers 4× higher throughput than HCMeta. Overall, even when MEGALON must allocate coherence records in read-write workloads, it still provides significant performance benefit.

6.4 Performance when Coherence Records Do Not Fit

We next examine the case where coherence records don't fit in SCR for MEGALON, causing churn under read-write workloads. Note that read-only workloads incur no churn in MEGALON. Churn frequency is driven by three factors: (1) dataset-to-SCR ratio, (2) write percentage, and (3) access skewness. Thus, we vary the SCR size while fixing the dataset at 18M objects, as well as the workload's write ratio and skewness. We examine two skewness levels (Zipf parameters): 0.99 (more skewed, YCSB default) and 0.7 (less skewed, used in Tigon [26]).

Figure 7(a)(i) shows throughput (left y-axis) and normalized churn (right y-axis) against SCR size for a 5%-write workload with high skew. For unrealistically large SCR sizes greater than 512MB [10, 27, 28] (the grey area), HCMeta performs well because, with such a large SCR, it incurs no churn (shown by the right y-axis). But as SCR becomes realistic (smaller than 512MB), HCMeta's throughput drops sharply. In contrast, MEGALON sustains its throughput until SCR reaches 128MB, which is an 8× smaller footprint than what HCMeta needs for high performance. Below 128MB, coherence records no longer fit, so MEGALON also incurs churn. However, MEGALON incurs far fewer churns because of the low write ratio in this workload. As a result, MEGALON still outperforms HCMeta even when MEGALON experiences churns; for instance, at 64MB SCR, it delivers 11× higher throughput.



(a) 5% write (b) 50% write

Figure 7: **Read-write performance of MEGALON vs. HCMeta with various SCR size**

Figure 7(a)(ii) shows the 5%-write workload with low skew. Because accesses are more uniform in this workload, HCMeta is more likely to access unshared objects and thus exhibits higher normalized churn than in the more skewed case, causing a sharper throughput drop. MEGALON's churn also rises compared to the more skewed workload, but remains far lower than HCMeta's, preserving its performance advantage.

Figure 7(b) presents results for 50% writes. When SCR exceeds 128MB, MEGALON incurs little to no churn; below 128MB, it sees more churn than in the 5%-write case. Thus, MEGALON shows a more pronounced throughput drop, yet still outperforms HCMeta. With low skew, the 50-% write case (7(b)(ii)) is the worst-case workload for MEGALON. However, even in this case, MEGALON continues to deliver much higher performance due to substantially fewer churns.

Churn Overhead. While MEGALON's lower churn frequency leads to higher performance than HCMeta, each churn in MEGALON is also cheaper, further boosting performance. Figure 8 shows MEGALON's lower churn overhead. A churn in MEGALON requires only allocating a coherence record and updating the index. In contrast, a churn in HCMeta occurs when a host accesses an unshared object, which triggers a shared-memory RPC to the host that owns the object. This adds substantial communication and synchronization cost. We also measured the churn overhead of HCMeta in the Tigon artifact [58], and found it be even higher ($\sim$55 μs).

In summary, MEGALON's split design greatly reduces precious SCR usage, allowing much higher throughput with far smaller SCR than HCMeta. Even when coherence records no longer fit, avoiding allocations for read-shared objects lets MEGALON sustain better performance. MEGALON's churns are also cheaper, further contributing to its performance gains.

6.5 Performance vs. Object Key Size

We next evaluate how object-identifier (i.e., key) size influences performance. Using a 4.8M-object dataset, we vary key size from 10 to 90 bytes under a read-only Zipfian workload. Figure 9 shows the throughput. Because HCMeta stores its index in SCR, its SCR footprint grows linearly with key size, leading to more churn and consequently lower throughput for larger keys. In contrast, MEGALON's split design keeps the index out of SCR, so key size does not affect SCR usage. Thus, MEGALON maintains high throughput across all key sizes.

6.6 Local-DRAM Usage and Performance

MEGALON's performance benefits come at the cost of higher local-DRAM usage for replicated indexes. This is justified for two reasons. First, the extra memory for index replicas is modest compared to coarse-granular (e.g., 1KB) objects. Take the 24M dataset point in Figure 5(a); each object has a 24-byte key and 1KB data. MEGALON uses 27.71GB memory, including the replicated indexes, host-side counters, coherence records, the shared log, and the object data. Compared to the 25.76GB footprint of HCMeta, MEGALON requires only 7.6% more memory. Second, the small added memory yields outsized improvements. As shown in 5(a), MEGALON reaches 24.4 MOps/s, achieving 0.88 MOps/s per GB of memory used. HCMeta, however, reaches only 1.6 MOps/s (or 0.062 MOps/s per GB). Thus, for just 7.6% more memory, MEGALON improves absolute performance by 15.25×, achieving 14.19× more throughput per GB of memory spent. With eight hosts, MEGALON's usage would be 33.51GB. Assuming similar performance, MEGALON would still have outsized benefits, offering 12.18× more throughput per GB than HCMeta.

6.7 Performance with Smaller Coherence Records

As shown in Figure 7(b)(ii), with very small SCR (32MB), high write ratios (50%), and less skew, MEGALON's performance drops due to churns. We now examine how making coherence records smaller improves performance for this worst-case workload. MEGALON's shared log enables this optimization: smaller records allow more coherence records to fit in SCR, delaying churn; the log safely handles counter wrap-arounds. We use a dataset of 18M objects and vary the size of coherence records by allocating them fewer bits. Figure 10 shows the result. As shown, throughput increases as we reduce the record size below the 32-bit default. With 8-bit records, throughput matches the maximum seen in Figure 7(b)(ii), as all records now fit in SCR. We observe that reducing below 8 bits hurts performance due to frequent wrap-around log events. Note that we use the default 32-bit records in all experiments; our current implementation does not dynamically pick the optimal size for a workload. However, the shared log provides the fundamental mechanism to explore this optimization.

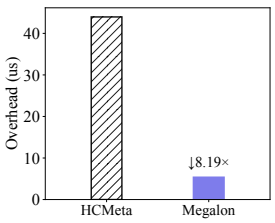


Figure 8: **Overhead of churns**

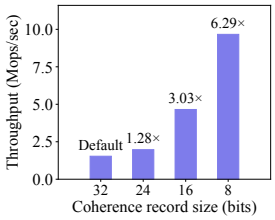

Figure 10: **Smaller coherence records**

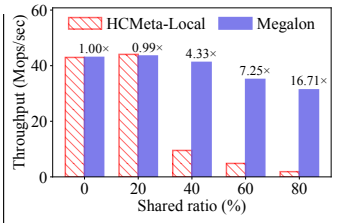

Figure 11: **Throughput vs. shared ratio**

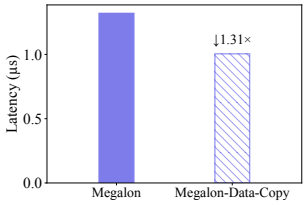

Figure 12: **Local replication**

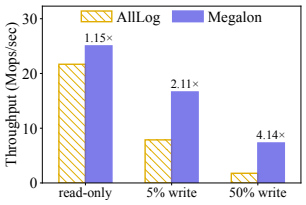

Figure 13: **AllLog variant**

6.8 Performance for Partitioned Workloads

We now evaluate the benefit of the local DRAM partitions enabled by the shared log. We compare MEGALON to HCMeta-Local, which keeps data in host-local DRAM and moves only shared objects in CXL. When hosts mostly access data from their own partitions, HCMeta-Local performs well. Using a read-only Zipfian workload on 18M objects, we vary the shared ratio (i.e., fraction of shared objects). For example, with 20% shared ratio, 20% objects are shared and 80% requests access exclusive data in host-local partitions. As shown in Figure 11, HCMeta-Local performs well at low sharing (0–20%) as it benefits from local DRAM access and little churn due to only small amount of sharing. MEGALON, by enabling local partitions, moves exclusively accessed objects to host-local DRAM and matches HCMeta-Local's performance at low sharing. As sharing increases, HCMeta-Local starts to churn and throughput drops, whereas MEGALON maintains significantly higher throughput by avoiding churns. Overall, by flexibly placing data between local DRAM and CXL, MEGALON matches HCMeta-Local under partitioned workloads and significantly outperforms it as sharing increases.

6.9 Benefit of Replicating Objects Locally

We now evaluate the benefit of replicating data objects locally. We skip comparison to HCMeta because it does not support local data copies as discussed in §3.5.3. We compare MEGALON-DATA-COPY to MEGALON under read-only Zipfian workload on 18M objects. As shown in Figure 12, MEGALON-DATA-COPY achieves 1.3× lower access latency than MEGALON because it avoids CXL accesses by replicating popular objects locally on hosts.

6.10 Performance of AllLog Variant

To showcase the benefit of the split metadata sharing approach, we implement a variant of MEGALON that does not split the metadata into physically shared coherence records and logically replicated indexes. Instead, it replicates all metadata through the shared log. We call this variant, AllLog. In this variant, lock acquisitions and counter increments create log events and are replayed on each metadata replica. We compare MEGALON against AllLog under a Zipfian workload with read-only, 5% writes, and 50% writes over 18M objects. As shown in Figure 13, AllLog performs similar to MEGALON under read-only workload because no locks are acquired or counters are incremented. However, as write ratio increases, AllLog incurs more log events, leading to higher logging overhead and lower throughput than MEGALON. With 50% writes, MEGALON achieves 4.14× higher throughput than AllLog. This demonstrates the benefit of the split approach: by keeping frequently updated metadata (the coherence records) in SCR, MEGALON optimizes performance by avoiding excessive log replays.

6.11 YCSB Macrobenchmark

We next analyze the performance under five YCSB [17] workloads: A (50% w, 50% r), B (5% w, 95% r), C (read-only), D (5% insert, 95% r; read latest), and F (50% read-modify-write, 50% r). The distribution is Zipfian and we use an 18M-object dataset. Figure 14 shows the result. Because HCMeta cannot fit the coherence records in SCR, it experiences churn across all workloads. In read-heavy B and C, MEGALON achieves the largest speedups (9.12×–14.18×). With A's 50% writes, contention reduces throughput of both systems, yielding a smaller benefit for MEGALON (3.93×). F shows the smallest gain (3.18×) because the writes immediately following the reads do not incur churns. D is the only workload where MEGALON requires shared-log updates for insertion. HCMeta incurs higher synchronization overhead because a host must contact the owner if the inserted object does not belong to the requesting host. MEGALON's shared-log-based insertion does not wait for other hosts and performs 4.55× better.

6.12 Page cache application

We finally evaluate the user-level shared page cache built with MEGALON. We run skewed workloads with different mix of reads and writes with a 48GB dataset of 4KB file pages.

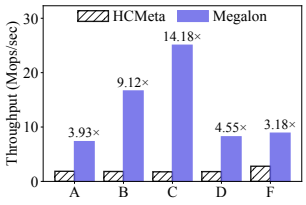

Figure 14: **YCSB workloads**

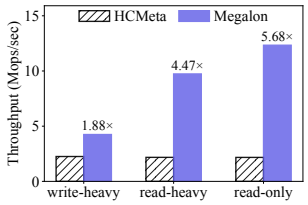

Figure 15: **Page cache**

As shown in Figure 15, HCMeta cannot share all pages as metadata does not fit in SCR; it suffers from churns and low performance. MEGALON is able to share a large page cache without churn, achieving notably higher throughput across all workloads. The throughput is lower than in the KV store due to larger object size. The page-cache application demonstrates that MEGALON can be incorporated into different applications to share large amounts of data in CXL with high performance.

7 Related Work

Disaggregated memory is an old idea [36] that has regained attention with CXL. Prior work on CXL mainly focus on *memory tiering* and *pooling*. Tiering solutions [32, 42, 55, 61–63] seek to hide CXL's higher latency by moving hot data to DIMM-attached memory. Pooling approaches [22, 33] improve memory utilization by apportioning CXL memory to hosts that need it. Other work [23, 33, 38, 56, 57] analyze CXL's raw performance and implications to application performance. None of the above considers CXL memory sharing.

A few recent papers consider sharing CXL memory across hosts [10, 26–28]. They note that cache coherence for all CXL memory is infeasible, motivating an SCR model. Tigon [26] shows how to build a database in this model, by moving objects to be shared from local memory to CXL. To share objects in CXL, Tigon uses hardware-coherent metadata-based sharing (HCMeta). The work in [28] outlines high-level sharing ideas for different CXL versions but provides few technical details. CXLfork [2] proposes remote forks via CXL, where the forked process shares read-only pages with its parent. Unlike our work that enables general data sharing across hosts, CXLfork uses sharing only for deduplicating memory between parent and child, and supports only read sharing.

Systems without any cache coherence have been considered before [5, 15, 30, 44]. However, such systems create significant complexity for applications, and so they have not been widely adopted. Cosh [8] enables transferring bulk data across CPUs, GPUs, and other accelerators that may share memory incoherently. That work has a different goal from ours, namely, bulk data transfers rather than data sharing.

RDMA also enables disaggregated memory, but unlike CXL, it requires processes to issue IO to access disaggregated memory, rather than loads and stores. RDMA-based disaggregated memory has been used to build object and KV stores [20, 21, 29, 35, 40, 45, 53]. However, these systems are unaffected by the lack of cache coherence in CPU caches, since RDMA operations are IO operations. As a consequence, RDMA systems require software-managed caches to avoid remote memory accesses, whereas CXL allows hosts to directly benefit from hardware caches.

Node replication (NR) [13] efficiently replicates data structures across NUMA domains using a log in shared memory, while subsequent work used NR to replicate page tables in the OS [11]. That work was not targeted at systems without full cache coherence. We borrow NR to replicate the index in MEGALON and apply it to our setting with an SCR, by observing that NR works correctly provided that the log tail pointer is in the SCR; even the log can be in incoherent memory provided threads flush or bypass the cache when accessing log entries.

The idea of replicating indexes has appeared in other contexts. DudeTM [39] mirrors durable memory pages in persistent memory to local DRAM, including the index, to speed up transaction execution by avoiding expensive persistent-memory accesses. HydraList [43], similar to NR, replicates the search index across NUMA nodes to avoid remote-memory stalls and cache-coherence traffic. It updates the search index asynchronously by aggregating operations and broadcasting them to all replicas. However, both works use index replication to improve performance, whereas our work uses it to conserve scarce SCR space.

Software-based distributed shared memory (DSM) systems (e.g., [1, 4, 9, 12, 34, 41, 46, 49, 51]) emulate shared memory among hosts connected by a network without any physical shared memory. These systems do not have an SCR to leverage, so they provide coherence entirely in software via message-passing protocols, which are known to be slow.

8 Conclusion

We propose MEGALON, a new data-sharing approach for partly coherent CXL. MEGALON shares the metadata essential for coherent data sharing using a novel split approach that is not limited by hardware-coherent memory capacity. MEGALON uses a CXL shared log to enable dynamic coherence records and provides coherence using the shared log when coherence records cannot. MEGALON improves performance compared to the current sharing approach under many workloads.

Inference in the Shadows: Taming Memory Bandwidth Contention in Mobile LLM Inference with SERENO

Tong Xin Xinrui Shi Mingkai Dong Zeyu Mi
Institute of Parallel and Distributed Systems, Shanghai Jiao Tong University

Abstract

The proliferation of large language models (LLMs) on mobile devices introduces a new performance challenge: resource contention between compute-intensive inference and latency-sensitive foreground applications. We identify a severe and *asymmetric* interference where concurrent LLM inference substantially degrades foreground applications' quality-of-service (QoS)—increasing the aggregate jank rate (the fraction of frames that appear as visible stutters) by 153%. In contrast, LLM throughput degrades by only 1.01% and 1.64% during prefill and decode stages, respectively. This imbalance arises because the hardware prioritizes NPU memory traffic—originally to guarantee critical media tasks (e.g., video recording)—a privilege that best-effort LLM inference inherits, causing aggressive bandwidth contention.

To address this asymmetric degradation, we present SERENO, a foreground-QoS-friendly LLM inference framework that resolves bandwidth contention between foreground applications and background LLM inference, without hardware modification. SERENO repurposes speculative decoding to introduce fine-grained yield points for preemptible execution, letting the system detect memory contention and dynamically yield bandwidth to the foreground without losing inference progress. Extensive evaluations on commercial smartphones across diverse categories of popular applications demonstrate that SERENO reduces the foreground jank rate by up to 92.6% (58.5% on average) while boosting LLM throughput by up to 67.9% (26.4% on average). Compared with vanilla speculative decoding, SERENO can reduce the foreground jank rate by up to 72.1% while incurring only a 6.2% performance degradation.

1 Introduction

Large language models (LLMs) are increasingly deployed on real-world mobile devices [1,54,58,106]. These models power a growing range of shipping on-device features: notification summarization and smart reply (Apple Intelligence [11]), real-time call translation and chat assistance (Samsung Galaxy AI [77]), and AI-powered on-screen search (Google Gemini Nano [28]) [63]. Beyond these, mobile agents [53,93,95,99] further expand the role of on-device inference, executing tasks such as form filling, calendar management, and cross-app automation. These features are not necessarily continuous services; many are sporadic background bursts triggered by notifications, messages, translation requests, or agent subtasks. They nevertheless overlap with foreground rendering at millisecond timescales, where even short memory bursts can violate frame deadlines.

However, as a resource-intensive background workload, LLM inference on smartphones contends for shared resources and interferes with user-visible tasks (e.g., UI rendering). Our analysis of co-running an LLM with 25 popular mobile applications, one foreground app at a time, reveals that the aggregate foreground *jank rate* surges by 153% and the system's peak CPU and GPU performance regresses to levels comparable to smartphones released up to three years ago—translating into substantially more frequent perceptible stutters, jitters, and input lags. Crucially, we identify a severe *asymmetric interference pattern*: while foreground performance degrades sharply, the degradation of LLM inference throughput is negligible. Specifically, when co-running LLM inference with applications, prefill and decode throughput decrease by only 1.01% and 1.64%, respectively.

To pinpoint the root cause, we profiled hardware subsystems: the degradation is attributable neither to CPU/GPU saturation nor to cache contention, but to a sharp spike in memory access latency during concurrent inference—i.e., severe contention for shared DRAM bandwidth within the mobile SoC's Unified Memory Architecture (UMA).

By further analyzing the software-hardware stack of various mainstream mobile SoCs, we reveal that the asymmetry originates from hardware-level prioritization of the NPU's memory traffic. Crucially, this is not a design oversight, but a consequence of legacy real-time design principle: mobile SoCs have traditionally treated accelerators (e.g., ISP and NPU) as latency-critical media engines and granted them high-priority access to memory. Consequently, best-effort LLM inference inadvertently inherits this privilege, acquiring

the same dominant memory bandwidth allocation as latency-critical media tasks (e.g., video recording). As a result, current system resource arbitration paradoxically prioritizes LLM inference, causing disproportionate harm to foreground tasks.

Preserving user-visible foreground performance necessitates resolving bandwidth contention between interactive foreground applications and background LLM inference. Specifically, it is imperative to enable LLM inference to dynamically yield memory bandwidth to foreground applications.

However, achieving this on commodity devices is impeded by the rigidity of current mobile SoCs, which pose three fundamental challenges: First, *lack of low-overhead bandwidth sensing*. Real-time contention sensing requires high-frequency, precise signals. Most mobile SoCs lack such hardware counters, while software methods incur prohibitive overhead for online deployment. Second, *lack of high-frequency LLM control knobs*. Mobile NPU inference typically executes static computation graphs to maximize efficiency, treating inference as an uninterruptible atomic operation. Third, *lack of efficient bandwidth regulation*. Commodity SoCs lack mechanisms for fine-grained NPU throttling. Coarse-grained regulation methods (e.g., sleeping or frequency scaling) are inefficient and underutilize bandwidth.

Our key insight is that *speculative decoding*—an inference acceleration technique that decomposes LLM decoding into draft and verification phases—provides natural opportunities to introduce yield points, enabling it to be repurposed to regulate bandwidth contention without losing inference progress.

Based on this insight, we propose SERENO, a software-only, foreground-QoS-preserving LLM inference framework that regulates bandwidth contention. First, to enable sensing, we derive proxy signals from the latency of execution blocks during the draft phase of speculative decoding. Observing a strong positive correlation ($R \approx 0.86$) between this proxy signal and physical memory bandwidth usage, we leverage it as an endogenous, near-zero-overhead contention probe. Next, SERENO introduces *Elastic Speculative Decoding* to transform the draft phase of speculative decoding into fine-grained, preemptible control knobs. Finally, we introduce a control system consisting of three bandwidth regulation primitives. It dynamically orchestrates the primitives' combination and intensity based on real-time contention, maximizing preserved progress while releasing bandwidth.

We implement SERENO and conduct extensive evaluations on commercial smartphones across diverse categories of popular applications. SERENO substantially mitigates the foreground QoS degradation caused by bandwidth contention.

Relative to an NPU inference baseline, SERENO reduces the foreground jank rate by up to 92.6% (58.5% on average) while boosting LLM throughput by up to 67.9% (26.4% on average). When compared with vanilla speculative decoding, SERENO can lower the jank rate by up to 72.1% with only a minor 6.2% performance penalty. Furthermore, SERENO outperforms the *llama.cpp* NPU backend, achieving 37.1% lower jank and 82.2% higher throughput.

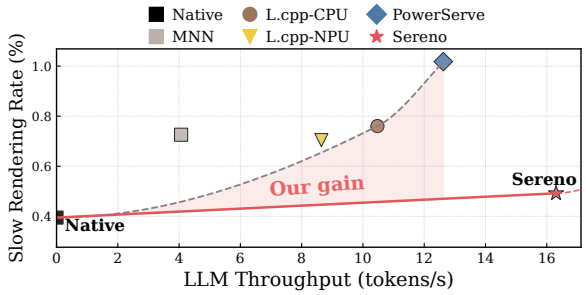

Figure 1: The New Pareto Frontier. Unlike systems that trade off LLM throughput for foreground smoothness, SERENO achieves both. Data are from co-running inference with 25 apps, one at a time.

Our contributions can be summarized as follows:

- We are the first to characterize and attribute the asymmetric performance interference between on-device LLM inference and concurrent foreground workloads.
- We provide systematic root-cause analysis of fundamental defects in mobile SoC unified resource management under LLM workloads.
- We propose a novel repurposing of speculative decoding, transforming it from an acceleration technique into a mechanism that creates fine-grained scheduling windows for QoS management.
- We present SERENO, the first foreground-QoS-aware LLM inference framework. On commercial smartphones, SERENO restores foreground smoothness to near-native levels while improving LLM throughput, achieving a "win-win" for user experience and performance (Figure 1).

2 Background

2.1 LLM Inference and Speculative Decoding

LLM inference comprises two phases: a compute-bound *prefill* phase that processes the prompt to populate KV caches, and a memory-bound *decode* phase. The decode phase generates tokens iteratively; since each step requires reading full model weights to produce a single token, performance is limited by memory bandwidth rather than arithmetic throughput.

To accelerate the decode phase, *speculative decoding* is adopted: a lightweight *draft model* proposes a sequence of candidate tokens, which the full *target model* then validates in parallel via a single large-batch forward (the *draft* and *verify* phases). If verification confirms the draft prefix, multiple tokens are committed at once; otherwise the process rolls back to the last valid token. This amortizes the high memory access cost over multiple tokens, typically decoding faster than autoregressive generation.

2.2 Mobile SoC Architecture and Rendering

Neural Processing Units (NPUs) are designed for compute-intensive tasks like AI, imaging, and sensor processing. Mobile inference is usually offloaded to NPUs [56, 72]. To maxi-

mize throughput, NPUs execute pre-compiled static computation graphs. Once submitted, a graph executes autonomously within the hardware pipeline as an atomic, run-to-completion unit. Critically, modern mobile SoCs adopt *Unified Memory Architecture* (UMA), i.e., CPUs, GPUs, and NPUs share a single DRAM pool and system interconnect. Memory access to unified memory is mediated by hardware priority arbitration.

The Android UI rendering pipeline is latency-bounded. Subsystems like *Choreographer* and *SurfaceFlinger* [10] coordinate CPU input handling, app-level drawing, and GPU composition. If the system skips frames, the user perceives recurring flicker on the screen, referred to as *jank* [7]. Jank encompasses two categories: ❶ *buffer stuffing*, where frames queue up due to backpressure, manifesting as input lag; and ❷ *deadline misses*, where rendering exceeds the Vsync interval, causing visible stutter. We denote the latter as *slow rendering* to isolate visual jitter from latency.

3 Interference and Analysis

3.1 Quantifying Interference

Though mobile LLM inference isolates computation on the NPU, it shares other resources with the rest of the OS. To quantify interference, we profile a OnePlus 13 (Snapdragon 8 Elite) running Llama-3.1-8B (W4A16) [31] using the *PowerServe* [66] alongside each of 25 popular foreground apps individually (selected via previous studies [69, 97] and Play Store rankings). Each ∼30 s run involves continuous swiping, with 1024 prefill tokens and 256 decode tokens.

Metrics. We focus on user-perceived fluidity. Using the *Perfetto* [30] toolchain, we report *jank rate* (percentage of stutter frames [7]) and the stricter *slow rendering rate* (frames missing the Vsync deadline due to execution delays [87]). Notably, slow rendering produces user-visible jitters, and thus is used by Google as a quality metric directly tied to app discoverability on Google Play [8].

Foreground QoS degradation. Figure 2 (left panel) visualizes the impact on user experience, where red bars represent the jank rate normalized to the native baseline (dashed line at 1.0). While the baseline implies no-LLM-inference smooth operation, the red bars for latency-sensitive apps increase sharply under concurrency. For instance, *Discord* reaches nearly 18× the native jank rate. This confirms that background LLM inference substantially degrades QoS across apps, causing large relative regressions even in highly optimized, lightweight apps. The aggregate jank rate of the 25 apps increases by 153%, while the mean per-app normalized jank rate shown in Figure 2 reaches 3.13×, and the slow rendering rate shows the same degradation trend—a stuttering, unresponsive experience.

System peak performance loss. The interference extends to system peak performance, as detailed in Figure 2 (right panel). Here, the grey bars depict benchmark scores normalized to the native baseline. Across both CPU (e.g., GB6 CPU [68]) and GPU (e.g., 3DM Nomad [88]) workloads, the significant drop in bars induces a 37.2%–49.6% loss in peak throughput. Effectively, the Snapdragon 8 Elite performs at the level of hardware from two to three years ago [67, 89], bringing a $1000 flagship down to the performance tier of a $400 device [4, 5].

Asymmetric performance impact. Crucially, the graphs highlight a severe asymmetry. In both panels of Figure 2, the *blue lines* representing LLM prefill and decode speeds stay almost flat near the 1.0 baseline. For example, while foreground performance (red bars) degrades sharply, background prefill/decode throughput degrades by only 1.01% and 1.64% on average. The same trend appears in benchmark scores. This implies a systemic priority inversion where latency-critical UI tasks are starved to feed a best-effort background workload.

3.2 Physical Attribution: Bandwidth

To identify the contended resource, we employ an elimination method using *Simpleperf* [9] and *Snapdragon Profiler* [76].

On the Snapdragon 8 Elite, although matrix computation is offloaded to NPU cores (HMX [71]), the data and control paths remain entangled with the host: high-volume DMA between NPU-internal cache and DRAM traverses the same interconnect used by the CPU and GPU, the CPU retains the inference control plane, and NPU vector units (HVX) interact directly with the cache hierarchy.

Compute and power metrics. Figure 3 plots the normalized performance ratios of key hardware metrics, where a value of 1.0 (dashed line) indicates the contention-free baseline. Under LLM concurrency, we observe that foreground compute metrics—specifically *IPC*, *CPU Util*, and *GPU Util* (green bars)—hover near 1.0. This stability confirms that the CPU and GPU are not saturated by the background task. Furthermore, we rule out thermal throttling, as core frequencies show no abnormal drops.

Cache metrics. Similarly, the blue bars of Figure 3 examine the cache hierarchy. The normalized miss rates for *L2 Cache*, *Last-Level Cache (LLC)*, and *TLB* remain largely unchanged relative to the native baseline. This flat trend indicates that NPU traffic does not significantly pollute the shared caches or thrash TLB entries, ruling out cache contention as the primary bottleneck.

Unified memory bandwidth metrics. In sharp contrast, the red bars of Figure 3 reveal substantial regression in the memory subsystem, with memory latency metrics increasing above the 1.0 baseline. Specifically, *Memory Stall Cycles* increase by 3.8×, and *LLC Miss Latency* (measured in cycles) increases by 3.5×. GPU memory stall rates exhibit a similar 3.1× spike. These metrics directly quantify the back-pressure from the DRAM controller. This data confirms that despite the NPU's compute isolation, its massive DMA traffic saturates the shared Unified Memory Architecture (UMA), blocking CPU/GPU memory requests.

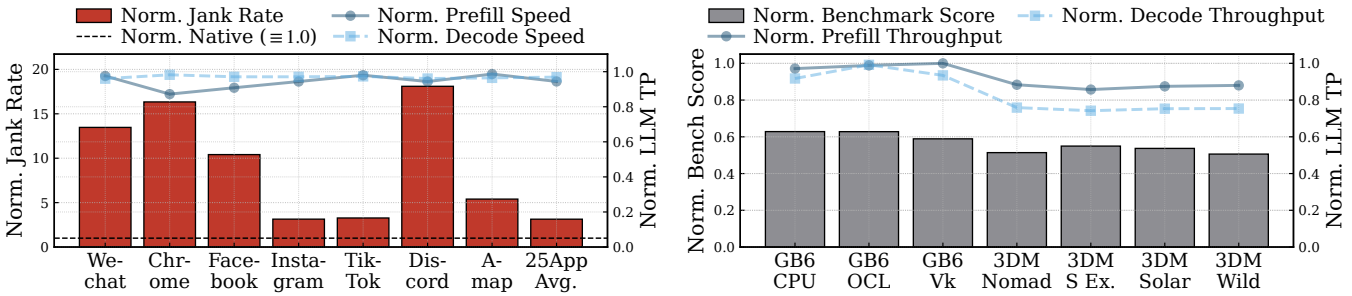

Figure 2: Interference when co-running LLM inference with each popular application. Background LLM inference severely degrades foreground QoS (e.g., jank) and peak system performance. Each application is evaluated individually with the background LLM, not concurrently with the other applications. The interference is asymmetric, as the LLM's own throughput is barely impacted.

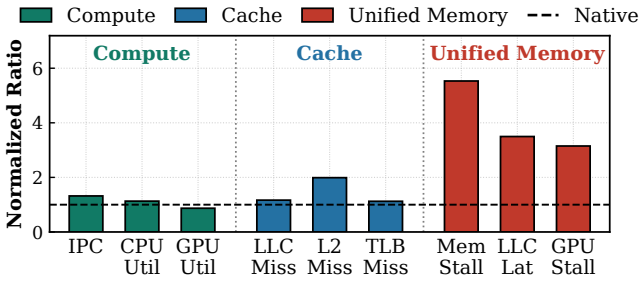

Figure 3: Root cause analysis: averaged metrics from co-running LLM inference with 25 applications, one at a time. Compute and **Cache** metrics remain flat, while **Unified Memory** contention metrics surge 3–4×, pinpointing bandwidth as the culprit. All values are normalized to *Native*, i.e., applications running alone averaged.

3.3 Architectural Root Cause Analysis

Why does the system fail to throttle aggressive NPU traffic? We analyzed the kernel and device tree sources for three flagship SoC families: Snapdragon 8 Elite [65, 75], Dimensity 9400 [57, 64], and Samsung Exynos 2400 [78]. Our analysis shows that the asymmetry arises from deep-rooted mechanism gaps and policy misalignments. As Table 1 shows through representative Snapdragon and Dimensity evidence, NPU workloads remain privileged compared to CPU/GPU workloads; the Exynos source tree exposes analogous vendor-specific BTS policy hooks for NPU traffic.

Missing NPU observability and control. Mobile OSes lack both observability and control handles for the NPU. On Snapdragon 8 Elite, governance frameworks like `memlat` [65] monitor CPU stalls but explicitly exclude NPU traffic, rendering it "invisible" to the OS scheduler. More critically, we find a hardware-level void in bandwidth partitioning. While the CPU cluster supports ARM's *Memory System Resource Partitioning and Monitoring* (MPAM) [12] to enforce QoS, the NPU driver stack lacks these hooks. This implies the NPU operates as an unmanaged bus master: the OS cannot enforce bandwidth quotas on it even if congestion is detected.

NPU-prioritized arbitration policies. Hardware and firmware arbitration structurally bias towards the NPU. Static analysis of the interconnect topology reveals that the NPU issues traffic through a dedicated on-chip lane (`nsp_noc` reaching `SLAVE_EBI1`) that bypasses the congestion of the shared multimedia fabric, and it is admitted into the top arbitration class—priority 0 with urgency forwarding (`prio` = 0, `urg_fwd` = 1), the same elite tier reserved for the latency-critical display—despite carrying merely best-effort LLM traffic. Crucially, this elevated service comes with no countervailing regulation: the CPU/GPU are reined in by MPAM bandwidth partitioning, `memlat` stall accounting, and thermal cooling maps, whereas the NPU is subject to none of the three. The few control loops that could otherwise intervene react far too slowly: while UI rendering demands strict latency (e.g., sub-8.3 ms for 120 Hz), the system's shared bandwidth DVFS governor escalates only after a coarse hysteresis window (∼64 ms), too slow to intercept bursty interference. Most starkly, thermal configurations explicitly exempt the NPU from throttling [64], letting it sustain aggressive bandwidth consumption even when the CPU is throttled. On Exynos 2400, the public kernel exposes Samsung's Bus Traffic Shaper (BTS) machinery and NPU-specific `npu_normal`/`npu_performance` scenarios, and the NPU device tree binds its MIF/INT hardware devices to BTS-controlled units [78]. This supports the same high-level conclusion: accelerator memory policy is configured through vendor-specific firmware/device-tree mechanisms rather than through portable per-application OS controls.

Rationale and workload mismatch. These privileges are not an oversight but a design choice. Consider 4K60 video recording: the image sensor streams massive raw data that the ISP and NPU must process within strict per-frame deadlines (<16 ms), so to prevent buffer overflows and dropped frames, architects established high-priority direct memory paths and disabled thermal throttling for the NPU. This is well matched to media-centric workloads but mismatched for persistent, best-effort AI: an on-device LLM is bandwidth-intensive (like video recording) yet semantically best-effort (like background downloading). Unable to distinguish the semantic intent of NPU instructions, the hardware grants the background LLM

Table 1: Hardware and OS mechanism gaps and policy misalignments. (✗: constrained / regulated; ✓: privileged / unregulated.) Foreground units (CPU/GPU) face strict visibility, latency, and thermal constraints, while NPU workloads remain privileged across SoCs [64, 65, 78].

Category	Dimension	Target SoC	Foreground (CPU/GPU)	Background (NPU)	Code Signature (Source)
Mechanism	**Visibility** *(Monitor)*	Snapdragon 8Elite	✗ **Sensed** (Stall cycles tracked by `memlat`)	✓ **Invisible (Blind Spot)** (No probe nodes in governor)	`qcom,cpulist` excludes NPU (*sun.dtsi*)
	Topology *(Bus Path)*	Snapdragon 8Elite	✗ **Shared Congestion** (Contends on shared `gem_noc`)	✓ **Dedicated High-Priority Path** (Top tier: `prio`=0, `urg_fwd`=1)	`nsp_noc` connects to `SLAVE_EBI1` (*sun.dtsi, sun.c*)
	Partitioning *(MPAM)*	Snapdragon 8Elite	✗ **Granular Task-Level** (cmax, cpbm, prio per PID)	✓ **No MPAM Support** (Not in MSC enum: L2/L3/SLC only)	`enum msc_qcom_id` lacks NPU type (*mpam_msc.h*)
Policy	**Regulation** *(Latency)*	Snapdragon 8Elite	✗ **Needs <8.3 ms** (120 Hz strict deadline)	✓ **BW DVFS @ ∼64 ms** (Too slow for UI bursts)	`zone1_thres_count = 16` (*icc-bwmon.c*)
	Thermal *(Throttling)*	Dimensity 9400	✗ **Aggressive Throttling** (Strict cooling maps applied)	✓ **Unrestricted** (Explicitly bypasses limits)	`THERMAL_APU_UNLIMIT` (*mtk_cooler_setting.h*)

the same high-priority treatment as a foreground camera, so it occupies memory paths designed for millisecond-critical media and delays latency-sensitive UI traffic.

Implication. Because image processing on the NPU is a genuinely critical media task where a single dropped frame is unacceptable, silicon vendors will likely continue to enforce this structural bias. Addressing the contention therefore necessitates a pure-software approach that regulates LLM bandwidth usage without relying on immutable hardware policies. Current vendor toolchains add further constraints: commercial NPU SDKs (e.g., Qualcomm QNN [74]) compile computation graphs into fixed static executables with predetermined batch sizes, and these opaque binaries expose neither per-operator memory behavior nor fine-grained traffic-shaping hooks—even inspection tools like Snapdragon Profiler [76] report only aggregate metrics. These limitations reinforce the need for a *software-level* approach that works within existing vendor ecosystems.

4 Challenges and Opportunities

To bridge this misalignment, our goal is to sense and regulate memory bandwidth, preserving foreground smoothness while the LLM runs in the background.

4.1 Key Challenges

Challenge 1: Lack of Low-Cost Sensing. Real-time visibility into the bandwidth contention is the first prerequisite for effective contention management. However, mobile SoCs typically lack accessible fine-grained hardware counters (e.g., MPAM or high-rate bandwidth PMUs) for the NPU. Software-only probes can infer DRAM latency, but they incur prohibitive CPU overhead and compete for the very bandwidth they seek to measure [23, 82, 90]. Without low-cost, high-frequency sensing, the system stays blind to the millisecond contention.

Challenge 2: Lack of High-Frequency Control Knobs. Effective mitigation requires intervening at a frequency that matches the interference dynamics. Android's SurfaceFlinger typically performs composition (the most bandwidth-intensive phase of rendering) in bursty windows, which we measured at $T_{comp} \approx 2.25$ ms on average. According to the Nyquist-Shannon sampling theorem [79], to effectively intercept these transients without aliasing, the control interval Δt_{ctrl} is strictly constrained by $\Delta t_{ctrl} \leq \frac{T_{comp}}{2} \approx 1.125$ ms. This theoretical limit conflicts with the realities of mobile NPUs. Specifically, modern NPU runtime such as QNN [72] executes computation graphs as monolithic units for maximal efficiency. Even with graph partitioning (i.e., chunking), the smallest runnable unit of an 8B model remains 5–8 ms ($> 4\times$ Δt_{ctrl}), making real-time control mathematically infeasible. Layer-level subdivision of the target model is therefore not sufficient: it creates control points only after long target-model subgraphs and any pause directly stalls committed decoding progress. Recent efforts [26, 34] to relax static-graph constraints offer finer control but at steep costs—reducing prefilling and decoding throughput by over 90% and 50%, respectively.

Challenge 3: Lack of Efficient Regulation. Even with real-time sensing of bandwidth contention and sufficient fine-grained control knobs, we still need a mechanism to yield bandwidth efficiently. Standard mechanisms like *Dynamic Voltage and Frequency Scaling* (DVFS) are ineffective because NPU energy efficiency degrades at low frequencies due to prolonged execution time and accumulated static power leakage [43, 94]. Alternatively, *chunk-and-sleep* strategies inject sleeps between LLM subgraphs, halting inference progress during the sleep interval and recovering foreground QoS only by sacrificing background progress. It is thus challenging to devise an elastic, soft-throttling mechanism that can reduce bandwidth pressure while maintaining forward computation progress.

4.2 Repurposing Speculative Decoding

Of particular interest, we find that *speculative decoding* offers a unique structural alignment with our requirements for solving the challenges described above. Speculative decoding structurally consists of a fine-grained, memory-bound *draft* phase and a heavyweight, compute-dense *verify* phase. The draft phase comprises a sequence of forward passes on a smaller model that naturally break the original LLM execution into smaller windows, thereby providing the missing

fine-grained knobs through draft interruption. The compute-intensive verification phase, in turn, introduces a complementary lower-bandwidth stage, offering opportunities for bandwidth regulation across phases. This is the key distinction from subdividing the target model itself: yielding during the draft phase discards only tentative work, while the target model still verifies already available candidates and preserves committed decoding state.

Based on the above analysis, we derive a key insight: rather than leveraging speculation solely for speed, we can **repurpose** it to serve as a vehicle for memory bandwidth regulation.

Throughput-oriented speculation under contention. However, translating this structural potential into a QoS mechanism is non-trivial because existing frameworks are designed to maximize throughput. Frameworks like Medusa [16] or EAGLE-3 [50] aggressively saturate memory bandwidth to maximize acceptance rates. Our profiling with EAGLE-3 reveals that 94.7% of the decoding time is bandwidth-bound.

Importantly, these algorithms are fragile when operating under constraints. Specifically, our profiling of EAGLE-3 reveals that a naive attempt to yield bandwidth—by enforcing a 50% bandwidth cap during the verification phase—causes decoding throughput to drop by 54% relative to the peak. Moreover, this throttled performance drops 8.4% below the non-speculative baseline. This *negative gain* phenomenon indicates that, without a specialized mechanism, simply throttling speculation can eliminate its benefits entirely.

5 SERENO Design

To enable the seamless coexistence of always-on background intelligence and interactive foreground experiences, we propose SERENO, a pure-software inference framework that resolves foreground–LLM bandwidth contention via a sub-millisecond *Sense-Decide-Act* loop that dynamically regulates the LLM's NPU bandwidth usage.

Design goals. SERENO pursues two objectives to resolve asymmetric foreground performance degradation. ❶ *Foreground Protection:* SERENO should restore foreground smoothness to near-native levels by strictly limiting memory bandwidth during interactive bursts; ❷ *Efficient Yielding:* SERENO should maximize background LLM throughput by avoiding zero-progress yields (e.g., long sleeping) that waste resources.

Design constraints. Despite the challenges we introduce in §4.1, SERENO is designed to be deployable on commodity smartphones, imposing strict boundaries: ❶ *Immutable Hardware:* We cannot modify SoC interconnect priorities, requiring software-only solutions; ❷ *User-Space Constraint:* To ensure compatibility, we avoid relying on vendor-specific kernel or driver modifications; ❸ *Black-Box NPU:* We must accommodate the opaque nature of commercial NPUs, where computation graphs are static and their execution is atomic. Meanwhile, the batch size of each graph must be fixed at export time, which is required by current NPU runtime [70].

System workflow. The control loop, illustrated in Figure 4, begins with the *Contention Sensor* (§5.2), which derives a real-time *Contention Score* from the execution latency of draft subgraphs. This score feeds into the *Controller* (§5.3), which computes the necessary yielding intensity. These decisions drive the *Elastic Speculative Decoding* engine (§5.1): during the draft phase, the controller may trigger an instant *Draft Preemption* to halt the memory bandwidth usage, employing *N-gram Filling* to compensate for incomplete speculative tokens. Then, *Selective Batching* chooses the execution graph with the appropriate batch size from the pre-exported graphs. Finally, the workflow transitions to the verification phase, where *micro-sleeps* might be injected to regulate the remaining bandwidth demand before the next cycle begins.

5.1 Elastic Speculative Decoding

To address the lack of fine-grained control knobs, SERENO introduces *Elastic Speculative Decoding*. We transform the monolithic inference process into a sequence of interruptible, fine-grained units, enabling the system to take actions at sub-millisecond timescales without sacrificing model correctness.

Preemptible draft execution. We leverage the inherent discardability of the speculative draft phase to create high-frequency intervention points. Unlike conventional designs that execute the draft model as a single atomic phase, we refactor it into a chain of fine-grained units.

Using the vendor SDK (e.g., QNN [72]), we compile the draft model at the granularity of individual Transformer layers. We use *subgraph* to denote one statically compiled NPU executable containing a contiguous set of operators, such as one draft Transformer layer or one verification-layer group. For the draft model, this creates execution subgraphs with sub-millisecond latency. At any subgraph boundary, SERENO can trigger an instant preemption: discarding the remaining draft steps and immediately transitioning to the verification phase. This converts the NPU from a run-to-completion black box into a preemptible task that can release memory bandwidth almost instantly upon foreground contention.

Crucially, we retain the static graph: unlike approaches that fall back to inefficient dynamic operators for flexibility [34], our method maintains near-native NPU execution efficiency.

N-gram candidate filling. Draft preemptions inevitably reduce the number of speculated tokens, potentially harming decoding throughput. To mitigate this penalty, SERENO employs a low-cost *N-gram Filling* mechanism to replenish the empty slots in the verification batch. When the neural draft produces fewer candidates than the selected verification batch can hold, SERENO looks up the latest committed token sequence in a local n-gram cache and appends the most likely continuation tokens as additional tentative candidates. These tokens are verified by the target model in the same way as neural draft tokens, so incorrect n-gram candidates are re-

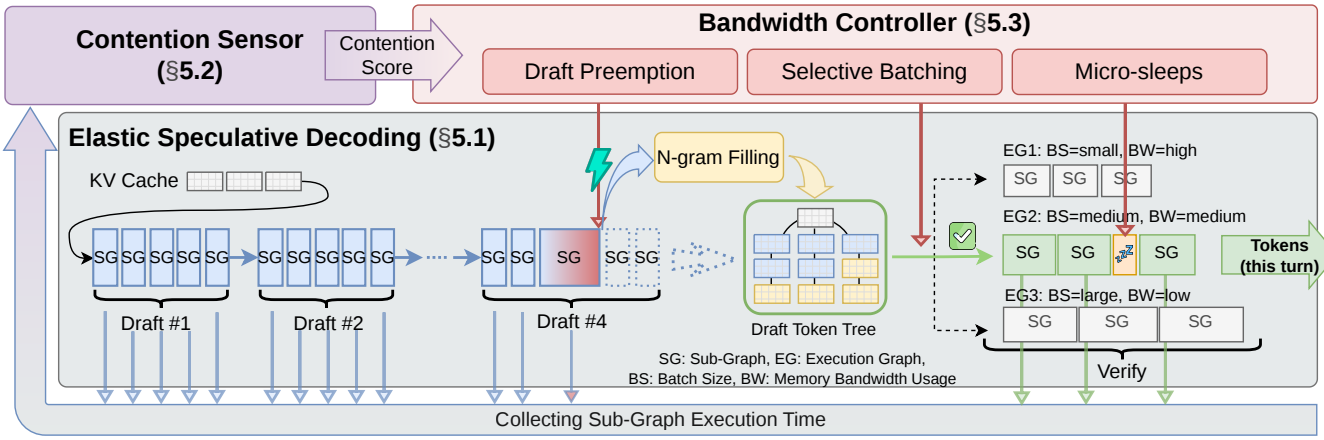

Figure 4: Design overview of SERENO. A Sense-Decide-Act loop to dynamically regulate LLM inference's NPU bandwidth usage.

jected without changing output semantics. We introduce three optimizations to standard N-gram speculation to maximize acceptance rates using only local context: ❶ *Multi-source Construction:* We build the N-gram cache by integrating tokens from three weighted sources: verify outputs (high confidence), prompts (medium), and crucially, rejected draft sequences (low). This recycles valuable local context that is originally discarded. ❷ *Self-Purifying Cache:* We filter candidates via hit-frequency tracking, automatically evicting low-quality sequences to suppress noise. ❸ *Adaptive Length Weighting:* We employ mixed x-gram lengths (e.g., 2-gram, 3-gram, ...), assigning higher weights to longer matches (capturing semantics) and lower weights to short collocations. This prevents noise from short-context matches. These enhancements let SERENO recover speculation candidates even when the neural draft phase is preempted early.

Selective batching. While the draft phase provides preemptible knobs, the verification phase offers various bandwidth control mechanisms. We pre-compile multiple verification graphs with varying batch sizes (e.g., $B = 8, 16, 32$) that share weights but differ in parallelism, resulting in varying bandwidth usage during verification.

During verification, SERENO dynamically selects the appropriate graph based on the contention sensor's output. We characterize each verification graph by its absolute average memory-bandwidth demand while it runs. This is a graph-level bandwidth pressure metric, not a per-candidate cost: normalizing the measured bandwidth of the $B = 1$ verification graph to 1.00, the demand falls to 0.82/0.79/0.74 for $B = 8/16/32$ and further to 0.61/0.38 for $B = 64/128$. Larger verification batches expose more parallel candidate work for roughly one target-model weight traversal, lowering the graph's average bandwidth demand, but they also form longer atomic verification bursts. This does not imply universally higher end-to-end throughput: larger verification batches require more candidate tokens, which may force additional draft work or lower-confidence n-gram candidates before verification can run. The resulting spread in bandwidth levels gives SERENO scheduling room: under heavy memory contention, SERENO switches to lower-bandwidth larger-batch verification graphs and relies on micro-sleeps between verification subgraphs to break up the burst. Under low contention, it prefers smaller graphs to minimize draft waiting and preserve decoding latency [91].

5.2 Endogenous Contention Sensing

Sensing rationale. To sense bandwidth contention, DRAM latency is the primary indicator [44, 45]. As highlighted in §4.1, conventional methods (e.g., pointer chasing) that measure DRAM latency incur prohibitive overhead. However, we observe that the memory-intensive LLM decoding step mimics these latency probes: it generates sequential DMA transfers between NPU SRAM and DRAM that inherently bypass host caches. Crucially, while synthetic probes require multiple rounds to resolve noise, the sheer volume of data processed in a single LLM step ensures high signal robustness against transient system noise. Therefore, instead of introducing external monitors, we leverage the latency of LLM workload itself as an endogenous, zero-cost contention sensor.

Based on this insight, SERENO repurposes the execution latency of fine-grained draft phase subgraphs as a real-time contention proxy. This signal is fully endogenous and nearly zero-overhead: it utilizes timing data captured during the decoding, eliminating the need for hardware counters or intrusive micro-benchmarks. When foreground applications contend for the memory bus, the resulting memory stalls manifest directly as latency spikes in subgraph execution.

Reactive sensing rather than prediction. SERENO uses reactive sensing because foreground behavior is dominated by user input, app-specific rendering paths, and OS composition timing. Predicting these bursts would require app-specific models and would either miss rare interactions or over-throttle inference conservatively. In contrast, the draft-subgraph signal is available at sub-millisecond granularity with no extra memory traffic, so the controller can react within the same timescale as rendering bursts while smoothing noise through

hysteresis and PI control.

Calibration. Specifically, we observe that static graph fusion strategies cause significant latency variance among Transformer blocks (e.g., up to 37% difference in Llama-3.2-1B). This is likely due to non-uniform compiler optimizations, such as different memory alignments and tensor tiling strategies assigned to specific graph nodes. Crucially, despite this spatial variance, the execution latency of any specific subgraph is temporally stable across iterations due to the deterministic nature of NPU static graphs. Therefore, SERENO performs a one-time offline calibration to profile the baseline distribution for *each* unique subgraph in a contention-free environment.

Runtime contention score. At runtime, we compute a normalized *Contention Score* per executed draft subgraph: $CS = (T_{actual} - T_{baseline})/T_{baseline}$, where T represents subgraph execution latency. As demonstrated in §7.3, this software-defined metric exhibits a strong correlation ($R \approx 0.86$) with physical *Memory Stall Cycles per LLC Miss*. This confirms that *CS* serves as a high-fidelity proxy for physical bandwidth contention.

5.3 Bandwidth Controller

To orchestrate the sensing signals and elastic knobs, SERENO implements a closed-loop control system comprising a hierarchical actuation mechanism and a feedback-driven controller. This design minimizes throughput loss while responding to sub-millisecond contention transients.

Actuation primitives. We define three actuation primitives, ordered by their aggressiveness in yielding bandwidth. Level ❶: *Draft Preemption* (instant relief). Since the draft phase executes with Batch=1 (high memory intensity), it saturates bandwidth most aggressively. Preempting the draft phase immediately releases the bus and stops occupying the bandwidth. Level ❷: *Selective Batching* (coarse adjustment). Upon preempting to the verification phase, the controller selects between precompiled graphs (e.g., Batch=16 vs. 32). It prefers smaller batches for low-latency progress under light contention, but switches to larger batches when moderate yielding should lower the verification graph's bandwidth demand. Level ❸: *Micro-Sleeps* (fine-tuning). While batch selection offers discrete control steps, micro-sleeps allow for continuous modulation of the bandwidth duty cycle during the verification phase. The controller injects precise sleep intervals only between verification subgraphs, not inside a running NPU graph. Because each target-model verification subgraph lasts 5–8 ms, a 1–2 ms sleep between subgraphs reduces the average verification bandwidth duty cycle by roughly 10–25%. This primitive complements draft preemption: preemption handles immediate relief during the high-bandwidth draft phase, while micro-sleeps fine-tune residual verification-phase pressure.

Controller. To dynamically orchestrate the actuation primitives, SERENO employs a standard *Proportional-Integral (PI) controller* [36], a classic feedback mechanism that modulates control inputs to minimize the error between a measured state and a desired setpoint. The controller computes the error term $e(t) = CS_{measured} - CS_{target}$, where $CS_{measured}$ is the real-time contention score and CS_{target} is the maximum allowable contention. Formally, the control output $u(t)$ is derived as $u(t) = K_p e(t) + K_i \int_0^t e(\tau) d\tau$. The proportional term (K_p) drives immediate reaction to the current error magnitude, while the integral term (K_i) accumulates historical errors to eliminate steady-state offset [13, 40, 41].

We specifically exclude the *derivative* term due to the stochastic nature of mobile system signals: the execution latency of LLM subgraphs contains minor noise from scheduling jitters and transient DRAM contention, which a derivative term would amplify into erratic control outputs and oscillation.

The controller's output $u(t)$ represents the aggregated *yielding intensity*. We employ a phase-aware mapping strategy to translate this continuous signal into discrete primitives: In the draft phase, we disable micro-sleeps to maximize speculative efficiency when the bus is free. Given the high bandwidth intensity of drafting, we enforce an aggressive preemption threshold: even a low magnitude $u(t)$ triggers immediate draft preemption. This ensures the system yields bandwidth instantaneously at the first sign of contention rather than stalling on speculative work. In the verification phase, $u(t)$ drives graded regulation to maintain progress. The signal is first mapped to selective batching (choosing larger batches for high $u(t)$), and then linearly mapped to micro-sleep durations inserted between subgraphs for fine-grained throttling.

To prevent oscillation from transient noise, we further apply a hysteresis filter to the draft preemption decision, requiring consecutive violation samples before triggering.

Minimum throughput guardrail. To prevent starvation, SERENO incorporates a *Token Bucket* mechanism that overrides the PI controller. The bucket fills at the instant generation rate and drains at a configurable baseline rate. This creates a three-stage gradation: ❶ *Nominal Enforcement:* As long as the bucket contains tokens over the lower bound (e.g., 10% of the maximum capacity), the system runs as normal. ❷ *Adaptive Relaxation:* Upon depletion below the lower bound, the system automatically relaxes the CS_{target} (raising the contention threshold), reducing yielding frequency to help the background task recover throughput. ❸ *Fail-Safe:* Under persistent deficit (i.e., if the bucket remains empty for a sustained duration), SERENO temporarily disables QoS interventions, falling back to standard speculative decoding to accelerate.

While these relaxations theoretically reintroduce some interference, it is a necessary compromise to ensure service continuity. Crucially, our evaluation (§7.2) demonstrates that even with this mechanism active in resource-constrained scenarios like *Heavy Gaming*, SERENO still delivers substantial QoS optimization compared to the uncontrolled baseline.

6 Implementation

Environment & framework. We implemented SERENO on Snapdragon chipsets using the Qualcomm QNN SDK (ver. 2.39) [74], atop the open-source PowerServe [66].

Core modules. SERENO adds ~6.4k lines of C++ code. ❶ *Elastic Speculative Decoding* (~2.8k LoC) manages the interruptible substrate. It carefully manages in-flight states and KV caches during preemptions without polluting committed state, guaranteeing consistency. ❷ *Bandwidth Controller* (~2.7k LoC) refactors the decoding loop for control and contains a PI controller to dynamically orchestrate the actuation primitives. ❸ *Contention Sensor* (~0.9k LoC) injects timer hooks directly into operator paths to derive the real-time contention score.

Automated tuning. For portability, we provide a Ziegler-Nichols [108] calibration script that sweeps the proportional gain under synthetic loads to find the *ultimate gain* (K_u)—the point where the contention signal sustains oscillation [14, 15, 33]—then derives stable coefficients (K_p, K_i) tailored to the SoC from K_u and the oscillation period.

Policy instantiation. We instantiate two policies to address distinct QoS requirements: ❶ *Policy A: Balanced Mode* is our default policy targeting daily multitasking. It sets a moderate contention threshold ($CS_{target} = 0.15$, permitting 15% latency hike) and enables the throughput guardrail (12 tokens/s for filling the bucket) to prevent starvation, balancing the smoothness and throughput. ❷ *Policy B: UI-First Mode* is a strict policy targeting competitive gaming; it enforces a tight threshold ($CS_{target} = 0.07$) and disables the throughput guardrail, prioritizing zero foreground stalls over LLM inference speed.

7 Evaluation

We evaluate SERENO by addressing four questions: ❶ **End-to-End Effectiveness:** How does SERENO perform in terms of foreground QoS and background LLM inference throughput compared to industry SOTA solutions and naive strategies? ❷ **Mechanism Analysis:** Does SERENO mitigate hardware bottlenecks? Do its software-aware signals and scheduling decisions function as intended? ❸ **Ablation Study:** What are the contributions of individual components? ❹ **System Analysis:** What are SERENO's overheads and robustness?

7.1 Experimental Setup

Hardware & Environment. Our primary testbed is the *OnePlus 13* (Snapdragon 8 Elite), alongside a *OnePlus 12* (8 Gen 3) for generality. Both feature a heterogeneous architecture where the CPU, GPU, and Hexagon NPU share 24 GB LPDDR5X unified memory. We measure full-system power with a power meter [17] and ensure no uncontrolled DVFS downclocking during experiments.

Workloads. We deploy *Llama-3.1-8B-Instruct* (W4A16). We use 15 diverse prompts from the GSM8K dataset [21] to cover varying prefill/decode complexities. In §7.5, we further discuss the generalization to other models.

Based on 25 popular applications in §3.1, we add 5 heavy games into the list and categorize these 30 applications by resource intensity from light to heavy: ❶ *Tools* (e.g., Chrome): bursty CPU loads; ❷ *Social* (e.g., WeChat): rich media list scrolling, with mixed CPU/GPU loads; ❸ *Media* (e.g., YouTube): multimedia decoding, with steady CPU/GPU loads; ❹ *Gaming* (e.g., Genshin Impact): sustained CPU/GPU loads and memory pressure.

Automation scripts replay fixed operation sequences: non-game apps simulate scrolls or clicks at ~1 Hz; game loads run complex control loops (e.g., camera rotation, jumps) at ~2 Hz. Each experiment runs one foreground application at a time with the background LLM; the 30 applications form a benchmark suite rather than a concurrent workload.

Protocol. We report the mean of 15 runs (~45 s each, one per prompt), excluding the two largest and smallest values. Continuous decoding serves as the default stress test to expose worst-case overlap with foreground rendering; we further evaluate a sporadic invocation pattern in §7.2 to capture assistant-style usage where bursts are short but still coincide with rendering deadlines.

Baselines. We compare SERENO against three categories of baselines. ❶ **Native:** Foreground only (i.e., the upper bound). ❷ **SOTA Frameworks:** *PowerServe* [66] (QNN-based), *llama.cpp* [27] (CPU/GPU(opencl)/NPU backends), and *MNN* [55]. ❸ **Strategies:** Implemented within *PowerServe* to represent standard approaches, including *Freq-Limit* (static NPU frequency capping to ~50% frequency), *Chunk-Sleep* (fixed 50% duty cycle sleep), and *Speculative* (throughput-oriented speculative decoding schemes like EAGLE-2 [48]). For SERENO and *Speculative*, we use *Llama-3.2-1B-Instruct* (W4A16) as the draft model.

Metrics. For foreground QoS, we extract *jank rate* and *slow rendering rate* from Perfetto FrameTimeline [87]. To evaluate system peak performance, we use Geekbench 6 and 3DMark scores [68, 88]. For background performance, we measure throughput (tokens/s) and latency in prefill and decode phases. Micro-architectural metrics are collected via Snapdragon Profiler [76] and simpleperf [9].

7.2 End-to-End Effectiveness

This section evaluates SERENO in multitasking scenarios, assessing whether it preserves foreground QoS and peak system performance while maintaining competitive background LLM throughput. Unless otherwise stated, we utilize the default *Balanced Policy* (§6).

Comparison with SOTA frameworks. We first compare SERENO against SOTA frameworks (Figure 5 top row). Uncontrolled NPU inference (PowerServe) causes substantial foreground QoS degradation: taking *Social* workloads as an example, the jank rate increases to 22.12% (vs. Native 6.18%, top left panel) while the slow rendering rate also increases to 3.7× the Native baseline (1.08% vs. 0.29%, top

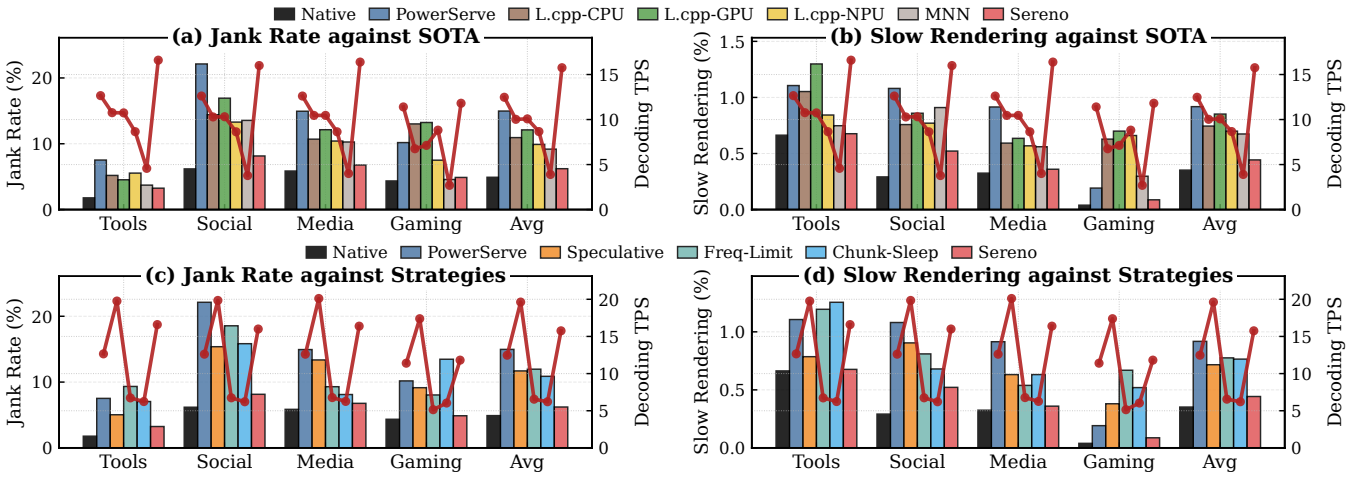

Figure 5: End-to-end effectiveness. SERENO restores foreground QoS to near-native levels while maintaining competitive throughput against SOTA frameworks (a,b) and naive strategies (c,d). Each foreground application is evaluated individually with the background LLM. L.cpp stands for llama.cpp.

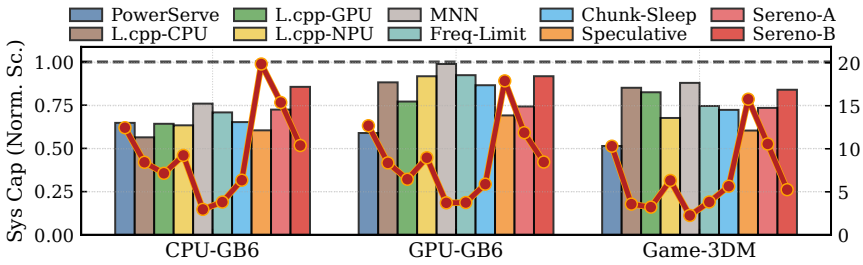

Figure 6: System peak performance recovery. Suffix -A and -B represent two policies in §6.

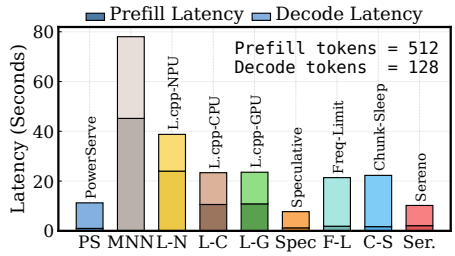

Figure 7: Latency breakdown.

right panel). Other frameworks also fail to resolve this contention: *llama.cpp-GPU* suffers high interference (16.92% jank rate) due to shared memory bottlenecks. *MNN*'s jank rate is 13.55%, and its throughput is severely reduced to 3.78 tokens/s. SERENO substantially mitigates this interference, suppressing the *Social* jank rate to 8.14% (approaching Native's 6.18%)—eliminating most induced stutter—while sustaining 16.00 tokens/s. SERENO delivers up to 92.6% reduction in jank rate and 67.9% increase in throughput in comparison with PowerServe. On average across all categories, SERENO achieves a jank rate of 6.21% (Native is 4.91%) and a slow rendering rate of 0.44% (Native is 0.35%), effectively restoring near-native fluidity. Compared to PowerServe, SERENO reduces the jank rate by 58.5% and improves throughput by 26.4%. Compared to *llama.cpp-NPU*, SERENO reduces the jank rate by 37.1% and improves throughput by 82.2%.

Comparison with scheduling strategies. The scheduling-strategy comparison (Figure 5 bottom row), against aggressive (*Speculative*) and conservative (*Chunk-Sleep*, *Freq-Limit*) baselines, highlights the necessity of SERENO's elastic design. While speculative decoding (*speculative* in the figure) maximizes throughput (19.84 tokens/s), its unregulated bandwidth usage keeps the *Social* jank rate high at 15.38% (far above the Native's 6.18%). SERENO trades a moderate throughput (16.00 tokens/s) to bring the jank rate down to 8.14%, significantly approaching the Native baseline. Under *Reader* application, SERENO achieves a 72.1% jank rate reduction with only a 6.2% throughput degradation. Regarding conservative strategies, *Freq-Limit* proves to be ineffective: by capping NPU frequency to ~50%, it suffers from both low throughput (6.74 tokens/s) and high interference (18.55% jank rate), as it lacks the responsiveness to handle micro-bursts. *Chunk-Sleep* behaves similarly, and the trend holds across categories. Overall, SERENO achieves 2.5× the throughput of these naive strategies while maintaining lower average slow rendering (0.44%), showing that SERENO's sub-millisecond elasticity improves the QoS-throughput balance.

System peak performance. Figure 6 evaluates the recovery of system peak performance using both SERENO policies (the -A and -B suffixes denote the two policies in §6). In *Gaming* scenarios, uncontrolled inference degrades scores to 51% of Native levels. For SERENO, balanced policy recovers this to 73% while maintaining high throughput (10.56 tokens/s), offering a middle ground better than uncontrolled execution. For maximum foreground protection, strict policy further prioritizes other tasks, restoring scores to 84% and GPU scores to 92% (vs. PowerServe's 59%). A critical comparison arises with MNN: while MNN achieves a high benchmark score

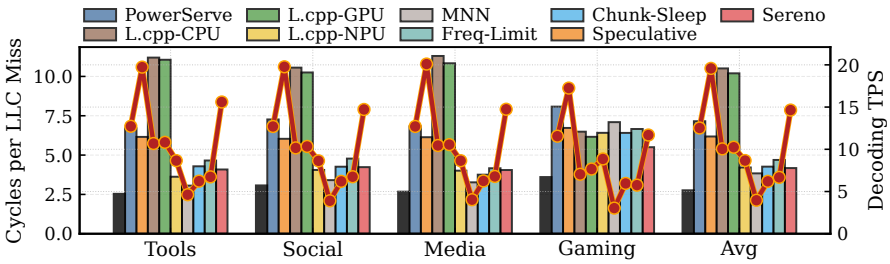

Figure 8: Physical memory stall reduction.

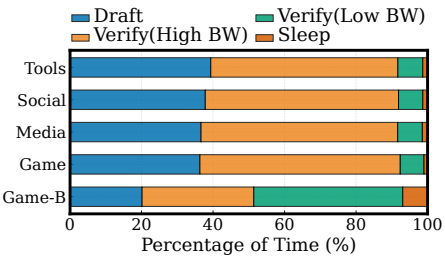

Figure 9: Dynamic mode adaptation.

(88%), it does so by throttling inference to a negligible 2.25 tokens/s. In contrast, SERENO (strict policy) maintains 5.25 tokens/s in the same scenario, indicating true resource elasticity rather than simple pausing.

Latency. Finally, Figure 7 analyzes the request turnaround time (512 prefilling tokens + 128 decoding tokens), averaged over the 30-application benchmark suite with one foreground app running at a time. SERENO's end-to-end latency (10.21 s) is 9% lower than the uncontrolled PowerServe baseline (11.25 s). This result stems from the underlying speculative acceleration: although the prefill phase is slower (2.09 s vs. 0.99 s) due to the smaller batch sizes required for preemptibility, the accelerated decode phase compensates for this delay. Among all systems, SERENO exhibits only slightly higher latency than *Speculative*, as the latter ignores other tasks to solely focus on inference acceleration.

Sporadic workload evaluation. We model SERENO under a sporadic invocation pattern using OnePlus 13. To simulate realistic intermittent usage scenarios, we sweep four invocation schedules, covering short intermittent requests such as notification summarization, smart reply, and short translation [11, 28, 77]. Each schedule holds the invocation period fixed at 50 s and varies only the decode-burst fraction, giving 10/40 s, 20/30 s, 30/20 s, and 40/10 s (burst/idle) schedules, i.e., duty cycles of 20%, 40%, 60%, and 80%. The lightest 10 s-burst/40 s-idle point reflects a single short assistant turn (e.g., a notification summary) per user think-time interval; sweeping toward the 40 s-burst/10 s-idle point progressively stresses the system with denser back-to-back invocations. For the foreground, we deliberately use lightweight, latency-sensitive applications from the categories that realistically co-occur with sporadic assistant turns—*Tools*, *Social*, and *Media* (5 applications in total)—rather than heavy workloads such as gaming. This matches the common case for short background invocations and is also a conservative setting: because such apps already render near the smoothness ceiling, the foreground has little slack to absorb interference, so any residual stutter is directly attributable to the background LLM rather than to foreground load itself. We construct 5 min traces covering six bursts for each system–application pair. Effective throughput is reported as the total committed tokens divided by wall-clock time, including idle intervals; therefore, it captures both useful decoding progress and the idle gaps imposed by sporadic invocation.

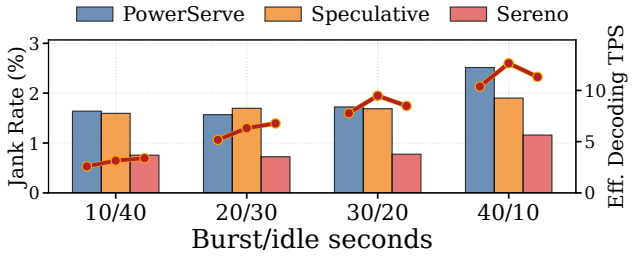

Figure 10: Sporadic workload sensitivity. We vary the decode-burst/idle schedule while keeping the trace length fixed. Effective decoding TPS includes idle intervals in the denominator.

Figure 10 reports the resulting sensitivity sweep. As the scheduled duty cycle increases, effective decoding throughput rises almost linearly for all systems because the LLM is active for a larger fraction of wall-clock time. At the same time, foreground interference remains visible: PowerServe's jank rate rises from 1.64% to 2.51%, and throughput-oriented speculative decoding stays between 1.59% and 1.90% jank across the sweep. SERENO consistently provides the lowest jank rate, ranging from 0.72% to 1.16%, roughly halving PowerServe's jank at each duty cycle. Absolute jank rates here are well below the continuous stress test (Figure 5), as expected from the lighter foreground load and reduced duty cycle; the meaningful signal is thus the consistent relative gap between systems, not the absolute floor. The throughput tradeoff is also bounded. SERENO achieves 3.38 and 6.78 effective tokens/s at 20% and 40% duty cycles, respectively, and remains ahead of PowerServe at the heavier 60% and 80% settings (8.48 and 11.32 effective tokens/s). Thus, increasing the burst frequency stresses all systems, but the relative conclusion is unchanged: intermittent LLM invocations still perturb foreground rendering when they overlap with user interaction, and SERENO's fine-grained yielding preserves a better QoS–throughput balance under both light and heavy sporadic load.

7.3 Mechanism Analysis

We dissect SERENO's internal mechanisms to validate three design principles: reducing memory contention, ensuring signal fidelity, and achieving dynamic elasticity.

Physical bottleneck mitigation. Figure 8 validates that SERENO addresses the root cause: shared memory contention. We quantify this using *Stall Cycles Per LLC Miss (CPLM)*—derived as the ratio of memory stall cycles to LLC misses (calculated as PMU counter `CYCLE_BACKEND_MEM_STALL` / `LLC_MISS`). CPLM serves as a high-fidelity proxy for the effective DRAM latency perceived by the CPU.

Under uncontrolled NPU inference (PowerServe), the average CPLM surges to 7.15 cycles, 2.6× the Native baseline (2.76 cycles), confirming that NPU DMA activity saturates the interconnect. SERENO effectively regulates this traffic, pulling the average CPLM down to 4.17 cycles—a 42% reduction compared to the uncontrolled baseline. Even in the most bandwidth-starved *Gaming* scenario, SERENO outperforms throttling strategies like *Chunk-Sleep* (6.41 cycles), reducing CPLM by a further 14%. This indicates that SERENO's high-frequency knobs and fine-grained yielding are significantly more effective at clearing memory bus congestion than coarse-grained sleep or unoptimized execution.

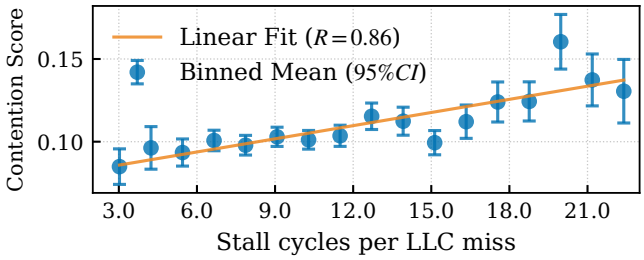

Figure 11: Signal correlation. CI stands for confidence interval.

Signal accuracy. The efficacy of our control loop hinges on the accuracy of SERENO's *Contention Score*. Figure 11 correlates our zero-overhead signal (draft subgraph latency) against CPLM. Across 125,060 samples ranging from light social scrolling to heavy gaming, we observe a strong linear correlation when CPLM ≤ 22 (Pearson $R \approx 0.86$). This correlation allows SERENO to sense congestion at sub-millisecond granularity without software overhead or hardware performance counters.

Controller actuation behavior. Figure 9 shows the dynamic distribution of execution modes. Under the default balanced policy, the distribution remains stable across standard workloads, with *Draft* occupying about 35–40% of the total time. In *Gaming* scenarios, the reduction in *Draft* (to 36.3%) is moderated by the *Minimum Throughput Guarantee*, which limits yielding to preserve baseline inference performance. To validate the mechanism's full adaptive range, we analyze the strict policy (Gaming-B) where this throughput constraint is disabled. Under this configuration, the system exhibits a substantial mode shift: the *Draft* time share drops to 20.1%, while the low-bandwidth, larger-batch verification mode rises to 41.7% (vs. 6.6% in default). This confirms that the controller effectively reconfigures the inference pipeline to reduce memory bus occupancy when policy constraints permit.

Controller effectiveness. Taken together—a stable input signal ($R = 0.86$), the 42% CPLM reduction, and a policy-driven Gaming mode shift that also raises micro-sleep time from 1.0% to 6.9%—these results show that the PI controller is not merely enabling static throttling: it maps measured contention into graded, phase-specific actions, all without a separate hardware mechanism.

Speculative acceptance and rejection. We also inspect the speculative statistics recorded by SERENO's runtime. Across SERENO runs in the continuous stress test with instrumentation, the tentative-token acceptance ratio is 18.9% on average, corresponding to an 81.1% rejection ratio. This token-level ratio is lower than throughput-oriented speculative decoding (30.4% acceptance in the instrumented baseline runs), and we emphasize that this gap is a deliberate design choice of SERENO rather than an unintended side effect. To minimize memory bandwidth occupancy under contention, SERENO intentionally (i) verifies in larger batches that amortize target-model weight traffic over more candidates, and (ii) adopts a more aggressive draft-abort policy that preempts the draft model whenever foreground bandwidth pressure rises. Both decisions trade per-token acceptance for bandwidth headroom; the resulting throughput loss is then compensated by *N-gram Filling*, which recycles high-confidence candidates to keep useful work flowing through the larger verification window. Correctness is unaffected because every candidate, whether produced by the draft model or the n-gram cache, is verified by the target model before commitment. Importantly, the higher rejection rate does not blow up the energy budget: as reported in Figure 13, SERENO reaches 3.52 tokens/J versus 3.78 tokens/J for throughput-oriented speculative decoding, a modest ∼7% efficiency gap. The marginal energy of a rejected candidate is small—the draft model is lightweight and verification is batched, so the extra candidates ride along amortized target-model weight traffic rather than adding proportional compute—and SERENO's race-to-sleep behavior recovers static-power leakage by completing useful work at high-performance operating points before yielding. We therefore attribute the bulk of the efficiency gap to control-plane overhead and forced yielding rather than to wasted draft work.

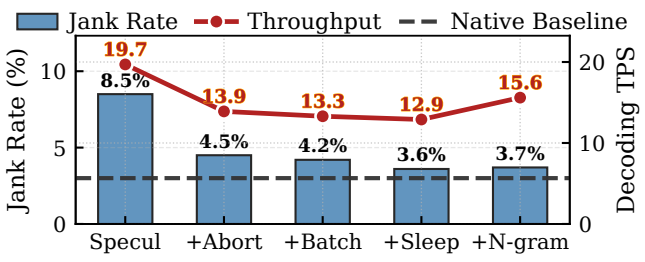

Figure 12: Ablation with dual axes: QoS and throughput.

7.4 Ablation Study

Component ablation. We quantify each component's contribution by enabling them one at a time on four representative apps (Chrome, WeChat, YouTube, and Genshin) covering all categories, as shown in Figure 12.

The baseline, i.e., standard speculative decoding, achieves the highest throughput (19.7 tokens/s) but suffers from a high jank rate of 8.5% (Native is 3.0%) due to unregulated memory bursts. Introducing *Draft Preemption* is the largest single intervention because it targets the bandwidth-dominant draft phase: it reduces the jank rate by 47% (to 4.5%). This confirms that sub-millisecond preemptibility is the primary prerequisite for responsiveness. The remaining components address different phases rather than competing with draft preemption. *Selective Batching* regulates verification by selecting lower-bandwidth verification graphs at a throughput cost, reducing jank from 4.5% to 4.2% while throughput changes from 13.9 to 13.3 tokens/s. *Micro-Sleeps* further handle residual verification bursts, lowering jank to 3.6%. However, this rigorous protection comes at a cost, reducing decoding throughput to 12.9 tokens/s. Crucially, *N-gram Filling* is not a contention-control primitive; it compensates for the throughput loss caused by preemption, recovering throughput to 15.6 tokens/s (+20.9% over the preemption+batch+sleep configuration) without compromising QoS.

This ablation demonstrates that SERENO's components are non-redundant and complementary: the control plane (Draft Preemption/Selective Batching/Micro-Sleeps, §5.3) establishes the safety boundary for foreground tasks, while the algorithmic plane (N-gram Filling, §5.1) maximizes the utilization of the remaining bandwidth budget.

N-gram filling ablation. To isolate the impact of our *N-gram Filling* enhancements, we follow the setup in §7.4 but operate in a contention-free environment. We restrict the neural draft model to 12 tokens and use N-gram Filling to pad the verification batch up to 32 tokens. This forces prediction on distal tokens, where model confidence is typically lower. Under this constraint, a naive baseline yields an acceptance rate of 0.64% and a throughput of 14.42 tokens/s. Integrating *Multi-source Construction* provides the first major improvement—increasing throughput to 16.40 tokens/s (+13.7%)—which confirms the value of recycled drafts. Subsequently, applying *Self-Purifying* and *Adaptive Length Weighting* further improves the acceptance rate to 2.59% and lifts the final throughput to 18.06 tokens/s. Collectively, these optimizations recover 25.2% of the decoding speed lost due to preemptions.

7.5 System Analysis

We evaluate the practical deployability of SERENO by analyzing its energy efficiency, hardware generality, task robustness, and resource overhead.

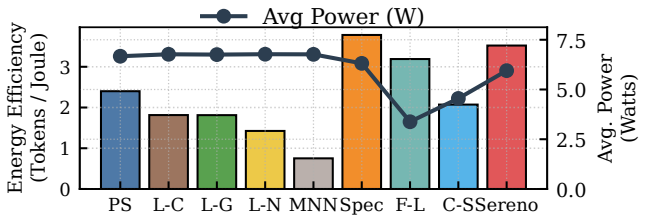

Figure 13: Energy efficiency. Abbreviations follow Figure 7.

Energy efficiency. Mobile inference is strictly energy-constrained. Figure 13 compares system-wide energy efficiency (tokens/J). SERENO achieves 3.52 tokens/J, significantly outperforming CPU-based solutions (1.81 tokens/J) and naive strategies like *Chunk-Sleep* (2.07 tokens/J). Although SERENO's efficiency is slightly lower than *Speculative* (3.78 tokens/J) due to the control overhead and forced yielding, it offers a better trade-off than heuristic throttling. This efficiency gain over *Chunk-Sleep* stems from a race-to-sleep strategy: SERENO utilizes the NPU's high-performance operating points to complete valid work quickly before yielding, while naive throttling prolongs execution time, incurring higher accumulated static power leakage.

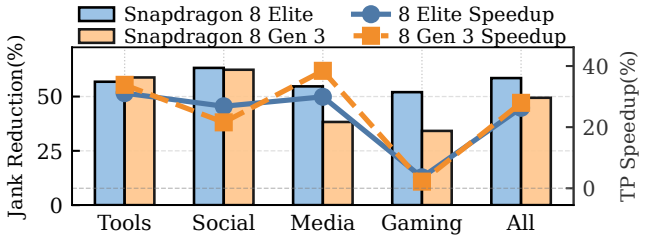

Figure 14: Robustness compared across generations. Jank rate reduction is compared with PowerServe.

Hardware generality. To verify hardware robustness, we replicate experiments on a Snapdragon 8 Gen 3 device (Figure 14). For CPU-dominant workloads like *Tools* and *Social*, SERENO maintains consistent effectiveness on the Gen 3 device, achieving jank rate reductions of 58.79% and 62.34% respectively, similar to the Snapdragon 8 Elite's 56.82% and 59.23% reductions. However, in *Gaming* scenarios, the reduction drops from 52.03% (Elite) to 29.70% (Gen 3). This is because the weaker Gen 3 GPU/CPU makes jank frames often stem from compute saturation rather than bandwidth contention, and SERENO's bandwidth regulation is naturally bounded once the bottleneck shifts to compute—though it remains effective in bandwidth-bound scenarios.

Task and model robustness. LLM speculation acceptance rates vary by task complexity. We use three applications (Chrome, WeChat, YouTube) to evaluate SERENO across three distinct datasets: ShareGPT, GSM8K, and HumanEval, randomly selecting 150 prompts from each. Despite semantic differences, SERENO maintains a stable throughput (15.89–17.16 tokens/s) and consistent jank rate (7.45–8.12%), con-

firming that our endogenous signal detects physical memory pressure regardless of token distribution. We did not evaluate output accuracy, as SERENO is lossless by design.

We standardize on the Llama family as representative of Transformer workloads with invariant memory access patterns. Our 1B-parameter draft model is relatively large for on-device use, establishing a conservative lower bound on control granularity: smaller drafts (e.g., <500M) incur lower per-layer latency, offering finer preemption points and further enhancing SERENO's responsiveness.

System overhead. Compared to the PowerServe baseline, SERENO introduces a marginal CPU utilization increase of ~4.7% (on a single core) due to the bandwidth controller and N-gram Filling. Regarding memory footprint, the system incurs an additional 0.86 GB usage (+19%). This increase is dominated by draft-model weights—an inherent cost of speculative decoding—not SERENO's control logic; the precompiled static graphs specific to SERENO add a negligible <70 MB. Given modern 12 GB+ RAM, this is a justifiable trade-off for the interactivity gains.

8 Related Work & Discussion

Efficient On-Device LLM Inference. Optimization techniques such as quantization [51, 85] and sparsity [6, 80] reduce overheads, while inference frameworks [19, 27, 29, 55, 60, 61, 66, 73, 86, 98, 100] use heterogeneous compute to maximize throughput. These works implicitly assume exclusive resource access and overlook contention in mobile multitasking. SERENO's control plane is orthogonal to these optimizations and can be integrated atop many of these engines.

Speculative Decoding Techniques. Speculative decoding [18, 46] and variants like EAGLE-X [48–50], and others [16, 25, 35, 37, 47, 59, 62, 81, 84, 101, 102] have become standard for on-device inference acceleration. Prior studies treat speculation purely as acceleration; SERENO instead repurposes its algorithmic elasticity into a mechanism for fine-grained, interruptible resource scheduling, turning an acceleration technique into a QoS control primitive. This principle also applies to other methods, such as early exit [22, 52], by steering shallow/deep paths under memory pressure.

Memory Bandwidth Management. Many works notice the importance of memory bandwidth management in system-level QoS [20, 42]. Server-grade systems like LIBRA [107], MT^2 [103], and others [2, 83, 105] rely on hardware enforcement (e.g., RDT [38]/MPAM), while BWLOCK-style systems [2, 3, 104, 105] throttle controllable CPU cores. Mobile NPUs expose neither portable flow control nor scheduler-visible bandwidth accounting, so these mechanisms do not apply. SERENO instead restructures inference via elastic speculative decoding, providing a software-only solution compatible with existing hardware.

Platform scope. Our experimental claims are limited to commercial Snapdragon devices, where we can run foreground/LLM co-execution; source analysis extends the architectural evidence to Dimensity and Exynos SoCs, which expose vendor-specific accelerator traffic or thermal hooks but no portable per-application NPU bandwidth quota. Apple SoCs and unified-memory laptops likely face similar UMA-plus-accelerator contention, though closed toolchains limit mechanism-level claims; discrete-GPU laptops differ because inference and rendering may reside in separate memory. SERENO is thus most relevant to unified-memory smartphones, tablets, AI PCs, AR/VR headsets, and robots.

Model architecture scope. SERENO is evaluated on dense Transformer LLMs, but its requirement is broader: autoregressive inference must expose fine-grained points where tentative work can be stopped without corrupting committed state. The principle applies to MoE models [24, 39] as long as decoding stays bandwidth-bound and speculative work is preemptible, and to SSM-style or hybrid models [32], though Mamba/SSM speculation requires architecture-aware state rollback and verification [92, 96]. What carries over is the control principle, not the exact Transformer-layer actuator.

Overhead optimization. The current prototype uses a 1B draft model, making the reported memory overhead conservative for smaller on-device assistants. Smaller or quantized draft models [51, 85], adaptive speculation depth, and shared KV-cache or shared-prefix representations could further increase the frequency of yielding.

Future hardware trends. We expect contention to remain relevant as mobile NPUs scale: compute throughput and accelerator count grow far faster than package-level DRAM bandwidth and energy, so on UMA devices the gap between how fast accelerators request data and how much shared traffic foreground tasks tolerate keeps widening. Unless future SoCs expose portable per-client NPU bandwidth controls, software-level cooperative yielding remains necessary even as absolute bandwidth improves.

9 Conclusion

We presented SERENO, a software-only framework that resolves the asymmetric interference from on-device LLMs by repurposing speculative decoding into a fine-grained control primitive. SERENO restores foreground smoothness to near-native levels while sustaining competitive LLM throughput.

Abstract

LifeLine is a garbage collection (GC) framework for Android that tackles the fundamental object–page lifetime mismatch. Existing copying collectors move objects, while the OS manages pages; mixed lifetimes within a page force excessive object copying instead of efficient page remapping. LifeLine explicitly aligns object lifetimes with physical pages via three components. First, lifetime-based graph partitioning monitors reference updates and partitions the object graph into subgraphs with strong lifetime affinity. Second, lifetime-aligned GC packs these subgraphs into pages so that each page contains almost entirely live or dead objects, enabling effective page-level management. Third, near-zero-copy GC exploits this bimodal per-page liveness by remapping mostly-live pages and copying only the few surviving objects from mostly-dead pages in cooperation with the OS. Implemented in the Android Runtime and evaluated on real smartphones and popular mobile applications, LifeLine significantly cuts GC copy volume by 57.4%, reduces GC time by 22.7% on average, and improves user-visible responsiveness with modest CPU and memory overhead.

1 Introduction

Android is one of the most widely used mobile operating systems, serving billions of users worldwide [9]. It relies on the Android Runtime (ART) to execute applications and uses a copying garbage collection (GC) mechanism to manage dynamic memory [35, 39, 49]. As shown in Figure 1, copying GCs reclaim fragmented memory by physically relocating live objects to a contiguous region. However, such physical data movement is expensive, as it consumes memory bandwidth and often requires suspending application threads to ensure consistency. For example, memory access latency can increase dramatically during GC execution, as shown in Figure 2. As a result, GC activity can hurt overall performance and cause frame drops and stuttering that visibly degrade the user experience [20, 49].

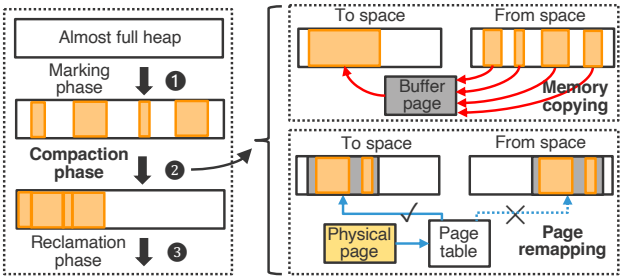

Figure 1: Garbage collection mechanisms in ART. (a) The standard three-phase lifecycle shared by collectors. (b) Compaction strategies utilized by the Concurrent Mark-Compact (CMC) collector: object copying versus OS-assisted page remapping.

To mitigate GC-induced copying overhead, state-of-the-art collectors in ART employ a more efficient memory-movement operation, i.e., page remapping [2, 3]. Supported by the operating system (OS), this operation moves entire pages of memory via modifying page table entries rather than copying the underlying data [31, 52, 61]. However, as illustrated in Figure 1(b), existing collectors fail to fully exploit this opportunity due to a fundamental *object–page lifetime mismatch* problem. Specifically, while the OS manages memory at page granularity, objects targeted by GC are typically much smaller and irregularly sized. Moreover, objects within the same page often have highly diverse lifetimes. As a result, most pages contain a mixture of live and dead objects. Existing collectors are forced to fall back to expensive object-level copying to reclaim space, leaving the OS-assisted zero-copy operation largely underutilized. Generational GC [22, 47, 53] can partially mitigate this issue by separating young objects from mature ones, but it only provides coarse-grained lifetime distinctions. Even within the mature heap, objects on the same page may die at different phases, preventing generational GC from fully utilizing OS-assisted zero-copy mechanisms.

This paper aims to bridge this object-page mismatch by

aligning objects with memory pages according to their lifetimes. When objects in the same page have similar lifetimes, each page is basically either entirely live or entirely dead. Such alignment unifies the basic unit of operation for both GC and the OS: the page. The garbage collector can then reclaim dead objects by freeing whole pages and move surviving objects by remapping the pages that contain them. However, achieving this goal presents three challenges: (1) Lifetime prediction. Object lifetimes in mobile applications are heavily influenced by user behavior and are inherently difficult to predict. (2) Object-page alignment. Packing variable-sized objects into fixed-size pages requires a precise relocation strategy. (3) Low overhead. Mobile devices have limited hardware resources, so the solution must respect tight CPU and memory budgets.

To address these challenges, this paper presents **LifeLine**, a GC framework that solves the object–page mismatch by leveraging the structural properties of the object reference graph. Our design is driven by empirical observations of the object reference graph in Android applications, which show that *reference mutability presents lifetime correlation*. LifeLine leverages graph-related insights to partition the object reference graph into multiple subgraphs based on the mutability of edges. Edges within the same subgraph have similar lifetimes. Specifically, LifeLine comprises three main components: (1) a lifetime-based graph partition method, which identifies subgraphs whose objects have similar lifetimes by relying on mutability information of references within the graph structure. It samples historical field-modification behavior and generates guidance on how to partition the graph. (2) a subgraph–page lifetime alignment GC, which facilitates object–page alignment by mapping entire subgraphs to pages. This GC performs a moving collection over the heap to align subgraphs with pages and explicitly considers subgraph lifetimes when placing objects during GC. (3) a near-zero-copy GC, which exploits page-level primitives after alignment to reclaim and move memory via page operations rather than object copies.

We implement LifeLine in the Android Open Source Project (AOSP) and evaluate it on a Pixel 7 Pro using popular commercial applications. Compared to Android's state-of-the-art production GC, LifeLine reduces total GC copy volume by 57.4% and total GC time by 22.7%, while improving frame rendering smoothness with low memory and CPU overhead. To the best of our knowledge, LifeLine is the first GC that explicitly coordinates the lifetimes of object subgraphs and memory pages. The main contributions are as follows:

- We identify the object–page lifetime mismatch as the primary bottleneck preventing the effective use of OS-assisted compaction in Android runtimes.
- We propose a subgraph-based approach that aligns objects with pages using reference-graph properties. The approach includes a lifetime prediction method based on reference mutability and a GC scheme that places subgraphs on pages according to predicted lifetimes.
- We design and implement LifeLine, a closed-loop system that enables GCs to better exploit OS page-level primitives for minimizing copying overheads and improving mobile application performance.
- We evaluate LifeLine on production Android workloads, and demonstrate a large ratio of GC performance gains.

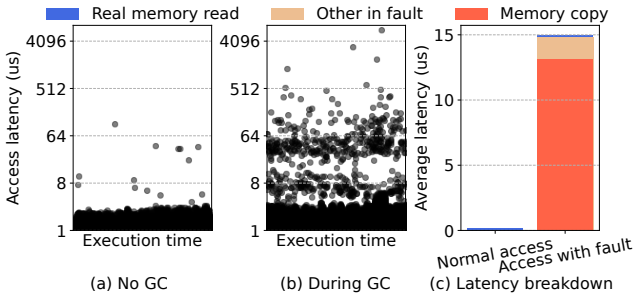

Figure 2: Impact of GC copying on memory access latency. (c) Breakdown of the tail access latency caused by Android's Concurrent Mark-Compact GC, showing that most of the time is spent copying memory to handle page faults.

2 Background

2.1 Garbage Collection in Android

Copying-based GC. Android executes all user applications on the ART [39, 49], which provides automatic memory management via a copying-based garbage collector. Copying GC is widely used in modern managed runtimes, including JVMs [7], .NET [43], and major JavaScript engines [29, 45]. Beyond automatic reclamation, it offers low fragmentation [11, 12], improved cache locality [34, 62], and fast bump-pointer allocation [66, 67]. Consequently, it serves as a fundamental building block in real-world systems.

GC Procedure. Figure 1(a) shows the overall GC process, which is triggered when memory runs low and consists of three phases. ❶ *Marking:* Starting from root objects, the collector traverses references and marks all reachable objects as live. ❷ *Compaction:* Live objects are relocated and packed contiguously. ❸ *Reclamation:* The remaining memory region is reclaimed and returned to the system. Among these phases, compaction typically dominates the performance overhead. During compaction, GC threads and application threads may concurrently modify the same heap regions, so the collector must enforce correctness with additional synchronization. There are three main approaches: (1) *Stop-the-world (STW) pauses* suspend all application threads while objects are moved. While simple to implement, the resulting latency is often unacceptable for interactive devices; therefore, ART re-

stricts STW primarily to root processing. (2) *Baker-style read barriers* [37] insert a small code snippet before each memory read, ensuring application threads only access objects already processed by the GC; Android's Concurrent Copying (CC) [5] GC uses this technique. (3) *Page-level memory protection* [38] uses the OS to protect unprocessed pages and redirects accesses through a fault handler that performs the necessary GC work. This approach underlies Android's Concurrent Mark-Compact (CMC) [1, 26] GC, the default and recommended collector in recent Android releases. However, regardless of the specific approach used, the physical movement of objects during the compaction phase remains a significant source of system overhead.

2.2 OS-assisted Memory Compaction

To move memory efficiently, ART's CMC collector cooperates closely with the OS. With OS assistance, CMC improves memory utilization and mitigates jank during GC [1, 49].

Concurrent Compaction. Conceptually, the collector incorporates two memory spaces: a *from-space* and a *to-space*. At the beginning of the compaction phase, it remaps the memory of all live objects into from-space using an OS remapping system call. It then progressively moves all live objects from from-space to to-space. During this process, CMC relies on the OS to regulate accesses to to-space. When an application thread accesses an unprocessed page, the OS blocks the thread and delivers a `SIGBUS` signal. A registered fault handler then migrates all objects on the faulting page from from-space to to-space. Once the handler completes, the thread resumes and proceeds on the now-processed page.

Strategies for Memory Movement. The key operation in compaction is migrating heap content, for which there are two main strategies, as shown in Figure 1(b):

• *Memory copying:* The straightforward approach is to copy live regions using memory copy operations. However, copying is costly, putting pressure on memory bandwidth, caches, and TLBs [31]. In GC, this cost is amplified [2] because application threads often have to wait for copying to complete.

• *Page remapping:* Recent Linux kernels introduce a zero-copy mechanism through the `userfaultfd` system call [30, 48, 64, 65]. Instead of copying data, the kernel updates Page Table Entries (PTEs) to remap the physical page backing a from-space address to the to-space address [2, 4]. This mechanism is significantly faster than physical copying, potentially reducing movement overhead by over 40% [4]. Within ART, GC threads can invoke `ioctl` with the `UFFDIO_MOVE` command to perform page remapping.

3 Motivation

With OS support, GC has the potential to achieve higher performance than traditional runtime-only approaches [1, 26, 49].

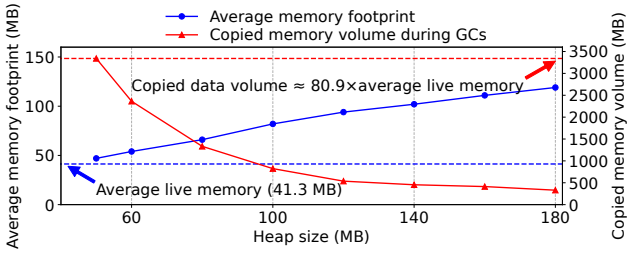

Figure 3: Memory copying overhead (red) and memory usage (blue) under different heap size settings. Smaller heaps reduce memory usage but dramatically increase memory copying.

We now examine how such support impacts the latest Android GC in practice, starting from a classic time–space trade-off.

3.1 Cost-Space Dilemma

Mobile devices are running increasingly rich and memory-intensive applications [10], while hardware scaling has not kept pace. RAM capacity has grown slowly: 8 GB devices still dominate the market, and 16 GB models are limited to a small set of high-end phones [9]. Consequently, GC must navigate a strict time–space trade-off to balance performance and memory usage.

To understand this trade-off in practice, we use Twitter (X) as a case study. We configure the application with a series of fixed heap sizes, run it for one minute under each setting, and measure the additional memory copying induced by GC. For each configuration, we also record the application's average memory footprint and the average live memory traced per collection. Figure 3 shows how average footprint and GC copy volume vary with heap size. With a small heap, the average footprint shrinks, improving memory efficiency, but the volume of copied memory grows rapidly. When the heap approaches its minimum, GC copies 3341 MB per minute, about 80.9× the application's live memory. With larger heaps, the footprint increases roughly linearly, reducing memory efficiency; GC copy volume drops but remains substantial. For example, even with a 140 MB heap, GC still copies about 10× the live memory.

High Cost of Memory Copying. These GC-induced copies impose significant overhead on the entire system, heavily interfering with normal execution [31]. They can directly block memory accesses: as discussed in §2.1, when GC and user threads run concurrently, each user thread must execute an extra read barrier or trigger a page-fault handler to copy the object before accessing it, substantially increasing memory access latency during GC. In addition, the large copy volume lengthens the compaction phase, causing longer GC-induced interruptions of application threads.

To quantify this impact, we again use Twitter (X) and compare memory access latency with and without GC activity. We treat the execution time of the code path that reads fields from

Java objects as the memory access latency, which includes both the actual memory access and GC-related handling. Because the number of accesses is huge, we sample: after every hundred object reads, we record one latency sample and mark whether it occurs during the GC compaction phase. As shown in Figure 2, memory accesses become much slower during GC. The tail latency (10-th parts per million, PPM) increases by about 60×. A closer look at these long-latency cases (Figure 2(c)) shows that, under normal conditions, average access latency is typically below 1 μs, whereas accesses that trigger GC work average about 15 μs, with roughly 87% of the time spent on GC-related copying. Since memory access lies on the critical performance path, blocking it with GC copying directly degrades overall application performance.

Object–Page Lifetime Mismatch Problem. To reduce copying, GC can, in principle, leverage the OS's page-remapping mechanism, as discussed in §2.2. However, current GCs still perform large amounts of copying and rarely benefit from page remapping. The core reason is the *object–page lifetime mismatch*. The OS manages memory at page granularity, whereas GC manages memory at object granularity. Page remapping is only useful when a page is almost entirely filled with live objects; if live and dead objects are heavily mixed, GC cannot reclaim memory simply by remapping that page.

To analyze this mismatch, we examine the liveness of each heap page in mobile applications. During GC tracing, we compute each page's survival ratio as the fraction of live-object size over page size, and then derive the distribution of per-page survival ratios across the heap, as shown in Figure 4 (bars above 100 denote pages whose survival ratio is 100%). A large fraction of pages exhibit medium survival ratios (e.g., 20–80%), where live and dead objects are interleaved, making page remapping ineffective. In contrast, remapping-friendly pages with very high survival ratios close to 100% account for only 16.1% and 13.5% of memory in these applications. Thus, for most of the heap, GC cannot exploit efficient page remapping and must fall back on expensive memory copying.

3.2 Key Idea and Challenges

Bridging Object–Page Lifetimes. To address the object–page lifetime mismatch, this paper aims to enable tighter cooperation between the runtime and the OS. Our key idea is: *by reorganizing the heap layout, we align object lifetimes with page lifetimes.* Concretely, we proactively place objects according to their lifetimes to turn the current roughly uniform, random survival-rate distribution into a *bimodal* one. We seek to reduce pages with medium survival ratios and increase those with very high or very low ratios, so that objects within a page tend to become live or dead together. Once object and page lifetimes are aligned, GC can apply fast page remapping to high-survival pages and perform only limited object copying on low-survival pages.

Challenges. However, realizing this idea in the context of mobile applications raises three major challenges:

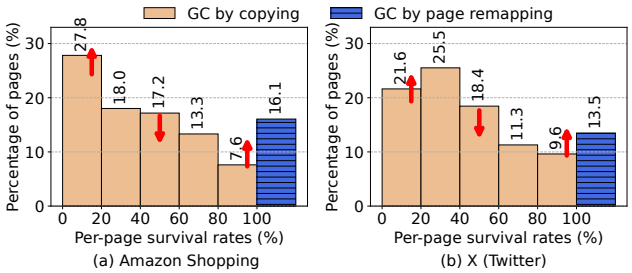

Figure 4: Per-page survival-rate distribution. The rightmost bars correspond to pages with a survival rate of 100%. Our goal is to reduce the number of pages with medium survival rates while increasing those with high or low survival rates.

• *Unpredictable object lifetimes:* In highly interactive mobile applications, object lifetimes are largely driven by unpredictable user behavior and are difficult to predict precisely. The first challenge is to extract and exploit usable lifetime-related information to approximate grouping of objects with similar lifetimes.

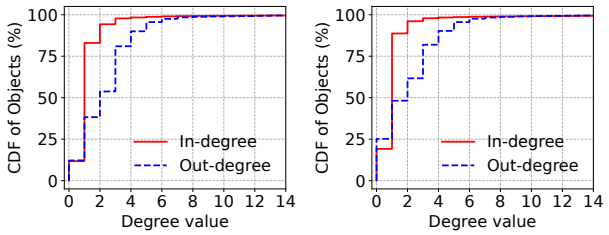
• *Finding structure in a highly dynamic environment:* Android objects are extremely dynamic: allocations and deallocations occur continuously, and object sizes and access patterns vary widely over time. The second challenge is to discover a simple, robust rule to physically organize objects onto pages efficiently and stably in this dynamic setting.

• *Resource constraints on mobile devices:* Our solution must be lightweight: mobile devices have limited CPU and memory, and object counts can reach tens or hundreds of millions. Even storing and updating detailed lifetime information for all objects can be prohibitively expensive. The third challenge is to ensure that, under these constraints, the overhead of our approach remains low enough for deployment on real devices.

4 Preliminary Study and Insights

To address these challenges, we first characterize lifetime-related properties of Android heaps. In this section, we analyze the object reference graph observed during GC tracing and derive three key observations.

Structural Sparsity of Object Reference Graphs. The object reference graph encodes rich lifetime information, as GC determines liveness by tracing this graph. We start by examining the in-degree and out-degree of each object. Using several applications, we instrument ART to record all references traversed during GC tracing and then compute the degree distributions (Figure 5). We find that most objects have an in-degree of exactly one. For instance, in Instagram, about 69% of objects are referenced by a single other object. Thus, the object reference graph is structurally sparse: most objects are pointed to by a single source reference, which largely determines their lifetimes.



(a) Amazon. (b) Instagram.

Figure 5: In-degree and out-degree distributions of objects.

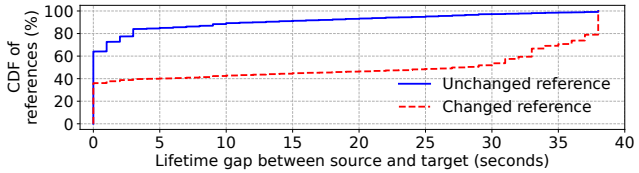


Figure 6: Distribution of lifetime gaps between source and target objects. Unchanged and changed references exhibit different patterns: object pairs connected by unchanged references tend to have small lifetime gaps, whereas those connected by changed references tend to have large gaps.

Insight 1: Strong correlation between object lifetimes and incoming references. For objects with exactly one incoming reference, their lifetime is highly likely to match that of this reference. Hence, the sparsity of the object reference graph allows us to approximate lifetime prediction as edge-lifetime prediction rather than node-lifetime prediction in Android. Edge lifetimes are often easier to model because they are driven by local update operations, whereas object liveness requires global reachability reasoning over the entire graph.

Lifetime Gap between Source and Target Objects. We next study how the lifetime of a reference relates to the lifetimes of its source and target objects. For each reference, we measure the *lifetime gap* between the two endpoints. Concretely, we launch Amazon Shopping, warm it up for 30 seconds, and trigger a GC to capture a snapshot of the current object reference graph. Over the next 38 seconds, we estimate the lifetimes of all objects that die within this window using an approximate reference-counting scheme implemented in the write barrier. During the same interval, we record whether each reference is modified. For every reference, we then compute the lifetime gap between its source and target objects and categorize the reference as *unchanged* or *changed*. Figure 6 shows the resulting distributions. The two patterns differ sharply: for unchanged references, the vast majority of gaps are near zero, indicating that source and target objects tend to have very similar lifetimes. For changed references, many object pairs exhibit large gaps close to the experiment duration: one object dies during the window while the other survives until the end. We conclude that object pairs connected by immutable references tend to co-survive, whereas pairs connected by mutable references are much more likely to have diverging lifetimes.

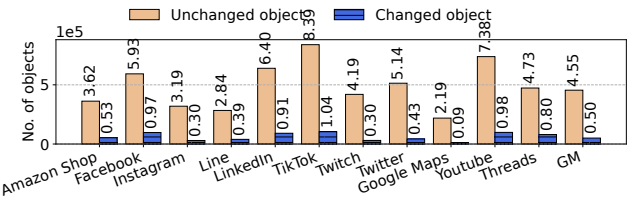

Figure 7: Distribution of unchanged and changed references across applications. GM denotes the geometric mean.

Insight 2: Subgraph-based lifetime estimation. Combining the above observations, we propose a subgraph-based lifetime estimation method. We conceptually cut the object reference graph along mutable edges, yielding subgraphs whose internal edges are all immutable. Objects within such a subgraph tend to survive and die together. We first align each object's lifetime with that of its enclosing subgraph, and then align each subgraph's lifetime with that of a memory page. Rather than predicting exact per-object lifetimes, we focus on lifetime gaps between neighboring objects: if a reference remains unchanged, the connected objects typically live and die together across user sessions. This transforms the complex problem of reasoning about a highly dynamic heap into the simpler problem of identifying and exploiting internally stable subgraphs.

Prevalence of Immutable References. To partition the object reference graph by reference mutability, we must understand how often references change. We record updates to object-reference fields in mobile applications and, over a 30-second window, count how many objects have their reference fields never modified versus modified at least once. As shown in Figure 7, across a set of popular Android applications, the number of objects whose reference fields remain unchanged far exceeds the number of objects whose fields are updated. In all applications, modified objects are much fewer than unmodified ones.

Insight 3: Mutable references are few and cheap to track. Because only a small fraction of references are actually mutated, we need to track only a small subset of fields to infer lifetimes for the entire object reference graph. This alleviates resource constraints on mobile devices: with relatively few cuts, we can partition the whole graph into subgraphs that cluster objects by lifetime.

5 Design and Implementation

5.1 Overview

Design Principles. LifeLine is a GC framework that reshapes the heap so that objects with similar lifetimes are packed onto the same pages, enabling page-granularity GC that fully exploits OS-level page operations. Guided by the empirical

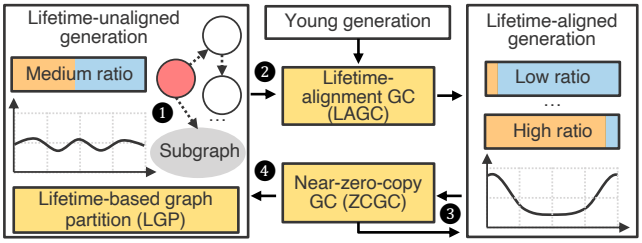

Figure 8: Overview of LifeLine.

insights in §4, it addresses the three challenges in §3.2 as follows: First, instead of predicting exact object lifetimes, LifeLine estimates *lifetime gaps* from reference changes and uses graph partitioning to form subgraphs whose objects have similar lifetimes. Second, it treats each subgraph as a stable intermediary, first aligning objects with subgraphs and then aligning subgraphs with pages. Third, to satisfy mobile resource constraints, LifeLine uses lightweight sampling to approximate reference changes, thereby avoiding expensive fine-grained per-object tracking. Moreover, to address the possibility that predictions may become stale as application behavior changes, LifeLine is designed as a closed-loop optimization framework rather than a one-shot predictor. When an app's workload shifts, the system conservatively falls back to the original object-copying mechanism and initiates a new round of lifetime alignment.

Heap Layout. As illustrated in Figure 8, LifeLine extends ART's generational heap with three logical spaces: (1) *Lifetime-aligned generation:* This is the core new space. Objects that belong to identified lifetime-correlated subgraphs are promoted into this generation. LifeLine strives to make each page in this space either almost fully occupied by objects that share similar lifetimes, making it an ideal target for page remapping or wholesale reclamation. (2) *Lifetime-unaligned generation:* Objects that cannot be reliably placed into any lifetime-correlated subgraph are promoted into this generation. (3) *Young generation:* Newly allocated objects reside in the young generation. Survivors from the young generation are promoted either to the lifetime-aligned generation or to the lifetime-unaligned generation.

Components. LifeLine consists of three components:

• *Lifetime-based graph partition (LGP):* This component partitions the object reference graph into subgraphs with high lifetime affinity based on how references are updated. LifeLine instruments the interpreter and compiler-generated code to intercept operations that update object fields, and samples these updates to identify highly mutable object fields. Using this information, it partitions the graph so that references between objects within each subgraph are mostly stable.

• *Object-page lifetime-alignment GC (LAGC):* The goal of this component is to align subgraphs with memory pages. Concretely, it is a garbage collector that reorganizes objects according to their lifetimes. During tracing, it analyzes the subgraph information produced by LGP. Then, in the compaction phase, it aligns one or more subgraphs with memory pages based on subgraph sizes and their dependency relationships. Each time it runs, it promotes objects into the lifetime-aligned generation.

• *Near-zero-copy GC (ZCGC):* This is a garbage collector that efficiently manages the memory of the lifetime-aligned generation. During the compaction phase, the collector estimates the live ratio of each page. For pages with a high survival ratio, it moves memory via page remapping, thereby avoiding physical data copying. Conversely, for pages with a low survival ratio, it reclaims them by copying objects. Pages with an intermediate survival ratio are rare and are treated similarly to sparse pages. All objects moved by copying are relocated into the lifetime-unaligned generation.

Runtime Workflow. As shown in Figure 8, LifeLine operates as follows: After an application starts, all objects are first allocated in the young generation and are then promoted to the lifetime-unaligned generation. During execution, LifeLine uses LGP to record mutability information for all objects ❶. Afterward, LifeLine uses LAGC to reorganize the heap by grouping objects with similar lifetimes onto the same pages and migrating them into the lifetime-aligned space ❷. In the lifetime-aligned space, LifeLine uses ZCGC to manage memory. For pages with a high survival ratio, ZCGC adopts an efficient page-remapping scheme ❸. For pages with a low or medium survival ratio, ZCGC uses an object-copying scheme to evacuate the page and relocate the surviving objects into the lifetime-unaligned generation ❹. As the application continues to run, new objects keep moving into the unaligned generation, and old objects keep dying in the aligned generation, so ZCGC also monitors these changes. If many objects accumulate in the unaligned generation, it triggers a new round of LAGC to reshape the page distribution and migrate objects into the aligned generation again.

5.2 Lifetime-based Graph Partition

LifeLine proposes a lifetime-based graph partition (LGP) to identify subgraphs of objects that tend to live and die together. As shown in Figure 9, the LGP procedure mainly consists of two steps. First, it modifies the execution engine of the runtime system to capture write operations to objects, and inserts small code snippets into the execution paths of these write operations so that the program executes a write-barrier function. Second, inside this write-barrier function, the captured object reference fields are recorded into a layered Bloom filter. This layered Bloom filter records all captured information about modified fields and uses it as the basis for partitioning the graph into subgraphs.

Write Interposition and Sampling. To record mutability of object fields, LGP inserts a small write barrier at object-field write sites in ART's execution engine. Specifically, the interpreter extends the bytecode handlers for instructions that

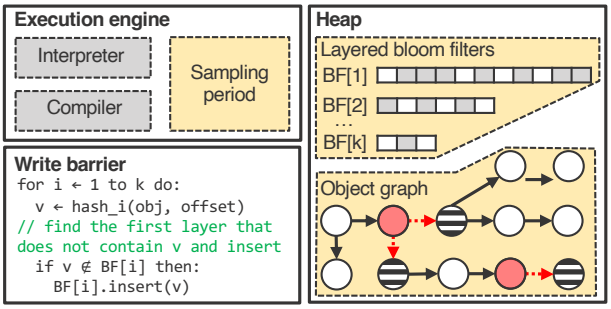

Figure 9: Lifetime-based graph partition.

store references into object fields. The JIT/AOT compiler inlines a few instructions along the object write path. Whenever the application executes a write operation, the operation can be intercepted and the execution flow redirected to the write-barrier function.

However, naively hooking write operations may introduce extra overhead because writes occur frequently, especially inside loops. To manage the overhead incurred by write interposition, LGP employs thread-based periodic sampling. It maintains a counter variable in thread-local storage for each thread and a sampling-period constant. Before calling the write-barrier function, it increments the thread-local counter and checks whether it has reached the period. If it has not reached the period, execution continues without calling the write barrier. Thus, it executes the write barrier for only a subset of write operations, while the remaining writes pay only the cost of a single inexpensive thread-local variable increment. Therefore, the overhead of write interposition remains low even for update-intensive applications.

Tracking Mutations with Layered Bloom Filters. At each sampling period, the program thread invokes a write barrier that records the modified object field and the number of times it has been updated. To maintain this information efficiently, LGP employs a layered Bloom filter [15, 19, 23, 24, 44]. Layered Bloom filters are commonly used for approximate counting in heavy-hitter detection [28, 51]. Here, we use them to maintain approximate write statistics for each object field.

Concretely, we allocate k Bloom filters, $BF[1..k]$, all initially empty. During each sampling operation, the write barrier receives the modified object and the offset of the updated field. The pair $(object, offset)$ uniquely identifies the modified object field. We use this pair as input to compute a hash value and insert the hash into the first Bloom filter that does not yet contain it. In this scheme, the number of layers containing a hash represents the number of sampled mutations. If an object field is present in the i-th Bloom filter, it has been modified at least i times. For example, a field whose hash appears only in $BF[1]$ has been observed once; if it appears in both $BF[1]$ and $BF[2]$, it has been observed at least twice, and so on.

LGP derives a simple mutation summary for any given object field from the layered Bloom filters: fields whose hash either does not appear are treated as mostly immutable owners. Their outgoing references are treated as candidates for lifetime-correlated edges. In contrast, fields whose hashes reach deeper layers (e.g., $BF[3]$ or beyond) are classified as mutable. Their outgoing references are likely to cross lifetime boundaries and thus become subgraph cut edges. This design keeps overhead low, requiring no explicit per-object counters, and amortizes mutation-tracking cost across inexpensive hash computations and bit operations on a small number of filters.

Graph Partition. Based on the field-level mutation information recorded in the Bloom filters, LGP partitions the whole graph into multiple subgraphs by cutting along mutable references. Using different layers of Bloom filters corresponds to applying different mutation thresholds, which in turn leads to different partitioning results. As shown in Figure 10, when a small partition threshold is used (e.g., information from the first Bloom filter), most of the resulting subgraphs are relatively small. In contrast, when a larger partition threshold is applied (i.e., information from higher-layer Bloom filters), the fraction of larger subgraphs increases. Nevertheless, for all thresholds, the distribution of subgraph sizes remains highly skewed: some subgraphs exceed the page size, while others are much smaller. In LifeLine, the partition threshold is set to 3, as this choice makes most subgraphs close to the page size while requiring only three Bloom filters, thus keeping the memory overhead relatively low.

Robustness of Mutability-based Prediction. Reference mutability provides strong robustness because it captures a relatively stable property of the program, rather than attempting to predict the exact moment at which an object becomes unreachable. For example, fields that are repeatedly overwritten often link a long-lived container to a succession of short-lived contents. This pattern is common in mobile applications: fields that remain stable after initialization typically connect objects that are owned and reclaimed together, such as a view hierarchy, a decoded content object, or a per-session data structure. Therefore, LifeLine's lifetime analysis focuses on distinguishing rarely modified stable edges from frequently modified boundary edges, instead of predicting the precise lifetime of each individual object; the latter is inherently difficult and highly dependent on user behavior. When runtime behavior changes, LifeLine's mutability-based lifetime-boundary prediction remains robust because it relies on a relatively stable property of mobile programs.

Although LifeLine's lifetime-prediction method is robust in most cases, significant changes in runtime behavior may still reduce the stability of lifetime alignment and decrease the number of pages that can be optimized through remapping. Such cases include abrupt changes in application behavior, such as navigating to an entirely different page, or substantial short-term fluctuations in user interaction patterns. In the worst case, LifeLine gradually falls back to the behavior of the underlying baseline copying collector, while incurring only bounded additional overhead from extra alignment operations

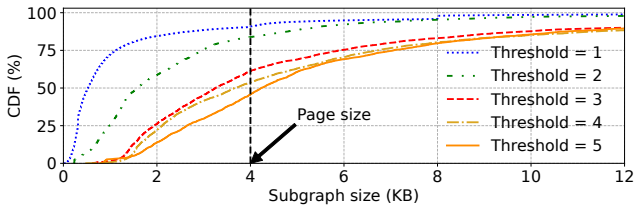

Figure 10: Distribution of subgraph sizes. This distribution is directly influenced by the partition threshold. A smaller threshold yields more small subgraphs, while increasing the threshold raises the proportion of large subgraphs.

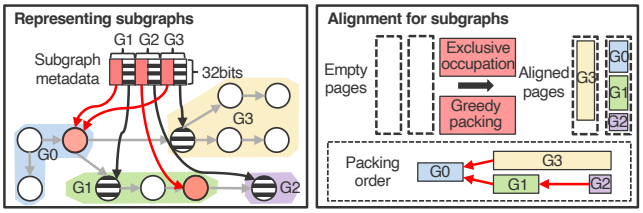

Figure 11: Object–page lifetime alignment GC.

and temporary metadata maintenance.

5.3 Object–Page Lifetime Alignment GC

After partitioning the object reference graph into multiple subgraphs, LifeLine's goal is to reshape the heap so that each page is either almost entirely live or almost entirely dead. To achieve this, LifeLine employs an object–page lifetime alignment GC (LAGC), as shown in Figure 11, which performs a full moving collection over the heap. After this collection, the mature heap exhibits a bimodal distribution of per-page survival ratios. This layout allows subsequent GCs to replace most object copying with inexpensive page remapping.

Representing Subgraphs. To reorganize the heap, LAGC first traces the entire object reference graph, as in conventional GCs, to obtain both liveness information and subgraph metadata. This metadata summarizes the partitioning of the graph according to LGP's records and the relationships among subgraphs. The metadata has three components: (1) It assigns each subgraph a 32-bit identifier, defined as the address of its root object. Using this identifier, LifeLine can locate all objects in the subgraph along the tracing order. (2) It maintains another 32-bit value per subgraph to represent ownership between subgraphs. For example, if a highly mutable edge connects subgraphs G0 and G3, LifeLine designates G0 as the logical owner of G3 and records the host object address of such mutable edges in this ownership field. Using this field, LifeLine can determine the owner of any subgraph, conservatively choosing the first candidate encountered during tracing when multiple owners exist. (3) It stores the total size of each subgraph in bytes, which the collector uses to align subgraphs with pages.

Constructing Metadata during Marking. During the marking phase, LAGC constructs subgraph metadata on the fly. As the GC thread traverses and marks the object reference graph, it checks for each field whether its referent is recorded in the k-th-layer Bloom filter. If so, LifeLine creates a new subgraph entry, uses this object as the subgraph identifier, writes it into the subgraph metadata as a new subgraph, initializes the subgraph size to 0, and pushes the referent onto the tracing stack.

During subsequent traversal, when an object is popped from the stack, the GC thread inspects the current subgraph metadata. If the object represents a subgraph identifier stored in the metadata, it is recognized as a subgraph root, and LifeLine immediately begins counting the size of this subgraph. Due to the depth-first traversal of the GC, all objects scanned thereafter are treated as belonging to this subgraph until another subgraph root is encountered or the stack backtracks past the root's position. For each such object, LifeLine increments the subgraph size and updates the current subgraph metadata.

Finally, LifeLine completes all subgraph metadata setup within this single, mostly concurrent marking pass, with minimal interference to the mutator. The resulting metadata induces an approximate but stable ownership relation over subgraphs. In practice, since ownership is predominantly singular (§4), this relation is sparse rather than dense, keeping the subsequent alignment phase simple and inexpensive.

Align Large Subgraphs: Exclusive Occupation. During compaction, LAGC uses the subgraph metadata to align subgraphs with pages. As shown in Figure 10, subgraph sizes are highly skewed: many are close to or larger than a page, while others are much smaller. LifeLine therefore classifies subgraphs using a size threshold (4 KB by default) and applies different strategies to large and small subgraphs.

For large subgraphs, LifeLine uses an exclusive-allocation policy: each large subgraph occupies one or more pages by itself. When computing target addresses, LAGC proceeds in two steps. (1) It first assigns a page-aligned starting address to the subgraph's root. (2) It then assigns contiguous addresses within those pages to all objects in the subgraph, traversing them in the same DFS order used during tracing. Allocation in the to-space is monotonically increasing. During this traversal, LifeLine accumulates the total size of allocated objects and stops when this total reaches the subgraph size recorded in the metadata or when it encounters the root of another subgraph. This procedure packs all objects in a large subgraph into a contiguous set of pages, so those pages are dedicated to objects with similar lifetimes. It also sidesteps complex binning decisions for very large objects, keeping the alignment algorithm simple and predictable.

Align Small Subgraphs: Greedy Packing. Given the dependency subgraph metadata, LAGC treats each subgraph as an indivisible item and each lifetime-aligned page as a bin, greedily co-locating related subgraphs. The packing algorithm has

two steps. First, ownership-based aggregation. For a small subgraph, LAGC follows ownership edges using the subgraph metadata: it finds the parents on which this subgraph depends, identifies the head of each parent's subgraph, then continues to their owners, and so on. All subgraphs visited during this reverse traversal are tentatively grouped as candidates for the same page, while LAGC tracks their cumulative size. When this total reaches the page-size threshold, the aggregation stops. Second, relocation by guided traversal. Starting from the highest-level owner discovered above, LAGC follows its outgoing references to enumerate all grouped subgraphs. This owner is placed first on the lifetime-aligned page. LAGC then performs a traversal pass similar to that of a normal GC, but with the crucial advantage that it already knows exactly which subgraphs can be merged. As it starts from the top-level owner, it lays out the subgraphs contiguously within the page, so siblings and nearby descendants naturally end up co-located.

This greedy, ownership-aware packing (1) increases the likelihood that objects on the same page have correlated lifetimes, (2) keeps pages tightly packed, since most clusters nearly fill a page, and (3) remains lightweight by maintaining lifetime relationships at subgraph granularity rather than object granularity.

Progressive Alignment across GCs. LifeLine does not require object–page alignment to be completed in a single GC cycle. Large heaps, in particular, may require multiple LAGC runs. As shown in Figure 8, LifeLine maintains two mature generations: one lifetime-aligned and one lifetime-unaligned. Each LAGC compacts only the unaligned generation, incrementally migrating objects into the aligned generation. This staged process helps stabilize the system during alignment.

5.4 Near-Zero-Copy GC

To exploit the bimodal per-page liveness created by LAGC, the near-zero-copy GC (ZCGC) minimizes data movement in the lifetime-aligned mature generation. It runs after the global marking phase of a major collection, when live objects in this generation are already known. As shown in Figure 12, a movement planner cooperates with the OS to decide, on a per-page basis, whether to migrate a page via zero-copy remapping or to compact it by copying surviving objects.

Per-Page Survival Ratio Estimation. Scanning all objects on a page would defeat the goal of fast compaction. Instead, the planner reuses statistics collected during the GC's marking phase. During tracing, the GC accumulates the total size of live objects for each page. The planner then simply divides this live-byte count by the page size to compute the page's survival ratio. Because this accounting piggybacks on the existing marking pass, it yields a robust estimate at essentially negligible additional cost.

Hybrid Page-Remap-or-Copy Strategy. Given the estimated live ratio, the planner chooses between two movement

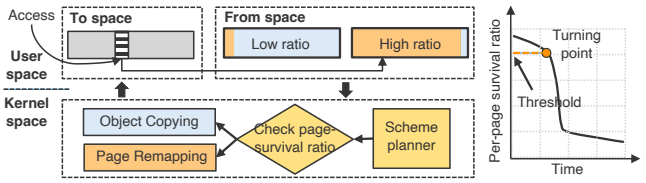

Figure 12: Near-zero-copy GC. It features an efficient hybrid scheme that combines page remapping with object copying.

schemes using two configurable thresholds:

• *Page remapping for dense pages.* If a page is almost entirely live (e.g., a live ratio above a high threshold such as 90%), copying would waste CPU cycles while reclaiming little space. For such pages, the planner uses `userfaultfd` with `UFFDIO_MOVE` to atomically remap the physical page from from-space to to-space. This operation updates only the page-table entries without modifying the underlying data, so the cost per page is effectively constant, while avoiding frequent copying of many small objects.

• *Object copying for sparse and medium-density pages.* If a page has a low live ratio, only a few objects survive. The planner then uses a copy-based scheme: the GC precomputes new locations for live objects on the page, and when an application thread later faults on the corresponding to-space page via `userfaultfd`, the handler copies only these survivors, leaving the rest of the page free for reclamation. Pages whose live ratio falls between the low and high thresholds are also handled by this copy path. Thanks to LAGC, such medium-density pages are rare and do not dominate the cost.

The thresholds correspond to the turning point in Figure 12, where the costs of remapping and copying intersect. Below this point, pages quickly become low-survival because co-located objects tend to die together, making copying cheaper. In our implementation, the thresholds are fixed per deployment but can be tuned using a simple cost model.

Adaptive Re-alignment Trigger. Over time, workload phases may change and the original alignment between subgraphs and pages can drift, causing objects to be repeatedly moved back into the lifetime-unaligned generation while new objects accumulate there. Consequently, the size of the aligned generation S_{align} shrinks and the unaligned generation $S_{unalign}$ grows. ZCGC monitors these sizes and checks:

$$\frac{S_{align0}}{S_{unalign0}} - \frac{S_{align}}{S_{unalign}} > \Delta \times \frac{S_{align0}}{S_{unalign0}} \quad (1)$$

Here, S_{align0} and $S_{unalign0}$ are the aligned and unaligned generation sizes at the first ZCGC after LAGC, and Δ controls when LAGC is re-triggered. When the inequality holds, it indicates significant misalignment, and a new LAGC is invoked.

Fallback and Maintainability. LifeLine preserves the correctness of a conventional tracing collector: reference-mutability information only guides placement, while live-

ness remains determined by normal marking. If phases shift, fields are misclassified, or pages contain mixed-lifetime objects, ZCGC falls back to treating pages as sparse or medium-density and relocates survivors through object copying. Thus, inaccurate prediction may reduce remapping opportunities, but cannot reclaim live objects or expose untraced objects to the mutator. LifeLine also remains maintainable: it adds metadata construction and page-aware placement to ART's GC pipeline, while reusing existing tracing and fault-based relocation mechanisms. Its extra runtime state is temporary and localized to alignment phases, making the design easy to disable, tune, or bypass for workloads that do not benefit from lifetime alignment.

6 Evaluation

We evaluate LifeLine on real hardware and mainstream Android applications, aiming to answer: (1) What is its end-to-end impact on GC work and user-visible performance? (§6.2) (2) What are the underlying causes of these effects? (§6.3) (3) What CPU and memory overheads does it introduce? (§6.4) (4) How sensitive is LifeLine to key parameters? (§6.5)

6.1 Experimental Setup

Comparisons. We compare LifeLine against all state-of-the-art production collectors in the Android runtime: (1) *Concurrent Mark-Compact (CMC)* [1, 26]. This has been the default and recommended collector since Android 13. It relies on a userfaultfd-based fault-and-copy compaction mechanism and, in our configuration, already incorporates OS-level assistance. (2) *Concurrent Copying (CC)* [5]. This was the default collector in earlier Android versions and is still widely deployed. It uses a Baker-style read barrier and performs all compaction via object-level copying. (3) *Semi-space (SS)* [49]. This collector is used during application startup in all Android versions and is a classic stop-the-world copying collector. These three collectors cover the deployed design space of object-copying and OS-assisted GC mechanisms. For LifeLine, we evaluate two LAGC-related configurations: (1) LifeLine (large), which aligns only large subgraphs with memory pages while ignoring small subgraphs; (2) LifeLine (large+small), which aligns both large and small subgraphs. Unless otherwise specified, LifeLine refers to the configuration that aligns both large and small subgraphs. Table 1 lists the key parameters used in LifeLine.

Workloads. Our workload consists of several highly popular Google Play Store applications that represent typical mobile use cases, including Amazon Shopping, Facebook, Instagram, Spotify, LinkedIn, TikTok, Twitch, Twitter (X), Threads, Telegram, Line, YouTube, and Google Maps. For each application, during experiments, we log in to a pre-configured account, wait for the application to finish initialization (10 seconds after launch), connect to a stable Wi-Fi network, and then drive the UI using a repeatable interaction script whose main procedure is to swipe the screen once every 0.4 seconds, covering scrolling and content-loading scenarios. We choose this interaction because it is repeatable across all applications, captures common mobile workloads, and continuously stresses allocation and object reclamation. This methodology also has limitations: it does not cover all application behaviors, such as randomly changing user interactions or short sessions with frequent foreground/background transitions. Nevertheless, the scrolling workflow we use represents the dominant interactive workload in most mobile usage scenarios and therefore provides a practical basis for evaluating performance under common real-world interactions.

Table 1: Summary of parameters used by LifeLine.

Symbol	Component	Semantic	Setting
N_B	LGP	Graph partition threshold	3
M_B	LGP	Sampling period	100
T_G	LAGC	Large subgraph threshold	4 KB
T_M	ZCGC	Page-survival ratio threshold	90%
Δ	ZCGC	Trigger for next alignment GC	30%

Testbed. Experiments run on a Google Pixel 7 Pro smartphone with a 120 Hz display, an octa-core CPU (two 2.85 GHz Cortex-X1, two 2.35 GHz Cortex-A78, and four 1.80 GHz Cortex-A55 cores), a 10-core Mali-G710 MP7 GPU, 12 GB of 3200 MHz LPDDR5, and 128 GB flash. The runtime is Android Open Source Project (AOSP) android-15.0.0_r3. The OS is a Generic Kernel Image (GKI) with the android-gs-pantah-5.10-android15-qpr1 kernel. This kernel does not support page remapping by default; we enable it by porting the corresponding patch [3].

Implementation. We implement LifeLine [1] on top of AOSP and its corresponding GKI kernel. Within AOSP, our modifications are mainly in the ART module, totaling approximately 2.3K lines of C++ code, organized as follows: First, for the GC mechanism, LifeLine introduces two new collector configurations, LAGC and ZCGC, by extending the existing CMC GC (about 1.5K lines). Second, for LGP, we implement the core layered Bloom filter and integrate it into the heap (about 200 lines). LGP also adds write-barrier sampling in both the interpreter and compiler, along with a sampling counter in thread-local storage (about 100 lines). Third, for the heap, we adjust the heap layout by introducing a lifetime-aligned generation while reusing the original bump-pointer space as the lifetime-unaligned generation (about 200 lines). The remaining modifications in ART consist mainly of glue code for configuration, statistics collection, and integration with the existing collector-management infrastructure. In the kernel, we add roughly 100 lines of C code, primarily modifying the `userfaultfd` and page-migration paths.

6.2 Overall Performance

Copy Volume. To quantify how replacing object copying with page remapping reduces memory-movement overhead, we measure the GC copy volume per cycle for all collectors. Each application runs a 30 s warm-up phase, after which we record the bytes copied per GC. The warm-up excludes application launch, account restoration, and initial content fetching, and gives all collectors a comparably mature heap before measurement. We fix the scrolling rate across experiments, collect 10 GCs per application, and report the mean and variance. Figure 13 shows the total data copied per GC. LifeLine substantially reduces physical copying: on average, copy volume drops by 57.4%, from 61.9 MB to 26.4 MB. LifeLine replaces many object copies with page remapping and shrinks both the number and size of the remaining copies. Compared to CMC, LifeLine exploits OS-level page remapping more aggressively, whereas CMC still performs object-level copying for most movements. Overall, LifeLine achieves effective compaction with far fewer memory-copy operations.

LifeLine's reduction varies across and within applications, so we next examine what drives its effectiveness. We first study how heap size (normalized to the SS collector's minimum heap size) affects copy volume (Figure 14a). Across heap sizes, LifeLine consistently copies less than the other collectors, and its advantage widens as the heap shrinks, indicating greater benefits under tighter memory constraints.

We then analyze the impact of the mature-object fraction using Amazon Shopping as a case study. Figure 14b correlates LifeLine's reduction in copy volume relative to CMC with the fraction of objects in the mature generation. As the mature fraction increases, LifeLine's benefit first grows, peaking at moderate maturity (e.g., at 65% mature objects, it cuts copy volume by about 60% on average), and then declines once mature objects dominate. Beyond roughly 80% mature objects, CMC can also leverage OS-level page remapping effectively, narrowing LifeLine's relative advantage. Thus, LifeLine's benefit is strongly tied to the proportion of mature objects and is maximized at intermediate mature fractions.

GC Duration. GC duration is critical on mobile devices because longer GCs increase the risk of blocking user interactions. We reuse the methodology above but now measure GC execution time. Figure 15 reports the average duration and variance for each GC method. LifeLine consistently shortens GC duration in most applications. On average, it reduces GC time from 198 ms (CMC) to 153 ms, a 22.7% reduction. The improvement varies with each application's workload. First, the reduction in duration closely tracks the reduction in copy volume: the more copies LifeLine avoids, the more GC time it saves. Second, applications with small heaps (e.g., Google Maps) already have short GCs, so even large percentage reductions translate into smaller absolute gains.

Frame Rendering Performance. For Android applications, frame-rendering smoothness is a primary user-visible metric. Interactive workloads dominated by touch and scrolling are especially sensitive to GC-induced stalls. We use Twitter and Instagram as case studies and measure frame-rendering-time distributions using the `gfxinfo` tool, capping heap size at 80 MB (roughly 2–3× their minimum heap). Figure 16 shows the cumulative distribution function (CDF) of frame latency for Twitter and Instagram, separating intervals with and without GC. Under CMC, GC causes a clear rightward shift in

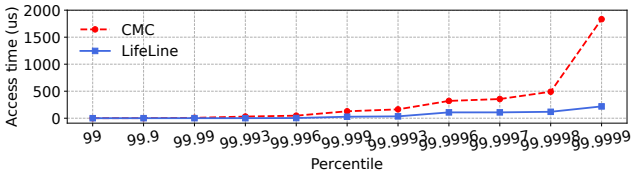

Figure 17: Tail memory access latency during GC.

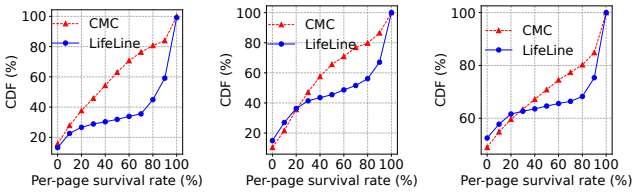

(a) Amazon. (b) Twitter. (c) Instagram.

Figure 18: Per-page survival-rate distribution.

the tail; for example, the 90th-percentile latency is around 30 ms, leading to noticeable stutters. LifeLine significantly improves tail latency when GC occurs. For Instagram, it reduces the 90th-percentile latency by about 29% relative to CMC. Overall, by reducing memory copying, LifeLine alleviates GC-induced stalls, leading to smoother scrolling and a more responsive user interface.

6.3 Benefit Breakdown

We now decompose LifeLine's overall gains into lower-level effects that explain how it reduces stalls and copying overhead.

Tail Memory Access Latency. As discussed in §3.1, memory copies on the GC critical path can inflate tail memory-access latency. To quantify LifeLine's effect, we use Amazon Shopping as a case study and sample read accesses during compaction. We record every 100th access, treating the time required to read a field from an object as the memory-access latency. Figure 17 shows the tail distribution for LifeLine and CMC. LifeLine substantially shrinks the tail. At the 1-ppm tail, it reduces latency by 85% compared to CMC. This improvement arises because LifeLine avoids large object copies on page faults and instead relies on zero-copy page remapping, eliminating many stalls on the GC critical path.

Accuracy of Object–Page Lifetime Alignment. In §3.1, we identified object–page lifetime mismatch as the main reason existing Android collectors struggle to cooperate with the OS. To assess how well LifeLine addresses this issue, we examine the per-page survival ratios at the next GC after alignment. Figure 18 shows that LifeLine reshapes the per-page survival distribution compared to CMC. Under CMC, survival ratios are roughly uniform, with many pages in the 20–80% range. Under LifeLine, the CDF over 20–80% is relatively flat, with

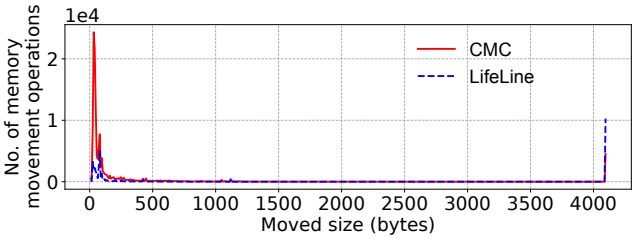

Figure 19: Detailed profile of memory movement.

steep jumps around 10% and 90%, meaning that most pages are either almost empty or almost full. LifeLine thus converts a near-random distribution into a bimodal one, aligning object lifetimes with page lifetimes.

The accuracy of this alignment is also robust to imperfect lifetime prediction. LifeLine does not require exact object lifetimes: it only needs enough correlation to make most pages clearly sparse or dense. When LGP occasionally groups objects whose lifetimes later diverge, the consequence is a medium-survival page rather than an incorrect reclamation decision. ZCGC handles such pages conservatively through the copy path, so inaccurate alignment degrades the opportunity for zero-copy remapping but does not compromise correctness. As objects on poorly aligned pages are copied back to the unaligned generation and newly promoted objects accumulate there, the aligned-to-unaligned generation ratio drops and triggers a new LAGC. Thus, alignment accuracy is self-correcting across GC cycles: transient prediction errors mainly reduce the immediate remapping benefit, while sustained workload changes are absorbed by re-alignment.

Distribution of Memory-Movement Granularity. Given such alignment, LifeLine can perform GC largely at page granularity instead of object granularity. To study this, we measure the size of each memory-movement operation during a single GC for Amazon Shopping. Figure 19 shows that CMC performs many small object moves (e.g., 0–100 bytes), each requiring explicit copying. LifeLine greatly reduces such tiny moves and increases page-sized (4 KB) movements, which are handled efficiently via OS page remapping. Once object and page lifetimes are aligned, LifeLine enables page-granularity GC and tighter GC-OS cooperation.

6.4 Overhead Analysis

Memory Overhead. LifeLine's memory overhead comes primarily from two sources: (1) LGP's layered Bloom filters and (2) LAGC's subgraph metadata. A three-level Bloom-filter design is sufficient in most cases (see §6.5). In our implementation, the first layer uses a 2 MB filter, while the second and third layers use 0.5 MB each, keeping the false-positive rate below 1%. Higher layers store less data and therefore require smaller filters. For each subgraph, LAGC stores two 4-byte pointers and one 4-byte size field, introducing only minor

memory overhead. For example, storing metadata for 5000 subgraphs requires only 59 KB. Overall, LifeLine adds less than 4 MB of auxiliary memory. Moreover, these auxiliary structures are dynamically allocated and used only during lifetime alignment. After alignment, LifeLine switches to near-zero-copy GC and releases these structures. Therefore, its memory overhead is modest relative to the performance gains.

CPU Overhead. Different LifeLine components affect CPU usage in distinct ways. Using System Tracing [6] and Perfetto [8], we profile CPU time per component. ZCGC reduces GC duration, decreasing GC-thread CPU time by 32% compared to CMC. The additional CPU work comes from LGP and LAGC. LGP tracks field mutability by interposing on object-reference writes and consulting the per-thread sampling counter. Because this code executes in the mutator, its cost depends on write frequency; however, the sampling period limits how often the full barrier records a field update. In our measurements, this write-sampling path increases average CPU time by roughly 3.8%. During LAGC, the collector maintains subgraph metadata while marking, identifying subgraph roots and recording ownership and size information. LAGC performs page-aware placement during compaction, assigning large subgraphs to page-aligned regions and packing small, related subgraphs together so that subsequent ZCGC cycles can efficiently remap pages. Metadata maintenance and page-aware placement together add approximately 12.5% CPU time relative to CMC during alignment. Notably, these expensive operations occur only during alignment phases, while steady-state ZCGC leverages the resulting layout and avoids much of CMC's copy work. For example, during a 3-minute Instagram run, LifeLine's average CPU overhead during LAGC is about 2.7% over CMC, which we consider modest given the reductions in GC copying and the improvements in user-visible performance.

6.5 Sensitivity Analysis

Table 1 summarizes the parameters of LifeLine. In this section, we examine how these parameters affect the system. Among them, the number of Bloom-filter levels, N_B, is a critical parameter, as it determines the quality of subgraph generation. We vary N_B from 1 to 5 (see Figure 10). A small N_B (e.g., 1) produces overly fine-grained subgraphs, which in turn multiplies the overhead of LAGC and makes it inefficient. Conversely, a large N_B (e.g., 5) mixes objects with different lifetimes and also introduces unnecessary Bloom-filter sampling and storage overhead, reducing the efficiency of ZCGC. We therefore set $N_B = 3$, which yields subgraphs whose sizes and lifetimes align well with page granularity while incurring relatively low overhead.

We similarly sweep the remaining parameters. If M_B is too small, CPU overhead rises sharply; if it is too large, objects with very different lifetimes are grouped together. For T_G, values below 4 KB create placement gaps for large subgraphs and waste space; since page size is 4 KB, we cap T_G at 4 KB. If T_M is too small, many well-aligned pages are unnecessarily migrated back to the unaligned generation; if it is too large, garbage is reclaimed too late. A 90% threshold works well in practice. Finally, if Δ is too small, LAGC runs too frequently; if it is too large, too many objects remain unaligned and LifeLine's behavior converges toward CMC.

6.6 Discussion on Generalizability

We focus on ART because, to our knowledge, it is the only mainstream open-source runtime whose GC is explicitly co-designed with the OS. Other major runtimes, such as the server-side JVM [7], .NET [43], and JavaScript engines [29,45], currently lack CMC-like OS-cooperative collectors, likely due to cross-platform and engineering constraints. Consequently, we evaluate LifeLine only on Android. LifeLine can, in principle, be integrated into other runtimes to enable stronger GC-OS cooperation and unlock optimizations unavailable to a standalone runtime.

7 Related Work

Garbage Collection. Automatic memory management is a cornerstone of modern managed runtimes [16, 18, 36, 42, 54, 58]. Prior work optimizes GC along multiple dimensions, including pause time [21, 25, 32, 63], throughput [41, 59, 68], fragmentation [11, 13], and memory footprint [32]. LifeLine belongs to this space but focuses on reducing unnecessary GC work through fine-grained lifetime prediction.

Lifetime-based strategies are central to generational collectors [14, 17, 55], which assign objects to a small number of generations based on expected remaining lifetimes. From the OS perspective, however, these schemes are coarse-grained: each generation exposes only a few categories, and pages within a generation may still mix short- and long-lived objects. LifeLine adopts a finer-grained mature-space layout, where each generation corresponds to a single page, aligning object lifetimes with page boundaries. This page-aligned organization improves GC efficiency and, as we demonstrate, reduces jank in Android applications. In this sense, LifeLine can be viewed as a page-level refinement of generational collection for runtimes that already support OS-assisted movement, rather than a competing policy for young-object management. Beyond general-purpose collectors, specialized schemes address disaggregated memory [41, 56, 57], non-volatile memory [40, 50, 60], and large-scale data-processing frameworks [27, 46]. Similarly, LifeLine is designed for mobile runtimes and specifically addresses GC-induced jank in Android deployments.

Cross-layer Memory Management. Recent GC–OS co-design efforts [2, 26] leverage kernel mechanisms [4] to reduce jank, lower energy consumption, and improve perfor-

mance. However, these approaches are fundamentally limited by the mismatch between object lifetimes and page layouts, constraining the benefits of page remapping and reclamation. LifeLine directly addresses this mismatch by producing lifetime-homogeneous pages, enabling more effective GC–OS cooperation. Other systems, such as Marvin [39] and Fleet [33], coordinate GC with the virtual memory subsystem to improve memory efficiency and hot-launch behavior for background applications. This line of work is largely orthogonal to LifeLine. By organizing objects into page-aligned lifetime classes, LifeLine can complement these GC–OS policies, enhancing both foreground GC performance and background-oriented reclamation and compaction.

8 Conclusion

In this paper, we revisit the copying overhead caused by GC in mobile applications and reveal a fundamental lifetime mismatch between objects and memory pages. LifeLine employs a graph-based lifetime alignment mechanism to cluster co-surviving objects onto the same pages, enabling reduced GC overhead and improving overall performance. Although our current prototype targets ART on Android phones, the core idea of aligning object and page lifetimes naturally extends to other managed runtimes and hardware platforms, paving the way for more efficient OS-assisted GC.

Abstract

Asymmetric Multiprocessing (AMP) CPUs are now central to mobile devices, but exploiting them for efficient Deep Neural Network (DNN) inference remains challenging. Naive scheduling across heterogeneous cores often triggers a performance-collapse paradox: adding LITTLE cores degrades throughput due to workload imbalance. Existing approaches rely on static partitioning, which partially mitigates imbalance but fails to adapt to runtime interference, incurs extra task acquisition overhead, and ignores core–kernel affinities—leaving substantial performance untapped.

We present SANI, a scalable, asymmetry-aware inference framework that unleashes the full potential of AMP architectures. SANI introduces three key mechanisms: (1) an affinity-aware kernel issuer that selects cluster-optimal kernels to exploit core–kernel efficiency from the outset; (2) an adaptive granularity scheduler that dynamically merges or splits tasks, balancing load under runtime interference by mapping smaller tasks to slower cores and larger ones to faster cores; and (3) an on-demand kernel switcher that efficiently transforms kernels during workload migration, preserving affinity across clusters. We implement SANI atop Arm-CL and evaluate it on five mobile SoCs. SANI reduces DNN inference latency by 17.6%–23.7% on average (up to 29.5% on some models) while lowering energy consumption by up to 39% compared to state-of-the-art baselines, scaling efficiently across both symmetric and asymmetric CPU configurations.

1 Introduction

On-device deep neural network (DNN) inference has become a cornerstone of modern mobile applications [21, 51, 56, 61]. While GPUs and NPUs provide high throughput, they are not always available across devices or workloads. In contrast, CPUs remain the most broadly deployable platform for mobile inference: they offer predictable performance when accelerators are absent and enable flexible scheduling for diverse application needs [2, 11, 12, 17, 30, 36, 48].

To meet the dual demands of performance and energy efficiency, modern mobile system-on-chips (SoCs) increasingly adopt AMP CPUs designs. These architectures integrate a mix of *high-performance* **big** cores for compute-intensive tasks and *energy-efficient* **LITTLE** cores for lighter workloads [4, 5, 26, 44]. This heterogeneity provides a powerful substrate for efficient inference—but also introduces new challenges for scheduling and workload balance.

A natural way to exploit AMP CPUs for DNN inference is to partition an operator's output tensor into smaller chunks and distribute them across all available cores for parallel execution. Intuitively, this should improve throughput. In practice, however, the asymmetry between big and LITTLE cores undermines this strategy. Our measurements reveal a **performance-collapse paradox**: adding LITTLE cores can increase end-to-end latency by up to 37%. The root cause is workload imbalance: faster threads on big cores frequently stall at synchronization barriers, waiting for slower LITTLE-core threads to complete. These latencies dominate execution time, erasing the benefits of using additional cores.

Existing mainstream solutions for DNN inference on AMP CPUs fall into three categories, each with inherent limitations. First, symmetry-only execution (e.g., Arm Compute Library (Arm-CL) [6]) confines computations to big cores, sidestepping asymmetry but leaving LITTLE cores idle and wasting available resources. Second, proportional static partitioning (e.g., MNN [25]) divides work according to fixed big-to-LITTLE performance ratios. This strategy reduces imbalance under ideal conditions but is brittle in the presence of runtime interference—ubiquitous on mobile devices—causing significant wait latencies. Third, fine-grained dynamic dispatch, such as AsyMo [49], partitions work into many small tasks guided by cost models. While more adaptive, the fine granularity introduces high task acquisition overhead due to the frequency of dequeue operations.

Beyond scheduling, core–kernel affinity plays a critical but underexplored role. Big and LITTLE cores have distinct mi-

*Corresponding author (dcheng@whu.edu.cn).

croarchitectures that favor different operator implementations (kernels). Existing frameworks typically select a single default kernel per operator and apply it uniformly across clusters, ignoring these affinities. When workloads migrate between clusters, performance often deteriorates. Our measurements show that aligning kernel choice with cluster affinity can yield over 30% performance improvement.

In short, prior methods lack two critical capabilities: (1) runtime control of workload granularity to maintain balance under interference, and (2) mechanisms to exploit core–kernel affinity for efficient execution. These limitations leave significant performance headroom untapped.

To overcome these limitations, we present **SANI**, a ***S***calable ***A***symmetry-aware ***N***eural ***I***nference framework, which is designed to exploit asymmetric mobile CPUs fully. SANI introduces two key innovations. First, an affinity-aware execution strategy that selects the most efficient kernel for each CPU cluster and preserves affinity even during workload migration. Second, an adaptive granularity scheduler that dynamically adjusts task sizes, assigning smaller tasks to slower cores and larger ones to faster cores, thereby sustaining load balance under unpredictable runtime interference.

Firstly, SANI employs a holistic approach to maintain core–kernel affinity throughout the inference pipeline. At initialization, it proactively selects cluster-specific kernels for each operator using a hardware-aware cost model that considers microarchitectural features such as SIMD width and cache hierarchy. This ensures that both big and LITTLE cores are issued their most efficient kernel from the outset, avoiding the one-size-fits-all choices made by existing frameworks. To preserve this efficiency under dynamic execution, SANI performs on-demand kernel transformations, remapping workload indices between the layouts of source and target kernels when workloads migrate across clusters. Unlike prior systems that suffer penalties after migration, this reactive step guarantees that cores continue executing their most-affine kernel, sustaining high performance even in the presence of runtime interference and rescheduling.

Secondly, SANI introduces an adaptive granularity scheduler to combat workload imbalance from core asymmetry and runtime interference. Unlike prior approaches that rely on fixed partitions or excessively fine-grained dispatch, SANI continuously monitors lightweight runtime feedback from each thread to guide scheduling decisions. Based on this feedback, it dynamically adjusts task granularity through two fundamental operations, Merge and Split. Faster threads are assigned larger, merged workloads to reduce task acquisition overhead, while slower threads receive smaller, split workloads to prevent them from becoming bottlenecks. This adaptive mechanism enables SANI to maintain balanced execution even under unpredictable interference from background processes, sustaining throughput while minimizing synchronization stalls and queueing costs.

Together, these mechanisms make SANI inherently scalable across heterogeneous CPU configurations, from symmetric big-core execution to fully asymmetric deployments with LITTLE cores.

In summary, the contributions of this paper are:

- We conduct a measurement study showing that adding LITTLE cores for DNN inference on asymmetric CPUs can paradoxically increase end-to-end latency, and we analyze workload imbalance as the root cause of this performance-collapse phenomenon.
- We design an affinity-aware kernel issuer to proactively select cluster-specific kernels, and an on-demand kernel switcher to transform workloads during migration; together, these components preserve core–kernel affinity and maximize execution efficiency.
- We propose an adaptive granularity scheduler that dynamically adjusts task sizes at runtime using merge and split operations, effectively balancing workloads and mitigating bottlenecks of runtime interference.
- We demonstrate that SANI scales efficiently across various CPU configurations, sustaining performance and energy efficiency on five commercial SoCs.

We implemented SANI atop the Arm-CL. Evaluated on five distinct mobile devices across six representative neural networks, SANI delivers average latency reductions of 17.6%–23.7% and up to 39% lower energy consumption, while demonstrating robust performance and significantly lower wait latency under runtime interference. Notably, SANI is the first inference framework designed to holistically address both the inherent compute asymmetry and runtime interference characteristic of mobile AMP CPUs. This work targets operator-level parallelizable workloads and is not designed for large-scale on-device LLM inference, where NPUs are the more suitable target. The core abstractions are operator-shape rather than model-class specific, and we discuss the carry-over to transformer workloads in § 5.5.

2 Background and Motivation

2.1 DNN Inference on AMP

Modern mobile SoCs increasingly employ AMP architectures that combine heterogeneous CPU clusters on a single die [4,5, 26,44]. A typical big.LITTLE configuration integrates high-performance cores with energy-efficient ones [5], offering a flexible trade-off between performance and power efficiency. These clusters share a unified physical address space and remain cache-coherent through the on-chip interconnect. Each cluster keeps its own private L1 and L2 caches, while the last-level L3 cache and main memory are shared across clusters. As a result, big and LITTLE cores can collaborate on DNN inference without explicit data movement.

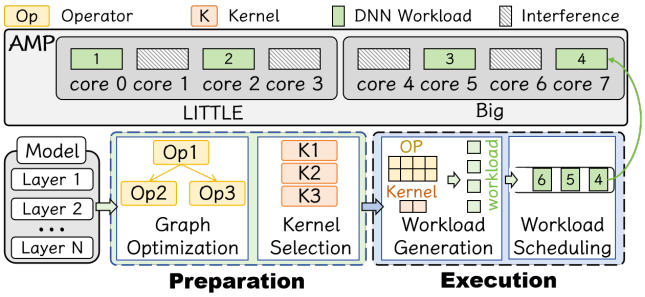

Figure 1: The process of DNN inference on AMP.

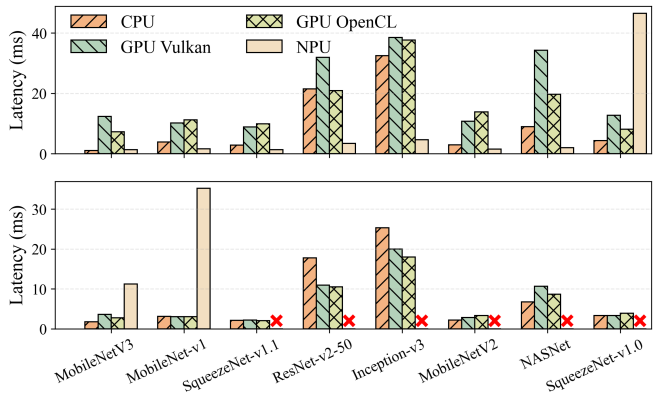

Figure 2: Inference latency comparison across CPU, GPU (Vulkan/OpenCL), and NPU backends on Google Pixel 9 (top) and OnePlus 12 (bottom). Missing bars indicate unsupported models or execution failures.

However, unlike dedicated servers, mobile environments are subject to runtime interference. Foreground applications, background services, and system daemons frequently contend for shared cores [53], leading to volatile compute availability [52, 57]. In this complex runtime environment, DNN inference pipelines translate a network's design into efficient execution flows. As shown in Fig. 1, the process begins with graph optimization, translating high-level layers into mathematical operators, followed by kernel selection, where hardware-tuned kernels are chosen to realize each operator. During execution, operators are partitioned into fine-grained workloads that are placed in task queues and fetched by CPU threads. Specifically, each workload is the schedulable unit handed to one inference thread, consisting of a contiguous sub-region of the operator's output tensor and a pointer to the kernel that executes it. These workloads collaboratively apply the chosen kernel to compute the operator's output tensor.

Why CPU Inference Matters. While mobile GPUs and NPUs are often considered preferred accelerators, CPU-based execution remains indispensable. As shown in Fig. 2, we benchmarked DNNs across CPU, GPU, and NPU backends using MNN [25] on the Google Pixel 9 [19] and OnePlus 12 [39]. Well-optimized CPU inference outperforms mobile GPUs for lightweight models such as MobileNetV3 [23] by 6–11× due to GPU kernel launch overhead and data transfer costs [58]. Moreover, mobile GPUs employ FIFO scheduling, causing inference tasks to compete with rendering and degrade user experience [20]. NPUs, while efficient for supported models, suffer from compatibility limitations: on the Pixel 9, SqueezeNetV1.0 [24] falls back to CPU with 10× slowdown (46.5 ms vs. 4.4 ms), while on the OnePlus 12, most tested models including ResNet-50 [22] and Inception-V3 [47] fail entirely due to vendor-specific operator support gaps. These observations underscore that CPUs are the only universally available and reliable backend for on-device inference, making CPU efficiency essential on AMP architectures.

2.2 Analysis of Existing DNN Inference on AMP

While many DNN inference frameworks exist for homogeneous multi-core systems [37, 54] and heterogeneous SoCs (CPU/GPU/NPU) [1, 9, 15, 27, 35], they face significant performance constraints on AMP architectures. Their limitation stems from an implicit assumption of core symmetry in multi-threaded execution. This prevents the effective use of asymmetric cores and results in suboptimal performance. Therefore, developing frameworks that efficiently utilize all cores is critical for on-device AI. To this end, we perform a measurement study to quantify the performance gap and identify its root causes.

Measurement Setup. We evaluated four convolutional neural networks: MobileNet [23], SqueezeNet, ResNet-50, and Inception-V3, on a Google Pixel 9 equipped with an asymmetric octa-core CPU (1×Cortex-X4, 3×Cortex-A720, 4×Cortex-A520) at their maximum frequencies. To streamline core-type comparisons, Cortex-X4 and Cortex-A720 were categorized as "big" cores throughout the experiments. All measurements were conducted without concurrent foreground or background applications. The baseline implementation leveraged the Arm-CL [6], Arm's official inference framework optimized for mobile architectures. Subsequently, we conducted a systematic analysis of inference latency scaling to thread number increments across heterogeneous core configurations.

Performance Gap and Causes. Fig. 3 illustrates a pronounced performance collapse, revealing a significant discrepancy between the observed *Native* performance and a theoretical *Expected* baseline. We established the *Expected* baseline to serve as a theoretical upper bound on performance. First, we profiled each model to characterize the proportion of its workload that can be parallelized. Then, based on Amdahl's Law [3], we projected the ideal latency scaling. This projection incorporates the fixed performance ratios between big and LITTLE cores, which are specified by chip manufacturers in configuration files [8]. The *Expected* curve, therefore,

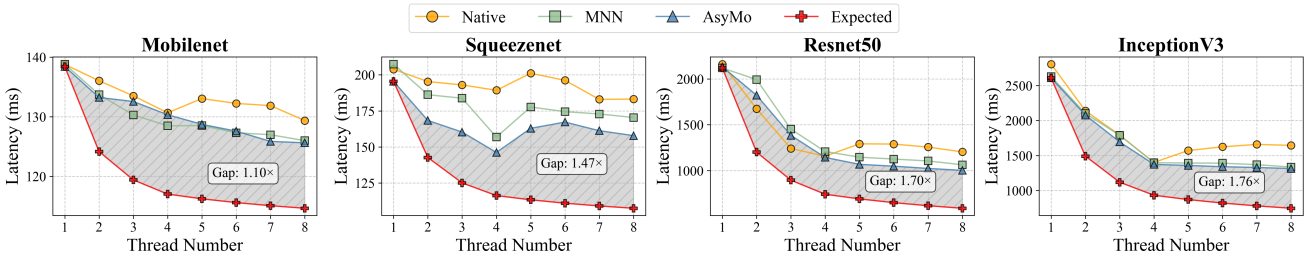

Figure 3: Performance Collapse Paradox: DNN inference throughput degradation with the introduction of LITTLE cores on AMP architectures. The first 4 threads run on different big cores. Others run on different LITTLE cores.

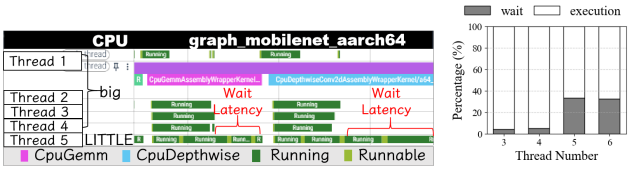

(a) *A real trace of thread execution timeline showing LITTLE cores becoming bottlenecks* (b) *Latency Breakdown*

Figure 5: Analysis of static workload size inefficiencies on AMP architecture.

represents an ideal scenario that assumes perfect scaling without accounting for real-world factors like scheduling overhead or interference.

Contrary to this theoretical expectation, our analysis reveals a paradox. Integrating LITTLE cores, despite increasing the total number of available threads, markedly increases the overall inference latency.

To pinpoint the cause, we decompose latency into two components in multi-threaded DNN inference: *execution latency*, which measures time spent on computation, and *wait latency*, which quantifies synchronization delays due to imbalanced task distribution and scheduling interference. We employed *Perfetto* [18], the Android's official performance tracing tool, to monitor thread behavior during MobileNet inference. As depicted in Fig. 4(a), on a configuration with 4 big cores and 1 LITTLE core, the thread on the LITTLE core requires substantially more time to complete identical workloads. This arises because the default scheduler in Arm-CL evenly distributes tasks across threads, disregarding core performance disparities and thereby transforming LITTLE cores into bottlenecks. The latency breakdown in Fig. 4(b) confirms this analysis, showing that introducing LITTLE cores increases wait latency from roughly 5% to 30% of the total inference time, as faster big cores remain idle waiting for slower LITTLE cores to complete their workloads.

To address this issue, current approaches can be categorized into three strategies. First, symmetry-only execution as employed by Arm-CL, which defaults to use only homogeneous cores (typically just one core in a common 1+3+4 CPU core set), sacrificing potential computational resources to avoid asymmetry complications. Using only big cores forgoes the energy efficiency that LITTLE cores can deliver for sustained inference, while using only LITTLE cores wastes the throughput that big cores can deliver on the critical path. Second, proportional workload partition that allocates tasks according to computational capability ratios between asymmetric processors, exemplified by MNN [25]. Third, fine-grained partitioning with dynamic scheduling, as in AsyMo [49], which divides computation into smaller tasks and balances load distribution with memory access efficiency.

As shown in Fig. 3, implementing these partitioning strategies in Arm-CL yield speedups of approximately 1.2× to 1.25× for complex models like ResNet-50 and Inception-V3 when using all cores.

Nonetheless, these improvements fall substantially short of theoretical expectations, highlighting a significant performance gap. This gap is particularly critical for on-device inference, which is highly latency-sensitive. Many real-time mobile applications operate under strict per-frame latency budgets (e.g., 8.3 ms for 120 FPS [53]), making even millisecond-scale improvements for DNN models highly significant in closing the gap to the theoretical optimum.

Key Observations. Through the measurement conducted on the same Pixel 9 setup as the earlier experiments, we have the following two key observations:

Observation 1: *Static workload size becomes particularly inefficient in AMP architectures operating under interference-prone systems.* Mobile devices concurrently run numerous system and user applications, creating a dynamic execution

environment where inference threads compete for shared resources and face frequent preemption. Consequently, the effective compute speed of any core can fluctuate unpredictably. Existing frameworks that rely on static workload partitioning are ill-equipped to handle this volatility. Specifically, an operator's computation is partitioned into fixed-size workloads that are dispatched to inference threads, and threads wait at a synchronization barrier once their workloads complete. The workload size here refers to the sub-region of the operator's output tensor that a single workload covers, determined by its extents along multiple dimensions. As shown in Fig. 5(a), their fixed-size workloads create a fundamental trade-off, where larger workloads reduce overhead but increase wait latency under interference, while smaller workloads do the opposite. A larger workload size amplifies wait latency, since the slow thread holding the final workload forces the others to idle at the barrier for its entire duration. A smaller workload size yields more workloads in total, adding task-acquisition overhead to the execution latency. This dilemma is illustrated in Fig. 5(b). Fine-grained partitioning, as used by AsyMo, incurs extra task acquisition overhead as faster cores (e.g., the big core) must fetch tasks multiple times, an issue that could be mitigated by merging workloads. Conversely, coarse-grained proportional partitioning, as used by MNN, leads to severe wait latency when interference slows down a core (e.g., the LITTLE core), a problem that could be solved by splitting its large workload for other cores to share.

Observation 2: *Different core types perform optimally with distinct kernel implementations, creating core-kernel affinity patterns.* The optimal code implementation for an operator is not universal across an AMP CPU, as different core types show distinct performance preferences. To quantify this, we benchmarked representative Convolution and DepthWiseConvolution operators on big and LITTLE cores using various kernel implementations. As detailed in Table 1, the results reveal clear affinities. The best-performing kernel for a GEMM operator on big cores is 9.1% faster than the alternative, while on LITTLE cores, the preference is reversed. This effect is even more pronounced for DepthWise convolutions, where using a suboptimal kernel can degrade performance by over 34%. Current frameworks, however, are blind to this. They select a single kernel for an operator during initialization and use it universally. This static choice inevitably leads to missed optimization opportunities, as one of the two core clusters is forced to execute a non-affine kernel. Moreover, when workloads migrate between clusters at runtime, the affinity mismatch persists, resulting in suboptimal performance and preventing the system from reaching its full potential.

Opportunities. These observations highlight a clear path toward optimization. The core challenge from observation 1 is that any static workload size is inherently suboptimal in dynamic mobile environments. This necessitates an *adaptive granularity scheduler* that can dynamically adjust task sizes to balance execution efficiency and wait latency under interference. Similarly, observation 2 presents a two-fold challenge related to core-kernel affinities. An effective solution must both proactively identify and prepare the optimal kernel for each cluster, which calls for an *affinity-aware kernel issuer*. It must also reactively handle workload migrations at runtime, requiring an *on-demand kernel switcher* to perform efficient, on-the-fly transformations. Together, these three components form the holistic SANI framework, designed to systematically address these challenges and achieve near-optimal performance on AMP architectures.

Table 1: Kernel execution time (ms) across core types. h1: $hybrid_6\times16$, sg: $sgemm_8\times12$, d1: $depthfirst_2\times2$, d2: $depthfirst_3\times3$. B/W: Best/Worst ratio.

3 SANI Design

3.1 System Overview

As shown in Fig. 6, SANI's architecture is composed of three synergistic components designed to maximize inference performance on asymmetric multi-core processors.

The workflow begins with the Affinity-Aware Kernel Issuer. This module evaluates operators within a neural network to identify opportunities for a dual-kernel issue, where distinct, cluster-specific kernel implementations are prepared for both big and LITTLE cores based on their hardware affinity. It then standardizes all workloads into a uniform 'block' format and organizes them into separate queues for each processor cluster (e.g., a big-core queue and a LITTLE-core queue). Here, a block is a kernel-agnostic partition unit over the operator's output tensor. Its tile dimensions are set to the least common multiple of the native output sizes of the big- and LITTLE-affine kernels. Blocks are designed as the uniform abstraction above workloads with which the scheduler organizes parallel dispatch. Next, the Adaptive Granularity Scheduler manages the runtime execution. It assigns threads to pull workload blocks from their corresponding cluster's queue. By monitoring the completion time of each block, the scheduler dynamically adjusts task granularity using two core operations: Merge and Split. Merging combines smaller blocks into larger ones to reduce acquisition overhead for faster threads, while splitting breaks down large blocks to prevent slower threads from creating bottlenecks, thus ensuring a balanced load. Finally, the On-Demand Kernel Switcher is triggered when the scheduler decides to migrate a workload between asymmetric CPU clusters to maintain workload balance. If the source and target clusters have different optimal kernels

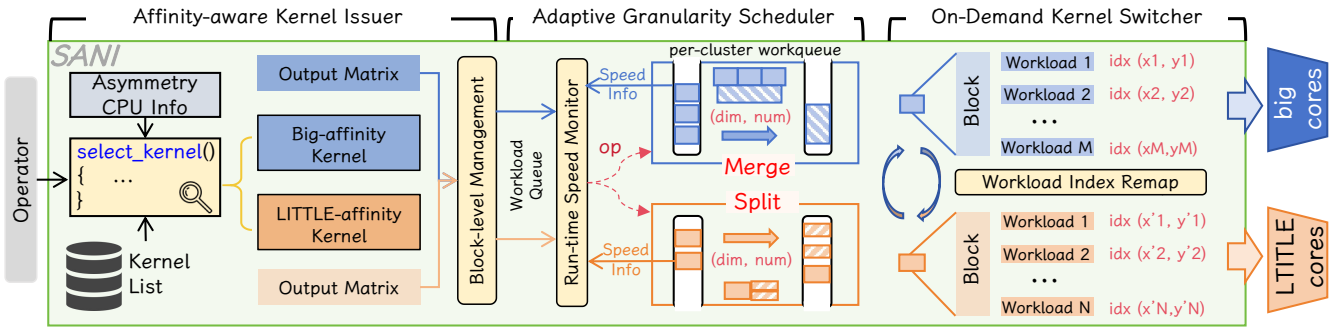

Figure 6: SANI architecture.

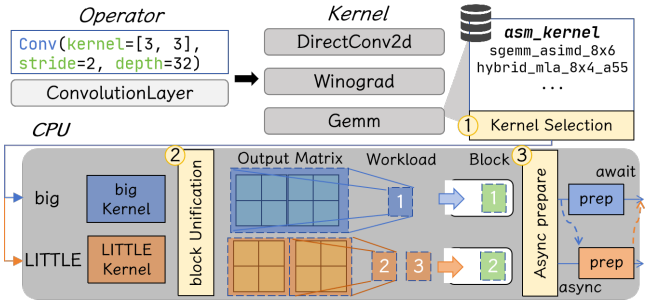

Figure 7: Workflow of affinity-aware kernel issuer.

for that workload, the switcher performs the kernel transformation. It uses a pre-computed map to correctly convert the workload's indices from the source kernel's layout to the destination's. This ensures the new kernel executes on the same computational region, preserving correctness while maximizing performance on the target core. This tightly integrated workflow, from multi-kernel preparation to dynamic scheduling and on-demand transformation.

3.2 Affinity-Aware Kernel Issuer

The affinity-aware kernel issuer prepares operators for efficient heterogeneous execution. Its primary role is to select optimal, cluster-specific kernels and unify their workload representations into a standardized format, all while hiding preparation overhead. As shown in Fig. 7, this process involves three key steps.

Kernel Selection. For each operator O_j in the neural network, the issuer selects the most suitable kernel implementation for a given CPU cluster H by predicting its performance. It leverages a cost model that calculates an affinity score, $A(O_j, K_i, H)$, for each available kernel variant K_i:

$$A(O_j,K_i,H) = \alpha \cdot C(O_j,K_i) + \beta \cdot M(O_j,K_i) + \gamma \cdot I(K_i,H) \quad (1)$$

where $C(O_j,K_i)$ represents the computational cost, which estimates the total number of arithmetic operations based on the operator's tensor shapes and the kernel's logic. $M(O_j,K_i)$ is the memory cost, estimating the total data movement by analyzing the kernel's specific data access pattern for the given operator shapes.

Finally, $I(K_i,H)$ is an instruction compatibility score that quantifies how well the kernel's instruction mix (e.g., specialized SIMD instructions) aligns with the target cluster's micro-architecture. The affinity score is designed to be inversely proportional to execution latency. The cluster-specific weighting factors α, β, and γ are pre-determined by fitting the model to empirical latency measurements using linear regression during an offline profiling stage. The selection process is thus formalized as finding the optimal kernel K_H^* for operator O_j on cluster H:

$$K_H^*(O_j) = \arg\max_{K_i} A(O_j,K_i,H) \quad (2)$$

This process allows the issuer to identify the optimal kernel pair—one for big cores and one for LITTLE cores—for each operator that can benefit from a dual-kernel strategy.

Block Unification. Different kernel implementations often have distinct output shapes and compute orders, which complicates scheduling and workload migration. To address this heterogeneity, we introduce a standardized 'block' abstraction for a consistent workload interface. This unification process involves two key steps. First, to align the computational sequence, we define a unified partitioning and iteration strategy. The operator's total output tensor is partitioned along its height and width dimensions based on the kernel's native tile size, and we enforce a height-first iteration order. This ensures that all kernel variants process workloads in a predictable and consistent sequence. Second, to harmonize the different output shapes, we define the unified block's dimensions using the Least Common Multiple (LCM) of the candidate kernels' output tile dimensions. For example, if a big-core kernel has a 2×4 output tile and a LITTLE-core kernel has a 2×2 tile, the unified block size becomes 2×4. The entire operator's output tensor is then logically partitioned into these blocks. This process establishes a clear mapping between a single block's index and the corresponding workload indices for both the big-core and LITTLE-core kernels, which is critical for subsequent scheduling and migration. For the initial dispatch, these blocks are distributed to the cluster-specific queues, with the

```
struct W {
  int split_dim;
  int start[MAX_DIM];
  int end[MAX_DIM];
  void (* kernel)();
};
W merge(vector<W> w) {
  int dim = w[0].split_dim;
  W w_m = w[0];    // initialize
  w_m.end[dim] = w.back().end[dim];
  return w_m;
}
```

```
vector<W> split(W w, int n, int d) {
  vector<W> w_v;
  W t_w = w;
  int k = (w.end[d] - w.start[d]) / n;
  for (int i = 0; i < n; i++) {
    t_w.start[d] = w.start[d] + i*k;
    t_w.end[d] = w.start[d] + (i+1)*k;
    t_w.split_dim = d;
    w_v.emplace_back(t_w);
  }
  return w_v;
}
```

Figure 8: Merge and Split APIs in SANI.

number of blocks for each queue proportional to the cluster's relative compute capacity. Using cluster-specific queues instead of a single global queue serves two purposes. First, threads on each cluster pull blocks that have been preloaded with the affine kernel and act on data already warm in that cluster's private caches, preserving locality. Second, separating the queues avoids the contention that a single global queue would impose on all inference threads at every dequeue.

Asynchronous Preparation. Preparing distinct kernels for each cluster could introduce significant latency if performed sequentially, as each requires setup tasks like memory allocation and weight pre-transpose. Concretely, preparation covers per-operator memory allocation for the dual-kernel pair, weight pre-transposition into each kernel's native layout, and construction of the index map used by block unification. It runs once at model load and is not repeated during online inference. To mitigate this overhead, SANI employs an asynchronous preparation strategy. The preparation tasks for multiple kernels are submitted to a thread pool concurrently. Since these preparation stages are typically single-threaded, this parallelism effectively utilizes available multi-core resources, hiding the latency of the additional kernel variants. A synchronization barrier ensures all preparations are complete before the online inference phase begins. The overhead introduced by this strategy will be quantified in our overhead analysis (§ 5.4).

3.3 Adaptive Granularity Scheduler

The primary goal of our adaptive granularity scheduler is to balance wait latency and execution latency to maximize overall system performance in AMP environments.

Design Rationale. Observation 1 shows that static workload size cannot fit all execution scenarios, so we propose an adaptive granularity scheduler that adjusts workload size and distribution. Our design philosophy follows the principle: *"With great power comes great responsibility"*. Threads demonstrating higher execution speed should handle larger workloads, as they are less likely to become performance bottlenecks even under system interference. Conversely, slower threads should process smaller workloads to prevent them from becoming system-wide bottlenecks.

Workload Operations. As shown in Fig. 8, we define a `struct W` to represent a workload, encapsulating both the computational region and the kernel to be executed. It contains start and end indices for each dimension, the dimension used for partitioning, and a pointer to its assigned kernel. Based on this structure, we define two fundamental operations: Merge and Split. The Merge operation takes a vector of contiguous workloads and a dimension as input, combining them into a single, larger workload. It creates a new workload that spans from the first workload to the last one along the specified dimension. Conversely, the Split operation takes a workload and divides it into multiple smaller sub-workloads along the dimension. Each resulting sub-workload maintains identical boundaries in all other dimensions. Both operations adjust workload size within a single cluster queue and preserve the kernel pointer carried by each workload.

Algorithm 1: Adaptive Granularity Scheduling

Input: W: Workloads Queue; T: Number of threads;
k: Number of threads to adjust per round;
Output: Completed execution of all workloads

1 Initialize counter $C_i = 1$ for each thread $i \in \{1, 2, ..., T\}$
2 Initialize round counter $r = 0$
3 **while** W *is not empty* **do**
4 $r \leftarrow r + 1$
5 **for** *each thread* $i \in \{1, 2, \ldots, T\}$ *in parallel* **do**
6 **if** $C_i \geq 1$ **then**
7 Fetch C_i workloads $\{w_1, w_2, \ldots, w_{C_i}\}$ from W
8 $w_i \leftarrow \text{Merge}(\{w_1, w_2, \ldots, w_{C_i}\})$
9 **else**
10 Fetch one workload w from W
11 Find the smallest d in `dim` such that $w[d] > T$.
$\{w_1, w_2, \ldots, w_T\} \leftarrow \text{Split}(w, T, d)$
12 Execute w_i with $w_i.kernel$
13 Record completion time t_i for thread i in round r
14 Sort threads by completion time $\{t_1, t_2, \ldots, t_T\}$
15 **for** *the k fastest threads i* **do**
16 $C_i \leftarrow C_i + 1$
17 **for** *the k slowest threads i* **do**
18 $C_i \leftarrow C_i - 1$

Adaptive Scheduling. Algorithm 1 implements our core scheduling strategy. The algorithm operates in rounds, processing workloads until the queue is empty. In each round, after all threads complete their tasks (Lines 6–15), they are sorted by completion time (Line 16). Following our design principle, the k fastest threads are rewarded with larger workloads for the next round by incrementing their counters, enabling them to merge more blocks (Line 8). Conversely, the k slowest threads are penalized by decrementing their counters. If a thread's counter drops below one, it must split its next workload (Lines 10-13). To prevent creating excessively small tasks, the split logic first identifies the smallest dimension whose iteration count is still larger than the number of threads

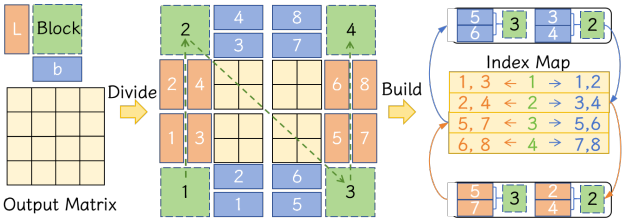

Figure 9: Workflow of on-demand kernel switcher.

before partitioning (Line 11). This adaptive approach gradually aligns task granularity with each thread's true runtime capacity, inherently accounting for both system interference and processor asymmetry.

With N workloads and T threads, each workload is dequeued once, giving a base cost $O(N)$. Moreover, merges across rounds sum to $\Theta(N)$. Splits add only a constant-factor overhead since each event produces at most T sub-workloads. The per-round sort over T completion times is $O(1)$. Therefore, the overall time complexity is $O(N)$.

3.4 On-Demand Kernel Switcher

To maintain workload balance when a cluster's workload queue is depleted, the adaptive granularity scheduler initiates workload migration from another cluster, which creates a challenge for exploiting core-kernel affinity. A core receives a workload prepared for a different architecture, leading to suboptimal performance if executed with a non-affine kernel. The on-demand kernel switcher addresses this by performing an efficient, on-the-fly transformation of the workload.

To ensure transformations are fast and effective, the on-demand kernel switcher incorporates three key optimization strategies. First, to accelerate the index mapping, it pre-builds and stores a direct-mapped lookup table. enabling constant-time lookups at runtime. Second, it employs a threshold-based filter. Workloads smaller than a pre-defined size are exempt from transformation, avoiding overhead where the potential performance gain is negligible. Third, it implements a specialized policy for merged workloads introduced by the scheduler. To handle the larger aggregated workloads efficiently, the switcher uses a columnar transformation strategy. It leverages the start and end indices of the merged block to retrieve the entire range of corresponding target workload indices from the pre-built map in a single operation, which avoids costly individual lookups for each sub-block and is further optimized by the height-first data layout.

When a workload is migrated at runtime, the switcher executes a kernel transform that leverages these optimizations, a process illustrated in Fig. 9. For instance, consider an operator where the selected big-affine kernel has a 1x2 tile size and the LITTLE-affine kernel has a 2x1 tile. Based on the LCM rule, this necessitates a unified 2x2 block for management. Consequently, a 4x4 output tensor for this operator is partitioned into four such logical blocks. The switcher's pre-built index map links each block index to the corresponding workload indices for both kernel types, following a height-first iteration order. Therefore, block index 2 corresponds to workload indices 3 and 4 for the big-affine kernel. Through the map, the switcher finds that this same computational region corresponds to workload indices 2 and 4 for the LITTLE-affine kernel. After passing the size threshold check, the switcher performs a constant-time lookup to retrieve these target indices. Finally, it updates the workload's payload, replacing the kernel pointer with the target cluster's affine kernel and setting the new workload index, which is then passed to the target kernel for execution. This process guarantees that the migrated workload computes the identical output region, preserving correctness while maximizing performance on the new host core.

3.5 Scalability by Design

SANI is designed to scale naturally across heterogeneous CPU configurations, rather than optimizing for a fixed device or core count. The affinity-aware kernel issuer ensures each cluster always executes its most efficient kernel, decoupling operator efficiency from the number or type of cores. The adaptive granularity scheduler rebalances workloads by merging or splitting tasks, which allows the system to maintain balance as concurrency increases or runtime interference fluctuates. Finally, the on-demand kernel switcher preserves affinity under workload migration by transforming kernels at runtime, preventing the penalties that usually arise when workloads shift between clusters.

Together, these mechanisms make SANI inherently scalable: it can seamlessly leverage both big and LITTLE cores across diverse SoCs without hardware-specific retuning. This scalability-by-design principle distinguishes SANI from prior approaches; in evaluation, we demonstrate its ability to sustain efficiency as the number of heterogeneous cores grows.

4 Implementation

We implemented SANI with approximately 11.6k LoC atop Arm-CL (tag v52.3) [6] and plan to publish the code. Our implementation addresses the following key areas:

Scheduler Integration. To maintain backward compatibility, we implement SANI as a custom scheduler that overrides Arm-CL's `schedule_common()` function, allowing it to intercept the execution flow without requiring user-code modifications. Our adaptive granularity scheduler maintains separate queues for each core cluster and implements thread affinity control to bind threads to specific big or LITTLE cores, leveraging standard `pthread` APIs to interact correctly with the Linux scheduler.

Kernel Issue and Transformation. For the affinity-aware kernel issuer, we re-implement Arm-CL's `estimate_cycles()`

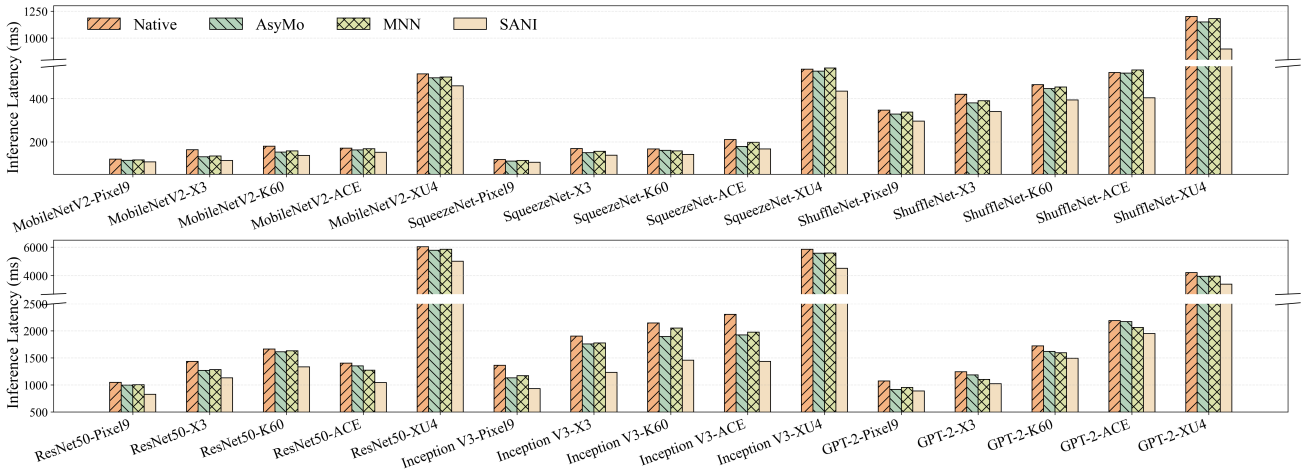

Figure 10: End-to-end latency on Pixel9, X3, K60, ACE, XU4 with *Native*, *AsyMo*, *MNN*, and our work.

Table 2: Device specifications.

Device	Release	SoC	CPU Set	OS
Google Pixel 9	Aug 2024	Tensor G4	1+3+4	Android 14
OPPO Find X3	Mar 2021	SM8350	1+3+4	Android 13
Redmi K60	Dec 2022	SM8475	1+3+4	Android 13
OnePlus Ace 5	May 2025	Mediatek 9400	1+3+4	Android 15
Odroid XU4	Jul 2015	Exynos 5422	4+4	Android 7

function. This allows us to feed the distinct hardware profiles of big and LITTLE cores into our cost model to determine the optimal kernel for each cluster. If the resulting affine kernels are different, SANI initiates a dual-kernel issue and utilizes an asynchronous mechanism to prepare them in parallel via a thread pool. For the on-demand kernel switcher, when a kernel transformation is required, SANI utilizes the pre-computed index map to retrieve the target workload's index with minimal latency, then generates a new workload to compute the same computational region for the new kernel.

5 Evaluation

5.1 Methodology

Testbed. To evaluate the effectiveness and generalizability of SANI, we conduct experiments on four smartphones and one development board, featuring a variety of SoCs from different manufacturers. These devices include the Google Pixel 9 [19], OPPO Find X3 Pro [41], Redmi K60 [55], OnePlus Ace 5 Ultra [40], and the Odroid XU4 development board [38]. Detailed specifications are provided in Table 2. Additionally, the OPPO Find X3 Pro was modified to support the use of Monsoon Power Monitor [34] for precise power consumption measurement.

Workloads. We evaluate SANI with five widely-used DNN models: MobileNetV2 [33], ResNet-50 [22], SqueezeNet [24], ShuffleNet [60], Inception-V3 [47], and one transformer model: GPT-2 [43]. All experiments use pre-trained models in FP32 precision with NEON acceleration enabled. For model compatibility, we deploy GPT-2 using the Arm NN [7] framework with its TensorFlow Lite parser, as Arm-CL lacks support for transformer architectures. Arm NN provides a high-level neural network API built atop Arm-CL while maintaining equivalent computational performance. For vision models, we use standard ImageNet-resolution inputs (224×224) that match common mobile deployment settings. For GPT-2, we use fixed-length 20-token prompts generated randomly, which stress both prefill and decode under a controlled setting.

Baselines. We compare SANI with three state-of-the-art approaches: *Native* (default configuration of Arm-CL [6]), *AsyMo* [49], and *MNN* [25], as detailed in Section 2.2. Our preliminary measurements show that other mainstream frameworks such as TensorFlow Lite [28], ONNX Runtime [13], and PyTorch Mobile [42] exhibit similar inefficiencies on AMP CPUs due to their static, symmetry-assuming workload partitioning. We therefore adopt AsyMo as the primary asymmetry-aware baseline, which has been shown to outperform these frameworks [49]. All implementations are based on Arm-CL, Arm's official open-source framework optimized for Arm architectures. For *AsyMo*, which offers both latency-first and energy-first modes, we implement its latency-first configuration for performance comparison and port its core algorithms to Arm-CL. Similarly, rather than directly comparing with *MNN*, which would introduce unfair comparison due to different framework-specific optimizations, we implement its scheduling strategy within Arm-CL to ensure consistent evaluation.

Metrics. We use three metrics to evaluate performance: 1) *Inference Latency*, measuring end-to-end execution time, 2) *Energy Consumption*, calculated from power measurements during inference, and 3) *Scaling Efficiency*, computed as the speedup relative to the execution on 4 big cores only.

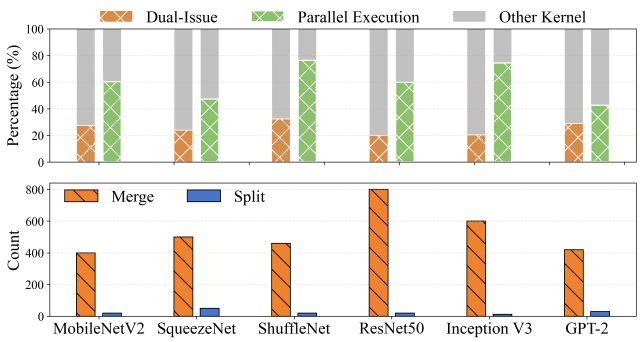

Figure 11: Model analysis: Dual-issue and parallel execution potential (top) and merge-split operation frequency (bottom).

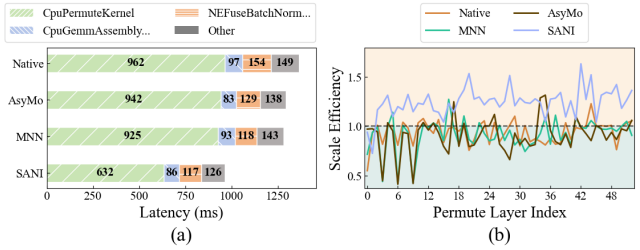

Figure 12: Performance over Inception-V3: (a) Execution time breakdown by kernel types, (b) Scaling efficiency across baselines for Permute kernels.

5.2 Overall Performance

Fig. 10 illustrates the end-to-end inference latency of SANI compared with three baseline approaches across different neural network architectures and mobile devices. SANI consistently outperforms all baselines across all tested models and hardware platforms. On Pixel 9, SANI achieves average latency reductions of 17.6%, 9.8%, and 12.0% compared to Native, AsyMo, and MNN, respectively. The performance gains are even more pronounced on other platforms, with average latency reductions of 23.7%, 14.4%, and 15.0% on the Find X3 Pro; 19.9%, 13.7%, and 15.0% on the Redmi K60; and 21.4%, 15.7%, and 16.7% on the OnePlus Ace. On the Odroid XU4 development board, the improvements are also substantial, with latency reductions of 19.0%, 15.5%, and 16.6% against the same baselines. These results demonstrate that SANI effectively addresses the performance collapse paradox in AMP architectures through its three integrated modules.

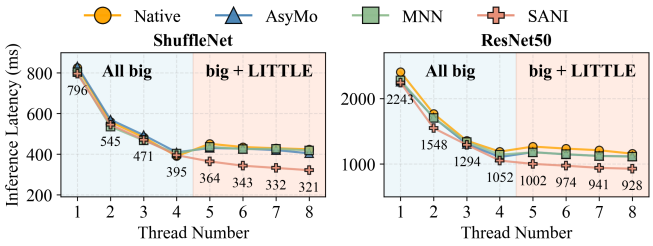
Model Difference. The performance gains vary across different model architectures. Compared to the Native baseline, SANI reduces average latency by 15.7% for MobileNetV2, 17.7% for SqueezeNet, 21.0% for ShuffleNet, 19.3% for ResNet-50, 29.5% for Inception-V3, and 16.1% for GPT-2. To understand this variation, we analyzed the potential for the dual kernel issue and dynamic scheduling. As shown in Fig. 11, models like ShuffleNet and Inception-V3 have a higher percentage of kernels that can be parallelized and benefit from dual-kernel implementations. This allows our affinity-aware kernel issuer to select core-affine kernels from the outset, while the adaptive granularity scheduler optimizes workload distribution at runtime, leading to significant performance gains. Furthermore, we observed that ResNet-50 exhibits the highest frequency of merge operations. This significantly reduces task acquisition overhead, contributing to its substantial performance improvement.

We take Inception-V3, which shows the most significant improvement, as an example for a more detailed analysis. As shown in Fig. 12(a), its performance is dominated by Permute kernels. A key challenge within Inception-V3 is that the Permute Kernel instance has a primary dimension of only 7, which severely limits the degree of parallelism. This results in poor scaling for baselines, as shown in Fig. 12(b). While AsyMo attempts to solve this with multi-dimensional partitioning, but creates excessively fine-grained workloads, which incur significant task acquisition overhead and thus diminish the parallelization benefits. SANI overcomes this with a more balanced approach. The affinity-aware kernel issuer's block unification strategy creates a pool of coarser-grained, manageable blocks. This provides sufficient parallelism to saturate the cores without introducing prohibitive overhead. Then, the adaptive granularity scheduler dynamically adjusts these block-level workloads , achieving a superior balance between wait and execution latency.

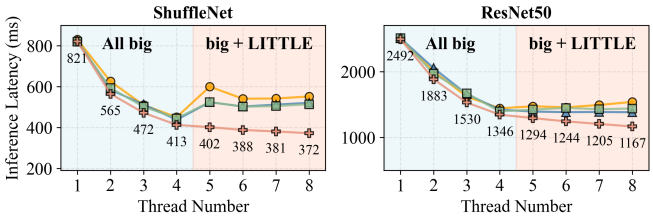
Hardware Difference. The performance variation across hardware platforms reveals a strong correlation between processor asymmetry and SANI's optimization potential. To quantify this, we benchmarked single-threaded performance using the `neon_sgemm` kernel from Arm-CL, revealing asymmetry ratios ranging from 2.6:1 to 3.4:1 across our testbeds. SANI's benefits are most pronounced on devices with higher asymmetry. For instance, it achieves a 23.7% average latency reduction on the Find X3 Pro (3.2:1 ratio) and 19.9% on the Redmi K60 (3.4:1 ratio), compared to a more moderate 17.6% on the Pixel 9 with its lower 2.6:1 ratio. This is because greater architectural asymmetry amplifies the inefficiencies of baseline schedulers, creating more optimization opportunities for SANI. This pattern suggests that SANI's advantages become increasingly valuable as processor asymmetry grows.

Scalability Analysis. Fig. 13 illustrates how SANI and baseline approaches scale across different thread numbers on ShuffleNet and ResNet-50. The results show different behaviors in symmetric configurations using only big cores versus asymmetric configurations incorporating LITTLE cores.

In symmetric scenarios, SANI offers improvements through its adaptive granularity scheduler that adaptively adjusts workload granularity based on runtime execution patterns. On Pixel 9 with ResNet-50 using two big cores, SANI reduces latency by 12.5% versus Native and 9.4% versus



(a) Google Pixel 9



(b) OPPO Find X3 Pro

Figure 13: Performance comparison with increasing thread number on ShuffleNet and ResNet-50.

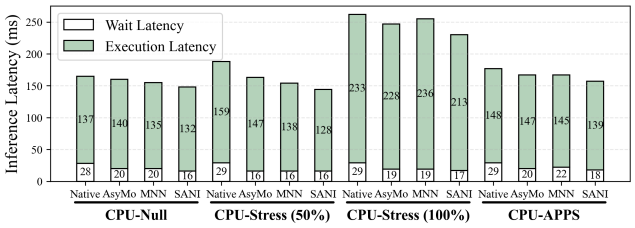


Figure 14: Performance of MobileNetV2 inference under varying system loads on Google Pixel 9.

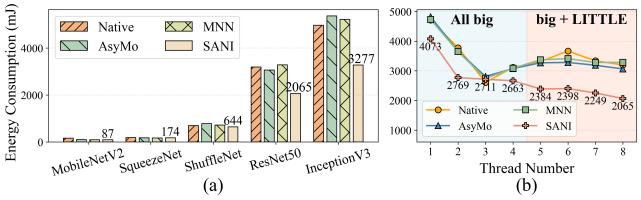

Figure 15: Energy consumption analysis on OPPO Find X3 Pro: (a) Comparison across different models using all cores, (b) Energy scaling behavior of ResNet-50.

AsyMo. This improvement primarily stems from the scheduler's ability to dynamically balance task sizes, optimizing the trade-off between execution efficiency and synchronization overhead rather than relying on fixed partitioning schemes.

The performance difference becomes more pronounced in asymmetric configurations where baseline implementations face the performance collapse paradox. When LITTLE cores are introduced, SANI shows improved performance across all tested models and devices through the coordinated operation of all three components. On Pixel 9 with ShuffleNet using four big cores plus one LITTLE core, SANI reduces latency by 19.3% versus Native and 15.3% versus AsyMo. As more LITTLE cores are added, SANI continues to show good scaling behavior, with performance improving on both devices. For ResNet-50, SANI achieves 19.4% latency reduction versus Native on Find X3 when using all available cores. In comparison, baseline approaches tend to show diminishing returns or performance degradation with additional LITTLE cores. This scaling efficiency highlights the synergy of SANI's modules. Beyond the gains from the adaptive granularity scheduler, SANI's advantage in asymmetric settings is magnified by its two other components. The affinity-aware kernel issuer selects the most efficient kernel for each core type, while the on-demand kernel switcher handles the necessary transformations for migrated workloads at runtime. This comprehensive strategy allows SANI to effectively utilize all cores and avoid the performance collapse paradox.

Dynamic loads. We evaluated SANI's robustness to runtime interference by running MobileNetV2 under four scenarios: idle system ("CPU-Null"), moderate CPU stress ("CPU-Stress (50%)") with 4 threads running `sqrt()` calculations, heavy CPU stress ("CPU-Stress (100%)") with 8 threads, and real application interference from YouTube video playback ("CPU-APPS"). We used a controllable load generator stress [32] to create compute threads. Fig. 14 presents the results decomposed into thread wait and execution latencies.

SANI consistently maintains lower wait times across all scenarios compared to baselines with 20%-40% reduction. This improvement stems from the adaptive granularity scheduler, which continuously adjusts task granularity based on measured thread execution speeds, thereby preventing performance bottlenecks caused by slow or blocked threads. The execution latency remains 7%-10% lower than baselines under interference due to our on-demand kernel switcher, which performs efficient kernel transformations when workloads migrate.

It should be noted that wait latency in moderate stress scenarios decreases slightly compared to idle conditions, as stress threads predominantly occupy big cores, effectively reducing the performance gap between asymmetric cores.

Energy Consumption. Fig. 15(a) demonstrates that SANI reduces energy usage across most models using all cores. For computation-intensive networks, SANI achieves significant improvements: 34.1%-35.3% versus Native, 32.5%-39.0% versus AsyMo, and 37.1%-37.3% versus MNN for ResNet-50 and Inception-V3. Lighter models show moderate gains with MobileNetV2 and ShuffleNet achieving 5.5%-30.5% reductions compared to baselines.

To analyze scaling behavior, Fig. 15(b) shows ResNet-50's energy consumption across thread configurations. Energy consumption decreases as thread number increases due to both reduced inference latency and the higher energy efficiency of

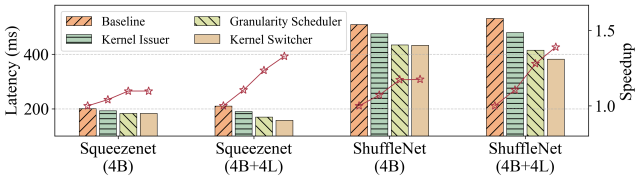

Figure 16: The overall performance breakdown of SANI.

LITTLE cores. Beyond the aggregate savings, these results clarify when the LITTLE cluster is worth using at all. For background or latency-tolerant DNN tasks, LITTLE-only execution remains a valid mode and is the most energy-favorable option. For interactive workloads, big-only execution leaves the LITTLE cores idle and forgoes their lower energy per operation, while naive all-core execution triggers the performance-collapse paradox of § 2.2. SANI's contribution is making the mixed regime both correct and efficient, so that the latency benefit of big cores and the energy benefit of LITTLE cores compound rather than cancel.

5.3 Ablation Study

We conducted experiments to evaluate the contribution of each SANI component to the overall performance improvement. Fig. 16 illustrates the incremental latency reductions achieved by sequentially enabling our three key techniques on SqueezeNet and ShuffleNet using different configurations.

Analysis on Symmetric Cores (4B). In the symmetric setting, adding the affinity-aware kernel issuer alone reduces latency by 4.0% on SqueezeNet and 6.7% on ShuffleNet. Although no dual-kernel selection is performed in this homogeneous environment, this improvement stems from its block unification strategy. Enabling multi-dimensional partitioning creates more parallelizable tasks than the baseline, especially for operators with challenging dimension sizes. Further enabling the adaptive granularity scheduler brings an additional 5.2% and 8.6% improvement, respectively. Even on homogeneous cores, runtime interference from background system processes can cause threads to execute at different speeds, and our scheduler's ability to dynamically adjust workload granularity is crucial for maintaining load balance. As expected, finally adding the on-demand kernel switcher provides negligible benefit (0.0%-0.2%), as no heterogeneous kernel transformations are triggered. These symmetric gains indicate that Arm-CL's single-kernel, fixed-partition pipeline leaves measurable parallelism on the table even when all cores are identical, with block unification recovering parallelism on awkward dimensions and the adaptive scheduler absorbing background interference. The same mechanisms that target AMP asymmetry thus continue to pay off in homogeneous configurations.

Analysis on Asymmetric Cores (4B+4L). In the asymmetric setting, the benefits of each module are magnified. The issuer's contribution increases to 9.5% on SqueezeNet and 9.6% on ShuffleNet, as it now performs dual-kernel issue, selecting the most hardware-affine kernel for both big and LITTLE cores. The scheduler becomes even more critical, delivering further improvements of 10.5% and 13.5% by effectively managing the significant performance disparities between the heterogeneous cores. Finally, the on-demand kernel switcher delivers a substantial 7.1% and 8.0% gain. When workload migration occurs, its ability to transform kernels on the fly prevents cores from executing a non-affine kernel. This study validates that all components are essential for achieving optimal performance, with their synergy being most pronounced in complex and asymmetric environments.

Table 3: Runtime overhead (ms) of SANI operations

Model	Async Prep	Merge & Split	Kernel Trans
MobileNetV2	3.8	2.2	0.08
Squeezenet	3.2	1.1	0.25
Shufflenet	11	2.2	0.18

5.4 Overhead Analysis

We analyze the overhead introduced by SANI in terms of both CPU latency and memory footprint.

CPU Latency. Table 3 quantifies the primary sources of SANI's runtime CPU overhead: the asynchronous preparation of dual kernels, the Merge and Split operations, and on-the-fly kernel transformations. The data shows that these operations are highly efficient. For example, on the complex ShuffleNet model, the cumulative overhead from these operations is well under 3 ms. This constitutes a small fraction of the model's total inference latency, which is typically in the hundreds of milliseconds. As demonstrated in our evaluation, the significant performance improvements delivered by SANI far outweigh this minimal computational overhead.

Memory Footprint. SANI introduces a minor memory overhead. This stems from two main sources: the additional working space required when the affinity-aware kernel issuer prepares a dual-kernel implementation for an operator, and the memory needed to store the pre-computed index maps for the on-demand kernel switcher. Evaluation results show that the peak additional memory footprint across all tested models is less than 2MB. Considering that typical neural network models require 60MB to 100MB of memory for execution, this additional footprint is negligible. That says SANI achieves its performance improvements without imposing a meaningful memory burden on the system. The footprint does not grow linearly with model depth. Index maps are kept per dual-kernel operator-shape pair, so repeated layer patterns such as stacked Conv-BN-ReLU blocks reuse the same map template. The peak therefore tracks the number of distinct operator shapes in the network rather than the raw layer count,

which is why even deep models stay well below the 2 MB ceiling.

5.5 Discussion

Our evaluation targets operator-level parallelizable workloads where mobile CPU execution is the dominant or fallback path, including the five CNN-family models and the GPT-2 transformer case study in Section 5.2. Large-scale on-device LLM inference is not the focus of this work. Our own profiling on a Google Pixel 9 shows that Qwen-1.5-4B sustains only 22.78 prefill tokens/s and 6.10 decode tokens/s on four big cores, far short of an interactive experience. Recent on-device NPU stacks such as llm.npu [56] report over 1000 tokens/s prefilling with substantially better energy per token, making NPUs the more suitable target for production-grade LLM serving on phones. The core abstractions of SANI, dual-kernel issue and adaptive granularity scheduling over a unified block interface, are operator-shape rather than model-class specific. The 16.1% latency reduction already observed on GPT-2 in § 5.2 comes from the same MatMul and GEMM kernels that dominate larger transformers, so we expect the design to carry over whenever CPU-side LLM execution becomes the right trade-off.

6 Related Work

Early on-device frameworks like TensorFlow Lite [28], Arm-CL [6], and NCNN [35] focused on general optimizations such as thread-level parallelism and cache affinity, primarily assuming core symmetry. As AMP architectures became prevalent, MNN [25] introduced a static task allocation strategy based on the compute power of different core types. AsyMo [49] advanced this with cost-model-guided block partitioning for asymmetric scheduling. However, these approaches remain static and fail to adapt to the dynamic mobile environment, where interference can alter a core's performance. In contrast, SANI's adaptive granularity scheduler adjusts workload sizes at runtime to maintain balance.

Workload scheduling on AMPs. While scheduling for DNN workloads on AMPs is an emerging area, general-purpose AMP scheduling has been widely studied [14, 16, 45, 46, 50]. Works like COLAB [59] and WATS [10] use predictive models and work-stealing to improve performance and load balancing. However, these OS-level schedulers are application-agnostic. They operate on coarse-grained OS threads, lacking the ability to partition work at the finer, operator-specific level. Furthermore, they cannot dynamically adjust the granularity of the workload. SANI overcomes these issues by being an application-aware framework that manages fine-grained workloads tailored to DNN operators.

Kernel selection optimizations. Kernel selection is critical for performance, and prior works have focused on making the best static choice. NeoCPU [31] adapts kernel parameters to different CPU architectures, NNV12 [58] selects kernels to optimize cold-start latency, and FlexNN [29] chooses implementations to maximize performance under memory constraints. The fundamental limitation of these approaches is that their selection is static, made once before and after execution. SANI addresses this with a two-part strategy: the affinity-aware kernel issuer prepares the best kernel for each core type, while the on-demand kernel switcher transforms workloads during migration, ensuring cores execute their most affine kernel.

7 Conclusion

In this paper, we explored the performance-collapse paradox in DNN inference on AMP architectures and introduced SANI, a scalable, asymmetry-aware framework. SANI combines three mechanisms—an affinity-aware kernel issuer, an adaptive granularity scheduler, and an on-demand kernel switcher—to preserve efficiency across heterogeneous cores. Evaluation on commercial SoCs shows that SANI scales efficiently, consistently outperforms existing approaches, lowers energy consumption, and sustains robust efficiency under interference across heterogeneous cores.

Looking ahead, we envision extending SANI's scalability principles to future mobile SoCs that integrate CPUs with GPUs and NPUs.

Abstract

CPU scheduling performance on mobile devices, especially under user interactions, is hindered by a fundamental semantic gap: the kernel scheduler lacks visibility into the user interaction context, treating latency-critical UI threads and background tasks equally. In this paper, we identify an impossible trinity, i.e., scarce prime cores, cross-process IPC dependencies, and tight latency deadlines, which exacerbate the mobile scheduling problem.

To survive the impossible trinity, we present MUSCHED, a semantic-aware scheduling framework for modern mobile devices that makes interaction capability a first-class scheduling objective. MUSCHED disentangles cross-process dependencies for critical threads along the interaction path and places these threads in a new VIP scheduling class between RT and CFS, allowing interaction-critical tasks to preempt normal background work without compromising system stability. Furthermore, MUSCHED proposes a scheduling policy plug-and-play mechanism that facilitates on-demand policy update in the user space without kernel recompilation for COTS mobile devices. In laboratory evaluations, MUSCHED reduces average application cold-start time by 14.8%. Furthermore, MUSCHED has been deployed on more than 20 million mobile devices since 2024. The deployment results show that MUSCHED reduces real-world startup anomalies by more than 30.7%. This deployment underscores the pivotal role of semantic-aware scheduling in achieving optimal mobile Quality of Experience.

1 Introduction

Mobile devices have evolved into the primary computing platform for billions of users [3], supporting workloads that range from immersive gaming [16] to high-fidelity multimedia processing [19, 24]. Unlike server workloads that prioritize aggregate throughput or tail latency [7, 11, 13, 20], the defining metric for mobile systems is *Quality of Experience* (QoE), which is dictated by the responsiveness and smoothness of user interactions. Whether launching an application or scrolling through a feed, users expect instantaneous feedback. The operating system's CPU scheduler acts as the critical arbiter in meeting these expectations, determining when and where tasks execute on the underlying hardware.

However, *achieving optimal interactivity on modern mobile platforms remains difficult*. Despite decades of optimization, mobile users still experience perceptible jitter, frame drops, and sluggish application launches [21, 25]. The root of this problem lies in a fundamental semantic gap: the kernel scheduler operates on low-level abstractions (threads and timeslices). It lacks high-level visibility into the user's interaction context. It cannot distinguish a critical thread rendering a UI animation from a background thread performing a routine backup, often treating them with "fairness" that is detrimental to interactivity. Designing a scheduler that bridges this gap faces three unique challenges that distinguish mobile systems from desktop or server environments.

1. Resource heterogeneity and constraints. Mobile System-on-Chips (SoCs) operate under strict power budgets and thermal envelopes. Consequently, high-performance execution resources are scarce; a typical modern SoC features a heterogeneous architecture with only one or two "prime" cores alongside several performance and efficiency cores. Unlike server environments where compute can be over-provisioned, the mobile scheduler must make zero-sum decisions to allocate these precious cycles. Existing scheduling heuristics such as ARM energy-aware scheduling (EAS) [23] infer task importance mainly from historical CPU usage, making them too slow and imprecise for short-lived interactive bursts under resource constraints.

2. Complex cross-layer dependency. Mobile applications are not monolithic; they rely on extensive system services. A single user touch event triggers a cascade of execution spanning the application process, the system server (e.g., *InputManager*), and the kernel. In Android, these interactions rely heavily on synchronous Inter-Process Communication

[*] Jun Xiao and Qinhui Gu contributed equally to this work.
[✉] Corresponding authors: Hao Wu and Borui Li.

(IPC) and lock-based synchronization. This creates deep and implicit dependency chains in which a high-priority UI thread may block while waiting for a lower-priority background service. This phenomenon is exacerbated by the scheduler's inability to see this cross-layer dependency. A delay in any link of the dependency chain propagates to the display, stalling the entire interaction.

3. Unforgiving latency deadlines. The window for processing user input is vanishingly small on mobile devices. Modern displays with 120Hz refresh rates demand that a new frame be rendered every 8.3ms. Furthermore, interactive workloads are characterized by extreme "burstiness": a touch event generates a sudden spike of short-lived, latency-critical threads (e.g., layout calculation, render commands) that must be serviced immediately. Neither CFS nor Real-Time (RT) classes can satisfy mobile latency deadlines safely. CFS prioritizes fairness over the immediate "unfair" preemption required by a touch event, leading to deadline misses during 120Hz rendering. Conversely, assigning static RT priorities is unsafe for the complex Android software stack; it cannot adapt to the rapidly changing context, where a thread is critical one moment and background noise the next, risking thermal throttling and system-wide starvation.

These three intertwined challenges are difficult to solve together, forming an *impossible trinity (a.k.a., trilemma)* for existing scheduling frameworks to navigate in this specific mobile landscape. Addressing this trilemma requires breaking the cross-layer fragmentation between application semantics and kernel scheduling, and moving beyond a one-size-fits-all policy toward adaptive scheduling decisions tailored to each application's interaction context.

However, this shift is far from straightforward. On the one hand, the scheduler must *capture the critical path* of an interaction and *disentangle its dependency chain* across threads, locks, and IPC transactions, so that urgency can be propagated end-to-end rather than stopping at a single runnable thread. On the other hand, such adaptivity must remain *practical for commercial off-the-shelf (COTS) devices*: policies must be updated safely, react quickly to changing runtime scenarios, and preserve system stability at production scale.

To solve this, we present MUSCHED, a semantic-aware scheduling framework designed for modern mobile SoCs. The core insight of MUSCHED is that *interaction capability should be a first-class citizen in scheduling*. Hence, we introduce a new "VIP" scheduling class that sits between RT and CFS, ensuring critical interactive tasks preempt normal background work without risking system stability. MUSCHED bridges the semantic gap between low-level kernel scheduler and high-level user interaction through two key mechanisms: *Scenario-Aware Annotation*, which identifies critical threads (e.g., Render, UI) based on runtime hooks; and *Priority Propagation*, which dynamically boosts the priority of any thread (even in other processes) holding a lock or handling an IPC transaction required by a VIP task. This ensures that the entire dependency chain of an interaction executes with high urgency. Moreover, MUSCHED fundamentally rethinks the division of labor between user space and kernel space. Instead of hardcoding policies into the kernel, MUSCHED proposes an eBPF-based scheduling policy plug-and-play mechanism to adapt the scheduling policy on demand in user space to break the one-fits-all problem for COTS mobile devices. This user-space design is practical and deployable, requiring no kernel recompilation to update policies.

We implement and evaluate MUSCHED under both controlled laboratory conditions and on a commercial smartphone powered by a Snapdragon 8 Elite running Android 15, as well as in large-scale production deployments. In laboratory tests across 10 representative apps, MUSCHED reduces average cold-start time by 14.8%. In production, deployed on over *20 million* devices since 2024, MUSCHED reduces cold-start anomalies by 30.7%, animation frame-drop anomalies by 24.9%, and swipe frame-drop anomalies by 35.7%, while maintaining system stability.

This paper makes the following contributions:

- We characterize the scheduling bottlenecks in mobile interactive workloads, identifying priority inversion and cross-process dependency as key sources of latency.
- We design MUSCHED, an extensible scheduler using eBPF that introduces a VIP priority class and a priority propagation mechanism for IPC and lock contention.
- We deploy MUSCHED on over 20 million commercial devices and show that user-space scheduling policies can be safely iterated on without kernel changes and deliver significant improvements across key interactive metrics.

2 Background and Preliminaries

This section details the unique characteristics of mobile interactive workloads, the heterogeneous hardware, and the current Linux scheduling policy used by Android. We highlight why existing mechanisms fail to bridge the semantic gap between high-level user expectations and low-level kernel schedulers.

2.1 Characteristics of Mobile Devices

Mobile Interactive Workloads. Unlike server workloads defined by aggregate throughput, mobile systems are driven by the user's perception of fluidity. Human sensitivity to visual latency is acute; research indicates that users can perceive delays as low as 100ms in discrete interactions (e.g., application launch) and jitter in animations if frame times exhibit high variance [18]. To maintain the illusion of fluidity, modern mobile displays operate at high refresh rates (60Hz-120Hz), imposing a hard deadline for frame rendering (16.6ms or 8.3ms). The Android graphics pipeline enforces this via the

vsync signal. Missing a vsync deadline results in a "jank" (i.e., frame drop), which directly degrades the QoE.

However, achieving this consistency is complicated by the workload's extreme variability. Mobile execution is event-driven and bursty: a period of idling can be instantly interrupted by a touch event, triggering a complex chain of computations. Furthermore, these workloads operate in a volatile environment, where network conditions (e.g., cellular handover) and background activities (e.g., notifications, updates) introduce unpredictable interference.

Heterogeneous SoCs and Power Constraints. Mobile System-on-Chips (SoCs) employ heterogeneous multiprocessing (HMP) architectures, such as ARM big.LITTLE or DynamIQ, to balance performance and battery life. A typical high-end SoC comprises three tiers of cores: (1) *Prime Core:* High frequency and out-of-order execution capacity for single-threaded bursts. (2) *Performance Cores:* Balanced cores for sustained heavy lifting. (3) *Efficiency Cores:* Low-power in-order cores for background tasks. The scheduler's placement decision is critical: placing a UI thread on an efficiency core causes jank, while running background tasks on the prime core wastes power. Moreover, these decisions are constrained by strict thermal envelopes. The system may cap frequencies or disable cores entirely to prevent overheating, thereby dynamically adjusting hardware capacity.

2.2 Status Quo Scheduler in Android

In this paper, we focus on the scheduling mechanism on Android, a widely adopted, open-source mobile operating system. Android relies on the Linux kernel's scheduling framework, augmented with mobile-specific policies. The kernel manages tasks using priority-based scheduling classes.

Priority Hierarchy. Linux maintains a global priority scale ranging from 0 to 139, where lower values denote higher priority. On Android, this priority scale is divided into two primary classes:

1. **Real-Time (RT) Class (0–99):** Threads in this range preempt all non-RT tasks. To avoid starving the system, Android grants RT privileges sparingly, typically reserving them for strictly latency-sensitive pipelines such as audio processing and the display compositor (i.e., `SurfaceFlinger`).

2. **Completely Fair Scheduler (CFS) Class (100–139):** This is the default class for the vast majority of application threads, including the UI thread. Priorities in CFS are mapped to "nice" values ranging from -20 (priority 100) to +19 (priority 139). CFS aims to distribute CPU time fairly among tasks based on their weights (derived from nice values) using a Red-Black tree to track the virtual runtime (`vruntime`).

Energy Aware Scheduling (EAS). Android augments CFS with the EAS policy. EAS uses an energy model to estimate the power impact of assigning a task to a specific core cluster. It relies on task load-tracking mechanisms, primarily Per-Entity Load Tracking (PELT) or Window-Assisted Load Tracking (WALT), to predict future CPU demand using historical execution times.

Android User-Space Policy. To bridge the gap between application semantics and kernel scheduling mechanisms, the Android framework dynamically adjusts the priorities of application threads based on the app's lifecycle state (e.g., Foreground, Background, Top-App). It employs two main knobs. (1) *Cgroups (cpusets):* Android segregates tasks into cgroups such as `top-app` (access to all cores), `foreground` (limited access), and `background` (restricted to efficiency cores). (2) *Nice Values:* The framework adjusts the nice values of threads. For instance, the UI thread of the currently focused app is typically assigned a favorable nice value (e.g., -10), while background threads are penalized (e.g., +10).

2.3 Limitations of the Status Quo

Despite these layered optimizations, the "battle of the schedulers" [5] continues on mobile devices because standard heuristics are fundamentally misaligned with interactive needs due to the following two reasons.

Reactive vs. Proactive. EAS and CFS are reactive; they rely on historical average observations through the PELT or WALT mechanism to ramp up frequency or migrate tasks. Such decisions are made from local signals, such as a task's recent CPU utilization or the current load of a core, rather than from the end-to-end structure of a user interaction. However, a mobile interaction is a short causal chain spanning UI, rendering, system services, Binder calls, and locks. A critical thread may spend most of its time blocked on another task and therefore appear lightweight to utilization-based heuristics, while the remote-side delay is already consuming the same frame or launch deadline. Consequently, boosting frequency or migrating a task after its load has become visible cannot recover the waiting time already accumulated along the interaction path; by the time the scheduler reacts, the end-to-end deadline may have already been missed.

Lack of Cross-Process Visibility. Android applications are heavily componentized, relying on synchronous IPC to communicate with system services, e.g., the Binder mechanism in Android. While Android can adjust the priority of the calling thread, the kernel scheduler is unaware of the semantic dependency chain. Standard priority inheritance mechanisms, such as those for local mutexes, do not automatically extend to complex IPC transactions or to cross-cgroup boundaries. Consequently, a high-priority UI thread often blocks waiting for a service thread that is stuck in a restricted cgroup or running with a low CFS priority. Linux implements priority inheritance for local futex and rt_mutex contention, but this mechanism does not extend to the Binder IPC path or across cgroup boundaries, leaving a common and consequential case

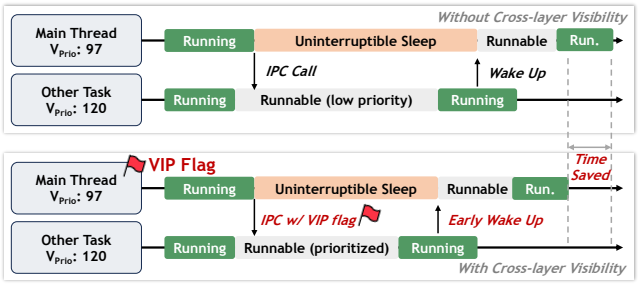

Figure 1: Motivating example: a main thread hands off an IPC request to a lower-priority task. OS scheduler lacks visibility into this dependency, leading to excessive waiting time.

of priority inversion unresolved in the stock kernel.

Figure 1 illustrates a common priority-inversion pattern in mobile interactions. Many latency-sensitive application tasks do not execute in isolation, but depend on cross-process communication with other system components. When the remote-side task of such an IPC path experiences a long scheduling delay, the caller thread is forced to wait as well, even if the caller itself has a much higher priority.

The example in Figure 1 shows this effect using a high-priority main thread (i.e., lower `prio` value) and a lower-priority dependent task (i.e., higher `prio` value). Before optimization, the main thread runs, then enters uninterruptible sleep while waiting for the dependent task to finish. However, the dependent task remains in the runnable state for an extended period before obtaining CPU time. As a result, the main thread cannot be woken up promptly, and its end-to-end waiting time is amplified by the remote-side scheduling delay.

This problem is especially harmful to Android graphics critical paths. For example, when SurfaceFlinger or another graphics-related thread issues a Binder request, a delayed remote-side service thread slows down the return of the IPC, which in turn delays layer composition and increases the likelihood of frame drops and visible jank. After optimization, MUSCHED marks the waiting main thread as VIP and propagates this urgency to the dependent task, thereby allowing the remote-side runnable interval to shrink and the main thread to wake up earlier.

3 System Overview of MUSCHED

Addressing the impossible trinity among scarce resources, cross-process dependencies, and tight deadlines requires the scheduler to understand each application's interaction structure: which threads lie on the critical path of user-visible operations, when these threads should be prioritized, and which cross-process dependencies they rely on. MUSCHED follows a split architecture that separates semantic policy decisions from scheduling implementation, as shown in Figure 2. The user-space layer captures interaction semantics and updates

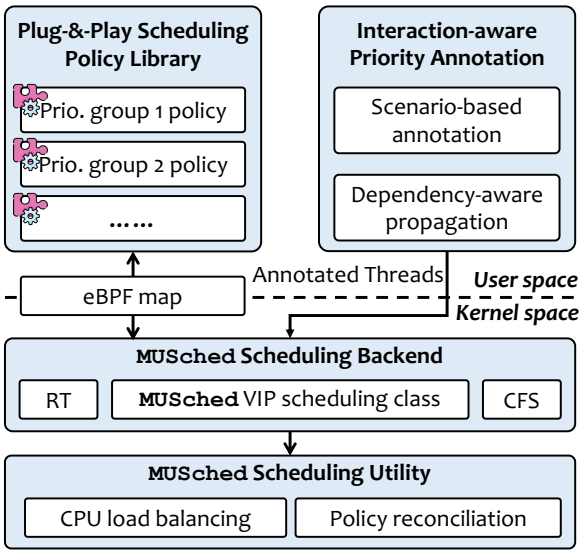

Figure 2: System overview of MUSCHED.

policies, while the kernel-space layer enforces these decisions on the scheduler fast path. This separation allows MUSCHED to adapt policies for different applications and interaction scenarios without recompiling the kernel or shipping a full firmware update.

In user space, a *plug-and-play scheduling policy library* stores scenario-specific policies, such as the task types to promote and the lifetime of each VIP promotion. These policies are loaded, unloaded, and updated through an eBPF-based gateway, which provides a narrow interface between policy management and kernel enforcement. VIP scheduling also relies on *interaction-aware priority annotation*: the user-space controller observes framework-level events, identifies key interactive threads, and marks them as candidates for MUSCHED's VIP scheduling class. Threads that are not annotated continue to follow the original Linux scheduling path. To handle dependencies that are not visible from a single thread alone, MUSCHED further introduces *dependency-aware propagation*, which carries VIP urgency across Binder calls and lock dependencies when a critical thread is blocked by another task.

In kernel space, MUSCHED introduces a VIP scheduling class between the RT and CFS classes. This class is implemented with per-core VIP queues that host threads requiring temporary priority elevation during user-visible interactions. During scheduling, RT tasks retain the highest priority; VIP tasks are served before normal CFS tasks only when no RT task is runnable. To preserve system stability under contention, a *load balancer* prevents VIP and RT tasks from accumulating on a single CPU core, while a *policy reconciliation agent* resolves conflicts among user-space policies and bounds their impact on existing RT and CFS policies.

4 MUSCHED Design

In this section, we introduce the essential building blocks of MUSCHED.

4.1 Kernel-space Scheduling Backend

To support interaction-aware prioritization on COTS mobile devices, MUSCHED introduces a VIP scheduling class between the built-in RT and CFS classes. The actual scheduling policy is built on top of eBPF to facilitate on-demand modification in user space. To keep this VIP scheduling class compatible with existing classes, MUSCHED also proposes a policy reconciliation module and a CPU load-balancing module, which are combined to maximize CPU utilization and task throughput.

Non-intrusive scheduling class. As we noted in Section 2, on Android OS, RT scheduling is used for system-defined critical tasks such as sensor management and system UI rendering, while other user-space non-critical tasks use the CFS strategy for fairness. As Android applications grow more complex, with multi-threaded rendering pipelines and application-specific critical threads, the two existing scheduling classes prove insufficient. The RT class is reserved for system-critical tasks such as audio and SurfaceFlinger; placing application threads there would risk starving these system services. CFS, while safe, weights threads by their historical CPU utilization, which does not reflect interaction criticality: a UI thread that has been idle waiting for a Binder reply appears less CPU-intensive than a background computation thread, and is consequently assigned lower priority. We therefore need *a scheduling class whose effective priority lies above CFS but below RT*, and whose priority decisions are informed by interaction semantics.

Priority conflict reconciliation. To avoid unnecessary CPU resource contention between VIP and RT tasks, we first try to prevent RT and VIP tasks, as well as multiple VIP tasks, from being placed on the same core during CPU selection. When a task is woken up, the scheduler first determines which CPU it should be executed on. At this point, the scheduler attempts to find a suitable CPU using the following strategy. First, it tries to find a CPU core that is idle and places the task in that CPU's local queue. If no CPU is currently idle, it tries to find a CPU whose task queue contains no RT or VIP tasks. If neither condition can be satisfied, the scheduler selects the CPU whose task queue contains no RT tasks and has the fewest VIP tasks.

CPU load balancing. Under heavy-load conditions, it is often unavoidable that multiple VIP and RT tasks are placed in the same CPU's task queue. Given that the completion times of various tasks differ, we further design a CPU load-balancing strategy, depicted in Figure 3, to fully utilize multiple CPU cores.

First, whenever a CPU enters the idle state, load balancing is triggered. The scheduler attempts to search for and pull tasks from other CPUs' task queues based on the following rules. It traverses the task queues of other non-idle CPUs and first tries to select those that contain both RT and VIP tasks. If none are found, it then selects the queue with the largest number of VIP tasks. From the selected queue, it chooses the first VIP task eligible to run on the idle CPU and migrates it to that CPU.

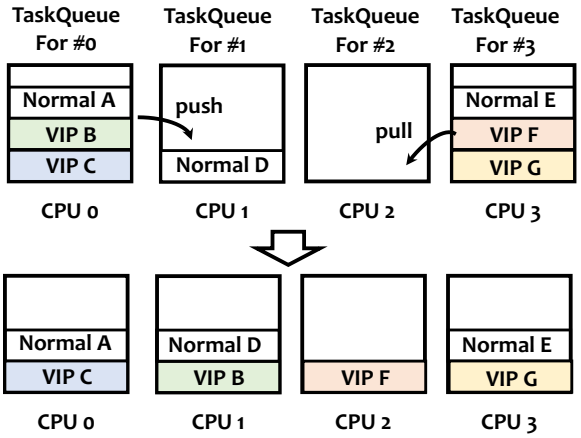

Figure 3: CPU load balancing in MUSCHED that balances both normal and VIP tasks on mobile CPUs.

In addition, on every CPU tick, the scheduler proactively checks the execution status of VIP tasks in the task queue. If it detects a VIP task that has remained runnable for too long, it will also attempt to balance the workload. More specifically, if the currently running task is an RT task and there exists a VIP task that has been runnable for a long time, the scheduler will actively select a new CPU during the tick. A 4 ms threshold is used to determine whether a VIP task has remained runnable for too long. If such a task exists, load balancing is also triggered: the scheduler traverses the CPUs where the task can be executed and selects the target CPU with no RT tasks and minimal VIP tasks. We set the migration threshold to 4 ms, which is approximately half of the 8.3 ms frame budget at 120 Hz. If a VIP task has already remained runnable for more than half a frame interval, further delay on the current CPU materially increases the risk of a missed frame deadline. Conversely, thresholds below 2 ms trigger excessive migrations, because transient run-queue delay of 1-2 ms is common even under moderate load, and the migration cost itself becomes non-negligible. In practice, this parameter is also influenced by hardware capability and product goals. For flagship or performance-oriented devices, we use lower thresholds, whereas we set higher thresholds to reduce frequent migration overhead for thermally constrained or battery-oriented products.

4.2 Plug-and-Play Policies based on eBPF

Different applications and interaction scenarios, such as app start and window switch, require different VIP time limits and dynamic promotion of selected tasks to VIP status. Moreover, these policies must be updated as applications evolve. To implement VIP scheduling policies for each application, traditional approaches that modify the kernel scheduler require intrusive changes to the kernel. This intrusive design is impractical for production-ready mobile devices because modifying the kernel requires frequent reboots to apply the new scheduling policy. MUSCHED adopts a fine-grained scheduling policy for each application, which can be updated when the applications are updated. Moreover, due to the variety of mobile applications, it is necessary to decide the scheduling policies on the fly for unseen applications. Hence, it is not possible for a large-scale mobile device vendor to publish policy patches that frequently require a system reboot.

According to the above analysis, MUSCHED therefore adopts an eBPF-based design because eBPF uniquely combines safe in-kernel programmability, rich observability, and efficient user–kernel communication. Specifically, eBPF facilitates MUSCHED to dynamically update the scheduling policy without a system reboot, which is necessary for application updates and new application installations.

MUSCHED implements the VIP scheduling class on top of Linux `sched_ext`. The kernel-side backend maintains per-core VIP queues, while the user-space scheduler updates scenario-specific policies through BPF maps and dispatch queues.

During scheduling, each CPU first serves RT tasks. If no RT task is runnable, it selects tasks from the local VIP queue before falling back to CFS tasks, ensuring that interaction-critical threads receive bounded priority elevation.

To prevent starvation of certain tasks under high load, tasks in the VIP queue are scheduled in a first-in-first-out (FIFO) manner, and each VIP task in the queue is assigned a 3 ms time slice. For the `cpu.share` allocation in cgroups, MUSCHED by default inherits the kernel's configuration. In addition, to prevent other normal tasks from starving when there are too many VIP tasks, a time limit is imposed on VIP tasks. For each VIP task, if it has used up its time slice but has not exceeded the limit time, it is reinserted into the back of the queue; if it runs out of both the slice time and the limit time, its VIP label is temporarily removed until the next enqueue. Since different types of VIP tasks have different computational requirements, we configure the time limit based on profiling of representative workloads: 20 ms for audio tasks, 10 ms for video tasks, 120 ms for webview tasks, and 20 ms for display tasks. These limit times reflect the computational profile of each interaction class and also serve as the main safeguard against starvation. Audio tasks use a 20 ms budget to match typical buffer-processing windows; video tasks use 10 ms to cover a decode-and-render cycle; WebView tasks use 120 ms because page layout and script execution often span multiple frames; and display tasks use 20 ms to align with composition-critical work. Once a task exhausts its limit, it is *demoted from VIP and returns to CFS* until the next qualifying event, ensuring that priority boosting remains temporary and bounded rather than allowing indefinite VIP service.

Table 1: Annotated scenarios related to user interaction.

Task Type	Examples
Animator	splashworker; wmshell.main; wmshell.anim
UI	Main thread; UI thread
Render	Render thread
WebView	CrRendererMain; Chrome_InProcRe

4.3 Semantic-aware Mobile Scheduling

Another key problem we face is identifying critical tasks currently queued in the CFS scheduler. To address this, we first introduce scenario-aware annotation, which provides guidance for labeling critical tasks based on a predefined list. Furthermore, considering that VIP tasks may depend on the completion of some normal tasks, we design a priority propagation for inter-process interaction. It dynamically propagates VIP tags to the normal task that a VIP task depends on, accelerating its execution and preventing bottlenecks caused by such dependencies.

Scenario-aware Annotation. To identify which threads belong to the critical path of user interactions, MUSCHED combines three complementary sources of information. First, Android already exposes several thread roles that consistently lie on interaction-critical paths across applications, such as the main/UI thread, RenderThread, MotionThread, and Binder worker threads serving user-facing requests. These roles generalize well across applications and therefore form the default annotation candidates in MUSCHED.

Second, we refine this default set through offline profiling. For each target scenario, such as app launch, swipe, or animation, we repeatedly execute the application and collect multiple systrace traces. From these traces, we analyze wake-up relationships and per-thread CPU load to identify additional threads that repeatedly appear on the end-to-end critical path. This step captures application-specific critical threads as a dependency graph, which is not directly exposed as standard Android roles.

Third, we further use jank traces collected from beta users in the field to diagnose missed cases and augment the annotation set. These online traces help us cover rare or highly application-specific behaviors that may not appear in controlled offline runs. Together, these three sources provide broad practical coverage of critical threads while keeping the annotation process lightweight.

These analyses yield the thread categories shown in Table 1.

Some categories, such as render thread and Binder worker pools, generalize across applications, while others require per-application identification of the concrete thread instances. At runtime, MUSCHED identifies these instances through framework hooks placed at SystemUI, Launcher animation transitions, app foreground/background switches, focus changes, and frame-rendering callbacks. When the framework detects that an application has entered a user-interactive state, it tags the corresponding threads with VIP labels so they can be scheduled with elevated priority.

Priority Propagation for Inter-Process Interaction. To optimize the waiting time of VIP tasks for locked resources, we design a VIP lock-waiting queue optimization strategy. In the native Linux mechanism, mutexes are awakened in a FIFO manner, while read–write locks are awakened in batches based on the top waiter type, also following a FIFO strategy. Since both regular tasks and VIP tasks may wait for the same lock resource, VIP tasks may experience long delays. To address this issue, we introduce a new wake-up strategy that allows VIP threads to bypass the strict FIFO sequence, enabling them to be inserted ahead of multiple non-critical threads and be awakened preferentially.

Considering that VIP tasks may depend on the completion of some normal tasks, we further design a call-chain priority propagation mechanism for inter-process interaction. When a VIP thread waits for a lock held by a normal thread, including futex, mutex, and rwsem, the VIP label can be propagated to that normal thread, elevating its priority to accelerate execution and shorten the VIP thread's waiting time. The core idea is that when a thread is blocked while acquiring a lock, it passes the thread ID of the lock-holding thread to the kernel. The kernel identifies whether the blocked thread is a VIP thread; if so, the VIP priority is dynamically propagated to the lock holder to accelerate its execution. For each supported synchronization primitive, we place hooks on the lock-acquisition and release paths to record the current owner thread ID in kernel-visible state. When a waiter blocks, the hook retrieves the recorded owner, checks whether the blocked task is tagged VIP, and, if so, transiently propagates the VIP label to the lock holder. A thread that merely acquires a lock is not proactively marked VIP; propagation is triggered only when a VIP waiter appears and identifies that holder as the blocking dependency. We apply this mechanism to futex, mutex, and rwsem contention, and revoke the inherited label when the owner releases the lock, when the dependency disappears, or when the boost exceeds its bounded lifetime. Once the regular thread releases the lock, it wakes the VIP thread, and the inherited VIP label is removed, restoring it to a normal task and returning to the fair CFS scheduling policy.

Besides, in Android, inter-process communication is also very common. When a task initiates a synchronous Binder call, it enters the sleeping state and waits for the remote process to return the result. If the remote process is under heavy load or its priority is low, the server binder may remain in the Runnable state for a long time, causing the caller task to be blocked. This issue becomes even more severe in scenarios such as layer composition in SurfaceFlinger.

We address this issue by monitoring the start of Binder transactions. When a VIP task communicates with another process through Binder, MUSCHED dynamically propagates the VIP label to the callee to accelerate its execution. Specifically, when a VIP thread initiates a synchronous Binder call, the scheduler immediately locates the corresponding service thread on the remote side and tags it as VIP. After the execution, the dynamically propagated label is cleared, and the task is restored to a normal task.

4.4 Case Study: Cold-start Acceleration

We take a cold-start acceleration scenario to demonstrate MUSCHED's user-space scheduling capability. Cold start is the most demanding application launch state [1]. It occurs when an app starts from scratch, with no existing process in memory. The system must create the app process, initialize the runtime, and build the first Activity before any frame can be shown. This procedure often triggers more than 300 thread creations, large memory allocations from hundreds of MB to several GB, and intensive file and network I/O. During this phase, many launch-critical threads become active, including UI, rendering, animation, web loading, composition, and system service binder threads, creating a short but extremely congested window of resource contention. Launch latency thus becomes a first-order performance objective, and standard startup metrics (e.g., TTID and TTFD) are highly sensitive to scheduling decisions. When cold-start time exceeds about one second, users typically perceive the app as sluggish. Traditional CFS schedulers prioritize fairness across tasks. Under heavy contention, this fairness causes critical-path threads on the launch pipeline to be preempted by less important work. Moreover, the kernel scheduler lacks semantic knowledge of the launch sequence and cannot distinguish threads on the cold-start critical path from best-effort background tasks.

Semantic-aware scheduling of MUSCHED addresses these limitations by injecting launch-specific knowledge into the scheduler. Sampling cold-start critical path offline [17], we annotate launch-critical tasks and add lightweight framework hooks to tag their threads as VIP. VIP threads receive elevated priority and are protected from preemption by non-critical work, directly mitigating CPU contention on the launch critical path. However, critical tasks frequently block on dependencies such as locks and binder IPCs. To handle this, semantic-aware scheduling incorporates priority propagation. When a VIP task waits on a lock, its VIP tag is propagated to the lock holder, temporarily boosting that thread to accelerate lock release and prevent priority inversion. Similarly, when a VIP task issues a synchronous Binder call, the scheduler locates the serving thread in the remote process and dynamically elevates its priority. The boosted priority is revoked once the lock

is released or the IPC completes, restoring normal fairness. By aligning priorities with cold-start semantics, MUSCHED reduces preemption and blocking delays and accelerates the launch pipeline, yielding significantly lower startup latency under load.

5 Implementation Details

Based on the MUSCHED design, we then describe how we facilitate these policies, with a focus on details specific to commodity Android devices.

Hooks and Maps based on sched_ext. sched_ext is an eBPF-based scheduler that allows users to implement scheduling classes using flexible BPF programs, thereby optimizing scheduling policies for specific workloads and scenarios. We implement the kernel scheduling behavior described in Section 4 via the hooks in the `sched_ext_ops` structure, and construct VIP task queues using BPF maps.

The key hooks of MUSCHED include CPU selection, enqueue, dispatch, and polling. `sched_select_cpu` selects a CPU based on energy efficiency when a task is woken up. It iterates over the system's performance cores, first preferring big cores in the idle state; if none are idle, it selects the least loaded big core, ensuring sufficient compute resources for VIP tasks. `sched_enqueue` assigns a task to the VIP queue of the corresponding task CPU, and invokes `scx_bpf_dispatch` to directly dispatch it to the target CPU core's high-priority dispatch queue (PRIO-DSQ). While `sched_dispatch` consumes tasks from the queue by placing them into the local DSQ, i.e., it determines from which DSQ the CPU fetches the next task to run. To achieve the load balancing described in Section 4.1, MUSCHED performs priority-based polling. `scx_bpf_consume(DSQ_ID_VIP)` first attempts to run tasks from the local VIP queue; if the local queue is empty, it then tries to consume tasks from the neighboring core's `DSQ_ID_VIP`, which we refer to as *Steal*.

MUSCHED creates a VIP task queue for each core via the `scx_bpf_create_dsq`. We use a per-CPU array eBPF map, named `cpu_contexts`, to store per-core state, including idle time, current load information, the number of enqueued tasks, CPU halt state, etc. We also use a task storage eBPF map, named `task_contexts`, to store per-task information such as weight, current execution state, compute load, enqueue time, and dequeue time. Together, these two maps maintain the metadata required by the custom scheduler.

Deploying eBPF on Mobile Devices. Deploying eBPF on commodity Android devices faces constraints that differ significantly from those in the upstream kernel community. The Android eBPF compilation and loading pipeline is tightly coupled to specific system libraries and SELinux policies. The system only allows eBPF programs to be loaded during boot by a dedicated process, `bpfloader`, and prohibits loading any new programs after boot completion [2]. Besides, the eBPF libraries provided by Android differ from community-standard libraries in both interfaces and evolution pace. To ensure implementation consistency and portability, we abandon Android-specific eBPF libraries and instead develop with the community-standard eBPF libraries. However, the existing `bpfloader` does not support the `BPF_MAP_TYPE_STRUCT_OPS` type required by sched_ext. To address this limitation, we extend `bpfloader` to recognize and load `struct_ops`-related objects during the boot phase, thereby providing the necessary foundation for subsequently activating the scheduler.

Enabling sched_ext. sched_ext leverages the eBPF `struct_ops` mechanism, whose enabling method differs from traditional kprobe or tracepoint attachments. The scheduler is enabled by registering and updating a BPF map of type `BPF_MAP_TYPE_STRUCT_OPS`, rather than simply attaching a program to a specific hook. Given the stringent stability requirements of the scheduler, this `struct_ops` map is restricted to a single update, and any modification requires destroying and recreating the map. The map also maintains an enum state with values `INIT`, `INUSE`, `TOBEFREE`, and `READY` to indicate the scheduler state, preventing transient intermediate states from causing system panics. In the Android environment, we do not unload the sched_ext program itself; instead, we indirectly drive the above state transitions via `BPF_F_LINK` [4]. This design enables secure activation and reliable operation of the sched_ext scheduler while adhering to the safety constraint that eBPF programs should be loaded only once during boot.

6 Evaluation

In this section, we first present the laboratory evaluation results of MUSCHED on commodity Android smartphones.

Evaluation Setup. We deploy the proposed approach on the Magic 7 smartphone, which equips the Snapdragon 8 Elite chipset featuring 2 super CPU cores (@4.32 GHz) and 6 performance CPU cores (@3.53 GHz). The software platform

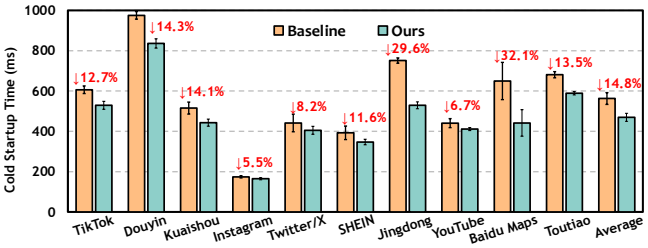

Figure 4: Cold-start time of 10 Applications.

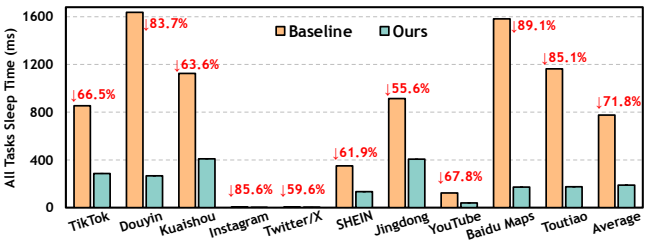

Figure 5: Time in sleep state during cold-start.

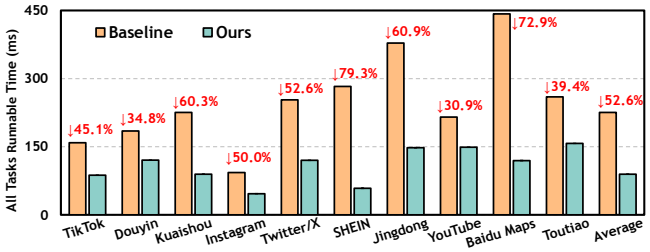

Figure 6: Time in runnable state during cold-start.

Table 3: Measured latency (in ms) of a foreground application with a background picture-in-picture video call with and without MUSCHED.

Foreground App.	Test Scenario	w/o	w/	Diff
Taobao Browsing	Application Cold Start	149.7	135.0	-9.8%
WeChat Moments	Application Cold Start	163.5	126.3	-22.8%
Douyin Live	Scroll 10 Live Room	449.0	386.9	-13.8%
News Browsing	Scroll Top News Article	584.5	480.5	-17.8%

is MagicOS 9, which is based on Android 15 with a Linux kernel version of 6.6.

Benchmarks. We choose 10 representative mobile applications, selected from the top-ranked applications in the application store, as test cases in our laboratory environment, as shown in Table 2. These applications cover commonly used categories such as short video, news, shopping, and navigation, etc. We use the native Android scheduling policy as the baseline, i.e., some predefined tasks are configured as RT task, while others are configured as normal tasks, and evaluate the cold-start performance of 10 applications. Each application is tested 100 times, and the average result is reported. To create reproducible yet realistic contention, we combine application-driven and synthetic background load. We emulate realistic concurrent usage by keeping representative background activities active while measuring the foreground app, e.g., short-video scrolling in the foreground together with navigation, music playback, or other common services in the background. we use tools such as `stress-ng` or `rt-app` to inject periodic per-core pressure. Unless otherwise stated, we fix the display mode, thermal state, battery mode, CPU governor, and cache-clearing procedure across runs so that the measured differences primarily reflect scheduling policy rather than platform drift.

End-to-end Performance. The cold-start performance of 10 applications is shown in Figure 4. Compared with the baseline, we reduce the average cold-start time by 14.8%, while also achieving more stable performance with the standard deviation decreasing by 24.25%. These improvements primarily stem from two aspects. First, we identify critical tasks during application startup and raise their scheduling priority, while preventing competition for CPU resources between VIP tasks and RT tasks. Second, our priority-propagation strategy temporarily boosts the priority of normal tasks that VIP tasks depend on, thereby reducing overall task completion time.

We further measure the total uninterruptible sleep time and waiting for scheduling time, i.e., in runnable state, of all VIP tasks during the startup process for the 10 applications. The results are shown in Figure 5 and 6, respectively. These results indicate that MUSCHED reduces both the resource-waiting time and scheduling-waiting time of critical tasks during application startup. This result is consistent with our analysis of why application startup time decreases.

We further evaluate MUSCHED in edge scenarios where a background picture-in-picture (PiP) video call coexists with foreground user interactions. Table 3 summarizes four representative cases, including application cold start in Taobao and WeChat Moments, live-room interaction in Douyin, and article browsing in a news application. Across these scenarios, MUSCHED consistently reduces foreground response latency by 9.8%–22.8% in all cases, with the largest gain observed in WeChat Moments. Overall, these results suggest that MUSCHED remains effective under mixed foreground/background workloads, while also highlighting that semi-interactive scenarios with concurrent media activity still expose cases that require finer-grained policy reconciliation, as we designed in Section 4.1.

Overhead of MUSCHED. We further evaluate the runtime overhead introduced by the scheduling backend of MUSCHED and its dependency-tracking path. We measure the overhead in two widely adopted scenarios: short-video playback and mobile gaming.

In a steady-state short-video playback scenario, we compare the average latency of two scheduler-critical operations, context switching and pick-next-task selection, before and after enabling MUSCHED. As shown in Table 4, the average context-switch latency remains unchanged at 5 µs, while the

Table 4: Runtime overhead and energy impact of MUSCHED under video and gaming scenarios.

Scenario	Metric	Baseline	Ours
Video	Avg. context-switch latency (µs)	5	5
	Avg. pick next task latency (µs)	2	3
Gaming	Avg. FPS	119.76	119.69
	Worst dropped frames	4	3
	Normalized current (mA)	726.62	718.16

Table 5: End-to-end QoE evaluation in large-scale production deployment. Values report anomaly frequencies per thousand hours of user activity before and after deploying MUSCHED.

Scenario	Anomaly Metrics	# of Anomalies		Improvement
		Baseline	Ours	
Animation	drop $>$ 50ms	27.2	20.4	25.0%
Swipe	drop $>$ 50ms	10.5	6.8	35.7%
Startup	startup $>$ 2s	94.5	65.5	30.7%

average pick next task latency increases only slightly from 2 µs to 3 µs. These results indicate that the IPC and lock tracking hooks and the dependency-propagation logic add little overhead to the scheduler fast path in a representative interactive media workload. We also evaluate a mainstream mobile game at 120 FPS with default graphics settings to assess runtime cost under sustained high-refresh load. As shown in Table 4, the average frame rate is nearly unchanged, the worst dropped-frame count is slightly improved, and the normalized current is comparable. Together, these results suggest that MUSCHED does not introduce non-negligible overhead in practice.

7 Experiences and Lessons Learned

In this section, we introduce the experiences and lessons learned during our development and deployment process of MUSCHED. We also present big data results on large-scale commercial smartphones, covering application cold-start performance, frame drop performance in UI animation, and user swipe scenarios.

7.1 Production Deployment of MUSCHED

Since its deployment in January 2024, the scheduling algorithm designed using MUSCHED has been deployed on over *20 million* mobile devices from Honor. The deployment spans multiple product tiers, including flagship and mid-range device series, and covers both MediaTek and Qualcomm platforms. Targeted scenarios include application cold-start, web browsing, and touch-sliding interactions.

To illustrate how MUSCHED performs in real-world scenarios, we validate it using large-scale user data. We measure anomaly frequency across various real-world scenarios, including application cold start, animation, and swipe, that significantly impact users' QoE. Specifically, for application cold-start, we define a cold-start time that exceeds 2 seconds as an anomaly; for animation and swipe scenarios, we define continuous frame drops lasting more than 50ms as an anomaly. We then measure the anomaly frequency in each scenario before and after deploying our approach. The anomaly counts reported here indicate how many times users encounter such failures per thousand hours of usage. These statistics are first collected on-device and then aggregated across the deployed user population for large-scale analysis.

The results in Table 5 demonstrate that our approach consistently delivers stable and significant performance gains in the real world. As shown in Table 5, we observe clear reductions in anomaly rates across animation, swipe, and startup scenarios. Specifically, animation anomalies decrease by 25.0%, swipe anomalies by 35.7%, and startup anomalies by 30.7%.

These findings indicate that across diverse workloads and complex user-interaction scenarios, our scheduling strategy can effectively identify critical tasks, prevent stalls along the critical path, and maintain smooth interactions even amid heavy system-resource contention. It validates the generalization ability and robustness of our approach in large-scale real-world deployments, enabling continuous improvements to overall user QoE.

7.2 Lessons Learned

Over the course of developing MUSCHED, from initial research prototyping in 2021 to production deployment in January 2024, we have learned several lessons about the practical realities of user space scheduling on commercial mobile devices.

Lessons Learned ①: Practical gains in development efficiency. Adopting a user-space scheduling framework based on Linux sched_ext delivers impactful practical benefits, addressing key challenges in deploying scheduling innovations on commercial mobile devices.

First, user-space design enables dynamic policy iteration without kernel recompilation: scheduling logic can be hot-updated, reducing iteration time from hours to minutes for scenario-specific policies (e.g., gaming, application cold-start). Combined with sched_ext's modularity, this decouples policy logic from core kernel components, mitigating stability risks by confining failures to user space.

Second, user-space scheduling facilitates fine-grained scenario adaptation and controlled experimentation. Dynamic conditional triggering aligns policies with context-aware demands—aggressive CPU provisioning for games, power-efficient scheduling for low-interaction phases, and lifecycle-aware core scaling for application foreground transitions. Its isolated execution also enables safe A/B testing on production

devices, supporting "small-batch" validation without potential global disruption.

Third, the approach lowers developer barriers via high-level abstractions (e.g., BCC, BPFtrace), enabling policy development in C or scripting languages without deep kernel expertise. It integrates seamlessly with Android's system services (e.g., Activity Manager) and leverages widespread kernel support for user-space scheduling frameworks.

***Lessons Learned ②: Future potentials of* MUSCHED.** First, on-demand activation via scenario recognition is non-negotiable for commercial viability. A single user-space scheduling framework cannot optimize all mobile workloads (e.g., interactive apps, background services, optimized games). We should integrate it with a scenario recognizer to dynamically trigger policies in critical contexts (e.g., application launches, UI animations) and to auto-exit during idle/background phases, thereby avoiding unnecessary overhead and ensuring compatibility across diverse use cases.

Second, tight integration with SoC-specific hardware characteristics is essential. Modern mobile SoCs feature heterogeneous cores, dynamic idle states, and CPU affinity constraints. While kernel mechanisms partially address these, user-space schedulers leverage fine-grained hardware telemetry (e.g., per-core utilization, thermal headroom) to make informed core-selection decisions, ensuring consistency across chipset models and unlocking full performance potential.

Third, co-optimization of core selection and frequency scaling is imperative. These two mechanisms are inherently coupled: a high-performance core assignment fails if frequency is throttled, and aggressive scaling wastes power without intelligent core selection. Future user-space frameworks should unify these controls to balance latency and energy efficiency, e.g., triggering frequency boosts only for critical tasks on performance cores. These lessons highlight that the commercial success of user-space scheduling depends on adapting to real-world hardware diversity, workload variability, and intertwined resource management challenges.

Lessons Learned ③: No silver bullets for workloads. Our previous results show that the MUSCHED can significantly improve some interactive Android workloads. However, its performance benefits are limited for highly optimized games with simple, well-understood critical paths.

There are two main reasons. First, mobile games are flagship workloads that showcase the overall device capability. Major SoC and OEM vendors, therefore, invest heavily in this domain. For mainstream devices, the frame rate of popular titles already meets the target cap under most conditions. Second, compared with the heavily interactive workloads discussed earlier, the scheduling patterns of mobile games are relatively simple. The critical threads (e.g., UnityMain, UnityGfxDeviceW) exhibit stable and highly regular switching behavior. Consequently, the primary bottlenecks shift to power and thermal constraints, while SoC/OEM mechanisms such as CPU load estimation, power governors, and power-aware schedulers (e.g., PELT/WALT) dominate performance.

We evaluate a large MOBA game and find that with and without the MUSCHED, the average FPS remains stable, and frame-time variability shows no statistically significant difference. Even after applying optimizations such as core selection and enqueue policies, we observe only a minor decrease in CPU utilization, while the electric current and device shell temperature become slightly worse.

Lessons Learned ④: No free escape with eBPF. In the in-kernel setting, eBPF is deliberately restricted and, in practice, not Turing-complete. For kernel safety, the verifier of eBPF enforces strict constraints: no direct modification of kernel data structures, no unbounded loops, a 512-byte stack limit, and no dynamic memory allocation. The verifier itself does not scale well to complex control-flow paths. When the code contains layered if-else conditions, the program can easily be rejected during verification.

In practice, we agree with these safety constraints, but fast prototyping and iteration often require us to escape the pure eBPF model. Our main strategy is to treat eBPF as a thin control plane and leave complexity back into the kernel (modules) via the kfunc mechanism. With simple annotations, selected kernel functions can be exposed as callable kfuncs to eBPF programs. To support updates to kernel data structures, we implement a memcpy-like BPF kfunc that performs the actual writes in kernel space. For existing complex scheduling algorithms, we encapsulate them as kfuncs rather than reimplementing them. To cope with stack and allocation limits, we store state and large data structures in global variables and BPF maps. To keep verifier complexity manageable, we avoid deep branching and, when necessary, split decision logic into multiple shallow control flows.

8 Related Work

MUSCHED builds on several pioneering works, including application-specific OS scheduling and eBPF-based user-space OS management. In this section, we introduce the works related to MUSCHED.

8.1 OS Scheduling Advancements

OS scheduling has been widely studied in the last few decades. Academia and industry introduce a spectrum of general-purpose policies as well as many domain-specialized schedulers that target latency, throughput, or energy trade-offs. Widely adopted policies such as FIFO and the Linux Completely Fair Scheduler (CFS) provide simple yet effective performance across a wide range of workloads.

Beyond general-purpose schedulers, recent years have seen a proliferation of scheduling work tuned to specific workloads or application patterns. For example, for remote procedure calls (RPCs) in data centers, existing works such as Shinjuku [13], Shenango [20], and eRPC [15] push the envelope on

tail latency and per-core efficiency. Work in this area often involves co-designing CPU scheduling with network transport, as RPCs typically encompass both networking and computing components. Another example is in the serverless computing domain, SFS [8] and Alps [9] focus on the peculiarities of short-lived, latency-sensitive function executions across highly bursty request arrivals. These designs explore techniques including lightweight isolation, fast placement, and resource reclamation to reduce cold-start and queuing delays and to improve utilization in multi-tenant environments.

Mobile systems introduce a different set of constraints where user experience and energy consumption are primary concerns. For example, SmartOS [10] leverages reinforcement learning to obtain the importance of each task on mobile devices and allocates resources according to user preference. Orthrus [22] proposes a framework that co-optimizes the process scheduling and CPU frequency governing on mobile OS for both energy efficiency and quality of service. Targeting the slow UI responsiveness problem, TIHMM [25] reconstructs the process state model on Android with new "hogging" states to reduce the suboptimal resource allocation of the original Android process management.

Compared with the above works, MUSCHED not only focuses on specific scheduling problems during cold start or UI animation but also acts as a fundamental framework to solve the trinity problem of mobile scheduling.

8.2 User-space OS Management with eBPF

Extended Berkeley Packet Filter (eBPF) is a lightweight in-kernel virtual machine that runs sandboxed programs at well-defined OS hook points. Programs interact with the kernel and user space via `maps`, enabling low-overhead telemetry, state sharing, and control. Because eBPF enforces safety and verification, it lets developers iterate on policy logic in user space while applying enforcement close to the kernel. This property makes eBPF a natural substrate for user-space OS management: user processes can define, tune, and deploy policies quickly, and eBPF provides fast, safe kernel mediation and observability. Prior work has explored both eBPF-based management and broader user-space delegation to make OS policies more reconfigurable.

A representative work is ghOst [12], which delegates CPU scheduling decisions to user-space agents. Its key idea is to keep the kernel responsible for safe enforcement and low-level task state management, while allowing developers to implement scheduling policies in user space and update them without redesigning the whole kernel scheduler. This design supports a variety of scheduling models, including centralized, sharded, and preemptive scheduling, and has demonstrated that user-space schedulers can provide both flexibility and low latency for datacenter workloads. Building on this direction, Syrup [14] extends user-space scheduling beyond CPU cores to jointly manage the networking stack and NIC, showing that policy delegation can coordinate multiple OS subsystems.

Beyond CPU scheduling, eBPF-based management has also been explored in the memory-management domain. CacheBPF [26] facilitates the modification of page-eviction policies without changing core kernel code. FetchBPF [6] uses eBPF to implement pluggable memory prefetch strategies. It highlights how introspective kernel probes enable workload-aware prefetching. Results show substantial throughput gains for memory-bound applications.

These prior systems either move selected OS functionality into user space or use eBPF to customize a single subsystem. In contrast, MUSCHED focuses on interaction-aware CPU scheduling for commercial mobile devices. It couples user-space policy adaptation with low-overhead kernel enforcement to support scenario-aware prioritization and cross-process dependency handling without invasive and frequent kernel changes, which is impractical on COTS devices.

9 Conclusion

This paper presents MUSCHED, a semantic-aware scheduling framework for modern mobile SoCs. MUSCHED addresses the fundamental semantic gap between low-level kernel scheduling and high-level user interaction, which becomes especially problematic in the face of the mobile scheduling trilemma: scarce high-performance cores, complex cross-process dependencies, and unforgiving latency deadlines. MUSCHED introduces a new VIP scheduling class between RT and CFS, identifies interaction-critical threads through scenario-aware annotation, propagates priority across Binder and lock dependencies, and supports user-space policy updates without kernel recompilation.

In laboratory experiments, MUSCHED reduces average application cold-start time by 14.8%. In large-scale production deployment on over 20 million commercial devices since 2024, MUSCHED reduces cold-start anomalies by 30.7%, animation anomalies by 24.9%, and swipe anomalies by 35.7%, while preserving system stability. These results demonstrate that semantic-aware, deployable user-space scheduling is a practical way to improve mobile QoE on commercial off-the-shelf devices.

qTPU: Hybrid Tensor Networks for Quantum-Classical Acceleration

Nathaniel Tornow Emmanouil Giortamis Dennis Sprokholt
Christian B. Mendl Pramod Bhatotia
Technical University of Munich

Abstract

Classical accelerators (GPUs, TPUs) excel at high-performance computing but cannot efficiently represent problems that scale exponentially, such as highly entangled quantum states. Quantum processors (QPUs) address these intractable problems but are constrained by noise, high error rates, and low throughput. This necessitates hybrid quantum-classical execution: computationally complex kernels are offloaded to QPUs, while scalable computation runs on classical accelerators.

Despite this clear need for hybrid systems, we currently lack a concise programming paradigm for expressing and optimizing them. Developers must manually partition and orchestrate applications across quantum and classical hardware through *ad hoc* approaches that produce fragmented, inflexible workflows. This prevents holistic optimization across the quantum-classical interface and limits scalability.

To this end, we introduce the *hybrid tensor network (hTN)* abstraction—a unified representation capturing quantum-classical computation—realized in qTPU, an end-to-end system comprising: the *qTPU programming model* for declarative hybrid computation specification; the *qTPU compiler* for holistic hTN optimization balancing classical cost against quantum error; and the *qTPU runtime* for scalable execution across heterogeneous QPUs and classical accelerators.

Our evaluation demonstrates that qTPU achieves 3–4 orders of magnitude lower classical overhead, up to 7.2× lower quantum error rates, up to 53× faster compilation, and over 20× end-to-end speedups across hybrid ML, circuit knitting, and quantum error mitigation.

1 Introduction

Data centers are increasingly relying on specialized accelerators, such as GPUs, TPUs, and FPGAs, to meet the demands of growing domain-specific compute workloads, *e.g.,* in machine learning and scientific computing [3, 44, 45, 68]. Through recent remarkable engineering efforts, quantum processors (QPUs) are becoming available as new domain-specific accelerators [2, 5, 30, 38]. When combined with classical computing, QPUs could help us address problems in materials science and chemistry that remain intractable on classical computers [40, 53, 66, 72, 78].

QPUs leverage quantum-mechanical properties such as superposition and entanglement to efficiently represent and manipulate exponentially large state spaces that cannot be encoded using classical memory [57]. This capability enables, *e.g.,* the simulation of strongly correlated quantum systems and the modeling of highly entangled or high-dimensional distributions in machine learning, and offers the potential for exponential speedups for certain problems [36, 75, 81].

Although QPUs offer unique advantages for specific classes of problems, they are subject to severe limitations: they are noisy, provide only limited computational resources in memory and availability of devices, and have throughput orders of magnitude lower than classical accelerators [41, 67].

As a result, quantum advantages – where they exist – typically apply only to the complex core of a computational problem, where classical devices fail due to the exponential complexity of representing quantum states [12, 41]. Many important workloads, such as complex machine-learning models or scientific simulations for material sciences, fall into a regime where they are both *(i)* too inefficient or outright infeasible to execute solely on classical accelerators, and *(ii)* too complex and large-scale to run entirely on today's QPU hardware [54, 66].

This motivates a *hybrid* quantum-classical execution paradigm. Instead of running a program entirely on classical hardware or entirely on a QPU, realistic applications distribute work across both: the quantum-inclined components are offloaded to QPUs, while the remaining computation runs on better-suited classical accelerators [12, 34].

To program such hybrid applications, the current approach relies on a rigid host–kernel programming model. Programmers must manually isolate portions of the algorithm that could benefit from quantum or classical acceleration and implement them as separate kernels [8, 59].

Unfortunately, this existing form of quantum–classical hybrid computing is tedious, inflexible, and inefficient to use in cloud environments, suffering from three core limitations:

(1) **Fragmented programming models:** Developing hybrid applications requires reasoning across two distinct programming paradigms and manually implementing separate routines for classical devices and QPUs [19]. This fragmented model forces developers to explicitly manage low-level data movement, control flow, and up-front partitioning decisions, making the development of hybrid applications tedious and prone to inefficiencies.

(2) **Lack of holistic compiler optimizations:** Current programming models require developers to define a fixed

boundary between quantum and classical kernels *a priori* [8]. This rigid separation prevents compilers from reasoning across the quantum–classical interface, hindering holistic, end-to-end optimization. As a result, no dynamic execution decisions are possible; *e.g.,* even if parts of a quantum kernel could be executed more efficiently on a classical accelerator, they cannot be automatically offloaded, locking the application into a potentially suboptimal execution path [88].

(3) **Poor scalability and rigid runtime:** Current hybrid workflows are inefficient and struggle to scale because they are manually orchestrated and executed as separate, sequential steps, lacking a unified program view [33]. This prevents dynamic execution decisions, *e.g.,* even if part of a quantum kernel would run more efficiently on a classical accelerator, the compiler cannot offload it automatically.

We argue that these limitations fundamentally arise from the lack of a concise representation that seamlessly captures both quantum and classical computation, leading to our main research question:

Research question

How can we design a concise and expressive hybrid computing paradigm that unifies quantum and classical computation while enabling efficient execution across heterogeneous accelerators?

Our key idea for addressing this challenge is the **hybrid Tensor Network (hTN)** abstraction, a necessary theoretical foundation to address the fragmentation in hybrid computing. In particular, we establish Tensor Networks (TNs) [61]—a core algebraic formalism for both quantum circuit simulation and accelerated classical computation—as a unifying computational substrate [52, 92]. The hTN extends this formalism by representing the complete hybrid workflow, including quantum components (quantum tensors) and classical components (classical tensors), as a single, connected graph. This unified expression bridges the classical-quantum gap, enabling holistic optimization and treatment of complex algorithms, such as hybrid machine learning models, as a single, coherent computational entity.

To realize hTNs in practice and to answer our posed research question, we present QTPU, an end-to-end systems approach for unified, flexible and scalable hybrid computing. *(1)* Our *QTPU Programming Model* formally defines the primitives built on hTNs, allowing programmers to specify only *what* to compute, *not how*; our *(2) QTPU Compiler* converts hTNs into executable hybrid code, which we holistically optimize for efficient computation across a set of QPUs and classical accelerators; and finally, *(3)* our *QTPU Runtime* dynamically adapts the hybrid computation to scalably execute across the available heterogeneous collection of classical and quantum accelerators.

Our evaluation shows that QTPU achieves substantial improvements across hybrid workloads: up to 53× faster compilation, 7.2× lower quantum error rate, 3,700× smaller generated code, and 10,000× lower classical overhead than state-of-the-art baselines. QTPU further scales to problem sizes that existing hybrid systems cannot handle, while enabling efficient utilization of heterogeneous QPU/GPU resources.

Contributions. We make the following contributions.

- We introduce the hybrid Tensor Network (hTN) abstraction, a unified representation that captures hybrid quantum-classical workflows as a single connected tensor graph, moving beyond existing host-kernel models (§ 3.2).
- We formally introduce the QTPU Programming Model, which realizes our hTN abstraction. We define its core primitives—including the iswitch (for specifying quantum tensors) and hEinsum (for hybrid contraction)—which enable the simple and declarative description of entire hybrid quantum-classical programs (§ 5).
- We introduce compiler transformations that jointly optimize across both modalities by balancing the classical cost of tensor contractions with the quantum execution error, ensuring optimal utilization of available quantum and classical compute paradigms. (§ 6).
- We design a scalable execution approach that distributes and dynamically adapts hybrid programs across a heterogeneous set of QPUs and classical accelerators. The QTPU runtime facilitates this through runtime code generation, tailoring device-specific kernels on demand to maximize parallel execution and efficient resource utilization based on available hardware. (§ 7).

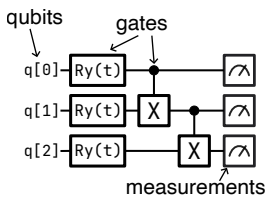
2 Background and Motivation

2.1 Foundations of Quantum Computing

Quantum computing could accelerate tasks in many areas, including quantum physics, materials science, and machine learning [36, 40, 72, 81]. Although current QPUs remain in their early stages, recent experiments have demonstrated behavior that is increasingly difficult to reproduce classically, suggesting potential advantages for specific problem classes [4, 16, 17, 37, 83].

QPUs are typically programmed under the *quantum kernel model*, illustrated in Fig. 1. A quantum kernel is a classical function that produces a *quantum circuit*, which is then compiled and executed on a QPU [59].

The basic computational unit of a quantum circuit is the *qubit*, a two-level quantum system. An n-qubit register corresponds to a complex-valued vector in a 2^n-dimensional Hilbert space, enabling it to represent vectors that would require exponentially many parameters to store classically [57]. A quantum circuit generally *(1)* initializes qubits, *(2)* applies single- and multi-qubit quantum gates, and *(3)* measures a



```
@qkernel
def simple_kernel(t)
    q = alloc_qubits(3)
    for i in range(3):
        ry(q[0], t)
    cx(q[0], q[1])
    cx(q[1], q[2])
    measure(q)

circuit = simple_kernel(0.3)
res = qpu.run(circ, shots=1000)
```

Figure 1: Example of the quantum-kernel model.

subset of the qubits in the computational basis. Measurement collapses each qubit to either 0 or 1 according to a distribution determined by the circuit; repeating the circuit for s *shots* yields bitstrings $b^{(\ell)} \in \{0,1\}^m, \ell = 1,\ldots,s$, over the m measured qubits.

2.2 Quantum-Classical Computing

Both quantum and classical accelerators can efficiently solve domain-specific problems; however, neither provides a one-size-fits-all solution.

On the one hand, modern *classical accelerators* (such as GPUs, TPUs) provide massive data and operation parallelism, large on-device memory, and extremely high throughput and low latency for, *e.g.*, dense numerical workloads. They are reliable, abundantly deployed, and scale to thousands of devices in distributed cloud environments. However, classical accelerators operate on data structures that cannot efficiently represent strongly correlated and entangled quantum systems, whose classical representations scale exponentially compared to their quantum representations [28, 31, 99].

On the other hand, *quantum accelerators* (QPUs) leverage unique quantum-mechanical effects to efficiently represent and manipulate highly correlated quantum states that classical systems cannot handle [41, 57]. This makes them attractive for tasks such as simulating highly correlated systems for material science or quantum chemistry. However, QPUs also have inherent limitations, since qubits are inherently noisy, and quantum operations are prone to errors, resulting in unreliable results at large circuit depths [64, 74]. Achieving fault tolerance requires substantial overhead in both qubit resources and execution time, making logical qubits a scarce resource and significantly limiting QPU throughput and latency.

The need for hybrid acceleration. Classical and quantum accelerators have complementary strengths and limitations, making neither suitable for all tasks. Realistic workloads therefore require a tightly integrated hybrid approach: QPUs are used selectively where quantum capabilities offer an advantage, while all other computation is handled by classical accelerators.

2.3 Blueprint of Hybrid Applications

Hybrid quantum-classical computing leverages the complementary strengths of classical accelerators and QPUs to solve

```
@qkernel # QNN kernel (input x, weights W, output o)
def quantum_layer(x, W, o):
    q = alloc_qubits(N)
    for i in range(N):
        ry(q[i], x[i]) # input encoding
    model(q, W) # apply some QNN-layer
    apply_obs(q, o) # measure specific observable
    measure(q)

@ckernel # a classical GPU/TPU kernel
def classical_layer(Z, V): # linear layer
    return matmul(V, Z) # matrix-matrix multiplication

def forward(X, W, V, O): # hybrid model evaluation
    # Stage 1: construct and run a family of circuits
    circuits = [quantum_layer(x,W,o) for x in X for o in O]
    Z = qpu.run(circuits, shots=1000)
    # Stage 2: perform classical processing
    Y_pred = classical_layer(Z, V)
    return Y_pred

def train(): # model training loop
    X,Y = dataset(); W,V = init_weights(); O = observables()
    for epoch in range(E):
        Y_pred = forward(X, W, V, O)
        update([W, V], loss(Y, Y_pred))
```

Listing 1: Fragmented quantum-classical ML example.

problems that neither can efficiently address on its own.

The *core* of virtually all hybrid quantum-classical algorithms and methods—including quantum simulation [56, 62, 97], circuit knitting [84, 90], error mitigation [50, 89], and quantum-enhanced machine learning (ML) [10, 14, 51]—shares a common computational blueprint, consisting of two tightly coupled stages. For example, Lst. 1 shows a quantum-classical approach to train a machine-learning kernel, implemented via the kernel's `forward`-pass.

Stage 1: Evaluate families of quantum circuits. The workflow begins by executing a *family* of closely related quantum circuits derived from classical inputs or intermediate computation. These circuits typically share a structural backbone but differ in controlled ways, together exposing the necessary information required for the hybrid computation.

In our example (Lst. 1, Line 16-17), we produce and run a family of quantum circuits that encode the individual inputs of our training dataset and measure observables, whose results are later fed into the next layer. This family needs to be explicitly generated and run on a specific QPU to produce all the results required for the next stage.

Stage 2: Perform classical processing. The measurement outcomes from the circuit family are then combined with additional classical inputs and processed using classical computation. Across algorithmic classes, this postprocessing is governed almost entirely by *linear-algebraic* operations, which transform the quantum-generated data into the quantities of interest and feed back into the host-driven control loop that produces the next family of circuit evaluations.

In our example (Lst. 1, Line 19), we apply a simple linear layer—*e.g.*, on a GPU—to the quantum outputs and classical

weights, producing the predicted results for the dataset.

Examples of hybrid applications. Beyond our example of hybrid machine learning, various other applications in quantum computing follow the same structure. In this work, we focus on three representative hybrid applications:

(i) **Hybrid Machine Learning** combines variational quantum circuits with classical layers to model functions or data distributions that cannot be efficiently captured by purely classical or purely quantum models [10], similar to our toy-example of Lst. 1;

(ii) **Scalable hybrid computing** uses circuit knitting techniques [84, 90] to execute circuits that exceed the qubit capacity of QPUs by decomposing a large circuit into families of smaller subcircuits, running them on small QPUs, and classically reconstructing the result; and

(iii) **Quantum Error Mitigation (QEM)** generates and executes families of circuit variations to estimate and suppress noise effects, combining the resulting measurements through classical postprocessing to approximate the noiseless output of the original circuit [26, 49, 89].

We evaluate our approach on these applications in § 8.

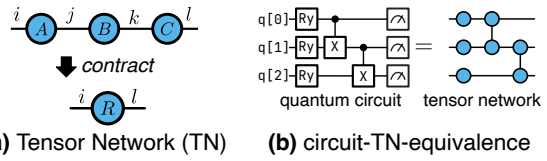
2.4 Limitations of the Current Practices

Using both quantum and classical resources leverages the full benefits of both worlds. Unfortunately, the current approach to writing quantum-classical programs follows a manual, ad-hoc workflow that is error-prone and complex due to several fundamental limitations, which we explain now.

Limitation #1: Fragmented programming model. In current hybrid workflows [8, 59], the quantum and classical parts of a program must be written in separate paradigms, as shown in Lst. 1. The programmer implements one kernel for the QPU and another for the GPU/TPU, and must manually coordinate them in the host code. In the example, the `forward` function builds a family of circuits, sends them to the QPU, waits for results, and then invokes a classical kernel. Thus, even though the programmer specifies *what* the computation should do, they must also express *how* the quantum and classical kernels interact, making hybrid programs unnecessarily complex.

Limitation #2: Inflexible compilation. The programmer must fix the quantum–classical boundary a priori, preventing holistic cross-paradigm optimization because the hybrid computation is not represented as a single unified object. In Lst. 1, the quantum and classical kernels are statically tied to their modalities—QPUs for `quantum_layer` and GPUs/TPUs for `classical_layer`. This rigidity blocks optimization of `forward` as a whole, since it consists of two separately compiled black-box kernels. As a result, tasks cannot be reassigned across paradigms, even when parts of `quantum_layer` could run more efficiently on a classical accelerator.

Limitation #3: Rigid runtime. Current hybrid workflows are manually orchestrated and executed as separate, sequential steps, giving the runtime no unified view of the computation. In Lst. 1, the manual orchestration inside `forward` fixes the quantum and classical stages in order and binds them to their respective devices, preventing dynamic parallelism or resource-aware scheduling. Because the assignment of work is static, the runtime cannot adapt to the availability or load of heterogeneous QPUs and classical accelerators, which severely limits scalability for larger problems.



(a) Tensor Network (TN) **(b)** circuit-TN-equivalence

Figure 2: Tensor Network background (§ 3.1).

Problem statement

We require a solution that unifies quantum-classical applications in a common foundation, thus allowing holistic optimization across both fragments, while adapting its execution to available quantum-classical devices.

3 Hybrid Tensor Networks (hTNs)

We propose *hybrid tensor networks* (hTN), which address the above limitations by unifying quantum and classical computing in a common framework.

3.1 Tensor Networks (TNs)

Tensor networks compactly describe an output tensor as a function of input tensors. TNs emerged in condensed-matter physics as a compact representation of many-body quantum states that would otherwise require exponential resources to describe [60, 91], and have since become the backbone of state-of-the-art classical simulators for quantum circuits [29, 58]. In parallel, the same einsum-based formalism is the standard language for specifying linear-algebraic computations in, *e.g.*, deep-learning frameworks [39, 63].

Intuitively, a tensor generalizes a vector or matrix to an array of arbitrary rank. A tensor network describes how such tensors are combined through *contractions*—pairwise summations over shared indices, of which matrix multiplication is the rank-two special case. Contracting a network composes its input tensors into a single output tensor by summing over all shared indices simultaneously.

Einsum expression. TNs specify pure linear-algebra expressions via the *Einsum* language. Formally, $T_O = \mathrm{einsum}(I_1, \ldots, I_n \to O;\ T_1, \ldots, T_n)$ defines the output tensor T_O entry-wise as

$$T_O[\mathbf{o}] \triangleq \sum_{\mathbf{i} \in (\mathcal{I} \setminus O)} \prod_{k=1}^{n} T_k[\mathbf{i}_{I_k}], \tag{1}$$

where T_i are tensors with index set I_i; O is the output index set, of which $\mathbf{o}$ denotes an assignment; $\mathcal{I} = \bigcup_{k=1}^{n} I_k$ is the

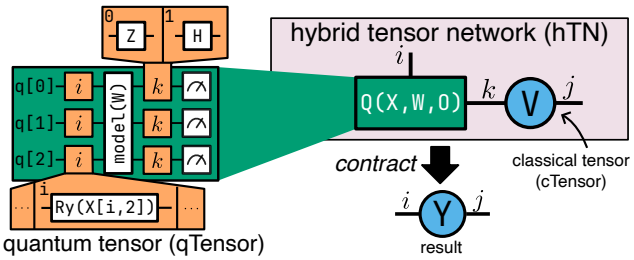


Figure 3: Our hybrid tensor network (hTN) abstraction (§ 3.2).

union of all index sets; and $\mathbf{i}_{I_k}$ is the restriction of the global index assignment $\mathbf{i}$ to the indices of tensor T_k. For example,

$$R = \text{einsum}(ij, jk, kl \to il;\ A, B, C) \qquad (2)$$

specifies the triple matrix product $R = A \cdot B \cdot C$, *i.e.,* $R_{il} = \sum_{j,k} A_{ij} B_{jk} C_{kl}$.

Tensor networks as graphs. An equivalent way to specify a TN is as an undirected graph, whose vertices represent tensors and the edges correspond to shared indices (*i.e.,* contractions). When two tensors are connected by an edge, the corresponding index is contracted (summed over), and dangling edges connected to only a single vertex specify the output indices. Fig. 2 (a) shows an example of such a TN-graph, equivalent to the einsum expression of Eq. 2.

Quantum computations as TNs. The connection between quantum and classical computation becomes explicit when we observe that any quantum circuit can be represented as a TN, as we show by example of Fig. 2 (b). Each k-qubit gate is a unitary linear map, and thus a rank-$2k$ tensor whose indices correspond to its k input and k output wires [52,60]. A quantum circuit then becomes a TN in which adjacent gates share the wires they act on as contracted indices, so that executing the circuit (*i.e.,* applying gates in sequence) is the same operation as contracting the network. Thus, quantum circuits can be expressed using the einsum-based formalism introduced above, enabling a unified representation of both classical and quantum computations.

3.2 Key Idea: Hybrid Tensor Networks (hTNs)

We introduce the **hybrid tensor network (hTN)**, an abstraction that extends the TN formalism to enable unified execution and flexible partitioning of computation across quantum and classical accelerators, yielding a simple and coherent abstraction for hybrid quantum-classical workloads.

Fig. 3 shows an hTN describing the computation of the hybrid `forward` function in Lst. 1. The program executes several circuits over a batch of input data $X \in \mathbb{R}^{|i| \times 3}$ containing $|i| = d$ data points, each represented as a vector of dimension 3, and a set of observables O with $|O| = 2$. The qTensor on the left in Fig. 3 compactly describes this circuit's entire family. The qTensor has two indices, i and k, with sizes $|i| = d, |k| = 2$. These indices are referenced by *index-instructions*, associating each with several operations. For instance, instantiating i=1,k=0 replaces every index-instruction that depends on i with the second operation in its family, and every index-instruction of k with the first operation in its family.

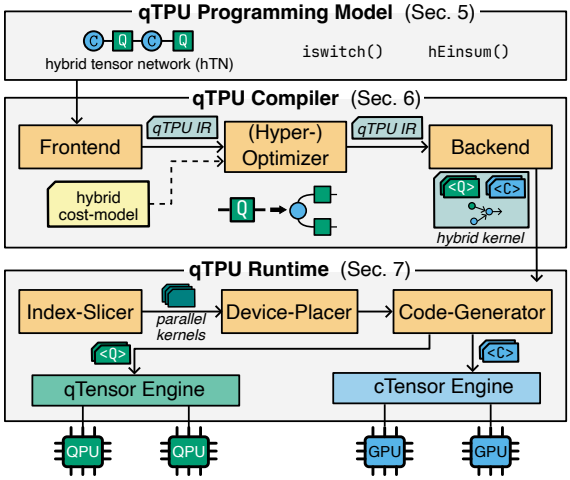

Figure 4: System overview (§ 4).

The hTN on the right in Fig. 3 compactly describes the hybrid program with the qTensor and a cTensor $V \in \mathbb{R}^{|k| \times |j|}$. The index k contracts with the qTensor's output index, while j denotes the dimension of the output vectors $y \in Y$. Contracting this hTN yields the result tensor $Y \in \mathbb{R}^{|i| \times |j|}$, corresponding to the output of the hybrid computation and containing the resulting ML-layer predictions for each input indexed by i.

Semantics. Unlike classical TNs, an hTN first executes its qTensors to its results-cTensor, before contracting the hTN to a tensor with einsum. An hTN, consisting of classical tensors $T_1^c, \ldots, T_n^c$, each with its own index set I_i^c, and qTensors $T_1^q, \ldots, T_m^q$, each with its own index set I_i^q, we contract as follows:

$$T_O = \text{einsum}(I_1^c, \ldots, I_n^c, I_1^q, \ldots, I_m^q \to O; T_1^c, \ldots, T_n^c, [\![T_1^q]\!], \ldots, [\![T_m^q]\!]),$$

where $[\![T^q]\!]$ denotes executing the qTensor for all its indices and transferring the results to a cTensor.

4 qTPU System Overview

To realize our hTN abstraction, we introduce qTPU, an end-to-end system that enables programmable and scalable hybrid computations. Fig. 4 shows an overview of the system.

To express hybrid programs with the hTN abstraction, users program in the **qTPU programming model**, which provides a simple, declarative interface based on the two primitives iswitch and hEinsum, while hiding the complexity of coordinating quantum and classical computation.

To automatically co-optimize a hybrid program, the **qTPU compiler** optimizes it to fully use both quantum and classical computing. The compiler's frontend first parses the program into the unified qTPU IR, after which the optimizer applies a hybrid quantum-classical cost model to identify Pareto-optimal rewrites that reduce quantum errors from noise and classical costs of operations and memory usage. Finally, the backend produces an optimized hybrid kernel comprising

device-agnostic quantum and classical kernels, along with a canonical operation schedule, ready for execution.

Finally, the **qTPU runtime** scalably executes the optimized hybrid program, adapting it to the available resources. To do so, its index slicer first partitions the hTN into smaller, independent, and parallelizable slices. The device placer then maps each concrete quantum and classical computation to an available device to maximize throughput, after which the code generator produces device-optimized kernel code for each computation. The hTN is then executed in a distributed pipeline, where the qTensor engine evaluates all qTensors on the available QPUs, and the cTensor engine contracts the resulting cTensors using the available classical accelerators.

5 qTPU Programming Model

We propose the qTPU programming model, which provides a unified abstraction for hybrid quantum-classical computation, enabling programmers to state hybrid computations *declaratively*, without their low-level execution details – such as manually stitching components into a single workflow.

Our qTPU model exposes two core constructs: (1) *quantum tensors*, created by annotating quantum programs with iswitch statements, and (2) a declarative multi-tensor contraction operator, hEinsum, which composes classical and quantum tensors into a single hybrid computation. These primitives are in addition to the classical tensor (cTensor) primitive, represented by a multi-dimensional array.

5.1 qTensor Primitives

A quantum tensor (qTensor) compactly represents a multi-index family of quantum kernels. It is structured as a quantum program annotated with iswitch operations, each binding a symbolic index to a discrete set of circuits. We consider a simple language t^Q of defining quantum circuits, consisting of gates and our novel iswitch operator:

$$t^Q := \text{gate}(G, \overline{q}) \mid \text{seq}(t^Q, t^Q) \mid \text{iswitch}(k, \overline{G}, \overline{q})$$

Here, G references a quantum gate, while $\overline{G}$ is a vector of gates, and seq refers to a sequence of instructions. $\overline{q}$ is a vector of unique qubit identifiers.

Materialization. Instead of executing the qTensor on a QPU, we could *materialize* it to a classical tensor, given an index set $\mathcal{I}$. U_G is the unitary transformation of gate G.

$$\begin{aligned}
[\![\text{gate}(G,\overline{q})]\!]^{\text{m}}_{\mathcal{I}} &= U_G \\
[\![\text{seq}(t_1^Q, t_2^Q)]\!]^{\text{m}}_{\mathcal{I}} &= [\![t_1^Q]\!]^{\text{m}}_{\mathcal{I}} \cdot [\![t_2^Q]\!]^{\text{m}}_{\mathcal{I}} \\
[\![\text{iswitch}(k,\overline{G},\overline{q})]\!]^{\text{m}}_{\mathcal{I}} &= U_{\overline{G}_{\mathcal{I}_k}}
\end{aligned}$$

5.2 hEinsum: Hybrid Einsum Primitive

We consider another language t^T for tensor computations, embedding quantum computations (t^Q) and our novel hEinsum operator. hEinsum *declaratively* specifies a hybrid TN operation, thus relieving the programmer from managing execution details, while enabling the compiler and runtime to execute it efficiently on QPUs and classical accelerators.

```
1  @quantum_tensor
2  def quantum_layer(X, W, O):
3      q = alloc_qubits(N)
4      for i in range(N):
5          # batch-dimension index
6          iswitch("i", [ry(x[i]) for x in X], q[i])
7      model(q, W)
8      # hidden-dimension index
9      iswitch("k", [apply_obs(o) for o in O], q)
10     measure(q)
11
12 def forward(X, W, V, O): # hybrid computation (declarative)
13     return hEinsum("jk,ik->ij", V, quantum_layer(X, W, O))
```

Listing 2: Unified Quantum-Classical ML example (cf. Lst. 1)

Operationally, hEinsum acts like a standard TN contraction over classical tensors, where qTensors are materialized first to cTensors. To formally state the semantics of our hEinsum term, we define our simple tensor language:

$$t^T := \text{cTensor}(T) \mid \text{qTensor}(t^Q) \mid \text{hEinsum}(\text{expr}; t_1^T, \ldots, t_n^T)$$

We can define the semantics of that language, in particular our hEinsum term, using the mathematical einsum operator (Sec. 3.2). Intuitively, we materialize any qTensor to its classical counterpart, over which we compute a classical einsum.

$$\begin{aligned}
&[\![\text{cTensor}(T)]\!]^{\text{s}}_{\mathcal{I}} &&= T \\
&[\![\text{qTensor}(t^Q)]\!]^{\text{s}}_{\mathcal{I}} &&= [\![t^Q]\!]^{\text{m}}_{\mathcal{I}} \\
&[\![\text{hEinsum}(I_1,\ldots,I_n \to O; T_1,\ldots,T_n)]\!]^{\text{s}}_{\mathcal{I}} &&= \\
&\qquad \text{einsum}(\text{expr}; [\![T_1]\!]^{\text{s}}_{I_1},\ldots,[\![T_n]\!]^{\text{s}}_{I_n}) \text{ where } \textstyle\bigcup_{k=1}^{n} I_k \subseteq \mathcal{I}
\end{aligned}$$

Summary. The qTPU programming model provides a simple, declarative framework for hybrid quantum-classical computation. QTensors introduce indexed quantum kernels via iswitch annotations, while hEinsum lifts classical einsum semantics to the hybrid setting. By deferring kernel specialization and execution until contraction time, the model separates logical specification from concrete realization, permitting the compiler and runtime to optimize placement and scheduling across QPUs and classical accelerators.

5.3 Example Continued

To demonstrate the versatility of the qTPU programming model, we revisit the hybrid ML task from Lst. 1, reimplemented in Lst. 2 (visualized in Fig. 3). The `quantum_layer` function (Line 2) defines a two-dimensional qTensor encoding the required circuit family: index `i` iterates over dataset X to select the input encoding, while `k` selects the measurement observable.

The iswitch primitive instantiates operations based on `i` and `k`. For instance, `i=1,k=0` maps to the second data point and first observable. This allows the programmer to declaratively specify the complete circuit family within the qTensor function, avoiding manual construction of individual circuits.

The `quantum_layer` kernel in Lst. 2 makes the qTensor concrete: each iswitch annotation becomes one index of the qTensor, so the kernel itself specifies the entire iswitch-indexed family. Executing the qTensor on a QPU yields a

cTensor whose entries are the measurement outcomes for each index assignment.

Finally, the hybrid computation in the `forward` function is realized via hEinsum, which defines the contraction over quantum and classical tensors (cf. Fig. 3). In this model, the programmer specifies the computation solely through tensor structure, while details of circuit scheduling, data movement, and coordination remain entirely hidden.

The QTPU programming model serves a dual role: as a user-facing interface for applications such as hybrid ML (Lst. 2), and as a compilation target that upstream tools emit into. For example, our circuit-knitting and error-mitigation pipelines (§ 8.2) lower their output directly into concise hEinsum expressions, obtaining unified optimization and execution without managing hybrid orchestration themselves.

6 QTPU Compiler

The QTPU compiler lowers the high-level, declarative hEinsum-description (§ 5) into an optimized hybrid kernel.

Workflow. Fig. 5 shows the overall workflow of the QTPU compiler. At the frontend, we parse the hEinsum into the intermediate representation (QTPU IR). The optimizer rewrites the QTPU IR to balance quantum and classical costs, leveraging both resource modalities. Finally, the backend emits an optimized hybrid kernel.

6.1 Frontend and QTPU IR

The frontend of the compiler converts a given hEinsum program (§ 5.2) to the unified QTPU IR.

qTensor graphs. We convert each qTensor into a graph $G_{\mathrm{QT}} = (V_{\mathrm{QT}}, E_{\mathrm{QT}})$ mirroring the structure of the underlying quantum circuit's TN (Fig. 2), allowing us to reason about which qTensor parts we can offload to classical operations. Each vertex $v \in V_{\mathrm{QT}}$ is a tuple (op_i, q_x), denoting applying operation op_i on qubit q_x. Edges are defined as (i) a *temporal* edge $\big((\mathrm{op}_i, q_x), (\mathrm{op}_k, q_x)\big) \in E_{\mathrm{QT}}$ if op_i immediately precedes op_k on qubit q_x, and (ii) a *spatial* edge $\big((\mathrm{op}_i, q_x), (\mathrm{op}_i, q_y)\big) \in E_{\mathrm{QT}}$ when op_i acts jointly on qubits q_x and q_y.

Operation graph. The operation graph is a directed acyclic graph capturing the order among computations in the hEinsum. Its initial nodes represent qTensors and cTensors, while its middle nodes are hEinsums. After transformations, we obtain a graph where each operation has two operands, allowing us to map each to an efficient classical implementation.

6.2 Hybrid Cost Model

The QTPU compiler optimizes an hEinsum under a dual-objective cost model that balances classical and quantum resources. It captures the classical contraction cost and the expected error of executing quantum circuits on noisy QPUs.

Classical cost. For a contraction $\mathrm{hEinsum}(I_1, \ldots, I_n \to O; T_1, \ldots, T_n)$, let $\mathcal{I} = I_1 \cup \cdots \cup I_n$, and let $|i|$ denote the size of index i. The FLOP cost of this contraction is $c_x = \prod_{i \in \mathcal{I} \setminus O} |i|$, i.e., the product of the sizes of all summed-out indices. The total classical cost of the hTN is then $C_{\mathrm{classical}} = \sum_{x \in \mathrm{hTN}} c_x$, the sum of the costs of all nodes in the operation graph.

Quantum cost (error). For each qTensor, we estimate the error of its quantum computation from the structure of its underlying circuit. Let $\mathcal{G}(Q)$ be the set of all quantum operations appearing in qTensor Q, and let $\varepsilon(g)$ denote the error probability of operation g due to noise on the QPU's. We define the per-qTensor error score as $E(Q) = 1 - \prod_{g \in \mathcal{G}(Q)} \big(1 - \varepsilon(g)\big)$. This score approximates the probability that at least one error occurs during the execution of Q. The overall quantum error is the maximum error score over all qTensors.

Optimization goal. The compiler seeks a Pareto-optimal front of points in the joint quantum-classical cost space, balancing classical FLOPs and quantum error to produce the most performant hybrid program for the given hardware.

6.3 Optimization Primitives

We optimize hybrid programs using optimization primitives illustrated in Fig. 6.

Tensorization and decomposition. Tensorization captures a linear combination of related hEinsums as a single hEinsum. As shown in Fig. 6(a), any linear combination of hEinsums differing only by small structural changes can be represented as one hEinsum where coefficients c_i are collected into a classical tensor c, and structural variations are encoded by a qTensor with iswitch operations.

When a qTensor contains separable subcircuits acting on disjoint qubit sets, it decomposes into an equivalent hEinsum of smaller qTensors, since subcircuit measurement outcomes are uncorrelated with the full result obtained by multiplying their individual outputs. This replaces one large quantum tensor with several smaller qTensors.

Spatial separation. Gate virtualization partitions circuits by cutting two-qubit gates into a linear combination of single-qubit operations, then recovers the original result by executing all variants and computing their weighted sum [90]. Spatial separation generalizes gate virtualization within our QTPU framework (Fig. 6(b)), replacing the original two-qubit operation with an equivalent hEinsum of one cTensor and one qTensor. When resulting subcircuits operate independently, tensor decomposition factorizes the qTensor into smaller, less noisy components.

Temporal separation. Temporal separation builds on wire cutting, which partitions circuits by cutting qubit wires at specific time steps [84]. The cut decomposes continuous qubit evolution into a linear combination of operations, splitting deep circuits into shallower fragments with reduced accumulated gate errors (Fig. 6 (c)). Applying tensorization and decomposition rewrites large quantum tensors into equivalent hEinsums with multiple shallower, less costly qTensors.

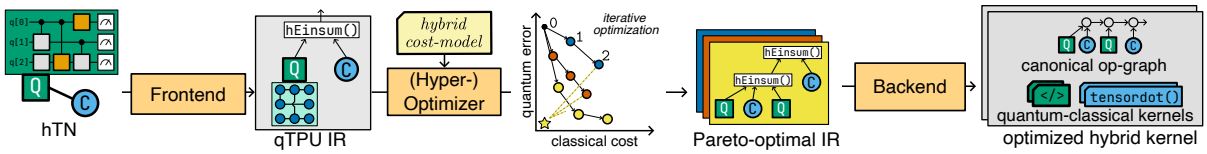

Figure 5: Compiler workflow (§ 6). *The frontend parses hTNs defined with hEinsum to the qTPU IR, the optimizer uses iterative graph partitioning to find Pareto-optimal IR variants, and the backend lowers IR to optimized hybrid quantum-classical kernels.*

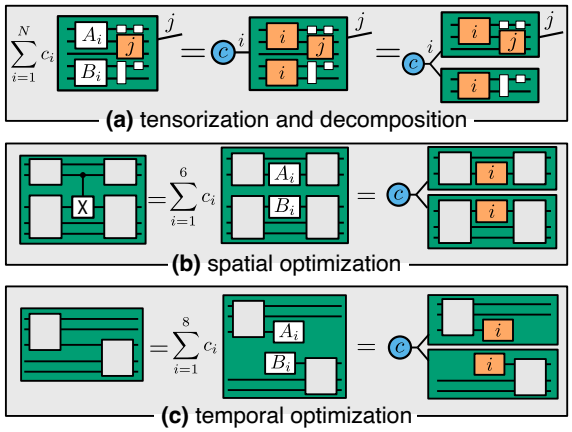

Figure 6: Semantic-preserving qTensor to hEinsum rewrites.

6.4 Optimizer

The optimizer applies the optimization primitives to achieve a Pareto-optimal hybrid cost. It systematically rewrites each qTensor, transforming infeasible quantum workloads into a more balanced hybrid computation.

Optimization workflow. We illustrate the workflow optimizing one qTensor into a hEinsum expression in Fig. 7. We start with the qTensor graph treated as a single partition, and the operation graph containing one qTensor node. At this point, the quantum error is high and the classical cost is zero, as shown by the upper-left point in the graph of Fig. 5.

In each iteration, we partition the qTensor graph into $p \geq 2$ balanced subgraphs to minimize cut edges. These boundary edges dictate the optimization primitive: temporal cuts trigger temporal optimization, and spatial cuts trigger spatial optimization (cf. Fig. 6). As shown in Fig. 7, each rewrite replaces the node with an equivalent subgraph of qTensors and cTensors. We greedily iterate by splitting the partition with the highest quantum cost.

The process continues until each rewrite decreases the distance to the Pareto-optimal point. This produces the cost trajectory shown in Fig. 8: each iteration reduces quantum cost (by shrinking qTensors) while increasing classical cost, thereby moving closer to the optimum. Once an iteration increases the distance to this optimum, we terminate.

Hyperparameter optimization. Because the effectiveness of each iteration depends on the chosen partitioning, we run the optimizer with multiple randomized hyperparameter configurations. These hyperparameters include the target partition count per iteration, p, and the relative weight of partition balance versus minimizing inter-partition edges.

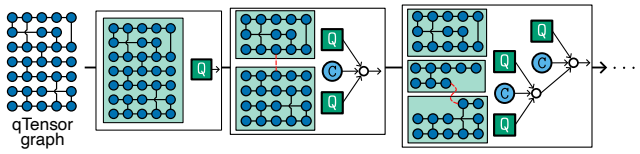

Figure 7: Optimizing a qTensor by iteratively partitioning and recursively building an optimized operation-graph.

Each hyperparameter configuration yields a distinct cost trajectory; from these, we select the Pareto-optimal solution, *i.e.*, the one with final cost closest to the theoretical optimum.

Optimization Constraints. The optimizer is subject to three primary optional constraints: (1) the maximum number of qubits per qTensor in the optimized hEinsum, reflecting the available physical resources of the underlying QPUs; (2) an upper bound on the quantum error accumulated within each qTensor; and (3) a cap on the allowable classical post-processing cost, measured in FLOPs. When such constraints are specified, we first restrict the solution space to Pareto-optimal candidates that satisfy all constraints, and then select the remaining Pareto-optimal solution.

6.5 Backend

Finally, the qTPU compiler lowers the optimized qTPU IR into concrete hybrid kernels.

Contraction scheduling. The operation graph is canonicalized so that every node has exactly two operands, ensuring that each contraction corresponds to a single accelerator operation that can efficiently be implemented on a classical device. We do so while optimizing the contraction order.

Lowering qTensors. Each qTensor across all slices is lowered into a single parametric quantum kernel. For every symbolic index of the qTensor, the compiler introduces a parameter, and each iswitch annotation becomes a corresponding `if-else` block that selects the appropriate gates.

7 qTPU Runtime

The qTPU runtime enables adaptable, scalable, and highly parallel execution of optimized hEinsum programs across a heterogeneous set of quantum and classical accelerators.

Workflow. Fig. 8 illustrates the workflow of the qTPU runtime. The runtime receives the compiler-optimized hybrid kernel, and execution proceeds in two conceptual phases.

In the *adaptation phase* (Fig. 8 (a)), the runtime adapts and lowers the hEinsum expression to the currently available resources. The index slicer and device placer partition

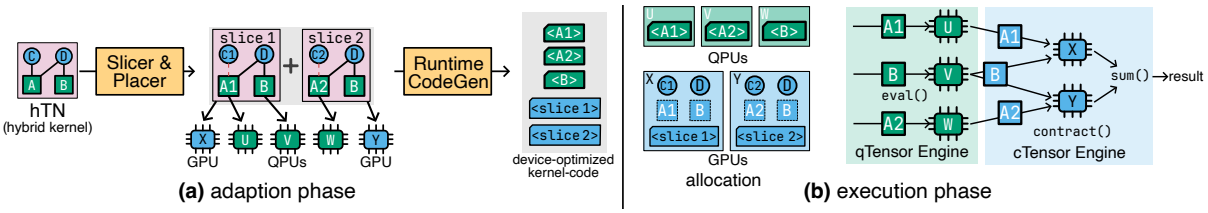

Figure 8: qTPU runtime (§ 7).*(a) Adaptation phase: the slicer and placer partition the hTN into independent slices assigned to QPUs and GPUs, then the code generator compiles device-specific kernels. (b) Execution phase: the qTensor engine evaluates quantum circuits in parallel on QPUs, the cTensor engine contracts results on classical devices to produce the final result.*

the expression into multiple independent slices to expose parallel work and assign each slice's quantum and classical operations to specific QPUs or classical accelerators. After placement, the code generator compiles the mapped quantum and classical operations into device-specific kernel code.

In the *execution phase* (Fig. 8 (b)), the runtime executes the sliced hEinsum across the distributed devices. The runtime first allocates all qTensors and cTensors and loads the generated kernels onto their assigned hardware. Execution proceeds in a map–reduce style: the qTensor engine evaluates all qTensors in parallel on QPUs, the cTensor engine contracts the resulting slices on classical accelerators, and the partial contractions are then combined into the result.

7.1 Index Slicing and Device Placement

During the adaptation phase (Fig. 8 (a)), the slicer and device placer prepare the optimized hEinsum for distributed execution across QPUs and classical accelerators, with the goal being to expose as much parallel quantum work as possible, as QPUs are typically the throughput bottleneck.

Let i be an index with domain $\{0,\dots,|i|-1\}$. Slicing along i simply means creating one hEinsum for each value of i, *i.e.,* a set of sub-expressions $\mathsf{hEinsum}(\text{expr}; T_1,\dots,T_n)\big|_{i=v}$. Each of these subproblems can be evaluated independently, and the original result is recovered by summing their outputs:

$$\mathsf{hEinsum}(\text{expr}; T_1,\dots,T_n) = \sum_{v=0}^{|i|-1} \mathsf{hEinsum}(\text{expr}; T_1,\dots,T_n)\big|_{i=v}.$$

In the example of Fig. 8, we slice an index with $|i| = 2$ at qTensor A, giving us two distinct slices.

To generate sufficient QPU parallelism, the slicer iteratively selects indices adjacent to each qTensor and slices along those that maximize the number of independent circuit instances, continuing until at least as many qTensor instances are produced as there are available QPUs.

This iterative procedure can be written compactly as:

$$\begin{aligned}
&S \leftarrow \{H\};\\
&\textbf{while } \textsc{qInst}(S) < P \textbf{ and } \textsc{adj}(S) \neq \emptyset :\\
&\quad i^* \leftarrow \arg\max_{i \in \textsc{adj}(S)} \textsc{qInst}(\textsc{slice}(S,i));\\
&\quad S \leftarrow \textsc{slice}(S,i^*)
\end{aligned}$$

where P is the target QPU parallelism, $\textsc{adj}(S)$ is the set of indices adjacent to any qTensor in some $H \in S$, $\textsc{qInst}(S) = \sum_{H\in S} \textsc{qInst}(H)$ counts qTensor instances across all slices, and $\textsc{slice}(S,i) = \bigcup_{H\in S} \textsc{slice}(H,i)$ extends per-expression slicing to the slice set. In the example of Fig. 8 with two QPUs, the slicer picks the $|i|$=2 index at qTensor A in a single step, producing two independent slices.

After slicing, the device placer assigns each qTensor instance to a QPU with available capacity, using a load-balanced assignment when the number of instances exceeds the devices. The remaining classical slice contractions are mapped to classical accelerators in a round-robin manner.

7.2 Runtime Code Generation

Following device placement, the runtime code generator compiles the hybrid kernel into device-specific executables: for every qTensor assigned to a QPU, it emits a quantum kernel using the native toolchain, while for classical slices, it compiles the shared operation graph into a single optimized kernel for the target accelerator using a tensor backend [15].

7.3 Tensor Engines

The tensor engines execute the sliced hEinsum across QPUs and classical accelerators.

The **qTensor engine** evaluates all qTensors on available QPUs. For each unique qTensor, it allocates quantum resources and the output buffer for its result cTensor entry, then loads the compiled quantum kernel onto the selected QPU. The compiled kernel is executed for each qTensor instance, returning results one by one into a result-cTensor.

The **cTensor engine** performs classical contractions for each slice. For every slice, it allocates slice-local cTensor buffers on the assigned classical accelerator and loads the compiled contraction kernel from the code generator. The engine waits asynchronously for cTensor inputs from the qTensor engine; once all required inputs arrive, it launches the slice's contraction kernel. Each slice produces a partial result, which the cTensor engine reduces across the sliced indices to yield the final output.

7.4 Fault Tolerance

The runtime handles failures gracefully, since QPUs and classical devices may become unavailable during execution. The sliced hEinsum structure naturally supports fault tolerance, as each slice represents an independent unit of work.

QPU calibrations. Unlike classical accelerators, QPUs require regular calibration to maintain low noise, typically going offline for about an hour daily [1]. The qTPU runtime

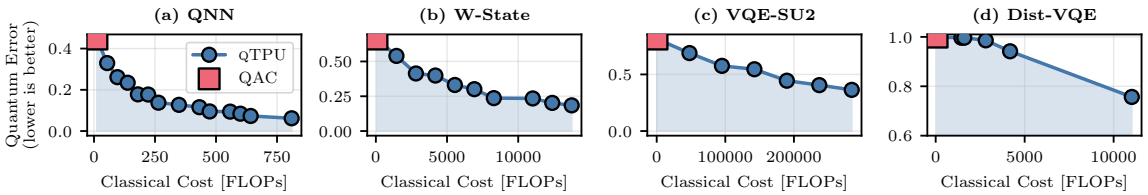

Figure 9: Compiler tradeoff (§ 8.4). *QAC produces a single solution, while QTPU exposes a flexible Pareto frontier.*

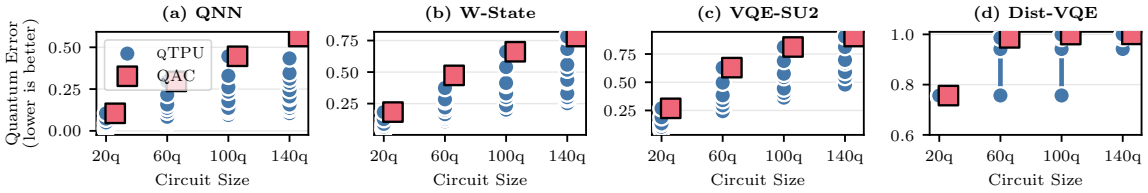

Figure 10: Compiler optimality analysis (§ 8.4). *While QAC yields a single solution with error scaling linearly with circuit size, QTPU maintains consistent error reduction across scale.*

models calibration as scheduled downtime: when a QPU enters calibration, the qTensor engine completes any in-flight circuit (usually seconds) and stops dispatching new qTensor instances to that device. Pending instances are reassigned to remaining QPUs using the same load-balanced policy.

Classical failures. If a classical accelerator fails during cTensor contraction, the cTensor engine re-executes only affected slice contractions. Since each slice depends solely on input cTensors (already in host memory), recovery requires no cross-slice coordination. Uncompleted contractions are reassigned to surviving accelerators.

8 Implementation and Evaluation

8.1 System Implementation

We implement an end-to-end QTPU prototype in Python.

Programming Model. We provide Python constructs for hEinsum and qTensors. To declare a qTensor, users annotate a QISKIT [71] quantum circuit with our custom iswitch operations. A hEinsum operation is then constructed with a einsum expression and corresponding qTensor objects and classical PYTORCH [63] tensors.

Compiler. The compiler uses KAHYPAR 1.3 [79] for graph partitioning at each recursive optimization level and explores the Pareto frontier of classical cost versus quantum error using randomized multi-start optimization. The backend returns a COTENGRA [35] operation graph and generates qTensors as CUDA-Q [18] kernels.

Runtime. The runtime leverages COTENGRA as an interface for contraction optimization and slicing, with PYTORCH for tensor operations. Our code generator JIT-compiles qTensors into optimized QPU-native code using CUDA-Q, and classical operations into GPU kernels using the PYTORCH toolchain.

8.2 Hybrid Application Implementation

To measure QTPU's performance on real-world hybrid applications, we implement three real-world applications in the QTPU programming model, enabling case studies on each (§ 8.6–§ 8.8): (i) for **hybrid ML**, we implement the example from Lst. 2, (ii) for **scalable hybrid computation**, we implement circuit knitting by decomposing a quantum circuit using the state-of-the-art circuit knitting library – QAC [11] and parsing the cut circuit into an equivalent hEinsum, and (iii) for **error mitigation**, we adopt probabilistic error cancellation (PEC), Pauli twirling and Zero-Noise-Extrapolation from the state-of-the-art error-mitigation library MITIQ [49], and convert them into an hEinsum.

	20q	40q	60q	80q	100q	120q	140q
QTPU [s]	0.76	1.05	1.25	1.77	2.01	2.34	2.51
QAC [s]	1.2	10.9	35.0	69.3	91.5	115.0	134.1
Speedup	**1.5**×	**10.3**×	**28.0**×	**39.2**×	**45.5**×	**49.1**×	**53.4**×

Table 1: Compile time scaling for VQE-SU2 circuits. QTPU's compile time is near-constant; QAC scales superlinearly.

8.3 Experimental Methodology

Experimental setup. We use a server with two AMD EPYC 9654 96-Core processors (384 cores with HT), 1.5 TB RAM, and an A40 GPU with 48GB HBM3 memory.

Baselines. We evaluate QTPU against Qiskit-Addon-Cutting (QAC) [11], the current state-of-the-art framework for hybrid quantum-classical execution through circuit decomposition. QAC is inherently hybrid, enabling scalable execution of large quantum circuits by partitioning the circuit into smaller subcircuits, executing them on a QPU, and classically postprocessing to obtain the result of the original circuit. We compare our runtime against cuTensorNet [58], NVIDIA's GPU-accelerated library for circuit simulation, to establish a classical-only baseline. For the error-mitigation case-study, we compare against MITIQ [49], the leading framework for quantum error mitigation. For our hybrid ML case-study, we compare against the BATCH method (Lst. 1), which is commonly used in quantum frameworks [9, 71]. Each baseline is a dedicated, state-of-the-art tool for its respective workload.

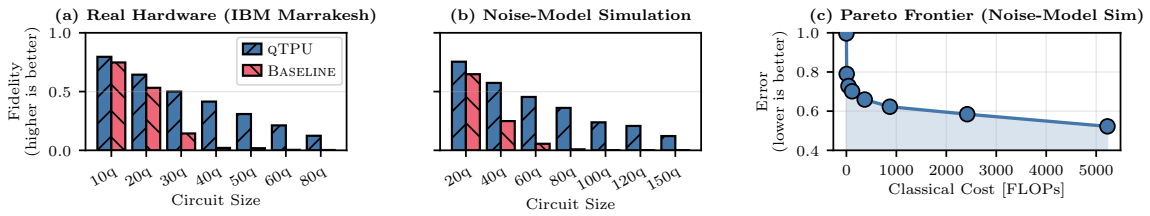

Figure 11: Hardware validation on real QPU (§ 8.4). *(a) Fidelity $\langle P \rangle$ on IBM Marrakesh for $n \in [10, 80]$ (higher is better; noiseless $\langle P \rangle$=+1). (b) Pauli-depolarizing noise-model simulation (ε_{cx}=10^{-2}, ε_{id}=10^{-3}) extending the fidelity sweep to 150 qubits. (c) Pareto frontier traversal at 80 qubits under the same noise model, plotting error (1−$\langle P \rangle$) vs. classical cost.*

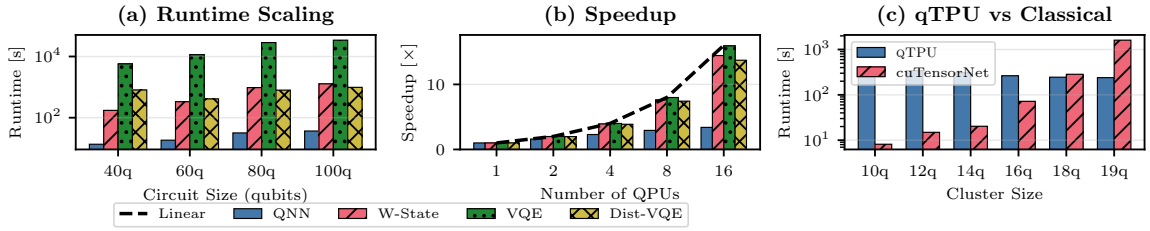

Figure 12: qTPU runtime analysis (§ 8.5). *(a) Total runtime scales with circuit size across benchmarks. (b) Near-linear speedup with multiple QPUs (14.4× at 16 QPUs for W-State) due to embarrassingly parallel qTensor execution. (c) qTPU vs. cuTensorNet on 100q Dist-VQE: qTPU outperforms classical beyond 18-qubit clusters, achieving 6.7× speedup at 19-qubit clusters.*

Benchmarks. We evaluate four quantum circuit families from MQT Bench [73], representative of hybrid quantum-classical applications: **QNN**, a quantum neural network for quantum machine learning [69]; **W-State**, preparing the n-qubit linearly entangled W-state [25]; **VQE-SU2**, a Variational Quantum Eigensolver ansatz with efficient $SU(2)$ rotations for quantum chemistry [66, 70]; and **Dist-VQE**, a distributed VQE variant with clustered connectivity modeling natural circuit partitioning across multiple QPUs.

Metrics. We evaluate qTPU using the following metrics: (1) **Quantum error**: The estimated probability of at least one error occurring during circuit execution (§ 6.2). We assume a uniform error model with 10^{-3} for single-qubit gates and 10^{-2} for two-qubit gates [1]. This uniform model reflects typical gate error rates on current superconducting QPUs and serves as a device-agnostic baseline. (2) **Classical cost**: The number of floating-point operations (FLOPs) required for classical computation (§ 6.2). (3) **Runtime**: Wall-clock execution time in seconds, measured either for classical or quantum or end-to-end hybrid execution. (4) **Code size**: The number of lines of generated CUDA-Q quantum-kernel code. (5) **QPU time**: Estimated quantum hardware execution time, computed by transpiling circuits to IBM Marrakesh using Qiskit's ASAP scheduling with optimization level 3 using 1000 shots [1, 71]. Per-shot execution time is deterministic, fixed by the scheduled gate sequence and device-level reset/readout overhead [71]. We validated this estimator against measured IBM Marrakesh job metadata: it matches monolithic QPU time within ±2% and is slightly conservative for cut variants, making qTPU's reported QPU time an upper bound. (6) **Fidelity**: The retention of a weight-n Clifford observable P under circuit execution, $\langle P \rangle \in [-1, 1]$. A noiseless execution gives $\langle P \rangle = +1$; hardware noise drives it toward 0.

8.4 qTPU Compiler

RQ1 (Compiler trade-off): *Can the compiler trade quantum error for classical computation?* We partition each 100-qubit benchmark into 50-qubit subcircuits using both QAC and qTPU, with qTPU configured to run 50 hyperparameter trials, retaining only Pareto-optimal solutions.

Fig. 9 shows that while QAC produces a single fixed solution, qTPU offers multiple configurations trading classical cost for quantum error. Mid-range solutions yield 1.5–3.4× error reduction, while maximum classical investment achieves 2.2–7.2× improvement across all benchmarks. At equal classical cost, both frameworks provide the same solution-quality.
RQ2 (Compiler scalability): *Does the compiler scale to large qTensors?* We vary the circuit size from 20 to 140 qubits, cutting each circuit into subcircuits of 50% the original size.

Fig. 10 shows qTPU maintains stable error reduction across scales, ranging from 2–26× depending on the benchmark. While QAC error scales linearly with circuit growth, qTPU's Pareto frontiers consistently trade FLOPs for reduced quantum error without diminishing returns.

Table 1 shows the compile time on VQE-SU2: QAC scales superlinearly (1.2s to 134s) due to exhaustive search, while qTPU maintains ~1–3s (up to 53× speedup for 140 qubits). Although graph partitioning, a technique used throughout the compiler, is NP-hard in general, the structure of quantum circuits makes it tractable for KaHyPar 's multi-level hypergraph algorithm [79].

Note that qTPU's cost model (§ 6.2) accepts any user-

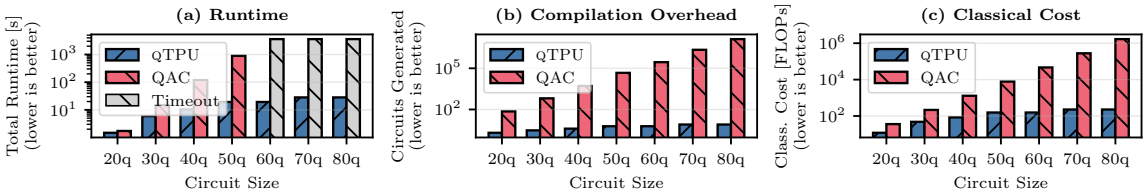

Figure 13: Scalable hybrid computing for QNN on a 10-qubit QPU (§ 8.7). We partition QNN circuits (20–80 qubits) into 10-qubit subcircuits using qTPU and QAC. *(a) qTPU scales to 80 qubits in <30s while QAC times out beyond 50 qubits. (b) qTPU generates 10–42× fewer subcircuits. (c) qTPU's classical postprocessing requires* 10^2–10^3 *FLOPs vs. QAC's* 10^6 *FLOPs.*

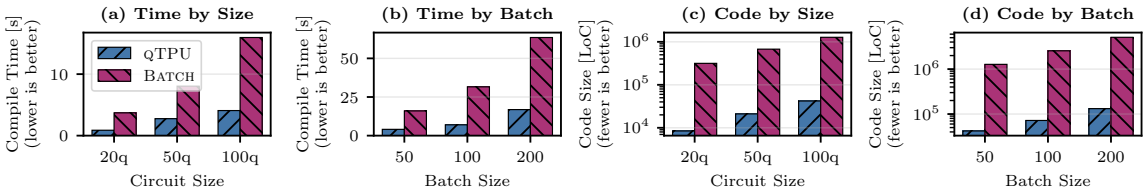

Figure 14: Case study: hybrid machine learning with Batch execution (Lst. 1) vs. qTPU (Lst. 2) (§ 8.6). *(a) Compilation time by circuit size, (b) compilation time by batch size, (c) generated code size by circuit size, (d) generated code size by batch size.*

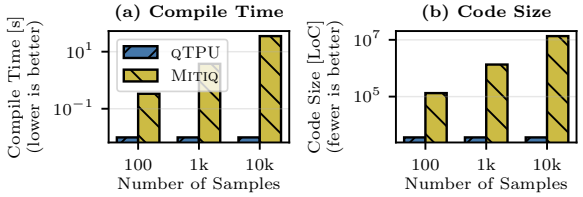

Figure 15: Quantum error mitigation (QEM) vs Mitiq the 100-qubit QNN benchmark (§ 8.8). ***(a)*** *qTPU is 3,500× faster in compilation.* ***(b)*** *qTPU generates 3,700× fewer lines of code.*

supplied error model. The negligible compile time makes recompiling with an up-to-date model of current calibration data practical for obtaining the best possible Pareto front.

RQ3 (Hardware validation): *Does qTPU's error reduction hold on real quantum hardware?* We run QNN circuits from 10 to 80 qubits on IBM Marrakesh with both qTPU and a monolithic Baseline, partitioning each circuit into 10-qubit subcircuits with qTPU.

Fig. 11 (a) shows fidelity on real hardware: Baseline collapses from 0.53 at 20q to 0.003 at 80q, while qTPU retains 0.12 at 80q—a 46× improvement. Fig. 11 (b) extends the sweep to n=150 under a Pauli-depolarizing noise model (ε_{cx}=10^{-2}, ε_{id}=10^{-3}), reproducing the same trend: Baseline reaches the noise floor by 100q, while qTPU maintains fidelity of 0.12.

Pareto frontier traversal. To test whether the compiler's cost model translates into measurable error reduction along the full frontier, we enumerate the Pareto solutions of an 80-qubit QNN circuit and execute one point per partition size. Fig. 11 (c) plots error (1−fidelity) against classical cost: error drops monotonically from 0.997 at the zero-cost solution to 0.522 at the most aggressive optimization—a 0.48-unit reduction, confirming that higher classical investment purchases lower quantum error.

8.5 qTPU Runtime

RQ4 (Runtime analysis): *What is qTPU's runtime performance and where is it spent?* We measure total runtime, including compilation, classical postprocessing, and QPU execution, on a 15-qubit QPU, requiring the compiler to optimize qTensors to a circuit size of 15 qubits or fewer.

Fig. 12(a) shows runtime scaling with circuit size across benchmarks. For 100-qubit circuits, quantum execution dominates at 75-100% of total runtime, while classical contraction accounts for <0.01% and compilation takes 2-3s. Network and I/O overhead is negligible compared to quantum runtime; further, qTPU's compact hTN representation transfers far less circuit data than approaches that enumerate variants.

RQ5 (Scalability): *Can the runtime leverage multiple QPUs?* Fig. 12(b) shows near-linear speedup as QPU count increases from 1 to 16, achieving 14.4× speedup with 16 QPUs (90% efficiency). The slicer produces embarrassingly parallel qTensor instances, thereby minimizing distribution overhead.

RQ6 (Comparison to classical simulation): *How does qTPU perform against pure classical simulation?* We evaluate 100-qubit Dist-VQE circuits with clustered connectivity. qTPU executes on 4 QPUs with 1,000 shots per subcircuit; cuTensorNet performs full simulation. qTPU's reported runtime includes compilation, estimated QPU execution, and classical contraction. cuTensorNet's runtime is total wall-clock simulation time.

Fig. 12 (c) shows that as cluster size increases, qTPU runtime decreases (fewer qTensors and cTensors) while cuTensorNet runtime grows exponentially (larger clusters yield harder contractions). qTPU outperforms classical beyond 18-qubit clusters, achieving 6.7× speedup at 19-qubits.

8.6 Case-Study: Hybrid Machine Learning

We compare manual batching (Lst. 1) against qTPU's unified model (Lst. 2) for evaluating hybrid quantum-classical ML. We use QNN quantum kernels of 20–100 qubits with

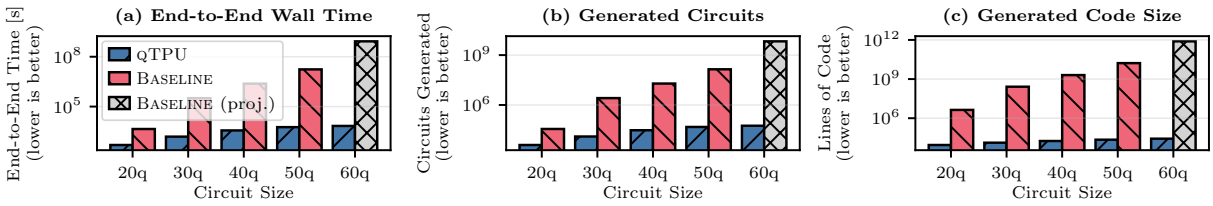

Figure 16: End-to-end application: QNN with circuit cutting, ZNE, and hybrid ML combined in one pipeline (§ 8.9). *(a) At 50q, end-to-end time drops from* $\sim 1.7{\cdot}10^7$*s to* $\sim 5.8{\cdot}10^3$*s* ($\sim 3{\cdot}10^3\times$). *(b)* QTPU *generates* $\sim 3{\cdot}10^3\times$ *fewer subcircuits at 50q (48k vs. 140M). (c)* QTPU *emits* $\sim 7{\cdot}10^5\times$ *less kernel code at 50q (23k vs. 16.7B lines).*

$X \in \mathbb{R}^{b\times h}$, $V \in \mathbb{R}^{h\times f}$, batch sizes $b \in \{50, 100, 200\}$, hidden dimension $h = 20$, and feature dimension $f = 8$. Manual batching (Lst. 1) is the standard practice in QML frameworks [9, 77].

RQ7 (Compilation Scalability): *How does compilation time scale with problem size?* Fig. 14 (a,b) shows compilation scaling with circuit and batch size. QTPU achieves 3.7× average speedup (up to 6×) over batch execution. Critically, QTPU scales sublinearly with batch size, whereas batch execution scales linearly by compiling each circuit independently. At 100 qubits, batch execution grows from 3.1s to 63.5s as batch size increases from 10 to 200, while QTPU grows only from 4.8s to 16.9s, a speedup of up to 4.5×.

RQ8 (Code Generation Overhead): *What is the impact on generated code size?* Fig. 14 (c,d) shows QTPU's code generation efficiency. By compiling the quantum kernel once with parametric control flow rather than instantiating separate circuits, QTPU achieves an average reduction of 33× (up to 48×). At 100 qubits with batch size 200, QTPU generates 132k lines vs. batch execution's 5.1M lines—a 38.7× reduction. This directly translates into faster compilation and a smaller memory footprint, with benefits that scale with batch size.

8.7 Case Study: Scalable Hybrid Computing

In this case study, we implement scalable hybrid computing using circuit knitting on resource-constrained hardware. We run QNN benchmarks on 20-80 qubits, targeting a 10-qubit QPU and enforcing aggressive circuit partitioning.

RQ9 (End-to-end runtime): *What impact does* QTPU *have on the end-to-end runtime with increasing problem size?* Fig. 13 (a) shows total runtime: QAC scales exponentially and times out beyond 40 qubits (20-minute limit), while qTPU completes 80-qubit circuits in under 30 seconds. This dramatic difference stems from QTPU's hTN representation, avoiding redundancies by compactly encoding the entire computation.

RQ10 (Compilation overhead): *How many circuits does* QTPU *generate with increasing problem size?* Fig. 13 (b) reveals the root cause of QAC 's exponential scaling: circuit generation grows combinatorially (12 to 6,480 circuits from 20q to 50q), whereas QTPU produces 10–42× fewer subcircuit instances. The hTN abstraction eliminates this overhead by representing subcircuits declaratively as qTensors rather than enumerating explicit circuit variants.

RQ11 (Postprocessing overhead): *What is the classical cost in FLOPs that* QTPU *incurs with increasing problem size?* Fig. 13 (c) shows the classical postprocessing cost: QTPU maintains modest overhead ($< 10^3$ FLOPs) across all sizes, while QAC grows to 10^6 FLOPs exponentially. The hTN formulation performs only the minimum necessary tensor contractions by structure-aware optimization, whereas QAC's explicit circuit enumeration incurs exponential classical reconstruction overhead proportional to the circuit size.

8.8 Case Study: Quantum Error Mitigation (QEM)

RQ12 (QEM scalability): *What impact does* QTPU *have on the compile time and code size requirements of a hybrid QEM workflow?* We implement three major error mitigation strategies (§ 8.2) using both QTPU and Mitiq on quantum circuits with 200 single-qubit gates. For Mitiq, we vary the sample count from 100 to 10,000 circuits; QTPU represents the full task symbolically as a hEinsum, independent of sample count.

Fig. 15 compares compile-time overhead and code size. While Mitiq explicitly generates each circuit variant, QTPU represents the entire ensemble symbolically, encoding up to $4^{200} \approx 10^{120}$ configurations (for combined PEC+Twirling applied to all gates) as a single qTensor. QTPU maintains constant ~10ms overhead regardless of sample count, while Mitiq scales linearly from ~335ms at 100 samples to 35s at 10,000 samples (~3,550×). Similarly, QTPU generates only ~3.7k lines of code, whereas Mitiq generates 13.5M (~3,700×).

8.9 Case Study: End-to-End Application

In this case study, we combine all three use cases—circuit cutting, ZNE error mitigation, and batched hybrid ML—into one end-to-end workload. We run QNN circuits from 20–60 qubits, partitioning into 10-qubit subcircuits, applying Richardson ZNE at three noise scales, and evaluating over a batch of 20 inputs. QTPU expresses the full pipeline as a single hEinsum; the BASELINE composes QAC, MITIQ, and a manual BATCH loop in a pipeline.

RQ13 (End-to-end runtime): *How does the unified hEinsum compare against pipeline composition?* The BASELINE circuit generation-time exceeded our timeout at 60q. Fig. 16 (a) shows end-to-end wall time. At 50 qubits, time drops from $\sim 1.7{\cdot}10^7$s to $\sim 5.8{\cdot}10^3$s ($\sim 3{\cdot}10^3\times$). QPU execution dominates (>99%). The core speedup from QTPU comes through the fact that it needs to enumerate fewer quantum circuit instantiations due to its compact hTN form.

RQ14 (Generation overhead): *What is the cost of pipeline composition in circuits and code?* Fig. 16 (b,c) shows the generation cost: at 50q the baseline materializes 140M subcircuits vs. 48k for QTPU ($\sim 3{\cdot}10^3\times$ fewer), and emits 16.7B lines of kernel code vs. 23k ($\sim 7{\cdot}10^5\times$ less). Composition multiplies each library's explicit enumeration, while QTPU's qTensors collapse it into a single symbolic expression.

8.10 Developer Productivity

The QTPU programming model reduces the effort of writing hybrid workloads. The hybrid-ML case study (§ 8.6) makes the contrast concrete: the BATCH formulation in Lst. 1 requires a two-stage `forward` pass that enumerates circuits, dispatches them, and threads the results into a classical layer, while the QTPU formulation in Lst. 2 collapses this into a single qTensor with two iswitch indices and one hEinsum. The same primitives carry over to the other studies: scalable hybrid execution (§ 8.7) treats QAC 's cutting recipe as an hEinsum, and error mitigation (§ 8.8) expresses QEM-routines as hTNs rather than separate library calls. Each baseline is scoped to a single workload; composing them requires chaining tools, whereas QTPU expresses any workload, or arbitrary compositions, as one hTN (§ 8.9).

9 Related Work

Hybrid quantum-classical applications. A wide range of quantum applications inherently rely on hybrid programming and execution models. Variational algorithms [27, 66], quantum machine learning [10, 51], quantum error mitigation [13, 20–22, 26, 65, 85, 86, 89, 98], and hybrid runtime systems [33,34,84,88,90] all interleave quantum circuit execution with classical optimization and/or postprocessing.

However, current approaches remain constrained by fragmented programming models, a lack of holistic optimizations, and a lack of resource-adaptable execution. In contrast, QTPU provides a unifying abstraction based on hTNs that encode entire hybrid computations. This enables global optimization, hardware-aware compilation, and flexible execution across QPUs and classical accelerators.

Tensor networks (TNs) in quantum simulation. TN-based quantum circuit simulation represents quantum gates and states as tensors, where simulation is performed through systematic tensor contraction operations [7, 56, 62, 76, 96, 97]. Prior work has used hybrid tensor-network ansätze as problem-specific variational constructions for particular Hamiltonians with small QPUs encoding part of a target wavefunction [80, 95]. QTPU is the first system to formalize hybrid tensor networks as a programming model that can concisely capture arbitrary hybrid workloads. Beyond simulation, TN abstractions also underpin applications such as quantum error analysis [87], which QTPU could naturally accelerate by exploiting its hybrid quantum-classical execution model.

Tensor optimization in classical systems. Deep learning compilers optimize tensor operators through scheduling transformations, operator fusion, and hardware mapping to maximize throughput on classical accelerators [15, 23, 43, 55, 82, 93, 100–102]. Similarly, general tensor compilers focus on efficient contraction and algebraic manipulation of dense and sparse tensors, addressing memory layouts, parallelization, and sparsity exploitation for scientific computing and machine learning workloads [6, 24, 32, 42, 46–48, 94]. QTPU addresses fundamentally different challenges: rather than optimizing dataflow graphs of deterministic, fully materialized tensor operations, QTPU optimizes hybrid tensor *network* contractions that integrate quantum and classical processing, requiring the compiler to determine an optimal trade-off between the two compute paradigms.

10 Conclusion

We introduce the hybrid tensor network (hTN) abstraction, a unified framework that seamlessly integrates quantum and classical computation. hTNs address current hybrid computing limitations—programming fragmentation, static partitioning, and poor scalability—through holistic representation and optimization. Our system, QTPU, realizes hTNs through a declarative programming model, a compiler that balances quantum error with classical cost, and an adaptable runtime for heterogeneous hybrid quantum-classical resources.

Evaluation across hybrid ML, circuit knitting, and error mitigation demonstrates that QTPU achieves up to 53× faster compilation, 7.2× lower quantum error rate, 3,700× code reduction, and 10,000× lower classical overhead than state-of-the-art baselines. Through its concise, flexible, and scalable abstraction for quantum-classical acceleration, QTPU enables automated and efficient heterogeneous resource utilization for next-generation quantum-enhanced applications.

A Artifact Appendix

Abstract

The QTPU artifact contains the source code of the QTPU compiler and runtime, the benchmarking scripts used to produce every figure and table in the evaluation (Sec. 8), and the pre-collected benchmark logs from which all plots are regenerated. The artifact ships as a Python package (Python 3.11–3.13) with a uv-managed lock file and an optional GPU-enabled Docker image. All figures and tables can be regenerated from the included logs in seconds; all benchmarks except those running on real IBM Quantum hardware can be re-executed end-to-end on a single workstation.

Scope

The artifact validates the central performance and scalability claims of the paper:

- Pareto-frontier exploration of the compiler vs. the fixed QAC baseline (Fig. 9, Fig. 10, Table 1).

- Hardware validation on IBM Marrakesh and Pauli-noise simulation up to 150 qubits (Fig. 11).
- Runtime scaling and multi-QPU speedup, including comparison against `cuTensorNet` on a 100-qubit Dist-VQE workload (Fig. 12).
- Scalable hybrid computing on a 10-qubit QPU (Fig. 13).
- Hybrid ML: compilation time and code-size reductions vs. batched execution (Fig. 14).
- Quantum error mitigation vs. Mitiq (Fig. 15).
- End-to-end composability (Fig. 16).

The artifact can additionally be used as a general-purpose library for expressing and executing hybrid tensor networks on user-defined circuits.

Contents

The artifact is organized as follows:

- `src/qtpu/` — the core library (compiler, runtime, transforms).
- `evaluation/` — a `run.py` and `plot.py` per evaluation section (`compiler/`, `runtime/`, `hardware/`, `use_cases/{scale,hybrid_ml,error_mitigation,end_to_end}/`).
- `logs/` — pre-collected benchmark results in JSONL. Every line is a self-contained JSON record with parameters and measurements.
- `examples/` — standalone usage examples.
- `REPRODUCE.md` — step-by-step instructions covering every figure and benchmark.
- `Dockerfile`, `pyproject.toml`, `uv.lock` — reproducible environment specifications.

Hosting

The artifact is hosted on GitHub at https://github.com/nathanieltornow/qtpu (branch `main`). The exact version evaluated by the AEC is tagged `osdi26-ae`. An archival snapshot with a citable DOI is mirrored on Zenodo.

Requirements

Software. Python 3.11–3.13 and uv (recommended) or `pip`. The full dependency set is pinned in `uv.lock` and installable via `uv sync`. A GPU-enabled Docker image is provided for `cuTensorNet` comparisons (Fig. 12c).

Hardware. All non-hardware experiments run on a commodity x86_64 Linux or macOS workstation; 16 GB of RAM is sufficient for the log-based plot regeneration, and 64 GB is recommended to re-run the larger simulations from scratch. An NVIDIA GPU with a recent CUDA toolchain is required only to reproduce the `cuTensorNet` comparison in Fig. 12c.

IBM Quantum access. Fig. 11a (IBM Marrakesh) requires an IBM Quantum account with access to the `ibm_marrakesh` backend; the credentials are supplied via the `IBM_TOKEN` and `IBM_CRN` environment variables. The pre-collected hardware logs are included so that Fig. 11a can be regenerated without IBM credentials.

Reproducing the Results

After `uv sync`, every figure can be regenerated from the included logs in seconds, e.g.:

```
uv run python -m evaluation.compiler.plot
uv run python -m evaluation.hardware.plot_qnn
uv run python -m evaluation.runtime.plot
uv run python -m evaluation.use_cases.scale.plot
uv run python -m evaluation.use_cases.hybrid_ml.plot
uv run python -m evaluation.use_cases.error_mitigation.plot
uv run python -m evaluation.use_cases.end_to_end.plot
```

Each section additionally exposes a `run.py` that regenerates the underlying logs from scratch; expected wall-clock times range from ~5 min (scale, error mitigation) to ~30 min (runtime, end-to-end). The Pauli-noise sweep to 150 qubits takes ~20 min and the 80-qubit Pareto sweep ~60 min on a single workstation. Full instructions, including the IBM-hardware path, are documented in `REPRODUCE.md`.

Acumen: A Platform for Encrypted and Accountable Collaborative Editing

Abstract

Modern-day collaborative editing tools must reconcile a prominent tension between user privacy and collaboration: encrypting user data prevents an application server from processing user edits. We present Acumen, a cryptographic system for real-time collaborative applications based on *conflict-free replicated data types* (CRDTs). Acumen is the first system to provide *strong snapshot consistency*, enabling untrusted users to create verifiable document snapshots used to invite new collaborators. Acumen also provides confidentiality, integrity, fork-causal consistency, and ensures that invited users do not learn the previous edit history of the document.

We achieve these properties through the use of cryptographic accumulators and a novel secure garbage collection mechanism. Our evaluation shows that Acumen can support 25 users each simultaneously typing 60 WPM with negligible degradation in latency and availability.

1 Introduction

There has been a recent shift towards real-time, cloud-based collaborative applications such as Notion, Google Docs, and Microsoft Office. These collaborative editors generally follow one of two separate approaches: operational transforms (OTs) [11, 13] or conflict-free replicated data types (CRDTs) [22, 30, 32, 36]. While convenient for users, this shift to the cloud naturally raises privacy concerns.

Although there has been considerable work on end-to-end encrypted file storage systems (e.g. SUNDR [26] and Depot [28]), these solutions are unsuitable to collaborative editing applications where users simultaneously edit the same files and must resolve concurrent user edits. Indeed, it is not immediately obvious how an application provider who cannot observe the contents of its users' behavior can consolidate, manage, and edit their data.

A recent line of *secure collaborative editors* [13, 21, 24, 25] aims to resolve this tension. In this paper, we focus on *decentralized* secure collaborative editors in which users maintain local document state and directly broadcast encrypted edits to each other. This model provides confidentiality against eavesdropping servers, but introduces another attack vector: *user adversaries* may attempt to disrupt the consistency of other users, such that users disagree on the correct edit history. This can be especially problematic if malicious users collude with a malicious network adversary, who can arbitrarily block or reorder network messages to and from users.

Our goal is to construct a secure collaborative editor that ensures confidentiality against unauthorized eavesdroppers and integrity against malicious users. We identify four key requirements that secure decentralized collaborative editors should provide:

1. Confidentiality. Passive eavesdroppers should learn nothing about the document beyond what can be inferred from network traffic. This includes document access patterns (e.g. that User A executed an insert at position k followed by a deletion).

2. Integrity. Honest users should maintain a consistent local document history comprised of authentic edits (e.g. no forking writes). In our decentralized setting, this corresponds to the notion of *fork-causal consistency* [28].

3. Performance. Performance should remain comparable to plaintext editors: users should process operations in real-time, encrypted edits should remain relatively small in size, and user storage should scale linearly with the current document size (rather than the overall edit history length).

4. Secure Dynamic Membership. Users should be able to add new collaborators into existing documents. The new user should not receive data beyond what currently exists in the document (*edit-history privacy*) and should maintain the same integrity guarantees as existing users (*snapshot consistency*).

Secure dynamic membership is particularly difficult to provide in decentralized editors due to the tension between snapshot consistency and edit-history privacy: *how can a new user verify their given snapshot is consistent without access to the corresponding history?*

Existing secure decentralized editors fail to provide all of these guarantees. For instance, the state-of-the-art system Snapdoc [24] leaks user access patterns (violating confidentiality), provides a weak notion of snapshot consistency (violating secure dynamic membership), and has performance scaling with the overall edit history length.

Acumen is the first secure collaborative editor to provide confidentiality, integrity, and secure dynamic membership against malicious users and network adversaries. We also provide real-time performance: Acumen is able to sustain 25 users each typing at 60 WPM, orders of magnitude greater than the state-of-the-art. Acumen's performance and guarantees hinge on two key ideas:

1. Cryptographic accumulators for snapshot consistency & hiding access patterns. At the core of our verifiable snapshot functionality are *cryptographic accumulators* [4, 6, 7]. To verify snapshot consistency, newly-invited users asynchronously compare their untrusted snapshot state against the signed, constant-space accumulators representing existing user states. Our key insight is to expand the use of accumulators to capture both the *CRDT's internal structure* and overall set of document edits. This approach eliminates the variable-length edit data in the state-of-the-art, preventing edit pattern leakage and bandwidth blow-up.

2. Secure garbage collection. We aim for our system to scale with the current document size rather than edit history length. To this end, we utilize garbage collection techniques to prune outdated components of the document data structure without compromising any of Acumen's guarantees. Garbage collection, however, is made more complicated by our snapshot consistency guarantee: each snapshot must have data sufficient to reconstruct every other user's state, such that data can only be deleted once every user has deleted it. We introduce a novel *second-order* asynchronous garbage collection protocol that eliminates this circular dependency.

In summary, this paper makes three contributions:

- We introduce a novel protocol to provide strong snapshot consistency with real-time performance.
- We identify and resolve access-pattern leakage in prior work, simultaneously reducing bandwidth costs by orders of magnitude.
- We introduce a secure garbage collection mechanism, eliminating runaway storage costs and providing competitive performance against standard CRDTs.

2 Background

We first provide the necessary background on collaborative text editors and CRDTs.

2.1 Collaborative Editing Data Structures

Conflict-free Replicated Data Types (CRDTs) [36] are a recent approach to asynchronous, distributed data structures. Acumen employs **operation-based CRDTs** in which users broadcast document edits that other users process locally. Under the guarantee that operations are reliably delivered in causal order, op-based CRDTs satisfy *strong eventual consistency* (users processing concurrent operations in different orders still arrive at the same state).

Treedoc Treedoc [33] is a popular *list CRDT*, often used to implement shared documents represented as character arrays. Treedoc models characters as individual nodes within a tree structure, with the document string derived as the tree's in-order traversal. Each node has an associated *disambiguator*, composed of the User ID and a user-specific counter (precisely the user's version vector counter). The disambiguator forms a unique tuple, which is used for node addressing and as a sorting key for deterministic ordering between sibling nodes. Finally, each Treedoc node contains a `data` field (comprised of a single character) and associated metadata.

Tombstone Nodes In Treedoc, deletion operations mark a corresponding insertion as a *tombstone*. This removes the corresponding node's `data` field, but does not remove the node itself. Tombstone nodes remain within the structure of the overall Treedoc but do not contribute to the final document string. These nodes are generally required to maintain the structure of the tree and are retained until safely garbage collected by our scheme (§5.3). Preserving security with garbage collection is one of the key challenges that Acumen must address.

We choose Treedoc for its useful causal guarantees, potential for fixed-length identifiers, concrete efficiency, and general simplicity. Our protocol could likely be generalized to use any op-based CRDT with tombstoning.

2.2 Fork-Causal Consistency (FCC)

While op-based CRDTs ensure that client states eventually converge given the same operations, they do not provide protection against malicious parties. In Acumen, we enhance CRDTs with fork-causal consistency (FCC) [28]. At a high level, FCC guarantees that honest users agree on the document state at all points in their shared (partially-ordered) edit history.

More precisely, each Acumen document instance implicitly maintains an **execution** E comprised of directed edges between operations and their causal dependencies. Each user u has an associated *local execution* $E_u \subseteq E$ comprised of operations created or processed by u. For our purposes, an execution E (informally) satisfies FCC if three conditions hold:

1. Operations by honest users are totally ordered in E.
2. Honest user executions only see totally-ordered operations from individual users (i.e. do not process forking operations from the same user).
3. All pairs of honest users a,b agree on the document state at each point in their shared history $E_a \cap E_b$.

We formally define FCC in Appendix B. Another key implication of FCC is that users are prohibited from processing operations belonging to conflicting *forks* in the causal graph. This occurs precisely when an adversarial user equivocates two operations o,o' to two distinct subsets of users, effectively branching the edit history. Users who process o will reject operations from those who processed o', and vice versa, forming a permanent fork in the execution graph.

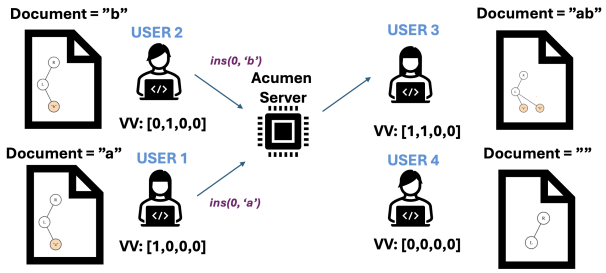

Figure 1: An Acumen setup with four users editing a shared document. User 1 inserts an "a" concurrently with User 2 inserting a "b". User 3 hears about both before User 4.

2.3 Merkle-Tree Accumulator

Cryptographic accumulators [4, 6, 7] enable the efficient representation of unordered sets in constant space. We adopt the *Merkle-tree accumulator* [7] which uses a cryptographic hash function to provide three key properties: constant-space representation, set collision resistance, and update efficiency.

- **Constant-space representation**: The size of acc is independent of the set cardinality $|S|$.
- **Set-collision resistance**: $acc_A = acc_B \iff A = B$ with overwhelming probability.
- **Update efficiency**: There exists a function `update` that can add or remove k elements from acc in time independent of the current set cardinality $|S|$.

Note that the accumulator can store local data to support efficient updates, as long as the final representation is constant size.

We briefly describe the Merkle-tree accumulator construction here. The accumulator state consists of a sparse binary Merkle tree of fixed height h, typically chosen to be the output length of the underlying cryptographic hash. Nodes are stored dynamically in a hash map, with non-existent nodes given a default value. Set elements are accumulated by inserting them into the leaf node determined via cryptographic hash. The root hash of the Merkle tree serves as our constant-space representation.

Following the standard Merkle tree construction, recomputing the root hash after modifying a leaf node takes $O(h)$ time. We can batch k edits in $O(h+k)$ time by using one recomputation pass after editing all k leaves.

3 System Overview

An Acumen deployment consists of n clients and a relay server, which is responsible for relaying all communication between clients as seen in Figure 1. Clients send their updates to the relay, which broadcasts them to the document's collaborators. We note that Acumen can function over peer-to-peer networks—a central server is useful for message availability but has no impact on our protocol guarantees.

3.1 Threat Model

Acumen assumes a threat model in which the relay server is actively malicious (functioning as the “network adversary”). Up to $n-1$ clients are compromised and deviate arbitrarily from the protocol. For example, malicious clients may engage in standard editing activities, such as inserting or deleting characters, but could also attempt more sophisticated attacks, such as sending inconsistent edits for the same document position to different clients.

We assume the presence of a trusted public-key infrastructure and a secure group messaging protocol [8, 9, 37]. Our protocol can be viewed as an additional layer over a secure group messaging platform, focused on enforcing document-level consistency.

Non-goals. Acumen does not offer protection against denial of service (DoS) attacks. That is, the server or ISP may prevent users from receiving or sending updates. Acumen does not defend against timing attacks that leverage knowledge of when a user makes an edit.

3.2 Security Guarantees

We now describe Acumen's security guarantees, which we bucket into three overarching categories: Confidentiality, Integrity, and Secure Dynamic Membership. Formal proofs can be found in our supplemental material. At a high level, *confidentiality* safeguards document contents, access patterns, and edit history from unauthorized access. *Integrity* guarantees a coherent document state across clients, preventing conflicts and maintaining a valid execution history even under adversarial conditions. *Secure Dynamic Membership* ensures that new users can be added to existing documents while maintaining the aforementioned integrity guarantees (snapshot consistency) and without revealing more than the current document state (edit-history privacy).

Confidentiality. Operations do not reveal information about document contents or access patterns to unauthorized parties.

Integrity. Acumen provides *fork-causal consistency* (FCC) [28]. Informally, FCC ensures that honest clients follow a causally consistent subgraph of a global execution graph. Forks can arise when malicious clients issue equivocating updates to different honest users. FCC ensures that honest users with divergent histories detect inconsistencies upon communicating. We give an informal definition of FCC in §2.2, and a formal definition in §B.

Secure Dynamic Membership. Acumen guarantees *strong snapshot consistency* (hereafter just snapshot consistency). Snapshot consistency ensures that new users can verify their document state is the product of a fork-causal consistent execution without requiring any communication with other honest users (formally stated in Definition 1). This definition is notably stronger than the one considered by prior work [24] (hence *strong* snapshot consistency). Informally, prior work allows adversaries to create snapshots that encode any *subset*

	§	Ours	Snapdoc	CRDT
Consistency (FCC)	2.2	✓	✓	X
Edit-Hist. Privacy	3.2	✓	✓	X
Snapshot Consistency	3.2	Strong	Weak	X
Access Patt. Hiding	5.1	✓	X	X
Local Storage	5.3	$O(D)$	$O(E+D)$	$O(D)$
Edit Size (bal.)	5.1	$O(1)$	$O(\log E)$	$O(1)$
Edit Size (WC)	5.1	$O(1)$	$O(E)$	$O(1)$
Snapshot Size (bal.)	5.3	$O(D)$	$O(D+\log E)$	$O(D)$
Snapshot Size (WC)	5.3	$O(D)$	$O(E+D)$	$O(D)$

Table 1: System Feature Comparison. E = edit history length, D = document size, bal./WC = balanced / worst case edit pattern. We consider the number of users to be $O(1)$.

of the correct document state, rather than precise equality as in strong snapshot consistency. We provide a formal comparison in §D.

Acumen also provides *edit-history privacy*: newly invited clients cannot access characters deleted prior to the snapshot creation, unless they collude with another client who had document access before their invitation. For instance, consider adding a collaborator to an existing research paper document — one might prefer that the collaborator not see previous draft versions. Edit-history privacy does **not** hide the access patterns of the document before snapshot creation, as this is inevitably leaked by the structure of the Treedoc object (§2.1) used to represent the shared document. Leaking the Treedoc structure reveals information about the causal order of prior operations, but not their contents.

Edit-history privacy and snapshot consistency are challenging to provide simultaneously. The core challenge in the design of Acumen is verifying a given document snapshot is the product of a fork-causal consistent history without access to the history itself.

4 Strawman Protocol

We now present a starting point for the Acumen protocol, providing only fork-causal consistency and snapshot consistency. In §5, we introduce several novel techniques to enhance the privacy and efficiency of this protocol such that access patterns are hidden, new collaborators cannot access the past edit-history, and user states can be securely garbage-collected.

In our basic rendition of Acumen, after a user creates a document, it can add *collaborators*. Changes to a document or its membership are processed as *operations*. More precisely, we define three types of operations: `Insertion`, `Deletion`, `AddUser`. The former two behave as outlined in §2.1, and we detail the latter in §4.3. Each operation is encrypted and broadcast using the abstracted secure group messaging scheme (§3.1). Users maintain a set called `operations` containing the set of all operations sent or received by a user.

We leverage version vectors [10, 14, 29] to track causal history. Each document collaborator maintains a local version vector as a unique document timestamp. A version vector VV is a mapping of IDs to integers, where $VV[u]$ represents the total number of operations processed from ID u. An operation's version vector is a copy of its sender's, with the sender's index incremented by one to account for the operation's creation.

4.1 History Hash Chains

As outlined in §3.2, we aim to achieve *fork-causal consistency* (FCC). Following prior work [13, 21, 28] we enforce FCC using hash chains over edit histories, referred to here as *history hashes*. Unlike SPORC [13] which utilizes a central server to provide a total order over operations, our environment implies a partially ordered execution graph (e.g. a DAG rather than a single chain).

Acumen defines one hash chain per user, representing the overall DAG as a collection of individual user hash chains. For simplicity, we define an Acumen operation's *causal dependencies* as the most recent operation from each document user, as seen by the operation creator.

Let $HH_{u,n}$ denote the history hash for user u after n operations, $o_{u,n}$ denote user u's n-th operation, and $H(o)$ be the cryptographic hash of an operation (elaborated on in §4.1.1). We define $HH_{u,n} = H(H(o_{u,n}), HH_{u,n-1})$ with $HH_{u,0} = 0$. We refer to HH_u as user u's local history hashes.

4.1.1 Operation Hash Construction

Hashing an operation as a raw bytestring will pose issues for edit-history privacy in our full protocol, due to the resulting hash leaking information about the encoded character data (we elaborate upon this in §5.2). To avoid this, we define the Operation struct to include a random nonce (Table 3). Formally, let `rand` be a λ-bit random value generated by the operation sender (λ is our security parameter), `op.metadata` refer to non-data fields concatenated into one bytestring, and $\mathsf{PRF}: \{0,1\}^\lambda \times \{0,1\}^* \to \{0,1\}^*$ be a secure pseudorandom function [18]. Define $H(\texttt{op})$ as follows:

$$H(\texttt{op}) = H(\texttt{op.metadata}, \mathsf{PRF}(\texttt{op.rand}, \texttt{op.data}))$$

Denote the value of $\mathsf{PRF}(\texttt{op.rand},\texttt{op.data})$ as the *intermediate data hash*. Each operation/node now includes a new `hdata` field consisting of this intermediate hash. This construction is later motivated in our snapshot consistency protocol (§5.2)—looking ahead, we will want to reconstruct $H(\texttt{op})$ using only `op.metadata` and $\mathsf{PRF}(\texttt{op.rand},\texttt{op.data})$ such that `op.data` remains hidden given only these values.

Tombstones Recall that processing a deletion operation marks the targeted operation/node as a *tombstone* (§2.1). More precisely, marking an operation/node as a tombstone sets `data, rand = null` in the associated object. For Treedoc nodes, we also set `tombstone = True`. This has the effect of permanently hiding the original character data of the

Operation Verification

Input: Operation $o = (VV_{update}, HH_{update}, \ldots)$ from v.

Let u be the receiver with version vector VV_u and history hash map HH (recall this is a map over (id, ctr) unlike the map over id like HH_{update}).

1. Verify that we have processed all the causal dependencies of o.

$$\forall j \in VV_{update}, \begin{cases} VV_u[j] \geq VV_{update}[j] & j \neq v \\ VV_u[j] = VV_{update}[j] - 1 & j = v \end{cases}$$

2. Let $k = VV_{update}[v]$ be the operation sender's latest counter. Compute v's next history hash value:

$$HH_{v,k} = H(H(o), HH_{v,k-1})$$

3. Verify that HH_{update} is equal to our local history hashes at each point:

$$\forall j \in HH_{update}, HH_{j,VV_{update}[j]} = HH_{update}[j]$$

Figure 2: Operation Verification

operation/node, which will become relevant for edit-history privacy in our full protocol (§5.2).

4.2 Verifying Operations

Our operation verification subroutine is straightforward and will be used in both the starting-point protocol and full protocol. At a high level, a user accepts an incoming operation o only if the following conditions hold:

- The user has processed o's causal dependencies.
- o's history hash chains are consistent with the user's.

Satisfying these conditions implies the receiver and operation sender agree on the execution graph up to the operation's version vector, i.e. are pairwise fork-causally consistent. A full description of the protocol is given in Figure 2. Once verified, an operation is applied according to its type and associated Treedoc semantics.

4.3 Adding a Collaborator

To add another user as a document collaborator in our basic scheme, an existing user ("snapshot sender") simply sends a copy of the (signed) operation log to the new user and broadcasts an `AddUser` operation specifying the new user ID.

Since the snapshot sender's set of operations encodes a full causal execution graph, the new user can simply replay the entire causal history and apply the operation verification subroutine (Figure 2) at each step to verify fork-causal consistency. In §5, we will update this scheme to only send data proportional to the current document size rather than the edit history size.

Variable	Definition	§
u	User ID	3.1
O	Primary operation set	4
$O^{(2)}$	Secondary operation set	5.3
T	Primary Treedoc obj.	2.1
$T^{(2)}$	Secondary Treedoc obj.	5.3
HH	Current History Hashes	4.1
VV_u	Current Version Vector	4.2
VV_{min}	Minimum Version Vector	5.3.1

Table 2: An Acumen user state with relevant fields. Fields in blue are introduced by our garbage collection changes in §5.3.

Variable	OpType	Definition	§
`u`	*	Sender User ID	3
`VV`	*	Version Vector	4
$\texttt{VV}_{\texttt{min}}$	*	Pairwise Min. V.V.	5.3.1
`HH`	*	History Hashes	4.1

`t_disamb`	Del.	Target disamb	4
`new_uid`	Add.	New user ID	4.3

Table 3: An Operation object, with operation type-specific fields marked in the OpType column. An Acumen state descriptor is comprised of the first seven fields.

5 The Acumen Protocol

We now present the full Acumen protocol. In this section, we update our protocol to hide user access patterns and efficiently offer edit-history privacy while retaining our confidentiality and consistency guarantees. We then introduce secure garbage collection.

5.1 Hiding Access Patterns

In the Treedoc CRDT (§2.1, [33]), a node's full path to the root node is serialized as part of its representation. Treedoc paths are influenced by the document's access patterns—for instance, an edit trace of N insertions each inserting at the end of the current list results in a linear tree structure, such that the last insertion has a path length of N nodes. On the other hand, a "balanced" edit trace would have path lengths on the order of $\log N$. The sizes of encrypted edits leak information about the document access pattern to network adversaries.

Fixed-Length Paths. To mitigate this issue, we replace the full serialized path with a fixed-length path consisting only of the parent node's disambiguator. This is essentially the

Variable	Definition	§
`disamb`	Disambiguator	2.1
`parent`	Parent node disamb.	2.1
`left/right`	Child node disambs.	2.1
`dir`	Direction (left/right child)	2.1
`tombstone`	Tombstone marker	2.1
`data`	Node data	4.1.1
`rand`	Random nonce	4.1.1
`hdata`	PRF(`rand`,`data`)	4.1.1

Table 4: Updated Treedoc Node

"tree representation" of the original Treedoc paper [33], with the tweak that individual atoms (edits) are also sent in their reduced form. One can view this as the op-based version of the Treedoc CRDT.

This approach has the downside of requiring reliable causal broadcast (RCB)—informally, edits must be processed only after their causal dependencies are processed. Acumen already requires RCB for history-hash verification (§4.2), so this downside is of no extra consequence. A full description of our new Treedoc node struct can be found in Table 4.

Crucially, this approach removes the path-length side channel; timing leakage remains outside our threat model as discussed in Section 3.1. This contrasts with the state-of-the-art system Snapdoc [24], which includes the variable-length paths. While nominally straightforward, this change introduces significant complications when adding secure snapshots and garbage collection. We outline our contributions towards resolving these complications in Sections 5.2 and 5.3.

We note that Snapdoc's construction is incompatible with this change as their snapshot verification explicitly relies on each operation encoding a full Treedoc path from root to leaf.

5.2 Snapshot Consistency

Recall that Acumen provides fork-causal consistency (§2.2, §3.2), which informally guarantees that honest users always see a consistent subset of a global execution. *Snapshot consistency* is the extension of fork-causal consistency (which considers a static, existing group of users) to the setting in which new users are invited to existing documents. For instance, a malicious user may invite a new user and send a malformed copy of the current document. Informally, snapshot consistency states that new user states should be the product of a fork-causal consistent execution, as if an honest user processed the full edit history up to the same point.

We now formalize the notion of (strong) snapshot consistency. Define a function $\mathsf{exec}(S,E)$ that returns the resulting Acumen state (as defined in Table 2) from applying the given (partial) [1] execution E to state S according to the Acumen protocol. Further let $\emptyset_m$ define the "empty state" of user m with no operations applied.

[1] A partial execution is a connected subgraph of some complete execution.

Variable	Definition	§
O_S	Sender's Operation Set	4
T_S	Sender's Treedoc Object	2.1
VV_S	Sender's Version Vectors	4
HH_S	Sender's History Hashes	4.1
A_S	State Descriptors	5.2.2

Table 5: Acumen Snapshot Fields

Definition 1 (Strong Snapshot Consistency)**.** A snapshot S from user s deriving state $S_{snapshot}$ satisfies (strong) *snapshot consistency* if there exists a fork-causal consistent execution E such that $S_{snapshot} = \mathsf{exec}(\emptyset_s, E)$.

Intuitively, a user u instantiating from a snapshot sent by user s should realize the same state as an honest user who processed the "full" history up to the same point. The term $\mathsf{exec}(\emptyset_s, E)$ can be thought of as the result of simulating E as if s was honest (thus deriving the correct snapshot state).

Corollary 1. A snapshot S is consistent if the following two conditions hold:

- There exists some partial execution $E_{missing}$ such that $\mathsf{exec}(S_{honest}, E_{missing}) = S_{snapshot}$ for some honest user state S_{honest}.
- $E_{honest} \cup E_{missing}$ is a fork-causally consistent execution.

Proof Sketch: Intuitively, we show that an honest user derives $S_{snapshot}$ given the operations between their current state and $S_{snapshot}$. Since honest users agree on the state at shared execution nodes, the simulated honest snapshot sender would also derive $S_{snapshot}$ under the same execution. We conclude that the snapshot satisfies Definition 1. □

5.2.1 High-Level Construction

We now outline a high-level construction for the creation and verification of snapshots. Creation is straightforward: a snapshot is simply the copy of the snapshot creator's state with additional metadata (Table 5).

Upon receiving a snapshot, new users will run a *snapshot verification protocol* that outputs an Acumen state if and only if the given snapshot S satisfies Definition 1. Following Corollary 1, our key idea to verify a snapshot will be to reconstruct an honest user state S_u and show that $\mathsf{exec}(S_u, E_{S,u}) = S_{snapshot}$ where $E_{S,u}$ is the partial execution corresponding to $E_{missing}$ for user u. We will then verify that $E_u \cup E_{S,u}$ is fork-causal consistent (where $\mathsf{exec}(\emptyset_u, E_u) = S_u$). Since at least one user included in the snapshot is honest [2], it suffices to verify this condition over all users included in the snapshot.

High-Level Snapshot Verification

[2] This assumption is implicit for snapshot consistency, as documents consisting entirely of malicious users can trivially provide an arbitrary snapshot.

Execute the following for each user u contained in S:

1. Verifiably reconstruct the user state S_u using S.
2. Verify that the history hashes of each S_u are consistent with (i.e. prefixes of) the snapshot history hashes.
3. Identify operations in S that were not processed in S_u. Verify that the partial execution $E_{S,u}$ defined by these operations is well-formed (i.e. satisfies FCC constraints).
4. Apply these missing operations to S_u and verify the result equals $S_{snapshot}$.

We briefly argue that these steps satisfy Corollary 1, and by extension Definition 1. Step 4 ensures that $S_{snapshot} = \mathsf{exec}(S_u, E_{S,u})$ for each user u (and therefore for at least one honest user h). Steps 2-3 ensure that $E_{S,h} \cup E_h$ is a fork-causal consistent execution (if all user history hashes are prefixes of the same history hashes, they must be pairwise consistent).

Achieving Step 1 of the high-level construction while maintaining edit-history privacy is the primary obstacle to efficient snapshot consistency. Our main technical contributions relate to this step, which we now detail in full. Section 5.2.2 will describe the notion of *state descriptors* for verifiably reconstructing user states from untrusted snapshot data. Section 5.2.3 then reconciles our approach with edit-history privacy by introducing *placeholder nodes* and related changes.

5.2.2 State Verification From State Descriptors

Recall that *cryptographic accumulators* [4, 6, 7] (§2.3) represent a set of items in a constant-space value. Given $acc_S = \mathsf{accumulate}(S)$, one can cryptographically verify $S' = S$ for a local set S' by comparing $\mathsf{accumulate}(S') \stackrel{?}{=} acc_S$.

We use accumulators to represent an Acumen state as a constant-space hash value. Define the *operation set accumulator* (denoted *acc*) as the accumulator over (the hashes of) a user's set of operations. Likewise, define the *Treedoc accumulator* (denoted *tacc*) to be the accumulator over a user's set of Treedoc nodes.

Following prior work [24], we now define the notion of a **state descriptor**. User u's state descriptor $A_{S,u}$ is comprised of the first 7 fields from their latest operation (Table 3), including the version vector, history hashes, and operation set and Treedoc accumulators.

$$A_{S,u} = (u, acc_u, tacc_u, VV_u, VV_{u,min}, HH_u, hsig)$$

These fields combine to form a signed description of the user's state at the included version vector, and are included in each Acumen snapshot (Table 5). Using $A_{S,u}$, the snapshot verifier can verify that their reconstruction of S_u using untrusted snapshot data equals user u's true state by comparing the respective accumulators and other metadata.

5.2.3 Edit-History Privacy From Placeholders

Acumen also satisfies *edit-history privacy*, which informally requires the snapshot to not reveal previously-deleted document characters. It is not immediately clear how to reconcile this requirement with state descriptors—how can the verifier reconstruct a user state containing a now-deleted character if the snapshot is not allowed to include said character?

Edit-History Private Operations. This situation occurs when the snapshot creator has processed a deletion, but at least one other user has not. Let u be a user included in some snapshot S. For a given snapshot $S = (O_S, T_S, \ldots)$, define the set of *edit-history private operations with respect to u* as the set of insertions witnessed by u that have an associated deletion *not* yet witnessed by u (equivalently, the set of operations deleted in S but not yet deleted in S_u). Likewise define the set of edit-history private nodes with respect to u as the set of Treedoc tombstones with an associated edit-history private insertion.

Key Insight. Our key idea is that *the original data of edit-history private operations/nodes is irrelevant to the outcome of* exec. Intuitively, the original character data is moot if the operation/node will be deleted in the end state.

Consider an example where the snapshot S contains multiple edit-history private insertions $(o_1, \ldots, o_k)$ with respect to user u. Following the high-level construction, let S'_u be the state reconstructed in Step (1), such that S'_u equals S_u except that $(o_1, \ldots, o_k)$ and their associated nodes are tombstones. Assuming that the execution $E_{S,u}$ from Step (3) contains deletion operations targeting $(o_1, \ldots, o_k)$ (as is the case in correct snapshots), we still have $\mathsf{exec}(S'_u, E_{S,u}) = S_{snapshot}$.

We introduce **placeholder nodes** in lieu of the edit-history private nodes. These nodes will represent a generic character while revealing nothing about their original contents. More precisely, define a placeholder node as a Treedoc node with `data, rand = null` and `tombstone = False` (effectively, a standard Treedoc character node with `data, rand` set to `null`).

Placeholder nodes function identically under Treedoc operations while hiding the original character data. Through this observation, we can relax Step (1) of the high-level construction—instead of verifying full state equality, we need only reconstruct S_u "up to placeholders".

Definition 2. Two states $S'_u = (O'_u, T'_u, \ldots)$ and $S_u = (O_u, T_u, \ldots)$ are *equal up to placeholders* (denoted $S'_u \leq_T S_u$) if their metadata fields are equal and $(O'_u, T'_u) = (O_u, T_u)$ except for a subset of edit-history private operations and associated placeholder nodes in S'_u.

We specify that $S'_u \leq_T S_u$ only if the set of placeholder Treedoc nodes is exactly the set of nodes corresponding to the edit-history private insertions with respect to u. Otherwise, the snapshot creator can violate snapshot consistency by marking nodes as tombstones without a corresponding deletion operation in the execution.

Theorem 1. Let S_u be an honest user state and $S'_u \leq_T S_u$ with edit-history private insertions $O_T = (o_1, \ldots, o_k)$. For all well-formed partial executions E such that there exists a deletion in E targeting each $o \in O_T$, the following equality holds:

$$\mathsf{exec}(S'_u, E) = S_{new} \iff \mathsf{exec}(S_u, E) = S_{new}$$

Input: $S = (O_S, T_S, VV_S, HH_S, A_s)$ (see Table 5)

1. Compute $VV_{S,min}$ as the pairwise minimum over user state descriptor version vectors.
2. Verify that O_S is a well-formed partial execution (e.g. all version vectors are unique, operations from individual users are totally ordered, and operations are within their user state descriptor).
3. If garbage collection enabled, set $(O_{final}, T_{final}) = \mathsf{GarbageCollect}(O_S, T_S, VV_{S,min})$ (where GarbageCollect is the protocol specified in §5.3.2), else $(O_{final}, T_{final}) = (O_S, T_S)$.
4. Verify T_{final} contains no placeholder nodes (i.e. nodes with `tombstone = False` and empty `data,rand` fields).
5. Execute the following for each $u \in VV_S$:
   (a) Let $A_{S,u} = (u, acc_u, tacc_u, VV_u, VV_{u,min}, HH_u, hsig)$ be the state descriptor for u in A_S. Verify $hsig$ with PK_u.
   (b) Compute the user operation set O_u and Treedoc object T_u:
   $$O_u = \{o \in O_S \mid VV_o \leq VV_u\} \text{ and } T_u = \{n \in T_S \mid \text{for } n\text{'s insert op. } o \in O_S, VV_o \leq VV_u\}$$
   (c) Define $O_{T,u}$ to be the set of edit-history private operations with respect to u:
   $$O_{T,u} = \{o \in O_S \mid o \text{ is an insertion} \wedge VV_o \leq VV_u \wedge \exists\, o_d \text{ targeting } o \text{ s.t. } VV_{o_d} \not\leq VV_u\}$$
   (d) For each $o \in O_{T,u}$, set `tombstone = False` in the corresponding node in T_u.
   (e) Set $(O_u, T_u) \leftarrow \mathsf{GarbageCollect}(O_u, T_u, VV_{u,min})$ with input $VV_{u,min}$.
   (f) Verify that $\mathsf{accumulate}(O_u) = acc_u$ and $\mathsf{accumulate}(T_u) = tacc_u$.
   (g) Let $S'_u = (O_u, T_u, VV_u, VV_{u,min})$ be the reconstructed user state. Verify that applying the operations in $O_{missing} = O_S \setminus O_u$ (as defined in Step 5b) to S'_u results in a state $S^{(F)} = (O_S^{(F)}, T_S^{(F)}, VV_S^{(F)}, HH_S^{(F)}, _)$ such that $(O_S^{(F)}, T_S^{(F)}, HH_S^{(F)}) = (O_{final}, T_{final}, HH_S)$.
6. Define primary/secondary objects: $(O, T) = (O_{final}, T_{final})$ and $(O^{(2)}, T^{(2)}) = (O_S, T_S)$

Figure 3: Snapshot Verification Protocol. A full description of the fields contained in a snapshot can be found in Table 5. Text in blue indicates steps added by the garbage collection protocol outlined in §5.3.

Proof Sketch: Deleting a placeholder has the same effect as deleting a live node, and all placeholders are deleted in E. Since the existence of these placeholders are the only difference between S'_u and S_u, the end result of applying E must be equal. □

We conclude that executing the high-level steps using a reconstructed user state equal up to placeholders to the "true" user state still satisfies Definition 1.

Adapting State Descriptors. Recall that our earlier approach exactly reconstructed S_u from untrusted data and compared the resulting accumulators to u's state descriptor. Our new approach derives a state $S'_u \leq_T S_u$, but the accumulators of S'_u will not necessarily equal those of S_u due to the presence of placeholder nodes.

We will resolve this by re-defining the hash of an operation/node such that the hash of a placeholder node equals the hash of its original node. It follows that $\mathsf{accumulate}(O'_u) = \mathsf{accumulate}(O_u)$ and $\mathsf{accumulate}(T'_u) = \mathsf{accumulate}(T_u)$ if $S'_u \leq_T S_u$. Recall that in §4.1.1 we defined $H(\mathtt{op})$ to use an intermediate data hash `op.hdata`. When computing the hash of a tombstone or placeholder operation, we use this intermediate field directly: $H(\mathtt{op}) = H(\mathtt{op.metadata}, \mathtt{op.hdata})$.

We define the hash of a Treedoc node likewise—note that the `tombstone` field will be included in metadata such that placeholder nodes and real tombstones have differing hash values. The resulting placeholder hash value is equal to the original, non-tombstone hash. Likewise, the hash of a tombstone operation is equal to its original hash. We briefly note that this definition does not violate our FCC guarantees from history hashes, as the value of $H(\mathtt{op})$ is originally calculated as a function of the character data.

5.3 Secure Garbage Collection

Without explicit garbage collection, the size of each user state (and of snapshots) will be linear in the edit history length. In practical terms, this results in a blowup in user storage and operation processing time. In this section, we introduce a garbage collection protocol that drastically improves the performance of Acumen, while maintaining our cryptographic and consistency guarantees (§3.2).

Garbage collection is often at odds with CRDT-based collaborative editors because collection is a non-commutative operation. As a result, such operations must often be preceded by a distributed consensus protocol. In this section, we construct *asynchronous* garbage collection for Treedoc by exploiting causal stability and existing reliable causal broadcast (RCB). While previous work [5, 17, 33] provides for mild forms of asynchronous garbage collection (such as pruning obsolete metadata or leaf nodes), our approach provides full garbage collection for Treedoc (i.e. including inner nodes).

We first define the notion of causal stability (§5.3.1), then outline our GC protocol (§5.3.2), show said protocol satisfies strong eventual consistency (§5.3.3), and finally adapt it to snapshot verification (§5.3.4).

5.3.1 Causal Stability

Garbage collection in op-based CRDTs generally relies on *causal stability* [1, 2, 35], the notion that certain operations can be pruned once all users have executed them. An operation is said to be *causally stable* if it has been processed by every user. In the language of version vectors, an operation o is causally stable if $VV_o \leq VV_u$ for each user u. Equivalently, o is causally stable if $VV_o \leq VV_{min}$ where VV_{min} is the component-wise minimum over all user version vectors:

$$VV_{min}[v] = \min\{VV_u[v] : u \text{ is a user ID}\}$$

As part of our garbage collection protocol, users will identify causally stable operations in their local state. However, our asynchronous environment implies no user knows the global VV_{min}, as they may not be fully up-to-date with other user operations. Fortunately, the definition of VV_{min} extends naturally to the local case.

Let $VV_v^{(u)}$ be v's latest version vector from u's perspective (e.g. the version vector of v's latest operation in u's state). Define $VV_{u,min}$ as the component-wise minimum over all $VV_v^{(u)}$ for each user v in user u's state. An operation o is said to be *locally* causally stable if $VV_o \leq VV_{u,min}$. Local causal stability implies (global) causal stability, but the converse is not necessarily true.

Causally Stable Tombstones. As defined in §2.1, deleted Treedoc nodes are marked as *tombstones*. In base Treedoc, tombstone nodes cannot be permanently deleted, as future insertion operations can create nodes referencing a tombstone node as a parent. This occurs precisely when the operation creator has not yet processed the associated deletion operation, such that the tombstone node appears as a live node from their point of view. Thus, a deletion operation being causally stable implies the associated node will never serve as a parent to a new insertion. This property motivates the definition of **causally stable tombstones** (CSTs): tombstone nodes whose associated deletion operation is causally stable. [3]

5.3.2 Garbage Collection Protocol

We now describe our asynchronous garbage collection protocol for Treedoc. The primary challenge to such a protocol is dealing with inner nodes (i.e. non-leaf nodes). While leaf CSTs can be pruned immediately, it is not immediately clear how to prune a CST inner node that has live child nodes without disrupting required consistency guarantees.

The original Treedoc paper [33] approaches this problem by transforming ("flattening") a subtree into a single list of sibling leaf nodes. Their protocol requires running a distributed consensus algorithm to ensure no conflicting insertion can occur. Our key idea is to define an asynchronous `flatten` operation that compresses a *single edge* of the tree, replacing a CST node with its child node(s). By identifying a key invariant relating to causal stability, we ensure that `flatten` cannot conflict with concurrent insertions and therefore does not require a distributed commitment scheme.

Conditions For Garbage Collection. Recall that Treedoc orders sibling nodes according to their disambiguator (as outlined in §2.1). Flattening a node can violate this total order, since its child node(s) have different disambiguators. More concretely, consider two concurrent operations: one flattens a node with parent P and the other inserts a new node under P. Since nodes are inserted into their new child list in sorted order, the `flatten` replacing a list item with child nodes containing a different (possibly out-of-order) disambiguator may change the insertion location of the new node.

In summary, we must not flatten a node N whose parent node P may be the target of a future insertion. We identify a simple sufficient condition to satisfy such a requirement: a Treedoc CST N can be flattened *only if its parent P is also a CST*. Intuitively, if P is a CST all users see it as a tombstone, and will therefore not reference it as a parent to any insertion.

Parametrized Causal Stability. We now define our garbage collection protocol `GarbageCollect`, which takes as input a version vector VV_{gc} to define causal stability (i.e. all operations $\leq VV_{gc}$ are considered causally stable). We will elaborate on this parameter in §5.3.3. For technical reasons, `GarbageCollect` will use $VV_{gc} - 1$, i.e. VV_{gc} with each value decremented by one [4].

For Treedoc nodes, `GarbageCollect` executes as follows: **prune all leaf CSTs, and flatten inner node CSTs whose corresponding parent node is also a CST**. Figure 5 provides an example showcasing both `flatten` and leaf-pruning. Garbage collecting operations is straightforward: prune causally stable deletions and insertions whose associated deletion is causally stable.

5.3.3 Maintaining Strong Eventual Consistency

Recall the definition of strong eventual consistency (SEC) from §2.1: informally, users applying the same execution (up to concurrent ordering) end up with the same state. This property implicitly underlies fork-causal consistency in CRDT-based distributed editors, as it ensures (honest) users agree on the document state at every point in their shared execution regardless of how they locally applied concurrent edits.

However, garbage collection based on causal stability may break SEC—namely, the local causal stability of an operation can differ between two users under the same execution. For example, suppose there exists a two-party document of users

[3] The concept of causally stable tombstones is well-known—we only introduce the term CST for brevity.

[4] This is to ensure that a user's most recent operation is never garbage collected, as it may be referenced for operation verification (Fig 2).

Input: Operation set O, Treedoc object T, causal stability barrier version vector VV_{gc}
Output: Operation set O', Treedoc object T'

Let $VV_{gc}-1$ denote VV_{gc} with each entry decremented by one.

1. Filter the operation set O to generate a new set O' by removing the following items:
   - `Insertion` operations o such that $\exists o_d \in O$, o_d targets o for deletion, and $VV_{o_d} \leq (VV_{gc}-1)$.
   - `Deletion` operations o_d such that $VV_{o_d} \leq (VV_{gc}-1)$.
2. Compute the set of CSTs: $C = \{n \in T \mid n \text{ is a tombstone} \wedge \exists o_d \in O \text{ s.t. } o_d \text{ deleted } n \wedge VV_{o_d} \leq (VV_{gc}-1)\}$
3. Prune all leaf nodes in C. Repeat this step as needed if this generates new leaf CSTs.
4. For each $n \in C$ such that $n.\texttt{parent} \in C$, run the `flatten` subprocedure:
   - Let p be n's parent node, and let $L_C = n.\texttt{left} \| n.\texttt{right}$ be the concatenated child lists of n.
   - Replace n in p's left or right child list with the elements of L_C.
5. Let T' be the Treedoc object created as a result of Steps 3-4. Output (O', T').

Figure 4: Garbage Collection Protocol.

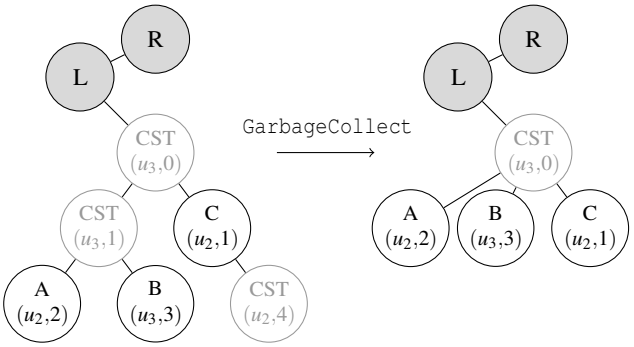

Figure 5: An example instance of garbage collection, with one call to `flatten` and one leaf node pruned.

A, B such that A inserted and deleted a single character (o_i,o_d respectively), with B processing these operations. User A does not see o_d as causally stable and does not prune the associated Treedoc node. However, User B does recognize o_d as causally stable and prunes the associated node.

To ensure strong eventual consistency, we specify `GarbageCollect` such that the set of CSTs is defined according to the *sender's* notion of (local) causal stability. More precisely, when processing an operation o with field $VV_{min,op}$ (the pairwise minimum version vector from Table 3) users run `GarbageCollect` with $VV_{gc} = VV_{min,op}$. When creating a new operation users run `GarbageCollect` with their local VV_{min}.

5.3.4 Adapting Garbage Collection For Snapshots

Recall that the high-level idea for snapshot verification (§5.2.1) is to reconstruct each user state from untrusted snapshot data and check equality via the user's signed state descriptor. This approach is at odds with the idea of permanent garbage collection—in order to retain the ability to create snapshots, a user can only remove operations/nodes that have *already been removed by every other user*. At face value, this is a circular requirement that prevents all garbage collection.

Key Insight. Our insight to avoid this issue is to perform *second-order* garbage collection by duplicating the operation set and Treedoc objects, maintaining a "primary" object (O,T) and secondary object $(O^{(2)},T^{(2)})$. Incoming operations will be applied to both primary and secondary objects. The primary object will be garbage collected as previously outlined, and user state descriptors (§5.2.2) will be computed over the *primary* object. The secondary object will be garbage collected as far as possible while still being able to reconstruct each user state descriptor. More precisely, for each user v with primary object (O_v,T_v), user u's secondary object $(O_u^{(2)},T_u^{(2)})$ must satisfy $(O_v,T_v) = \mathsf{GarbageCollect}(O_u^{(2)},T_u^{(2)},VV_{v,min})$ where $VV_{v,min}$ is defined as in §5.3.1.

Latest Garbage Collection Version Vector Recall that Acumen users run $\mathsf{GarbageCollect}(O,T,VV_{min})$ after processing or creating an operation o (where VV_{min} is taken from o). Let $VV_{v,min}^{(u)}$ denote this field from a user v's latest operation as seen by u. We now define the (local) *pairwise minimum garbage collection version vector*:

$$GCVV_{u,min}[w] = \min\{VV_{k,min}^{(u)}[w] : k \text{ is a user ID}\}$$

We define $GCVV_{u,min}$ as user u's local $GCVV$, computed from the latest state descriptors in their operation set. This definition is essentially a second-order pairwise minimum version vector (§5.3.1), in that $GCVV_{min}$ represents the maximal version vector such that $GCVV_{u,min} \leq VV_{v,min}^{(u)}$ for all users v, as seen from u's state.

Adapting Garbage Collection. As before, the primary operation set/Treedoc is garbage collected with $VV_{gc} = VV_{min}$ where VV_{min} is taken from the processed/created operation o. The secondary object will be garbage collected up to $VV_{gc} = GCVV_{min}$. To reconcile snapshot consistency with garbage collection, we make minor changes to the snapshot verification algorithm (highlighted blue in Figure 3).

Trace Index ≈:	50	250	425	850
Automerge (ins)	<0.01	<0.01	<0.01	<0.01

Snapdoc (ins)	5.63	23.81	37.5	193.7
Snapdoc (del)	11.3	22.3	42.9	190.7

Table 6: Local operation creation timings (ms) taken from the $N=5$ user Automerge trace (§6.1).

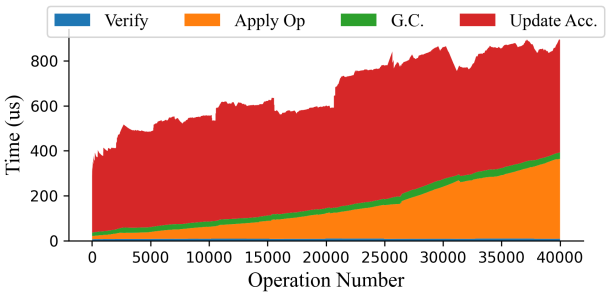

Figure 6: Acumen timings for processing remote operations. Averaged over $N=5$ users alternating to type the first 40,000 edits of the Automerge trace as outlined in §6.1.

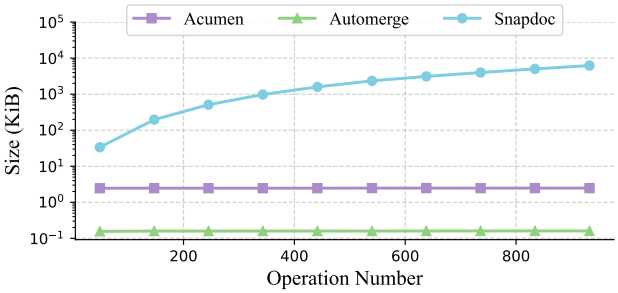

Figure 7: Log-scale insertion update sizes averaged over $N=5$ users typing the first 1,000 edits of the Automerge trace (§6.1).

6 Evaluation

We aim to answer three key questions with our evaluation:

1. How does each component of our protocol affect its ultimate performance?
2. How do user count, edit-history length, and current document size affect snapshot size and verification timing?
3. How does performance scale in real-world concurrent editing scenarios?

6.1 Local Performance

We first evaluate performance over a realistic document workload: the sequential edit trace [15, 16] of the original Automerge research paper [22], containing 182,315 single-character insertion operations and 77,463 single-character deletion operations. We compare against two baselines: Snapdoc [24], the closest prior work in terms of security guarantees, and Automerge [22], a popular open-source CRDT library without security guarantees.

Setup We evaluated the Automerge trace over $N=5$ users in alternating steps. More precisely, the k-th edit is executed by user $k \bmod N$ and the resulting update is immediately processed by each other user. This trace is evaluated on a `c2-standard-16` GCP server (16 vCPU, 64GB memory).

Local Operations Table 6 displays local operation processing times taken at different indices in the Automerge trace (corresponding to well-spaced deletions). Both Acumen and Automerge maintain real-time [5] processing times less than 1ms, whereas Snapdoc insertions and deletions take time proportional to the edit-history length (approaching 200ms after only 850 edits).

Remote Processing We quantify which aspects of Acumen contribute towards processing remote updates in Figure 6. The bulk of Acumen's overhead comes from updating our accumulators (§5.2.2), requiring $\approx 2 \cdot \lambda$ hash function evaluations and hashmap insertions per operation. Aside from periodic memory re-allocation as the hashmap grows in size, this component remains largely constant. Likewise, garbage collection ("G.C.") remains a small fraction of overall processing time, which is to be expected in documents with all users reasonably up-to-date. The bulk of the increase in processing time seen in Figure 6 comes from inserting a new character into the Treedoc and associated list (primarily the latter).

Update Size We plot update sizes under the same trace in Figure 7. As expected, both Acumen and Automerge update sizes remain constant over time. The same cannot be said about Snapdoc, whose update sizes grow linear in the edit-history length. This growth is enough to significantly degrade performance for non-trivial document sizes: after typing $\approx$ 1000 edits ($\approx$ 200 words), a Snapdoc update is already 7 MB in size.

6.2 Snapshot Performance

We next evaluate the impact of three key scaling factors on the load time and size of document snapshots: [6] the number of users in the current document, the size of the current document, and the size of the overall edit history.

Setup We instantiate a document with $|\text{users}| \in [1,10]$ and apply the aforementioned Automerge document trace up to $|\text{ops}| \in \{0,10,50,100,200,400,1000\}$. We then delete 0% or 90% of the remaining characters starting from document end.

We plot the snapshot size and load times for all combinations of $(|\text{users}|,|\text{ops}|)$ in Figure 8. To handle Snapdoc's extreme demand for memory, evaluations are run in the `n2-highmem-48` virtual machine (48 vCPUs, 384 GB memory).

[5] Acumen insert performance will eventually degrade due to inserting into a large list, as seen in Figure 6.

[6] We exclude snapshot save time for space concerns, as it scales almost exactly with current document size across all systems.

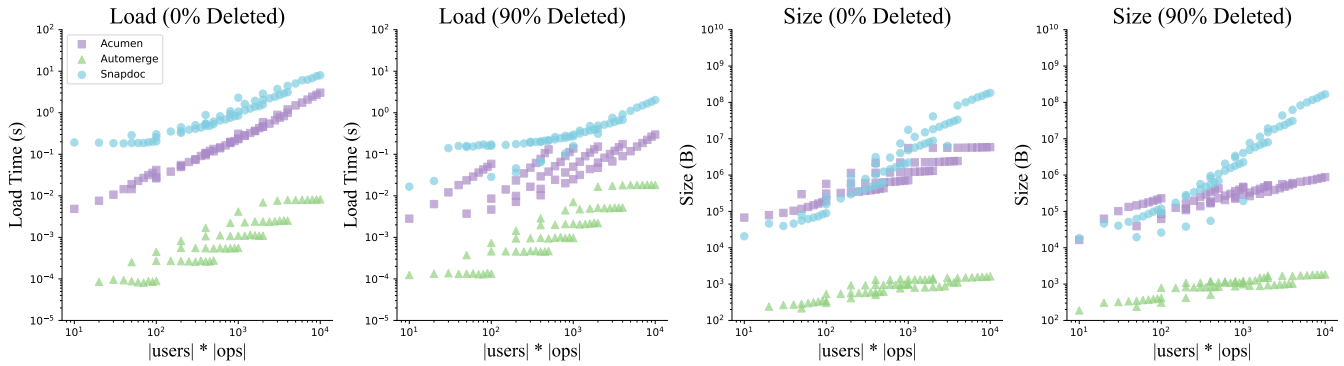

Figure 8: Snapshot Evaluations. The x-axis is composed from the product of combinations over user counts in $[1, 10]$ and operation lengths up to 1000. The first row consists of snapshots created after executing the first k operations of the Automerge trace (§6). The second row applies the same trace but deletes 90% of the document prior to creating the snapshot.

User Scaling The snapshot load performance of Acumen and Snapdoc scale approximately proportional to the number of users (all else constant). This is in contrast to a basic CRDT like Automerge which has negligible scaling on $|\text{users}|$. The impact of extra users is also visible in the snapshot size due to the inclusion of an extra state descriptor (§5.2.2), though the effect is additive and much less pronounced.

Edit-History Scaling As expected, Acumen has better performance than Snapdoc in documents with a large ratio between the edit-history length and current size (captured in the 90% deletion parameter). This is due to our garbage collection protocol: unlike Acumen, the path lengths of Treedoc nodes in Snapdoc snapshots grow proportional to edit-history length (also seen in Figure 7). Even though Snapdoc is able to exclude (most of) the deleted Treedoc nodes from its snapshot, the leftover nodes remain exceptionally large. [7]

Concretely, we see an order of magnitude improvement in load times in 0% deletion environments. In 90% deletion documents with low user count, this increases to nearly two orders of magnitude. Size difference is particularly pronounced in the 90% case: with just 1000 edits in the trace, Acumen already provides *three* orders of magnitude improvement in snapshot size.

6.3 Throughput/Latency Benchmarks

We next evaluate Acumen in full, including network overheads. Each benchmark consists of N users editing a single document, with edits broadcast over a network to individual client machines (`c2-standard-8`) through a central relay server (`c2-standard-30`). Each user repeatedly types and deletes the abstract of this paper ($\approx$ 800 characters). We compare Acumen to a baseline system using the Acumen network framework that sends and receives 200-byte edits, but does not process them locally. [8]

[7] Almost all of Snapdoc's performance degradation is caused by the variable size inherent to their Treedoc atom representation.

[8] We opt to not use Automerge as a baseline due to its performance degrading with edit history length, which prevented the measurement of steady-state ping/throughput numbers.

	# Users:	2	5	10	25
Latency (ms)	Baseline	0.37	0.465	0.51	1.5
	Acumen	1.03	1.17	1.38	2.7
Throughput	Baseline	19672	11400	7983	2240
	Acumen	1340	645	402	270

Table 7: Round-trip latency (5 ops/sec) and maximum throughput (measured as ops/sec processed by a single user).

Results Table 7 contains the results of the aforementioned benchmark. Latency is calculated as the local time difference between sending an update and receiving an acknowledgment packet (sent after the receiver processes the update in question). Direct client-to-server round-trip latency (measured via the `ping` Unix command) is approximately 0.125 ms.

We see that Acumen latency remains in the single-digit millisecond range even for large documents. Adjusted for baseline latency, our protocol adds $<$ 1ms of overhead on average. We also see that Acumen throughput scales inverse with the number of active users, since each user waits for $N-1$ updates before sending their own. Despite this, Acumen maintains throughput into the hundreds of operations per second even with large user counts.

7 Related Work

Untrusted Cloud Storage. SUNDR [26] and Depot [28] are notable secure filesystems that use signed version vectors to securely enforce causal guarantees. SPORC [13] is a central-server based secure collaborative editor utilizing *operational transforms*, but does not consider user adversaries.

(Secure) CRDTs. Many CRDT-based text editors and frameworks have been developed, an incomplete subset of which is as follows: Treedoc [33], Logoot [38], Peritext [27], Automerge [22], YJS [30], and ARDTs [25]. Barbosa et al. [3] developed a model for secure CRDTs for *honest-but-curious* adversaries. Kuessner et al.'s Algebraic Replicated Data Types (ARDTs) [25] utilize symmetric encryption at the

clients with an untrusted server that forwards the edits, but likewise only consider an honest-but-curious threat model.

Malicious-secure CRDTs have generally used hash-graphs [8, 20, 21, 31] and our work is no exception. Snapdoc [24] is the first to implement the CRDT-based snapshot consistency notion (§3). Snapdoc provides only a subset of our guarantees: their solution leaks edit patterns and does not offer the performance and scalability of the Acumen system. Also of note is work by Elvinger et al. [12] outlining a theoretical notion of authenticated snapshots. Though they did not provide an implementation, their approach shares many of our (and Snapdoc's) high-level ideas of state fingerprinting and authenticated logs from collision-resistant hashing.

CRDT Garbage Collection Efficient CRDT garbage collection has been explored in a variety of contexts. The causal stability approach is explored in [5, 17, 34] and particularly for tree-based CRDTs in [23, 33]. Zawirski et al. [39] propose a two-tiered solution involving a "core" set of highly available servers that execute the commitment protocol, then share their result with the remaining nodes.

8 Conclusion

This work introduces Acumen, a secure platform for collaborative editing with real-time performance. Our system is the first to provide confidentiality, integrity, fork-causal consistency, strong snapshot consistency and edit-history privacy in the presence of untrusted clients and servers.

A Strong Eventual Consistency

Recall the definition of strong eventual consistency [36]:

Definition A.1. (Strong Eventual Consistency, Informal) A CRDT satisfies strong eventual consistency if for all users A,B receiving the same set of updates (possibly in a different order), A's state equals B's state.

It is known that a CRDT satisfies SEC if concurrent operations commute [19]. We now sketch a proof that Acumen with garbage collection satisfies SEC over all well-formed executions.

At a high level, our proof will proceed as follows:

- We first show that garbage collection is commutative with itself: GC at VV_1 before VV_2 results in identical outcomes to GC at VV_2 before VV_1.
- Next, we show that GC is unaffected by insertions and deletions.
- Finally, we conclude that GC satisfies SEC.

Lemma A.1. Let $S_u = (O_u, T_u)$ be an arbitrary Acumen state, and `GarbageCollect` be as defined in Figure 4. The following identity holds:

$$\texttt{GarbageCollect}(\texttt{GarbageCollect}(O_u,T_u,VV_1),VV_2) = \texttt{GarbageCollect}(O_u,T_u,VV_1 \cup VV_2)$$

where $VV_1 \cup VV_2$ denotes the component-wise maximum of VV_1 and VV_2.

Proof Sketch: We first briefly argue that `flatten` is commutative within the same call to GC — that is, we can flatten parent/child nodes in any order. It is easy to see that pruning leaf nodes and operation tombstones commute. The primary case to consider is thus a chain of CSTs $A \to B \to C$, and whether flattening (A,B) preceding (B,C) affects the outcome. It is straightforward to see that this is not the case: both executions collapse into the single node C. We note that this holds even for different-direction children (e.g. $A \to B$, $A \to C$ for left-child B, right-child C), since flattening A moves both children into its current position (e.g. inserts them into the same list in their respective order).

We now argue that this individual commutativity applies to GC operations themselves. Intuitively, the GC protocol identifies a set of eligible operations/nodes as those $\leq VV_{gc} - 1$. The set identified at $VV_1 \cup VV_2$ is equal to the union of the sets at VV_1,VV_2. Since flattening elements in the set can occur in any order, it follows that the GC two sets sequentially is equal to the GC of the union. (Note `flatten` does not impact the CST status of other nodes)

Lemma A.2. (Informal) Insertion and deletion operations commute with garbage collection.

Proof Sketch: Intuitively, an insertion can only target non-CST parent nodes. It follows that insertions do not affect the resulting state of any call to GC, as they modify node state untouched by GC. Deletions follow likewise.

Theorem A.1. Acumen with garbage collection satisfies strong eventual consistency.

Proof Sketch: Immediate from the previous lemmas: garbage collection is commutative and unaffected by concurrent operations, so overall Acumen operations are commutative ($\implies$ SEC).

B Fork-Causal Consistency

We now provide a formal definition and proof sketch of fork-causal consistency, assuming strong snapshot consistency (to be proved in §C). To do so, we construct a *happens-before* global execution graph G that represents the causal relationships between operations. This graph represents a "global view" of the causal execution (restricted to honest users). We then construct individual client execution graphs G_n to represent their "local view" of the causal execution. By comparing G and G_n at every shared node, we prove that our system is fork-causal consistent.

Definition B.1. Let G be a directed acyclic graph. The partial order $\prec_G$ holds if there is a directed edge $a \to b$ or a transitive path from a to b in G.

Definition B.2. For any vertex v in the graph G, define $\mathsf{read}(G,v)$ to be the tuple (O,T) of operation set / Treedoc nodes from the state $\mathsf{exec}(\emptyset,E)$ where $E = \{n \in G \mid n \preceq v\}$ (the subgraph leading into v).

Likewise, define $\mathsf{read}(G_n,v)$ to be the operation set/Treedoc of $\mathsf{exec}(\emptyset_u,E)$, where $E = \{n \in G_n \mid n \preceq v\}$.

Definition B.3. A global execution E is **fork-causal consistent** if there exists a directed acyclic graph G that satisfies the following properties:

FCC0. G contains a vertex for every operation in E sent by an honest user, and also a vertex for every operation that is sent by a malicious user and processed by at least one honest user.

FCC1. The operations of honest users are totally ordered in G, consistent with the actual execution order of the operations at that device.

FCC2. For each honest user n there exists a directed acyclic graph G_n in which there is a vertex for every operation message sent or processed by n. By FCC0, for each vertex v in G_n there is a corresponding vertex m in G. We then require that for each vertex v in G_n, the document state is the same as the document state at the corresponding vertex in G: $\mathsf{read}(G_n,v) = \mathsf{read}(G,v)$.

FCC3. The operations of all users appear totally ordered to honest clients. Formally, if $v \in G$ is a node created by an honest client and $v_1, v_2 \prec v$ are vertices from a user u, then $v_1 \prec v_2$ or $v_2 \prec v_1$.

Definition B.4. We construct G_n (the local execution graph for an honest user n) as follows:

1. Add a vertex for every operation witnessed or sent by n.
2. Add a directed edge $a \to b$ for locally witnessed/sent operations a, b where a is a causal dependency of b. That is, draw an edge from each operation as defined in the version vector, excepting the sender's which draws an edge from the operation with counter $VV[u]-1$. [9].
3. For users joining from snapshots, add the partial execution as given by O_S (i.e. $E_{snapshot}$). Add edges into an `AddUser` node from its causal dependencies present in partial execution.

Definition B.5. We construct G (the global execution graph) as follows:

1. Add a vertex for every operation witnessed or sent by an honest client.
2. Add a directed edge $a \to b$ for locally witnessed/sent operations a,b where a is a causal dependency of b.

   This includes edges from a new user's first message upon joining, which has an edge to the associated `AddUser` node and edges to the same dependencies as the `AddUser` node.

Lemma B.1. G is a DAG.

Proof Sketch: By construction, an edge $a \to b$ exists only if $VV_b > VV_a$ (since operations have edges from their causal dependencies, and the version vector of a given operation dominates the version vectors of its dependencies). This prevents any cycles from appearing on the graph, as the version vector counter is monotonically increasing.

[9] This is precisely the dependencies checked by our operation verification protocol in Fig. 2

Lemma B.2. G satisfies FCC0, FCC1, and FCC3.

Proof Sketch: FCC0 is by definition. FCC1 follows immediately from our definition involving version vectors, as mentioned in Lemma B.1. An edge always exists between a user's k-th node and their $k+1$-th as required.

FCC3 follows much the same as FCC1. An honest user accepts an operation from user u only if its counter is precisely $+1$ from that user's most recent operation counter. Therefore forking operations with identical counters will be ignored, and honest users always see a total order for the operations from any given individual user.

The above reasoning holds for nodes added from a snapshot, as snapshot verification will ensure the well-formedness of the partial execution.

Lemma B.3. Assume that each snapshot node in G satisfies snapshot consistency as in Definition 1 (§5.2). Then G satisfies FCC2.

Proof Sketch: Suppose not, i.e. suppose there exists some global execution E that leads to a FCC2 violation. By snapshot consistency, the state of a snapshot user is precisely equal to that of an honest user processing the same execution up to and including the relevant `AddUser`.

Consider then the same execution over our basic protocol (§4), i.e. where snapshots are created by including the entire edit history. This protocol is clearly fork-causal consistent (for a proof, see Snapdoc [24] "basic protocol").

We claim that the counterexample execution E would also break FCC over the basic protocol. Consider an arbitrary FCC2 violation in E such that $\mathsf{read}(G_n,v) \neq \mathsf{read}(G,v)$ for some v and honest snapshot user n. By strong snapshot consistency, the respective user n in the basic version would have an equal value at v in their $G_{n,basic}$. This would imply $\mathsf{read}(G,v) \neq \mathsf{read}(G_{basic}, v_{basic})$, but this is a contradiction as G is solely determined by E.

C Snapshot Consistency Proof Sketch

We prove that our snapshot verification algorithm given in Figure 3 satisfies Definition 1, assuming that the underlying Acumen system is fork-causal consistent (§B) and that every existing user snapshot satisfied snapshot consistency (effectively inducting over snapshots). Namely, we prove that an arbitrary snapshot S satisfying the verification protocol must satisfy Definition 1.

Our proof will proceed according to the following outline:

1. We first prove that the protocol correctly reconstructs each user state S'_u up to placeholders (§5.2.3).
2. We then prove Theorem 1, which informally states that the outcome of applying the operations between the reconstructed state S'_u and the snapshot S has equal outcome to applying the same execution to the real state S_u (intuitively, that placeholders do not affect the result of `exec` under snapshot conditions).

3. Next, we prove that the result of applying $E_{S,u}$ (the missing operations between S_u and $S_{snapshot}$) to the real user state S_u results in $S_{snapshot}$. This will follow directly from the previous step and the fact that verification ensures $\mathsf{exec}(S'_u, E_{S,u}) = S_{snapshot}$.
4. We then show that $E_u \cup E_{S,u}$ forms a fork-causal consistent execution.
5. Finally, we apply the previous two steps to show S satisfies Corollary 1, and conclude it satisfies Definition 1.

The following statements implicitly assume the snapshot S passed snapshot verification as in Figure 3.

Lemma C.1. Let $S'_u = (O'_u, T'_u)$ be the state derived in Step 5 of the snapshot verification protocol (Fig. 3) for some user $u \in VV_S$. We have $S'_u \leq_T S_u$ (where $\leq_T$ denotes equality up to placeholders as defined in Def. 2).

Proof Sketch: Intuitively, this lemma proves that the reconstruction of the user state during snapshot verification is correct. More precisely, we show that $O'_u = O_u$ and $T'_u = T_u$ except for a subset of placeholders.

Recall that the hash of a placeholder is equivalent to that of the standard operation/node, and that our accumulator construction (§2.3) functions over the hash values of its inputs rather than their direct values. It follows that the accumulator over the placeholder-free set O_u equals that of the placeholder set O'_u.

Any other difference between two sets will violate the set-collision resistance of accumulate, since the difference will appear in the individual hashes. We conclude that $\mathsf{accumulate}(O_u) = \mathsf{accumulate}(O'_u)$ if and only if $O'_u \leq_T O_u$. The same for Treedoc accumulators follows immediately.

Since these accumulators are signed as part of the state descriptor (e.g. Step 5a), we conclude that the overall state $S'_u \leq_T S_u$. □

We now prove Theorem 1. Restated:

Theorem C.1. Let S_u be an honest user state and $S'_u \leq_T S_u$ with edit-history private insertions $O_T = (o_1, \ldots, o_k)$. For all well-formed partial executions E such that there exists a deletion in E targeting each $o \in O_T$, the following equality holds:

$$\mathsf{exec}(S'_u, E) = S_{new} \iff \mathsf{exec}(S_u, E) = S_{new}$$

Proof Sketch: This follows directly from the idempotency of deletion operations (intuitively, deletions are permanent — once marked as a tombstone, an operation/node remains so). Moreover, deleting a placeholder op/node has the same effect as deleting a live op/node.

It follows that in both executions, each edit-history private insertion o and node n_o are marked as (normal) tombstones by the end of E. Since the placeholders in O_T are the only difference in S'_u, S_u, the resulting end states are exactly equal. □

Lemma C.2. Define $E_{S,u}$ as the partial execution derived from $O_{missing,u} = O_S \setminus O_u$ (step 5g). Let E_u be the real execution corresponding to S_u. The following expression holds:

$$\mathsf{exec}(S_u, E_{S,u}) = S_{snapshot}$$

Proof Sketch: Immediate from Lemma C.1, Theorem C.1, and Step 5g.

Lemma C.1 implies that $S'_u \leq_T S_u$ (where S'_u is the reconstructed state from 5g, and S_u is the real user state). Step 5g of the verification protocol ensures that $\mathsf{exec}(S'_u, E_{S,u}) = S_{snapshot}$. Finally, Theorem C.1 states that $\mathsf{exec}(S'_u, E) = S_{new} \implies \mathsf{exec}(S_u, E) = S_{new}$. We conclude the statement. □

Lemma C.3. The execution $E_u \cup E_{S,u}$ is fork-causal consistent.

Proof Sketch: Immediate from Step 2 (verifies the execution from O_S is FCC, implying the subset of O_S induced by u is FCC). □

Finally, recall Corollary 1:

Corollary 1. A snapshot S is consistent if the following two conditions hold:

- There exists some partial execution $E_{missing}$ such that $\mathsf{exec}(S_{honest}, E_{missing}) = S_{snapshot}$ for some honest user state S_{honest}.
- $E_{honest} \cup E_{missing}$ is a fork-causally consistent execution.

Theorem C.2. Snapshots verified by the Acumen snapshot verification algorithm (Figure 3) satisfy Corollary 1 and therefore Definition 1.

Proof Sketch: Lemma C.2 proves the first condition. Lemma C.3 proves the second. □

D Snapdoc's Snapshot Consistency

The full Snapdoc snapshot comprises an operation set O_S and set of state attestations A_S, one per user with at least one operation in O_S. The snapshot verification protocol executes the following high-level steps per user u listed in the snapshot:

1. Using the snapshot operation set O_S and u's version vector VV_u from their state attestation, derive
$$O_S \cap O_u = \{o \in O_S \mid VV_o \leq VV_u\}$$
2. Verify that the derived value for $O_S \cap O_u$ is a subset of O_u using u's state attestation.
3. Verify that the history hashes HH_u are a prefix of the snapshot history hashes (derived from O_S), and conclude that no forks exist between users up to VV_S.

We note that this protocol differs from our high-level approach in that the set of snapshot operations at time VV_u is checked to be a **subset** of O_u, rather than full equality. This is due to the aforementioned edit-history privacy (§5.2) requirement that the sensitive data in operations in $O_S \setminus O_u$ remain hidden. Snapdoc opts to directly withhold these operations from the snapshot.

This difference results in Snapdoc satisfying a weaker form of snapshot consistency, where an attacker can produce a valid snapshot comprised of any subset of the "true" state. For instance, an attacker can issue a snapshot for a document reading "AC" when it should be "ABC". More formally, if S_A is the set of operations in a valid snapshot, then it is possible to create a valid snapshot for any $X \subset S_A$.

Careful readers will notice that any user can locally transform the document with an arbitrary set of operations before creating a snapshot, such that the resulting document is edited to the sender's liking. The resulting snapshot is technically valid, but the key difference to above attack is that the sender edits are *codified as operations* and are visible to the snapshot receiver. This satisfies Definition 1, since these operations are part of a fork-causal consistent execution. This contrasts with the Snapdoc attack, since the deletion of operations is not caused by any operation in the execution. For instance, suppose an honest user issued insertions to create the word "TRAIN". A malicious user could create a snapshot *consisting only of the honest user operations* deriving "RAN", even though this state never appeared in the global causal execution.

Snapdoc requires new users to broadcast a `noop` operation including their own state attestation. The new user will then only accept messages that include the `noop` as a causal dependency. If the user's snapshot is malformed (in a non-trivial way as to pass local verification), they will never process honest user edits, nor will honest users process their updates, as if they were on different causal forks.

This satisfies the overall definition of fork-causal consistency, but is still undesirable since the new user cannot tell that their state is malformed without out-of-band communication from an honest party.

Drs.NAS: Ultra-Efficient Neural Architecture Search for Recommendation Systems

Ruixuan Wang, Xun Jiao
Villanova University

Abstract

Deep learning-based recommendation systems (DRS) have become a dominant workload in hyperscale data centers. However, designing DRS architectures that balance high predictive performance with computational efficiency remains a major challenge due to ever-increasing model complexity and scale. Neural architecture search (NAS) has recently emerged as a promising automated design approach and is now adopted in production by major hyperscalers. Yet, existing NAS methods face two critical limitations: (*i*) prohibitive search costs—often requiring several GPU hours to days—which hinder rapid iteration, and (*ii*) the resulting architectures are typically computation- and memory-intensive, limiting practical deployment. In this paper, we propose Drs.NAS, an *ultra-efficient* NAS framework for DRS. (*i*) **Ultra-efficient search:** We propose a novel metric, *superproxy*, which enables NAS without the costly training and validation required by existing NAS methods. Compared to SOTA NAS search times of $5\sim18$ GPU-hours, Drs.NAS completes the search *within two minutes* on a commodity *CPU*. (*ii*) **Ultra-efficient results:** The models discovered by Drs.NAS drastically reduce resource demands—achieving on average $108.3\times$ and $34.9\times$ smaller model sizes, and $88.8\times$ and $14.7\times$ fewer FLOPs, compared to handcrafted and SOTA NAS results, respectively. Crucially, these gains come *without sacrificing predictive quality*: Drs.NAS delivers on par or even superior predictive performance, surpassing handcrafted and NAS baselines by 0.0123 and 0.0056 in average AUC across three representative benchmarks, respectively.

1 Introduction

Recommendation systems play a crucial role in delivering personalized content across diverse applications, including e-commerce, advertising, social media, and search engines [Zhang et al.(2019), Song et al.(2020), Guo et al.(2017), Song et al.(2019), Zhang et al.(2023)]. With the advent of deep learning, their scale and complexity have grown by more than an order of magnitude since 2017, giving rise to deep learning-based recommendation systems (DRS). Today, DRS workloads have become dominant in hyperscale data centers; for instance, they account for over 70% of all AI inference cycles at Meta's data centers [Gupta et al.(2020)].

While deep learning greatly improves predictive performance by capturing complex multi-modal feature interactions, it also introduces substantial computational demands. These demands strain data center resources and challenge quality-of-service (QoS) requirements, such as tail latency and response time [Berger et al.(2018), Chen et al.(2024)]. Designing efficient architectures for DRS is further complicated by the reliance on manual, domain-expert-driven design, which involves costly and iterative exploration of large architectural design spaces—an approach that does not scale.

To overcome these challenges, neural architecture search (NAS) has emerged as a promising paradigm for automating DRS architecture design and has been adopted in production by several hyperscalers, e.g., Meta [Song et al.(2020), Zhang et al.(2023), Wen et al.(2024)]. NAS effectively explores large design spaces with heterogeneous operators and connection types. For example, AutoCTR [Song et al.(2020)] introduces a hierarchical search space with diverse feature interaction operators, while NASRec [Zhang et al.(2023)] expands the space further by incorporating heterogeneous operations and flexible connection patterns. By leveraging enriched search spaces and automation, NAS methods often achieve state-of-the-art (SOTA) performance across benchmarks, while often reducing model complexity compared to manually designed DRS [Zhang et al.(2023), Song et al.(2020), Zhu et al.(2022)].

Main Challenges: Despite achieving SOTA predictive performance, existing NAS methods for DRS architecture search face two major challenges:

- **Prohibitive search costs:** Current NAS approaches for DRS [Zhang et al.(2023), Song et al.(2020), Zhu et al.(2022)] rely on iterative training and validation cycles to perform the search process. This results in substantial computational overhead, often requiring hours

Table 1: Performance comparison between the SOTA NAS approaches and Drs.NAS over three widely adopted recommendation system benchmarks. **In this paper, the "performance" specifically denotes the model predictive performance**, and Drs.NAS achieves the best or second-best Log Loss (lower is better) and AUC score (higher is better) among all NAS baselines, with significant search cost reduction (from GPU-hours to CPU-minutes) listed in this table and computational overhead reduction of NAS-discovered models as shown in Fig. 4(g) to Fig. 4(l).

	Criteo		Avazu		KDD		Average
	Log Loss↓	AUC↑	Log Loss↓	AUC↑	Log Loss↓	AUC↑	Search Cost
PROFIT [Gao et al.(2021)]	0.4427	0.8095	0.3735	0.7883	-	-	12 hours on GPU
AutoCTR [Song et al.(2020)]	0.4413	0.8104	0.38	0.7791	0.152	0.8011	18 hours on GPU
NAS-CTR [Zhu et al.(2022)]	0.4421	0.8104	0.3754	0.7884	-	-	5.04 hours on GPU
NASRec [Zhang et al.(2023)]	0.4398	0.8116	0.3744	0.7891	0.1491	0.8155	6 hours on GPU
Drs.NAS (proposed)	**0.4404**	**0.8109**	**0.3736**	**0.7905**	**0.1479**	**0.8204**	**1.56 minutes on CPU**

or even days on GPUs. Such costly procedures make NAS time-consuming, resource-intensive, and difficult to scale, thereby hindering the rapid iteration of model architecture design for ever-increasing application tasks.

- **Computation- and memory-heavy architectures:** Existing NAS methods for DRS primarily optimize for predictive performance metrics such as Log Loss or AUC (area-under-curve), while neglecting the computation overhead of the searched architectures, including memory usage (i.e., the number of parameters) and computational cost (i.e., the number of FLOPs).

Our Solution: To overcome these limitations, we propose Drs.NAS, an *ultra-efficient* NAS framework for DRS architecture search. Unlike conventional NAS methods, Drs.NAS avoids the requirement for expensive training and validation of candidate architectures. The key idea is a novel composite metric, *superproxy*, which integrates seven different NAS proxy dimensions as a composite indicator for predictive performance and architectural efficiency. Building on the superproxy, we develop a composite loss function based on the superproxy that allows joint optimization of predictive performance and computational efficiency.

The performance comparison between Drs.NAS and SOTA NAS baselines is indicated in Tab. 1. To the best of our knowledge, Drs.NAS is the first zero-cost proxy-based NAS framework for DRS architecture search that simultaneously delivers three key advantages:

- **Ultra-efficient search:** By leveraging the superproxy, Drs.NAS eliminates the need for costly training and validation during architecture search. As a result, the entire search process completes in *under two minutes* on a commodity *CPU*, compared to $5 \sim 18$ GPU-hours required by SOTA NAS baselines [Gao et al.(2021), Song et al.(2020), Zhu et al.(2022), Zhang et al.(2023)], yielding up to a $692\times$ improvement in search time efficiency.
- **On par or superior predictive performance:** Despite the drastic architecture search efficiency gains, Drs.NAS achieves comparable or better predictive performance. Specifically, Drs.NAS delivers on par or even superior predictive performance and surpasses NAS baselines by 0.0056 in the averaged AUC score.
- **Ultra-efficient architectures:** Drs.NAS enables co-optimization of both predictive performance and computational efficiency. Beyond marginal predictive performance gains, Drs.NAS reduces model size and FLOPs by averages of $34.9\times$ and $14.7\times$, respectively, across three widely adopted recommendation system benchmarks compared to SOTA NAS baselines.

This paper makes the following contributions:

- We propose Drs.NAS, an ultra-efficient NAS framework for DRS. By introducing the superproxy as a composite performance/efficiency indicator, Drs.NAS removes the need for expensive training and validation during search, reducing search time from GPU-hours to CPU-minutes.
- We develop a composite loss function based on superproxies and formulate a multi-objective optimization problem that balances predictive performance and computational efficiency. We solve this optimization problem utilizing a gradient-based search strategy.
- We conduct comprehensive evaluations of both the Drs.NAS framework and the architectures it produces. Results show that Drs.NAS consistently achieves substantial efficiency improvements in computation and memory, while delivering on par or even superior predictive performance compared to handcrafted and NAS baselines on three representative recommendation system benchmarks.

2 Background and Related Work

2.1 Background of DRS Development

DRS are extensively developed and widely adopted in different fields [Guo et al.(2017), Song et al.(2019), Naumov

et al.(2019)]. Specifically, DeepFM [Guo et al.(2017)] integrates factorization machines with neural networks to learn different feature interactions, demonstrating strong performance and efficiency. AutoInt [Song et al.(2019)] leverages the self-attention mechanism and residual connections to capture feature interactions more effectively, and the AutoInt+ [Song et al.(2019)] model further boosts the predictive performance by integrating implicit feature interactions. Moreover, the widely deployed Deep Learning Recommendation Model (DLRM) [Naumov et al.(2019)] employs both dense and sparse features, providing a scalable architecture with high performance.

Despite the mainstream DRS achieving strong performance, these models heavily rely on manual development, requiring substantial domain expertise and interventions. Such manually designed DRS not only increase development cost but also limit the architectural design space exploration, potentially leading to suboptimal performance and inefficient implementation.

2.2 Background of NAS

Weight-Sharing NAS: Weight-sharing NAS approaches [Cai et al.(2019), Zhang et al.(2023), Zhu et al.(2022), Gao et al.(2021)] mitigate the prohibitive computational costs of traditional NAS methods by training a single over-parameterized supernet to represent the entire search space. A search algorithm, such as the evolutionary algorithm (EA), is then employed to select the best-performing subnet [Cai et al.(2019),Zhang et al.(2023)]. Despite being widely applied for DRS architecture search, training the supernet requires substantial computational resources, and each subnet often requires iterative validation and fine-tuning, both of which are time-consuming and computationally expensive.

Hardware-aware NAS: Hardware-aware NAS methods integrate execution latency into the search objective to discover computationally efficient and high-performance architectures on target devices [Wu et al.(2019), Cai et al.(2018), Gao et al.(2025)]. However, most existing approaches depend on latency profiling or auxiliary latency prediction models, which introduce additional measurement complexity and computational overhead. Moreover, conventional hardware-aware NAS methods still require training large supernets, resulting in substantial search costs.

Zero-cost proxy-based NAS: In parallel, to reduce search cost, the zero-cost proxy-based NAS strategy utilizes saliency metrics to estimate the performance of DNN models without any training [Li et al.(2023), Abdelfattah et al.(2021), Jiang et al.(2023)]. These proxies are computed on model weights, activations, or gradients using a single forward and backward propagation and aggregated across all model parameters to approximate predictive performance. While highly efficient, existing zero-cost proxies were primarily developed for CNN and Transformer architectures [Abdelfattah et al.(2021), Li et al.(2023), Mellor et al.(2021), Jiang et al.(2023), Zhou et al.(2024)], and their applicability to DRS architectures, characterized by dense/sparse operations and corresponding feature interactions, remains largely unexplored. In addition, prior methods mainly focus on model accuracy, with limited attention to jointly optimizing predictive performance and computational efficiency [Abdelfattah et al.(2021), Li et al.(2023), Jiang et al.(2023)]. Furthermore, recent studies show that no individual proxy generalizes reliably across tasks and benchmarks [Abdelfattah et al.(2021), Huang et al.(2024), Cortês et al.(2025)], inspiring the ensemble design that aggregates multiple proxies in the NAS methods for more robust performance estimation.

2.3 NAS for DRS

The NAS methods have emerged as a promising strategy for automating the development of DRS architectures, demonstrating strong performance on various recommendation system benchmarks. In particular, PROFIT [Gao et al.(2021)] proposes a progressive differentiable NAS algorithm to discover optimal feature-interaction layers in deep sparse networks, using a low-rank approximated search space. AutoCTR [Song et al.(2020)] utilizes evolutionary algorithms to automatically explore the effective feature interaction architectures in a graph-based search space. NAS-CTR [Zhu et al.(2022)] further integrates architecture optimization with parameter learning via a differentiable NAS method. More recently, NASRec [Zhang et al.(2023)] adopts the weight-sharing NAS paradigm and substantially broadens the search space by incorporating heterogeneous operators such as sigmoid gating [Wang et al.(2021)] and transformer-based modules [Vaswani et al.(2017)], achieving promising performance on multiple benchmarks.

However, prior NAS approaches remain computationally intensive and time-consuming, often requiring substantial GPU resources for architecture search, while the discovered architectures can be resource-intensive and costly to deploy, making these NAS methods impractical for real-world deployment. Moreover, as observed in recent industrial studies [Wen et al.(2024)], NAS for DRS becomes an iterative execution in the recurring engineering cycle to continuously battle the dynamic baselines instead of a one-time investment per task. Therefore, reducing per-task search time and the inference cost of searched architectures is critical to making automated architecture optimization practically deployable.

To overcome these limitations, Drs.NAS introduces a superproxy that comprises seven zero-cost proxies as a performance/efficiency indicator to guide DRS architecture search, which can eliminate the requirement for supernet training or subnet fine-tuning and discover architectures with strong predictive performance and high computational efficiency. While individual zero-cost proxies have been explored in other domains, the strategic composition of the superproxy in NAS

for DRS represents a significant and non-trivial advancement.

3 Proposed Approach: Drs.NAS

3.1 Drs.NAS Overview

Fig. 1 presents the overview of Drs.NAS framework, which is mainly composed of four major phases. In phase 1 (Sec. 3.2), we propose and formulate the superproxy metric, which maps each candidate operator to a seven-dimensional proxy representation. In phase 2 (Sec. 3.3), we construct a graph-based search space built on top of the computed superproxies, where vertices represent candidate layers and edges represent candidate dataflows. This search space eliminates the requirement of expensive training and validation of candidate architectures based on superproxies. In phase 3 (Sec. 3.4), we relax the discrete graph search space, using Gumbel-Softmax, to enable a differentiable NAS process. Finally, in phase 4 (Sec. 3.5), we formulate a multi-objective optimization problem over the relaxed space and develop a composite loss that balances predictive performance and computational efficiency. We utilize a gradient-based method to solve the optimization and discover the optimal model architecture.

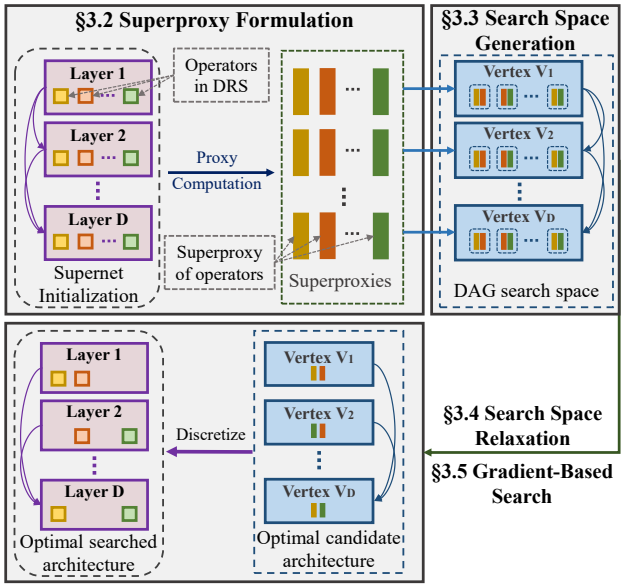

Figure 1: The overview of Drs.NAS framework for the DRS architecture search, consisting of four sequential phases.

3.2 Superproxy Formulation

In Drs.NAS, we focus on two types of zero-cost proxies: the overhead-relevant proxy, which is correlated with the model size and computational overhead, and the overhead-irrelevant proxy, which reflects the model performance and trainability. We initialize a supernet following NASRec [Zhang et al.(2023)], and compute the corresponding proxies. By ensembling these proxies, the superproxy serves as the performance and efficiency indicator, guiding the optimization toward improved predictive performance while regularizing the stability of the gradient-based search process.

3.2.1 Overhead-relevant Proxy

First of all, we consider two standard proxies: the number of parameters (#Params) and FLOPs (#FLOPs). These proxies are generally highly connected with the model size and computational overhead, while the #Params and #FLOPs are also widely utilized proxies in prior NAS methods [Li et al.(2023), Jiang et al.(2023), Lin et al.(2020)] as model performance indicators. The #Params and #FLOPs for weight matrix θ are indicated in Eq. (1). Here, the $Numel(\theta)$ indicates the total number of elements in the weight matrix θ, and X is a subset of randomly selected training samples.

$$S_{param}(\theta) = Numel(\theta);\ S_{flops}(\theta) = FLOPs(\theta; X) \quad (1)$$

We also include the weight norm (w_{norm}) and the gradient norm (g_{norm}) proxies, defined as the Frobenius norm of the weight matrix θ and the corresponding gradients, respectively. These proxies are correlated with the parameter counts and are widely adopted for efficient NAS [Lukasik et al.(2025), Abdelfattah et al.(2021)]. The computation of the w_{norm} and g_{norm} proxies for the weight matrix θ is shown in Eq. (2).

$$S_{w_{norm}}(\theta) = \|\theta\|_F;\ S_{g_{norm}}(\theta) = \left\| \frac{\partial L}{\partial \theta} \right\|_F \quad (2)$$

3.2.2 Overhead-irrelevant Proxy

Additionally, we incorporate the well-established zero-cost proxies that are leveraged to estimate the predictive performance and trainability of DNN models directly from the model initializations [Li et al.(2023), Jiang et al.(2023), Tanaka et al.(2020), Abdelfattah et al.(2021)]. These proxies are not strongly correlated with model size and computational overhead. Specifically, we leverage the zico [Li et al.(2023)], synflow [Tanaka et al.(2020)], and meco [Jiang et al.(2023)] proxies in Drs.NAS.

Zico captures the relationship between the gradient statistics of the weight matrix θ, such as the mean and standard deviation of the corresponding gradient, and the trainability and generalization capacity of the DNN models. The zico proxy computation of θ is demonstrated in Eq. (3).

$$S_{zico}(\theta) = \log\left(\frac{\mathcal{E}[|\partial L/\partial \theta|]}{\sqrt{Var(|\partial L/\partial \theta|)}} \right) \quad (3)$$

Synflow utilizes the Hadamard product of the model weight θ and the corresponding gradients to represent the contribution of each weight matrix θ within the computational flow of

the entire DNN model. The computation of the synflow proxy for θ is denoted as Eq. (4).

$$S_{syn}(\theta) = \frac{\partial L}{\partial \theta} \circ \theta \tag{4}$$

Meco computes the Pearson correlation matrix $P(\cdot)$ of feature maps $\mathcal{F}$ derived from the model weight matrix θ and relates the minimum eigenvalue of the correlation matrix to the model accuracy and trainability. The meco proxy computation for weight matrix θ is shown as Eq. (5), where $\lambda_{\min}(\cdot)$ represents the minimum eigenvalue.

$$S_{meco}(\theta) = \lambda_{\min}(P(\mathcal{F}(X;\theta))) \tag{5}$$

To construct the operator-level superproxy, we first compute the seven different proxies for each weight matrix θ within an operator, ranging from S_{param} to S_{meco}. Then we sum the corresponding proxies across all weight matrices in that operator. For instance, the S_{param} for operator o is computed as $S_{param}(o) = \sum_{\forall \theta \in o} S_{param}(\theta)$. Finally, we concatenate these seven different operator-level proxies into a 7-dimensional tensor, defined as $\mathcal{S}_o \in \mathbb{R}^7$ in Eq. (6), which represents the superproxy of operator o.

$$\mathcal{S}_o = [S_{param}(o), S_{flops}(o), \ldots, S_{zico}(o), S_{meco}(o)] \tag{6}$$

This superproxy integrates information from multiple proxies of the operator to estimate the performance of different candidate architectures and discover the optimal architectures within the search space, eliminating the need for supernet training and candidate architecture validation. Notably, we hypothesize that overhead-relevant proxies can serve as indicators of model capacity and expressive ability in the domain of DRS. Intuitively, we interpret that higher values of overhead-relevant proxies correlate with improved predictive performance, while potentially increasing the computational overhead of candidate architectures. To counterbalance this effect, we further incorporate the overhead-irrelevant proxies, which are weakly correlated with model size but remain informative of trainability and predictive performance, as regularizers within the composite loss function (detailed in Sec. 3.5) to stabilize the optimization process. By integrating these proxies, we enable joint optimization that balances both predictive performance and computational efficiency.

3.3 Search Space Generation

Drs.NAS constructs a directed acyclic graph (DAG) as the search space using the superproxy $\mathcal{S}$ computed from the supernet initialization. Following the design in [Zhang et al.(2023)], in each layer of a candidate architecture, Drs.NAS selects one dense operator, one sparse operator, and the corresponding feature fusion operators from a heterogeneous operator set. The search space additionally permits arbitrary connections between any pair of layers.

In particular, for dense operators, we include the fully connected (FC), sigmoid gating [Chen et al.(2019), Wang et al.(2021)], summation, and dot-product [Cheng et al.(2016), Zhang et al.(2024), Naumov et al.(2019)], while for sparse operators we utilize the Embedded FC and transformer [Song et al.(2019), Vaswani et al.(2017)] operators in Drs.NAS. Furthermore, Drs.NAS incorporates two feature fusion strategies, as adopted in prior work [Zhang et al.(2023)], to enhance the feature interaction between dense and sparse outputs. Drs.NAS leverages both dense-to-sparse and sparse-to-dense feature fusion. The dense-to-sparse feature fusion first transforms the dense tensor through FC and concatenates the resulting output with the sparse tensor, while the sparse-to-dense feature fusion projects the sparse tensor into the dense feature space based on Factorization Machine (FM) [Guo et al.(2017), Rendle(2010)] and sums the resulting output with the dense tensor. Together, these operators cover a wide range of computation modules in modern DRS.

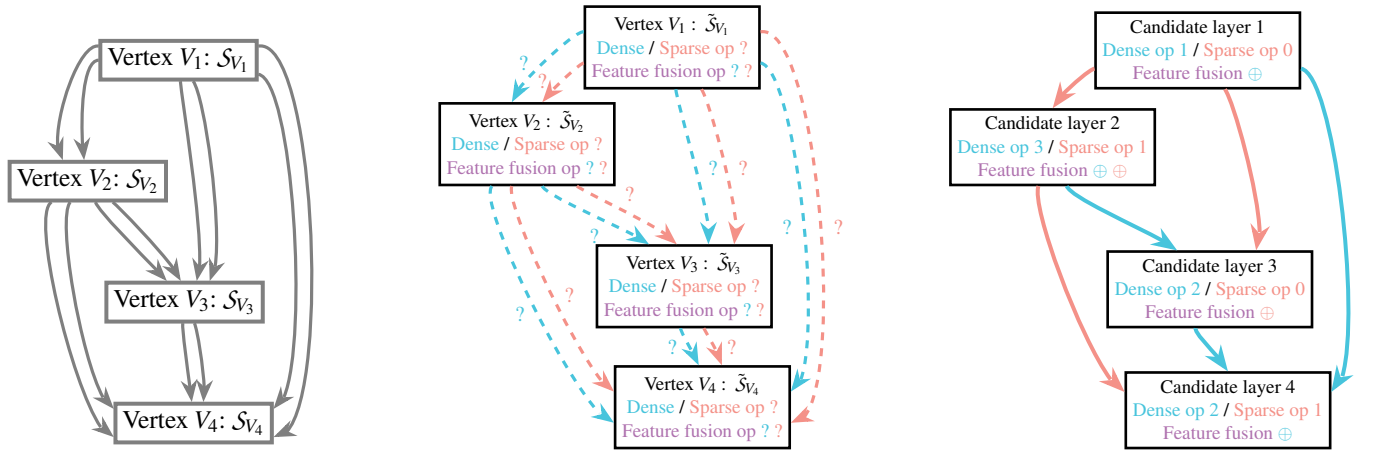
Fig. 2(a) illustrates an example four-layer DAG search space. Formally, the DAG search space is defined as $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. The vertex set $\mathcal{V} = [V_1, \ldots, V_\mathcal{D}]$ contains $\mathcal{D}$ vertices, corresponding to the $\mathcal{D}$ layers in supernet. Each vertex V_i includes p candidate layers at layer i, denoted as $V_i = [v_1, v_2, \ldots, v_p]$, where each candidate layer v_i denotes a specific combination of one dense operator, one sparse operator, and the associated feature fusion.

The superproxy of a candidate layer $\mathcal{S}_{v_i}$ is defined as the element-wise sum of the superproxies of all operators and feature interactions $\mathcal{S}_o$ within that candidate layer: $\mathcal{S}_{v_i} = \sum_{\forall o \in v_i} \mathcal{S}_o$. The superproxy of the vertex $\mathcal{S}_{V_i}$ is then represented as the concatenation of the superproxies of all candidate layers, denoted as $\mathcal{S}_{V_i} = [\mathcal{S}_{v_1}, \mathcal{S}_{v_2}, \ldots, \mathcal{S}_{v_p}]$, where $\mathcal{S}_{V_i} \in \mathbb{R}^{p \times 7}$.

In the meantime, the edge set $\mathcal{E} = [E_1, \ldots, E_\mathcal{D}]$ represents the data flow connections within the supernet, where E_i denotes the set of all candidate incoming edges (in-edges) of the vertex at layer i. The superproxy $\mathcal{S}_e$ for candidate in-edge $e \in E_i$ is computed by the element-wise sum of the superproxy of the source candidate layer $v_s \in V_{j<i}$ and the superproxy of the target candidate layer $v_t \in V_i$ in the DAG search space.

3.4 Search Space Relaxation

Based on the defined DAG search space, Drs.NAS formulates the architecture search problem as candidate architecture sampling over the DAG. The search objective is to discover an optimal candidate architecture by selecting one candidate layer per vertex and a subset of candidate in-edges from the search space. However, directly optimizing over the discrete DAG is non-trivial due to its non-differentiable nature. To address this challenge, Drs.NAS employs continuous relaxation over the DAG search space based on the Gumbel-Softmax [Jang et al.(2016), Maddison et al.(2016)], a strat-



(a) **DAG Search Space** constructed based on superproxies

(b) **Relaxed DAG search space** based on Gumbel-Softmax

(c) **Discretized candidate architecture** from relaxed DAG search space

Figure 2: Illustration of the DAG search space construction, search space relaxation, and sampled candidate architecture in Drs.NAS, utilizing a four-layer architecture as an example

egy widely adopted in differentiable NAS methods [Chang et al.(2019), Xie et al.(2018)], to enable smooth architecture sampling from the discrete DAG.

Formally, let V_i and E_i denote the set of candidate layers and candidate in-edges at layer i. Each candidate layer $v \in V_i$ and candidate in-edge $e \in E_i$ is assigned with a learnable weight parameter, defined as $w_v, w_e \in \mathcal{W}$. The smooth architecture sampling in Drs.NAS includes two components. Firstly, the edge sampling is performed over candidate in-edges E_i iteratively across each layer utilizing Gumbel-Softmax relaxation, as indicated in Eq. (7). Here, the g indicates the Gumbel noise $g \sim Gumbel(0,1)$, and the τ represents the temperature parameter controlling the smoothness of the sampling in the Gumbel-Softmax.

$$\tilde{\mathcal{S}}_E = \sum_{e \in E_i} \frac{\exp\left(\frac{w_e + g_e}{\tau}\right)}{\sum_{e' \in E_i} \exp\left(\frac{w_{e'} + g_{e'}}{\tau}\right)} \mathcal{S}_E \tag{7}$$

Secondly, a similar Gumbel-Softmax relaxation is deployed over candidate layers v_i iteratively across each vertex, and the vertex sampling is performed as Eq. (8). The relaxed search space is illustrated in Fig. 2(b), enabling the joint sampling of the candidate layers and in-edges. Notably, the architecture sampling strategy mainly focuses on the selection of candidate layers and in-edges and ensures valid forward paths without requiring additional graph-level constraints.

$$\tilde{\mathcal{S}}_V = \sum_{v \in V_i} \frac{\exp\left(\frac{w_v + g_v}{\tau}\right)}{\sum_{v' \in V_i} \exp\left(\frac{w_{v'} + g_{v'}}{\tau}\right)} \mathcal{S}_V \tag{8}$$

After the architecture sampling, the candidate architecture refers to $\mathcal{G}_{\mathcal{A}} \subset \mathcal{G}$. The discrete candidate architecture can be obtained through architecture discretization based on the weight parameters $\mathcal{W}$, as illustrated in Fig. 2(c). For vertex discretization, Drs.NAS selects the optimal candidate layer $\tilde{\mathcal{S}}_v$ with the highest candidate layer weight from each vertex V_i, i.e., $argmax_{v \in V_i}(w_v)$. For edge discretization, Drs.NAS sets a fixed threshold d to determine the optimal candidate in-edges and selects the edges with the top d candidate in-edge weights w_e from the candidate in-edges set E_i. Here, we define the threshold $d = 50\%$ to balance the trade-off between model complexity and computational efficiency.

3.5 Gradient-Based Search

To discover the optimal architecture with both predictive performance and computational efficiency, we develop a composite loss function based on the superproxy and define the architecture search loss $\mathcal{L}_{\mathcal{A}}$ that jointly optimizes three objectives, as formulated in Eq. (9). Similar to prior research [Liu et al.(2018), Wu et al.(2019)], we adopt a gradient-based approach to solve this co-optimization problem.

$$\mathcal{L}_{\mathcal{A}} = \lambda_1 * \mathcal{L}_{vertex} + \lambda_2 * \mathcal{L}_{edge} + \lambda_3 * \mathcal{L}_{cost} \tag{9}$$

In Eq. (9), we define the three components in the composite loss function corresponding to the selection of candidate layers, the connection of candidate in-edges, and the computational cost of the candidate architecture, respectively. In particular, $\mathcal{L}_{vertex}$ encourages effective operators in each candidate layer to achieve high performance. $\mathcal{L}_{edge}$ regularizes the data flow of in-edges within the architecture. $\mathcal{L}_{cost}$ controls the computational overhead by penalizing architectures that introduce high computational overhead.

In Drs.NAS, within $\mathcal{L}_{vertex}$ and $\mathcal{L}_{edge}$, we encourage the selection of architectures with high overhead-relevant proxies

to maximize the overall predictive performance, motivated by the insight that overhead-relevant proxies are strongly correlated with predictive performance and trainability [Li et al.(2023)]. However, this strategy may induce increased memory and computational overhead. To counterbalance this effect, we incorporate the overhead-irrelevant proxies as the regularizer to stabilize the optimization process.

Formally, let $\mathcal{V}_{\mathcal{A}}$ and $\mathcal{E}_{\mathcal{A}}$ denote the set of all candidate layers and candidate in-edges within the candidate architecture. $\tilde{\mathcal{S}}^{\mathcal{R}}$ and $\tilde{\mathcal{S}}^{I}$ represent subsets of superproxy $\tilde{\mathcal{S}}$, where $\tilde{\mathcal{S}}^{\mathcal{R}}$ contains the overhead-relevant proxies indexed by $\mathcal{R}$ and $\tilde{\mathcal{S}}^{I}$ includes the overhead-irrelevant proxies indexed by I. The computation of $\mathcal{L}_{vertex}$ is indicated in Eq. (10). In $\mathcal{L}_{vertex}$, we employ the parameter related overhead-relevant proxies $\mathcal{R}_v = \{S_{param}, S_{g_{norm}}, S_{w_{norm}}\}$, while using all the overhead-irrelevant proxies $I_v = \{S_{syn}, S_{zico}, S_{meco}\}$ as regularizer.

$$\mathcal{L}_{vertex} = \sum_{v \in \mathcal{V}_{\mathcal{A}}} \rho_v \left[\tilde{\mathcal{S}}_v^{I_v} - \tilde{\mathcal{S}}_v^{\mathcal{R}_v} \right] \tag{10}$$

Additionally, we compute the $\mathcal{L}_{edge}$ based on the superproxies of the candidate in-edges. Here, we mainly focus on the data flow and gradient flow related proxies in $\mathcal{L}_{edge}$, such as $\mathcal{R}_e = \{S_{g_{norm}}\}$, and overhead-irrelevant proxies $I_e = \{S_{syn}, S_{zico}\}$ as the regularizer in this loss function to optimize the data and gradient propagation within the candidate architecture. The computation of $\mathcal{L}_{edge}$ is denoted as Eq. (11).

$$\mathcal{L}_{edge} = \sum_{e \in \mathcal{E}_{\mathcal{A}}} \rho_e \left[\tilde{\mathcal{S}}_e^{I_e} - \tilde{\mathcal{S}}_e^{\mathcal{R}_e} \right] \tag{11}$$

Last but not least, we define the loss function for the computational overhead, $\mathcal{L}_{cost}$, which integrates both computational and memory usage. We define the $\mathcal{L}_{cost}$ as indicated in Eq. (12), incorporating the #FLOPs and #Params of the candidate architecture. The $degree(\cdot)$ is utilized as a layer-specific normalizer for distinguishing the contribution of different layers. Based on our definition, high #Params encourages the candidate architecture to have better predictive performance and trainability, while high #FLOPs are penalized to promote model computational efficiency. In $\mathcal{L}_{cost}$, we assign equal weight to #FLOPs and #Params, enabling a balance between computational efficiency and predictive performance during the architecture search process.

$$\mathcal{L}_{cost} = \sum_{v \in \mathcal{V}_{\mathcal{A}}} degree(v) \cdot \left[\tilde{\mathcal{S}}_v^{flops} - \tilde{\mathcal{S}}_v^{param} \right] \tag{12}$$

It is worth mentioning that the hyperparameters $\lambda = [\lambda_1, \lambda_2, \lambda_3]$ and $\rho = \{\rho_v, \rho_e\}$ are trainable weighting parameters that dynamically balance the contribution of each component during optimization without manual fine-tuning. To avoid any single loss function from being disregarded, we normalize the learnable parameters λ and ρ via softmax. In Drs.NAS, we utilize a gradient-based optimization strategy to minimize the $L_{\mathcal{A}}$, as illustrated in Algorithm 1, and discover the corresponding optimal architecture.

Algorithm 1 Gradient-based search in Drs.NAS

Input: Given DAG search space $\mathcal{G} = (\mathcal{V}, \mathcal{E})$
Input: Architecture Sampler $Sampler(\mathcal{W}, \rho, \lambda)$
Output: Optimal candidate architecture $\mathcal{G}_{\mathcal{A}} = (\mathcal{V}_{\mathcal{A}}, \mathcal{E}_{\mathcal{A}})$

4 Experimental Setup

4.1 Evaluation Benchmarks and Metrics

Following prior work [Song et al.(2020), Zhang et al.(2023)], we evaluate Drs.NAS on three representative real-world recommendation system benchmarks, including Criteo [Tien et al.(2014)], Avazu [Wang and Cukierski(2014)], and KDD [Aden and Wang(2012)]. We select these benchmarks for two primary reasons: (1) they are standard public benchmarks for Click-Through Rate (CTR) prediction, widely adopted across both academia and industry research settings; and (2) they are consistently used in prior studies, enabling direct and fair comparisons with existing work. We adopt the standard preprocessing procedures from [Song et al.(2020), Zhang et al.(2023)] to ensure consistency across different models. The statistical information of the three benchmarks is summarized in Tab. 2.

Table 2: Statistics for three representative recommendation system benchmarks, detailing the number of dense and sparse features alongside the total number of samples.

Benchmark	# Dense	# Sparse	# Samples
Criteo	13	26	45,840,617
Avazu	0	23	40,428,967
KDD	3	10	149,639,104

To systematically evaluate the performance and efficiency of Drs.NAS searched architectures, we leverage four widely adopted metrics. For the predictive performance, we evaluate **Log Loss** and **AUC score**. For memory and computational efficiency, we measure the model size **#Params** and computational costs **#FLOPs**. In general, better performance corresponds to lower Log Loss and higher AUC score, while better efficiency is indicated by lower #Params and #FLOPs.

Note that Drs.NAS focuses on neural architecture design, namely searching for effective backbone structures that determine how feature representations are combined and transformed to produce predictions, which is consistent with prior work [Zhang et al.(2023),Zhu et al.(2022)]; the embedding tables are fixed and not part of the search space. In fact, the size of embedding tables is determined by the dataset-specific configurations rather than architectural decisions, because they are used to encode categorical input features. In short, we measure model size and computational cost primarily based on the searched backbone architectures.

4.2 Drs.NAS Implementation

In this study, all experiments are implemented based on PyTorch [Paszke et al.(2019)]. For superproxy computation, we randomly select 2,048 samples (one batch) from the training set and utilize the binary cross-entropy (BCE) loss function to compute the gradient-related proxies, such as $S_{g_{norm}}$ and S_{zico}. Architecture #FLOPs are measured using DeepSpeed [Rasley et al.(2020)] and FvCore [Facebook Research(2022)]. To handle the scale differences among proxies, we apply logarithmic transformations to #Params and #FLOPs and z-score normalization to other proxies in the superproxy. Following previous differentiable NAS studies [Zhu et al.(2022),Liu et al.(2018)], we utilize the Adam optimizer [Kingma and Ba(2014)] with learning rate from {0.02, 0.05, 0.1, 0.2, 0.5}. Due to the ultra-efficient search (minutes on CPU), early stopping is unnecessary, and we run all the architecture search experiments for $N = 10000$ iterations across all benchmarks.

To comprehensively evaluate the scalability of architectures searched by Drs.NAS, we consider different model depths $\mathcal{D} \in \{5,6,7,8,9\}$. In contrast to conventional NAS approaches that typically rely on coarse-grained dimension sets [Song et al.(2020),Zhang et al.(2023),Zhu et al.(2022)], such as sparse integers in {16, 32, 64, 128}, we select hidden dimensions from a fine-grained set of consecutive integers ranging from 4 to 32, resulting in a significantly expanded but more flexible search space. The fine-grained architecture search space allows Drs.NAS to better balance the trade-off between model predictive performance and computational efficiency on different benchmarks.

Furthermore, we conduct the architecture search experiments based on two different search space configurations, following the definition in NASRec [Zhang et al.(2023)]. The "Search space - Small" includes two dense operators (FC and Dot-Product) and one sparse operator (Embedded FC), while the full search space, indicated as "Search space - Full", consists of all four dense operators and two sparse operators mentioned in Sec. 3.3. Both "Search space - Small" and "Search space - Full" search spaces include the dense-to-sparse and sparse-to-dense feature fusion operators.

All the Drs.NAS architecture search processes are conducted on an AMD Ryzen 5975WX CPU. After Drs.NAS produces the optimal DRS architectures, we evaluate these architectures on an NVIDIA A6000 GPU to validate the performance of the resulting models across different benchmark datasets and architecture search configurations.

5 Evaluation

Based on our experimental setup, we investigate the following key research questions (RQs). Specifically, we explore:

- **RQ1**: How much improvement does Drs.NAS provide in the search efficiency and search cost compared with the SOTA NAS baseline approaches [Gao et al.(2021),Song et al.(2020),Zhu et al.(2022),Zhang et al.(2023)]?
- **RQ2**: How much improvement in predictive performance do Drs.NAS searched architectures provide compared with handcrafted [Guo et al.(2017),Song et al.(2019),Naumov et al.(2019)] and NAS baselines across different benchmarks?
- **RQ3**: How much improvement in computational and memory efficiency do Drs.NAS searched architectures provide compared with handcrafted and NAS baselines across different benchmarks?

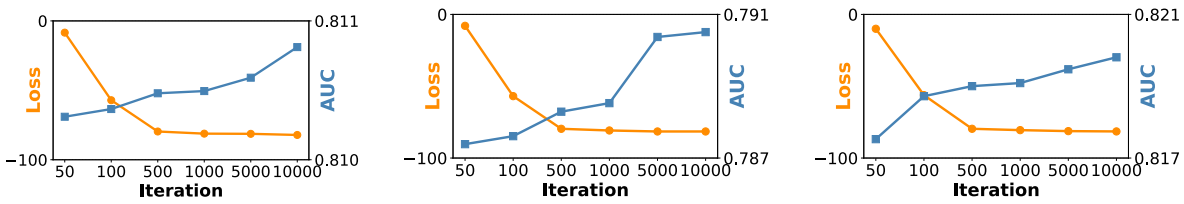
Furthermore, we investigate:

- **RQ4**: How consistent and robust are the Drs.NAS searched architectures under different search space configurations and hyperparameter selections, from both the performance and efficiency perspectives?

5.1 Search Efficiency Evaluation

Answering RQ1: Drs.NAS presents an ultra-efficient search procedure compared with SOTA NAS approaches by providing up to 692× faster NAS process, reducing search cost from GPU-hours to CPU-minutes.

As indicated in Tab. 1, Drs.NAS outperforms all the NAS baselines in the search efficiency. In particular, compared with SOTA NAS approaches including PROFIT [Gao et al.(2021)], AutoCTR [Song et al.(2020)], NAS-CTR [Zhu et al.(2022)], and NASRec [Zhang et al.(2023)], Drs.NAS achieves 461×, 692×, 193× and 230× search time reduction, averaged over three benchmark datasets.



(a) Criteo (b) Avazu (c) KDD

Figure 3: The optimization curve of loss $\mathcal{L}_A$ (●) and the AUC score curve (■) of corresponding candidate architecture during Drs.NAS architecture search process across three benchmarks.

Meanwhile, Drs.NAS requires substantially less computational resources for architecture search. Prior NAS approaches involved the supernet training and fine-tuning procedure of candidate architectures that required significant computation and GPU memory. For instance, NASRec [Zhang et al.(2023)] utilizes over 16 GB of GPU memory for the supernet training and more than 20 GB for the NAS process on the KDD benchmark. In contrast, Drs.NAS performs the NAS process on a commodity CPU only, without GPU acceleration, denoting a dramatic reduction in memory usage and computational cost.

According to our analysis, the improved efficiency of Drs.NAS can be attributed to the superproxy-based performance estimation, which eliminates the requirement for massive training of the supernet and iterative training and validation of candidate architectures [Zhang et al.(2023)]. As a result, Drs.NAS utilizes the superproxies as performance indicators to guide the selection of candidate architectures by minimizing the architecture search loss and significantly reducing the architecture search costs.

Furthermore, we visualize the optimization curve of architecture search loss in Drs.NAS and the corresponding performance of candidate architectures, as illustrated in Fig. 3(a) to Fig. 3(c). Here we select the learning rate of 0.02 and model depth $\mathcal{D} = 9$ in this case study. Six milestone iterations $\{50, 100, 500, 1000, 5000, 10000\}$ are selected to evaluate both the architecture search loss $\mathcal{L}_\mathcal{A}$ and the AUC score of the corresponding candidate architectures. Notably, at early iterations, the AUC scores remain low across different benchmarks, as the initial architectures are randomly sampled from the search space without optimization. As composite loss decreases across optimization steps, the validation AUC of candidate architectures exhibits monotonic improvement. These evaluation results provide potential support for the effectiveness of the gradient-based search in Drs.NAS.

5.2 Model Predictive Performance Evaluation

Answering RQ2: Drs.NAS demonstrates on par or even superior predictive performance compared with the SOTA NAS baselines, across three widely adopted benchmarks.

The performance evaluation of various DRS is presented in Fig. 4(a) to Fig. 4(f). In our experiment, we compare the Log Loss and AUC score of Drs.NAS searched architectures with mainstream handcrafted and SOTA NAS approaches.

In CTR prediction tasks, a 0.001-level improvement in AUC or Log Loss can lead to a substantial impact on the overall performance [Zhu et al.(2022), Song et al.(2020)]. In particular, Drs.NAS searched architectures consistently achieve better predictive performance than the mainstream handcrafted baselines [Guo et al.(2017), Song et al.(2019), Naumov et al.(2019)] and achieve 0.0028, 0.0078, and 0.0046 of averaged Log Loss reduction on the Criteo, Avazu, and KDD benchmark datasets, respectively. Furthermore, across the SOTA NAS approaches [Gao et al.(2021), Song et al.(2020), Zhu et al.(2022), Zhang et al.(2023)], Drs.NAS achieves competitive Log Loss, with 0.0011, 0.0022, and 0.0026 averaged Log Loss reduction on the three benchmarks, respectively.

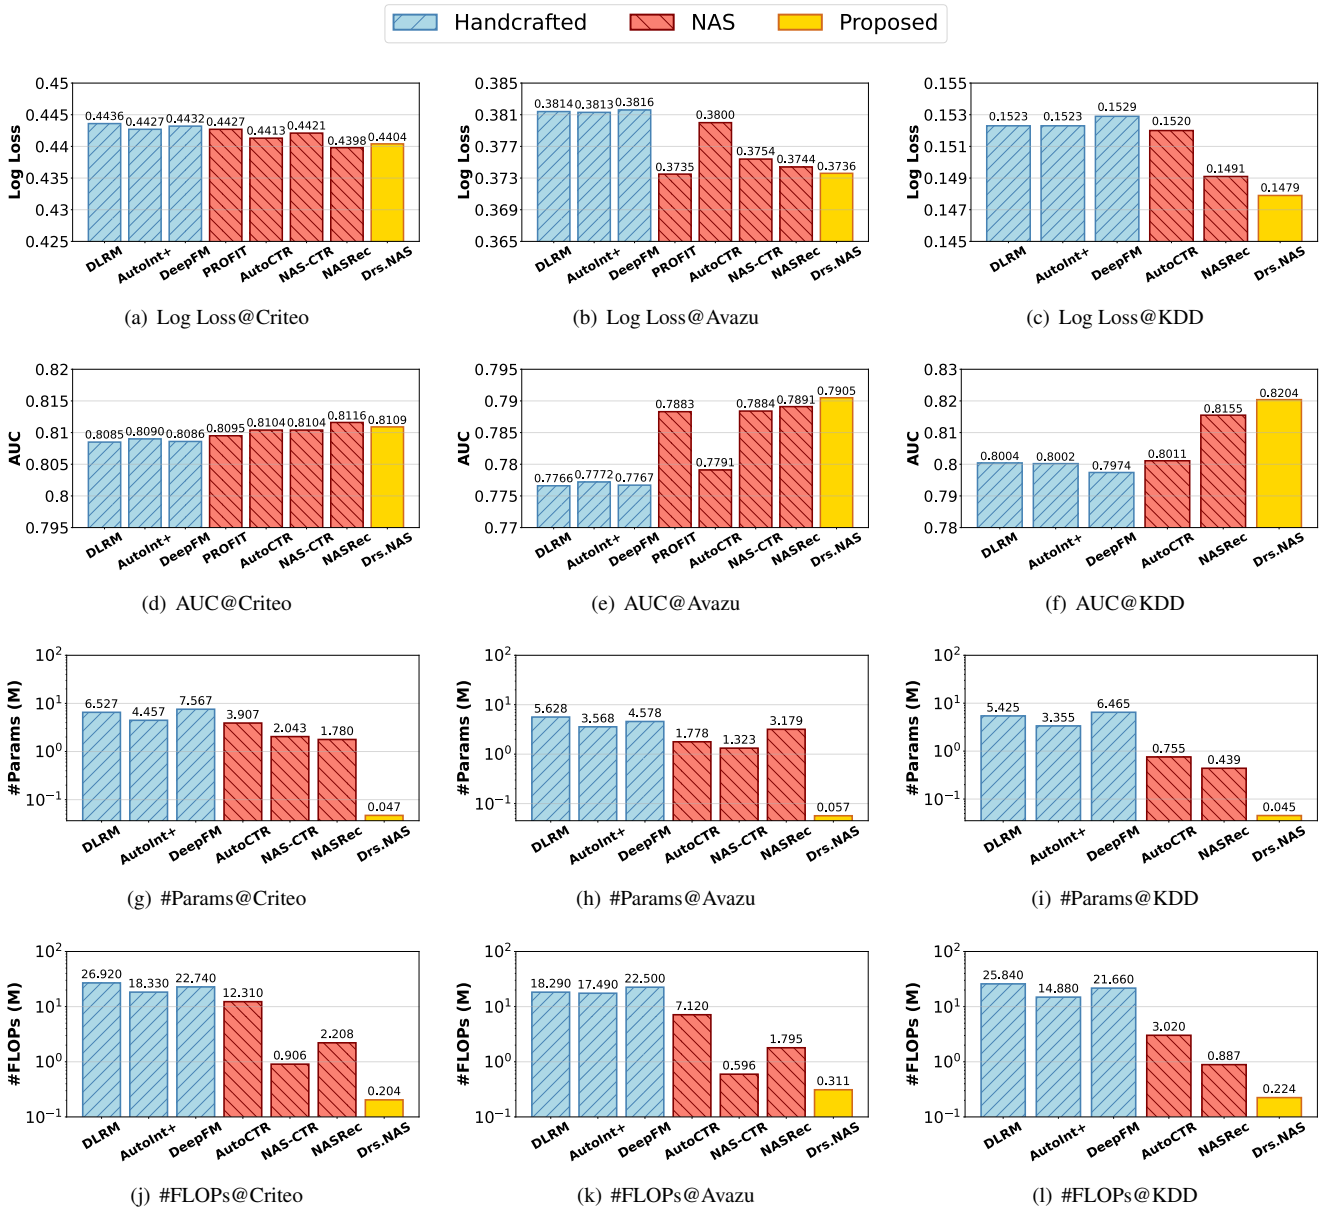
Meanwhile, regarding the AUC score, Drs.NAS achieves better predictive performance than all the mainstream handcrafted baselines by achieving 0.0022, 0.0137, and 0.0211 averaged AUC score improvements on the three benchmark datasets. Furthermore, Drs.NAS searched architectures achieve 0.0004, 0.0043, and 0.0121 of averaged AUC score improvements over the SOTA NAS baselines, on the three benchmarks, respectively. Our experimental results show the effectiveness of Drs.NAS in discovering the high-performing architectures for DRS.

5.3 Model Efficiency Evaluation

Answering RQ3: Drs.NAS searched architectures demonstrate substantial efficiency improvements in both computation and memory compared to SOTA NAS baselines, achieving, on average, 34.9× smaller model size and 14.7× fewer #FLOPs across three benchmarks.

The evaluation results of inference costs are illustrated in Fig. 4(g) to Fig. 4(l). In this section, we compare the #Params and #FLOPs of the optimal architectures with handcrafted and NAS baselines to comprehensively evaluate the memory and computational efficiency of Drs.NAS searched architectures.

Based on the experimental results, Drs.NAS consistently achieves better memory and computational efficiency than the



(a) Log Loss@Criteo (b) Log Loss@Avazu (c) Log Loss@KDD

(d) AUC@Criteo (e) AUC@Avazu (f) AUC@KDD

(g) #Params@Criteo (h) #Params@Avazu (i) #Params@KDD

(j) #FLOPs@Criteo (k) #FLOPs@Avazu (l) #FLOPs@KDD

Figure 4: Evaluation of the optimal architecture searched by Drs.NAS against handcrafted and NAS baselines on three benchmarks, based on Log Loss (↓), AUC score (↑), #Params (↓), and #FLOPs (↓).

baselines across all benchmarks. For the evaluation of model efficiency, we focus primarily on the DRS architectures and exclude the parameters in embedding tables for a fair comparison, following previous works [Song et al.(2020), Zhu et al.(2022), Zhang et al.(2023)]. On average, compared with handcrafted baselines [Guo et al.(2017), Song et al.(2019), Naumov et al.(2019)], Drs.NAS reduces the #Params by 131.6×, 80.5×, and 112.9× on the three benchmarks. Additionally, compared with the SOTA NAS baselines [Gao et al.(2021), Song et al.(2020), Zhu et al.(2022), Zhang et al.(2023)], Drs.NAS achieves 54.8×, 36.7×, and 13.3× averaged #Params reduction across all NAS baselines on Criteo, Avazu, and KDD benchmarks, respectively. In parallel, for computational efficiency, Drs.NAS provides 111.1×, 62.5×, and 92.8× averaged #FLOPs reduction across the handcrafted baselines, and 25.2×, 10.2×, and 8.7× averaged #FLOPs reduction across the NAS baselines, on the three benchmark datasets, respectively.

Our analysis attributes the significant improvement to the cooperation between the fine-grained search space design and the cost-aware optimization. Different from conventional NAS approaches [Song et al.(2020), Zhang et al.(2023)]

that utilize coarse-grained hidden dimension configurations, Drs.NAS employs a low-value range but high-granularity definition based on consecutive integers, enabling an expanded search space with reduced hidden dimension and model size. In the meantime, we incorporate the computational overhead as part of the composite loss function, which allows Drs.NAS to discover optimal architectures with reduced computational overhead.

Table 3: Comparison of **inference time** (μs) for optimal architectures searched by Drs.NAS and SOTA approach NASRec [Zhang et al.(2023)] across three benchmarks and two search space configurations.

Model	Criteo GPU/CPU	Avazu GPU/CPU	KDD GPU/CPU
NASRec - Small	4.96/43.26	3.78/44.15	2.47/53.94
NASRec - Full	8.18/86.36	5.99/69.36	6.19/76.42
Drs.NAS - Small	**4.69/19.72**	**3.44/20.33**	**1.84/18.56**
Drs.NAS - Full	5.21/25.92	3.98/24.91	4.06/33.25

Additionally, we evaluate the inference time of DRS models using Drs.NAS searched architectures based on both GPU and CPU devices, compared with the SOTA NAS baseline [Zhang et al.(2023)]. We select the same model depth, $\mathcal{D} = 7$, for a fair comparison. The inference time evaluation, reported in microseconds (μs), is presented in Tab. 3. We evaluate the inference time per sample, and each measurement is repeated three times to mitigate variance and experimental bias. On average, Drs.NAS searched architectures achieve 60.8% reduction in CPU inference time and 24% inference time reduction on GPU across three benchmarks and two different search space configurations. These results indicate that the decrease in #FLOPs obtained by Drs.NAS can consistently convert to lower inference latency for the DRS deployment on both hardware platforms.

5.4 Ablation Study

Answering RQ4: Drs.NAS demonstrates robustness across diverse architecture search configurations, consistently discovering high-performing and efficient architectures. Different configurations enable distinct design choices and performance-efficiency trade-offs.

To evaluate the configurable components in the Drs.NAS architecture search process, we conduct comprehensive ablation studies to explore the robustness of Drs.NAS, defined by the consistency of the performance and efficiency across different searched architectures. In our ablation study, we select different model depths, learning rates, and search space configurations to systematically investigate the robustness of Drs.NAS searched architectures. Meanwhile, we measure the coefficient of variation (CV) for different performance and efficiency metrics to evaluate the robustness of Drs.NAS.

Takeaway 1: Drs.NAS is robust to model depth and can consistently discover efficient architectures across various model complexities.

We investigate the impact of model depth $\mathcal{D}$. Here we mainly focus on the AUC scores since the #FLOPs and #Params will naturally increase with greater model depth. The evaluation results are illustrated in Fig. 5(a) to Fig. 5(c). We compute the CV of the AUC scores across different model depths. The evaluation results indicate that Drs.NAS searched architectures exhibit the CV of 0.0002, 0.0006, and 0.0004 on various benchmarks, indicating significant robustness in model predictive performance across different model depths.

We can observe that optimal model depth varies across benchmarks. For instance, on the Avazu benchmark, the architecture searched by Drs.NAS achieves the highest averaged AUC at model depth $\mathcal{D} = 9$, and on the Criteo and KDD benchmarks, the optimal depth is $\mathcal{D} = 7$. Notably, even at model depth $\mathcal{D} = 9$, the optimal architecture achieves superior efficiency compared to prior NAS baselines.

Takeaway 2: Lower learning rates during architecture search tend to yield architectures with improved predictive performance.

Meanwhile, we examine the impact of different learning rates within the gradient-based search process. The evaluation results are presented in Fig. 5(d) to Fig. 5(f). Specifically, we observe that the optimal architecture is searched with a lower learning rate, such as 0.02 and 0.05. In particular, we compare the averaged AUC scores of Drs.NAS searched architectures across all three benchmarks, and the lower learning rates (0.02 and 0.05) achieve 0.02%, 0.05%, and 0.03% higher averaged AUC scores than the higher learning rates (0.2 and 0.5).

We evaluate the CV on both #FLOPs and #Params of different optimal architectures, and the inference costs remain stable over varying learning rates. The averaged CVs of #FLOPs and #Params are 0.05 and 0.02 over three benchmarks, which denotes the robustness of Drs.NAS in architecture search. Additionally, we notice that the improvement in performance does not significantly influence the computational or memory efficiency. We hypothesize that higher learning rates may overshoot the sweet spot in the search space, resulting in suboptimal architectures. In contrast, lower learning rates enable a finer search process and discover architectures with improved performance, without introducing extra computational and memory overhead.

Takeaway 3: Different search space configurations induce trade-offs in Drs.NAS searched architectures between predictive performance and computational efficiency.

In addition, we evaluate and compare the computational efficiency of Drs.NAS searched architectures based on the "Search space - Small" and "Search space - Full" search space configurations, as discussed in Sec. 4.2. As indicated in Fig. 5(g) to Fig. 5(i), the experimental results show that Drs.NAS searched architectures demonstrate clear trade-offs between performance and efficiency depending on the search

spaces. Specifically, the optimal architectures searched from "Search space - Small" achieve higher AUC scores, and models discovered from "Search space - Full" exhibit reduced #Params and #FLOPs.

In this ablation study, consistent with the NASRec approach, we fix the model depth $\mathcal{D} = 7$ and utilize the lower learning rate in $\{0.02, 0.05\}$. According to our analysis, the architecture searched in "Search space - Small" achieves 0.17%, 0.33%, and 0.1% higher averaged AUC scores, while models from "Search space - Full" search space induce 56%, 58%, and 64% #Params reduction and 17%, 21%, and 14% #FLOPs reduction across the Criteo, Avazu, and KDD benchmarks, respectively. On average, the CVs of AUC scores, #FLOPs, and #Params are 0.0005, 0.05, and 0.02 across different search spaces and varying benchmarks, indicating noticeable robustness of Drs.NAS in architecture search.

We hypothesize that "Search space - Full" includes an expanded operator set, which allows Drs.NAS to bypass the computationally expensive operators, such as FC, leading to more efficient architectures. This high efficiency may trade off the predictive performance, because the overhead-relevant proxies, such as #Params and #FLOPs, are correlated with the model predictive performance [Li et al.(2023), Lin et al.(2020)]. This phenomenon can potentially support the effectiveness of Drs.NAS on balancing the performance and efficiency of candidate architectures.

Furthermore, the searched architectures with higher #Params or #FLOPs, when used as the sole selection crite-

(d) Criteo - Learning rate (e) Avazu - Learning rate (f) KDD - Learning rate

(g) Criteo - Search space (h) Avazu - Search space (i) KDD - Search space

Figure 5: Ablation study on the (1) model depth, (2) learning rate selection, and (3) search space configuration in Drs.NAS, based on averaged AUC score, #FLOPs, and #Params across different benchmarks.

rion, do not consistently achieve better predictive performance across different model depths, learning rates, and search space configurations. This is consistent with prior findings [Huang et al.(2024), Cortês et al.(2025)] that individual proxies, such as #Params and #FLOPs, are insufficient to indicate model performance reliably. More importantly, this observation validates the superproxy rather than relying on a single proxy alone as the performance indicator. In particular, the consistent performance and efficiency of Drs.NAS searched architectures across all configurations indicate that the ensemble design of the superproxy captures more reliable optimization signals than individual proxies.

6 Discussion

The key idea of Drs.NAS is the superproxy, which comprises seven zero-cost proxies and serves as a composite indicator for predictive performance and architectural efficiency. While extensively validated in the DRS context, it is unclear how the strategy scales to different model families and application domains (e.g., LLMs) [Abdelfattah et al.(2021), Yang et al.(2025), Cortês et al.(2025)]. An important direction of our future work is to systematically characterize the boundary conditions under which Drs.NAS remains reliable through evaluation across more diverse search spaces and cross-domain applications, enabling a comprehensive evaluation of the generalizability and robustness of Drs.NAS.

7 Conclusion

In this work, we presented Drs.NAS, an ultra-efficient NAS framework for DRS. Unlike conventional NAS approaches that rely on computationally expensive training and validation during search, Drs.NAS introduces the novel *superproxy* metric, enabling rapid architecture exploration within minutes on CPUs. By integrating superproxy into a composite loss function, Drs.NAS co-optimizes predictive performance and efficiency and produces architectures that are high-performing, computation- and memory-efficient. Extensive evaluations on widely used recommendation benchmarks demonstrate that Drs.NAS achieves drastic efficiency improvements—reducing search costs by nearly three orders of magnitude and lowering model size and FLOPs by averages of 34.9× and 14.7×, respectively, compared with SOTA NAS baselines—while delivering on par or superior predictive performance compared to SOTA NAS and mainstream handcrafted baselines.

Abstract

SMART attributes are the main telemetry for monitoring Solid State Drives (SSDs) and predicting failures in large fleets, but existing methods rely on heavy feature engineering and large supervised pipelines that must be retrained as hardware or workloads change and that compress rich temporal behavior into opaque numeric scores. Large Language Models (LLMs) offer structured reasoning and explanations, yet perform poorly on raw SMART logs because the histories are long and multivariate, their temporal inductive bias is weak, and they hallucinate on numeric inputs. We present **SMARTTalk**, a new systems architecture that introduces a representation layer for device telemetry. SMARTTalk converts each n day SMART window into a sequence of symbolic trend tokens that an LLM can reliably reason over. The system separates numerical trend extraction from language based reasoning through three stages. (1) It slices n-day SMART windows into short temporal patches and encodes them with lightweight Convolutional Neural Network (CNN), then it clusters the resulting embeddings to form compact libraries of attribute-level and cross-attribute temporal patterns; (2) It converts each pattern into concise, human-readable text tokens that are stable across drives and over time; and (3) It feeds these pattern summaries to an LLM with chain-of-thought prompting, augmented with an online pattern memory that detects and incorporates previously unseen behaviors without retraining. By reasoning in natural language, SMARTTalk gives transparent explanations and interactive workflows.

Evaluations on production datacenter SSD traces, across both open-source and proprietary LLMs, show that SMARTTalk delivers roughly 50× higher $F_{0.5}$ than Raw-LLM, about 4× higher than the Heuristic-LLM, and approximately 25% more accurate health classification than existing SMART-based methods, while achieving time-to-failure estimates with bucketed MAE near 10 days. SMARTTalk's natural-language outputs are rated highly by LLM-as-judge, with explanation and recommendation scores around 4.5 out of 5 and perturbation robustness above 80%, making the system operator friendly and ready for the deployment.

1 Introduction

SMART (Self Monitoring, Analysis and Reporting Technology) attributes [2] are the primary telemetry for monitoring the health of Solid State Drives (SSDs) in production datacenters [5, 7, 8, 17, 22–25, 30, 36, 38]. Each drive reports daily counters such as reallocated sectors, pending sectors, and media errors that evolve over time. These long multivariate histories allow operators to identify at-risk drives before failure, enabling proactive replacement and minimizing downtime.

A large body of work converts SMART logs into predictive models. Classical approaches use summary statistics and hand crafted temporal features fed into supervised learners such as random forests and gradient boosted trees [7, 8, 10, 22, 37]. Subsequent work introduces sequence models including autoencoders, LSTMs, and temporal convolutional networks to capture richer temporal behavior [12, 19, 38]. Recent industrial systems such as MVTRF [40] and MSFRD [41] incorporate more elaborate feature engineering, multi view statistics, and mutation based temporal encodings to improve both failure prediction and diagnosis. We discuss the existing body of work in detail in Section 2.4 and 2.5.

Despite these advances, existing methods face three key limitations. First, they rely on heavy feature engineering and large labeled datasets, particularly for rare failures and emerging drive models. Second, models must be retrained to handle firmware, workload, or hardware changes. Third, most methods reduce complex temporal behavior to numeric scores or class labels, providing limited interpretability and actionable guidance for operators.

Large Language Models (LLMs) offer an opportunity to unify prediction, explanation, and interaction. They excel at pattern abstraction, multi step reasoning, and natural language explanation [16, 21, 27–29, 31, 33, 35, 42]. However, directly prompting LLMs with long numeric SMART traces is ineffective. Raw tables obscure temporal structure, overwhelm token budgets, and cause models to hallucinate trends that are not present [18]. This is one of the unavoidable barrier of using LLM that motivates our architecture. As discussed in

Section 2, key signals are local temporal patterns, slow drifts, spikes, bursts, and cross-attribute correlations that standard LLMs do not readily interpret.

Rare failures, evolving patterns, and long multi-attribute histories push classical models toward brittle feature engineering, sequence models toward failure under class imbalance and continual retraining, and LLMs toward hallucinations on raw telemetry, so prior architectures cannot solve this problem. What is needed is a new representation layer rather than another model tweak. These observations motivate our architecture that combines reliable temporal pattern extraction with LLM-based reasoning. Our core insight is to translate an n-day SMART window into a compact, human-readable event language that: (1) Preserves essential temporal structure (local patterns, slow drifts, spikes, bursts). (2) Captures attribute-wise and cross-attribute correlations. (3) Expands naturally over time as new failure modes emerge. (4) Exposes the right "interaction surface" for LLM reasoning, expressive enough for diagnosis, concise enough for token budgets, and structured enough to avoid hallucinated trends.

SMARTTalk is a system that enables LLMs to infer drive health, time to failure, likely causes, and recommended operator actions without heavy feature engineering or large labeled datasets. The design centers on three mechanisms. First, SMARTTalk introduces a temporal patch to pattern to phrase representation: each SMART history is sliced into short patches, embedded, mapped to a learned vocabulary of temporal patterns, and then rendered as concise natural language trend descriptions that LLMs can reliably interpret. Second, SMARTTalk maintains an online pattern memory for novelty tracking, allowing the system to detect patches whose embeddings exceed a learned novelty threshold, accumulate these previously unseen behaviors, recluster them into new temporal patterns, and expand the pattern library as new failure modes appear. This helps SMARTTalk handle rare or evolving failure modes. Third, SMARTTalk performs LLM reasoning over a structured sequence of semantic events; the LLM consumes this event sequence using a small in-context prompt and a Chain of Thought scaffold [34], enabling accurate status inference, time to failure prediction, cause identification, and actionable recommendations.

The design of SMARTTalk is guided by the following research questions (RQ): **(RQ1:)** How can LLMs analyze SMART logs to predict drive health and time-to-failure accurately without heavy feature engineering or large labeled datasets? **(RQ2:)** Does the patch→pattern→phrase representation reliably prevent trend hallucination and capture temporal structure? **(RQ3:)** How does an online pattern-memory improve robustness to rare and emerging failures compared to static encoders? **(RQ4:)** Are SMARTTalk's explanations ("why the drive is at risk") and recommendations ("what to do next") align with operator needs?

We evaluate SMARTTalk on production traces from Alibaba (MB1 and MB2 SSD models). Across five LLM backbones, SMARTTalk raises the average $F_{0.5}$ score for failure status prediction roughly 50× times higher than Raw-LLM, about 4× times higher than the Heuristic-LLM baseline, and approximately 25% improvement over the average of existing SMART-based methods and recent time-series SOTA models (Table 5). For drives that are correctly flagged at risk, the same backbones achieve TTF bucket macro-F_1 around 0.6 with bucketed MAE near 10 days and more than half of failures landing within ±5 days of the predicted bucket (Table 6). SMARTTalk's natural-language outputs are also rated highly by an independent LLM-as-judge, with explanation and recommendation scores around 4.4–4.6 out of 5 and perturbation robustness metrics above 80% (Table 7). Together, these results suggest that SMARTTalk is operator friendly and can substantially reduce the extra work spent deciphering raw SMART logs and triaging spurious alerts, while still providing timely, precise warnings and concrete actions.

2 Understanding SMART Logs

Our goal is not just to predict failures, but to make raw SMART logs *talk* to LLMs in a way that preserves the underlying behavior of the device to support qualitative decision making. Before designing SMARTTalk, we first inspect the data to understand what kinds of temporal patterns appear in SMART attributes and how a human operator would naturally describe them. These observations directly motivate our patching, pattern, and text-generation design.

2.1 SMART Attributes and Their Semantics

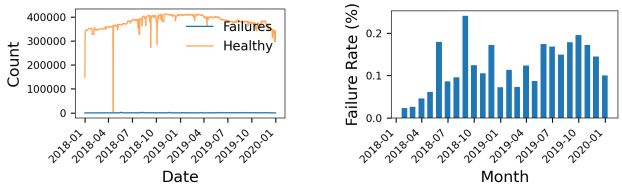
SMART exposes dozens of device–specific counters and indicators [17]. In this work we focus on a subset of 19 *raw* attributes that are both widely used in prior studies and relatively interpretable across models [17]. Table 1 summarizes these fields and the direction in which they are considered "healthy" (e.g., error counts ideally remain low, spare capacity ideally remains high). For a human operator, these attributes naturally suggest qualitative descriptions such as: "this error counter stayed flat for months and then spiked," "this wear indicator is slowly drifting down," or "this attribute is noisy but bounded." SMARTTalk aims to recover exactly such phrases automatically and feed them to an LLM.

The semantic structure of SMART attributes motivates three design choices in SMARTTalk. First, because different attributes reflect health through distinct patterns (e.g., slow wear trends versus sudden error spikes), we require attribute-specific patch encoders rather than a single global model. Second, since operators naturally describe these behaviors linguistically, SMARTTalk must convert temporal shapes into short phrases that mirror operator vocabulary. Third, because attributes interact during many failures, these phrase-level descriptions must later be composed to express cross-attribute events.

Table 1: Selected raw SMART attributes grouped by trend.

Ideal	SMART attributes
Low	r_5: Reallocated Sector Count; r_174: Unexpected Power Loss Count; r_175: Power Loss Protection Failure; r_177: Wear Range Delta; r_181: Program Failed Count; r_182: Erase Failed Count; r_183: SATA Downshift Error Count; r_184: End-to-End Errors; r_187: Reported Uncorrectable Errors; r_197: Current Pending Sector Count; r_199: UltraDMA CRC Error Count.
High	r_173: Wear Leveling Count; r_180: Available Reserved Blocks; r_195: Hardware ECC Recovered; r_233: Media Wearout Indicator.
Monitor	r_9: Power On Hours; r_12: Power Cycle Count; r_241: Number of Blocks Written; r_242: Number of Blocks Read.

2.2 Dataset and High-Level Behavior



(a) Healthy vs. failed counts. (b) Monthly failure rate.

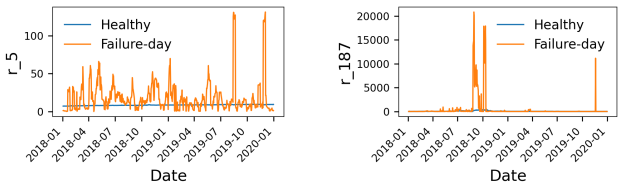
Figure 1: Behavior of the Alibaba SMART dataset.

We use a publicly released dataset of SSD SMART logs from Alibaba Cloud [1, 37]. The dataset spans two years (2018–2019) and covers six SSD models (`MA1`, `MA2`, `MB1`, `MB2`, `MC1`, and `MC2`), each monitored daily with up to 105 SMART attributes. We keep the 19 raw attributes from Table 1 and treat each drive's history as a multivariate daily time series. We focus on the **`MB1`** and **`MB2`** models in our experiments because they have very few missing values for each of the 19 attributes and are also used by prior work for evaluation making it straightforward to compare.

Figure 1 summarize several aggregate trends. Figure 1a shows the total number of healthy and failed drives over time, highlighting the extreme imbalance between the two classes. Figure 1b plots the monthly failure rate, which exhibits a slowly changing baseline with occasional spikes. The long histories and extreme class imbalance observed in the dataset suggest that global features across months or years are ineffective. This motivates our use of short, localized temporal patches that isolate informative behavior. The heterogeneous behavior across SSD models further argues for a learned pattern vocabulary rather than fixed, hand-engineered features. Finally, because failures evolve slowly with occasional bursts, the system must track patterns over time and allow new patterns to emerge, motivating use of online pattern memory.

2.3 Attribute-Level Patterns and "How a Human Would Say It"

To understand what kinds of temporal shapes an LLM should see, we zoom in on individual attributes. Figure 2 shows representative trajectories for two important SMART attributes: Reallocated Sector Count (`r_5`) and Reported Uncorrectable Errors (`r_187`). For each attribute we plot typical traces from days labeled healthy and from days that belong to drives that eventually fail. Two observations are important for designing SMARTTalk:



(a) Reallocated Sector Count. (b) Uncorrectable Errors.

Figure 2: Temporal patterns for two SMART attributes.

Attributes express risk in different ways. `r_5` shows noisy, slowly increasing behaviour with repeated medium-sized spikes, while `r_187` stays flat for long periods and then exhibits sudden, extreme jumps. A human would describe these as "gradual degradation with bursts" versus "quiet then a sharp spike". We want the LLM to see precisely such phrases, not just raw numbers.

Informative structure is local. In both plots, the informative changes happen over tens of days, not over the entire multi-year history. Global features such as a single slope over n days cannot capture whether the last week was stable, noisy, or spiky.

From an LLM's perspective, feeding a long list of daily numbers (e.g., "0, 0, 1, 3, 4, 0, . . . ") is a poor interface: the model must implicitly rediscover all the relevant temporal shapes. Instead, we want to convert each local segment of the time series into a short description that already encodes how an operator would talk about it. These attribute-level observations lead directly to SMARTTalk's patch–pattern–phrase pipeline. The fact that informative structure is local motivates our 5–10 day patch granularity. The diversity of shapes (flat, bursty, drifting) motivates learning a pattern library rather than relying on canned statistical features. The operator-like descriptions motivate generating compact natural language summaries for each patch so that the LLM receives structured, semantically meaningful events instead of raw numbers.

2.4 Challenges for Making SMART "Talk" and How SMARTTalk Responds

These observations reveal three challenges in turning SMART logs into LLM-friendly input:

Multivariate, long histories. Each drive exposes many attributes over years of daily logs, so listing all values overwhelms the LLM and hides the critical behavior.

Attribute and model-specific patterns. As seen in Figures 1 and 2, different attributes and SSD models exhibit distinct

temporal shapes (flat, slowly drifting, bursty, oscillatory). It is challenging to accurately capture the relevance and pattern (as discussed in Section 2.3) of these shapes without requiring in-depth feature engineering for each attribute.

Need for human-like diagnostic thinking. Operators naturally think in terms of phrases like "stable low", "gradual increase", "noisy high", or "repeated spikes in the last 10 days" to clearly understand the cumulative issue to make informed decision. To make the LLM's to be able to clearly understand the issue and reason transparently, we want SMART logs to be expressed in the same style. *SMARTTalk is designed to address above challenges.*

In the next subsection, we place SMARTTalk in the context of existing SMART-based modeling approaches and how they handle the temporal trends.

Table 2: Qualitative comparison of SMART modeling approaches. ✓ = provided; △ = partially or indirectly provided; "–" = not a primary goal. Abbreviations: **TS** = time series aware, **FE** = heavy feature engineering, **LD** = labeled data need, **EP** = evolving patterns, **OF** = operator friendly, **EX** = explanations, **TXT** = text level representation and interaction.

SMARTTalk	✓	△	Low	✓	✓	✓	✓	✓

2.5 Existing SMART Models and Why SMARTTalk

Table 2 summarizes the major classes of SMART-based prediction methods. Prior work largely falls into three categories.

Classical supervised models (RF, NN). Early systems treat each SMART snapshot as a feature vector and train models such as Random Forests and feed-forward NNs [5]. These methods need to be trained on large amount of data to predict accurately, operate solely on numerical features, and provide little operator-oriented insight beyond feature importance or binary risk flags.

Unsupervised and sequence models (AE, LSTM). Autoencoders [9] learn low-dimensional representations of SMART sequences and detect anomalies via reconstruction error, reducing labeled data demand but still yielding only numeric anomaly scores and need heavy feature engineering. LSTM-based models [19] capture temporal dynamics more faithfully, yet typically focus on binary failure prediction rather than structured time-to-failure (TTF) reasoning or interpretable explanations. After elaborate training, these models may show good statistical accuracies, hence we use these models as baselines in our evaluation 4.

Feature-engineered temporal systems (MVTRF, MSFRD, EC). Recent state-of-the-art (SOTA) works combine SMART with extensive temporal feature engineering. MVTRF [40] integrates short-term values, long-term histograms, and trend features to jointly predict failure status, type, and TTF, and exposes rule-like decision paths for diagnosis. MSFRD [41] leverages fine-grained telemetry and computes *mutation similarity* between current and historical attribute changes to assign fine-grained failure levels. Alibaba's production ensemble model for SMART logs [10] likewise uses rich temporal features and tree-based ensembles tuned for very low false positives, but, like MVTRF and MSFRD, ultimately exposes only scores and binary labels rather than operator-facing narratives or structured TTF reasoning. These approaches achieve strong accuracy but rely on complex, hand-crafted features and communicate results mainly through scores, labels, and rating levels.

Prior SMART based prediction models across classical supervised methods, unsupervised sequence models, and heavily engineered temporal pipelines share limitations that tuning cannot fix. They depend on fixed feature schemas that miss new failure modes, unstable and costly supervision on rare failures, rigid numeric features that ignore cross attribute correlations and causal structure, and they provide little human interpretable reasoning from SMART trends to failures and operator actions. SMARTTalk differs from these approaches along three main axes: **(1) Representation.** Rather than handcrafted histograms or mutation features, SMARTTalk learns CNN-based patterns over local SMART patches and translates each pattern into a short, human-readable phrase (e.g., "`r_187` stable low", "joint spike in `r_5` and `r_197`"). **(2) Reasoning.** Instead of using a numeric classifier, SMARTTalk feeds these textual trend summaries to an LLM, which, via chain-of-thought prompting, produces joint predictions of device status, TTF buckets, likely causes, and operator actions. **(3) Adaptivity.** SMARTTalk maintains an online pattern memory that detects, clusters, and promotes novel temporal patterns, enabling the system to capture emerging failure modes without retraining and expose them to the LLM in natural language.

In summary, SMARTTalk shifts from designing new numeric predictors to building a representation-and-reasoning pipeline that makes SMART logs *readable* and *explainable* to LLMs, improving operator-facing interpretability while retaining strong predictive performance.

3 SMARTTalk Design

SMARTTalk is a new systems architecture that translates numeric, multivariate telemetry into a stable symbolic trend language that LLMs can reason over. Its novelty is not in using CNNs, clustering, or LLMs, each component is standard, but in how the system composes them into a hybrid sym-

bolic–numeric pipeline that creates a new abstraction layer for telemetry: patch → pattern → phrase. This layer acts as a symbolic intermediate representation that is (i) human-interpretable, (ii) stable across drives and workloads, and (iii) locally adaptive through an online, continual Pattern Memory that recognizes novel failure modes without retraining.

SMARTTalk separates numerical trend extraction from language based reasoning. Offline, it processes historical SMART logs to learn patch encoders and a compact vocabulary of temporal trend patterns, calibrates pattern distance cutoffs, and stores the resulting patterns, cutoffs, and text phrases in a *pattern memory*. Online, a current n day window is sliced into patches, encoded with the frozen encoders, matched against the pattern memory, translated into short textual summaries, and then passed to an LLM that outputs drive status, time to failure, explanations, and recommended actions. This patch → pattern → phrase translation is the core abstraction: it elevates SMART telemetry from dense numeric sequences to interpretable, compositional symbols that support robust LLM reasoning and continual adaptation.

Instead of giving an LLM raw time series, we structure the input to balance detail, abstraction, and explainability. Specifically, SMARTTalk: **(1) Segments windows into patches:** Each $A \times n$ SMART window is split into short per-attribute and cross-attribute patches, capturing both local temporal trends and inter-attribute interactions. **(2) Learns a trend vocabulary:** We build a compact set of *trend patterns* from historical data, e.g., "stable low", "sharp spike", or "joint spike in `r_5` and `r_187`". **(3) Converts windows into textual summaries:** Each window is mapped to a sequence of pattern IDs, rendered as concise, human-like sentences.

The LLM then operates on these summaries using chain-of-thought reasoning, producing health predictions, time-to-failure estimates, explanations, and recommendations.

SMARTTalk consists of two phases: (i) an *offline phase* that learns patch encoders, patterns, and textual labels, and (ii) an *online phase* that maps incoming SMART windows to patterns, constructs textual summaries, and queries the LLM.

In this section, we formalize the problem and explain how SMART logs interface with LLMs through our three-stage pipeline across these two phases.

3.1 Problem Formulation

We consider a fleet of SSDs deployed in a production datacenter. Each drive $u \in \mathcal{U}$ exposes a set of A SMART attributes, which are logged at regular discrete time steps (e.g., daily). Let, $x_{u,a,t} \in \mathbb{R}$ denote the value of attribute $a \in \{1,\ldots,A\}$ for drive u at time t. We assume that for a subset of drives we also observe failure events and their timestamps.

SMART windows. For each drive u and reference time t, we define an n-day SMART window as the $A \times n$ matrix

$$M_{u,t} = \begin{bmatrix} x_{u,1,t-n+1} & \cdots & x_{u,1,t} \\ \vdots & & \vdots \\ x_{u,A,t-n+1} & \cdots & x_{u,A,t} \end{bmatrix} \in \mathbb{R}^{A\times n}.$$

which contains n consecutive time steps of all SMART attributes ending at time t. In our experiments we use $A = 15$ attributes and $n = 30$ days, but the formulation is general.

Status and time-to-failure (TTF) labels. For windows with ground truth, we assign two labels:
1. A *health status* label $y^{\text{status}}_{u,t} \in \mathcal{Y}^{\text{status}}$, which can represent, for example, {healthy, failed}.
2. A *time-to-failure* (TTF) label $y^{\text{ttf}}_{u,t} \in [0,+\infty]$, defined as the time (e.g., in days) from the end of the window t until the first observed failure of drive u. If the drive does not fail within a fixed horizon H, the label can be treated as censored or clipped at H.

Target outputs. Given a new SMART window $M_{u,t}$, **SMARTTalk** aims to produce:
1. A predicted health status $\hat{y}^{\text{status}}_{u,t} \in \mathcal{Y}^{\text{status}}$.
2. A predicted time-to-failure $\hat{y}^{\text{ttf}}_{u,t}$, either as a bucket (e.g., < 7 days, 7–30 days, > 30 days).
3. A natural-language *explanation* $e_{u,t}$ that describes which SMART trends and patterns led to the decision.
4. A natural-language *recommendation* $r_{u,t}$ (e.g., continue monitoring, migrate workload, replace drive) that is actionable for operators.

We therefore seek a mapping $f : \mathbb{R}^{A\times n} \longrightarrow \mathcal{Y}^{\text{status}} \times \mathbb{R}_{\geq 0} \times \mathcal{E} \times \mathcal{R}$, where $\mathcal{E}$ and $\mathcal{R}$ denote the spaces of explanations and recommendations, respectively. Each of these outputs is evaluated and discussed in Sections 4.2, 4.3, and 4.4.

LLM-based reasoning with summaries. *SMARTTalk* decomposes f into two stages:

$$S : \mathbb{R}^{A\times n} \to \mathcal{T}, \qquad F_{\text{LLM}} : \mathcal{T} \to \mathcal{Y}^{\text{status}} \times \mathbb{R}_{\geq 0} \times \mathcal{E} \times \mathcal{R},$$

where, S is a learned summarization function that converts $M_{u,t}$ into a compact textual representation $T_{u,t} \in \mathcal{T}$ describing per-attribute and cross-attribute trend patterns (e.g., "SMART-5 stable, then repeated spikes in the last 10 days"). F_{LLM} is an LLM-based reasoning module that, given $T_{u,t}$ and a chain-of-thought style prompt, infers status, TTF, explanations, and recommendations.

3.2 Offline Pattern Learning

The offline phase of SMARTTalk learns a compact library of patch-level patterns and their associated distance cutoffs from historical SMART logs, as shown in Figure 3, which summarizes the pipeline. Given long sequences of raw SMART attributes, we first form fixed-length windows and slice them into short temporal patches. Small self supervised [6, 11, 15, 20] CNN encoders then map these patches into low dimensional embeddings. We train these encoders with self supervised objectives defined directly on *unlabeled SMART windows*, such as predicting masked days within a

patch from the remaining days or distinguishing a real patch from a time shuffled or attribute permuted version, so that the learned representations capture reliability relevant trends without using failure labels. We cluster these embeddings with k-means to obtain a finite set of attribute and cross-attribute patterns, and finally use failure labels *only* to calibrate distance cutoffs that separate typical patches from out-of-library behavior. The resulting pattern centers, distance cutoffs, and textual phrases initialise the *PatternMemory* used at inference time.

3.2.1 Patch-Based Representation of SMART Windows

Recall from Section 3.1 that an n-day SMART window for drive u ending at time t is represented as $M_{u,t} \in \mathbb{R}^{A\times n}$, where A is the number of SMART attributes. SMARTTalk first converts each window into a set of short views that capture local behaviour while preserving temporal order.

Per-attribute 1D patches. For each attribute $a \in \{1,\dots,A\}$ we consider its length-n time series within the window and split it into $T = n/L$ contiguous blocks of length L (we use $n = 30$ days and $L = 5$ days in our experiments):

$$p^{(a)}_{u,t,\ell} \in \mathbb{R}^L, \quad \ell = 1,\dots,T.$$

Each $p^{(a)}_{u,t,\ell}$ captures a short-term local trend for attribute a over L days and can be mapped back to a concrete time range (e.g., days 0–4, 5–9, ..., 25–29).

Cross-attribute 2D patches. We also form 2D patches that include *all* attributes over the same L-day blocks:

$$P_{u,t,\ell} \in \mathbb{R}^{A\times L}, \quad \ell = 1,\dots,T.$$

Each $P_{u,t,\ell}$ summaries how attributes evolve jointly over the same time segment.

For an $A \times n$ window we therefore obtain $A \cdot T$ 1D patches and T 2D patches. The choice of L trades off temporal resolution and noise averaging: shorter patches isolate rapid changes, whereas longer patches smooth noise but may blur short bursts.

3.2.2 Self-Supervised Patch Encoders

SMARTTalk represents each patch with a low-dimensional embedding using small self-supervised CNNs; failure labels are not required for this stage.

1D attribute encoder. For a 1D patch $p^{(a)}_{u,t,\ell}$ we learn an encoder $f_{\text{attr}} : \mathbb{R}^L \to \mathbb{R}^{d_a}$ implemented as a lightweight 1D CNN:

$$z^{(a)}_{u,t,\ell} = f_{\text{attr}}(p^{(a)}_{u,t,\ell}) \in \mathbb{R}^{d_a}.$$

A decoder g_{attr} reconstructs the original patch; the encoder and decoder are trained jointly via reconstruction loss to ensure that $z^{(a)}_{u,t,\ell}$ preserves the essential local trend.

2D cross-attribute encoder. Similarly, for each cross-attribute patch $P_{u,t,\ell} \in \mathbb{R}^{A\times L}$ we train a 2D CNN encoder $f_{\text{cross}} : \mathbb{R}^{A\times L} \to \mathbb{R}^{d_c}$:

$$z_{u,t,\ell} = f_{\text{cross}}(P_{u,t,\ell}) \in \mathbb{R}^{d_c},$$

with a small decoder g_{cross} trained to reconstruct $P_{u,t,\ell}$.

Self-supervised objective. The encoders are jointly trained on unlabeled historical SMART windows using a combined reconstruction loss $\mathcal{L} = \sum_{u,t,a,\ell} \left\| p^{(a)}_{u,t,\ell} - g_{\text{attr}}(f_{\text{attr}}(p^{(a)}_{u,t,\ell})) \right\|_2^2 + \lambda \sum_{u,t,\ell} \left\| P_{u,t,\ell} - g_{\text{cross}}(f_{\text{cross}}(P_{u,t,\ell})) \right\|_2^2$, where λ balances the two branches. Once converged, we discard the decoders and freeze f_{attr} and f_{cross}.

3.2.3 Pattern Learning and Memory Initialization

A three stage symbolic representation pipeline. SMARTTalk introduces a structured, three stage pipeline that converts raw telemetry into symbolic trends that an LLM can reason about. First, *patch extraction* slices each window into short one dimensional and two dimensional views that capture local temporal behaviour and cross attribute interactions as discussed in Section 3.2.1. Second, *pattern discovery* runs self supervised encoders and clustering on these patches to build a vocabulary of reusable temporal and cross attribute trends as discussed in 3.2.2. Third, *phrase generation*, which we discuss in this section, renders each learned pattern as a concise natural language phrase so that every window is represented as a sequence of symbolic tokens rather than raw numeric traces. This abstraction layer decouples how trends are extracted (numeric and learned) from how they are understood (symbolic and interpreted), which makes the representation modular and robust and allows it to be reused across drives, time periods, and LLM backends.

Pattern learning via k-means. We run k-means on the frozen embeddings to obtain base trend patterns. For attribute-level patterns, we cluster all $\{z^{(a)}_{u,t,\ell}\}$ across drives and windows into K_{attr} clusters with centres $\{c^{\text{attr}}_k\}_{k=1}^{K_{\text{attr}}}$. Similarly, we cluster $\{z_{u,t,\ell}\}$ into K_{cross} centres $\{c^{\text{cross}}_k\}_{k=1}^{K_{\text{cross}}}$. These centres correspond to recurring temporal trends such as "stable near zero", "gradual increase", "late sharp spike", or "joint spike in `r_5` and `r_187`".

Calibrating pattern distance cutoffs with labels. After obtaining the pattern centres, we leverage failure labels to determine distance thresholds that separate typical behaviour from patches that fall outside the learned pattern library. Specifically, for each training patch, we compute its distance d to the nearest pattern centre and record whether it originates from a healthy or failing window. For a candidate cutoff τ, we classify patches with $d > \tau$ as outside the library and compute the corresponding patch-level metrics: the false positive rate $\text{FPR}(\tau)$ on healthy windows and the true positive rate $\text{TPR}(\tau)$ on failing windows. We then sweep τ across a

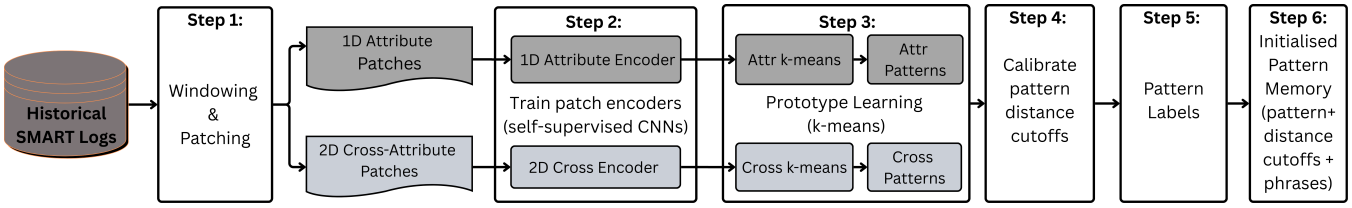

Figure 3: Offline phase of SMARTTalk: from historical SMART logs to self-supervised patch encoders, base patterns, calibrated distance cutoffs, and an initial *PatternMemory*.

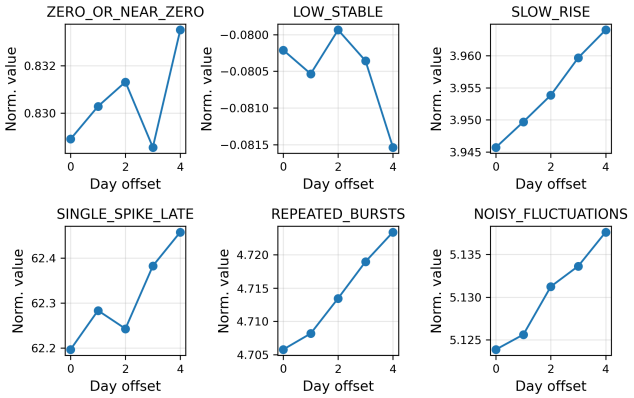

Figure 4: Example attribute-level patterns and their phrases.

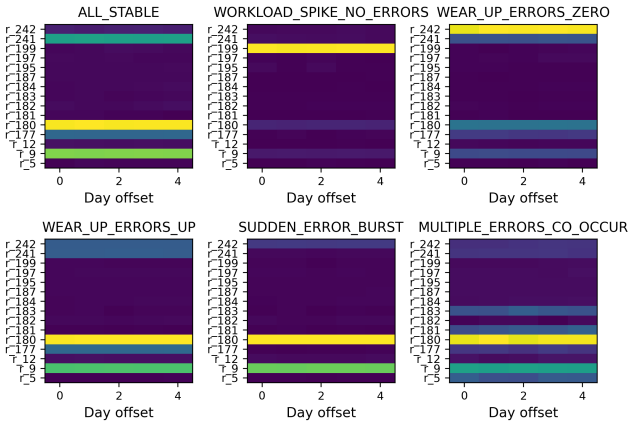

Figure 5: Example cross-attribute patterns and their phrases.

grid of quantiles and select the optimal cutoffs τ_{attr} and τ_{cross} such that $\text{FPR}(\tau) \leq \alpha$ (we use $\alpha = 0.05$) while maximising the F1-score over all patches. These calibrated cutoffs ensure that only a small fraction of patches from healthy drives are mistakenly flagged as anomalous, while a large fraction of patches from failing windows with unusual behaviour are correctly identified.

Learning pattern phrases and initial memory. The final offline step converts numeric patterns into a compact vocabulary of text tokens that the LLM can interpret. Given the attribute and cross-attribute pattern centres along with their calibrated distance cutoffs, phrase learning is formulated as an offline summarisation task over patches that are well represented by each pattern.

Figure 4 illustrates six representative attribute-level patterns and their traces. For each attribute pattern k, we collect all patches whose closest centre is c_k^{attr} and whose distance falls below the cutoff τ_{attr}. We then compute simple temporal statistics from these patches, including mean level, variance, start–end difference, maximum change, number of large excursions, and the position of the largest excursion within the L-day patch. Using rule-based heuristics, we map these statistics to a coarse trend label (e.g., ZERO_OR_NEAR_ZERO, LOW_STABLE, SLOW_RISE, SINGLE_SPIKE_LATE, REPEATED_BURSTS, NOISY_FLUCTUATIONS) and to a short natural-language phrase describing the trend (e.g., "flat near zero", "slowly increasing", "single late spike").

Figure 5 shows examples of these cross-attribute patches. We apply a similar procedure to cross-attribute patterns. For each cross pattern k, we collect patches whose closest centre is c_k^{cross} and whose distance is below τ_{cross}, compute per-attribute statistics over the $A \times L$ patch, and identify which attributes exhibit stable behaviour, gradual wear-out signals, or error bursts. Heuristics then group these patterns into categories such as ALL_STABLE, WORKLOAD_SPIKE_NO_ERRORS, WEAR_UP_ERRORS_ZERO, and assign phrases like "all attributes stable", "workload spike without new errors", or "multiple error counters rise together".

The resulting phrase dictionaries $\mathcal{V}_{\text{attr}}$ and $\mathcal{V}_{\text{cross}}$ associate each pattern index with a discrete trend label and a canonical phrase. These tokens are stable across drives and over time, and they form the vocabulary that will later be presented to the LLM in the online phase. We store all base patterns, calibrated distance cutoffs, and phrase dictionaries in a *PatternMemory* structure that is initialised at the end of the offline phase.

Phrase dictionary selection and generalization. The phrase dictionary is not manually written for individual test examples. It is selected offline from the training split by clustering patch embeddings and then describing each cluster using aggregate temporal statistics such as level, variance, start–end change, spike magnitude, and spike position. This produces coarse phrases such as "flat near zero", "slow rise", "single late spike", or "multiple error counters rise together". The dictionary is expected to generalize when the same SMART attributes preserve similar device semantics, because phrases describe normalized temporal shapes rather than drive identi-

fiers or absolute timestamps. When a new workload or device family produces a patch that does not match the current dictionary, SMARTTalk marks it as out-of-library and logs it for later insertion into *PatternMemory*. The main limitation is that a device with different SMART semantics, new attributes, or failure modes that do not appear as local trends or cross-attribute co-occurrences may require recalibrating the pattern library and phrase dictionary.

3.3 Online Inference

The online phase applies the frozen patch encoders and the *PatternMemory* to each new SMART window and queries an LLM as shown in Figure 6. Given a current n-day window, SMARTTalk maps short patches to pattern phrases using the stored centers and distance cutoffs, builds a natural language summary, and asks the LLM to produce exploratory analysis.

3.3.1 Window Encoding and Pattern Lookup

Given a fresh window $M_{u,t} \in \mathbb{R}^{A\times n}$ for drive u, SMARTTalk first standardizes attributes using the offline mean and variance and performs the same windowing and patching as in Section 3.2.1 to obtain 1D patches $p^{(a)}_{u,t,\ell}$ and 2D patches $P_{u,t,\ell}$ of length L days. Each patch is embedded with the frozen encoders f_{attr} and f_{cross} and compared against the patterns stored in *PatternMemory*.

For each patch we compute its distance to every pattern center and select the closest one. If the distance is below the corresponding distance cutoff τ_{attr} or τ_{cross}, the patch is treated as an instance of that pattern. Otherwise it is marked as an *out-of-library* pattern and its embedding, attribute index, and time range are logged for possible future extension of the pattern library. This yields, for each attribute and for the cross-attribute view, a short sequence of pattern IDs together with flags indicating which patches are out-of-library.

Online pattern-memory growth. Out-of-library patches identified during pattern lookup are appended to a small buffer rather than discarded. At regular intervals, SMARTTalk clusters the buffered embeddings to propose candidate new patterns and reuses the offline calibration procedure to assign each accepted pattern a center, distance cutoff, and phrase before inserting it into *PatternMemory*. This lightweight online update mechanism *allows SMARTTalk to absorb emerging workload regimes and failure signatures without retraining the encoders or rerunning the offline pipeline*, so the pattern library gradually becomes more representative of the field deployment over time.

3.3.2 Summary Construction and LLM Query

SMARTTalk next converts the pattern assignments for window $M_{u,t}$ into a structured textual summary. Pattern IDs are mapped to phrases using the attribute and cross-attribute phrase dictionaries $\mathcal{V}_{\text{attr}}$ and $\mathcal{V}_{\text{cross}}$ in *PatternMemory*. Phrases that repeat over multiple neighboring patches are merged into longer descriptions (e.g., "stable near zero for three segments" or "repeated bursts over the last 10 days"), and out-of-library patches are described explicitly as "unusual" behavior.

The resulting summary $T_{u,t}$ is inserted into a chain-of-thought prompt that instructs the LLM to reason about (i) whether the drive is currently healthy or at risk, (ii) the likely TTF bucket, and (iii) why the recent behavior is benign or concerning, followed by recommended operator actions. The LLM's answer is parsed into a status label, TTF bucket, explanation text, and recommendations, which are logged together with the summary for later analysis.

Role of the LLM. The CNN encoders and pattern memory extract local temporal evidence, but they do not by themselves decide how multiple pieces of evidence should be combined into an operator-facing decision. The LLM bridges this critical gap by composing attribute-level and cross-attribute patterns over the full window, distinguishing workload-driven changes from reliability signals, and mapping evidence to a status and TTF bucket. It also generates concise explanations and recommended actions. In this design, earlier stages provide a structured symbolic interface, while the LLM performs the higher-level reasoning needed for diagnosis, urgency assessment, and operator guidance that raw CNN patterns cannot provide alone.

3.4 Example and Usage Scenarios

Example setup. We select a 30-day window for a single drive and focus on two error-related attributes, `r_5` and `r_187`. Using a patch length of $L = 5$ days, each series is split into six contiguous patches P1–P6. The top panel of Figure 7 shows the raw series; the bottom panel shows the pattern phrases assigned to each 5-day patch.

Pattern assignments. In P1 and P2 (days 0–10), both attributes stay near zero, so `r_5` maps to "stable" and `r_187` to "flat zero". In P3 (days 10–15), `r_5` shifts to "noisy increase" while `r_187` remains "flat zero", indicating the first deviation in `r_5`. In P4 (days 15–20), `r_5` becomes "spike" and `r_187` is still "flat zero", capturing an isolated burst in `r_5`. In P5 and P6 (days 20–30), both attributes are labeled with "spike" patterns, reflecting sustained large spikes in `r_187` together with continued spikes in `r_5`. The cross-attribute patches for P5–P6 map to a pattern such as MULTIPLE_ERRORS_CO_OCCUR, which *PatternMemory* records as frequently appearing shortly before failures on this model family.

Example summary sent to the LLM. For this window, SMARTTalk aggregates the per-patch phrases into a natural-language summary $T_{u,t}$ such as:

```
Over days 0-10, error counters r_5 and r_187 stay near zero
and stable. Between days 10-15, r_5 shows a noisy upward drift
while r_187 remains flat at zero. From days 15-20, r_5 exhibits a
short spike but r_187 is still flat zero. Over days 20-30, both r_5
and r_187 show repeated spikes, and the joint pattern in the last
```

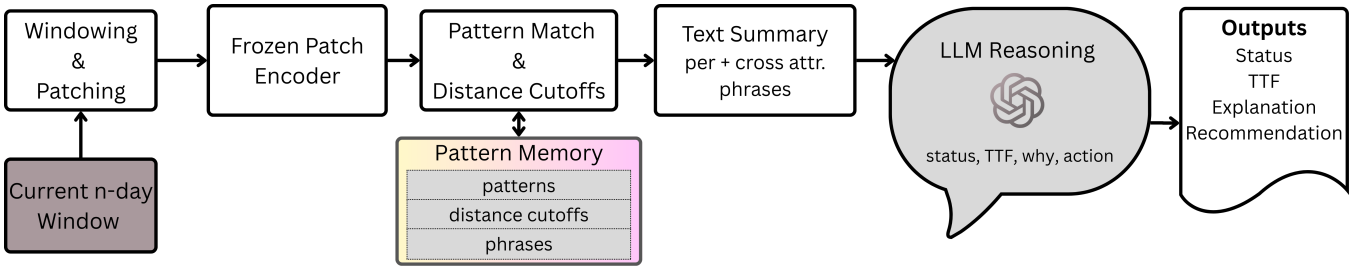

Figure 6: Online phase of SMARTTalk: a current n-day SMART window is mapped to pattern phrases via *PatternMemory* (patterns + distance cutoffs + phrases) and fed to an LLM that returns status, TTF, explanation, and recommended actions.

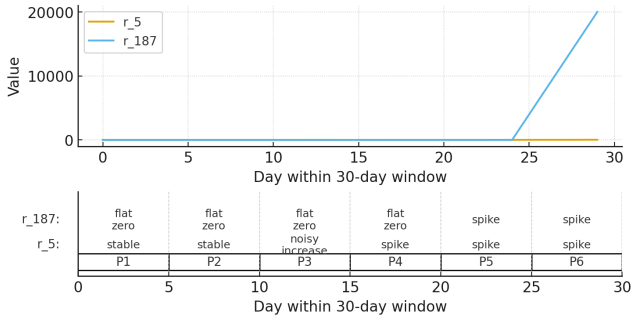

Figure 7: Example of SMARTTalk processing a 30-day window for attributes `r_5` and `r_187`. Top: raw trajectories. Bottom: six 5-day patches (P1–P6) and their attribute-level pattern phrases (e.g., "stable", "noisy increase", "spike").

```
two 5-day segments matches the "MULTIPLE_ERRORS_CO_OCCUR" pattern,
which has historically preceded failures within about one week on
this model family.
```

This summary is inserted into the CoT prompt described in Section 3.3.2. Given this input, the LLM typically reasons that error-related attributes exhibit recent sustained spikes and that the cross-attribute pattern matches one that often occurs shortly before failures; it therefore assigns the drive to a high-risk status with predicted TTF in the "<7 days" bucket and recommends migrating critical workloads and scheduling replacement. When all patches instead map to "stable" or "noisy but bounded" patterns, the same mechanism produces benign assessments.

This example illustrates SMARTTalk in practice. In routine monitoring, error counters and bounded workload changes lead to low concern and continued monitoring. In early warning cases, spikes in reliability-related attributes such as `r_5`, `r_187`, or `r_197` lead to migration, diagnostics, or scheduled replacement depending on urgency. In false alarm triage, a workload spike without error, spare, or wear degradation can be reported as unusual but not immediately dangerous, so the recommendation remains monitoring rather than automatic replacement. In novel pattern handling, out-of-library patches are logged into *PatternMemory*, allowing operators to inspect emerging behaviors and update the pattern library without retraining the pipeline.

4 Evaluation

In this section, we evaluate *SMARTTalk* on real Alibaba SMART logs and study three questions. First, how well does it predict drive status compared with conventional SMART-based baselines and recent state-of-the-art (SOTA) methods? Second, how accurately can it predict time-to-failure (TTF) buckets? Third, how good are the generated explanations and recommendations, both in terms of automatic metrics and their alignment with desired actions?

4.1 Experimental Setup

Dataset and temporal splits. We use the Alibaba SSD dataset as introduced in Section 2.2. For each drive, we construct sliding 30-day windows; labels in the dataset provide the status (failed or healthy) and the time to failure in days. To avoid temporal leakage, windows are partitioned by calendar month: the earliest months are used for training, the subsequent month for validation, and a later month for testing. Table 3 summarises the partitions for three experimental rounds; month indices will be adjusted to match the final datasets.

Table 3: Data partitions for SMARTTalk experiments.

Dataset	Round	Train	Val	Test
MB1, MB2	1	1–22$^{\text{nd}}$	23$^{\text{rd}}$	24$^{\text{th}}$
	2	1–21$^{\text{st}}$	22$^{\text{nd}}$	23$^{\text{rd}}$
	3	1–20$^{\text{th}}$	21$^{\text{st}}$	22$^{\text{nd}}$

SMART windows, patches, and patterns. Unless otherwise stated, we use windows of $n = 30$ days and patch length $L = 5$ days, which yields $T = n/L$ patches per attribute. The 1D and 2D patch encoders described in Section 3 are trained offline using only the training split and then frozen. The number of attribute and cross-attribute patterns is set to $K_{\text{attr}} = 16$ and $K_{\text{cross}} = 8$, and distance cutoffs $(\tau_{\text{attr}}, \tau_{\text{cross}})$ are learned as discussed in Section 3.2.3. Pattern phrases are curated once per dataset and reused across experiments.

Existing solutions. We compare SMARTTalk against wide range of the classical SMART-based methods, recent SOTA, and LLM-based variants. Random forests (**RF**) and feed-forward neural networks (**NN**) follow the feature engineering in [5]. Ensemble Classifier (**EC**): After choosing the most

important features, the data are given to several different classifiers. Their individual predictions are then combined into one final decision about whether the drive is healthy or failing [10]. An autoencoder (**AE**) reconstructs healthy windows and uses reconstruction error as a failure score [9]. An LSTM sequence model (**LSTM**) is trained directly on the SMART time series [19]. The multi-view temporal random forest (**MVTRF**) [40] and the fine-grained telemetry based method (**MSFRD**) [41] are recent SOTA for SMART-based reliability modelling; we treat them as strong reference points. Since there is no published LLM-based solution for this task, we define two LLM baselines. **Raw-LLM** directly verbalises raw SMART values over the window and prompts the LLM without using any patterns. **Heuristic-LLM** converts simple threshold-based rules into textual prompts for the LLM. In contrast, **SMARTTalk** employs the full pipeline: it encodes patches, leverages the pattern memory, generates textual summaries, and applies LLM reasoning to provide diagnostics and predictions.

LLM backbones. We evaluate SMARTTalk with four open-weight, instruction-tuned LLMs and one proprietary LLM as summarized in Table 4. All five LLMs use the same chain-of-thought style prompt and decoding configuration; we vary only the backbone model so that differences in accuracy and explanation quality can be attributed to the underlying LLM rather than prompt design. For the proprietary model, we treat the system as a black box and use only public APIs, without any fine-tuning or access to internals.

Table 4: LLMs used as SMARTTalk backbones.

ID	Model name	Params (B)	Context
$\mathbf{OS}_1$	Llama-3.1-8B-Instruct	8	128K tokens
$\mathbf{OS}_2$	Qwen2.5-14B-Instruct	14.7	131K tokens
$\mathbf{OS}_3$	Phi-4	14	16K tokens
$\mathbf{OS}_4$	Gemma-2-27B-it	27	8K tokens
PROP	GPT-4o	—	128K tokens

Evaluation Metrics. For **status prediction**, we focus on the failure (high-risk) class and treat each window as positive if the drive is truly at risk and negative otherwise. A true positive (TP) is a window where the drive is actually at risk and the model predicts RISK; a false positive (FP) is a healthy window that is incorrectly flagged as RISK, i.e., a false alarm; a true negative (TN) is a healthy window correctly predicted as healthy; and a false negative (FN) is an at-risk window that is incorrectly predicted as healthy, i.e., a missed failure. Because the processed window-level dataset is highly imbalanced, all methods are evaluated on the same fixed imbalanced sampled test set so that confusion-matrix metrics are comparable across methods while keeping LLM inference tractable.

We compute precision as $\text{Prec} = TP/(TP+FP)$ and recall as $\text{Rec} = TP/(TP+FN)$ by aggregating counts over the test windows. We then report the $F_{0.5}$-score, $F_{0.5} = \frac{(1+0.5^2)\,\text{Prec}\,\text{Rec}}{0.5^2\,\text{Prec}+\text{Rec}}$. This is the harmonic mean of precision and recall, where precision is weighted more heavily. In operational settings, SSD failure prediction must limit spurious alarms, so practitioners prioritize precision [37]. Consequently, we adopt the $F_{0.5}$-score, which emphasizes precision, as our main metric for comparing schemes in production-like environments.

To quantify false alarms and missed failures, we report the false positive rate (FPR) and false negative rate (FNR): $\text{FPR} = \frac{FP}{FP+TN}$, $\text{FNR} = \frac{FN}{TP+FN}$. FPR measures healthy windows incorrectly flagged as at risk, while FNR measures missed at-risk windows. Thus, FPR reflects operator burden and FNR reflects failure risk.The results of status prediction are discussed in Section 4.2.

For **TTF prediction** we discretize the time-to-failure (TTF) into coarse urgency buckets (e.g., <7 days, 7–30 days, >30 days) and ask the LLM to choose one bucket per at-risk window. Let t_i denote the true TTF (in days) for window i and $\hat{b}_i$ the bucket predicted by the LLM; each bucket $\hat{b}_i$ is associated with a midpoint $m_{\hat{b}_i}$ (e.g., 3.5 days for <7 days). We compute a macro-averaged TTF F_1 by treating each bucket as a class, computing its per-bucket F_1, and then averaging these scores uniformly across buckets so that short-horizon and long-horizon failures are weighted equally. To quantify how far the predicted urgency is from the true TTF, we report a bucketed mean absolute error $\text{bMAE} = \frac{1}{N}\sum_{i=1}^{N}|t_i - m_{\hat{b}_i}|$, where smaller values indicate that predicted buckets are, on average, closer in days to the true failure times. Finally, we measure the fraction of failure windows where the predicted bucket is time-consistent with the true TTF via $\text{Cov}_{\pm 5} = \frac{1}{N_{\text{fail}}}\sum_{i=1}^{N_{\text{fail}}}\mathbf{1}\big(|t_i - m_{\hat{b}_i}| \le 5\big)$, i.e., the proportion of at-risk windows whose true TTF lies within ± 5 days of the bucket midpoint; higher macro-F_1, lower bMAE, and higher $\text{Cov}_{\pm 5}$ all correspond to better guidance about how urgently a drive needs attention. The results of TTF prediction are discussed in Section 4.3.

For **explanations and recommendations**, operators care about why a drive is at risk and what to do next, but evaluating such explanations is challenging because it is expensive to obtain ground-truth natural language annotations for each window; instead, we use two label-free strategies. First, we evaluate output quality using an external LLM-as-judge [43] (GPT-5.1 Thinking [26]) that scores each explanation and action for correctness and operator usefulness. Second, we run perturbation-based tests that check whether explanations and actions react consistently when we synthetically increase or decrease specific SMART risk signals [14]. The full protocol and results, including the LLM-as-judge prompts and perturbation design, is described in Section 4.4.

4.2 Status Prediction

Table 5 reports status prediction performance of existing solutions (RF, NN, AE, and LSTM), recent SOTA methods (MVTRF and MSFRD), and LLM-based variants on MB1 and MB2. SMARTTalk is evaluated with both open-source

and proprietary backbones. In addition to precision, recall, and $F_{0.5}$, We report FPR and FNR to distinguish false alarms on healthy drives from missed warnings on at-risk drives. This is crucial under highly imbalanced data, where a model may appear conservative by predicting few failures yet still miss most true failures.

Table 5: Status prediction performance on the fixed imbalanced sampled test set. Precision (P), Recall (R), $F_{0.5}$, false positive rate (FPR), and false negative rate (FNR) are reported.

Method	MB1					MB2				
	P↑	R↑	$F_{0.5}$↑	FPR↓	FNR↓	P↑	R↑	$F_{0.5}$↑	FPR↓	FNR↓

The results show that simply prompting an LLM on raw SMART values is not enough for reliable status prediction. Raw-LLM variants almost never predict a drive as failed and label nearly every window as healthy. This behavior produces near-zero precision and recall and leads to an FNR close to one, showing that Raw-LLM misses almost all at-risk windows despite producing few useful warnings. Heuristic-LLM variants perform slightly better by using hand-crafted threshold summaries, and on MB2 they sometimes achieve high precision and low FPR. However, they fire only on the most extreme cases and still miss most true failures, which leads to low recall, high FNR, and poor $F_{0.5}$ scores. These results show that raw numeric prompting or simple hand-written summaries are insufficient because the LLM needs structured temporal abstractions that expose degradation patterns without overwhelming it with noisy variability.

Existing solutions such as RF, NN, AE, LSTM, MVTRF, and MSFRD provide a broad set of numerical baselines because they learn directly from SMART trends and expose different precision, recall, FPR, and FNR tradeoffs. MVTRF and MSFRD achieve strong precision and competitive recall on MB1, but SMARTTalk matches or exceeds their precision-biased $F_{0.5}$ across both SSD models while maintaining low FPR and non-trivial recall. In particular, SMARTTalk achieves the best $F_{0.5}$ on MB1 and the best or comparable $F_{0.5}$ on MB2, while keeping false alarm rates low. This indicates that the patch–pattern–phrase representation gives the LLM discriminative temporal signals similar to carefully engineered numerical features, but in a form that also supports natural-language reasoning, time-to-failure estimation, explanations, and operator actions.

Handling false positives and false negatives. In SMARTTalk, false positives are treated as early warnings, not automatic replacements. The output includes patterns, explanations, concern levels, and recommendations, enabling operators to decide between immediate action and monitoring. False negatives are more critical as they reflect missed risks; SMARTTalk mitigates this through sliding-window evaluation, multi-attribute evidence, and updates to *PatternMemory*, though weak or delayed signals remain a limitation. Unlike numerical predictors that provide only scores, SMARTTalk improves auditability by exposing decision-driving patterns. While Raw-LLM and Heuristic-LLM achieve low FPR by predicting fewer failures, this results in high FNR. SMARTTalk maintains a more practical balance between false alarms and missed failures.

The key takeaway is that converting raw SMART logs into abstract trend patterns turns LLMs from ineffective status predictors into detectors that are competitive with or better than state-of-the-art SMART baselines. SMARTTalk achieves about $50\times$ *higher* $F_{0.5}$ *than Raw-LLM, about* $4\times$ *higher* $F_{0.5}$ *than Heuristic-LLM, and roughly* 25% *better health classification than existing SMART-based methods, while also reporting low false alarm rates and reducing missed failures compared with naive LLM baselines. It further provides richer outputs such as time-to-failure guidance, explanations, and operator recommendations.*

4.3 Time-to-Failure Prediction

We now examine how accurately SMARTTalk predicts time-to-failure (TTF) buckets. Although MVTRF can estimate remaining lifetime, its published setups produce continuous risk or lifetime scores under different horizons and evaluation protocols, which are not directly comparable to our discrete urgency buckets (<7, 7–30, >30 days), we therefore focus our TTF evaluation on LLM-based methods, comparing SMARTTalk across multiple LLMs under the same pattern-based summaries and TTF instruction.

Table 6 reports macro-F_1 across TTF buckets and bucketed mean absolute error (bMAE) for five open-source LLM backbones. Each backbone appears twice: once with Raw-LLM and once with SMARTTalk. For each method the LLM is instructed to choose among the predefined TTF buckets (for example <7 days, 7–30 days, and >30 days); bMAE is computed from the bucket midpoints.

Across backbones, SMARTTalk's TTF performance follows a consistent pattern: weaker open-source models lag behind, while stronger open-source and the proprietary model

Table 6: TTF prediction: We report macro-F1 over TTF buckets (<7, 7–30, >30 days), bucketed MAE (bMAE), and coverage Cov$\pm$5, computed only on windows whose status is correctly predicted as RISK.

LLM	MB1 TTF $F_1 \uparrow$	MB1 bMAE $\downarrow$	MB1 $Cov_{\pm5} \uparrow$	MB2 TTF $F_1 \uparrow$	MB2 bMAE $\downarrow$	MB2 $Cov_{\pm5} \uparrow$
OS_1	0.58	11.0	0.52	0.52	11.8	0.48
OS_2	0.63	9.8	0.57	0.60	10.0	0.56
OS_3	0.70	9.0	0.61	0.58	10.5	0.54
OS_4	0.64	9.5	0.59	0.57	10.7	0.53
PROP	0.65	9.3	0.60	0.59	10.2	0.55

deliver substantially better bucket accuracy, lower timing error, and higher coverage. The best-performing backbone differs slightly between MB1 and MB2, but the gap between the top several models is small, suggesting that once the LLM is reasonably capable, the pattern-based summaries dominate the quality of TTF guidance.

The key takeaway is that SMARTTalk can provide reliable urgency estimates with multiple LLM backbones, achieving TTF bucket macro-F_1 around 0.6 *with bucketed MAE near* 10 *days and more than half of failures landing within* $\pm$5 *days of the predicted bucket, allowing operators to choose an open or proprietary model based on deployment constraints without sacrificing TTF quality.*

4.4 Explanations and Recommendations

LLM-as-judge. We first sampled windows from MB1 and MB2 for failing drives (True Positives predicted by SMARTTalk) and across time-to-failure buckets. For each method, we run the full pipeline and record its predicted status, time-to-failure bucket, free-form explanation, and recommended action for each window. We then use GPT-5.1 Thinking as an *external* LLM-as-judge. The judge is given (i) a short textual summary of the SMART window, (ii) the method's predicted status and time-to-failure, and (iii) the explanation and recommended action, but not the method name. It is prompted to rate, on a 1–5 Likert scale, (a) how *correct and faithful* the explanation is to the status/TTF prediction and the SMART trends, and (b) how *useful and safe* the recommended action would be for an operator. We report the average explanation score (**ExpScore**) and action score (**RecScore**) across windows.

Perturbation-based robustness. Second, we probe how sensitive each method is to controlled changes in the SMART attributes. For a subset of windows, we construct synthetic *perturbations* by modifying one or two reliability-related attributes (e.g., `r_5`, `r_187`, `r_197`) while keeping the others fixed. We consider "risk-up" perturbations (e.g., injecting a monotone increase or spike in an error counter) and "risk-down" perturbations (e.g., clamping an attribute to a healthy baseline). For each original/perturbed pair, we rerun the method and measure:

AttrSens: the fraction of risk-up perturbations for which the explanation explicitly mentions the perturbed attribute (via a fixed attribute-name lexicon), indicating that the method notices the changed signal.

ActDirAcc: the fraction of perturbations for which the recommended action moves in the intuitively correct direction: it becomes *more* conservative (e.g., from "monitor" to "backup and replace") when risk is increased, and does not become more conservative when risk is decreased.

These metrics do not require human reference explanations: we control the perturbations and only check whether each method's explanations and recommendations react in a consistent and sensible way.

Table 7: Quality of explanations and recommendations on MB1+MB2 for SMARTTalk. ExpScore and RecScore are 1–5 ratings (LLM-as-judge). AttrSens and ActDirAcc are perturbation-based robustness metrics (higher is better).

Method	ExpScore (1–5)	RecScore (1–5)	AttrSens ($\uparrow$)	ActDirAcc ($\uparrow$)
OS_1	4.34	4.26	0.79	0.82
OS_2	4.22	4.30	0.84	0.88
OS_3	4.50	4.75	0.87	0.91
OS_4	4.45	4.90	0.90	0.93
PROP	4.50	4.60	0.82	0.90

Table 7 summarises explanation and recommendation quality for SMARTTalk variants. "ExpScore" and "RecScore" are 1–5 scores from GPT-5.1 Thinking (higher is better), while "AttrSens" and "ActDirAcc" are proportions in $[0,1]$. Across the open-source variants, SMARTTalk consistently produces explanations that the judge rates as both accurate and useful, with later-generation backends yielding slightly stronger and more stable judgements than earlier ones. The proprietary configuration delivers explanation and recommendation quality that is broadly comparable to the best open-source variant, indicating that our design does not rely on a single LLM family. The perturbation-based metrics show that the judge is sensitive to attribute-level degradations and usually prefers the original, higher-quality text over perturbed variants, suggesting robust alignment between scores and explanation quality.

The key takeaway is that SMARTTalk can provide high-quality, perturbation-resilient explanations and operator guidance across multiple LLMs, with explanation and recommendation scores around 4.4–4.6 *out of* 5 *from LLM-as-judge and perturbation robustness metrics above* 80%.

4.5 Ablation on Observation Window and Patch Length

We study sensitivity to observation window N and patch length L around the default setting. We fix $L=5$ and vary $N \in 10,20,30,40,50$, and fix $N=30$ and vary $L \in 2,4,5,10,15$. For each setting, we retrain patch encoders and PATTERN-MEMORY on training data and evaluate on a fixed test set.

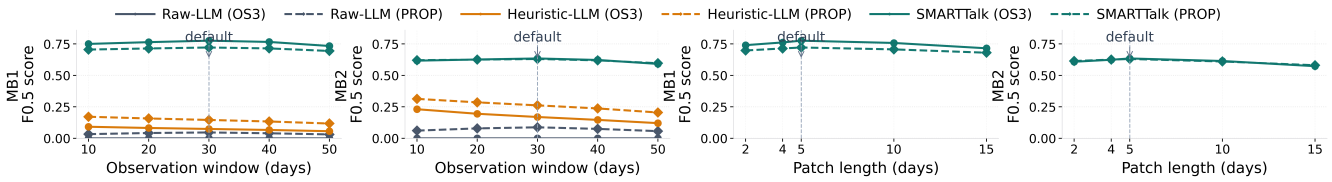

Figure 8: Sensitivity of $F_{0.5}$ to observation window N and patch length L on MB1 and MB2. Top: vary N with $L = 5$; bottom: vary L with $N = 30$. Solid lines show OS3 and dashed lines PROP; the vertical line marks the default setting. SMARTTalk consistently outperforms Raw-LLM and Heuristic-LLM. Performance is non-monotonic in both N and L, with the default near the best $F_{0.5}$ region across both models.

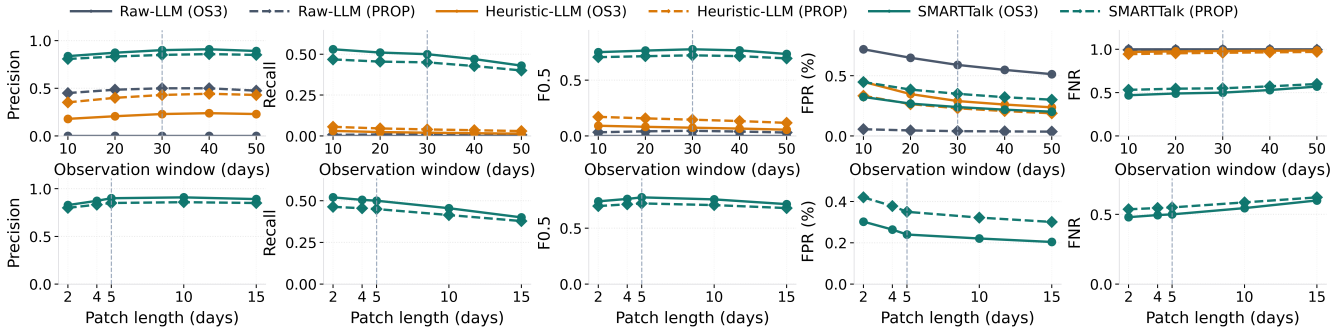

Figure 9: Detailed sensitivity metrics for MB1. Top row varies N with $L = 5$; bottom row varies L with $N = 30$. We report precision, recall, $F_{0.5}$, FPR, and FNR, with the default marked by a dashed line. Increasing N generally improves precision and FPR but may reduce recall due to smoothing of recent failures. Increasing L lowers FPR but raises FNR by smoothing short bursts. The default $(N = 30, L = 5)$ achieves the best precision–recall tradeoff.

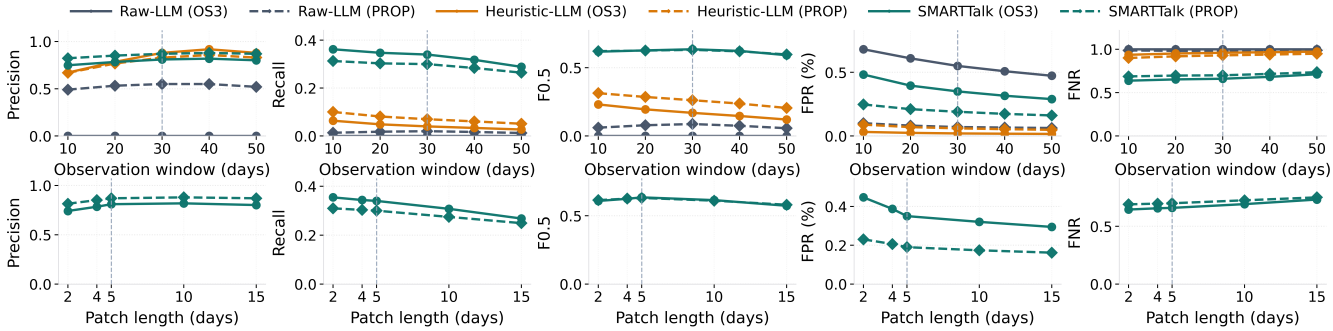

Figure 10: Detailed sensitivity metrics for MB2. Top row varies N with $L = 5$; bottom row varies L with $N = 30$ for SMARTTalk. MB2 exhibits the same pattern as MB1: performance is non-monotonic in N, and larger L reduces FPR but increases FNR. The default $(30, 5)$ remains in a stable high-performing region.

The default $(N = 30, L = 5)$ is highlighted by the vertical dashed line in the figures 8, 9 and 10.

Figure 8 shows that SMARTTalk is stable across a broad range of observation windows. On both MB1 and MB2, very short windows provide less historical context and can miss slow degradation patterns. Performance improves from $N = 10$ to 30 due to better temporal context, but saturates or degrades beyond 30 as older behavior dilutes recent failure signals. Thus, gains saturate around 30 days.

The patch-length study shows a similar tradeoff (Figures 9 and 10). Shorter patches improve temporal resolution and capture rapid spikes but increase noise, while longer patches smooth noise but can obscure failure bursts and reduce recall. The default $L = 5$ balances these tradeoffs, preserving local patterns while limiting noise, and achieves near-optimal $F_{0.5}$ on MB1 and MB2.

Encoding assumptions and information loss. SMARTTalk intentionally uses coarse temporal patches and phrase-level tokens rather than preserving every daily value. This design assumes that many useful SMART failure

signals appear as local trends, spikes, bursts, or cross-attribute co-occurrences in reliability-related fields, while small day-to-day fluctuations are often less useful for operator decisions. The compression can lose some fine-grained numeric detail, but our sensitivity results show this does not dominate performance. Our approach is therefore expected to generalize best when failures manifest through similar SMART trend shapes, but it may require recalibration for devices or telemetry streams where the meaningful signal is not concentrated in local extreme values, trends, or cross-attribute events.

The key takeaway is that SMARTTalk is not dependent on a fragile choice of N or L. Accuracy does not simply improve by increasing the observation window or patch length. Instead, there is a tradeoff: shorter windows and patches can miss longer degradation trends or become noisy, whereas longer windows and patches can smooth away recent failure bursts.

5 Related Work: LLMs for System Logs

Recent work explores how LLMs can assist system operations across many settings. For anomaly detection in scientific and workflow systems, LLMs have been used as supervised models and in-context learners over traces and configuration metadata [21], and more broadly as enablers for autonomic computing and self-managing services [42]. In storage and I/O optimization, ION uses LLMs to guide HPC I/O tuning and configuration [13], while LogLLM applies LLMs directly to system logs to highlight suspicious events and patterns [16]. LLMs have also been explored for root-cause analysis, incident management, and control in cloud environments, where single- and multi-agent designs couple LLM reasoning with log search, dashboards, and code inspection [29, 33]. For scheduling, control, and tuning, LLM-based methods guide policy learning, task coordination, key–value store tuning, and HPC I/O optimization [13, 31, 32, 39].

Within storage management, prior work uses LLMs to manage hybrid SSD tiers by selecting parameters and policies that balance performance and endurance [35]. SSD-specific LLM work has also modeled environmental effects and knowledge-graph-guided operational reasoning for SSDs [3, 4]. These efforts focus on high-level control, environmental what-if analysis, or graph-grounded operational reasoning rather than fine-grained SMART log analysis. In parallel, LogLLM and related systems operate on textual or semi-structured logs for anomaly detection and incident reasoning [16], but they do not target fine-grained SMART attributes or explicit time-to-failure prediction for individual drives.

SMARTTalk differs from prior LLM-for-system-logs work in three ways. First, it targets SSD SMART telemetry with a single pipeline for both health classification and bucketed time-to-failure prediction. Second, it introduces an attribute-aware *patch* $\rightarrow$ *pattern* $\rightarrow$ *phrase* layer that turns raw SMART windows into short, composable trend descriptions. Third, it maintains an adaptive pattern memory so LLM reasoning operates over an evolving library of interpretable SMART behaviors instead of raw logs.

6 Broader Impact

Although *SMARTTalk* focuses on SSD SMART telemetry, the same patch–pattern–LLM pipeline can be applied to a wide range of time-series system logs (e.g., HDD, GPU, CPU, memory, network, and power telemetry), helping operators surface emerging anomalies and interpret them in natural language. On top of SMARTTalk, one can build operator-facing applications such as what-if analysis tools, interactive dashboards, and exploratory diagnostics interfaces that let engineers probe alternative scenarios, inspect pattern-level histories, and compare failure modes across devices and clusters. Deployed as a decision-support layer alongside existing monitors and operator expertise, SMARTTalk encourages transparent, auditable use of LLMs in operations and opens the door to safer, more data-driven maintenance and capacity-planning practices.

7 Conclusion

This work asked whether LLMs can serve as effective reasoning engines for SSD SMART telemetry while preserving temporal structure. For **RQ1**, our results show that SMARTTalk can predict drive health and time-to-failure, without heavy feature engineering or large labeled datasets. For **RQ2**, we find that converting each n-day SMART window into per-attribute and cross-attribute patches, learning trend patterns, and verbalizing them as short natural-language summaries enables LLMs to correctly track temporal behavior while reducing trend hallucinations. For **RQ3**, the online pattern memory improves robustness to rare failures and emerging failure modes compared to a static offline model by detecting, clustering, and promoting novel patterns into new patterns. Finally, for **RQ4**, operator-facing evaluations indicate that SMARTTalk's explanations and its recommendations are aligned with operational needs. Together, these results suggest that pattern-based verbalization plus lightweight LLM reasoning is a promising path for interpretable, adaptive analysis of datacenter SMART logs. The implementation and artifact for SMARTTalk are publicly available at https://github.com/Damrl-lab/SMARTTalk.

A Additional Paper Details

A.1 Explanations and Recommendations

A.1.1 Perturbation Method

Algorithm 1 summarizes our perturbation-based sanity check for the LLM-as-judge scores. In Step (P-A) we start from a set of windows for which we already have the method's original prediction, explanation, and recommendations, and we obtain baseline `ExpScore` and `RecScore` by querying the judge

prompt once per window. Step (P-B) then applies a library of perturbation operators (e.g., deleting mentions of key error attributes, flipping the trend description, or replacing the explanation with generic boilerplate) to produce systematically degraded or altered variants of the original explanation and recommendations. In Step (P-C) we feed these perturbed variants to the same judge prompt, keeping the SMART summary and predicted status/TTF fixed, and record the new scores. Step (P-D) compares perturbed scores against the baseline for each operator to measure sensitivity, for example how often a quality-degrading perturbation lowers the score. Finally, Step (P-E) aggregates these differences across windows and operators to report summary robustness metrics used in our evaluation.

Algorithm 1 Perturbation-based evaluation of explanations and recommendations

Require: Set of evaluated windows $\mathcal{W}$, each with SMART summary S_w, method prediction (y_w, TTF_w), original explanation E_w, original recommendations R_w; perturbation operators O; judge prompt template P_{judge}

Ensure: For each operator $o \in O$: perturbation metrics over $\mathcal{W}$

1: **(P-A) Collect baseline judge scores:** For each window $w \in \mathcal{W}$, query the LLM-as-judge with $(S_w, y_w, \mathrm{TTF}_w, E_w, R_w)$ using P_{judge} and record baseline scores $\mathrm{ExpScore}_w^{\text{base}}$ and $\mathrm{RecScore}_w^{\text{base}}$.

2: **(P-B) Generate perturbed variants:** For each window w and each operator $o \in O$, apply o to (E_w, R_w) to obtain a perturbed pair (E_w^o, R_w^o). Examples include dropping mentions of key SMART attributes, flipping risk language (e.g., "low concern" $\rightarrow$ "serious concern"), or replacing the text with generic boilerplate.

3: **(P-C) Score perturbed variants with the judge:** For every (w, o) pair, query the same judge prompt with $(S_w, y_w, \mathrm{TTF}_w, E_w^o, R_w^o)$ and record $\mathrm{ExpScore}_w^o$ and $\mathrm{RecScore}_w^o$.

4: **(P-D) Compute sensitivity metrics:** For each operator $o \in O$, compute score differences $\Delta\mathrm{Exp}_w^o = \mathrm{ExpScore}_w^o - \mathrm{ExpScore}_w^{\text{base}}$ and $\Delta\mathrm{Rec}_w^o = \mathrm{RecScore}_w^o - \mathrm{RecScore}_w^{\text{base}}$ across all $w \in \mathcal{W}$, and summarise them via statistics such as mean drop, median drop, and the fraction of windows where $\mathrm{ExpScore}_w^o < \mathrm{ExpScore}_w^{\text{base}}$.

5: **(P-E) Summarise robustness across operators:** Aggregate the per-operator statistics into a table of perturbation metrics, highlighting whether the judge is (i) sensitive to quality-degrading edits and (ii) stable under neutral or minor edits. Use these metrics in our evaluation to validate the reliability of the LLM-as-judge scores.

Algorithm 2 HeuristicSMART-LLM baseline

Require: Raw SMART logs $\mathcal{D}$; window length n; attribute set $\mathcal{F}$; heuristic prompt template P_{heur}

Ensure: For each window: status label, TTF bucket, explanation, recommendations

1: **(H-A) Windowing:** Slice each drive history in $\mathcal{D}$ into n-day windows $M_{u,t} \in \mathbb{R}^{A \times n}$.

2: **(H-B) Per-attribute statistics:** For every window $M_{u,t}$ and attribute $a \in \mathcal{F}$, extract the 30-day vector $v_{u,t,a}$ and compute basic statistics (min, max, mean, first, last, delta, and late/early means).

3: **(H-C) Heuristic trend labelling:** Apply a hand-crafted rule set $\textsc{ClassifyTrend}(v_{u,t,a})$ to assign a coarse phrase $h_{u,t,a}$ (e.g., "mostly zero across 30 days", "sharp late spike") for each attribute.

4: **(H-D) Summary and prompt construction:** Concatenate the phrases $\{h_{u,t,a}\}_{a \in \mathcal{F}}$ into a textual summary $T_{u,t}$ and substitute $T_{u,t}$ into the heuristic LLM prompt template P_{heur} to form the final query $Q_{u,t}$.

5: **(H-E) LLM inference and parsing:** Send $Q_{u,t}$ to the LLM, parse the JSON response into status, TTF bucket, explanation, and recommendations, and store these outputs for later metric computation.

A.2 Heuristic LLM

Algorithm 2 summarizes our heuristic LLM pipeline. In Step (H-A) we first slice the raw SMART logs into 30-day windows so that each example contains the recent history of one drive. Step (H-B) computes simple statistics for every attribute in a window (minimum, maximum, mean, first and last value, delta, and late-versus-early means), which provide the inputs to the hand-crafted trend rules. In Step (H-C) a rule set CLASSIFYTREND maps these statistics to one coarse phrase per attribute (for example "mostly zero across 30 days" or "steady increase with strong late growth"), without any learned prototypes. Step (H-D) concatenates the attribute phrases into a short textual summary and injects it into the Heuristic LLM prompt, producing the final query for the LLM. Finally, Step (H-E) sends this query to the LLM, parses the returned JSON into status, time-to-failure bucket, explanation, and recommendations, and logs these outputs for evaluation.

B Artifact Appendix

B.1 Artifact Overview

We provide the SMARTTalk artifact to support independent inspection and reproduction of the main results in this paper. The artifact contains the implementation of the SMARTTalk pipeline, including SMART log preprocessing, N day window construction, patch extraction, offline pattern learning, phrase dictionary construction, PATTERNMEMORY, LLM based in-

ference, and evaluation scripts. The artifact is publicly available at:

https://github.com/Damrl-lab/SMARTTalk

The repository README gives the most up to date execution commands, data placement instructions, and troubleshooting notes. The appendix summarizes the artifact at a high level so that readers can understand what is included and how it connects to the paper.

B.2 Artifact Contents

The artifact is organized around the main stages of SMARTTalk. It includes: (i) preprocessing and split generation scripts for the Alibaba SMART dataset; (ii) configuration files for MB1 and MB2 experiments; (iii) offline training code for the patch encoders and pattern discovery; (iv) saved PATTERNMEMORY, phrase dictionaries, and cached model outputs; (v) prompt templates for SMARTTalk and the LLM baselines; and (vi) scripts for regenerating paper tables, figures, ablations, and artifact sanity checks.

The repository also includes sample processed data and cached outputs so that reviewers can run a lightweight check without downloading the full raw dataset or invoking live LLM APIs. Full end to end reproduction is also supported when the public Alibaba SMART logs and the required compute resources are available.

B.3 Hardware and Software Requirements

The quick artifact check can be run on a standard CPU machine with a recent Python environment. Rebuilding the full SMARTTalk pipeline from raw SMART logs is more expensive because it requires preprocessing large time series files, training CNN based patch encoders, rebuilding PATTERNMEMORY, and optionally running LLM inference. GPU acceleration is recommended for full offline training and local open model inference, although cached outputs allow the main paper tables to be regenerated without repeating all expensive steps.

The artifact provides environment specifications through the repository documentation, including Python package requirements, a Conda environment file, and Docker support. Live LLM inference requires either local model endpoints or API credentials, but the cached reproduction path does not require private API keys.

B.4 Getting Started

The fastest way to check the artifact is to run the quick reproduction script from the repository root:

```
bash scripts/07_reproduce/reproduce_quick.sh
```

This quick check validates the package structure, loads sample SMART windows, checks cached SMARTTalk artifacts, and regenerates representative evaluation outputs from cached state. It is intended as a smoke test rather than a full rerun of all experiments.

B.5 Reproducing the Main Results

The artifact supports three reproduction modes. First, the quick check uses bundled sample data and cached outputs for a lightweight validation. Second, the cached reproduction path regenerates the main paper tables and figures from saved predictions, pattern memory outputs, phrase dictionaries, and sampled test results:

```
bash scripts/07_reproduce/reproduce_from_cache.sh
```

Third, the full reproduction path reruns preprocessing, offline pattern learning, inference, evaluation, and ablation scripts from the public Alibaba SMART logs:

```
bash scripts/07_reproduce/reproduce_full.sh
```

The full path assumes that the raw Alibaba SMART logs have been downloaded and placed according to the repository documentation. It also assumes sufficient compute resources for CNN training and, when live inference is desired, access to either local LLM serving or external model APIs.

B.6 Expected Outputs

The artifact reproduces the main evaluation components reported in the paper: status prediction results with precision, recall, $F_{0.5}$, FPR, and FNR; time to failure bucket metrics; explanation and recommendation evaluation; sensitivity studies for observation window length N and patch length L; phrase dictionary and PATTERNMEMORY inspection; and selected ablation results. The default paper setting is $N = 30$ days and $L = 5$ days, while the sensitivity scripts evaluate multiple values around this default.

Svalinn: Overload Control in Large-Scale Servers with Multiple Resource Bottlenecks

Bhaskar Pardeshi Peidi Song Ahmed Saeed
Georgia Tech

Abstract

Modern overload controllers treat application binaries as monoliths and react to aggregate performance, a misconception we call *the single-queue fallacy*. Real applications have diverse, data-dependent execution paths that stress different resources. Reacting to overall performance forces the controller to focus on the most bottlenecked resource while leaving others underutilized.

We present Svalinn, a modular overload controller designed to maximize utilization across multiple potential bottlenecks such as CPU, memory bandwidth, and contended locks. Svalinn separates throughput control and latency control. A credit-based admission controller regulates offered load to maximize a user-defined utility function. Per-bottleneck controllers then enforce latency targets using Active Queue Management (AQM) policies. While AQM is straightforward for resources with explicit software queues, managing memory-bandwidth-intensive operations is challenging due to the absence of such queues. To handle this case, we introduce `m_semaphore`, which adaptively limits the number of concurrent memory-bandwidth-intensive requests to achieve high memory-bandwidth utilization using the minimum necessary CPU cores. We integrate Svalinn into four applications and two runtimes and show that it improves goodput by up to 6.51× without compromising latency.

1 Introduction

Modern datacenter applications have strict performance and cost-efficiency requirements. Thus, applications attempt to maximize resource utilization while meeting strict Service Level Objectives (SLOs). Historically, packing has meant maximizing the utilization of CPU, measured as the percentage of active CPU time out of total elapsed time, and memory capacity, measured in bytes. However, as datacenter operators push server utilization to higher levels, other resources such as memory bandwidth, network bandwidth, and storage IOPS have become bottlenecks that limit overall server utilization [2, 21, 39]. In particular, a single application can produce requests with heterogeneous resource requirements (e.g., CPU, network, or memory bandwidth). Such bottlenecks can cause hard-to-debug packet drops [2, 3], receive livelock scenarios where a server is busy processing incoming requests instead of serving already received requests [9, 10, 37], and transaction failures [32]. To that end, overload control systems are employed to balance utilization and latency, maximizing the utilization of *all* resources while avoiding SLO violations.

Despite the heterogeneity in per-request resource requirements, modern admission controllers typically treat applications as a monolith, reacting to overall server performance (e.g., latency) [9, 31, 55, 59] or limiting the maximum number of requests in flight to a certain replica [50, 52, 56]. These approaches implicitly assume that all requests are constrained by the most congested resource on the server. We refer to this assumption as *the single-queue fallacy*. Under this false assumption, once the most congested resource becomes overloaded, aggregate signals such as end-to-end latency or requests in flight immediately reflect that state. As a result, the controller reduces admitted load, leaving uncongested resources stranded. We show in several applications that this behavior can lead to severe underutilization, corresponding to a loss of up to 83% in aggregate machine throughput.

The challenge of balancing the utilization of multiple resources is exacerbated by the fact that the resource requirements of a request can be data-dependent, and may only be precisely known during its execution. For example, a request to a cache server will be CPU-intensive when fetching a small value, memory-bandwidth-intensive when fetching a large value, and lock-intensive when accessing hot, lock-protected data. Thus, typical approaches of resource isolation [7, 19, 25, 41] are insufficient as they operate at the granularity of an application, not a request. Moreover, prioritization-based techniques fail because they assume prior knowledge of the resource requirements of each request. Finally, it is particularly challenging to manage resources that can be accessed implicitly from any part of the code (e.g., memory bandwidth). Intra-application isolation [22] and prioritization [13, 20, 29, 30] techniques conflate congestion of such resources and CPU congestion.

In this paper, we present Svalinn, a novel overload controller that can handle heterogeneous requests with diverse resource requirements. Svalinn can balance the utilization of multiple resources by separating throughput control from latency control. In particular, throughput control is performed by a credit-based admission controller that admits more load as long as a user-defined utility function improves. This utility function may be as simple as aggregate system throughput or as complex as a weighted combination of throughput, loss rate, and resource utilization. Separately, latency control is performed in a distributed fashion at each resource, based on the state of the resource at the time it is accessed. Latency con-

trol is particularly challenging for memory, which is accessed implicitly. To that end, we present the memory semaphore (`m_semaphore`), a lightweight API that limits the number of concurrent threads that can execute memory-bandwidth-intensive code paths. Developers can profile parts of their code and call `m_semaphore.try_wait()` conditionally based on the nature of the request (e.g., before reading a large value from memory). `m_semaphore` adaptively adjusts the number of concurrent threads allowed to consume memory bandwidth based on the observed memory bandwidth utilization using a Multi-Armed Bandit (MAB) algorithm. If a request cannot access a resource, it is queued or dropped, following user-defined Active Queue Management (AQM) policies.

We evaluated Svalinn using synthetic workloads and three real applications: Memcached, RocksDB, and DataFrame. To demonstrate the robustness and generality of Svalinn, we evaluate Svalinn on two different hardware setups. Moreover, we implement it in two runtimes: Shenango's runtime exemplifying a low-latency environment and Go exemplifying a runtime common to modern microservices. We compare Svalinn with SEDA [55], a latency-based overload controller that reacts to the overall performance of an application, and Protego [10], a state-of-the-art overload controller that reacts to a large number of bottlenecks, tailored for lock contention. We observe that Svalinn can improve the goodput of applications by up to 6.51× compared to SEDA without compromising latency. Compared to Protego, Svalinn improves the goodput by up to 6.49× for the same application.

The contributions of this paper are as follows:

- We present Svalinn, a novel overload controller that can balance the utilization of multiple resources by separating throughput control from latency control.
- We present `m_semaphore`, a lightweight API that allows developers to limit the number of concurrent threads accessing memory-bandwidth-intensive code paths.
- We evaluate Svalinn using a synthetic workload as well as by integrating it into three real-world applications: Memcached, RocksDB, and DataFrame.

Svalinn is available as open-source software for Shenango at github.com/GT-ANSR-Lab/svalinn-shenango and for Go at github.com/GT-ANSR-Lab/svalinn-go.

2 Background and Motivation

2.1 Problem Context

Modern applications are typically broken into microservices, each exposing a large number of entrypoints (APIs) [26]. Each of these entrypoints may have different resource requirements. For example, a data processing service may have some APIs that are CPU-intensive, while others are memory-bandwidth-intensive. Both types of requests can be processed by the same binary and share the same pool of resources. However, the resource requirements and usage patterns of each request type are different. Moreover, the same request type can be bottlenecked on a different resource based on the size of its working set or the data it requires.

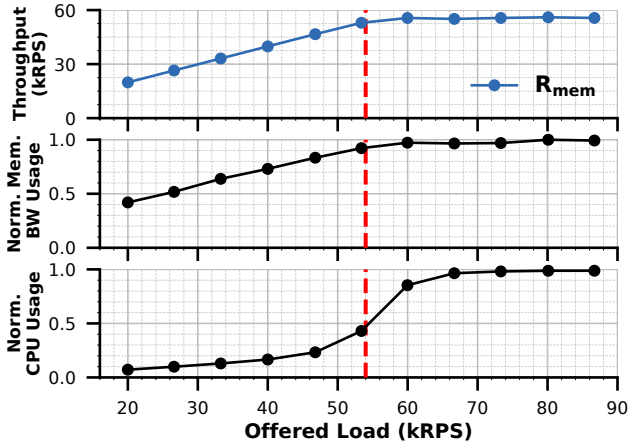

Figure 1: Throughput, normalized memory-bandwidth usage, and normalized CPU usage when the application receives only memory-intensive requests (R_{mem}). The red line marks the load at which throughput and memory bandwidth saturate, and indicates the minimum CPU required to reach peak throughput and memory-bandwidth utilization.

Existing overload controllers typically ignore request heterogeneity and treat all traffic uniformly. They operate under a common assumption, which we call *the single-queue fallacy*, that a single, shared bottleneck queue constrains all requests. Consequently, congestion at this bottleneck triggers a global load reduction, even when underutilized resources could safely serve a subset of incoming requests.

The single-queue fallacy manifests in two distinct ways. First, some controllers react to aggregate server-level signals, such as end-to-end latency [31, 32, 55] or requests-in-flight [50, 52, 56], without distinguishing which specific resource is overloaded. Second, others react exclusively to a fixed resource, such as CPU [9, 59] or storage [21, 35]. Consequently, both approaches prematurely throttle overall machine load when one resource peaks, failing to exploit idle capacity elsewhere. Furthermore, fixed-resource controllers suffer from the additional vulnerability of being entirely blind to congestion in unmonitored resources.

2.2 Modern Multi-Resource Overload Control

To illustrate the impact of the single-queue fallacy, consider a service with two types of requests: R_{cpu} is CPU-intensive and R_{mem} is memory-intensive.[1] For simplicity, each request type in this example performs a completely different set of operations and does not share any common code paths. R_{cpu} requests perform square root computations for 25μs, while the R_{mem} requests perform non-temporal stores on a 32KB buffer,

[1] We will use memory-intensive as a shorthand for memory-bandwidth-intensive for the rest of the paper.

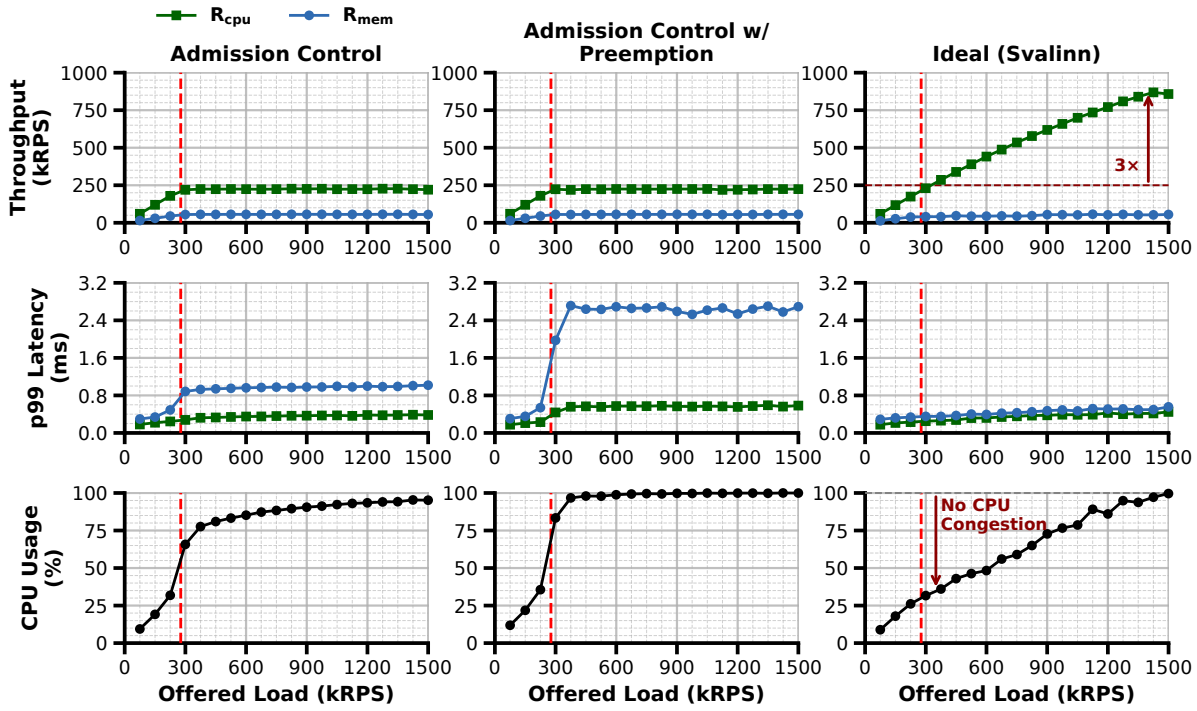

Figure 2: Throughput, tail latency, and CPU usage for an application receiving two types of requests: a CPU-intensive request (R_{cpu}) and a memory-intensive request (R_{mem}). The first column shows performance with an admission controller. The second column shows performance with an admission controller and a preemption-based scheduler. The third column shows the ideal or expected performance of the application. The red line marks the incoming load at which memory bandwidth saturates.

leading to a service time of 100μs. We run this example in experimental SETUPB, discussed in Section 5.1.

We start by profiling the machine capacity for each request type. R_{cpu} requests can achieve a maximum throughput of 1M requests per second (RPS) when a client issues only that type of request, while the R_{mem} requests can achieve a maximum throughput of roughly 55K RPS. R_{mem} requests can saturate the memory bandwidth of the machine while using 50% of the cores. On the other hand, R_{cpu} requests consume a negligible fraction of the memory bandwidth of the machine. Figure 1 shows the performance of the system when clients only issue R_{mem} requests at different offered load values. At low load, CPU utilization and memory bandwidth utilization grow linearly with load. As the system becomes bottlenecked on memory bandwidth, CPU utilization grows superlinearly with load, reflecting the fact that different threads are competing for memory bandwidth, leading to excessive stalling that manifests as high CPU utilization. It is obvious from this experiment that in such scenarios, a replica will seem fully utilized when, in fact, the CPU is underutilized.

Per-replica overload control. Next, we mix the two request types by having clients generate a load that is made of 80% R_{cpu} and 20% R_{mem} requests. We vary the total offered load to the service and measure overall throughput, tail latency, and CPU and memory bandwidth utilization. To keep latency bounded, we rely on a simple admission-control mechanism that limits the number of requests in flight based on the observed overall latency of the service [9, 55, 59]. Results are shown in the first column of Figure 2. We observe that the overall throughput peaks at around 300K RPS.

At first glance, this behavior seems reasonable. In particular, resource usage at peak throughput is high: CPU utilization is between 60-90% and memory bandwidth utilization is near 100%. However, consider that the throughput of R_{cpu} requests plateaus when R_{mem} requests saturate the memory bandwidth of the machine. At that point, we observe that CPU utilization grows superlinearly with the offered load, leading to a situation where the CPU becomes the bottleneck of the system. This behavior is due to the fact that R_{mem} requests consume CPU cycles stalling due to memory bandwidth congestion, which lowers the effective CPU capacity available to serve R_{cpu} requests. As a result, the CPU becomes a bottleneck, although it is effectively underutilized. This suggests that if R_{mem} requests are restricted to the number of cores required to fully utilize memory bandwidth, they do not stall excessively because their aggregate memory bandwidth demand no longer congests memory bandwidth. The remaining cores can then be used by R_{cpu} requests, enabling up to 3× higher R_{cpu} goodput, as shown in the third column of Figure 2.

The challenge of this scenario is exacerbated by the fact that

memory bandwidth is a resource accessed implicitly through LOAD and STORE instructions, not through an explicit queue. Unlike network, disk, and locks, which have their own queues, enabling monitoring and control [3, 10, 21, 32, 38], memory bandwidth is shared implicitly among all requests running on the machine. Access to hardware-level queues is not always feasible and can complicate the design and operation of applications. Thus, simple extensions to existing admission control mechanisms that monitor and control explicit queues are not sufficient. Moreover, memory access is spread throughout the whole application, and high utilization requires simultaneous access by multiple threads within a single application. Thus, precise tracking of memory bandwidth consumption might require tracking the behavior of all the instructions executed by an application, an untenable objective.

Preemption-based scheduling. A natural question is whether effective multiplexing of shared resources can mitigate this problem. To test that hypothesis, we repeat the same experiment but enable preemption. In particular, we use Aspen, a lightweight interrupt-based preemption mechanism [20]. The objective of preemption in this scenario is to improve CPU utilization by preempting R_{mem} requests when they are stalling, replacing them with R_{cpu} requests. This choice comes at the expense of increased latency for R_{mem} requests and added context switching overhead. The results are shown in the second column of Figure 2. Surprisingly, we observe that only the preemption overhead manifests without any significant improvement in throughput.

Preemption does not help because it is based on the assumption that multiplexing the use of resources leads to higher overall utilization. However, in this scenario, we do not only need to multiplex resources; we need to limit the resource usage of a specific type of resource by a specific type of request. In particular, R_{mem} requests in this example saturate the memory bandwidth of the machine using only 24 cores out of the available 45 cores. Thus, any R_{mem} request that is scheduled on the remaining cores will still waste CPU cycles. Moreover, preemption does not differentiate between different types of requests, nor does it react to specific resource usage patterns. As a result, preemption ends up being ineffective as it does not reduce the amount of wasted CPU cycles. Another downside of preemption is that it might be harmful if the service time of R_{cpu} requests is longer than the service time of R_{mem} requests.

Atropos [23], a recent overload system, attempts to address this gap through targeted task cancellation, judiciously aborting requests to maximize resource release. However, this approach relies on the assumption that congestion is driven by a small number of disproportionately heavy requests, a condition that does not hold in the scenario described above. Furthermore, Atropos is limited in its scope: it neither supports memory bandwidth regulation nor provides a framework for proactive admission control.

Inter-application interference vs. intra-replica resource contention. While in this example the two request types can be separated into their own binaries, which can be allocated separate resources and isolated from each other using OS-supported primitives [19, 25, 41, 44], this approach is not always feasible. First, separating request types into different binaries increases the operational complexity of the service, as it requires managing multiple deployments and scaling policies. Second, in many cases, different request types share significant portions of the code path, making it impractical to separate them into different binaries without code duplication. The difference can even lie in their working set size, which would make it impossible to separate them without significant code changes. Finally, separating request types into different binaries can lead to resource fragmentation, as resources allocated to one binary may be underutilized while other binaries are overloaded. Thus, there is a need for an admission control mechanism that can effectively manage the resource usage of different request types within the same binary, avoiding the single-queue fallacy.

2.3 Objectives and Challenges

The single-queue fallacy can lead to significant underutilization of resources in modern data centers, especially as applications become more complex and diverse. To address this issue, we propose Svalinn, an admission control mechanism that aims to maximize the utilization of all resources in a system without affecting latency. Such an ambitious objective requires Svalinn to be extensible, allowing the incremental addition of new resource controllers as new bottlenecks are identified. Another key requirement is that Svalinn functionality should introduce minimal changes to the application logic. Thus, the realization of Svalinn requires overcoming the following challenges:

- **Nondeterministic behavior / unprofilable workloads.** Requests of the same type may have different resource requirements based on their input data or other dynamic factors. This variability makes it difficult to identify the resource requirements of a request before it actually starts to run on the server. Moreover, workload characteristics can change dynamically, requiring the system to adapt to such changes without reconfiguration.
- **Balancing performance objectives.** Maximizing utilization typically corresponds to an improvement in throughput. However, Svalinn should achieve that objective without increasing latency. Moreover, the fact that some requests will need to be executed in order to identify their resource requirements implies that some requests will be dropped after they start executing because of resource congestion. Thus, Svalinn must balance multiple performance objectives, including throughput, latency, and drop rate.
- **Minimal changes to application logic and added overhead.** Tracking and controlling resource usage of different request types within the same binary may require changes to the application logic. This challenge is significant given that memory access is typically performed implicitly through

`LOAD` and `STORE` instructions. Tracking such accesses may require changes to the application code or the use of specialized libraries or frameworks. However, such changes should be minimal to avoid increasing the complexity of the application and hindering adoption. Moreover, the added overhead of tracking and controlling resource usage should be minimal to avoid negating the benefits of improved resource utilization.

- **Scalability.** Modern data centers host services that handle millions of requests per second from hundreds or even thousands of clients. Thus, any admission control mechanism needs to be scalable to handle such high request rates and number of clients without becoming a bottleneck itself.

3 The Design of Svalinn

We design Svalinn as a modular system that separates throughput and latency control. Each of the controllers is designed to be configurable to meet the requirements of the application. The modular design ensures extensibility and minimizes the amount of changes needed to application logic.

Throughput is controlled through a credit-based admission controller. A single credit indicates that the client can send one request to the server. The total number of issued credits is determined based on a user-defined utility function that balances different performance objectives (e.g., throughput, drop rate, or utilization level of a specific resource). This user-defined utility function enables operators to customize application behavior according to their needs; however, the resulting admission decisions may be independent of the status of individual bottlenecks. Consequently, an admitted request can still incur high latency when it competes for a bottlenecked resource.

Latency is minimized by distributed controllers, each independently applying an Active Queue Management (AQM) policy to the queue of a single bottleneck. For example, a latency controller can drop requests at risk of violating SLOs. This modular design allows for extensibility, as latency controllers can be independently designed and incrementally deployed as new bottlenecks are detected.

We focus on memory bandwidth as a bottleneck that is accessed implicitly, building a latency controller for this unique bottleneck. In particular, we present the memory semaphore (`m_semaphore`) to limit the number of concurrent threads performing memory-intensive operations. The `m_semaphore` has two functions. First, it minimizes the number of CPU cycles wasted on stalling by only allowing a limited number of threads to concurrently consume memory bandwidth, maximizing memory bandwidth utilization without wasting CPU cycles. Second, it allows for building a queue of threads awaiting to consume memory bandwidth. That queue enables latency control by applying AQM policies, turning an implicit bottleneck to an explicit bottleneck. Our proposed design is shown in Figure 3.

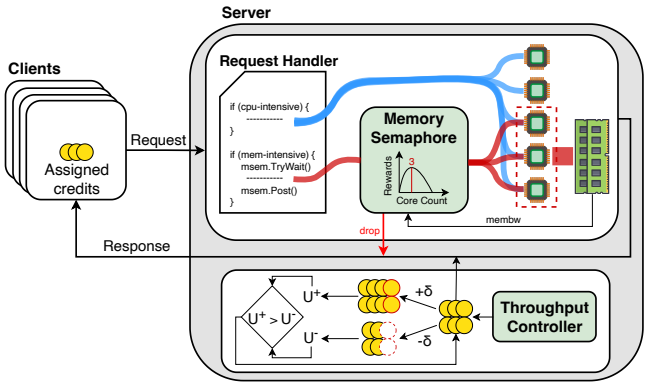

Figure 3: Svalinn system architecture.

3.1 Utility-Based Throughput Control

The throughput controller admits requests to optimize a user-defined utility function that captures different performance metrics (e.g., throughput, drop rate, resource utilization). The controller optimizes the utility function by exploring different levels of admitted load through micro-experiments, adapting to changing workload characteristics over time. Our approach is inspired by innovations in network congestion control, particularly the PCC family of algorithms [14, 15]. Unlike recent proposals that use fixed heuristics to regulate load based on low-level signals (e.g., queueing delay [9] or efficiency [10]), our controller admits general convex utility functions. A server regulates incoming load by controlling the size of a single credit pool (i.e., the maximum number of credits it can issue at a given time). In other words, different request types use the same credits which are issued indiscriminately to clients. When a client wishes to issue a request, it first reports its demand to the server. The server replies with credits, if available, and the client may only send a request if it has sufficient credits. The controller attempts to identify the credit pool size that maximizes the user-defined utility function through micro-experiments.

A micro-experiment is a short test interval during which the controller evaluates the application's performance under a perturbed credit-pool size. In each control cycle, the controller runs two micro-experiments: a credit-increase experiment, denoted by δ^+, and a credit-decrease experiment, denoted by δ^-. During each micro-experiment, the controller either increases or decreases the credit pool by δ credits, monitors the application for $\Delta\, t_{monitor}$ interval, and records relevant performance metrics. Monitored metrics include the number of received requests, the number of successfully sent responses, the number of dropped requests, queueing delay, and the duration of the experiment. The controller calculates utility values $utility_{\delta^+}$ and $utility_{\delta^-}$ for the two micro-experiments. After both micro-experiments finish, the controller increases the pool size if experiments show that $utility_{\delta^+}$ is higher than $utility_{\delta^-}$, or vice versa. This process repeats continuously.

While this micro-experiment framework is conceptually sound, realizing it in practice introduces a key complication: increasing the credit pool size does not guarantee a higher request arrival rate when clients are not backlogged. Because a credit represents only permission to send a request, the actual arrival rate during a δ^+ experiment can inadvertently fall below that of a δ^- experiment. In such cases, if $utility_{\delta^+}$ exceeds $utility_{\delta^-}$, the controller would incorrectly attribute the higher utility to the larger pool size and expand it further. To address this, we leverage the insight that the controller ultimately cares about the request arrival rate, for which the credit pool size is merely a proxy. When the arrival rate during the δ^+ experiment is lower than that of the δ^- experiment, we swap their metrics, computing $utility_{\delta^+}$ using the higher-arrival data and vice versa. This relabeling ensures the controller evaluates the perturbations against actual traffic variations rather than nominal pool adjustments.

Compounding the issue of accurate utility computation is the physical propagation delay between modifying the credit pool and observing its impact on the incoming traffic rate. This propagation delay can be comparable to individual request execution times. For instance, a network RTT of ten microseconds is on par with a key-value store request processing time of a few microseconds. Consequently, the controller must enforce a warmup interval ($\Delta\, t_{warmup}$) immediately following each pool adjustment. This allows the new configuration to stabilize across the network before the controller attributes any subsequent performance metrics to the perturbation. The complete controller algorithm is detailed in Appendix A.1.

A final challenge remains at low to medium loads: clients may hold onto issued credits indefinitely without utilizing them. If the server strictly limits the total issued credits to its exact processing capacity, this credit retention prevents the expected load from fully materializing, leaving the server underutilized. To bridge this gap between nominal credit allocation and actual resource utilization, the controller safely overcommits credits. This ensures the server pipeline remains fully saturated even when a subset of clients retains their credits, mirroring the overcommitment strategies employed by other receiver-driven, credit-based transport and admission control systems [9, 10, 38].

3.2 Making Memory Bandwidth Access Explicit Using `m_semaphore`

Our objective is simple: determine the minimum number of concurrently executing memory-intensive requests required to saturate the available memory bandwidth. While the objective is simple, achieving it in practice is challenging due to the dynamic nature of real workloads and their constituent requests. As demand and request mix evolve over time, the optimal concurrency level changes, necessitating a mechanism that can adjust this level dynamically and be applied selectively to specific requests. To address these challenges, we introduce `m_semaphore`, a semaphore whose capacity is dynamically adjusted based on the available memory bandwidth and the per-request memory bandwidth demand. The `m_semaphore` is used by developers to protect access to memory-intensive sections of their code. Requests that cannot acquire `m_semaphore` are held outside the section, making access to memory bandwidth explicit and moving excess memory-intensive requests into an explicit queue. `m_semaphore` is implemented as a singleton, so all instrumented sections share the same underlying semaphore instance. We discuss how developers identify and instrument such sections in Section 3.4.

Algorithm 1: `m_semaphore` Capacity Controller.

$cores_{current}$: Current `m_semaphore` capacity
$cores_{max}$: Maximum possible `m_semaphore` capacity
$membw_{max}$: Maximum memory bandwidth seen so far
$R_{avg}[cores_{max}]$: Average reward at each core count
τ_{last}: Last time $cores_{current}$ was updated
Parameter α: Weight given to memory bandwidth usage over CPU usage in reward computation
Parameter ω: Weight assigned to the latest reward sample when updating each core's average reward
Parameter ε: Probability of exploration
Parameter $\Delta\, t_{msem}$: Interval at which $cores_{current}$ is recomputed

Function `UpdateCapacity()`:
  `// Run once every control cycle`
  if $\text{now} - \tau_{last} < \Delta\, t_{msem}$ **then**
    return;
  `// Get memory bandwidth usage`
  $membw_{current} \leftarrow$ `GetMemoryBandwidthUsage()`;
  $membw_{max} \leftarrow \text{Max}(membw_{max}, membw_{current})$;
  `// Calculate reward for current capacity`
  $R \leftarrow \alpha \cdot \frac{membw_{current}}{membw_{max}} - (1-\alpha) \cdot \frac{cores_{current}}{cores_{max}}$;
  $R_{avg}[cores_{current}] \leftarrow \omega \cdot R + (1-\omega) \cdot R_{avg}[cores_{current}]$;
  `// Find best performing capacity`
  $cores_{best} \leftarrow \arg\max_{1 \le i \le cores_{max}} R_{avg}[i]$;
  `// Update the capacity`
  $u \sim$ `Uniform`$(0,1)$;
  if $u < \varepsilon$ **then**
    `// Explore`
    $explore_direction \leftarrow$ `RandomChoice`$(-1,+1)$;
    $cores_{current} \leftarrow cores_{best} + explore_direction$;
  else
    `// Exploit`
    $cores_{current} \leftarrow cores_{best}$;
  $\tau_{last} \leftarrow now$;

The semaphore dynamically adjusts its capacity using a Multi-Armed Bandit (MAB) controller (Algorithm 1). The MAB controller treats each possible semaphore capacity as an arm. Once an arm is pulled, the system runs with that configuration for $\Delta\, t_{msem}$ duration, during which we observe the resulting performance. At the end of this control cycle, we compute a reward associated with the chosen capacity and

update the average reward for that arm. Our objective is to identify the minimum semaphore capacity that can saturate memory bandwidth. Consequently, we design a reward function that increases with memory bandwidth utilization but penalizes CPU usage.

$$\alpha \cdot \frac{membw_{current}}{membw_{max}} - (1-\alpha) \cdot \frac{cores_{current}}{cores_{max}}$$

This function encourages configurations that achieve high memory bandwidth utilization with minimal CPU utilization. The parameter $\alpha \in [0,1]$ controls the balance between memory-bandwidth utilization and CPU utilization. We discuss the choice of our reward function and its sensitivity to the parameter α in Appendix B.3 and B.4 respectively.

The controller balances exploration and exploitation using an ε-greedy strategy [6, 48, 51]. In each control cycle, with probability $(1-\varepsilon)$, it selects the capacity with the highest reward, which under our reward design corresponds to high memory bandwidth utilization with minimal core usage. With probability ε, it explores an alternative capacity. Rather than exploring uniformly over all possible capacities, we restrict exploration to capacities adjacent to the current best one. This keeps exploration local, reduces performance noise, and avoids erratic jumps in concurrency.

Continued exploration is important because the workload properties can be non-stationary. For example, a key-value store can experience significant variation in the sizes of values being read, which changes the per-request demand for memory bandwidth, shifting the optimal capacity of the semaphore over time. A controller that only exploits past observations can therefore remain stuck at a capacity that was previously good but is no longer appropriate. We use ε-greedy because it provides this continued exploration explicitly. In contrast, more sophisticated MAB strategies, such as softmax, upper confidence bound, or Thompson sampling, are typically used in stationary settings, and their exploration naturally narrows over time. As a result, under regime changes they may not explore enough to reach the new operating point.

3.3 AQM at Bottleneck Queues

Distributed latency control is achieved by deploying AQM policies at each identified bottleneck. It is possible for a single request to face multiple bottlenecks along its execution path. Therefore, we avoid having a different per-bottleneck AQM policy configuration. Instead, all bottlenecks make AQM decisions using a single per-request property: queueing-delay budget, similar to Protego [10]. Specifically, each request is tagged with an SLO-derived queueing-delay budget when it enters the system. As the request traverses the execution path, latency controllers at subsequent bottlenecks dynamically compute the remaining budget by deducting the time the request spent waiting in each bottleneck's queue. If the remaining budget is less than the bottleneck's instantaneous queueing delay, the request is proactively dropped before being enqueued.

Handling dropped requests. The proposed approach implies that requests may be dropped after being partially executed. When a request is dropped, the server can issue a failure message to the client so that the client can issue the request to another replica of the application. Another potential approach is to have the server spillover the dropped request to another replica directly, similar to load balancing behavior in some sidecars [18]. Moreover, developers have to specify a "cleanup" callback function to be invoked when a request is dropped. This function allows developers to perform any necessary cleanup actions, such as releasing resources or reverting any state changes. Recent work shows that such cleanup support is already common in practice: 76% of 151 popular open-source applications support task cancellation and already provide handlers to clean up request state on abrupt termination [23]. Developers also have the option to label requests as "non-droppable." Such requests are not dropped and treated as high-priority requests by the AQM logic to minimize their queueing delay.

3.4 Svalinn Deployment Guidelines

Identifying bottlenecks. Explicitly accessed bottlenecks can be identified using profilers such as LDB [8] and GigiProfiler [24], which provide function-level latency information and help locate the code paths responsible for bottleneck-induced delay. For memory-intensive bottlenecks, developers can use tools such as Intel VTune [27], HiresPerf [33], or perf [34] to identify memory-intensive functions. These tools also expose the call paths leading to such functions, which helps determine where `m_semaphore` should be placed in the request execution path.

Instrumenting explicit bottlenecks. System designers expose resource contention points to the application through new APIs that serve as enforcement points for latency control. For system- or runtime-level bottlenecks, these APIs can be implemented by interposing the underlying system or runtime calls, as in Protego [10]. For application-internal bottlenecks, these APIs are instrumentation APIs that expose the relevant resource usage needed to estimate queueing delay and perform AQM [22, 23]. In both cases, developers update the application to use these APIs and incorporate custom cleanup logic to handle request drops.

Instrumenting memory-intensive bottlenecks. Developers leverage the runtime-managed singleton `m_semaphore` object to instrument the call path leading to the memory-intensive code region. This explicitly isolates the critical region and exposes a queue for AQM enforcement. In practice, such bottlenecks are rare; for instance, Memcached and RocksDB each require only a single instrumented call path, terminating at the `memcpy` that copies keys into the response buffer. Consequently, while explicit annotation is required, the modification scope remains minimal across our evaluated applications.

4 Implementation

We implement Svalinn in two runtimes: Shenango [41] and Go. Our Shenango implementation builds on the RPC layer originally implemented for Breakwater [9] and Protego [10]. Our Go implementation adds Svalinn to a bare-bones RPC layer. Both RPC layers follow the dispatcher model: a dispatcher thread parses incoming packets into requests and spawns a worker thread for each request. The throughput controller is implemented as an event-driven state machine and runs inline when each worker finishes executing a request. As a result, workers update controller state on the fast path, eliminating the need for dedicated control threads. For each micro-experiment, the controller records the number of received requests, completed responses, and dropped requests, along with queueing delay, energy consumed, memory bandwidth consumed, and experiment duration, and passes these metrics to a user-defined utility function.

`m_semaphore` is implemented as a C++ library with C bindings for Shenango applications, and as a separate Go library for Go-based applications. It exposes three methods: `try_wait()`, `wait_if_uncongested()`, and `post()`. Using `try_wait()` mimics a non-blocking semaphore and thus enforces an AQM policy that maintains a zero-length queue. It returns `true` if admitting the request to the memory-intensive section does not exceed the permitted concurrency, and `false` otherwise. In contrast, `wait_if_uncongested()` allows requests that exceed the permitted concurrency to be enqueued, provided they have sufficient remaining SLO-derived budget, and returns `true` if the request is enqueued and later granted access to the region, and `false` otherwise. By default, all workloads in our evaluation use `try_wait()`. The `UpdateCapacity()` routine is invoked inline with `try_wait()`, `wait_if_uncongested()`, and `post()`, but a capacity update takes effect only once per control cycle. `m_semaphore` reads memory bandwidth counters using Intel PCM [28]. Since fetching memory bandwidth usage can introduce noticeable overhead at small timescales, we move this operation off the request fast path. In Shenango, we modify the IOKernel scheduler, which runs every 5–10 μs, to collect memory bandwidth usage periodically. In Go, we dedicate a logical core to collect performance metrics, including memory bandwidth, once every 5 μs.

The utility-based throughput controller in Shenango extends the existing Breakwater [9, 10] RPC library and adds 1815 LoC. The `m_semaphore` library for Shenango contributes 961 LoC, and the modifications to the Shenango IOKernel needed to expose host memory bandwidth readings add another 631 LoC. Integrating the RPC library into applications required 1462 LoC for DataFrame and 1668 LoC for RocksDB. We reuse Memcached and the synthetic application from Protego, adding 1082 LoC and 812 LoC, respectively, to support heterogeneous request types. Each application required only 4–10 LoC to wrap memory-intensive paths with `m_semaphore` and handle dropped requests.

The Go implementation of the admission-controller-enabled RPC library adds 5696 LoC. Exposing thread queueing delay from the Go runtime required 93 LoC in SysMon. We add a perf goroutine pinned to a logical core that periodically refreshes memory bandwidth usage, thread queueing delay in the Go runtime, and TCP RX buffer delay, which adds 1502 LoC. The Go version of `m_semaphore` adds 454 LoC, and the Go synthetic application adds 961 LoC.

5 Evaluation

Our evaluation answers the following key questions:

1. Does Svalinn deliver high utilization and bounded latency across heterogeneous bottlenecks?
2. Can Svalinn improve application performance even when resources are overprovisioned?
3. Does Svalinn accommodate and optimize different user-defined utility functions?
4. How sensitive is Svalinn to retransmissions, dynamic workloads, parameter changes, and request mixes?
5. Do Svalinn's benefits persist across different machines and runtimes?

5.1 Evaluation Setup

Testbed. We evaluate Svalinn on two testbeds: SETUPA and SETUPB. SETUPA consists of eleven CloudLab [17] xl170 nodes, each equipped with a 10-core (20-logical-core) Intel E5-2640v4 @ 2.4 GHz, 64 GB ECC RAM, and a Mellanox ConnectX-4 25 GbE NIC. The memory bandwidth of each node is approximately 45 GB/s. Nodes are connected via a Mellanox 2410 switch, with an average RTT of 10 μs. All machines run Ubuntu 24.04 with Linux 6.8, and our applications use 18 logical cores per node. SETUPB consists of two machines, each with dual-socket Intel Xeon Gold 6442Y processors (24 local cores per socket @ 2.6 GHz), 128 GB ECC RAM, and Mellanox ConnectX-7 200 Gb/s NICs connected back-to-back. Each machine provides roughly 180 GB/s of memory bandwidth. We use a single socket per machine for the application and observe a 40 μs RTT. Both machines run Ubuntu 22.04 with Linux 6.0, and applications use 45 logical cores per machine. Unless otherwise noted, all applications run on Caladan [19] and are linked with its runtime. For Go-based tests, we run all experiments on SETUPA with Go runtime version 1.25.3. In both setups, one node acts as the server and the remaining nodes act as clients. We use an open-loop load generator based on a Poisson arrival process, with a total of 100 client threads distributed across the client machines. Each thread maintains one connection to the server and generates requests of different types according to the target mix. We disable TurboBoost, frequency scaling, and c-states as done in other works using similar systems [9, 10, 20, 41].

Workloads. We evaluate Svalinn using synthetic workloads and three real applications: Memcached [1], RocksDB [16], and Dataframe [36]. Each application implements up to

three request types: R_{cpu} (a CPU-intensive), R_{mem} (a memory-intensive), and R_{lock} (a mutex-intensive) request.

The synthetic workload represents applications whose requests have different resource requirements but comparable processing times.[2] In particular, an R_{cpu} request performs 7500 square-root computations in a loop. An R_{mem} request issues 25 non-temporal stores over a 32 KB buffer. An R_{lock} acquires a global mutex and executes 5000 square-root computations in a loop. On SETUPA, the average processing times are 40 μs for R_{cpu}, 80 μs for R_{mem}, and 40 μs for R_{lock}.

RocksDB and Memcached are widely used key-value stores in datacenter applications. In both, R_{cpu} requests issue `GET` operations on small values, with sizes drawn uniformly between 5 B and 1000 B, while R_{mem} requests issue `GET` operations on large values, with sizes drawn uniformly between 800 KB and 1200 KB. In Memcached, R_{lock} requests issue `SET` operations on small values using the same size distribution as R_{cpu}. Small values represent the common case of caching text objects, whereas large values represent the less common case of caching media objects. For Memcached, the average processing times are 15 μs for R_{cpu}, 20 μs for R_{lock}, and 275 μs for R_{mem} on SETUPA. For RocksDB, the average processing times are 20 μs for R_{cpu} and 230 μs for R_{mem} on SETUPA, and 40 μs for R_{cpu} and 230 μs for R_{mem} on SETUPB.

DataFrame is a C++ column store. We run an instance operating on a 370K-row EUR–USD FX dataset [11]; its R_{cpu} request computes the maximum of the *Closing* price column, while its R_{mem} request applies a decay-based smoothing operation to the same column and writes the smoothed values back. On SETUPA, the average processing times are 15 μs for R_{cpu} and 750 μs for R_{mem}.

In the Go-based synthetic application, the R_{cpu} request performs 1000 square-root computations in a loop, while the R_{mem} request performs stores to a 1 MB in-memory buffer. On SETUPA, the average processing times are 200 μs for R_{cpu} and 462 μs for R_{mem}.

Baselines: We compare Svalinn against SEDA [55] and Protego [10]. We choose these baselines because SEDA represents the classic approach of using overall server performance to determine how much load to admit.[3] SEDA controls server load by rate-limiting clients, with each client adjusting its sending rate based on the 99th-percentile end-to-end latency it observes. Protego optimizes overall server throughput while performing per-lock AQM. As such, its objective and design are the closest to Svalinn. Protego regulates load at the server through a credit-based mechanism, dynamically adjusting the credit-pool size based on the observed efficiency of request processing. We do not compare against Atropos [23] or pBox [22], as neither provides an admission controller or a technique for handling memory bandwidth contention, making Protego the closest comparison point.

[2]Processing time refers to the request completion time observed by the client at low to medium load.

[3]We observe that other systems that react to overall server performance like Breakwater [9] and Dagor [59] behave similar to SEDA. We omit the result to maintain the clarity of the presentation.

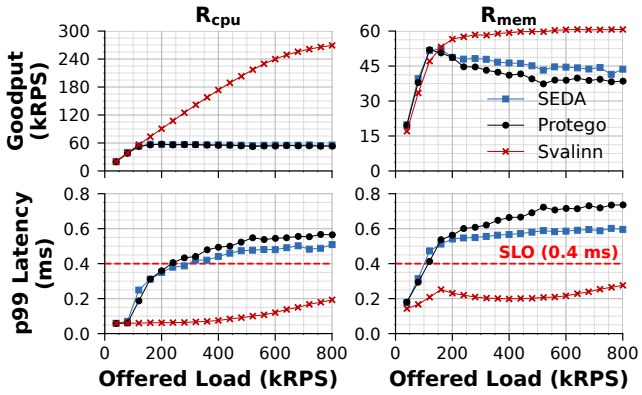

Figure 4: Performance of SEDA, Protego, and Svalinn for synthetic application on SETUPA.

Parameter configuration. We tune each system to operate at its best configuration. Most parameters are a function of the application SLO. We set the SLO to $5 \cdot (\textit{mean service time} + \textit{mean RTT})$. This is consistent with recent work [9, 10, 12, 46]. Since our applications have multiple request types, we use the service time of the longest request type when computing the SLO. In almost all applications, this corresponds to the R_{mem} request.

For SEDA, we set the target delay and timeout according to the application SLO. We further tune adj_i (rate increase factor) and adj_d (rate decrease factor) for each application to achieve high throughput while keeping latency under control. We use the default configuration from [55] for all other parameters.

For Protego, we tune the control-loop period according to the application's service time and configure the per-request queueing-delay budget for each workload. We compute this budget as $\textit{SLO} - \textit{p99 service time} - \textit{p99 RTT}$, using the service time of the longer request type. We use the default configuration from [10] for all other parameters.

For Svalinn, the throughput controller uses a utility function based on overall server throughput. We set δ to 1 for all applications, since this worked well across all workloads. We set $\Delta\, t_{warmup}$ and $\Delta\, t_{monitor}$ based on the application's service time and the RTT between clients and servers. Svalinn uses the same per-request queueing-delay budget as Protego. For `m_semaphore`, we set $\Delta\, t_{msem}$, α, ω, and ε to 500μs, 0.7, 0.8, and 0.3, respectively. These settings are shared across all workloads and setups. As a result, the only Svalinn parameters whose configuration varies across applications are the throughput controller's $\Delta\, t_{warmup}$ and $\Delta\, t_{monitor}$.

Evaluation metrics. For each application, we report goodput and 99th-percentile tail latency. Goodput is the throughput of requests that complete within the configured SLO. We report these metrics separately for each request type. In select experiments, we also report the drop rate, defined as the fraction of

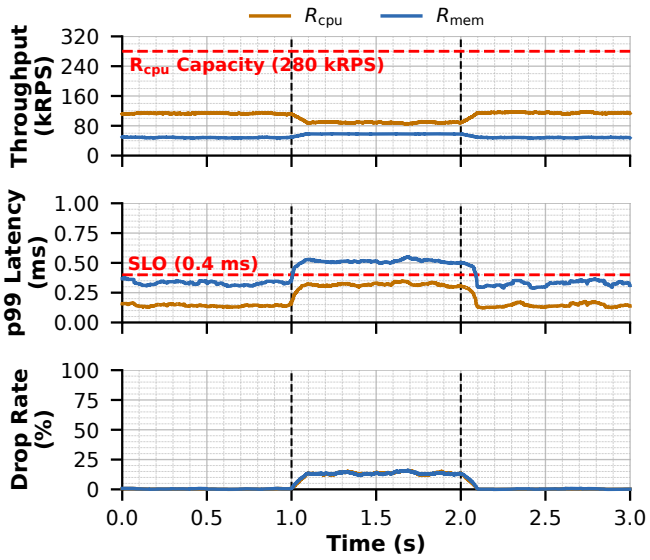

Figure 5: Performance of an overprovisioned server under an R_{mem} burst when using Protego on SETUPA

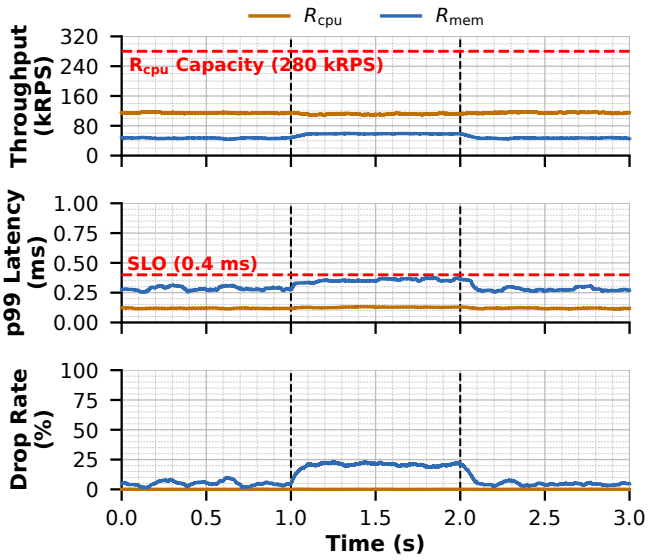

Figure 6: Performance of an overprovisioned server under an R_{mem} burst when using Svalinn on SETUPA

received requests that are dropped.

5.2 End-to-End Performance

We start by studying the performance of Svalinn in a single setup (SETUPA) across multiple applications. We study the robustness of Svalinn across different setups and configurations later.

Synthetic workload. Since the service times of R_{cpu} and R_{mem} are comparable, clients generate a 50/50 mix of R_{cpu}/R_{mem} requests. On SETUPA, six concurrently running R_{mem} requests saturate the available memory bandwidth (Figure 4). SEDA reacts to end-to-end client delay, unaware of the distinct CPU and memory bandwidth bottlenecks at the server. SEDA applies its rate limit based on the state of the most congested resource (memory bandwidth in this scenario), wasting CPU cycles that could have been used to serve R_{cpu} requests (i.e., leads to low throughput). SEDA also suffers from high tail latency that exceeds the SLO due to incast scenarios.

Protego aims to avoid the pitfalls of SEDA by admitting load until all request-execution paths appear fully utilized. In principle, Protego should achieve high throughput for both R_{cpu} and R_{mem} requests. In practice, we observe that R_{cpu} throughput collapses once memory bandwidth saturates, similar to SEDA. This behavior arises because R_{mem} requests stall when memory bandwidth saturates, wasting CPU cycles and eliminating any capacity that could have been used by R_{cpu} requests. Moreover, Protego does not provide any mechanisms to limit the latency of requests bottlenecked by memory bandwidth, leading to tail latency that exceeds the SLO.

Svalinn avoids the pitfalls of both systems. Its `m_semaphore` limits the number of concurrently running R_{mem} requests to the smallest number of cores that saturate memory bandwidth (six on SETUPA). Thus, R_{mem} requests can achieve their maximum throughput while leaving plenty of CPU capacity for R_{cpu} requests. Svalinn's throughput-oriented admission controller then admits additional load until this CPU headroom is fully utilized. As a result, Svalinn improves the goodput of R_{cpu} and R_{mem} requests by up to 5.06× and 1.60× without compromising latency. Svalinn achieves up to 5.48× and 5.95× lower p99 latency for R_{cpu} requests compared to SEDA and Protego, and 2.87× and 3.49× lower latency for R_{mem} requests.

Performance when CPU is overprovisioned. We evaluate how memory bandwidth congestion can undermine an operator's provisioning assumptions, and demonstrate how Svalinn enables the server to fully realize its provisioned CPU capacity. We run the synthetic workload on a SETUPA server with a steady load of 115 kRPS R_{cpu} requests and 50 kRPS R_{mem} requests for 3 seconds. The server can process up to 280 kRPS R_{cpu} and 60 kRPS R_{mem} requests (Figure 4), so the steady demand does not overload either bottleneck. At the 1 second mark, we add a 25 kRPS R_{mem} burst for 1 second, increasing total R_{mem} demand to 75 kRPS and overloading memory bandwidth.

As shown in Figure 5, Protego sustains the steady-state demand prior to the burst. However, during the burst, excess R_{mem} requests saturate the memory bandwidth and stall the CPU. This interference severely diminishes the CPU capacity available for useful R_{cpu} execution, despite the server being nominally overprovisioned for R_{cpu} demand. Consequently, R_{cpu} throughput plummets from 115 kRPS to approximately 90 kRPS (a 21.7% reduction), while tail latencies for both request types spike. Driven by memory bandwidth contention, R_{mem} latency violates its SLO, causing both workloads to

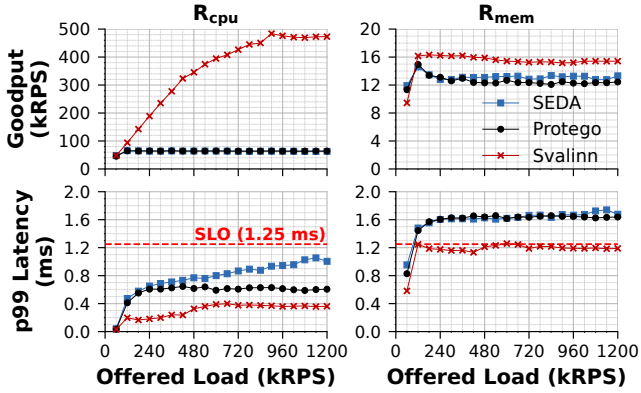

Figure 7: Performance of SEDA, Protego, and Svalinn for RocksDB on SETUPA.

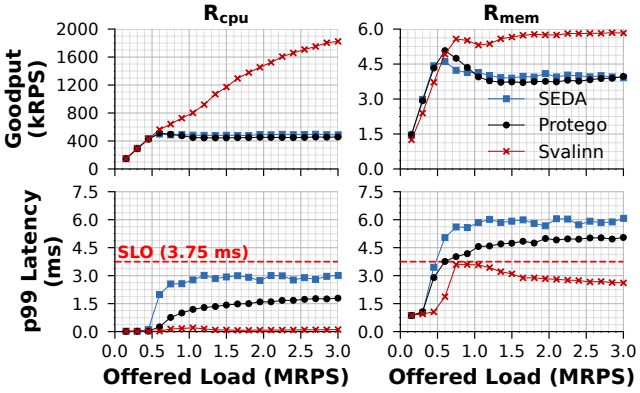

Figure 8: Performance of SEDA, Protego, and Svalinn for Dataframe on SETUPA.

experience a roughly 20% drop rate during the burst. These results demonstrate that a server provisioned adequately for steady-state workloads can still fail under resource contention.

In contrast, Svalinn prevents this hidden capacity degradation by explicitly managing memory bandwidth (Figure 6). Rather than allowing the burst to saturate the CPU, the `m_semaphore` restricts R_{mem} concurrency and drops excess R_{mem} requests before they can occupy CPU cores and waste CPU cycles by stalling. This proactive isolation enables Svalinn to fully sustain the 115 kRPS R_{cpu} demand, maintaining stable R_{cpu} tail latencies and achieving a 0% drop rate throughout the burst. Concurrently, R_{mem} tail latency increases only moderately, remaining well within its SLO bounds. To maintain this uncongested state, Svalinn sheds approximately 25% of R_{mem} requests during the peak of the burst. One note about Svalinn's behavior is that outside of the burst window, while nominal R_{mem} demand remains safely below the server's total memory bandwidth, transient arrival spikes can still briefly saturate the `m_semaphore` capacity, resulting in a baseline R_{mem} drop rate of roughly 5%.

RocksDB. Due to the difference in the service time between the different request types, clients generate an 80/20 mix of R_{cpu} and R_{mem} requests. The results are shown in Figure 7. On SETUPA, 13–14 concurrent R_{mem} requests saturate memory bandwidth. Once this happens, SEDA stops admitting additional load, causing R_{cpu} goodput to plateau together with R_{mem} goodput. SEDA also exceeds the configured SLO because of request incast. Protego admits load until all request paths are saturated but performs no AQM for memory bandwidth, resulting in high tail latencies and no throughput gain for R_{cpu} requests, similar to the synthetic workload.

Svalinn constrains R_{mem} requests to the minimum number of cores needed to saturate memory bandwidth, avoiding memory bandwidth congestion. Moreover, it allows R_{cpu} requests to utilize the remaining CPU. This yields up to 1.26× higher R_{mem} goodput and up to 7.62× higher R_{cpu} goodput than the baselines. Svalinn also reduces R_{cpu} and R_{mem} p99 latency by up to 2.95× and 1.47× relative to the baselines.

DataFrame. Due to the very high variation in request service time, clients issue a 99/1 mix of R_{cpu} and R_{mem} requests. On SETUPA, 7–8 concurrent R_{mem} requests saturate memory bandwidth. Figure 8 shows that SEDA stops admitting additional load as soon as memory bandwidth becomes the bottleneck, while Protego continues admitting load but cannot prevent R_{mem} requests from stalling once memory bandwidth is congested. As a result, both systems limit R_{cpu} goodput and suffer high R_{mem} tail latency, due to request incasts in SEDA and the lack of AQM for R_{mem} requests in Protego.

Svalinn restricts the number of concurrent R_{mem} operations to avoid memory bandwidth congestion and continues admitting additional R_{cpu} operations until CPU capacity is fully utilized. As a result, Svalinn reduces R_{cpu} p99 latency by up to 42.77× relative to SEDA and 21.17× relative to Protego, and reduces R_{mem} p99 latency by 2.33× and 1.93×, respectively. At high load, uncontrolled bandwidth contention causes SEDA and Protego to deliver only 0.67× the R_{mem} goodput of Svalinn. Overall, Svalinn achieves up to 3.99× higher R_{cpu} goodput than both baselines.

We observe similar behavior in Memcached, where clients generate R_{cpu}, R_{mem}, and R_{lock} requests. There, Svalinn improves overall goodput by up to 2.47× relative to the baselines without compromising latency; detailed results are provided in Appendix B.2.

5.3 Microbenchmark

Versatility of the throughput controller. The default utility function used by Svalinn's throughput controller is purely throughput oriented: $Utility_{tput} = \frac{stats.resps_{out}}{stats.duration}$. We compare it against $Utility_{drop}$, which balances throughput and drop rate by enforcing a maximum drop-rate of 10%. Specifically, $Utility_{drop}$ is computed as follows:

$$Utility_{drop} = \begin{cases} \frac{stats.resps_{out} - stats.reqs_{drop}}{stats.duration} & \text{if } \frac{stats.reqs_{drop}}{stats.reqs_{in}} < 0.1 \\ -\frac{stats.reqs_{drop}}{stats.duration} & \text{otherwise} \end{cases}$$

Figure 9 compares the performance of the two utility functions under a synthetic workload consisting of an 80/20 mix of

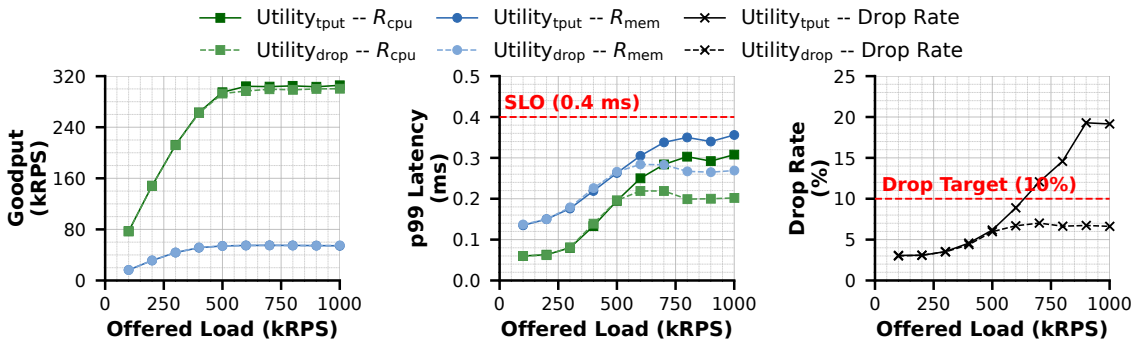

Figure 9: Comparison of throughput-oriented and drop-oriented admission utility functions on SETUPA.

R_{cpu} and R_{mem} requests. Compared to $Utility_{drop}$, $Utility_{tput}$ yields up to 1.03× and 1.01× higher R_{cpu} and R_{mem} goodput, respectively. However, this gain comes at the expense of elevated tail latencies and drop rates reaching 19%. Conversely, $Utility_{drop}$ strictly enforces the 10% drop-rate target, capping actual drops at 7%, while simultaneously reducing R_{cpu} and R_{mem} p99 latencies by up to 1.52× and 1.32×. These results demonstrate that Svalinn 's configurable utility function provides operators with flexible control to effectively balance trade-offs among throughput, latency, and drop rates. The tradeoff becomes sharper at more memory-intensive mixes. For example, with a 50/50 R_{cpu}/R_{mem} mix, memory bandwidth saturates earlier than in the 80/20 case, causing `m_semaphore` to begin dropping requests sooner. As a result, $Utility_{drop}$ favors a lower drop rate over higher throughput, leading to significant throughput degradation while keeping drop rate and latency low. More generally, Svalinn's performance gains vary with the request mix, and we provide a detailed study of this effect in Appendix B.5.

Latency of retransmitted requests. When overload controllers drop requests, clients often retransmit them to an alternate replica. To evaluate whether Svalinn rejects dropped requests quickly enough to prevent inflating end-to-end latency, we execute a synthetic workload (70/30 R_{cpu}/R_{mem} mix) on SETUPA using a two-server configuration. Clients initially direct all traffic to Server 1; if Server 1 drops a request due to overload, the client retransmits it to Server 2 [10, 40]. We drive Server 1 beyond its processing capacity to deliberately induce drops and retransmissions. To accommodate the additional network hop, we scale the workload SLO to twice the single-server baseline defined in Section 5.1.

Figure 10 illustrates the resulting performance. Across all offered loads, the tail latency for both R_{cpu} and R_{mem} requests remains safely within the adjusted SLO, and even tracks below the single-server latency target. This efficiency stems from `m_semaphore` maintaining a zero-length queue for threads attempting to enter the memory-intensive section. Consequently, excess requests are rejected near-instantaneously rather than enduring queuing delays at the congested Server 1, a behavior confirmed by the rapid failure-delivery times highlighted in red in Figure 10. Server 2 then seamlessly absorbs this shed load, as evidenced by the sustained goodput plots.

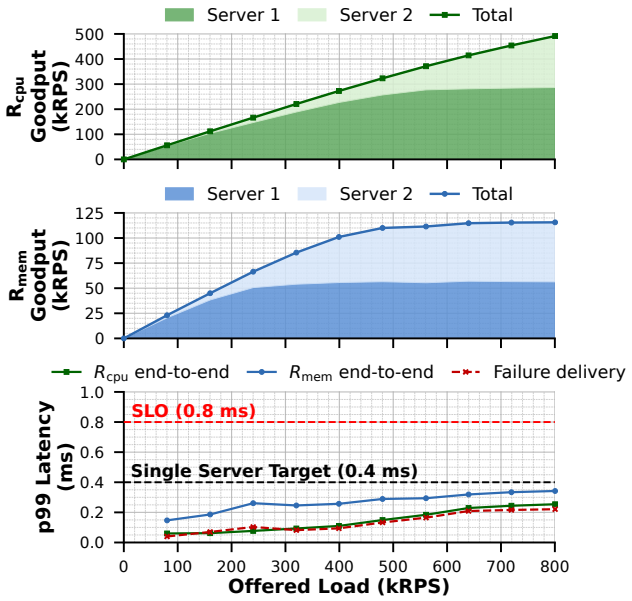

Figure 10: Multi-server performance of Svalinn for synthetic workload with retransmission on SETUPA.

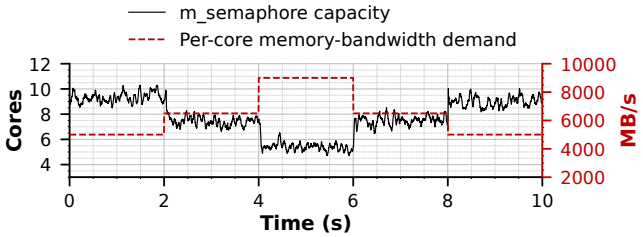

Figure 11: Memory semaphore's ability to adapt to changing per-request memory-bandwidth demand on SETUPA.

Adaptability of `m_semaphore` to workload dynamics. The per-request demand for memory bandwidth can vary, requiring the `m_semaphore` to be able to adapt its capacity quickly. We evaluate this using a synthetic workload with

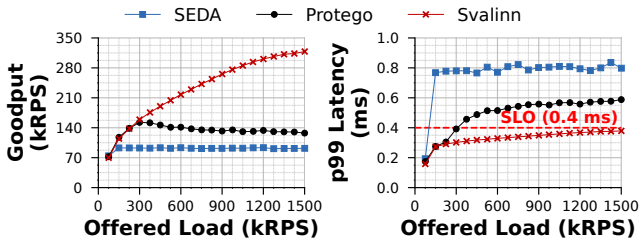

Figure 12: Performance of SEDA, Protego, and Svalinn for synthetic application with multiple bottlenecks on SETUPA.

three R_{mem} request types: a low-demand request performing 25 non-temporal stores on a 3 KB buffer, a medium-demand request performing 500 such stores on a 3 KB buffer, and a high-demand request performing 26 stores on a 128 KB buffer. Their approximate per-core bandwidth demands are 5000, 6500, and 9000 MB/s, respectively. We fix the offered load and switch the request type every two seconds (low to medium to high to medium to low). As shown in Figure 11, `m_semaphore` rapidly converges to the correct capacity after each shift. On average it takes 50 ms for the controller to converge to the new optimal capacity. This adaptability stems from the periodic exploration performed by our ε-greedy MAB algorithm.

Performance under multiple bottlenecks. We evaluate Svalinn's ability to manage multiple concurrent bottlenecks using a synthetic workload that generates a 25/25/50 mix of R_{cpu}/R_{mem}/R_{lock} requests on SETUPA. In this scenario, the global mutex acts as the primary point of contention, causing R_{lock} requests to saturate first at approximately 180 kRPS of offered load (Figure 12). This behavior clearly exposes the single-queue fallacy: SEDA reacts exclusively to this initial bottleneck and halts further admission, leaving the remaining capacity of the R_{cpu} and R_{mem} execution paths entirely unexploited.

Protego mitigates this specific failure mode by applying AQM directly at the global mutex, which enables it to continue admitting traffic beyond the R_{lock} saturation threshold. However, as observed in previous experiments, Protego lacks a mechanism for memory bandwidth latency control. Consequently, once memory bandwidth saturates at roughly 300 kRPS, stalled R_{mem} requests monopolize CPU cores and degrade the capacity available for the R_{cpu} workload.

Svalinn successfully navigates both bottlenecks simultaneously: its mutex AQM isolates R_{lock} latency, while `m_semaphore` bounds R_{mem} concurrency to prevent memory bandwidth congestion from stalling the CPU cores. This joint enforcement allows Svalinn to continuously harvest the remaining CPU capacity for R_{cpu} execution. As a result, Svalinn improves overall application goodput by up to 3.46× and 2.50× compared to SEDA and Protego, respectively, while simultaneously reducing p99 tail latency by up to 2.80× and 1.61×. A detailed per-request breakdown of these metrics is provided in Appendix B.1.

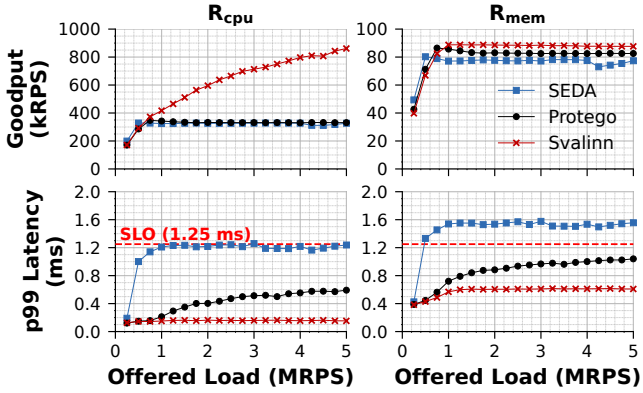

Figure 13: Performance of SEDA, Protego, and Svalinn for RocksDB on SETUPB.

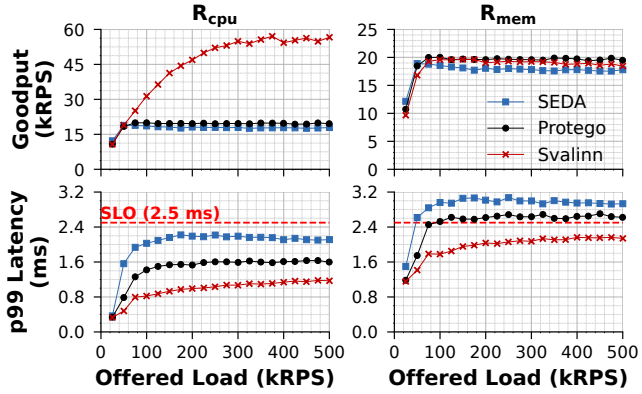

Figure 14: Performance of SEDA, Protego, and Svalinn for synthetic application in Go on SETUPA.

Performance with different machines. We run RocksDB on SETUPB (Figure 13). Svalinn's relative performance persists in this setup. Compared to SEDA, Svalinn reduces tail latency by up to 8.09× for R_{cpu} requests and 2.58× for R_{mem} requests. Compared to Protego, Svalinn reduces tail latency by up to 3.87× for R_{cpu} requests and 1.71× for R_{mem} requests. Svalinn improves the goodput of R_{cpu} requests by 2.65× over both SEDA and Protego without harming R_{mem} requests.

Svalinn in Go. We test a synthetic workload in Go with an 80/20 R_{cpu}/R_{mem} request mix, and observe that the benefits of Svalinn continue to hold across runtimes. As shown in Figure 14, Svalinn achieves up to 3.21× higher R_{cpu} request goodput. Moreover, Svalinn delivers up to 3.25× and 1.85× lower tail latency for R_{cpu} and R_{mem} requests, respectively, than the baselines.

6 Related Work

Receiver-driven admission control. Receiver-driven admission control regulates load at the server using the most accurate view of local capacity. Transport-level schemes such as Homa [38] and SIRD [45] operate on packets to reduce switch congestion. RPC-level systems such as Breakwater [9], CoreSync [42], and Protego [10] control request admission

at the host. These approaches are particularly effective for handling incast. Svalinn follows this receiver-driven model while overcoming the single-queue fallacy in prior work.

Overload control. The importance of the overload problem has led to a wide range of solutions. Some solutions attempt to optimize performance across microservice chains [43, 49, 57, 59]. Other solutions consider the performance of a single host, focusing on a single resource (e.g., CPU [9, 55], locks [10, 23], and storage [21, 35]). Most existing controllers are designed primarily for their narrow set of bottlenecks. Atropos [23] particularly is the most general purpose technique. However, its focus is still on resources that applications can explicitly track (i.e., memory buffers, locks, and queues). Moreover, it does not offer an admission controller, offloading the responsibility of deciding the precise load per replica to a separate system. Svalinn handles implicitly accessed memory bandwidth bottleneck and introduces an admission control scheme that integrates with its per-resource latency controller.

Resource isolation. Another approach to improve resource utilization is to perform isolation between different requests. Typical approaches perform coarse-grained isolation at the binary level [7,19,47,58]. Recently, pBox [22] proposed intra-application isolation, focusing on explicitly visible resources (i.e., it is nontrivial to deal with memory bandwidth contention in pBox). However, pBox does not drop any of the competing requests, leading to potentially high latencies for executing requests. Moreover, it does not provide an admission control technique. Another common technique for dealing with potential intra-application interference or head-of-line blocking is preemption [20, 29, 30]. We demonstrate that such techniques do not address problems solved by Svalinn. Among existing systems, Persephone [13] is closest to Svalinn as it explicitly limits the number of cores allocated to long-running requests. However, Persephone bases this allocation strictly on execution service times, a strategy that can inadvertently assign more cores to memory-intensive requests and thereby exacerbate memory-bandwidth contention. Furthermore, while Persephone relies on the assumption that request types are classified and known a priori, Svalinn requires no such prior knowledge, dynamically adapting to heterogeneous workloads on the fly.

Memory and interconnect congestion. Recently, there has been growing interest in congestion within the host interconnect [2, 3, 39, 53]. Solutions typically operate at the packet level, tackling the host interconnect as an extension of the network path between a client and a server. In particular, HostCC [3] assumes interference between a low-priority memory-intensive application and a high-priority latency-sensitive application, and mitigates it by throttling the memory-intensive application's cores using Intel MBA. Svalinn addresses a different setting: heterogeneous requests within the same application. In our setting, throttling memory-intensive requests with MBA would only cause them to stall longer on the CPU, exacerbating the very inefficiency that Svalinn seeks to eliminate.

Learning-based control. Learning-based controllers are widely used for dynamic optimization, including network congestion control [4, 14, 15], overload control [43, 54], and isolation [47, 58]. Svalinn follows this direction, relying on interpretable algorithms that can accommodate a wide range of user-defined utility functions.

7 Conclusion

This paper demonstrates that traditional, monolithic overload control systems are fundamentally limited by the *single-queue fallacy*. By treating modern server binaries as homogeneous black boxes and reacting solely to aggregate metrics like end-to-end latency, state-of-the-art controllers prematurely throttle inbound load and leave vast swaths of machine capacity stranded. We present Svalinn, a modular overload control architecture that structurally decouples throughput optimization from distributed, per-resource latency management. Through the introduction of the `m_semaphore` abstraction, Svalinn successfully converts the implicit memory bandwidth bottleneck into explicitly managed, observable software entities, optimizing resource execution paths without the need for intrusive application re-architecting. Our evaluation across diverse runtimes and applications proves that Svalinn achieves substantial goodput improvements (up to 6.51×) while strictly preserving latency guarantees.

Beyond its immediate performance gains, Svalinn provides a fundamental architectural blueprint for the future of microsecond-scale infrastructure. As modern hardware trends continue toward massive core parallelism coupled with complex, non-uniform memory and interconnect topologies, the intersection of data-dependent application paths and shared hardware constraints will only intensify. By rejecting the single-queue assumption, Svalinn demonstrates how a resource-agnostic admission controller, guided by a multi-dimensional utility function, can be composed with resource-aware, per-bottleneck latency control. Svalinn establishes an extensible foundation for a new generation of overload control systems capable of harvesting the full potential of next-generation cloud architectures.

A Additional Design Discussion

A.1 Utility-Based Throughput Controller Algorithm

The throughput controller continuously runs the `UpdateCredits()` routine, shown in Algorithm 2, while the application is running. In each iteration, the controller performs two micro-experiments (lines 7–11 and 12–16). During each micro-experiment, the controller either increases or decreases the credit pool by δ. To allow the newly set credit pool value to take effect, the controller waits for $\Delta\, t_{warmup}$ period before attributing observed performance to the new credit pool value. Finally, the controller monitors the application for $\Delta\, t_{monitor}$, and records relevant performance metrics. The controller computes a utility value from these metrics for each micro-experiment (lines 17–18). To handle cases in which perturbing the credit pool does not produce the expected change in incoming request rate, we relabel the micro-experiments using the actually observed incoming request rate (lines 19–20). After both micro-experiments complete, it updates the credit pool in the direction that yields higher utility (lines 21–24).

B Additional Evaluation Results

B.1 Request-level Performance with Multiple Bottlenecks

Figure 15 shows a detailed breakdown of the experiment in Figure 12 on SETUPA. Clients issue three request types: $\mathtt{R}_{\mathrm{cpu}}$, $\mathtt{R}_{\mathrm{mem}}$, and $\mathtt{R}_{\mathrm{lock}}$. As soon as the $\mathtt{R}_{\mathrm{lock}}$ path saturates at around 180 kRPS of offered load, SEDA stops admitting additional load. As a result, the goodput of both $\mathtt{R}_{\mathrm{cpu}}$ and $\mathtt{R}_{\mathrm{mem}}$ also plateaus at that point. SEDA also suffers from high tail latency due to request incasts at the most congested bottleneck, namely the global mutex. In contrast, the $\mathtt{R}_{\mathrm{cpu}}$ and $\mathtt{R}_{\mathrm{mem}}$ paths remain unsaturated and continue to exhibit low tail latency.

Protego continues admitting load past the global-mutex saturation point. It controls $\mathtt{R}_{\mathrm{lock}}$ tail latency by performing AQM at mutex access points and continues increasing load as long as throughput improves. Consequently, its goodput rises until memory bandwidth saturates at around 300 kRPS. Beyond this point, $\mathtt{R}_{\mathrm{mem}}$ requests stall on the CPU, causing CPU congestion and leaving no capacity for $\mathtt{R}_{\mathrm{cpu}}$ requests. As a result, $\mathtt{R}_{\mathrm{cpu}}$ goodput saturates together with $\mathtt{R}_{\mathrm{mem}}$ goodput. The $\mathtt{R}_{\mathrm{lock}}$ goodput declines at higher loads because client bursts can still enqueue many $\mathtt{R}_{\mathrm{lock}}$ requests at the global mutex. Since Protego's AQM uses an instantaneous queueing-delay estimate [10], requests arriving in the same short burst can observe a low estimate and be enqueued together, only to incur high delay later.

Svalinn behaves similarly to Protego until memory bandwidth becomes congested. At that point, `m_semaphore` limits the concurrency of $\mathtt{R}_{\mathrm{mem}}$ requests and prevents the resulting CPU congestion. This allows Svalinn's throughput-driven admission controller to admit more load and use the remaining CPU capacity. As a result, Svalinn achieves up to 8.71× and 4.18× higher $\mathtt{R}_{\mathrm{cpu}}$ goodput than SEDA and Protego, respectively. Throughout the experiment, Svalinn keeps tail latency within the configured SLO, although it is still affected by $\mathtt{R}_{\mathrm{lock}}$ bursts at high load.

B.2 Memcached Performance

Clients generate a modified VAR [5] workload in which 82% of requests are $\mathtt{R}_{\mathrm{lock}}$, 9% are $\mathtt{R}_{\mathrm{cpu}}$, and the remaining 9% are $\mathtt{R}_{\mathrm{mem}}$ on SETUPA. In Memcached, the $\mathtt{R}_{\mathrm{mem}}$ path is the most congested and saturates at around 300 kRPS of offered load. As seen in Figure 16, both SEDA and Protego stop admitting additional load beyond this point, leaving the $\mathtt{R}_{\mathrm{cpu}}$ and $\mathtt{R}_{\mathrm{lock}}$ paths underutilized. SEDA suffers from extremely high $\mathtt{R}_{\mathrm{lock}}$ tail latency because of request incasts, whereas Protego keeps tail latency much better controlled.

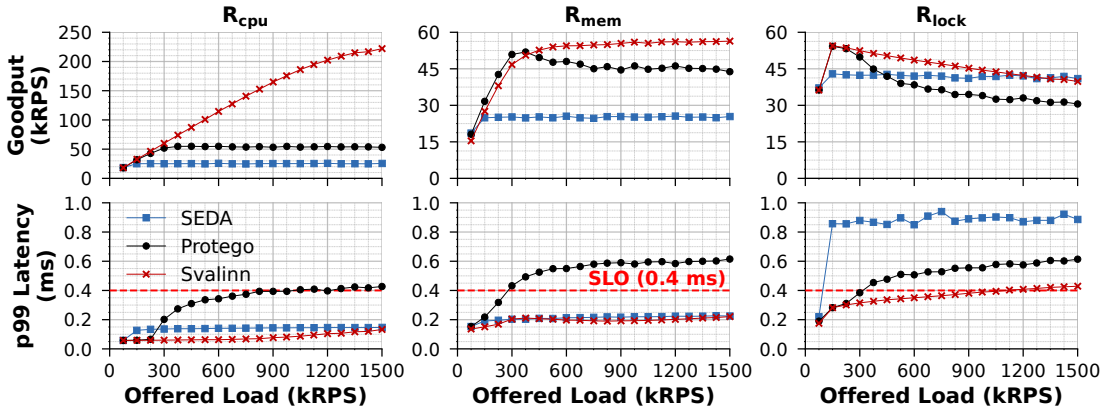

Figure 15: Request-level performance of SEDA, Protego, and Svalinn for synthetic application on SETUPA.

Svalinn addresses the most congested bottleneck, memory bandwidth, using `m_semaphore`. By limiting R_{mem} concurrency, `m_semaphore` preserves CPU capacity for R_{cpu} and R_{lock} requests. As a result, Svalinn achieves up to 2.53× higher R_{cpu} goodput than SEDA and Protego, and up to 2.58× higher R_{lock} goodput than both baselines. Svalinn also achieves up to 13.57×, 1.74×, and 17.32× lower tail latency for R_{cpu}, R_{mem}, and R_{lock} requests, respectively. These gains come from performing AQM at both bottlenecks: memory bandwidth and the global slabs lock on the `SET` path. Tail latencies remain well below the SLO because `m_semaphore` uses an aggressive AQM policy that tolerates no queueing and drops requests as soon as a queue is about to form. This slightly increases drops, but achieves the lowest possible latency.

B.3 Choice of `m_semaphore` Reward Function

In Svalinn, we introduced an MAB-based controller to dynamically update the `m_semaphore` capacity and outlined the reward function that best meets our objective. To design an appropriate reward, we built a simulator that runs the ε-greedy MAB algorithm for our specific problem: finding the minimum number of cores needed to saturate memory bandwidth. We model SETUPB, where 16 cores saturate memory bandwidth, and design reward functions that (i) increase with achieved bandwidth and (ii) penalize using more cores than necessary. We define the normalized memory bandwidth at a given `m_semaphore` capacity as $\hat{m} = \frac{membw_{capacity}}{membw_{max}}$ and the normalized core count as $\hat{c} = \frac{cores_{capacity}}{cores_{max}}$. We evaluate three variants shown below:

$$reward_{simple} = \alpha \cdot \hat{m} - (1-\alpha) \cdot \hat{c}$$

$$reward_{hardgate} = \begin{cases} \alpha \cdot \hat{m}, & \text{if } \hat{m} > 0.98, \\ \alpha \cdot \hat{m} - (1-\alpha) \cdot \hat{c}, & \text{otherwise.} \end{cases}$$

$$reward_{softgate} = \alpha \cdot \hat{m} - Sigmoid_k(\hat{m} - 0.98)(1-\alpha) \cdot \hat{c}$$

We simulate a simple bandwidth model that increases linearly up to 16 cores and plateaus thereafter, running experiments with and without Gaussian noise (3 GB/s). As shown in Figure 17, all three reward functions converge near the optimal core count when the readings are noise-free: $reward_{simple}$ converges exactly to 16, while the other two settle at 15.

With noise, however, $reward_{hardgate}$ and $reward_{softgate}$ converge to core counts much larger than the optimum. Because noise frequently masks whether $\hat{m}$ exceeds 0.98, the penalty condition rarely triggers, allowing high-core configurations to appear equally good or better. Their learned reward curves reflect this by assigning maximal rewards to all core counts beyond the true optimum, preventing stable convergence. In contrast, $reward_{simple}$ consistently converges to the correct core count, and its learned reward curve peaks at the true optimal arm. For this reason, we adopt $reward_{simple}$ in Svalinn.

B.4 Sensitivity to Reward Function Parameter

Our reward function includes a parameter $\alpha \in [0,1]$ that controls the tradeoff between maximizing memory bandwidth and minimizing CPU usage. We evaluate different α values using the same simulator. We disable the memory bandwidth noise in this experiment. As shown in Figure 18, when $\alpha \leq 0.3$, the learned rewards favor core counts below the optimal value. For α between 0.3 and 0.9, the reward peaks exactly at the true optimal core count. At $\alpha = 1.0$, all core counts above the optimal receive the same reward, leading to oscillatory behavior similar to $reward_{hardgate}$ and $reward_{softgate}$.

B.5 Performance with Different Request Mixes

We use the synthetic workload with R_{cpu} and R_{mem} requests on SETUPA. We configure the offered load so that the R_{mem} path is overloaded by 20%, 60%, or 100%. For each overload level, we vary the request mix by increasing the R_{cpu} fraction from 10% to 70%, while keeping the R_{mem} overload level fixed. This lets us evaluate whether Svalinn's benefit holds across different workload mixes, rather than only for one engineered mix.

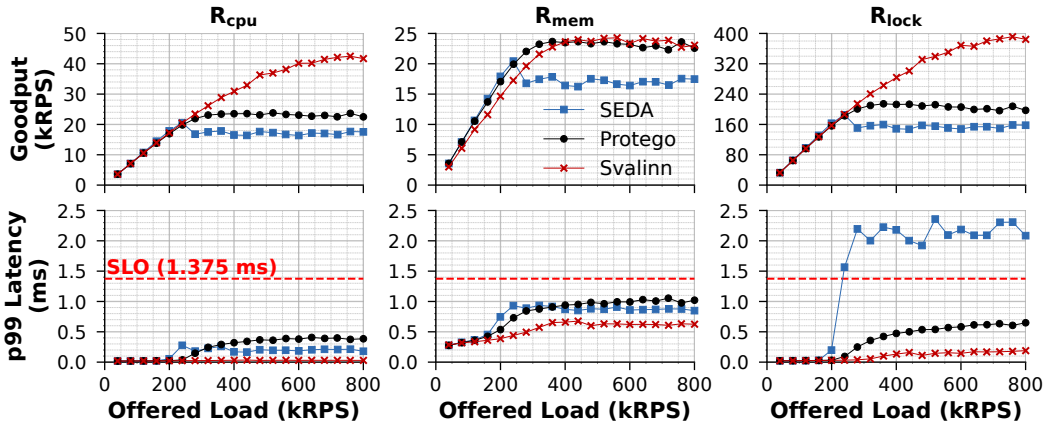

Figure 16: Request-level performance of SEDA, Protego, and Svalinn for Memcached on SETUPA.

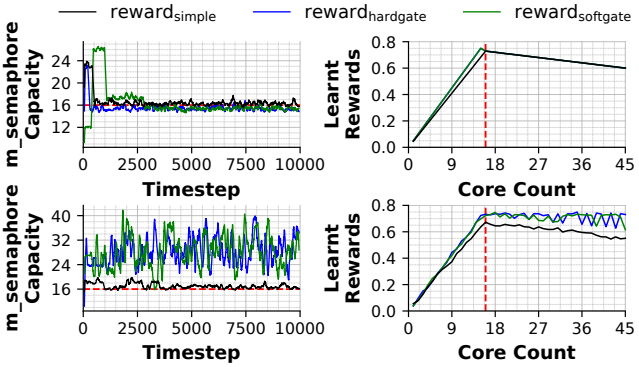

Figure 17: Simulation of ε-greedy MAB controller comparing different reward functions without memory-bandwidth noise (top) and with memory-bandwidth noise (bottom). The red line indicates the optimal core count.

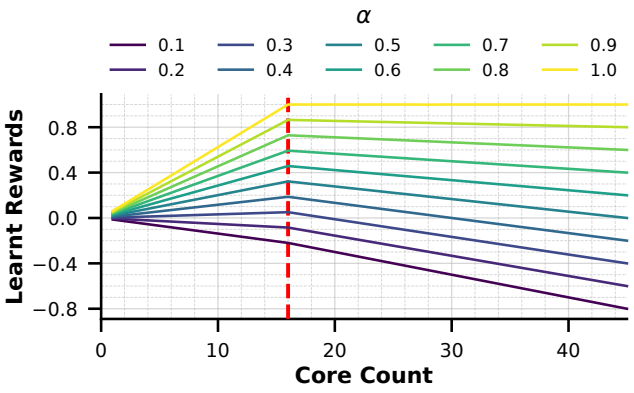

Figure 18: Simulation of ε-greedy MAB controller to analyze the sensitivity to parameter α. The red line shows the optimal core count.

Figure 19 shows the goodput gain of Svalinn over Protego. Svalinn achieves the largest gains when the workload is dominated by R_{mem} requests. In this regime, Protego saturates memory bandwidth early. The stalled R_{mem} requests

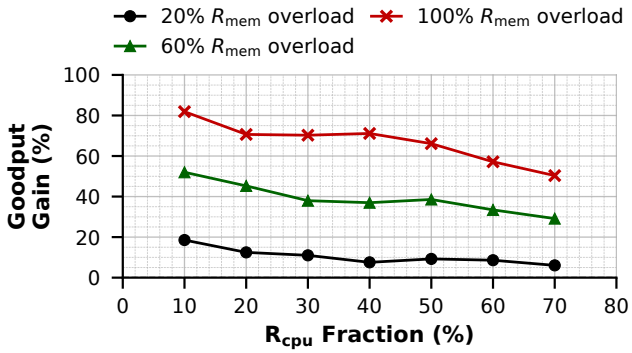

Figure 19: Goodput gain of Svalinn over Protego across different R_{cpu}/R_{mem} request mixes and R_{mem} overload levels on SETUPA.

then occupy CPU cores and leave less capacity for useful R_{cpu} work. Svalinn avoids this by limiting R_{mem} concurrency with `m_semaphore`, preserving CPU capacity for R_{cpu} requests. As the R_{cpu} fraction increases, memory bandwidth becomes congested later, allowing Protego to achieve more R_{cpu} goodput before R_{mem} stalls dominate. Consequently, the gap between Svalinn and Protego narrows at higher R_{cpu} fractions. Overall, Svalinn's goodput gains persist across a range of R_{cpu}/R_{mem} mixes and R_{mem} overload levels.

Manya Ghobadi *MIT CSAIL & Systalyze*

Abstract

We present PeeR, a novel eBPF runtime that makes latency-critical eBPF programs preemptable and schedulable while maintaining low overhead. As eBPF programs grow more complex, they expose a fundamental gap: performance-critical hooks execute in a non-preemptable `softirq` context, which is invisible to the scheduler. These programs bypass resource controls, break isolation, and cause head-of-line blocking, degrading tail latency. PeeR exploits two key properties of eBPF: the verifier enforces clean program state at helper function boundaries, making these sites natural preemption points, and non-trivial programs frequently call helpers, ensuring fine-grained preemption opportunities. Building on these properties, PeeR brings *cooperative preemption* to eBPF: lightweight budget checks, inserted at each helper call, force programs exceeding their budget to yield and resume later on per-CPU kernel threads. To handle a wide variety of workloads, PeeR uses a two-level scheduling model that integrates with `sched_ext`, where the outer level controls aggregate CPU time for eBPF workloads, while an inner micro-scheduler orders individual tasks according to an operator-defined policy. Our evaluation on Redis, Memcached, echo-server, and TPC-C workloads shows that PeeR reduces p99 latency for latency-sensitive requests by 3× to 19.8× over the current eBPF runtime, without starving competing long-running requests.

1 Introduction

eBPF (extended Berkeley Packet Filter) [26] is becoming the de facto standard for building *latency-critical* networking and storage applications inside the Linux kernel. By allowing applications to execute custom logic inside the kernel, eBPF avoids costly context switches and redundant data copies from the critical path, enabling microsecond-scale processing for networking and storage workloads. While kernel-bypass frameworks (e.g., DPDK [47], SPDK [48]) achieve similar performance, they sacrifice kernel services such as isolation, scheduling, and multi-tenancy. eBPF instead delivers high performance while preserving the kernel's safety and resource-sharing model, driving its widespread adoption across industry and academia.

With growing adoption, eBPF programs are becoming increasingly complex. Developers are now offloading complicated application logic into the kernel, including key-value stores [9, 28], distributed transactional systems [58], load balancers [33], DDoS protection [23], transport protocols [6], and storage engines [56]. These programs often run for tens of thousands to millions of instructions, resulting in execution times of hundreds of microseconds.

While eBPF programs have grown dramatically in complexity, their execution model, which was originally designed for tiny packet filters, has remained largely unchanged. On latency-critical I/O paths, each eBPF invocation runs to completion in arrival order and cannot be preempted, so later latency-sensitive invocations wait behind long-running ones. Another important aspect of eBPF's execution model, for latency-critical applications, is that it runs in software interrupt context (`softirq`) [45], allowing quick and low-overhead execution upon I/O events.

The current eBPF execution model creates two fundamental problems for modern workloads. First, because these latency-critical eBPF programs run in `softirq` context, their execution time is accounted to the interrupted userspace process, rather than the eBPF program itself. To make matters worse, eBPF execution begins immediately after an I/O interrupt handler, abruptly preempting any colocated userspace process. This misaccounted and interrupt-driven execution leads to unfair CPU allocations that starve colocated workloads and introduce unpredictable interference. Second, the lack of preemption means that long-running eBPF programs block later invocations, increasing latency for small and latency-critical invocations, defeating the very purpose of in-kernel execution.

We find that this mismatch has severe practical consequences. For a colocated scenario, Redis-KFlex, a Redis-compatible store built on KFlex [9], running under a fair-share scheduler consumes up to 90% of CPU despite receiving only a 50% allocation, starving colocated workloads. This problem is especially concerning in modern datacenter environments, where colocation is the norm due to CPU oversubscription and utilization-driven scheduling policies, leading to unpredictable performance interference. Beyond unfairness, the inability to preempt long-running programs inflates tail latency. For a mixed point-scan workload, Redis-KFlex experiences 7.4× higher p99 latency when short requests are blocked behind long eBPF handlers as compared to a preemptable execution model (§3). Taken together, these effects show that the kernel's existing execution model no longer provides the control over the eBPF fast path that applications and developers expect.

To address these issues, this paper introduces PeeR, a runtime that makes eBPF programs schedulable while preserving their low-overhead execution model. PeeR achieves this by transforming each eBPF invocation into a schedulable *eBPF task*, subject to CPU accounting, preemption, and scheduling policy enforcement. First, PeeR attributes and accounts eBPF execution time, making eBPF visible and accountable to the scheduler. Second, PeeR extends the traditional `softirq` execution model with a hybrid `softirq`-worker thread model. eBPF tasks run in `softirq` context as long as they remain within their execution budget;

once the budget is exceeded, PeeR safely preempts the task using a lightweight preemption mechanism and resumes it on a worker thread. Finally, instead of enforcing a fixed scheduling policy, PeeR integrates with Linux's extensible scheduler interface (`sched_ext`) [49], allowing flexible scheduling policies to control CPU allocations within eBPF and across applications.

Designing PeeR requires addressing three key challenges. The first challenge is enabling *low-overhead preemption* of eBPF tasks without violating their safety and correctness guarantees. A naive approach is to use existing timer-based interrupts to preempt long-running eBPF tasks. However, timer interrupts incur high overheads, negating the performance benefits of eBPF. More importantly, arbitrary interruption risks leaving the eBPF task execution state inconsistent, violating eBPF's safety guarantees. Our key insight is that eBPF's design inherently provides natural preemption points. Because eBPF restricts interaction with kernel state to helper functions, *helper-call boundaries* are safe and well-defined preemption points that PeeR leverages to enable preemption.

To address this, PeeR instruments the JIT compiler to inject budget checks at each helper call site, transforming helpers into lightweight, verifier-safe preemption points (§5.1). When a task exceeds its budget, PeeR forces it to yield execution at the next helper call, avoiding arbitrary mid-execution preemption that breaks eBPF's correctness guarantees. We bring this technique, known as *cooperative preemption*, to the eBPF runtime.

The second challenge is *correct context recovery at resumption*. When a long-running eBPF task exceeds its budget, PeeR must preempt it in `softirq` context and later resume it on a worker thread. Resuming execution in a different context, however, introduces subtle correctness issues. The pointers stored on the eBPF task's stack during `softirq` execution are invalid when the task resumes on a worker thread, as they point to kernel stack memory that is no longer valid in this new context. Such invalid pointers lead to memory-safety violations and incorrect program behavior.

To address this, PeeR leverages the strong type information maintained by the eBPF verifier to automatically patch pointers in the saved context during resumption, ensuring correctness without any changes to the eBPF programs (§5.2). PeeR does this by exporting the verifier's compile-time type information for use at runtime. These two mechanisms guarantee safe preemption and resumption of eBPF tasks.

The third challenge is *efficient integration with the scheduler*. To handle this, PeeR integrates with Linux's extensible scheduler interface, `sched_ext`. PeeR exposes eBPF execution time to `sched_ext` so the kernel correctly tracks CPU consumption and enforces allocation policies. Further, PeeR enables a unified and configurable scheduling framework for both eBPF tasks and userspace processes. PeeR provides two layers of configurability: (1) inter-application CPU allocation, which governs how PeeR schedules its worker threads and other colocated processes, and (2) intra-eBPF task scheduling, which determines the order in which eBPF tasks are executed on each worker thread (§7).

We implement PeeR atop the Linux kernel 6.16, extending the eBPF runtime and scheduler with ≈ 5000 lines of code. We evaluate PeeR with several popular workloads (Redis, Memcached, echo-server, TPC-C [51]). Our evaluation shows that PeeR reduces p99 latency for latency-sensitive requests by 3× to 19.8× over the current eBPF runtime, without starving competing long-running requests within the same application (§8.1). We implement multiple scheduling policies (FIFO, shortest-remaining-processing-time, weighted round-robin) using PeeR's scheduler interface and show that PeeR enforces operator-defined resource-sharing goals across colocated eBPF and userspace applications (§8.2). We quantify PeeR's overhead for a preemption-resumption cycle to be 247 ns, making PeeR suitable for fine-grained scheduling even for microsecond-scale workloads (§8.3). PeeR is, to our knowledge, the first system to make eBPF programs preemptable and schedulable in `softirq` context. We envision PeeR as a foundation for future latency-critical eBPF applications, enabling scheduling models beyond the reach of today's kernel.

PeeR is open source and available at `github.com/hipersys-team/PeeR`.

2 Background

eBPF [26] allows users to execute verified programs at predefined kernel hook points. eBPF use cases fall into two categories: kernel extensibility (e.g., tracepoints and LSM hooks) and latency-critical I/O processing (e.g., XDP and `tc` hooks). This paper focuses on the latter, where eBPF programs run on performance-critical paths.

Users implement eBPF programs in a restricted subset of C; the programs are then compiled into eBPF bytecode and loaded into the kernel. Before execution, the eBPF verifier performs static analysis to ensure memory safety, bounded control flow, and non-blocking behavior. Once verified, a just-in-time (JIT) compiler translates the bytecode into native machine instructions, enabling near-native execution speed.

eBPF enforces a restricted execution model. The bytecode targets a simple abstract machine with no direct access to kernel memory or functions [12]. Programs interact with the kernel only through predefined *helper functions* and kfuncs [11, 39] (referred to as *helper functions* hereafter), ensuring safe, mediated access to kernel services. Together, these mechanisms enable eBPF to extend the kernel, even on performance-critical paths, without compromising system integrity.

Execution model of eBPF on the fast path. For latency-critical eBPF hooks on the I/O-path, the kernel invokes an eBPF program each time an I/O event occurs (e.g., packet ingress or egress). These programs execute inside `softirq` context because their hook points lie on the kernel's interrupt-driven I/O paths. In `softirq`, preemption is disabled: CPU time spent there remains invisible to the scheduler and is effectively charged to the process that was preempted by the interrupt. This avoids context-switch overhead.

This design reflects what we call the *fast-path assumption*:

Application	Static Analysis (largest program)			Execution
	#Ins	#Calls	Instrs. between helper calls	p50/p99
Katran [33]	2,587	88	28±54	0.3/7.6
Cilium [1]	7,622	233	32±33	1.5/22
Memcached (BMC) [28]	289	11	21±27	2.1/37
Redis-KFlex [9]	1,356	95	12±10	0.5/248
DINT [58]	1,373	25	48±42	0.3/1.1
eTran [6]	1,194	14	79±102	0.4/1.4
RocksDB (XRP) [56]	891	17	27±26	4/882

Table 1: Characterization of common eBPF applications. We report static properties of each application's *largest single eBPF program* (one tail-call target plus the bpf-to-bpf subprograms it calls), not the sum over its tail-called suite. #Ins is the instruction count, #Calls the helper and kfunc call sites, and the last static column is the mean±stddev number of instructions between consecutive helper or kfunc calls. Because PeeR yields only at these calls, this gap bounds its preemption granularity. All programs contain loops, and p50/p99 (μs), measured under representative workloads, differ by up to 500×.

work inside `softirq` completes quickly and uniformly, so the impact on the preempted process is negligible. Under this assumption, request processing proceeds in strict first-come, first-served (FCFS) order and continues as long as the CPU has available budget for `softirq` execution. If processing in `softirq` exceeds a threshold, the kernel defers later requests to a special kernel thread called `ksoftirqd`. `ksoftirqd` operates at request granularity: it defers entire batches of pending requests, but does not pause a long-running eBPF task mid-execution. This execution model works well for small tasks.

Growing eBPF complexity. eBPF was initially designed for small, predictable programs suitable for fast-path packet filtering. Over time, its capabilities have expanded significantly [19]. The verifier now admits much larger programs with complex control flow, including bounded loops, BPF-to-BPF function calls, and tail calls, permitting long executions whenever a static bound exists [18, 26]. As a result, the verifier's one-million-instruction limit no longer guarantees short or uniform runtimes. Modern features further decouple static limits from execution time. Programs iterate over large data structures stored in maps or auxiliary memory regions [9], and runtime behavior often depends on workload-specific states, raising questions about whether the fast-path assumption still holds.

3 Measurement Study

We study real-world eBPF applications using static analysis and runtime profiling. Our measurements show that modern programs are complex enough to break the fast-path assumption, causing latency inflation and unfair CPU allocation.

3.1 Quantifying eBPF Application Complexity

We characterize seven recent eBPF applications spanning load balancing, networking, key-value storage, and storage. For each application we statically analyze its compiled BPF objects to extract, per program, the instruction count, the number of helper and kfunc call sites, the presence of loops, and the distribution of instruction intervals between consecutive helper or kfunc calls. We measure one eBPF program at a time, defined as a single tail-call target together with the bpf-to-bpf subprograms it invokes, rather than summing across the tail-called suite; all counts and intervals are derived from the disassembled bytecode. We then deploy each application under representative workloads and measure execution-time distributions using BPF-based tracing. Table 1 summarizes our findings.

A single eBPF program is already large and helper-dense. The largest Cilium program alone spans 7,622 instructions and 233 helper calls, and Katran's balancer runs 2,587 instructions with 88 helper calls, even though each suite compiles into many tail-called programs (33 for Cilium). Programs with loops also exhibit large variance between median and tail latency due to data-dependent execution paths. Redis-KFlex implements a skiplist where point queries complete quickly, but range scans traverse nodes linearly, a 500× difference between p50 and p99. RocksDB (XRP) linearly scans up to 2,000 entries per data block, inflating tail latency. Finally, because PeeR can preempt only at helper and kfunc calls, the gap between consecutive calls bounds its preemption granularity. These gaps can be large, with maximum gaps of 484 instructions for Katran and 286 for eTran, and the longest occur in compute loops with no intervening call: XRP's data-block scan executes a roughly 100-instruction loop body with no helper call up to 2,000 times. Iterator-based loops are an exception, as Redis-KFlex emits a kfunc on each iteration and keeps its maximum gap to 44 instructions.

Our analysis confirms that while the verifier preserves eBPF's safety guarantees, the assumption that programs complete quickly and uniformly no longer holds.

3.2 Breaking Fast-Path Assumptions

To understand the consequences of this mismatched assumption, we construct experiments that illustrate two problems: *latency inflation* within an application and *unfair CPU allocation* across applications.

Intra-application latency inflation. Due to *non-preemptive* and FCFS execution, long-running eBPF tasks block shorter ones, increasing latency for latency-critical operations.

To illustrate this problem, we run eBPF-based key-value stores, a typical use case for eBPF with XDP hooks [9, 28, 58]. For simplicity, we focus on XDP, but these issues generalize to other fast-path hooks. In the first experiment, we run a bimodal point-and-scan workload with 99.5% short (0.2 μs) and 0.5% long requests (200 μs), a mix common in key-value stores. Redis-KFlex handles requests on eight CPU cores generated by an open-loop load generator. More details are in Section 8.

Figure 1 shows the p99-latency of point queries with increasing load. We compare this with a hypothetical eBPF system that supports preemption with a 5 μs time slice (not achievable in current kernels). Even at low load, the current eBPF implementation exhibits high p99 latency due to head-of-line blocking from long scan requests. As load increases, this effect worsens, resulting in up to 7.4× higher p99

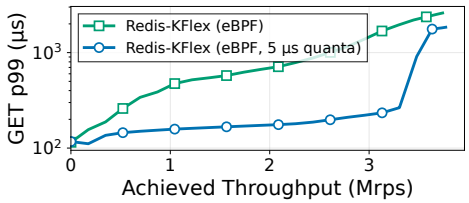

Figure 1: Latency inflation within an application. In eBPF, long-running SCAN operations (200 μs each) block GET queries, increasing GET (0.2 μs each) p99 latency. With 5 μs preemption quanta, point queries p99 latency improves by up to 7.4×.

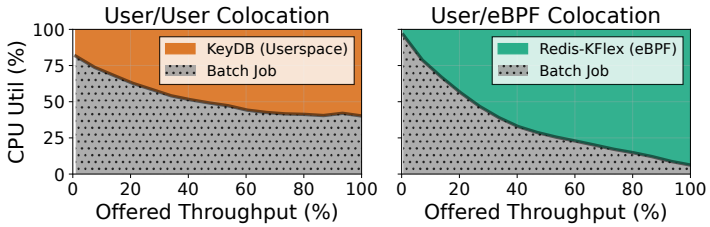

Figure 2: Unfair CPU allocation for colocating eBPF and userspace jobs. CPU utilization breakdown when a colocated job (allocated 50% CPU) shares cores with KeyDB (multithreaded userspace, left) and Redis-KFlex (eBPF, right). The scheduler correctly throttles KeyDB, but Redis-KFlex starves the colocated job because it executes in a context invisible to the scheduler.

latency compared to the preemptable-eBPF implementation.

Offloading to `ksoftirqd` does not resolve the blocking. `ksoftirqd` offers no way to prioritize short tasks. Thus, an eBPF task runs to completion regardless of whether it executes in `softirq` or `ksoftirqd` context, and shorter tasks always wait behind longer ones.

Inter-application unfairness. Across applications, long eBPF execution allows a single workload to monopolize CPU time because the eBPF execution time remains invisible to the scheduler. Moreover, most I/O-intensive eBPF hooks run in interrupt context, so the kernel must execute them immediately upon I/O events. These eBPF workloads monopolize CPU and starve colocated tasks, violating fairness and performance isolation.

We demonstrate this by extending the previous setup to colocate a CPU-bound job on the same eight CPU cores with the key-value store, configuring Linux's scheduler to allocate up to 50% of CPU resources to each job. We compare userspace KeyDB [37] against Redis-KFlex to highlight the differences in scheduling behavior. Figure 2 (left) shows CPU utilization breakdown as we vary the load on KeyDB. At low load, the CPU-bound job uses most of the CPU, as expected. However, as KeyDB load increases, the scheduler allocates CPU time fairly between KeyDB and the CPU-bound job, throttling KeyDB as needed. Figure 2 (right) shows the same experiment but with Redis-KFlex. At low load, the colocated job again gets its fair share of CPU time. However, Redis-KFlex starves the colocated job as load increases, using 90% of the CPU because XDP executes in an interrupt context invisible to the scheduler. Prior systems, such as DINT [58] and eTran [6], have observed similar unfairness, corroborating our findings.

Deferring to `ksoftirqd` does not restore fairness: the kernel charges CPU time to `ksoftirqd` itself rather than the application that installed the hook, leaving the scheduler unable to distinguish between tenants or enforce per-application limits.

3.3 Challenges in Making eBPF Schedulable

The current eBPF runtime lacks mechanisms for schedulability and execution-time attribution. Our goal is to bridge this gap by making eBPF programs schedulable without sacrificing safety or performance. However, making eBPF schedulable is challenging because its execution model differs fundamentally from that of other kernel work. We identify three key challenges:

- **Enabling fine-grained preemption with low overhead.** Performance-critical eBPF programs are invoked at high frequency. Any scheduling mechanism must preserve fast-path performance when preemption is unnecessary, and impose minimal overhead when preemption occurs.
- **Preserving eBPF correctness under preemption.** The eBPF verifier reasons about programs as single, uninterrupted executions and assumes atomic completion. Introducing preemption risks violating assumptions about register state, stack contents, and helper function behavior. A schedulable eBPF must preserve these correctness guarantees without requiring uninterrupted execution.
- **Providing expressive scheduling abstractions.** eBPF currently has no interface to interact with schedulers. A schedulable eBPF requires new abstractions that are expressive enough to support per-task priorities, budgets, and policies.

Addressing these challenges requires rethinking the execution model of eBPF programs on the I/O path. In the next section, we present PeeR, a system that achieves schedulability while preserving eBPF's safety and performance guarantees.

4 PeeR: Preemptable eBPF Execution Runtime

PeeR is a new eBPF runtime that makes latency-critical eBPF programs preemptable and schedulable in `softirq` context, where preemption is otherwise disabled. We implement PeeR for native XDP and describe extending it to other hooks in §6. We build PeeR on a simple but important observation: non-trivial eBPF programs must interact with the kernel through eBPF helper functions and kfuncs, as shown in Table 1. To safely call into kernel code, the verifier already tracks strict invariants at helper boundaries: held locks, borrowed references, and incomplete map operations. PeeR exploits this structure for *cooperative preemption*. Helper boundaries are candidate preemption points where the verifier has precise register and stack types. PeeR enables yielding at a site only when the verifier reports no unsafe resource is live and the enclosing hook has passed the audit in §6.

Figure 3 summarizes PeeR's key components. PeeR adopts

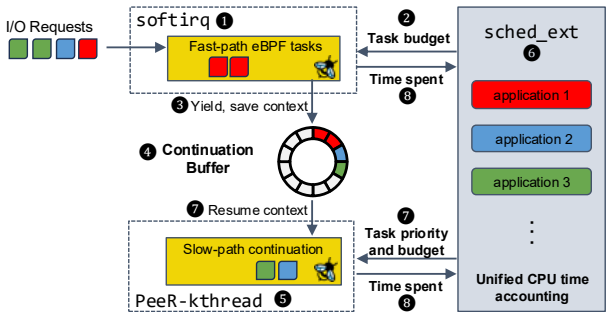

Figure 3: PeeR's design overview. eBPF tasks execute in `softirq` under `sched_ext`-provided budgets. Tasks exceeding budget yield to a continuation buffer and resume on PeeR-kthreads. Both paths report CPU time to `sched_ext` for unified accounting.

a hybrid execution model: short tasks run in `softirq` as a *fast path*, while long-running tasks are deferred to per-CPU PeeR worker kernel threads (PeeR-kthreads) as a *slow path*. On the surface, this model resembles `ksoftirqd`'s threaded model, but PeeR operates at eBPF task level with distinct mechanisms for budget checks, control-flow transfers, and scheduling. In this work, tasks remain on their originating CPU and are not migrated.

Fast path. Each eBPF task enters `softirq` ❶ with a configurable budget ❷, a global preemption quantum set by `sched_ext` (§7.2). Budget checks occur at helper call sites: PeeR augments eBPF's JIT compiler to wrap each helper with a prologue that checks remaining budget (§5.1). This turns helpers into precise, low-overhead preemption points compatible with the verifier. Tasks within budget enter the helper with minimal overhead and run to completion in FCFS order. Tasks that exceed their budget yield ❸: PeeR saves their execution state, consisting of a 512-byte stack, 11 registers, and program context, to a per-CPU array. It then returns control to `softirq` immediately, allowing subsequent I/O to proceed. Upon exiting `softirq`, PeeR flushes yielded tasks into a continuation buffer ❹ and wakes the local PeeR-kthread.

Slow path. Yielded tasks resume on PeeR-kthreads ❺ (§5.2). PeeR instantiates one PeeR-kthread per CPU at boot time. Scheduling occurs at two levels: at the outer level, `sched_ext` schedules PeeR-kthreads as ordinary kernel threads, controlling the aggregate CPU time all eBPF tasks on the slow path receive ❻. At the inner level, a *micro-scheduler* running within each PeeR-kthread orders eBPF tasks ❼. The micro-scheduler pulls continuations from the buffer, restores their state, and resumes them in policy-determined order. Resumed tasks follow the same budget enforcement; if a task yields again, control returns to the micro-scheduler, which requeues it and selects the next task. This two-level model enables operators to implement policies such as priority scheduling or shortest-remaining-processing-time (§7). Both paths report CPU time to `sched_ext` ❽, closing the feedback loop for system-wide scheduling.

5 Cooperative Preemption

Preemption sits at the core of making eBPF schedulable. For eBPF programs on I/O paths that execute millions of times per second, the preemption mechanism must be lightweight while preserving eBPF's correctness guarantees. PeeR therefore avoids traditional interrupt-based preemption, whose timer signals and context switches would be too costly on the fast path, and instead adopts a *cooperative preemption* model.

In classical cooperative scheduling, threads run until they explicitly call `yield()`, giving up the CPU at well-defined points. This avoids frequent interrupts and reduces context-switch overhead, but relies on applications to correctly insert yield points. PeeR retains these benefits while automating the process: rather than requiring programs to call `yield()`, PeeR enforces budgets and checks for preemption at *eBPF helper sites*, i.e., invocations of helper functions that eBPF programs use to interact with the kernel. These sites are natural points for preemption: helpers are fundamental to any non-trivial eBPF program, and the verifier already enforces strict pre- and post-conditions at these call sites (e.g., no held locks, valid pointers, and constrained stack usage).

Figure 4 illustrates a state machine of this model. Each helper site triggers a *preemption check*. If the program remains within budget, execution continues into the helper. If the budget has expired, however, the program starts *yielding*: PeeR invokes a yield handler that saves the current execution state, including preemption site identifier, eBPF stack, and registers (§5.1). The handler then transfers control back to the kernel. The program enters a *preempted* state until `sched_ext` reschedules it (§7), when the program starts *resuming*. PeeR restores the saved state, performs necessary pointer patching, and resumes at the original preemption site (§5.2).

Cooperative preemption via compiler-inserted yield points is well established. Wasmtime [4] inserts epoch checks at function entries and loop headers, and low-latency schedulers approximate preemption for userspace RPC handlers through compiler instrumentation: Concord [34] polls a dispatcher-written cache line, while Compiler Interrupts [2] and TinyQuanta [40] trigger yields from instruction-count-driven probes. Go [7] instead preempts asynchronously with signals, using compiler-emitted metadata to avoid unsafe points. Like these systems, PeeR may yield only where program state is safe; Concord, for example, avoids yielding inside locks or external libraries. PeeR faces analogous but distinct constraints. Rather than choosing yield points heuristically, it reuses the eBPF verifier's helper-boundary invariants (no locks held, valid pointers) and adds eBPF-specific rules that forbid yielding while RCU-protected pointers or other BPF-held resources are live. PeeR adds two mechanisms that userspace runtimes do not require. It rebases `PTR_TO_CTX` and `PTR_TO_STACK` values across a context switch using verifier-derived type information (§5.2), and it resumes through CFI-safe trampolines.

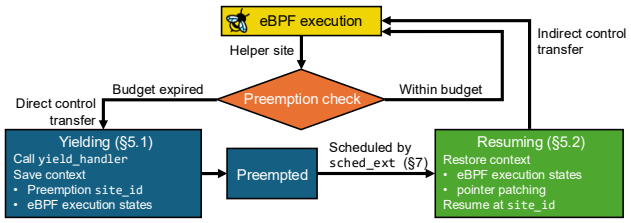

Figure 4: PeeR's state diagram. At each helper site, PeeR checks the task's budget. Tasks within budget continue; tasks over budget yield, saving their context until `sched_ext` reschedules them.

```
1     call preempt_check        ; check if execution budget has expired
2     test eax, eax             ; check if eax != 0 (should preempt)
3     jnz  yield_site_1         ; jump to yield_site_1 (line m) if eax != 0
4
5   helper_site_1:              ; address of helper site 1
6     call bpf_map_lookup_elem  ; call helper function
7     mov  [elem], eax          ; store helper return value
...
m   yield_site_1:               ; atomic state saving for site_1
m+1   mov  r11, 1               ; load site_id (1) to r11
m+2   jmp  yield_handler        ; execute yield handler; store eBPF context
...
```

Figure 5: JIT-augmented assembly for a `bpf_map_lookup_elem()` helper site. The preemption check (orange) tests a global flag and conditionally jumps to the yield stub (blue), which records the site identifier before invoking the yield handler.

5.1 Preemption Path

PeeR augments helper functions to implement preemption at helper sites. Since eBPF is JIT-compiled, PeeR modifies the JIT compiler to emit the necessary code snippets for preemption budget checks and state saving.

Preemption check and yield handler in assembly. Figure 5 shows how PeeR's JIT compiler augments an eBPF helper site, `bpf_map_lookup_elem()`, in pseudo x86 assembly. PeeR assigns a unique `site_id` (line 5 shows site 1), enabling it to identify where a program was preempted for later resumption. During JIT compilation, PeeR inserts a short preemption check prologue (orange highlight, lines 1 to 3) immediately before each helper site. Because helpers are called frequently, this check must be lightweight. Furthermore, it needs to preserve register values to save the execution state to the continuation buffer.

The `preempt_check()` call on line 1 evaluates a per-CPU preemption flag; the scheduler sets this flag at the end of each budget period (details in §7.2). We measure that the prologue costs one to two cycles when the flag is not set (§8.3), adding negligible overhead to fast-path execution. This flag is retrieved into register `eax` (line 2). Since `eax` would be overwritten by the helper call regardless, reusing it is safe; the function also uses the `no_caller_saved_registers` GCC attribute to avoid clobbering BPF argument registers. If the flag indicates the budget has expired (line 3), PeeR jumps to a per-site stub (blue highlight) that stores the `site_id` into x86 register `r11` (line `m+1`), a register not used by eBPF programs. Control then transfers to a shared yield handler (line `m+2`) that saves execution state and returns control to `softirq` or the worker thread.

Execution state capture. When the budget check triggers a yield, PeeR captures all execution state without clobbering live registers or stack contents. The shared handler at line `m+2` immediately saves state into a continuation buffer of type `struct peer_cont` before any other operations. An eBPF program's execution state consists of 11 registers (88 bytes), a 512-byte stack, and a program-specific context. The context type varies by hook; for instance, XDP programs receive `struct xdp_md`, and socket programs receive `struct __sk_buff`. Since the hook type is known at compile time, PeeR can generate type-specific context-saving routines for each program. The handler also stores the `site_id` and a reference to the current task. Because registers and stack are laid out contiguously, the handler copies all 600 bytes with a single `memcpy()`, then saves the context and returns control to the kernel.

Context saving for XDP. In this paper, we implement context saving for XDP, one of the most performance-critical hooks. In Linux's networking stack, the NIC driver polls incoming packets in batches via *NAPI polling*; XDP programs execute immediately upon arrival, before socket processing or routing. The XDP context, `struct xdp_md`, contains pointers to the packet's start and end. Saving this struct alone is insufficient: packets are allocated from the driver's buffer pool and remain valid only within the current NAPI poll cycle.

To extend packet lifetime without copying, PeeR rebinds the packet to an independently owned frame managed via reference counting. This preserves packet data in place and stores minimal metadata in the buffer's headroom. PeeR then returns a new verdict, `XDP_YIELD`, in place of the program's. The driver treats `XDP_YIELD` as a consumed packet and continues its NAPI poll, so the fast path never blocks waiting for the deferred result. The continuation records a pointer to this frame; upon resumption, the worker reconstructs a consistent packet view from the same underlying buffer. After the program completes, PeeR decrements the reference count and returns the buffer to the pool.

5.2 Continuation Path

PeeR wakes the local PeeR-kthread when fast-path execution finishes, or `sched_ext` does so when it schedules the kthread. The micro-scheduler (§7.3) selects the next eBPF program from the continuation buffer; the PeeR-kthread then restores its state and resumes execution from the preempted helper site on the slow path.

Pointer patching. Resuming a preempted eBPF program requires restoring execution state to registers and memory. However, pointer values saved at yield time become invalid when execution resumes on a worker thread: the stack resides at a different address, and the execution context has been remapped. Naively restoring stale pointers causes memory corruption. PeeR has access to the old and new base addresses, but patching is not straightforward: a 64-bit value could be a pointer or an integer, and the kernel retains no type information at runtime.

PeeR extracts type information from the eBPF verifier. In eBPF's calling convention, `r10` serves as the frame pointer (stack base) and `r1` holds the context pointer `ctx` at program entry. The verifier tracks the type of each register

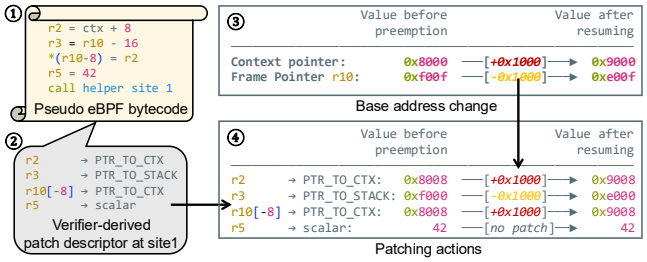

Figure 6: Pointer patching at resumption. ① Pseudo-eBPF bytecode calling helper at site 1. ② Patch descriptor with verifier-derived types at this site. ③ Base address changes between preemption and resumption. ④ PeeR applies pointer rebases according to the patch.

and stack slot at every instruction; two types are relevant for PeeR: `PTR_TO_STACK` for frame-pointer-derived values and `PTR_TO_CTX` for context-derived values. PeeR intercepts this information before JIT compilation, recording which locations hold `PTR_TO_STACK` or `PTR_TO_CTX` values at each helper site in a *patch descriptor*. At resume, PeeR consults the descriptor and rebases each pointer to its new base address.

Figure 6 illustrates this mechanism. ① shows pseudo-eBPF bytecode where `r2` derives from the context pointer, `r3` derives from `r10`, stack slot `r10[-8]` stores `r2`'s value, and `r5` holds a scalar. PeeR leverages the verifier to generate a *patch descriptor* at this site (shown at ②), which stores the type information of variables in registers and on the stack. ③ illustrates that when the program yields and resumes, the context moves from `0x8000` to `0x9000` (`+0x1000`) and the frame pointer from `0xf00f` to `0xe00f` (`-0x1000`). Using the patch descriptor, PeeR rebases pointers according to their types, as shown in ④. It shifts `PTR_TO_CTX` values `r2`, `r10[-8]` by `+0x1000` (`0x8008` → `0x9008`), adjusts `PTR_TO_STACK` value `r3` by `-0x1000` (`0xf000` → `0xe000`), and leaves scalar `r5` unchanged.

One complication arises when multiple control-flow paths converge at a yield site with different types for the same pointer. PeeR uses intersection semantics: a location appears in the patch descriptor only if all paths agree on its type. This is safe because the verifier enforces type consistency for any dereferenced value, hence conflicting pointers are always demoted to scalars and require no patching.

Control-flow transfer under CFI. Finally, the worker must transfer control back to the helper call where the program yielded. This requires an indirect jump, but modern CPUs enforce Control-Flow Integrity (CFI) through Indirect Branch Tracking: indirect jumps must land only on valid entry points marked with special instructions (e.g., `endbr64` on x86), or the CPU triggers a hardware exception. PeeR satisfies CFI by emitting a trampoline for each yield site during JIT compilation. Each trampoline begins with an `endbr64` instruction, marking it as a valid indirect branch target, followed by a relative jump to the corresponding helper call. Trampolines are stored consecutively in the JIT code section, with addresses recorded in an array indexed by `site_id`. At resume, the worker looks up the trampoline for the saved `site_id` and jumps to it. The

Interface	Description
`runtime_event ringbuf`	Per-CPU stream of execution records for accounting
`set_budget(ns)`	Sets the global preemption quantum
`struct peer_cont cont`	Per-task continuation buffer and metadata
`enqueue(cont)`	Handles a newly-preempted eBPF program
`requeue(cont, runtime_ns)`	Handles when an eBPF program is preempted again

Table 2: PeeR's interfaces to schedulers. The top part interacts with the macro-scheduler across threads, while the bottom part implements the micro-scheduler that decides task order within a PeeR-kthread.

`endbr64` satisfies CFI, and the relative jump transfers control to the correct program location. Because PeeR places the yield check immediately before the helper executes, resuming at the helper call runs it exactly once, so a yield never skips or duplicates a helper's side effects.

5.3 Handling RCU Pointer Safety

Many eBPF hooks in `softirq`, such as XDP, execute under an implicit *RCU read-side critical section*. Under *Read-Copy-Update (RCU)*, readers proceed without locks and writers defer freeing data until all pre-existing readers finish. This allows programs to safely dereference pointers returned by helpers like `bpf_map_lookup_elem()` without explicit locking. When `softirq` completes, the critical section ends. This behavior poses a risk for PeeR: if PeeR yields a program holding such pointers, the kernel exits the protected section, risking other programs updating these pointers or even freeing them to cause use-after-free after the task is rescheduled on PeeR-kthreads.

PeeR prevents this by restricting preemption to helper sites where no RCU-protected pointers are live. We again rely on the verifier: its type tracking identifies RCU-protected values, such as map-value pointers (`PTR_TO_MAP_VALUE`) and RCU-tagged kernel pointers (`MEM_RCU`), and its liveness analysis marks a value dead after its last dereference, even if it remains on the stack. PeeR queries this information at each helper site and injects preemption checks only where no RCU values are live. At first glance, this restriction reduces PeeR's preemption opportunities, but in practice it rarely does. The common pattern is to look up an RCU-protected value and dereference it within the same stretch of code, before the next helper call. The pointer is then dead under liveness analysis at the following helper boundary, so that site can still yield. A yield point is forgone only when a program holds an RCU-protected pointer live *across* a helper or kfunc call, which is uncommon. When a program does guard shared state with a BPF spin lock, that region cannot yield: the verifier forbids helper calls while a lock is held, and PeeR, consulting the verifier's lock state (`active_locks`), emits no check at the few data-structure kfuncs still permitted there. Sleepable RCU [41] could lift the restriction entirely by allowing a critical section to span a preemption point; we leave this to future work.

6 Correctness and Hook Safety

PeeR preempts and resumes an eBPF invocation while preserving the safety guarantees of the verifier. Two conditions

are required to guarantee safety: *eBPF-level safety* (§6.1) requires that, at any point where an eBPF program can yield, the program's own state is clean and reconstructable. *Hook-level safety* (§6.2) requires that the kernel path invoking the program can tolerate it being preempted and resumed later. The eBPF verifier guarantees the first requirement. To evaluate the second, we characterize eBPF's common hooks individually and determine whether each is compatible with PeeR.

What PeeR guarantees. PeeR makes a fast-path eBPF invocation *reentrant*: it can yield at a helper boundary, let other work run on the core, and resume from the same site under the same invariants as the fast path, however long it was suspended. Across that yield, PeeR preserves *memory safety* for the three kinds of state an invocation depends on:

1. Its eBPF state, the registers and stack, is saved and restored with each pointer rebased to its new address (§5.2).
2. Its kernel state, any RCU-protected object or acquired reference, stays valid because PeeR never yields while one is live (§5.3).
3. Its hook context, the program's input, stays valid past the original call. For XDP, PeeR retains the packet as an `xdp_frame` (§5.1).

What PeeR does not guarantee. Similar to prior work on preemptive scheduling [34, 35, 40], PeeR allows for interleaving of eBPF program invocations. Normally on the `softirq` fast path, an eBPF invocation runs uninterrupted, so an eBPF application may be written with the assumption that accessing shared state is atomic. Under PeeR, a later invocation can run while a program is preempted and modify that state, so the program might read a map entry, yield, and resume to find a different value. Logic written on the assumption that the entry is stable across the invocation can then incur a race condition. As a result, the program must synchronize explicitly, for example by guarding the access with a spin lock. This is already the case for existing eBPF programs that run in preemptable context, and PeeR extends this requirement to eBPF programs running in a previously non-preemptable context. This interleaving can also change per-core completion order. If a program yields and a later invocation runs on the same core, the later one can complete before the first resumes, so a program that requires per-core completion order must serialize explicitly.

6.1 eBPF-level safety

PeeR establishes eBPF-level safety with two conditions, both derived from the eBPF verifier. First, it yields only at a helper function boundary where the verifier has already proved the call safe and reports no eBPF lock held, so the program's registers, stack, and pointers all carry assigned types. This leaves a clean snapshot that PeeR can later reconstruct. Second, it yields only where the verifier reports no outstanding eBPF resource, such as a live RCU-protected pointer or an acquired reference, since yielding while one is live could let the kernel reclaim it under the suspended program (§5.3). The verifier guarantees both conditions; a site that cannot satisfy them emits no yield point.

6.2 Hook-level safety

The verifier exists only within eBPF context and does not have visibility into the surrounding kernel context. A hook must meet three conditions for compatibility with PeeR:

1. The program's input stays valid after it yields. For XDP, PeeR holds the packet past the original call.
2. The caller does not require the result immediately, so it can continue while PeeR applies the result later.
3. The calling kernel code holds no lock while the program runs.

Resumption runs in process context on an ordinary PeeR-kthread, not inside `softirq`. Deferring eBPF work to a kernel thread has the same properties that already exist when the kernel hands `softirq` processing to `ksoftirqd`. The difference is in granularity; PeeR defers a single eBPF invocation rather than a batch. Before resuming, the PeeR-kthread re-creates the environment the hook runs in, so the continuation executes under the same invariants as the fast path. Below we describe how XDP meets each condition.

Input lifetime. The program's input must stay valid until PeeR applies the result. For XDP, the packet buffer is owned by the driver's page pool and is valid only for the duration of the NAPI poll. The driver can recycle it locklessly only because the program runs to completion within that poll. PeeR must therefore extend the buffer's lifetime past the original call. It retains the packet as an independently owned `xdp_frame` (§5.1), so the driver does not recycle it before the continuation finishes.

Deferred result. The caller must accept the program's verdict after the original call returns rather than during it. PeeR returns `XDP_YIELD` in place of the program's verdict (§5.1); the driver treats it as a consumed packet and continues its NAPI poll, so the fast path does not wait. On resume, PeeR applies the program's real verdict, covering all native single-buffer actions: `XDP_DROP` and `XDP_ABORTED` free the frame, `XDP_PASS` builds an `skb` and injects it, `XDP_TX` transmits via `ndo_xdp_xmit`, and `XDP_REDIRECT` completes through the standard redirect path.

Caller-side invariants. The verifier reasons only about eBPF-visible state and cannot prove that surrounding kernel code holds no lock across the call, so we check this per hook. For XDP, the NAPI receive path invokes the program without holding a driver or stack lock that must be released by the time the verdict is produced, so deferring the verdict leaves no caller-side critical section open. The one piece of caller state a yield could disturb is the XDP redirect bookkeeping, kept in a per-task networking context (`bpf_net_context`). PeeR handles this by completing redirects from the PeeR-kthread's own networking context and flush list rather than the original poll's, similar to `cpumap`.

PeeR does not check a hook at runtime. It is built only for hooks that meet these conditions, and every other hook runs unchanged. Table 3 applies this audit to common hooks, as a design-time classification rather than a runtime test. As §2 explains, PeeR targets latency-critical I/O processing, not eBPF as a whole. These are the packet and storage fast paths such as

Hook	Compatible?	Why
Native XDP [22, 31]	✓	The driver runs the program on an `xdp_buff` and expects a packet verdict. PeeR retains the packet as an `xdp_frame` on yield and applies the verdict on resume, covering all five native actions. Multi-buffer and tail-call programs are rejected at load.
tc / TCX (direct-action) [16]	✓	The hook runs over an skb and returns a TC action. PeeR can apply terminal actions such as drop, stolen, and redirect after a yield, once it retains the skb and the redirect state. Continuing actions re-enter the classifier chain or the network stack, which lies outside the eBPF continuation, so PeeR supports only the terminal actions.
TC action chains (`act_bpf`) [15]	✗	An eBPF program is one action inside a larger action list. After it returns, the caller may run later actions, repeat, or jump to another chain. Reconstructing this requires the full action-list and chain state, which the eBPF continuation does not capture.
XRP storage (NVMe) [56]	✓	The hook runs in NVMe completion on a request-scoped context and either completes the read or resubmits the next I/O. PeeR can retain that request and resumption state across a yield and apply the action later. We do not implement this adapter, but the contract fits the model.
Tracing, LSM, sockets, block [13, 14, 17]	✗	These hooks fall outside PeeR's model for two reasons. PeeR cannot defer the result for tracing or LSM: tracing runs under locks held by the caller, and LSM must return its allow-or-deny decision before the caller continues. Socket and process-context hooks already run preemptably and do not require deferral.

Table 3: Hook compatibility with PeeR's correctness model. A hook is compatible only if the eBPF continuation and the retained hook object suffice to apply the final action without resuming caller-side kernel control flow. PeeR currently implements native XDP.

XDP, `tc`, and XRP. The hooks PeeR does not support, including tracing and LSM, are also not its target: their programs are short and event-driven, not the long request processing that causes head-of-line blocking, so they have little need for preemption. `softirq` packet hooks such as LWT and netfilter share the same skb-verdict structure, and applying PeeR to them is future work.

7 Scheduling eBPF Tasks

The mechanisms in §5 make eBPF programs preemptable, but preemptability alone does not determine *when* to preempt or *which* continuation to resume next. This section describes how PeeR integrates with `sched_ext` [49] to provide schedulability through operator-defined policies.

`sched_ext` is a Linux scheduler interface that allows users to implement arbitrary scheduling policies via a set of callbacks. The core abstraction is the *dispatch queue* (DSQ), into which tasks are enqueued and from which CPUs pull work. `sched_ext` determines scheduling order by controlling how tasks flow through DSQs, enabling policies such as priority scheduling or weighted fair sharing.

7.1 Two-Level Hierarchical Scheduling

Scheduling preempted eBPF programs presents a challenge: on the fast path, programs execute first-come-first-served with bounded budgets, matching existing eBPF semantics to minimize overhead. On the slow path, however, multiple preempted programs accumulate within a single PeeR-kthread, requiring a policy to determine resumption order. `sched_ext` cannot distinguish among them because they share the same PeeR-kthread, which is treated the same as all other kernel threads.

We address this with a two-level hierarchy. At the outer level, `sched_ext` acts as a *macro-scheduler*, making task-level decisions at millisecond granularity: which applications to run, how long they execute, and how CPU time is divided among workloads. Once `sched_ext` schedules a PeeR-kthread onto a CPU, the *micro-scheduler* takes over. The micro-scheduler runs within the PeeR-kthread context at microsecond granularity. It distinguishes among accumulated eBPF tasks and selects the subsequent continuation to resume. This division of responsibility allows `sched_ext` to control how much CPU time eBPF programs receive in aggregate, while the micro-scheduler determines which programs benefit from that time.

7.2 Accounting and Budget Enforcement

Table 2 shows the interface between PeeR and `sched_ext`. The macro-scheduler uses the top two entries to account for eBPF program execution time and enforce the execution budget:

Accounting execution time. PeeR exports a per-CPU `runtime_event` ring buffer. Each record contains the logical owner (e.g., a process or cgroup identifier), the CPU, the execution duration, and whether the task completed or yielded. Each eBPF task execution updates the `runtime_event` buffer. A userspace daemon consumes these events asynchronously and aggregates them into per-application CPU usage. This closes the feedback loop: `sched_ext` observes how much CPU time each eBPF application consumes and adjusts when and how often it schedules PeeR-kthreads accordingly. For example, if an application's eBPF programs have exceeded their fair share, `sched_ext` can deprioritize the PeeR-kthread or delay its next scheduling opportunity. This makes eBPF execution visible to system-wide scheduling policy.

Enforcing execution budgets. The macro-scheduler controls *when* eBPF programs yield through quantized budget enforcement. `set_budget()` configures the preemption quantum, a time interval that defaults to 5 μs in our evaluation. The scheduler advances a per-CPU epoch counter once per quantum. When an eBPF program begins execution, PeeR records the current epoch. At each helper call site, the JIT-inserted preemption check compares the current epoch against the recorded value, and if the epoch has advanced, the program yields.

7.3 Ordering Continuation Tasks

The micro-scheduler controls *which* eBPF task resumes next on a given PeeR-kthread. It uses a simplified version of `sched_ext`'s DSQ abstraction, with priority-based ordering to determine the next continuation task. Operators implement

```c
/* enqueuing new task: set the remaining time to an
 * application-provided runtime estimation.
 */
u64 enqueue(struct peer_cont *cont) {
    return cont->peer_metadata.estimated_work;
}
/* requeueing a task: remove the executed time from
 * the task remaining time.
 */
u64 requeue(struct peer_cont *cont, u64 runtime_ns) {
    /* underflow check omitted in this example */
    return cont->prio - runtime_ns;
}
```

Figure 7: Sample SRPT implementation. The scheduler prioritizes continuations closest to finishing by tracking remaining work.

scheduling policies via the bottom three rows of Table 2 by setting extra fields inside the continuation structure `cont` and two DSQ management callbacks.

The `enqueue()` and `requeue()` callbacks order tasks on the per-kthread DSQ. The first time an eBPF task is preempted, PeeR calls `enqueue()` to put this task on the DSQ to be scheduled. Each subsequent time the same task is preempted within the PeeR-kthread, `requeue()` is called with the time spent executing. These functions return a priority number that determines scheduling order: continuations with a lower priority number are resumed first. When priorities are equal, a sequence number provides FIFO ordering. Without application modification or a custom queueing policy, the micro-scheduler processes task continuations in FIFO order. Beyond that, the `cont` structure allows eBPF programs to provide scheduling hints (such as flow identifiers, weights, or deadlines) that the scheduler uses in its priority calculations.

Sample SRPT policy implementation. The priority-based interface supports a variety of scheduling policies. We demonstrate the Shortest Remaining Processing Time (SRPT) implementation as an example in Figure 7. SRPT prioritizes tasks with the least remaining work, minimizing average completion time. When a task is first preempted, `enqueue()` initializes its priority to an application-provided estimate of remaining work, stored in `cont`. When the same task is preempted again, `requeue()` subtracts the elapsed execution time from the current priority, reflecting progress toward completion. Since tasks with lower priority numbers are scheduled first, tasks closer to completion naturally rise to the front of the queue. Such an estimate is available in many of the workloads PeeR targets, since the program already parses each request to dispatch it and can derive a work hint from the request type, for example a scan's range or a transaction class.

8 Evaluation

This section evaluates PeeR's performance and expressiveness; we implement PeeR in Linux kernel 6.16 with ≈ 5000 lines of C code. We first show how PeeR's preemption mechanism eliminates head-of-line blocking within an application, using a mixed GET/SCAN workload and a TPC-C workload, and use TPC-C to demonstrate expressiveness across multiple scheduling policies (§8.1). We then evaluate inter-application allocation by colocating batch and latency-sensitive jobs under CPU-sharing policies (§8.2), and finally present microbenchmarks of preemption and resumption overhead (§8.3).

System setup. We evaluate PeeR on two servers (application and client), each with a 28-core Intel Xeon Gold 5420+ and 256 GB RAM, connected via Mellanox ConnectX-7 400 Gbps NICs through an Intel Tofino 2 switch. Both run Ubuntu 24.04 with Linux 6.16 modified for PeeR, with hyperthreading, adaptive interrupt coalescing, and IOMMU disabled for low latency.

Our scheduler extends `scx_layered` [30], Meta's production `sched_ext` scheduler, with PeeR's accounting and budget enforcement. We generate requests using `loadgen`, an open-loop generator with Poisson arrivals over UDP and TCP. We use NIC flow steering to evenly distribute load across cores. For Redis-KFlex, we use a lightweight in-eBPF TCP stack that executes in the XDP hook. We set PeeR's preemption budget to 5 μs by default unless otherwise noted.

8.1 Intra-Application Scheduling

PeeR enables preemption within an application and supports operator-defined policies. We first evaluate the preemption mechanism on a bimodal workload, then assess expressiveness across policies on TPC-C [51].

8.1.1 Preemption for Latency-Critical Tasks

We evaluate bimodal Redis and Memcached workloads mixing latency-sensitive GET requests with long-running SCAN queries, similar to the setup in Figure 1. For this workload, we use simple FIFO ordering with preemption enabled; no additional scheduling policy is required to demonstrate the benefits. For Redis, we compare two multi-core key-value stores: the userspace baseline KeyDB [37], a multithreaded fork of Redis (we use it rather than single-threaded stock Redis), and Redis-KFlex, a Redis-compatible store in KFlex [9] that runs entirely in the XDP hook. We also add a cpumap-deferral baseline that tests whether the application can address head-of-line blocking itself, without kernel changes. The workload is 99.5% GET (0.2 μs) and 0.5% SCAN (200 μs). For Memcached, we compare the standard userspace server, BMC [28] (a common pattern where the fast path runs in-kernel but cache misses fall back to userspace), and KFlex (entirely in eBPF), under a 50/50 GET (0.2 μs)/SCAN (30 μs) mix. For both, we measure in-kernel performance with and without PeeR to isolate preemption's impact.

Figure 8 plots achieved throughput against tail latency, with Redis (left) and Memcached (right) columns; top plots show GET p99 latency versus throughput (krps) and bottom plots show the same for SCAN.

For Redis-KFlex (left column), SCAN queries block GETs and inflate tail latency under default eBPF. Enabling PeeR reduces GET p99 latency by 19.8× over default eBPF while achieving 3.77× higher throughput than userspace KeyDB. The bottom plots confirm SCANs are not starved: below 1000 krps, PeeR even improves SCAN latency by reducing blocking among SCANs themselves. PeeR also achieves 10.3% higher throughput than default eBPF, because preempting long

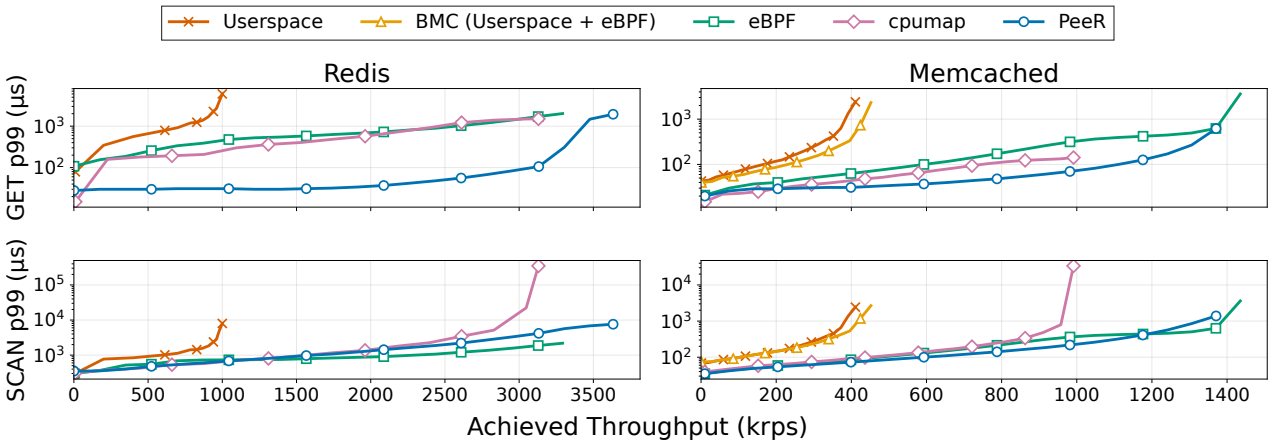

Figure 8: Point/scan workloads for Redis (99.5% GET, 0.5% SCAN) and Memcached (50% GET, 50% SCAN). PeeR retains the performance benefit of in-kernel execution over userspace, while reducing GET p99 latency by preventing long-running scan operations from blocking point queries compared to the default eBPF runtime. Userspace baselines: KeyDB and stock Memcached. The x-axis is total achieved throughput across both query types; curves end at saturation.

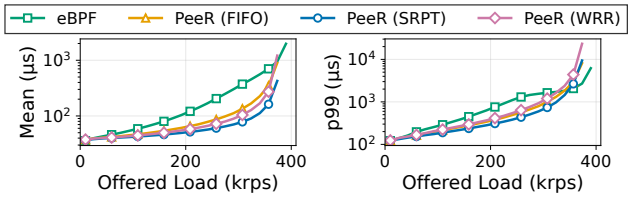

Figure 9: Aggregate TPC-C latency under different scheduling policies. FIFO with preemption outperforms baseline eBPF; SRPT achieves 3× lower mean latency by prioritizing short requests.

SCANs keeps the receive queue drained, whereas under default eBPF the queue fills behind blocked GETs and drops requests.

The application can also chunk long requests itself. The cpumap baseline bounds the work per XDP invocation and defers the rest of a long SCAN to a per-CPU kernel thread without kernel changes, but this only relocates the blocking: a packet batch drains fully before the next, deferred work reaches the thread only at batch boundaries, and the thread runs those SCANs with softirqs disabled, so later GETs wait behind them. At 1.5 Mrps cpumap brings GET p99 to 403 μs (against 581 μs for default eBPF and 31 μs for PeeR), is the first to saturate, at 3.1 Mrps, and near saturation its SCAN p99 climbs to 350 ms against 4 ms for PeeR.

For Memcached (right column), both KFlex configurations (with and without PeeR) achieve 3.46× higher throughput than userspace; BMC matches userspace because cache misses fall back to it. PeeR reduces GET p99 latency by 4.5× over default eBPF. Unlike Redis-KFlex, PeeR's overall throughput is slightly lower than default eBPF: with a 50/50 mix and shorter queries, queue buildup is milder, so preemption overhead is not offset by reduced drops. Still, PeeR isolates GET latency regardless of SCAN load, while the cpumap baseline tracks default eBPF and saturates earlier. At peak, Redis's 3.6 Mrps is 9 Mpps and 12 Gbps, and Memcached's 1.5 Mrps is 3.0 Mpps and 3.1 Gbps.

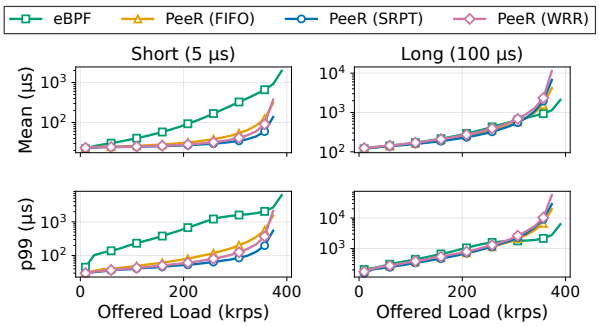

Figure 10: TPC-C latency by request type. Short queries (Payment) benefit from preemption across all loads; long queries (StockLevel) are not impacted until load exceeds 300 krps.

8.1.2 Expressing Scheduling Policies

To demonstrate expressiveness, we run a TPC-C workload and implement multiple scheduling policies in PeeR. We use a synthetic XDP echo server to emulate the compute workload, where each UDP request specifies a spin duration drawn from TPC-C transaction profiles: Payment (5.7 μs, 44%), OrderStatus (6 μs, 4%), NewOrder (20 μs, 44%), Delivery (88 μs, 4%), and StockLevel (100 μs, 4%), taken from prior in-memory database measurements [8]. We implement three policies in PeeR's `sched_ext` component: FIFO, SRPT (shortest-remaining-processing-time), and WRR (weighted round-robin).

Figure 9 compares baseline eBPF (no preemption) against PeeR under each policy, with load (krps) on the x-axis and mean (left) and p99 (right) latency on the y-axis. Even the simplest FIFO scheduler with PeeR outperforms baseline eBPF, but PeeR's expressiveness enables more effective policies: SRPT achieves the best mean and tail latency by prioritizing short requests, cutting mean latency 3× over baseline at 300 krps, while WRR is a practical alternative

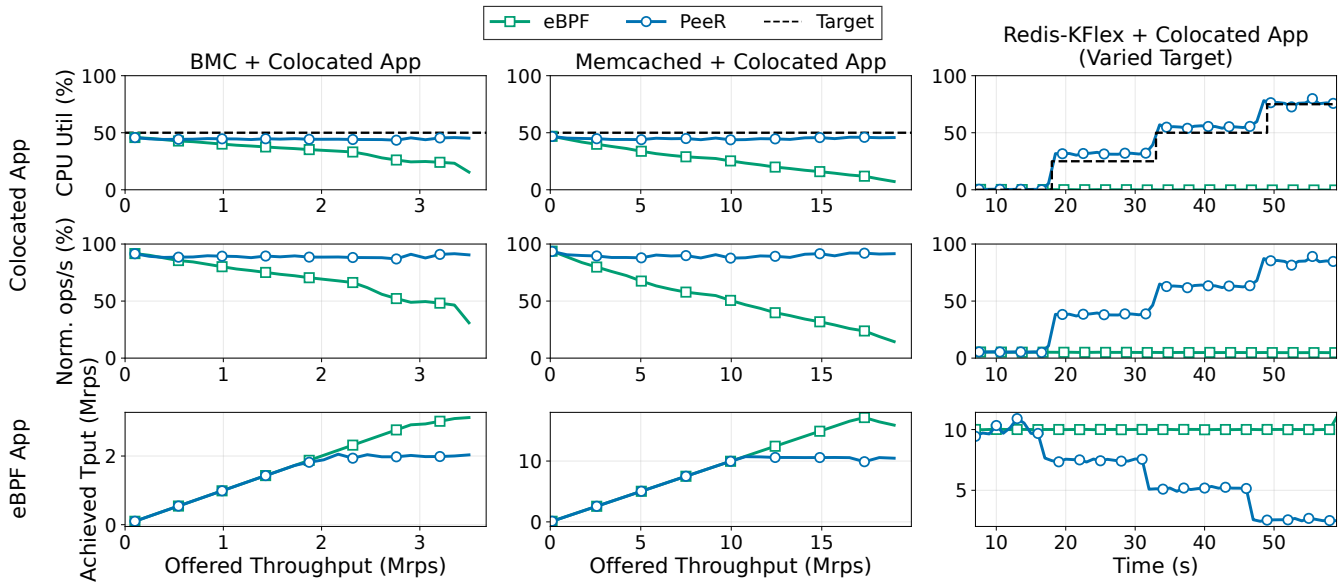

Figure 11: Colocation experiments showing latency-sensitive applications (Memcached, Redis) colocated with batch jobs. PeeR enforces operator-defined CPU allocation among workloads.

when execution time is unknown a priori.

Figure 10 breaks down latency by request type. Short queries (Payment) benefit from preemption across the entire load range under all three policies, while long queries (StockLevel) match baseline until load exceeds 300 krps, so PeeR improves short-request latency without starving long ones. These gains come at a deep-tail cost for long requests, which are delayed when preempted and resumed on a worker. For the Redis point/scan workload, SCAN p99.9 is comparable to the non-preemptive baseline at low load (946 μs vs. 924 μs at 1 Mrps) and rises to 2.3× near saturation (5952 μs vs. 2562 μs at 3.1 Mrps); in TPC-C, StockLevel has 1.5–1.7× higher p99.9 under PeeR, and SRPT concentrates this cost on the single longest class while improving the next-longest (Delivery p99.9 of 1145 μs under SRPT vs. 2042 μs for the non-preemptive baseline). An operator who must protect long requests can raise the budget or give them higher micro-scheduler priority; PeeR's flexibility to match policies to workloads is itself expressiveness beyond today's eBPF.

8.2 Inter-Application Scheduling

We evaluate PeeR's ability to enforce scheduling policies when eBPF applications compete with other userspace workloads for CPU time. We colocate a latency-sensitive eBPF application (BMC, Memcached, and Redis-KFlex serving GET queries) alongside a compute-bound batch job, similar to the setup in Figure 2. A successful scheduler must enforce the configured CPU allocation while preserving throughput and latency for both workloads.

Figure 11 shows the results; each column is an eBPF application, with offered load (left, middle) or time (right) on the x-axis. Rows show the batch job's CPU utilization vs. its target, its normalized throughput, and the eBPF application's achieved throughput. With vanilla eBPF, the batch job starves as load rises: for BMC under a 50/50 fair-share policy, BMC exceeds its allocation and the batch job's throughput drops to 30.9% of its fair share, because eBPF execution is invisible to the scheduler. PeeR fixes this by making eBPF execution time visible and accountable, capping BMC's utilization at its share so the batch job keeps its throughput; the middle column shows the same for Memcached, where the batch job's CPU collapses to 7% without PeeR but holds its fair share with it.

Beyond equal sharing, PeeR enforces weighted allocations. The right column varies Redis-KFlex's batch-job target from 0% to 75% over time: PeeR tracks it within 6% across all configurations, whereas without PeeR the batch job's utilization bears no relation to its target, receiving only what Redis-KFlex leaves behind. PeeR thus makes eBPF workloads first-class scheduling citizens, subject to the same policies as userspace processes.

8.3 Microbenchmarks

PeeR's performance depends on the low overhead enabled by the cooperative preemption mechanism, while the preemption granularity depends on the budget we set. This section studies PeeR's instrumentation overhead, its preemption and resumption cost, and the impact of different preemption budgets.

8.3.1 Overhead Breakdown

We measure preemption and resumption overhead by running an XDP echo server under high load, preempting once per packet. Figure 12 shows the time spent in each phase, averaged over more than one million measurements.

Preemption costs 77 ns: reading the `sched_ext`-set flag incurs an L1 miss (17 ns), and checking it, transferring to the yield handler, and saving state adds 60 ns. Resumption costs

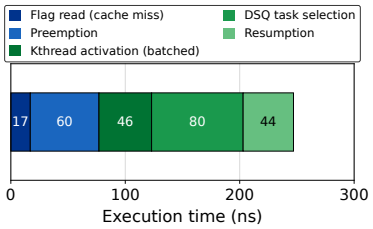

Figure 12: PeeR overhead breakdown for a preemption-resumption cycle. The total 247 ns cost enables fine-grained scheduling while remaining practical for microsecond-scale workloads.

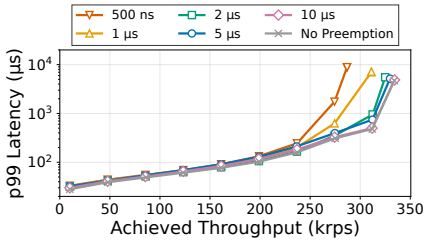

Figure 13: Throughput vs. p99 latency for an XDP echo server under varying preemption budgets. Smaller budgets reduce peak throughput; a budget of 10 μs matches the no-preemption baseline.

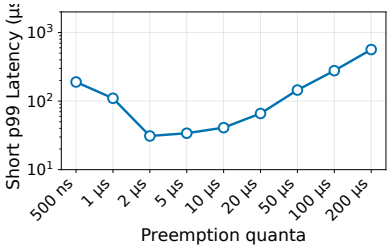

Figure 14: Preemption budget tradeoff for a bimodal workload. Small budgets incur context-switch overhead for the latency-critical short task, while large budgets lead to head-of-line blocking.

170 ns: activating a PeeR-kthread takes 46 ns (amortized across batched wakeups), selecting the next task from the dispatch queue 80 ns, and restoring context 44 ns. A full preemption-resumption cycle thus costs 247 ns, making fine-grained scheduling practical even for microsecond-scale eBPF tasks.

8.3.2 Instrumentation Overhead

The budget check the JIT inserts before each helper call is PeeR's only always-on cost, paid even by a program that never preempts. We measure it with an XDP program that calls `bpf_get_prandom_u32` in a loop, comparing the stock JIT against PeeR's JIT with a budget set so the check executes on every call but never fires. The check adds one cycle per helper call, and two when the scheduler is actively writing the per-CPU budget flag.

8.3.3 Impact of Preemption Budget

While the overhead per preemption-resumption cycle is constant, the overall overhead depends on the preemption frequency, which is controlled by the budget. We evaluate the application-level overhead of PeeR.

Throughput impact. Figure 13 shows how the budget affects throughput for an XDP echo server processing 5 μs requests under uniform load. Smaller budgets check more often, consuming cycles that would process requests: at 500 ns the server saturates at 275 krps, while at 10 μs requests complete without preemption, matching the no-preemption baseline at 330 krps. A 2–5 μs budget sacrifices some throughput for scheduling responsiveness under more complex workloads, which we quantify next.

Latency impact. Figure 14 isolates the budget's effect on tail latency using a bimodal workload: 95% short requests (0.5 μs) and 5% long requests (100 μs) at fixed 20 krps. We sweep budgets from 500 ns to 200 μs and measure p99 latency for short requests. The results show a U-shaped curve. At small budgets (500 ns–1 μs), frequent preemption dominates, inflating latency to 110–190 μs. As the budget increases, overhead drops and latency reaches a minimum of 31 μs at a 2 μs budget. Beyond this, head-of-line blocking takes effect: long requests yield more slowly, thereby delaying short ones. At a 200 μs preemption budget, p99 of the short requests rises to 565 μs.

The U-shape captures a fundamental tradeoff: smaller budgets provide finer scheduling granularity but increase context-switch overhead; larger budgets reduce overhead but allow longer blocking. The optimal budget is workload dependent.

9 Discussion

Existing mechanisms for deferred eBPF execution. Linux provides several mechanisms to defer eBPF work off the fast path, such as eBPF timers [20], workqueues [21], and XDP's `cpumap` redirect [50]. eBPF timers schedule callbacks for later, but they still run in `softirq`, steal time from interrupted applications, and lack hook context or I/O capabilities. Workqueues defer to a sleepable kernel worker, but each callback executes as a single eBPF invocation; the scheduler sees only the worker thread, not individual eBPF tasks. `cpumap` queues packets to a per-CPU kernel thread, but the XDP program still runs to completion per packet and can head-of-line block.

PeeR generalizes this pattern of executing minimal work in an interrupt context, deferring the rest, but with finer-grained control. No existing mechanism combines per-invocation preemption, scheduler visibility, and policy control. None exposes fast-path eBPF execution time to schedulers or supports policy-driven decisions over when and how long each invocation runs. PeeR addresses this gap by treating preemption as a first-class primitive, rather than requiring developers to split programs or accept run-to-completion semantics.

Kernel bypass. Kernel-bypass systems achieve high throughput and low tail latency by removing the kernel from the critical path, but require monopolizing cores and hardware. eBPF offers similar performance while retaining OS-provided isolation, safety, and unified resource management.

Kernel-bypass systems usually assume that scheduling flexibility requires moving to userspace. Systems such as Shinjuku [35] and Shenango [42] implement preemption and core reallocation in userspace because the kernel provides no equivalent. Our work challenges this assumption: eBPF combined with `sched_ext` supports similar policies without sacrificing kernel interposition or dedicating cores to userspace runtimes. Kernel-bypass retains advantages in hardware-specific optimizations, custom allocators, and direct device queue

access, but expanding eBPF capabilities may narrow this gap.

Enabling new eBPF applications. Beyond improving existing workloads, PeeR opens possibilities for applications previously unsuitable for eBPF. File-serving, for example, requires sleepable contexts: programs must yield while waiting for disk I/O rather than blocking the CPU. eBPF's current run-to-completion model cannot express this. PeeR's yield mechanism allows programs to suspend mid-execution during I/O and resume once data is ready, bringing I/O-bound workloads within reach of in-kernel execution.

10 Related Work

PeeR builds on a large body of prior work.

eBPF for extensibility and latency-critical applications. eBPF has been widely adopted for extending kernel functionality safely and efficiently, with applications spanning memory management [55], file systems [5], page caches [60, 61], and networking [6]. Beyond traditional extensibility, eBPF has also been adopted for low-latency, high-performance applications. XDP [31] and BMC [28] leverage eBPF for high-performance packet processing and caching. KFlex [9], DINT [58], and eTran [6] implement full application logic in XDP to bypass the kernel network stack entirely. XRP [56] and Electrode [57] use eBPF for storage and for accelerating distributed systems. However, these systems inherit the non-preemptable execution model of fast-path eBPF hooks, which increases tail latency when operations vary in duration, an issue that DINT and eTran have explicitly noted. PeeR addresses this by enabling cooperative preemption, allowing eBPF programs to handle longer operations without blocking other tasks.

Preemptive scheduling for low latency. A complementary line of work reduces preemption overhead itself to achieve low latency for applications. Shinjuku [35] achieves 5 μs preemption quanta using hardware virtualization, but requires a specialized OS and dedicated dispatcher cores. ZygOS [43] adds work stealing to IX [3]'s run-to-completion dataplane, and Arachne [44] manages user-level threads to rebalance load at microsecond granularity. Shenango [42] achieves similar responsiveness through fast core allocation rather than fine-grained preemption. Compiler-assisted preemption is used more broadly: Wasmtime [4] inserts epoch checks, Go [7] preempts via signals at compiler-identified safe points, and Concord [34], Compiler Interrupts [2], and TinyQuanta [40] approximate preemption with compiler instrumentation that polls a shared cache line or counts instructions. PeeR brings this technique to the eBPF runtime. While Concord is similar in spirit, the eBPF setting imposes different constraints, since yield sites must align with verifier state, hook-object lifetimes, and kernel CFI requirements. User interrupts [29, 38] provide low-overhead userspace preemption but do not extend to kernel code. Recent work also proposes *hybrid* cooperative-preemptive designs that fall back to timer-based preemption when cooperative yields are too sparse [52]. PeeR instead stays purely cooperative: on the eBPF fast path a timer could fire between helper calls, where the verifier leaves no clean state to checkpoint, so PeeR confines yields to helper boundaries and relies on the bounded inter-helper gap (Table 1) to keep them frequent. These systems target userspace applications; PeeR brings similar benefits to unmodified kernel extensions without specialized hardware.

Inter-application performance isolation. Performance isolation is critical in multi-tenant environments. Junction [24] and Caladan [25] isolate application performance through smart resource multiplexing. Static analysis techniques [27] verify safety and performance properties of kernel extensions. These approaches do not address long-running eBPF operations that escape scheduler visibility. PeeR enhances isolation by making eBPF execution time visible to the scheduler and allowing programs to yield, preventing resource monopolization.

User-defined scheduling. Frameworks such as ghOSt [32] and Syrup [36] allow defining custom scheduling policies for threads and network packets in userspace. FlexNet [10] proposes coroutine-based structural extensibility for the network stack, with yield points at protocol-layer boundaries. However, these systems schedule userspace threads and packets, not in-kernel eBPF execution. The `sched_ext` framework [49] enables implementing custom CPU schedulers in eBPF, but it does not schedule eBPF programs themselves. PeeR complements these frameworks by treating existing eBPF programs as schedulable entities that can be preempted and rescheduled without modification.

Extending eBPF to enable new capabilities. Recent work extends eBPF's capabilities. eNetSTL [53] provides STL-like data structures for in-kernel network functions; eGPU [54] executes eBPF on GPUs; and Zussman et al. [59] implement new eBPF hooks to enable custom page-fault handling. These extensions increase both the complexity and execution time of eBPF programs. PeeR complements this trend by providing the scheduling and preemption infrastructure needed as eBPF workloads grow beyond the fast-path assumption. SchedBPF [46] also explores preemptable and schedulable eBPF, with a focus on periodically executed programs and continuous workloads. In contrast, PeeR targets event-driven eBPF hooks in `softirq` context on the critical path. We characterize problems quantitatively in these settings and provide a concrete implementation of preemption and scheduling mechanisms.

11 Conclusion

We presented PeeR, a runtime that makes latency-critical eBPF programs preemptable and schedulable in `softirq` context, where preemption is otherwise disabled, by bringing cooperative preemption to eBPF and integrating with `sched_ext`. Our evaluation shows that PeeR reduces p99 latency by 3× to 19.8× for latency-critical requests in mixed workloads, and enforces resource-sharing policies across colocated eBPF and userspace applications.

Abstract

Improving software efficiency often involves optimizing data locality to reduce memory stalls. However, identifying such optimization opportunities, particularly in complex production software like the Linux kernel, is challenging. Existing profiling tools typically provide metrics such as cache and TLB misses for instructions, loops, functions, or heap allocations, still requiring substantial manual efforts to identify optimization opportunities. To overcome this, we introduce TypeCraft, a lightweight, high-resolution data type profiler, integrated into the Linux `perf` tool, that annotates individual memory access instructions with their associated data types and fields. TypeCraft provides detailed type-centric telemetry such as access counts, CPU cycle costs, cache or TLB misses, which helps identify optimization opportunities around the expensive types. Applying TypeCraft to the Linux kernel, we gain insights that guide us in implementing simple yet effective optimizations. These optimizations, including reordering structure fields and removing pointer chasing patterns, result in significant performance improvements for both benchmarks and real-world workloads.

1 Introduction

Memory access latency has consistently posed a critical performance bottleneck in contemporary data centers. Past research conducted within Google's data centers indicates that a substantial 40-60% of CPU cycles are consumed during data retrieval from memory [37]. This bottleneck has intensified in recent years [57]. To mitigate the lengthy latencies associated with memory accesses, modern CPU processors utilize a cache system for storing frequently accessed data. A common optimization strategy is to improve data locality, which involves staging data into caches and thoroughly accessing it before eviction [24, 31], thereby reducing memory stalls.

The analysis and optimization of data locality have been a subject of extensive research for decades, leading to the development of various profiling tools. Examples include Linux `perf` [67], Intel VTune [21], OProfile [44], SCALENE [9], HPCToolkit [5], Witch [84], and RDX [81], which gather performance metrics from hardware performance monitoring units (PMUs). These tools associate performance metrics, such as cache and TLB misses, with instructions/loops/-functions (aka code-centric view) and data object allocations (aka data-centric view). These tools are able to identify the hotspots in functions and object allocations that are worthy of further investigation. However, they fail to provide a holistic view to connect memory layouts of data types and their access patterns for effective optimization guidance.

We introduce TypeCraft, a new profiler designed to enhance memory inefficiency analysis. TypeCraft annotates performance profiles with data type information, offering a more detailed, higher-dimensional view of performance. TypeCraft aggregates performance costs based on data types and their fields, and then ranks them to prioritize optimization efforts. This capability facilitates two key optimizations on data locality: (1) optimizing memory layouts to minimize the number of cache lines required in hot paths and (2) optimizing access patterns to reduce memory transactions.

TypeCraft is designed to be both lightweight and high-resolution, making it suitable for integration into current data center profilers [2, 6, 33, 70, 71] without adding an online data collection burden. This integration allows TypeCraft to deliver a comprehensive, type-centric profile view of the entire data center. Consequently, this enables effective optimization strategies for common libraries across the data center, moving beyond optimizations tailored only to individual workloads. Furthermore, TypeCraft provides high-resolution analysis by identifying data types for individual memory instructions and concentrating on the type field level. This detailed focus allows TypeCraft to offer specific optimization guidance regarding data type layouts and memory access patterns.

TypeCraft artifact and availability TypeCraft is open source and available as part of Linux `perf` tool [67], which is released together with Linux kernel. Kim [38, 77]

Listing 1: The part of patch for reordering the fields of `rq`.

developed the first version of TypeCraft with integration into Linux `perf` tool. Multiple patch series [39–41, 46, 47] have been upstreamed to enable high accuracy and coverage of TypeCraft for production usage.

1.1 Motivation

The Linux kernel is the de-facto operating system used by most data centers. Prior studies [37] show that the Linux kernel functions account for a significant amount of CPU cycles and cache misses. TypeCraft profiles the Linux kernel v6.17 with the scheduler stressed on a 24-core Intel machine. TypeCraft reports a list of expensive types that account for the majority of CPU cycles and last-level cache (LLC) misses. The structure `rq` is among the top of the list, accounting for more than 1% of kernel CPU cycles to access it in our environment (detailed in Section 7). TypeCraft shows the expensive fields of `rq` and their affinities.

By using this information, we can concentrate on optimizing the layout of `rq` by strategically placing frequently accessed fields (hot fields) with high affinity near each other. For instance, Listing 1 shows a patch that groups the `clock_update_flags` and `clock` fields alongside other clock-related fields because they are often accessed concurrently. The enhanced cacheline utilization resulted in a 5.1% rise in instructions per cycle (IPC) for the microbenchmark stressing `rq`. Section 7.1 elaborates on this optimization.

It is worth noting that existing tools make it challenging to find such opportunities and design optimization strategies because they do not provide performance insights about data types and their fields.

1.2 TypeCraft Overview

Figure 1 overviews TypeCraft. TypeCraft accepts fully optimized binary executables and profiles gathered by Linux `perf` as input. It then uses DWARF debugging information and static binary code analysis to determine types for memory instructions. The final output is the profiles, which are annotated with the resolved types. TypeCraft is specifically engineered to address the following challenges, ensuring its suitability for production use.

- DWARF records are focused on debugging rather than performance analysis, making it challenging to precisely link type information to individual memory access instructions. TypeCraft addresses this challenge in Section 3.
- Aggressive optimizations, such as automatic feedback-directed optimization (AutoFDO) [16], link-time optimization (LTO) [35] and post-link optimizations, e.g., BOLT [64] and Propeller [75], often compromise DWARF quality. This hinders TypeCraft's ability to achieve high accuracy and coverage in type resolution. TypeCraft addresses this challenge in Section 4.
- Introducing a new profiler into a modern data center is complex, requiring careful management of production code and the need to maintain low overhead. TypeCraft addresses this challenge in Section 5.

1.3 Contributions

This paper makes four major contributions as follows:

- We introduce TypeCraft, the first profiler capable of attributing data types and fields to individual memory access instructions.
- We employ novel data-flow analysis to ensure high accuracy and coverage, especially for highly optimized binaries with limited DWARF information.
- We validate TypeCraft using real-world workloads, including the off-the-shelf Linux kernel, and demonstrate its suitability for use in data center environments.
- We utilize TypeCraft to guide several Linux kernel optimizations, resulting in notable performance gains. These patches have been submitted for inclusion upstream.

2 Background

Precise PMU sampling Performance Monitoring Units (PMUs) are an indispensable component in modern CPU processors, which are able to monitor various events (aka, metrics), such as cycles, retired instructions, and cache misses. Existing profilers [5, 21, 67] typically configure PMUs via the kernel driver to sample interesting events to enjoy both lightweight measurement and insightful profiles. Although traditional PMUs are powerful, they suffer from *skid* [17], causing them to fail to accurately attribute metrics to the corresponding program counters (PC). Fortunately, most CPU vendors support precise PMUs in their latest CPU generations. Intel's Precise Event-Based Sampling (PEBS) [82], AMD's Instruction-Based Sampling (IBS) [7], and ARM's Statistical Profiling Extension (SPE) [8, 48] are typical examples. These advanced PMUs deliver precise, unskidded profiles, which allows TypeCraft's insightful per-PC type resolution.

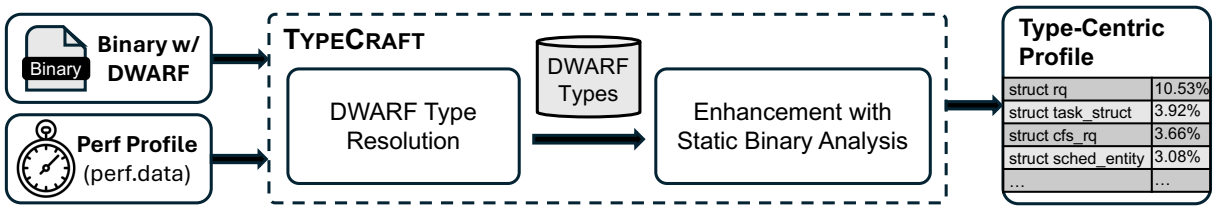

Figure 1: TypeCraft takes as input an unedited, fully optimized binary file that includes DWARF debug data and a profile generated by Linux `perf`. TypeCraft utilizes DWARF and static code analysis to determine the types associated with individual instructions. The final output is a type-annotated profile, which enables metrics to be grouped by specific types and fields.

DWARF debugging information Debugging With Attribute Record Format (DWARF) [19] is the standardized format for embedding debugging metadata within binary files. DWARF provides rich debugging information, such as line mapping from instructions to source code, call frame information, and variable/type names in different lexical scopes. DWARF is widely used in debuggers and profilers to obtain source code insights and determine call paths. It is worth noting that while debuggers (like gdb [78]) can resolve variable names and types—a capability comparable to TypeCraft's—TypeCraft offers three key advantages: (1) TypeCraft maps from program counters to types, while debuggers do not provide such mapping; (2) TypeCraft aims to handle all memory access instructions in the code, unlike debuggers which process a limited subset upon user request; (3) TypeCraft functions on fully optimized binaries, which can have reduced DWARF quality due to various optimizations, whereas debuggers are most effective on unoptimized binaries and require DWARF with high quality.

3 Type Resolution with DWARF

This section shows how TypeCraft leverages the standard DWARF information to resolve the data type for a given memory instruction at a program counter (PC). Although this approach may not achieve high accuracy and coverage, it serves as the foundation of TypeCraft. The enhancement of TypeCraft with static code analysis is described in Section 4.

Figure 2 overviews the workflow of TypeCraft's type resolution based on DWARF. TypeCraft first identifies a series of nested lexical scopes that enclose the input memory instruction. From DWARF, TypeCraft extracts the variables defined and used in these scopes. TypeCraft then decodes the memory instruction for its memory addressing mechanism, which typically includes a base register and a displacement; TypeCraft uses this information to locate the accessed variable at this instruction and resolve its type. Finally, TypeCraft handles conflicts when resolving types in different scopes. TypeCraft uses a heuristic method to produce the deterministic results.

3.1 Identify Lexical Scopes

As shown in Figure 2, DWARF records the lexical scopes and their ranges for a given binary. Such scopes, determined by the PC ranges, include compilation units, subprograms, and (inlined) function frames. For a given PC, TypeCraft is able to identify a series of nested scopes that encloses this PC. TypeCraft limits its analysis to these nested scopes because the input PC can only reference the variables and their types in these scopes. It is worth noting that TypeCraft handles instructions that access global variables by recording global variables from all compilation units.

3.2 Match the Variables and Types

TypeCraft uses the memory addressing formula embedded in the instruction to determine the variable (e.g., local/global variables and function parameters) and type information from all enclosing lexical scopes. The fundamental element for this association is the location descriptions recorded by DWARF. A DWARF location description specifies a variable's data location at a particular PC. This location can be a dedicated register, an offset on the stack, or a complex expression involving memory access, arithmetic, and several registers. We classify the resulting type matches into two categories based on whether the instruction interacts with a value or a pointer.

Interacting with values This scenario arises when an instruction accesses variables by value. The DWARF location description stores the memory address where the variable value is located. For example, a local variable defined as `struct A a` is usually positioned at a specific stack address. This memory address is calculated using the DWARF base-plus-offset operator (e.g., `DW_OP_fbreg` or `DW_OP_bregN` plus an offset). If the instruction's base register aligns with this calculation, and the difference between the instruction's displacement and the DWARF offset is within the size bounds of `struct A`, it signifies that the instruction is directly accessing a field of the variable `a`.

Interacting with pointers This scenario arises when an instruction accesses variables by dereferencing pointers. Specif-

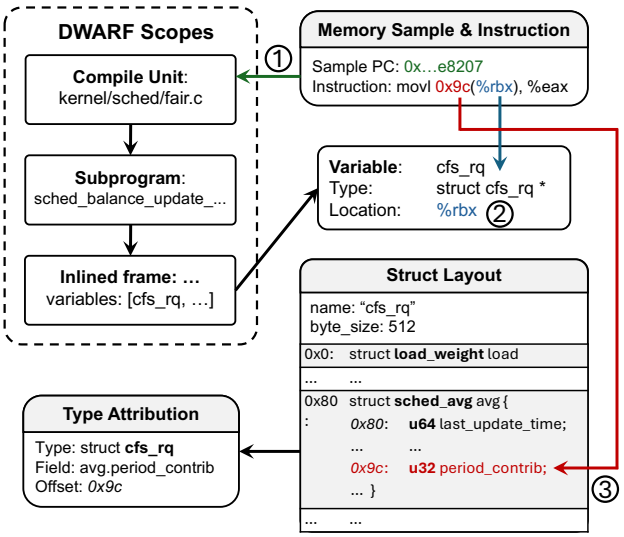

Figure 2: Workflow of type resolution with DWARF. The process involves three steps: ① TYPECRAFT finds candidate scopes by resolving the PC to the nested scope chain. ② TYPECRAFT scans these scopes to link the instruction's base register (`%rbx`) to a variable `cfs_rq` whose location is `%rbx`. ③ TYPECRAFT resolves the offset (`0x9c`) against the struct `cfs_rq` layout to identify the field `avg.period_contrib`.

ically, this happens when the DWARF location description indicates that the variable's value is stored at the location, and the variable itself is a pointer type (e.g., `struct A a*`). If the instruction dereferences `a`'s value, the access is resolved to its pointed-to type, `struct A`. This mechanism primarily appears in two configurations:

- Register location (`DW_OP_regN`): The pointer variable (e.g., `a*`) is stored directly in a register (like `%rbx`). The instruction then performs a memory access operation, such as `mov 0x9c(%rbx), %eax` in Figure 2.
- Base-plus-offset with value tag (`DW_OP_bregN + offset + DW_OP_stack_value`): The variable's value (i.e., the memory address that stores the pointed-to object) is calculated by adding an offset to a register. The presence of the `DW_OP_stack_value` tag explicitly signifies that the result is the variable's value, distinguishing it from an address calculation. This pattern often occurs due to compiler optimizations where a register might point to an internal part of a structure rather than its start.

Handling complex addressing modes Some instructions use more than one register for addressing in x86. In this case, DWARF location descriptions store complex expressions, which make the type matching impossible without a precise symbolic execution engine. To make the system simpler and more robust, we devise a method based on the fact that one register typically acts as the base register while the other acts as an index register. In fully optimized code, DWARF may treat either register as the base register and store it in the location description. Thus, TYPECRAFT attempts to use each register plus the displacement for the type resolution and reports the valid type match.

3.3 Match the Fields inside Types

Once the variable and its fundamental data type are identified, the subsequent step is to precisely locate the specific field being accessed within that type. For composite types (such as structs or classes), fields dictate the internal layout, with their positions defined by either constants or expressions. TYPECRAFT uses the displacement from the instruction to select the member whose offset matches the access point. The output includes the type name, the specific field, and its offset. For primitive types, TYPECRAFT does not further identify fields. If the total size of the data type is available, TYPECRAFT performs a validation check to ensure the access offset remains within the type's memory boundaries. If the size is undetermined (e.g., due to flexible array member [34]), we deduce the field location using other fields whose offsets are known. In cases involving union types, the tool will report the type names and offsets. For bit fields, the tool reports the field that aligns with the byte boundary being accessed.

3.4 Resolve Conflicts

Given the fact that multiple scopes can record the type and field information for a given instruction, we may see conflict analysis results from different scopes. For example, a function passes `a->b` as a parameter to its inlined callee for access. In the caller scope, we are able to resolve the type of `a` and its field `b`, while in the callee scope, we can only obtain the field `b`, as the type information of `a` is not stored in the callee scope. When such a conflict occurs, TYPECRAFT prefers to report the one with richer information. In this example, the type and field resolved from the caller's scope are desired.

It is worth noting that the outer scope does not always produce the desired type and field information. For example, the Linux kernel frequently uses the `container_of` macro to extract the data type for a given field. If this macro is called by a callee, the type information is stored in the callee's scope, rather than the caller's scope. Thus, TYPECRAFT uses the following heuristic method to resolve the conflict and report the deterministic type/field information.

- If TYPECRAFT resolves a composite type in one scope and a primitive type in another scope, TYPECRAFT reports the composite type with a primitive type as its field.
- If TYPECRAFT resolves different types with offsets in different scopes, TYPECRAFT reports the one with the largest offset or within the largest composite type. This typically

happens for nested composite types (i.e., a struct is a field of another struct). This heuristic helps TYPECRAFT report the outermost type with more optimization opportunities.

4 Enhancement with Static Binary Analysis

Relying exclusively on DWARF for type resolution presents two main challenges in maintaining high coverage and accuracy. (1) DWARF cannot handle pointer chasing patterns with a chain of pointer dereferences because of missing variable information. For instance, in the statement `int i = foo->bar->baz`, the DWARF format lacks a record for `bar` to access `baz`. This is because there is no variable corresponding to the intermediate field `bar` explicitly defined in the lexical scopes. This results in the failure of the type resolution for these memory accesses. (2) Another major challenge is that DWARF's accuracy can significantly degrade [45] on heavily optimized code with various optimization passes such as automatic feedback-directed optimization (AutoFDO) [16], link-time optimization (LTO) [35] and post-link optimizations, e.g., BOLT [64] and Propeller [75].

To address these two challenges, TYPECRAFT analyzes the control and data flows of binary code statically to recover missing type information from neighboring instructions. TYPECRAFT combines local analysis on the basic block level and global analysis on the function level. With this effort, TYPECRAFT can significantly improve the coverage and accuracy, which is evaluated in Section 6.

4.1 Abstract Domain

TYPECRAFT structures the static analysis as a *forward data-flow analysis*, a direction chosen to enable the propagation of type data from variable definitions to subsequent memory accesses not covered by DWARF. This simultaneously allows for monitoring any arithmetic modifications to offsets. The execution state at any point in the program is represented by an abstract store σ. This store maps storage locations to abstract values that are sourced from a lattice $\mathcal{L}$, with data types serving as the abstract values used in this analysis.

We partition the domain of storage locations into two categories: *Data Registers (DReg)* and *Stack Frame Locations (SFL)*. While the x86-64 notation is used here, this model is applicable to any ISA. DReg is a subset of general-purpose registers designed to hold a machine word, such as a quadword held by `rax/rdi`. *DReg* excludes stack pointer (`rsp`), instruction pointer (`rip`), and base pointer (`rbp`) when acting as a frame pointer. *SFL* encompasses memory locations situated within the active stack frame. These locations are referenced using offsets relative to the frame base. To ensure coherence between the base and stack pointers, all stack-relative addressing is normalized to offsets originating from the DWARF Canonical Frame Address (CFA) [19]. The mapping for the

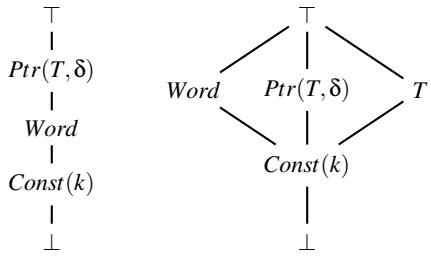

Figure 3: Lattices for DReg (on the left) and SFL (on the right).

abstract store is defined as:

$$\sigma : (DReg \cup SFL) \to \mathcal{L}$$

An update to the store σ is denoted by $\sigma[x \mapsto v]$, which results in a new store identical to σ, except that the location x is mapped to the value v:

$$\sigma[x \mapsto v](y) = v \text{ if } y = x, \text{ else } \sigma(y)$$

The distinction between these domain partitions is based on their unique addressing semantics. Registers within *DReg* typically correspond to a single data object (e.g., a pointer or scalar) over its live range, requiring the tracking of their states for type resolution. In contrast, the registers supporting *SFL* (specifically, `rsp/rbp`) act as base pointers for a memory region containing multiple objects (e.g., local variables and register spills). Consequently, type resolution is achieved by monitoring the state of individual stack locations rather than the `rsp/rbp` registers themselves. Thus, *DReg* and *SFL* possess distinct lattice structures as shown in Figure 3.

***DReg* lattice** The hierarchy of the abstract states for the *DReg* lattice (left in Figure 3) is defined as follows:

- $\bot$ (*Uninitialized*): The location has not been initialized or has become invalid.
- $Const(k)$: The location contains a known integer constant k. This is tracked primarily for resolving pointer offsets.
- *Word*: The location holds a defined machine word (e.g., a 64-bit integer or a memory address on a 64-bit machine), but whether it refers to a memory address is unknown.
- $Ptr(T, \delta)$ (*Pointer to type*): The location is interpreted as a pointer to a composite type T at a byte offset δ from the type's starting point.
- $\top$ (*Conflict*): The location has conflict definitions (e.g., pointers to different types) originating from different paths.

The ordering $Word \sqsubseteq Ptr$ is used to enforce an *optimistic promotion policy* for attributing memory accesses. This policy means that if two control-flow paths suggest that a register

holds a generic *Word* on one path and a specific $Ptr(T)$ on the other, their join results in $Ptr(T)$ instead of *Word*. This is a sound heuristic because TYPECRAFT only resolves types at memory dereference instructions. Consequently, if a path holds a non-pointer value (e.g., a loop counter), it will never execute a dereference and cannot cause a false positive type resolution. This optimistic promotion prevents false positives while significantly decreasing false negatives caused by compiler register reuse and the conservative merging of potentially infeasible control-flow paths.

***SFL* lattice** We use a flatter lattice (right in Figure 3), where *Word*, $Ptr(T,\delta)$, and T are treated as siblings. Note that T appears in this lattice because the object of type T can be directly stored on the stack. Given a stack frame location, we cannot distinguish these states so we treat the join result among them as `Conflict` ($\top$).

4.2 Local Type Analysis

Local type analysis determines the state at the end of each basic block. It tracks the flow of type information including register moves, memory loads, and stack spills at every program counter (PC), beginning from the entry state. DWARF injections are used to source the data-flow analysis and transfer functions are applied for each instruction.

DWARF injection The analysis incorporates DWARF debug data as an external source of information. An injection function, $I_{pc}(\sigma)$, is applied to the current state before processing a given program counter (pc). This DWARF injection serves to restore reliable type information, particularly after instructions like function calls that cause context loss. For example, if DWARF specifies that a variable of a composite type T resides in register r at pc, the state σ is updated to $\sigma[r \mapsto Ptr(T,0)]$. However, injecting DWARF information indiscriminately introduces noise. Therefore, we only apply DWARF injection for variables where the offset δ is 0. The rationale for this constraint is as follows:

- If offset $= 0$, the register points to a variable so we safely set the register to $Ptr(T,0)$, where T is the variable's type.
- If offset $\neq 0$, ambiguity arises as DWARF may provide an inner type but we expect to resolve for an outer one.

Transfer functions for instructions We model the transfer function for each assembly instruction $f_{\text{instr}} : \sigma \to \sigma'$, and Table 1 summarizes these transfer functions in four categories.

- *Data transfer instructions:* The preservation of type information is consistent for values moved between memory and registers. Register-to-register operations replicate the exact state of the source register, and memory loads retrieve the specific field type based on the calculated offset. Stores to the stack are mapped to normalized stack frame locations using DWARF's CFA.
- *Address calculation instructions:* The `lea` instruction is primarily used for pointer arithmetic and creation. When applied to a register base (`lea` $r_d, [r_b + k]$), it modifies the pointer offset δ. If the instruction references the stack, we must determine if the offset falls within the boundary of a known local variable of type T; if so, a pointer is generated to T, adjusted by the relative offset.
- *Arithmetic operations:* Integer arithmetic instructions, such as `add` or `sub`, alter a register's value. When constant arithmetic is applied to a pointer, the offset δ is updated. This principle holds for both immediate values and registers classified as $Const(k)$ in the lattice. However, other arithmetic operations, such as `and`, or non-constant modifications, lead to the invalidation of the destination state. TYPECRAFT adopts a conservative strategy of invalidating the state to prevent the assignment of incorrect types.
- *Function calls:* The call instruction serves as a boundary, invalidating all caller-saved registers by setting them to $\perp$. If DWARF provides the callee's return type, the state of the return register (e.g., `rax` for x86) is updated to this type.

Instruction	**Precondition (σ)**	**Update ($\sigma \to \sigma'$)**
Data transfer instructions		
`mov` r_d, r_s	—	$\sigma' = \sigma[r_d \mapsto \sigma(r_s)]$
`mov` $r_d, [r_b{+}k]$	$\sigma(r_b){=}Ptr(T,\delta)$	Let $f = \text{Field}(T, \delta{+}k)$ $\sigma' = \sigma[r_d \mapsto f]$
`mov` $SFL(x), r_s$	—	$\sigma' = \sigma[SFL(x) \mapsto \sigma(r_s)]$
Address calculation instructions		
`lea` $r_d, [r_b{+}k]$	$\sigma(r_b){=}Ptr(T,\delta)$	$\sigma' = \sigma[r_d \mapsto Ptr(T, \delta{+}k)]$
`lea` $r_d, SFL(x)$	$SFL(x) \in [T_s, T_e]$	$\sigma' = \sigma[r_d \mapsto Ptr(T, x - T_s)]$
Arithmetic operations		
`add/sub` r_d, I	$\sigma(r_d){=}Ptr(T,\delta)$	$\sigma' = \sigma[r_d \mapsto Ptr(T, \delta \pm I)]$
`ARITH` r_d, r_x	$\sigma(r_d){=}Ptr(T,\delta)$	$\sigma' = \sigma[r_d \mapsto \perp]$
Function calls		
`call` *func*	—	$\forall r \in \text{CallerSaved}, \sigma'[r] \leftarrow \perp$ $\sigma'[r_{ret}] \leftarrow \text{RetType}(func)$

Table 1: Transfer functions for different types of instructions. $SFL(x)$ denotes the stack frame location at CFA offset x, k is an integer constant, and I is an immediate or constant register.

Transfer functions for basic blocks The transfer function F_{BB} for a basic block is defined as the composition of instruction transfers and DWARF injections for the instruction sequence $i_1, \ldots, i_n$:

$$F_{BB}(\sigma) = f_{i_n} \circ I_{pc_n} \circ \cdots \circ f_{i_1} \circ I_{pc_1}(\sigma).$$

This composition guarantees that instruction semantics are always interpreted considering the presence of available debug facts. To ensure that the subsequent data-flow analysis

Algorithm 1 The Worklist algorithm used by TYPECRAFT.

```
1:  Input: CFG G = (V, E), DWARF information D
2:  Output: Exit states OUT[b] for all b ∈ V
3:  Initialize: ∀b ∈ V, OUT[b] ← ⊥
4:  I_pc ← BuildFromDWARF(D)  ▷ Build DWARF inject function
5:  Worklist ← {b | Pred(b) = ∅}  ▷ Initialize with entry
6:  while Worklist ≠ ∅ do
7:      b ← Worklist.pop()
8:      σ_in ← ⊔_{p∈Pred(b)} OUT[p]  ▷ Join predecessors
9:      σ_out ← F_BB(σ_in)  ▷ Apply local analysis
10:     if σ_out ≠ OUT[b] then
11:         OUT[b] ← σ_out
12:         Worklist.push(Succ(b))
13:     end if
14: end while
```

terminates, these transfer functions must be monotone with respect to the lattice order $\sqsubseteq$; specifically, if $\sigma_A \sqsubseteq \sigma_B$, then $f(\sigma_A) \sqsubseteq f(\sigma_B)$. Our transfer functions satisfy this monotonicity property for two key operation types:

- *Overwrites* are monotone because the final destination state is set to a fixed abstract value regardless of the source state.
- *Updates* also preserve the lattice order. For example, applying a constant addition to $\bot$ results in $\bot$, and applying a constant addition to $Ptr(T,\delta)$ results in $Ptr(T,\delta')$. Crucially, no operation based on the incoming state can refine a less specific state (like $\top$) into a more specific one (like $Ptr(T,\delta)$).

4.3 Global Type Analysis

To approximate the meet-over-all-paths (MOP) solution [36], a standard worklist algorithm is used, which ensures the analysis spans all basic blocks in a procedure, incorporating control flow merges (joins) and loops during global propagation. Iteration continues until a fixpoint is achieved for the abstract state at the beginning of every block.

Algorithm 1 describes the worklist algorithm for global analysis. We define $OUT[b]$ as the abstract store upon exiting basic block b. The process begins by setting all states to $\bot$ and taking the DWARF injection. It then initializes a worklist with all entry blocks, which addresses disjoint control flow graph (CFG) components often found in optimized binaries. For each block, the entry state is calculated by joining the exit states of all its predecessors (Line 8). Subsequently, the basic block transfer function F_{BB}, derived in Section 4.2, is applied (Line 9). If the resulting output state changes, the successors of the block are then added to the worklist to process in the next iteration.

Join operator ($\sqcup$) The analysis centers on the join operator, which is utilized to reconcile potentially contradictory states inherited from predecessor nodes. The join mechanism, $\sigma_{out} = \sigma_A \sqcup \sigma_B$, applies the lattice hierarchy on a pointwise basis for every location, x. The join operation on two comparable states in the lattice (i.e., when $s_1 \sqsubseteq s_2$) defined in Section 4.1 yields the greater element with respect to $\sqsubseteq$. This behavior is key for several functions: managing initialization by overwriting $\bot$, processing *Word* over *Const* types, and implementing optimistic promotion for registers, which upgrades a generic *Word* to a specific *Ptr* type. We handle the following disagreement raised at the join point.

- *Constant disagreement:* When a location contains different constant values (for instance, $Const(0)$ versus $Const(8)$), the outcome is generalized to the overall *Word* type.
- *Pointer disagreement:* When a location is associated with pointers to different types (such as $Ptr(A,\delta_A)$ versus $Ptr(B,\delta_B)$), the conflict is resolved by checking the relationship between the two types (to be described later). If one type is structurally contained within the other, the state is unified to the composite pointer that encloses it.
- *Other disagreement:* Any other kind of disagreement yields $\top$. For example, merging two pointers, $Ptr(T,\delta_1)$ and $Ptr(T,\delta_2)$, with different offsets results in $\top$, which guarantees that loops involving pointer arithmetic will eventually terminate.

Check relationship between types A problem arises during the merging of two pointer states that refer to the identical memory region but have conflicting type definitions. Consider the scenario where two execution paths converge at block B: Path 1: Register R contains $Ptr(A,0)$; Path 2: Register R contains $Ptr(B,-k)$. A simple approach would result in a Conflict ($\top$) because $A \neq B$. This specific pattern, however, frequently occurs when one path handles a composite type pointer and the other provides a pointer to a distinct member of that type, accompanied by certain offsets. To resolve this, we recursively examine the structure of the larger candidate type to confirm whether the smaller type is a member at offset k. If `struct B` is confirmed to be the type of a member of `struct A` at offset k, the paths are unified as pointing to the same type: $Ptr(A,0) \sqcup Ptr(B,-k) = Ptr(A,0)$. The enclosing type is prioritized because data layout optimizations (such as field reordering) are most effectively applied to the outermost composite type (`struct A`).

4.4 Discussions

Algorithm termination Termination of the analysis is guaranteed because the lattice has finite height, and both the transfer function F_{BB} and the join operator $\sqcup$ are monotonic. Consequently, the state of any location progresses strictly upward from $\bot$ to $Word/Ptr$ until it reaches $\top$, thereby assuring that the worklist algorithm converges to a maximal fixed point that approximates the MOP solution.

Algorithm soundness The analysis utilizes a conservative methodology to ensure the soundness of the algorithm. This approach dictates that if any ambiguity or lack of certainty is encountered during a join operation, the resulting value is explicitly marked as `Conflict`.

5 System Implementation

TypeCraft is implemented as an extension to the Linux `perf` ecosystem [67]. TypeCraft is able to annotate any profile generated by `perf` by sampling precise PMUs. Like `perf`, TypeCraft requires no instrumentation to the target workloads. The type resolution component of TypeCraft is entirely offline, which does not incur any online profiling overhead. TypeCraft has been successfully deployed in a commodity data center and produced unique insights. This section shows the engineering challenges when TypeCraft handles complex production codebases, especially the Linux kernel. We then discuss some limitations of TypeCraft.

5.1 Engineering Challenges

TypeCraft is designed to address various challenges inherent in real-world workloads, specifically those arising from language features and compiler optimizations.

Fragmented data types Scalar Replacement of Aggregates (SROA) [54] is a standard compiler optimization that transforms a composite variable into its constituent, independent scalar fields. This technique improves performance but complicates debugging, as the original composite variable is no longer located at one continuous memory address. TypeCraft addresses this by reconstructing the variable's value from its fragmented locations, which are identified using the `DW_OP_piece` DWARF tag.

KASLR and relocation Kernel Address Space Layout Randomization (KASLR) [26] improves security by randomizing the location of the kernel image at boot time. To overcome the challenges this poses, TypeCraft employs a two-pronged strategy: it leverages the kernel's `kallsyms` and utilizes `perf` to match build-IDs. By combining these methods, TypeCraft successfully computes the difference between runtime and static addresses, allowing it to accurately link program counters sampled at runtime back to their original static DWARF offsets, thus ensuring that address randomization does not interfere with our type resolution.

Per-CPU and segment addressing The Linux kernel frequently uses per-CPU variables accessed via segment registers, such as `mov %gs:0x10, %rax`. TypeCraft resolves the type for this kind of instructions with a segment-aware analysis pass that successfully handles these accesses. The overall process includes: identifying segment-relative addressing patterns; separating structural data, such as fixed-offset stack canaries, from actual data accesses; mapping the offset to the `__per_cpu_offset` array or `this_cpu_off` symbols; and promoting the destination register to a specialized per-CPU pointer type. This approach ensures subsequent accesses are correctly attributed to the specific per-CPU instance of a structure.

Type aliases In production code, typedef is commonly used to create type aliases, which enhances readability. These newly defined types, identified by the DWARF `DW_TAG_typedef` tag, function as symbolic links to specific concrete types but lack their own type layout definitions. To resolve this, TypeCraft is designed to traverse the chain of typedef-defined types until it locates a concrete type, whose information is then used for type resolution.

5.2 System Limitations

First, while TypeCraft generally works for any binary with DWARF, TypeCraft yields the best type resolution for C programs. TypeCraft has a relatively low coverage for Go and C++ programs because of additional language features such as structure embedding in Go and class inheritance in C++. TypeCraft needs to handle extra DWARF information to support these features, which will be our future work. Second, TypeCraft currently works for the x86 ISA. It is straightforward to extend TypeCraft to other architectures, such as ARM, by integrating the necessary ISA decoders. Third, TypeCraft cannot resolve the types that are not recorded in any DWARF scope. This occurs when special pointer encoding [32] and obfuscation [20] are in use. Fortunately, this case is uncommon in practice.

6 Evaluation

We evaluate TypeCraft for the type resolution coverage and overhead. All the experiments are run on a workstation with a 24-core, 48-thread Intel w7-2495X processor with 2.5 GHz frequency, 48KB L1 data cache, 2MB L2 cache, 45MB shared L3 cache, and 128 GB DDR5 memory. We evaluate off-the-shelf Linux 6.17 [80], memcached 1.6.39 [60], Redis 8.4 [69], Git 2.51.1 [29], FFmpeg 8.0 [27], and system software such as Binutils 2.45 [28]. All these workloads are built with `GCC 13.3 -O3 -gdwarf-5`. Moreover, we evaluate CachyOS kernel 6.17 [1], a highly optimized Linux kernel with ThinLTO [35] enabled.

Coverage We evaluate TypeCraft's coverage in two modes. (1) We analyze the entire binary executable and try to resolve types for every memory access instruction. The coverage is computed as the percentage of memory instructions

Workloads	# Instructions	DWARF only		Local analysis		Local+Global analysis		
		Coverage	Time	Coverage	Time	Coverage	Time	Cycle Coverage
Linux 6.17 Ubuntu [80]	4.6M	75.2%	2248s	77.6%	2299s	92.7%	2900s	92.8%
Linux 6.17 CachyOS [1]	4.4M	66.2%	6030s	67.9%	6101s	86.2%	6729s	90.2%

[1] For the H.264 decoding workload, 96% of the uncovered memory cycles are attributed to functions with hand-written SIMD assembly codes that operate on raw character buffers. The type information is not available in the DWARF debugging information for such codes. However, TYPECRAFT still recovers the dominant decoder structures to guide optimization as decribed in Section 7.4.

Table 2: Coverage and overhead of TYPECRAFT.

with type annotations relative to the total number of memory instructions. (2) We resolve types for memory instructions that have profiling metrics and compute the coverage for these important instructions. We use standard workloads for profiling and measure CPU cycles via Intel PEBS PMUs. Table 2 shows the results, which indicate that TYPECRAFT can yield high coverage, especially for instructions with profiling metrics. While TYPECRAFT yields more than 90% coverage for the Linux kernel, TYPECRAFT achieves 70-80% coverage for userspace workloads. The reduced coverage is caused by userspace workloads utilizing a higher number of unnamed literals and constants. These are stored in the `.rodata` section without DWARF information.

TYPECRAFT offers reliable type profiles as its coverage typically exceeds 80%. For example, TYPECRAFT covers memory instructions with 92% CPU cycles in the Ubuntu Linux kernel. The highly optimized CachyOS also shows 90% coverage. Note that compared to Ubuntu, the DWARF quality of CachyOS is noticeably reduced (66% vs. 75% coverage with DWARF only), but the cycle coverage is comparable thanks to TYPECRAFT's data-flow analysis. We observe a similar coverage in the production kernel fully optimized with AutoFDO [16], ThinLTO [35], and Propeller [75].

Overhead As a unique advantage, TYPECRAFT does not incur any online overhead because the type resolution occurs offline. We measure TYPECRAFT's overhead when resolving types for all memory instructions, which serves as the overhead upper bound. Table 2 shows that TYPECRAFT has a reasonable processing time across workloads. Note that TYPECRAFT's overhead can be amortized by reusing the type resolution for different profiles of the same binary executable.

7 Case Studies

This section demonstrates the efficacy of TYPECRAFT. By employing TYPECRAFT, we successfully pinpointed costly types within the Linux kernel 6.17 and developed practical solutions to address them. Our analysis and subsequent optimizations were derived from performance profiles gathered in a production data center environment. While the specific data center profiles cannot be shared due to confidentiality, we have replicated the observed data center behaviors using carefully configured microbenchmarks and open-source workloads. Crucially, internal measurements performed in Google's data center confirmed substantial performance improvements resulting from these optimizations. The optimization patches are currently awaiting upstream review. Besides the Linux kernel optimization, we also show several case studies on the userspace workloads at the end of this section.

Environment setup We use the same system as described in Section 6 for the case study. To stress on the Linux kernel, we run MySQL Server 8.0.44 [3], a popular, open-source relational database management system. We enable up to 256 servers in a 4-width and 5-depth cgroup hierarchy. We place the 75% MySQL servers in throttled cgroups that utilize 50% machine resources at most, which simulates the batch jobs in data centers. We place the remaining 25% MySQL servers in unlimited cgroups with no resource constrains, which simulates latency sensitive jobs in data centers. We run the Sysbench OLTP read-only benchmark [42] in the unlimited cgroup creating the requests to all the MySQL servers. We run four threads per server. The database size is set to two tables with 10k rows each for each server. We run the experiment for 30 seconds for 10 times to report the average

Data Type	Cycles %	LLC misses %
cfs_rq	7.58%	49.02%
sched_entity	4.73%	6.05%
rq	1.05%	0.35%
cfs_rq *	0.21%	0.86%
sched_entity *	0.16%	2.41%

Table 3: Hot type reported by TYPECRAFT in Linux kernel. The percentages of these metrics are relative to the total metrics consumed in the kernel.

and standard deviation.

Profiles and insights We collect the metrics—CPU cycles, retired instruction counts, and last-level cache (LLC) misses—via TYPECRAFT. The top expensive types in the Linux kernel are structures `rq`, `cfs_rq`, and `sched_entity`. Table 3 shows the percentage of these metrics caused by accessing these types over the total metrics consumed in the kernel. All these types are from the kernel scheduling subsystem, which aligns with the prior study [37] that shows the scheduling subsystem is a major bottleneck in modern data centers.

Optimizations and validation We devise two optimizations (Sections 7.1 and 7.2) for these expensive data types guided by TYPECRAFT. We use microbenchmarks to validate the effectiveness of these optimizations and also quantify the throughput improvement across all MySQL servers (Section 7.3).

7.1 Reordering Fields for Expensive Types

Field reordering [22] is a well-known optimization technique to improve cacheline utilization, which rearranges the fields of a given data type according to the following rules.

- Group the hot fields together. Hot fields are defined as the fields that are frequently accessed.
- Group the fields of high affinity together. Fields of high affinity mean they are frequently accessed together.
- Separate the read- and write-intensive fields as placing them together may result in false sharing.

Insights from TYPECRAFT The fields of data type T are ranked by TYPECRAFT using retired instruction counts to determine their hotness. Specifically, one can choose the top several hot fields within `T` that have the highest instruction counts to access them. For each hot field, TYPECRAFT provides all the monitored PCs that access it. For each PC, TYPECRAFT analyzes all the adjacent memory instructions in the same function to obtain other fields of type `T` accessed. TYPECRAFT treats these fields as of high affinity and weighted by

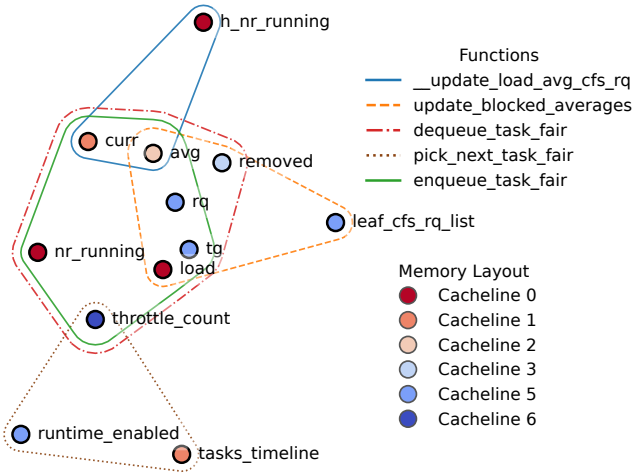

Figure 4: Field affinity of `cfs_rq` reported by TYPECRAFT. This graph only shows the hot fields in `cfs_rq`.

their hotness. By analyzing these instructions, TYPECRAFT is able to determine whether the access is a load or a store. Thus, TYPECRAFT can provide all the information necessary to guide the field reordering optimization.

TYPECRAFT outputs a hypergraph that visualizes the affinity of hot fields for a given data type. Figure 4 shows an example for `cfs_rq`. Each point denotes a field with its name and the color reflects the cacheline number it resides relative to the start of the struct. Each line scope defines a function, meaning the fields are accessed together in this function. From the figure, we observe that field affinity varies in different functions. For example, in the blue line scope, `h_nr_running` affinities with `curr` and `avg` but not in the brown and orange line scopes. Since we optimize a type layout for the whole software rather than individual functions, we define fields of high affinity if they are accessed together in contexts with high instruction counts. For `cfs_rq`, we place the `curr`, `throttle_count`, `rq`, `tg` fields to the same cacheline to improve data locality in hot paths. Although fields such as `leaf_cfs_rq_list` and `tasks_timeline` are also frequently accessed, they are only used in one function. Thus, we place them in a different cacheline from other hot fields.

Performance impact With the guidance of TYPECRAFT, we optimize all `rq` (as shown in Section 1.1), `cfs_rq`, and `sched_entity`. For `rq`, a microbenchmark was utilized. This benchmark generates 960 tasks that execute a loop, sleeping for 1ms per iteration. This resulted in a 5.1% reduction in kernel cycles. To evaluate `cfs_rq`, we configure schbench [4], a kernel scheduling benchmark designed to stress the hot paths associated with these types. Our configuration creates 1024 cgroups and 1024 tasks, showing a 26.4% reduction in kernel LLC misses.

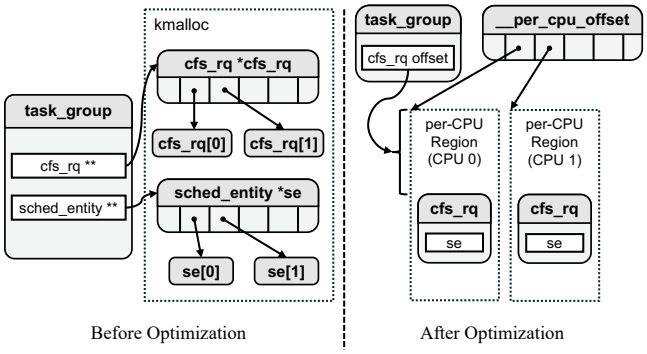

Figure 5: Memory layout before vs. after pointer chasing optimization, which matches the access patterns to avoid expensive pointer chasing.

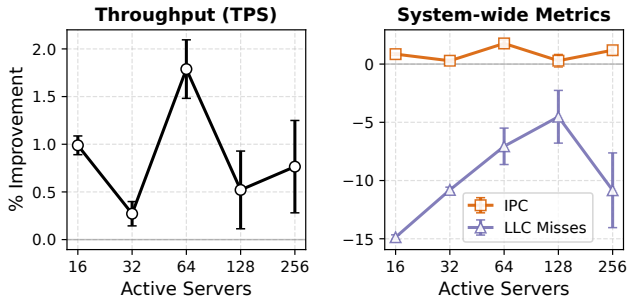

Figure 6: TPS and PMU metric improvement for MySQL. Error bar shows the standard deviation across 10 runs.

7.2 Avoiding Pointer Chasing

Pointer chasing [18] is a well-known access pattern in which a memory load depends on the result of its prior memory load. Due to such dependency, the two loads cannot overlap in the pipeline, resulting in long exposed memory latency.

Insights from TypeCraft TypeCraft pinpoints 0.4% of kernel CPU cycles and 3.3% of kernel LLC misses for accessing `sched_entity*` and `cfs_rq*` pointers themselves, resulting in even more costs to access the objects via these pointers. This suggests that expensive pointer chasing is occurring. Furthermore, the tool provides the associated program counters that are mapped to the source code with a typical access pattern: `cfs_rq->tg->se[cpu]`. There are multiple pointer indirections from `cfs_rq` to access a `sched_entity` object `se[cpu]`, confirming the pointer chasing pattern.

To eliminate pointer chasing, we employ two optimizations: (1) embedding `sched_entity` objects into `cfs_rq` and (2) changing the allocations for `cfs_rq` objects. Figure 5 highlights the memory layout changes with our optimizations. With the new memory layout, accessing `sched_entity` from `cfs_rq` does not incur pointer chasing.

Embedding `sched_entity` As shown in Figure 5, all `sched_entity` objects are allocated randomly in the memory and managed by an array of pointers (i.e., `sched_entity **`) owned in `task_group`. We observe that both `cfs_rq` and `sched_entity` objects are allocated per core and have the same life ranges. Thus, we are able to embed `sched_entity` object as a field in `cfs_rq` with a constant offset. With this optimization, the original pointer chasing pattern can be optimized to avoid pointer indirections, i.e., `cfs_rq + offset`.

Per-CPU allocation for `cfs_rq` objects Similarly, each `task_group` object (i.e., `tg`) stores `cfs_rq` pointers in an array. Hot functions such as `tg_throttle_down` and `tg_unthrottle_up` traverse the list of task groups and repeatedly access a `cfs_rq` object for a given `cpu`. Our optimization is to use the per-CPU allocator for `cfs_rq` objects rather than maintaining them in an array of pointers. When accessing the `cfs_rq` object for a given `cpu`, we use an efficient per-CPU addressing via `__per_cpu_offset`. This optimization enjoys a more efficient addressing strategy and avoids the costly pointer chasing on `struct cfs_rq *`.

Performance impact We reuse the `cfs_rq` microbenchmark described in Section 7.1. Eliminating pointer chasing generally reduces cache misses and saves CPU cycles. However, our optimization on embedding `sched_entity` shows a significant performance regression in microbenchmarks—the LLC misses are increased by more than 50% when accessing `cfs_rq`. The reason is that the optimized `cfs_rq` type is enlarged by embedding a `sched_entity` object. This makes the kernel slab allocator align all `cfs_rq` objects to the 1024-byte boundary. When we traverse different `cfs_rq` objects, we can have power-of-two strided accesses that incur conflict cache misses. Fortunately, our follow-up optimization of per-CPU allocator for `cfs_rq` objects can avoid cache conflicts because the per-CPU allocator does not force a power-of-two overalign for `cfs_rq` objects. The combination of these two optimizations further reduces kernel LLC misses by 33% on our microbenchmark on top of the reordering optimizations. Intel kernel test robot also confirms this improvement, showing 8.8% improvement on the `stress-ng.session.ops_per_sec` benchmark.

7.3 Performance Impact on MySQL

Figure 6 demonstrates the effects of our kernel optimizations on MySQL's throughput (TPS) and microarchitectural metrics. A consistent reduction in LLC misses is observed across all setups, with the most significant reduction, 14.9%, occurring when 16 servers are active. This enhanced data locality directly boosts execution efficiency. Consequently, throughput improves at every concurrency level, reaching a peak TPS increase of 1.8% (along with a 1.8% rise in IPC) when running

on 64 active servers. As the number of active servers increases, so does the scheduling contention, resulting in greater variability in these performance indicators. We also see a throughput improvement of the same magnitude for the Google data center with our optimizations. Note that even a 1% improvement for a data center means saving millions of dollars.

7.4 Analysis of Other Workloads

In addition to the Linux kernel, we evaluate TypeCraft on several prevalent and highly optimized user-space applications. Through profiling FFmpeg, Git, and Binutils using realistic workloads, TypeCraft discovers various prospects for improving data layout. Note that though we obtain nontrivial improvement in memory subsystems on the function level, we do not see obvious end-to-end improvement for FFmpeg and Git. The potential reason is that isolated benchmark runs face much less cache and memory pressure than the datacenter, where contention for the shared L3 cache and memory bandwidth could amplify the benefit of our data layout optimization.

FFmpeg During H.264 decoding in FFmpeg, TypeCraft identifies `H264SliceContext` as a significant consumer of CPU cycles (3.4%). This 35KB structure contains a 2KB set of frequently accessed fields (per-macroblock inner loop) that are separated by `pwt`, a 20KB sub-struct written only once per-slice outer loop and rarely read in the inner loop. By moving the cold fields, such as `pwt` to the end of the structure, we cluster the hot fields into a contiguous memory region. This reorganization prevents hot fields from spanning disjoint cachelines and multiple memory pages, leading to a 4.8% reduction in L1-dcache misses and a 2.5% decrease in dTLB misses.

Git For the `git log --stat` workload, TypeCraft highlights the 112B `xdlclassifier_t` structure. Despite its compact size, its hot fields are split across two cachelines. By consolidating these hot fields into the first cacheline and shifting cold fields to the second, we minimize unnecessary cacheline fetches. This change reduces L1-dcache misses by 24% in the hot `xdl_prepare_env` function and 4% for the overall Git stat execution.

Binutils (nm) When running `nm` on a Linux kernel binary, TypeCraft finds that the 48-byte `asymbol` structure accounts for nearly 10% of cycles. Although it fits in one cacheline, `asymbol` objects are fragmented in memory. This causes pointer-chasing patterns in functions like `qsort` and binary search, resulting in significant cache misses. To address this, we implement structure splitting for `asymbol`. We introduce a dense `slots[]` array containing only the critical sorting keys—`name`, `section`, and `value`—extracted from the original structure. This allows sorting and searching routines to leverage better spatial locality by processing contiguous, packed data. This optimization yields a 32.1% reduction in L1-dcache misses and a 55.4% drop in dTLB misses, ultimately improving end-to-end execution time by 2.7%.

8 Related Work

There are substantial efforts [49, 61, 62, 76, 87, 90, 91] in the security domain to reverse engineer the binary code for types. Typically, these approaches assume DWARF is not available, which is different from TypeCraft. This section only reviews the performance analysis tools that target CPU memory subsystems. We categorize existing approaches into code-centric, data-centric, and type-centric profilers.

8.1 Code-Centric Profilers

Code-centric profilers associate performance metrics with code regions, such as instructions, loops, and functions. Tools such as Linux `perf` [67], HPCToolkit [5], VTune [21], OProfile [44], SCALENE [9], CodeAnalyst [25], and a variety of data center profilers [2, 6, 30, 33, 70, 71] collect PMU events or OS timers with low overhead. Many of these tools are used in production and provide insights on the code level. These tools can identify the hot code that worth optimization but provide limited guidance on optimization.

Some advanced tools provide additional metrics beyond PMU events. CPROF [43], MemSpy [58], SLO [10], DrCCTProf [92], and MACPO [68] collect memory reuse distance [23, 59] to guide the optimization of capacity cache misses. HOTL [86] calculates the memory footprint to complement the reuse distance. RVN [85], DeadSpy [14], RedSpy [83], ZeroSpy [88], and LoadSpy [79] identify redundant memory transactions with value profiling [13]. CacheGrind [74] simulates cache behaviors and identifies cacheline fragmentation [22]. SHERIFF [50] analyzes multithreaded programs to identify false sharing. These tools pinpoint a series of instructions that are involved in the memory inefficiencies and give insightful guidance to optimize the code. These tools instrument memory accesses with compilers or binary engines such as Pin [56], DynamoRIO [11], and Valgrind [73]. Thus, they typically incur high overhead, which are not used in production environment.

Furthermore, some lightweight tools aim to collect these advanced metrics. ThreadSpotter [55, 65], Witch [84], Feather [15], Cheetah [51], and RDX [81] use PMUs, debug registers, or OS page protection to pinpoint redundant memory transactions, identify false sharing, and compute reuse distances. None of these code-centric profilers provides the type information. Actually, TypeCraft can complement these profilers by annotating their assembly profiles.

8.2 Data-Centric Profilers

The data-centric profilers associate metrics with global/static data symbols or heap data allocations. Cache Scope [12], HPCToolkit [52], MemPerf [93], and Oracle Developer Studio [63] are the typical profilers in this category. Advanced analyses based on these tools, such as LWPTool [89], ArrayTool [53], and StructSlim [72], guide array regrouping and structure splitting to reduce cache misses.

The optimization guidance shared between data-centric profilers and TypeCraft centers on memory layout optimization. However, TypeCraft distinguishes itself from data-centric profilers in three key areas. First, TypeCraft offers a global perspective on data types to inform memory layout optimization; while data types can be allocated across various contexts, TypeCraft can aggregate them, whereas data-centric profilers demand significant manual analysis of allocation call sites to determine types. Second, TypeCraft directly examines memory access instructions, eliminating the need to intercept memory allocators as is required by data-centric profilers. Third, TypeCraft provides detailed information at the type field level, in contrast to existing data-centric profilers, which provide information only for the entire allocated data object.

8.3 Type-Centric Profilers

Perhaps DProf [66] is the most relevant work to TypeCraft. DProf leverages PMUs to identify memory inefficiencies in the Linux kernel. DProf offers limited type resolution for dynamically allocated objects. DProf relies on (1) a modified allocator to record the type of each allocation and (2) per-type memory pools that record the types for the allocations from these pools. Moreover, DProf requires manual efforts to resolve some types. TypeCraft differs in three aspects.

- TypeCraft uses DWARF to resolve data types without depending on any customized allocators or manual efforts.
- TypeCraft offers fine-grained type resolutions on the fields, so it can guide the field-level optimization.
- TypeCraft works on an off-the-shelf Linux kernel, while DProf requires a customized kernel and necessary modules.

9 Conclusions and Future Work

This paper introduces TypeCraft, a lightweight, high-resolution data type profiler. TypeCraft utilizes the standard DWARF information embedded in the binary executable to determine the type and field details for memory instructions. To boost the coverage of type resolution in highly optimized binaries, TypeCraft employs a novel data-flow analysis to disseminate type information to memory instructions missing DWARF records due to various optimizations. Our assessment of the latest off-the-shelf Linux kernel indicates that TypeCraft successfully resolves types for over 90% of memory instructions. Moreover, we have employed TypeCraft to direct several optimizations within the Linux kernel, resulting in considerable performance gains in benchmarks and the production data center at Google. All resulting optimization patches are currently awaiting upstream inclusion. TypeCraft will be released with the Linux `perf` tool for public access.

Our future development strategy focuses on three key areas. First, we plan to enhance support for languages beyond C, specifically targeting C++, Go, and Rust by addressing the DWARF extensions necessary for their unique language features. Second, we aim to enable support for the ARM architecture, which is becoming prevalent in modern data centers. Third, we will work on improving DWARF generation for mainstream compilers to further increase the coverage and effectiveness of TypeCraft.

Acknowledgement

We are grateful for Namhyung Kim's contributions to this project. In addition to reviewing all patch series for the upstreaming of TypeCraft into the Linux `perf` tool, Namhyung Kim was responsible for developing the initial version of TypeCraft built upon Linux `perf`. We also thank our shepherd and all reviewers for their valuable comments. This work is partially supported by the National Science Foundation (NSF) under Grants No. CISE-2316201.

All Along the Watchtower: Achieving the Trinity of Observability in Cloud with DiTing

Zhenyu Ren[1], Shuzhi Feng[1], Erci Xu[2]*, Changsheng Niu[1], Haoyu Mao[1], Beibei Wang[1], Chong Gao[1], Zhenshan Zhang[1], Xinrui Yu[1], Jiangwei Huang[1], Jiesheng Wu[1], Hong Tang[1]

Abstract

Observability is crucial for diagnosing and troubleshooting cloud systems as they grow in scale and complexity. However, telemetry data are often stored and processed in siloed systems, leading to high latency, redundant data movement, and low operational efficiency. To address these challenges, we present DiTing, an observability framework that unifies the storage and processing of heterogeneous telemetry data, including logs, metrics, and traces. The key idea of DiTing is to harvest underutilized cloud resources for cost-effective processing while relying on centralized storage systems for reliable data persistence and failover. We have deployed DiTing in production at scale, and DiTing can achieve sub-second data ingestion, high-throughput query processing, and up to 65× lower CapEx than existing solutions.

1 Introduction

Modern cloud computing has been advancing in scale (e.g., globally distributed data centers) [7, 11, 2], heterogeneity (e.g., diverse workloads and new hardware) [19, 37, 31], and disaggregation (i.e., compute-to-storage architectures) [45, 29]. As cloud systems evolve, software bugs [30, 42], performance issues [44, 28], and hardware failures [24, 23, 21] have become more prevalent and harder to diagnose.

Observability via telemetry is crucial for diagnosing and troubleshooting cloud systems. Typical telemetry data include traces [38], logs [20], and metrics [33]. Specifically, traces provide detailed information about execution, logs record events that occur during execution, and metrics summarize quantitative measurements of system behavior.

These three types of telemetry are complementary and often used together for diagnosis. For example, consider a site reliability engineer (SRE) investigating a performance issue such as slow I/Os in a cloud virtual disk. The SRE may first be alerted by abnormal metrics. The SRE then examines end-to-end traces (e.g., from the user's VM to the physical disks) to narrow down the problematic component. Finally, after locating a likely culprit (e.g., a misbehaving switch), the SRE can cross-check device logs to determine the root cause and apply a fix.

*Corresponding author: Erci Xu <jostep90@gmail.com>.

The example highlights the need for multiple perspectives on observability, yet it also reveals a bleak reality. In today's cloud environments, SREs often have to use multiple systems with different query languages and manually correlate data sources with custom scripts for a single investigation. This friction stems from the fact that telemetry datasets are typically stored and processed in separate infrastructures, such as Dapper [38] for traces, LogStore [20] for logs, and Prometheus [33] for metrics. Such siloing not only creates operational barriers for SREs but can also degrade performance due to high latency and excessive data transfer.

It is therefore tempting to host and process different types of telemetry data in a single system. Such a *trinity* of logs, traces, and metrics would eliminate much of the manual effort and allow users to query telemetry with a holistic view of an incident. Inspired by this vision, we explored several paths toward unified observability.

We first unified query processing while leaving data in their original storage systems, for example by adopting a data-lake approach (e.g., Iceberg [5] and Delta Lake [17]). While this provides a unified interface without moving the data, it falls short in performance because the different types of telemetry remain scattered, incurring substantial data-transfer overhead. Second, hyperscalers (e.g., Kraken [26], Monarch [15], and Scuba [14]) have built in-memory NewSQL databases to enable fast queries. Although these systems deliver strong performance by keeping processing in memory, they are impractical for us: the total cost of ownership (TCO) is prohibitively high given the volume of logs and traces that would need to be processed and stored in memory. Finally, we attempted to build our observability framework on an open-source OLAP system, ClickHouse, and managed to deploy it on around 600 physical nodes. However, when scaling to serve the entire cloud, CPU and memory quickly became bottlenecks. Simply provisioning more CPU and memory would increase infrastructure CapEx by more than 20%.

Our initial explorations, though unsuccessful, led to several observations. First, when building a centralized system to unify observability, the main bottleneck is not storage capacity but limited CPU and memory for processing. Second, as a cloud vendor, our server fleet is often underutilized, leaving substantial resources available for harvesting.

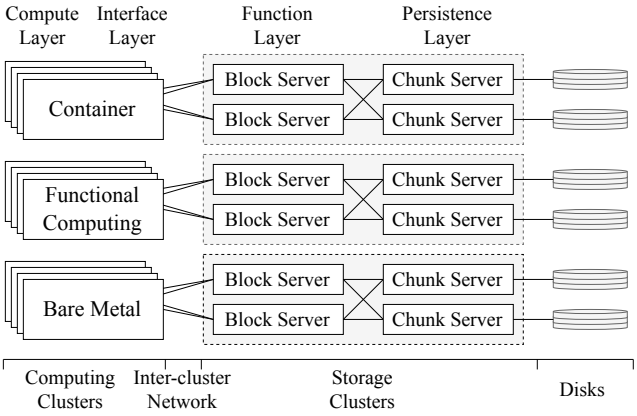

Figure 1: **Overview of our cloud architecture (§2.1).**

However, a fully harvested design is infeasible because end nodes may become unavailable during traffic bursts or failures. Third, telemetry queries exhibit strong temporal locality (i.e., most queries target recently generated data) and spatial locality (i.e., processing queries close to where the data are generated to minimize data transfer).

Based on these lessons, we propose `DiTing`, an observability infrastructure that unifies the storage and processing of heterogeneous telemetry data. `DiTing` is a hybrid query framework that combines AZ-level centralized services with node-level resource harvesting. `DiTing` has three layers: a global layer that serves as the entry point for SREs, an availability-zone (AZ) layer that provides centralized storage and fallback execution, and a node layer that processes queries using harvested resources. On top of this architecture, `DiTing` incorporates a set of optimizations, including multi-level indexing and pre-aggregation.

Our evaluation shows that `DiTing` achieves sub-second data ingestion, 2K QPS using a single CPU core, and 3-65× lower capital expenditure (CapEx) than existing solutions. `DiTing` has been deployed at production scale, serving millions of servers with millions of QPS and storing up to hundreds of PiB of data.

2 Background

2.1 Our Cloud Architecture

Our cloud offers various services such as computing (e.g., virtual machines), storage (e.g., object storage), and SaaS (e.g., MySQL). At a high level, our cloud spans the globe. Each region consists of multiple availability zones (AZs), and each AZ is a separate data center with multiple clusters.

In Figure 1, we highlight the compute-to-storage architecture across clusters. The computing layer consists of physical servers that provide a variety of services, such as containers, serverless functions, and bare-metal instances. The interface layer comprises clients in the compute-node hypervisor which receives users' requests (to remote storage) and

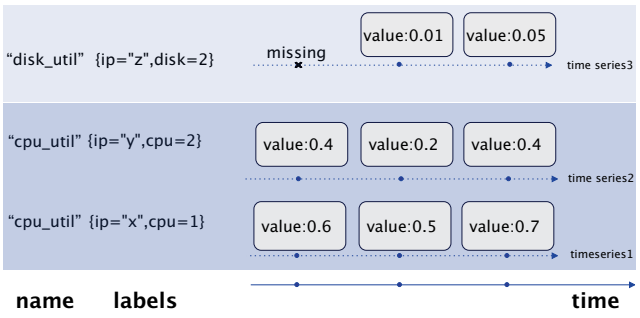

Figure 2: **An example metric record (§2.2).**

packages them into network packets. The function layer consists of servers that process incoming requests and interact with the persistence layer to store or retrieve data. The persistence layer is a distributed storage system. The network between the interface and function layers is inter-cluster, whereas the network between the function and persistence layers is intra-cluster.

2.2 Metrics

Metrics record quantitative measurements of a system, such as health, performance, and behavior. A metric typically includes a name, a set of labels, and one or more values. The name specifies the type of measurement (e.g., CPU utilization), and labels encode contextual information such as location (e.g., CPU #1 on a node with IP address 192.154.123.77). Values form a time series (e.g., 60% at 00:10). Due to their simplicity and broad coverage, metrics often serve as the first-line signal for detecting system anomalies in the field.

Metrics do not consume an exceedingly large amount of storage. As of today, the total compressed size of stored metrics in our cloud is only several PB. However, metrics are often challenging to query. Besides common metrics, each service may export its own attributes, resulting in a high-dimensional space (i.e., many distinct metric types, such as CPU, memory, and NIC utilization). Moreover, users often query across multiple dimensions and over long time ranges (hours to days), which requires scanning and aggregating substantial amounts of data. Therefore, maintaining high queries per second (QPS) at low latency for metric workloads remains challenging.

2.3 Logs

Logging records events across the software, hardware, and network stack. A log entry typically contains a timestamp, a severity level (e.g., INFO or CRITICAL), and a message. In Figure 3, we show an example log entry from a network library. Traditionally, logs are unstructured, but we have recently adopted structured logging (e.g., JSON) to facilitate parsing and querying.

In our cloud, logs are widely used for debugging and trou-

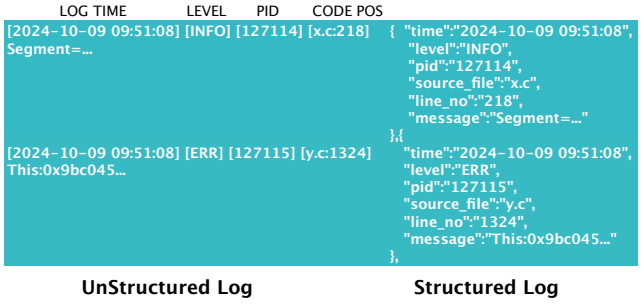

Figure 3: **An example log record (§2.3).**

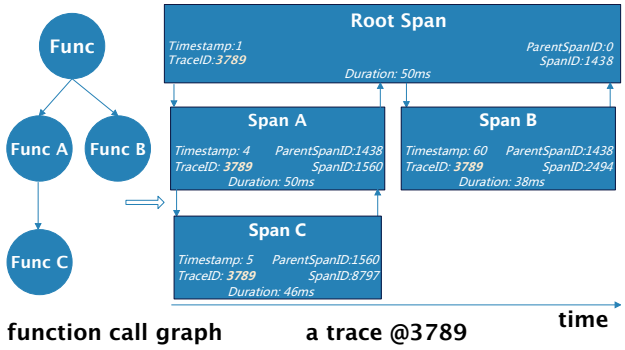

Figure 4: **An example chain of trace records (§2.4).**

bleshooting. In practice, system reliability engineers (SREs) are often first alerted by abnormal metrics and then inspect logs to identify the root cause. Log volume is large: the daily ingestion rate is at the PB scale, and the total stored log data reaches hundreds of PB. Note that most logs are generated by users and thus cannot be discarded.

2.4 Traces

In contrast to point-in-time event records such as logs, tracing provides a fine-grained view of system behavior by recording sequences of events together with timing information. For example, Figure 4 shows a trace of a function call that triggers three sub-procedures. An end-to-end trace consists of multiple spans, each representing a procedure (e.g., Functions A, B, and C).

In our cloud, we primarily use tracing to understand complex call relationships within and across services. Trace data are typically large, with PB-scale daily ingestion, and the total stored volume has reached nearly one hundred PB. To minimize overhead on critical components, we often use static instrumentation (i.e., embedding tracing APIs into source code) to collect traces, making them schema-based. Trace queries usually have low QPS (e.g., tens per second), are range-based (e.g., querying traces within a time window), and focus on short intervals (e.g., up to 30 minutes).

3 Motivation

3.1 A Day in SRE's Life

Maintaining high observability in the cloud is crucial but challenging. Unlike single nodes or small clusters, diagnosing bugs in a geo-distributed service can span multiple layers (e.g., interface and persistence) and involve different clusters (e.g., compute and storage), protocols (e.g., TCP and RDMA), and types of telemetry (e.g., logs, metrics, and traces). Next, we use a recent real-world case for demonstration (with certain details redacted for confidentiality).

Liam is an SRE on our Elastic Block Storage (EBS) team. He receives an alert from the metrics monitoring system indicating a surge of slow requests in a cluster hosting over 4,000 virtual disks. The slowness is worsening and may trigger failures (e.g., I/O hangs), potentially impacting several large customers and thousands of smaller ones.

Liam first double-checks the metrics by logging into the monitoring service (❶ in Figure 5). After confirming severe latency degradation in virtual disks (❷), he scans other metrics (e.g., network throughput and disk IOPS) and finds that cluster-level metrics remain normal, but the top-of-rack switch reports CRC errors (❸). To further narrow down the culprit, he switches to the tracing service to follow the request path along the network topology (❹) and cross-checks logs from each component (❺). Finally, he identifies a BGP down event on a second-layer switch (i.e., PSW), caused by a power failure (❻). He then applies a hotfix to the PSW to prevent escalation (❼).

This incident highlights the complexity of debugging in the cloud. SREs often need to correlate telemetry sources—metrics, logs, and traces—across layers and clusters to confirm symptoms, delineate the blast radius, and identify the root cause. While SREs can develop scripts to assist analysis, these scripts are often ad hoc and hard to reuse across different incidents.

3.2 Why Not Use or Adapt Existing Solutions?

Ideally, SREs would like a unified system that handles both the processing and storage of telemetry data from different sources. With such a system, SREs would no longer need to switch between observability platforms (e.g., Prometheus and Monarch) and correlate results using ad hoc scripts. Moreover, integrating processing with persistence can reduce data-transfer overhead, enabling better query performance and storage efficiency. Next, we discuss why existing solutions are infeasible to port to our cloud. In particular, we describe a failed attempt in which we deployed more than 600 nodes but could not scale further.

Unifying computation only. One intuitive approach is to adopt a data lake solution (e.g., Iceberg [5], Hive [40], Hudi [4], and Doris [3]). This approach keeps different data sources (e.g., logs, traces, and metrics) in their original systems while providing a unified processing interface (e.g., via

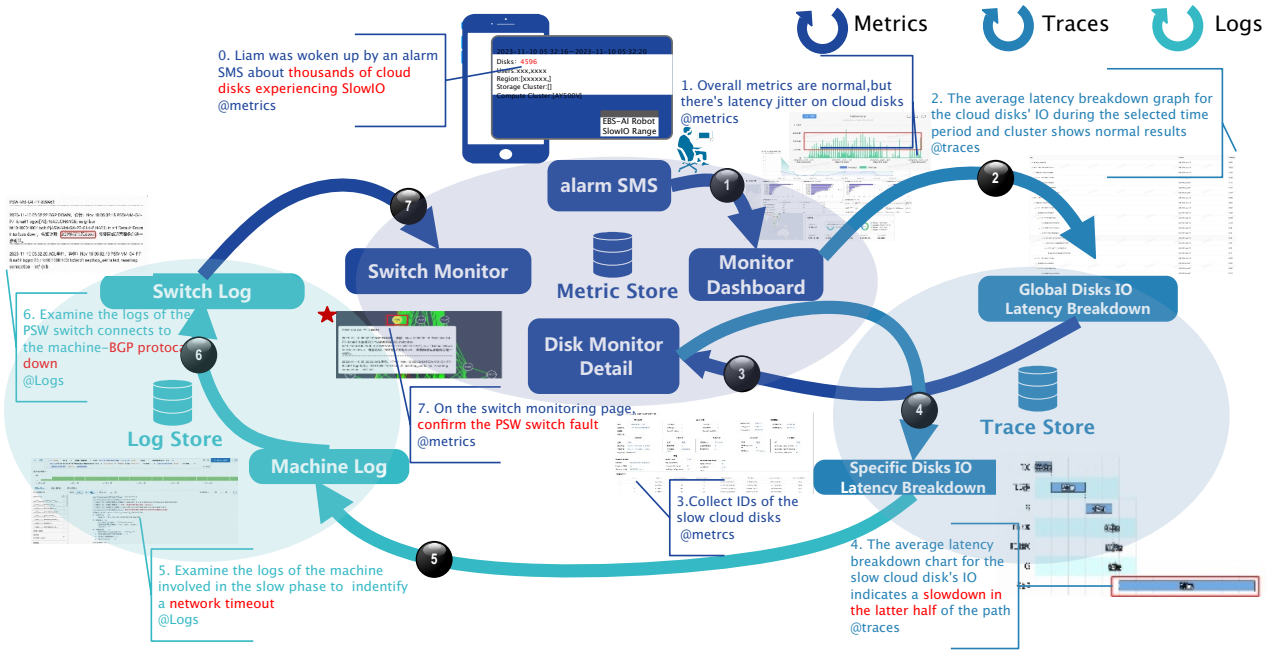

Figure 5: **A Day in SRE's Life.(§3.1).**

Apache Spark). While this is inexpensive to implement because it largely reuses existing ingestion and storage infrastructure, it can lead to high query latency. For example, a typical diagnosis in our cloud may require scanning more than 100 GB of data, which can take tens of seconds (or even minutes) due to network transfers [18]—far slower than the sub-second latency that SREs expect.

Unified storage in memory. For high performance, an alternative is to adopt an in-memory solution, which is common among hyperscalers (e.g., Scuba [14] and Kraken [26] at Meta, and Google's Monarch [15]). These systems are essentially in-memory time-series databases and primarily target metric workloads. On the one hand, they provide fast queries and low ingestion latency (e.g., hundreds of milliseconds in Kraken/Monarch). On the other hand, they are prohibitively expensive at our scale, especially when storing hundreds of PB of telemetry data. Therefore, we do not adopt an in-memory-only design.

ClickHouse: a failed attempt. The above analysis led us to build an OLAP-based solution on top of a set of geo-distributed dedicated clusters, aiming to unify processing and storage with high performance. We chose ClickHouse [35], an open-source OLAP system with strong community support, and started building the service in 2022. At that time, we scaled the deployment to eight clusters across multiple availability zones (AZs), totaling more than 600 nodes (detailed node configuration is listed in §5). The system stored about 8 PB of observability data, including traces and metrics from multiple services.

When attempting to scale ClickHouse further, we encountered several critical challenges. First, ClickHouse bottlenecks when hosting more than one million partitions for a single service [1]; monitoring data from many components across a large fleet can easily exceed this limit. Second, ClickHouse's memory usage grows with the number of columns. Many of our servers produce metric data with thousands of columns, and the per-node memory usage in several clusters reached around 85%, even causing out-of-memory (OOM) events when scanning large amounts of data. These issues indicate that the main constraints are CPU and memory rather than storage capacity. Simply provisioning more CPU and memory is not feasible: our estimates suggest that doing so would account for more than 20% of the cloud infrastructure CapEx.

Alternative-1: a cloud-backed system. One possibility is to use a cloud database (e.g., Snowflake [22] or Amazon Redshift [25]) and adopt a serverless computing model. This disaggregates compute and storage, allowing us to elastically allocate CPU and memory while using object storage as the backend. In principle, this can improve cost efficiency by reducing over-provisioning. However, it introduces a circular dependency (i.e., relying on the cloud to monitor the cloud) and is therefore not feasible in practice.

Alternative-2: harvesting the cloud. Clouds often have abundant idle resources, which makes harvesting appear attractive. In this approach, we push queries to the nodes where observability data are generated and use on-node resources (e.g., CPU and disk) for processing and temporary storage, reducing both data transfer and CapEx. However, end nodes are not always available (e.g., node crashes or in-

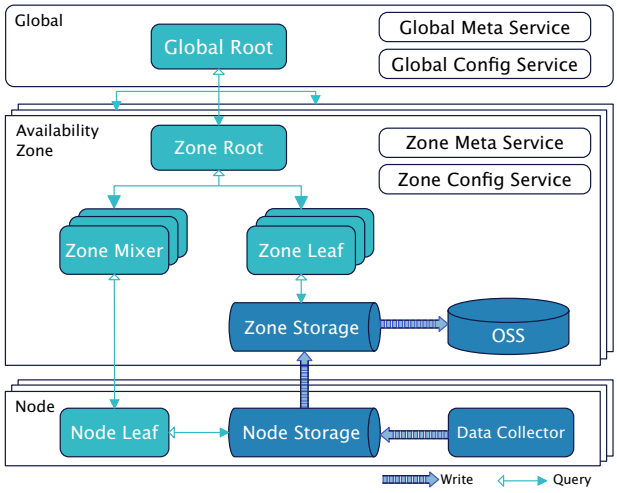

Figure 6: **Overview of `DiTing` (§4.1).**

sufficient resources during traffic bursts). Worse, failures and busy periods are often exactly when SREs need observability the most. Moreover, unlike centralized storage where data can be replicated easily, end nodes are more susceptible to data loss due to disk failures or software-induced corruption.

4 DiTing

Key idea. We now present the key idea behind DiTing, a unified framework for processing and storing telemetry data at cloud scale. Our failed attempt to scale a centralized ClickHouse deployment, together with the limitations of relying solely on idle end-node resources, motivates a hybrid design that combines a centralized system with node-level resource harvesting. We refer to this design as *Central–Node Collaboration* (CNC). After receiving a query, CNC first attempts to push it down to the relevant nodes for in-situ processing. If this fails (e.g., due to node crashes), CNC falls back to the centralized system to execute the query.

Benefits. CNC leverages both spatial and temporal locality in observability workloads. Spatially, it pushes queries to the nodes where the target data are generated. Temporally, SREs most often query recently generated data (e.g., from the last hour or week). CNC therefore keeps recent data on nodes and periodically uploads them to the centralized system for long-term storage. As a result, most queries can be served in situ using harvested resources (e.g., CPU and memory), reducing data transfer overhead and infrastructure CapEx. Meanwhile, the centralized system provides durable storage and serves as a reliable fallback when target nodes are unreachable, improving availability.

4.1 Architecture.

These benefits lead to two design goals: (1) accurate query pushdown and (2) minimizing the use of centralized resources for query processing. To achieve these goals, DiTing adopts a three-layer architecture consisting of the *Global*, *Availability Zone (AZ)*, and *Node* layers, as shown in Figure 6. Note that DiTing serves multiple cloud services (e.g., Elastic Block Service, Object Store Service, and Elastic Compute Service) using the same set of clusters, rather than maintaining service-specific dedicated fleets; this also enables cross-service debugging.

Global. This layer serves as the entry point for queries. Requests that do not specify a target AZ are sent to *Global Root*, which locates the corresponding AZs for execution. To sustain high QPS, Global Root neither processes queries nor stores data; it only forwards requests. Routing relies on the *Global Meta Service*, which maintains mappings (e.g., from a virtual disk ID to the physical nodes and disks that store its data). DiTing also uses the *Global Config Service* to manage configurations such as node-level resource limits and the upload interval for node telemetry to AZ-level centralized storage. To balance load and avoid a single point of failure, we deploy multiple Global Root instances across AZs.

AZ. In this layer, DiTing maintains an AZ-level centralized system, typically consisting of 20–100 dedicated physical machines for query processing and observability-data storage. All nodes share the same configuration. The system usually includes three dedicated zone-root nodes that form a Raft group for high availability. The remaining nodes act as zone-mixer and zone-leaf nodes, which are interchangeable. Upon receiving queries from the global layer, DiTing builds a query tree, partitions the query via zone-root and zone-mixer (i.e., non-leaf) nodes, and pushes sub-queries down to node-level leaf nodes for execution. If pushdown fails (e.g., due to an error or timeout), DiTing falls back to executing the query on an AZ-level leaf node. Periodically, the AZ layer receives observability data uploaded from underlying nodes for long-term persistence. These data are stored on non-root nodes (i.e., zone-mixer and zone-leaf nodes). For higher reliability, DiTing can optionally store an additional copy in the Object Store Service (OSS) within the same AZ. To support different deployment scenarios, the AZ layer manages metadata and configuration through the *AZ Metadata Manager* and the *AZ Configuration Manager*.

Node. Subject to the resource limits enforced by the Global or AZ layer, DiTing harvests idle resources on each node to execute pushed-down queries. Typically, after queries are split and scheduled by the upper layers, sub-queries are pushed down to the node layer for processing. Each node also runs an agent, called the *Data Collector*, which collects observability data including metrics, traces, and logs. DiTing caches recently ingested data, persists it locally on harvested disks, and periodically uploads it to the AZ layer.

4.2 Data Model: co-Log

co-Log format. We now describe DiTing's data format. For metrics, traces, and logs, we use a unified format called

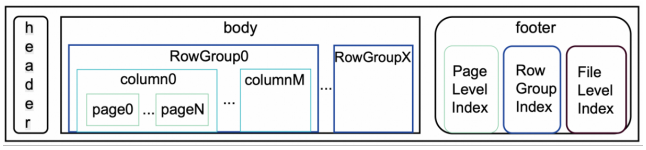

Figure 7: **co-Log data format (§4.2).**

co-Log. To provide a familiar and simple query interface, DiTing supports standard SQL; therefore, telemetry data are organized as relational tables.

- *Metrics.* We adopt a *multi-value* model in which each timestamp is associated with multiple measurements. In a metric table, the first column is the timestamp, and the second column stores labels, i.e., location information (e.g., IP address, hostname, and cluster ID) of the node producing the data. Columns 3 onward store different measurement types (e.g., CPU and memory utilization). A node typically reports 10K–20K metric types. Every 15 seconds, a new row is appended.
- *Traces.* Traces are stored as spans. In a trace table, the first column is the span ID, the second is the timestamp, the third is the parent span ID, the fourth is the trace ID (assigned by the root span), and the last column is the span duration. Each span inserts one row. In Figure 4, there would be four tables corresponding to the root, A, B, and C spans.
- *Logs.* Logs are stored as table entries. Columns include timestamp, location (as in metrics), log severity level, and message body.

Each table is stored as a co-Log file. Similar to Parquet [41] and ORC [6], co-Log uses a PAX (partition-attributes-across) layout: it splits a co-Log file into fixed-size row groups, each containing multiple columns, resulting in a hybrid of row and columnar storage. Each column is further divided into pages to facilitate lookup. To avoid ambiguity in query results [15], we enforce schemas for metrics and traces. For logs, DiTing allows users to specify regular expressions or rules to extract structured fields from unstructured log messages.

We also extend co-Log to store metadata. In DiTing, metadata map telemetry data to their physical locations, enabling accurate query pushdown. co-Log stores metadata in a header and a footer: the header records file size and compression type, and the footer stores indexing information at multiple granularities (file, row group, column, and page).

co-Log features. Beyond standard columnar-storage features, co-Log is tailored to observability workloads. First, SRE queries heavily depend on temporal and spatial attributes. For example, when debugging performance issues, SREs often correlate metrics, traces, and logs within a specific time range and location (see §3.1). Hence, co-Log indexes temporal and spatial fields by default during ingestion.

Second, our dataset exhibits a *wide-table* pattern: while the number of columns can be very large (up to tens of thousands), most queries touch only a small subset (typically around ten columns). Moreover, the hot columns can change over time (e.g., focusing on IOPS and latency during peak events and shifting to failure-related signals during normal periods). To support efficient indexing and adapt to such changes, co-Log stores multi-level indexes (file, row group, column, and page) together in the file footer. For the same reason, schema access is highly skewed and random, with a small set of columns being queried frequently. Unlike Parquet/ORC, we therefore avoid using ProtoBuf [13] or Thrift [39] for metadata serialization; instead, we use a raw format to enable faster access. The larger metadata size is acceptable in our high-speed datacenter networks.

	Feature	P	O	co-Log
1	Mixed row and column storage	✓	✓	✓
2	Multiple compression support	✓	✓	✓
3	Column-based encoding	✓	✓	✓
4	Column-based indexing	✓	✓	✓
5	Temporal and spatial indexing	✗	✗	✓
6	Split data and indexes	✗	✗	✓
7	Random-accessible metadata	✗	✗	✓
8	CRC checking	✓	✗	✓
9	ACID transaction	✗	✓	✗
10	Multi-granularity column compression	✓	✓	✗
11	Complex data types	✓	✓	✗

Table 1: **Comparison between co-Log and parquet/ORC. P refers to parquet and O refers to ORC (§4.2).**

Third, to accommodate frequent hardware changes and software upgrades, co-Log supports schema evolution (e.g., adding new columns) without breaking existing queries. For reliability, we also enforce CRC checking (Table 1, row 8) on both metadata and data to detect silent corruption.

co-Log intentionally omits several features to reduce complexity and overhead. For example, it does not provide strong ACID guarantees (Table 1, row 9), since telemetry workloads can tolerate short-term unavailability and minor inconsistencies. We also do not implement "multi-granularity"column-level compression: given modern high-capacity SSDs, we trade space for query performance. Finally, we do not support complex types (e.g., arrays and maps), which are rarely needed for observability and incur high processing overhead.

4.3 Optimizing Querying

Procedure. We now walk through the query execution flow in DiTing. SREs can either send a query to a global root for cross-AZ lookup or directly to a target AZ. After receiving the query, the zone root in the corresponding AZ first

estimates the load (i.e., how many nodes the query should be pushed to), builds a query tree, and asks zone mixers to identify the specific nodes that hold the target data. DiTing then pushes sub-queries down to these nodes, which execute them using harvested CPU and memory. If pushdown fails (e.g., due to inaccessible nodes or timeouts), DiTing reroutes the query to an AZ-level zone-leaf node for execution. In production, only about 1% of queries fall back to zone-leaf execution. Finally, the zone root aggregates the results and returns them to the user. Next, we highlight key optimizations.

Building the query tree. After receiving a query (either forwarded by the global root or submitted directly by an SRE), DiTing constructs a zone-level query tree consisting of three node types: root, mixer (internal), and leaf. Two key parameters are the tree height and the fan-out. Prior work proposes heuristic policies for choosing these parameters. For example, Monarch [15] uses a fixed height of 3, whereas Kraken [26] dynamically adjusts fan-out to balance parallelism (higher fan-out) against straggler impact (i.e., by lowering fan-out).

A recent study [35] shows that query latency, while largely insensitive to fan-out, scales logarithmically with the number of leaf nodes involved. Based on this insight, DiTing first determines whether a query requires aggregation. If so (e.g., an AZ-level aggregation), and the query needs to be pushed to N nodes, DiTing sets the fan-out to $\min(N, 1000)$. Otherwise (e.g., scan queries), it sets the fan-out to N. This is because, unlike Monarch and Kraken, DiTing must support aggregation-heavy queries that span multiple telemetry types (logs, traces, and metrics) and potentially involve millions of nodes. Such queries can impose substantial aggregation load on mixer nodes; we therefore cap fan-out at 1000.

Query pushdown. Pushing query processing to where the target data reside is a classic approach. Prior systems such as Monarch [15] reuse schema fields (e.g., location) to select target nodes by matching them against query predicates. They also employ Bloom-filter-like indexes (e.g., Monarch's Field Hints Index (FHI) [15]) to speed up target selection.

DiTing does not follow this practice due to precision requirements. If a query is pushed to the wrong nodes (e.g., due to Bloom-filter false positives), the resulting latency penalty and traffic amplification are significant and unacceptable at scale. Instead, DiTing achieves accurate query pushdown by aligning its hierarchy (global, AZ, and node) with the cloud's physical infrastructure (region, AZ, cluster, and node; see §2.1). Each node has an IP address, and its hostname encodes the cluster name. DiTing therefore uses IP and cluster information, together with metadata, to precisely locate target data. For example, hardware components (e.g., NICs and SSDs) have fixed physical locations (e.g., installed on a specific node). For logical entities (e.g., a virtual disk in EBS), DiTing maintains mapping tables (e.g., from a virtual-disk ID to the physical nodes and disks that store its data) and periodically refreshes these mappings from the corresponding services (e.g., EBS block masters).

Query pushdown is not always successful because target nodes may be temporarily unavailable (e.g., due to network partitions or traffic bursts). DiTing therefore provides three fallbacks. First, if a node is deemed unavailable before pushdown (e.g., missing heartbeats), DiTing directly executes the query on AZ-level leaf nodes. Second, if a node becomes unavailable after pushdown, a configurable timeout triggers rerouting to AZ-level leaf nodes. Third, if a node is responsive but overloaded, DiTing switches the node to a fetch-only mode (Figure 6), where the node returns only the latest data and AZ-level leaf nodes complete the computation.

Metadata pushdown. DiTing stores metadata at the global and AZ layers to enable query pushdown. However, node-level execution may still require metadata for joins and filters. For example, a query may join disk traces with disk metadata (e.g., user ID) that would otherwise reside at the global or AZ layer, forcing additional round trips and increasing latency and network overhead.

To avoid this, DiTing slices metadata by node IP and pushes the relevant partitions down to nodes. We first allow users to declare which metadata fields can be associated with nodes. DiTing then combines these metadata with the physical-location table to construct a spatial partitioning scheme, partitions the metadata accordingly, and pushes each partition to the corresponding nodes. This reduces query latency by 33% and lowers node-side CPU utilization from about 45% to 16%, while incurring only a small additional memory overhead (a few MB per node).

Limiting node-level resource usage. DiTing harvests idle node resources for query processing and temporary storage, which requires resource management to avoid interfering with tenant workloads. DiTing therefore enforces user-configurable limits (set at the global and AZ layers) on CPU, memory, and disk usage. To tolerate traffic bursts, users can also specify a short grace period during which resource usage may exceed the thresholds. Severe or sustained limit violations trigger termination of the node-level DiTing agent.

4.4 Optimizing Ingestion

Procedure. All types of observability data—metrics, traces, and logs—are generated on end nodes and formatted as co-Log files. Node-level agents insert metric entries by computing the corresponding statistics every 15 seconds (e.g., average or maximum). Trace and log entries are appended upon function calls and log events. Periodically, node-level agents merge co-Log files and upload them to the AZ layer for persistence. Optionally, the AZ layer can also send a copy of the uploaded data to the object store service for higher reliability.

Node-level in-memory buffer. User access exhibits strong temporal locality: most queries target recently generated

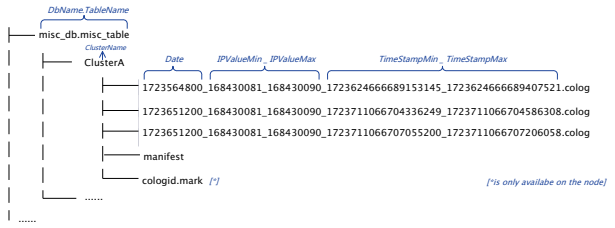

Figure 8: **co-Log file layout (§4.4).**

data. We therefore implement a fixed-size, node-level in-memory buffer to cache the latest data, prioritizing low latency and low cost. AZ-level leaf nodes do not maintain such a buffer because temporal/spatial locality are weaker there.

Surprisingly, for a server that produces 20K distinct metrics (an extreme case), a 900 MiB per-node buffer achieves cache hits for over 99.9% of queries. Even on nodes with fewer idle resources, we find that a 100 MiB buffer is sufficient to reach a hit ratio of around 90%. This effectively provides an in-memory-database experience for most queries.

Pre-aggregation for metrics. Beyond short-term monitoring, SREs often query metrics over long time ranges (e.g., weeks or months) to understand trends. Returning raw 15-second-granularity data would incur high storage and processing overhead while providing limited additional insight. For example, querying a VM's CPU utilization over the past 30 days at 15-second granularity yields 172,800 points, placing a heavy burden on node resources and network traffic. `DiTing` therefore supports pre-aggregation for metrics, computing aggregates such as average, sum, max, and min at coarser granularities (e.g., 1 minute, 5 minutes, and 1 hour). This optimization applies only to metrics.

File merge. In `DiTing`, because end nodes periodically upload co-Log files to the AZ layer (every 1 minute by default), the AZ layer must provide durable storage for a massive number of co-Log files (e.g., billions). This creates a substantial maintenance burden. However, we cannot simply merge all files into large ones, because doing so would erase spatial information (i.e., metadata used to enable accurate query pushdown). `DiTing` therefore employs a two-step merging strategy. First, we merge row groups (Figure 8) from files produced by the same server, and attach the server IP to each row group's metadata. Next, we merge row groups from servers in the same cluster into a single co-Log file, sort the row groups by IP address, and append cluster information and an IP-to-zone map to the file footer. This design also guides the folder structure in Figure 8: the directory structure is flat, and the file layout and naming conventions are explicit and easy to manage.

4.5 Consistency, Integrity, and Availability

We intentionally do not build `DiTing` as a database because supporting transactions (i.e., strong ACID guarantees) is too costly and unnecessary for telemetry workloads. Nevertheless, `DiTing` employs several mechanisms to improve consistency, integrity, and availability.

Consistency. We make several observations. First, most observability data are append-only and produced by a single writer (i.e., the per-node agent). Second, data are replicated by being uploaded from the node layer to the AZ layer and then backed up to the object store. Third, SREs do not directly query nodes: if pushdown fails, `DiTing` reroutes the query to AZ-level leaf nodes. This avoids consistency issues caused by multiple clients reading from and writing to different replicas. Finally, in observability scenarios, results from node-level and AZ-level execution may differ slightly due to freshness. `DiTing` estimates this potential staleness from the query results and notifies users, who can optionally re-run the query against the centralized copy.

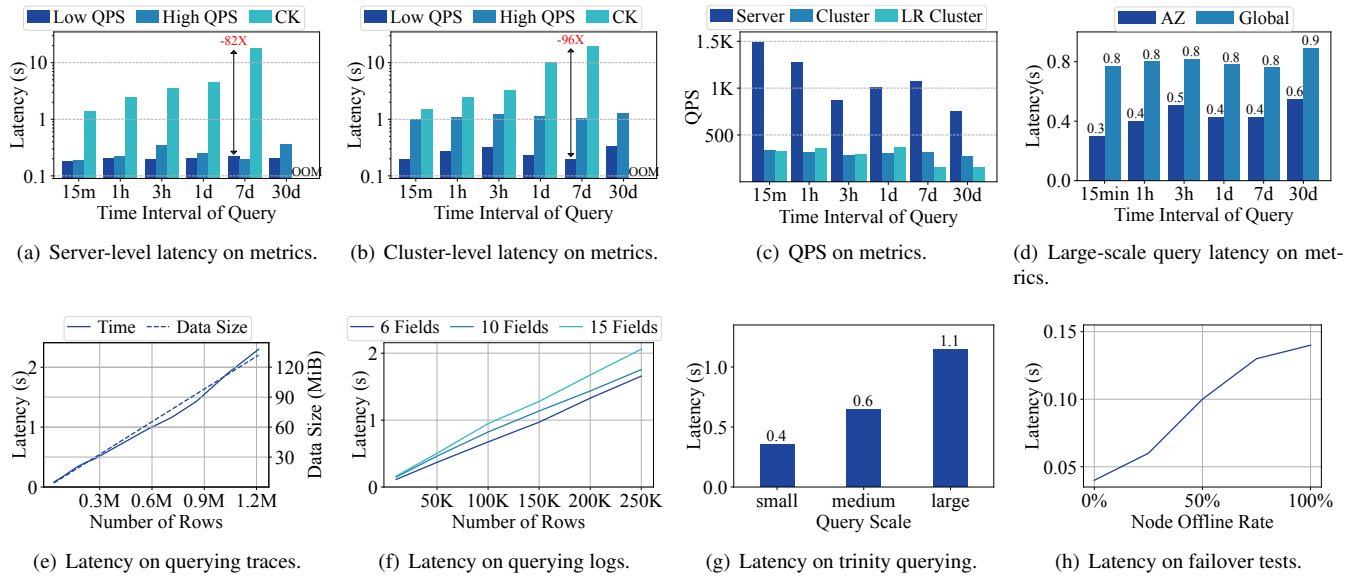
Based on these observations, `DiTing` adopts a simplified Raft-like protocol for each replicated unit spanning node storage, AZ storage, and object-store storage. For example, with 1K nodes, we form 1K independent Raft groups. The key idea is to always treat the node as the leader (i.e., no leader election as in standard Raft): because each node is the sole writer, if it goes down, no new telemetry data will arrive for that group. SREs can still query replicas in the AZ layer or object store. This design substantially simplifies engineering and operations, which is critical at `DiTing`'s scale.

Integrity. `DiTing` uses CRC to verify data integrity from generation, through network transmission, to persistence on disk. We learned two lessons in practice. First, we still need to periodically scrub data and cross-check against the object store to detect corruption. At hundreds of PB (or more), bit flips are inevitable. Second, when computing CRCs over nested data blocks, we leverage the compositional properties of CRC (i.e., combining precomputed CRCs for sub-blocks) to avoid repeated reads and recomputation. This reduces overhead and helps detect corruption that might otherwise be missed due to inconsistent results across repeated reads.

Availability. The two replicas in `DiTing` (node-level and AZ-level) already provide approximately nine nines of availability based on our failure-rate analysis. With an additional backup in the object store, `DiTing` can provide roughly twelve nines. Note that the object store is an independent service rather than a third `DiTing` replica tier. It is also more cost-effective than other storage options (e.g., EBS and cloud databases), which helps meet our CapEx requirements.

5 Evaluation

We organize our evaluation into three parts. First, we evaluate `DiTing` on a microbenchmark, focusing on query latency and queries per second (QPS). Second, we present deployment statistics from `DiTing`'s large-scale production rollout. Finally, we compare capital expenditure (CapEx) against existing solutions.



(a) Server-level latency on metrics. (b) Cluster-level latency on metrics. (c) QPS on metrics. (d) Large-scale query latency on metrics.

(e) Latency on querying traces. (f) Latency on querying logs. (g) Latency on trinity querying. (h) Latency on failover tests.

Figure 9: **The performance of `DiTing` on various circumstances. (§5.1)**

5.1 Microbenchmark

We evaluate `DiTing` using a microbenchmark that issues queries over metrics, logs, traces, a mixture of all three, and metadata. We additionally run failover experiments to assess `DiTing`'s robustness under node unavailability.

Metrics. We construct the metrics microbenchmark as follows. First, we use real-world production metrics from an 80-server cluster in our object store service. For each query, we randomly select 12 fields from a table with more than 1,000 fields. This matches field-access statistics in production: on average, a query touches 11.2 fields, and no more than 1% of all fields are accessed by any single query.

Second, we query metrics over a range of time windows: the most recent 5 minutes, 1 hour, 3 hours, 1 day, 7 days, and 30 days. This reflects common SRE workflows, where recent data are used for real-time monitoring and historical data are used for trend analysis. For long-range queries, `DiTing` serves data pre-aggregated at 5-minute or 1-hour granularity.

Third, we set the benchmark concurrency to 400, simulating 400 SREs continuously issuing queries to the cluster. We compare against ClickHouse, deployed on an 18-node cluster where each node has 96 CPU cores, 256 GB RAM, 12×14 TB QLC SSDs, and 2×1 TB PMEM devices. In contrast, the AZ-level `DiTing` deployment uses three nodes, each with 64 CPU cores, 128 GB RAM, and 12×3.5 TB QLC SSDs.

Figure 9(a) reports query latency and QPS for `DiTing` and a centralized-only variant of `DiTing` when targeting a single server. For 5-minute, 1-hour, and 3-hour windows, metrics are not pre-aggregated. At around 1K QPS, `DiTing` achieves about 0.2 s latency, whereas the centralized-only variant is 7–82× slower. The gap widens for longer time ranges (e.g., 0.2 s vs. 18.1 s) because `DiTing` can pre-aggregate metrics on nodes and thus reduce processing overhead. Somewhat surprisingly, the centralized-only variant may even fail to return results for 30-day queries due to out-of-memory (OOM) errors. Note that we do not enable pre-aggregation in the centralized-only variant because it would introduce additional CPU overhead and write latency.

		15min	1h	3h	1d	7d
Latency (s)	In	1.01	1.09	1.22	1.14	1.05
	Out	9.54	9.68	9.66	9.07	9.71
QPS	In	333	313	279	304	320
	Out	16.0	17.2	17.5	19.3	16.0

Table 2: **Comparison between queries in and out of cache.**

When extending the target from a single IP to an entire cluster, Figure 9(b) shows consistent results, although latency may increase under high QPS due to higher network traffic. Moreover, Figure 9(c) shows that `DiTing` reaches about 1,500 QPS while using only one CPU core in our microbenchmark. Even on low-resource machines with a 300 MB memory limit, `DiTing` can achieve similar QPS in many cases.

Table 2 further compares `DiTing` with and without the in-memory cache under a concurrency of 400. The results highlight the importance of caching recent metric data in memory, since metrics require high-QPS reads. Without caching, leaf nodes cannot sustain such high-rate disk reads, leading to substantial performance degradation and potentially affecting system stability.

We further scale metric queries to the region and global

levels. Specifically, we randomly select 10 fields from the same table but target (i) one region of the object store service (∼20K nodes) and (ii) multiple regions (∼60K nodes). Figure 9(d) shows that even at these scales, latency increases only modestly to about 0.5 s and 0.8 s, respectively. This demonstrates the effectiveness of query pushdown.

Traces. Trace workloads typically have fewer columns but many more rows (with millisecond-level granularity). To evaluate trace queries, we use production trace data from an Elastic Block Service (EBS) server and issue queries that read 10 columns sampled from different column ranges. As shown in Figure 9(e), latency increases linearly with the amount of data read, indicating that `DiTing` scales well for trace workloads.

Logs. Compared to metrics and traces, logs have much larger volume. Due to their unstructured nature, logs are often inspected manually and thus have a lower query rate. Recall that we adopt schema-on-read for logs, converting them to the unified format only at query time; we therefore focus on the throughput of reading and filtering.

We use production log data and apply a 30% selectivity filter, meaning that out of every 100 lines read, 30 lines are returned. We query 6, 10, and 15 fields over log datasets ranging from 10K to 250K rows. Figure 9(f) shows that processing time grows linearly with the amount of data scanned.

Trinity. A key feature of `DiTing` is the ability to query and correlate metrics, traces, and logs in a single request. We construct a trinity microbenchmark that follows production field-access patterns and includes three scales (small, medium, and large):

- **Metric table:** ∼500 columns, one row every 15 s. Small (last 5 min), medium (last 30 min), large (last 1 h).
- **Trace table:** ∼30 columns, ∼2K rows every 15 s. Small (65K rows), medium (210K rows), large (460K rows).
- **Log table:** ∼20 columns, ∼25 rows every 15 s. Small (4.5K rows), medium (5K rows), large (5.5K rows).

Under this setup, each query first retrieves server CPU usage, then joins with a trace table for a cloud component, and finally joins with the component's error logs on the time field. Figure 9(g) shows that latency increases with the amount of queried data; most of the time is spent retrieving trace data due to its larger volume.

Failover. Node-level leaf nodes may be unavailable during failures or traffic bursts. To evaluate robustness, we select a 200-node cluster and vary the fraction of unavailable node-level leaf nodes from 0% to 100% in a single-threaded setup. We query metrics over the most recent 1-hour window. Figure 9(h) shows that latency increases gradually as node unavailability increases.

Metadata. Metadata in `DiTing` map logical entities and fields to physical locations. To evaluate metadata lookup, we query all virtual disks (VDs) subscribed by a major customer.

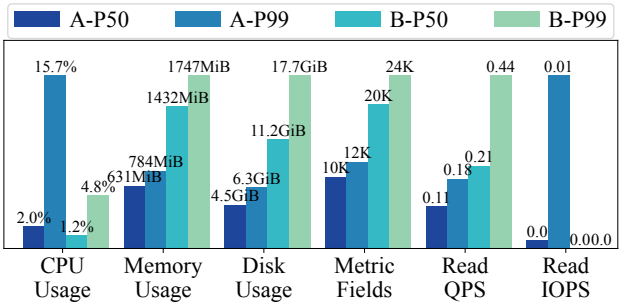


Figure 10: **Deployment statistics of `DiTing`.**

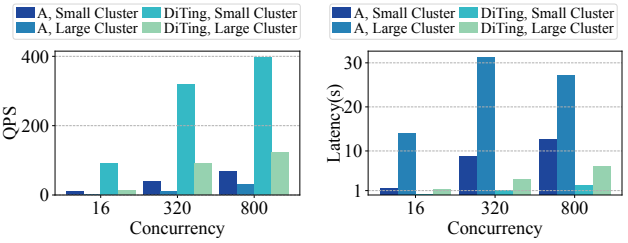

(a) Cluster-level qps on metrics. (b) Cluster-level latency on metrics.

Figure 11: **The performance of `DiTing` on production environments, compared with solution A. (§5.2)**

These VDs (about 430K) are distributed across regions and AZs. We then query the total traffic for these VDs. Without metadata, the query would need to scan the entire dataset (∼1.4 PiB) to locate the disks, taking tens of minutes. With metadata-assisted pushdown, the query completes in 2 s.

5.2 Deployment Statistics

At the time of writing, we have deployed `DiTing` for multiple services (e.g., OSS and EBS) on more than one million nodes across multiple regions worldwide. Next, we report deployment statistics for two services in a single region. Service A emits a typical metrics workload (about 10K metrics per node), whereas Service B emits a larger workload (about 20K metrics per node). The statistics are collected from more than 300 clusters and 36K nodes. The AZ-level monitoring data stored in this region reach about 600 TB. Our AZ-level nodes serve about 1,200 QPS on average, and node-level leaf agents collectively serve about 40K QPS. Figure 10 summarizes node-level overhead (CPU, memory, and disk consumed by `DiTing`) and per-node QPS, reported at the 50th and 99th percentiles.

Overall, the node-level resource overhead of `DiTing` remains low. On average, `DiTing` consumes GB-scale memory per node (about 0.5% of total DRAM), uses fewer than 2% of CPU cores, and requires only 10–20 GB of local disk for short-term persistence. Even for Service B, our implementation occupies only about 0.55% of memory and 7% of the system disk on average. However, when amortized over

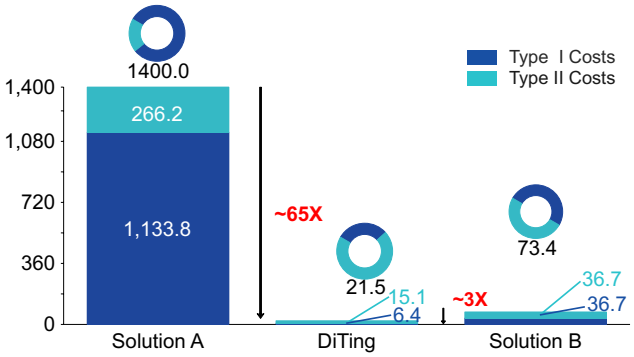

Figure 12: **CapEx comparison of `DiTing`, Solution A, and Solution B.**

a large fleet (36K nodes across Services A and B), the aggregate memory footprint reaches about 34 TB. This large distributed cache is a key reason for `DiTing`'s low query latency, resembling the behavior of a distributed in-memory database. At the global scale, `DiTing` runs on millions of nodes and stores tens to hundreds of PiB of compressed data.

Figure 11 further compares `DiTing` with Solution A in production. Solution A is a classic time-series high-performance DB developed by our company (serving a wide range of users for over a decade). We run experiments on a small deployment (50 nodes) and a large deployment (400 nodes), varying concurrency from 16 to 800. Each experiment queries a single metric over the most recent 1.5 hours. As shown in the figure, `DiTing` improves QPS by 4–9× while reducing latency to 1/10–1/4 of Solution A.

5.3 CapEx Analysis

We compare the CapEx of `DiTing` against two baselines, anonymized as Solution A and Solution B. Solution A corresponds to the system used in the deployment study above, and Solution B is our internal distributed logging service with EB-scale capacity. Both represent state-of-the-art production systems and provide Prometheus-like functionality. We choose internal services as baselines because we can obtain detailed CapEx numbers that have been strictly audited by our finance department. Due to confidentiality constraints, we cannot disclose absolute costs. Instead, we report normalized comparisons to highlight `DiTing`'s CapEx reduction in the field.

We categorize CapEx into two types, following common accounting practice: Type I (*persistence*) and Type II (*ingestion*). Type I captures long-term storage costs. `DiTing` primarily relies on the Object Store Service (OSS), built on top of our internal distributed file system. Both Solution A and Solution B use the same underlying file system directly. Thus, the three systems have similar cost per stored GB. Even so, `DiTing` incurs only about 1/180 and 1/6 of the Type I cost compared to Solutions A and B, respectively. This reduction comes from `DiTing`'s multi-value data model and the co-Log format (see §4.2), which efficiently stores and queries high-cardinality, high-dimensional metrics.

Type II captures ingestion cost and can be decomposed into three factors: (1) *Physical cost*, including hardware depreciation, power, and datacenter (IDC) expenses; (2) *Selling rate*, defined as the fraction of provisioned resources that are actually subscribed/serving; and (3) *Other overheads*, including software licensing and additional infrastructure fees. We summarize this as:

$$\text{TYPE-II COST} = \left(\frac{\text{PHYSICAL COST}}{\text{SELLING RATE}}\right) \times (1 + \text{OTHER}).$$

Note that `DiTing` does not attribute Type II cost to harvested node resources, since those nodes are already paid for by the services. Hence, `DiTing` mainly incurs Type II cost in the centralized (AZ-level) cluster. Overall, `DiTing` reduces Type II cost by about 17.6× and 2.4× compared to Solutions A and B, respectively. In total, `DiTing` achieves about 65× and 3× CapEx reduction relative to Solutions A and B.

6 Lessons Learned

Unifying is not equal to identical handling. In hindsight, "unified" does not mean "handled identically." Although `DiTing` uses one storage format (co-Log) and one processing interface to cover metrics, traces, and logs, each data type still needs its own engineering focus.

For traces, the biggest operational lesson is that the SDK matters as much as the backend. If the instrumentation is unstable or too heavyweight, the system fails exactly when it is needed most: abnormal paths are often rare, time sensitive, and the first to be dropped under pressure. For metrics, high cardinality and long-range queries are the primary cost driver. We repeatedly hit cases where adding a few high-cardinality dimensions (or expanding a monitoring scope) silently multiplied storage footprint and query cost. Our experience suggests the only sustainable approach is to continuously watch growth signals and proactively apply summarization (e.g., pre-aggregation) and retention controls. For logs, we learned to optimize for lossless and fast ingestion first. Heavy preprocessing (parsing, extraction, normalization) is best treated as a best-effort or asynchronous step. Keeping the write path simple makes the system far more robust under bursty incidents.

Stability comes first. `DiTing` relies on a per-node agent for data collection, local persistence, pushdown execution, and metadata handling. This consolidation improves locality and reduces CapEx, but it also enlarges the blast radius. A regression in the agent can affect an entire fleet within hours.

Operationally, the most effective measures were not sophisticated algorithms, but disciplined rollout and guardrails. For example, we implemented canary releases with clear success criteria, staged expansion across clusters/regions, and automated rollback when key SLOs regress. We also found it necessary to bake "self-protection" into the agent

and the control plane—rate limits, circuit breakers, backpressure, and load shedding—because at cloud scale, rare corner cases happen daily, if not hourly. Finally, we intentionally keep the consistency design simple (our Raft-like variant with a fixed leader) so that failure behavior is always predictable and easy to operate.

CapEx! CapEx! CapEx! Our early prototypes focused on making a centralized `DiTing` work for more services and more data types, because that was the fastest way to validate functionality. As deployment scaled, we learned the hard way that a centralized architecture has a steep cost curve for telemetry: ingestion grows continuously, and a design that looks "reasonable per node" can become unsustainable once multiplied by millions of machines.

Two practical lessons stood out. First, cost regressions often come from small, local changes: adding an index, increasing a sampling rate, enabling a new dimension, or extending retention by a few days. Each change is easy to justify in isolation, but the fleet-wide effect can be enormous. Second, the only way to keep costs under control is to make them visible and reviewable. In our deployment process, every major feature must come with an explicit cost model (e.g., added bytes per node per day, incremental write amplification, and extra CPU for ingestion/query), and we routinely run "what-if" analyses during design reviews.

This is also why the final architecture embraces Central–Node Collaboration: we use harvested resources to flatten the steady-state cost curve, while keeping the AZ-level centralized clusters as a bounded, reliable fallback. In practice, treating *cost to serve* as a continuous optimization target—alongside latency and availability—was essential to making `DiTing` viable at cloud scale.

7 Related Work

TSDB. Time-series databases (TSDBs), such as OpenTSDB [12], BlueFlood [32], KairosDB [10], Graphite [8], InfluxDB [9], and Prometheus [33], are designed for storing and querying time-series data and are therefore widely used as building blocks for observability. However, traditional TSDBs primarily optimize for time-partitioned access and often provide limited support for *spatial* attributes (e.g., region/AZ/cluster/node) that are fundamental in cloud telemetry. At large scale, this mismatch can lead to skewed placements and I/O hotspots (e.g., many operators concurrently scanning recent windows for the same AZ or service). Recent in-memory TSDBs, such as Scuba [14], Kraken [26], and Monarch [15], demonstrate that real-time querying can scale to very large datasets with low latency, but their in-memory designs make them expensive to operate at the hundreds-of-PB scale.

OLAP. Online analytical processing (OLAP) systems, such as Druid [43], ClickHouse [35], and Napa [16], provide fast interactive analytics and are widely adopted in practice. Their columnar storage and vectorized execution are a good fit for many observability queries (e.g., scans with filters and aggregations). However, in cloud observability deployments, OLAP systems can become cost-inefficient due to high CPU and memory consumption, especially for wide tables, high-cardinality dimensions, and massive partition counts. Moreover, many existing deployments target PB-scale datasets, whereas cloud-scale observability can accumulate data at the EB scale, making the "scale-up more clusters" approach financially and operationally challenging.

SQL Engines. Modern SQL engines, such as Impala [27], Presto [36], and F1 Query [34], commonly adopt a storage–compute disaggregated architecture and provide full SQL support over large datasets. This model is attractive for flexibility and ecosystem integration. However, complex joins and global aggregations typically require runtime data reshuffling (e.g., repartitioning/shuffles), which can introduce substantial network overhead and sensitivity to stragglers. These characteristics make it difficult to achieve predictable low-latency, high-QPS performance for global observability, where queries frequently target "recent windows" and must remain responsive during incidents.

Cloud-native Data Warehouses. Cloud data warehouses, such as Snowflake [22] and Redshift [25], move the warehouse stack to managed cloud infrastructure to gain elasticity and simplified operations. To mitigate write throughput and query latency challenges, these systems often incorporate intermediate caching/buffering layers and rely on object storage as the durable backend. Nevertheless, they may incur additional data redundancy (e.g., multiple copies for performance) and provide limited flexibility for real-time observability analysis under heavy ingestion. Moreover, using a managed cloud warehouse as the foundation of observability introduces a circular dependency: the cloud service is relied upon to monitor itself, complicating failure diagnosis.

8 Conclusion

The complexity of modern cloud environments calls for a unified observability infrastructure. `DiTing` leverages underutilized resources and a layered architecture to streamline telemetry processing and storage. Beyond improving performance and reducing cost, `DiTing` also enhances reliability and scalability for cloud-scale observability.

Acknowledgments

We sincerely thank the OSDI'25 reviewers for their constructive feedback, which significantly improved both the technical content and the presentation. We also thank the OSDI'26 organizers for their help and support throughout the process. In addition, we are grateful to the EBS, ECS, and OSS teams for their long-term support in deploying and running `DiTing` at scale. Finally, we acknowledge the support of the Alibaba Research Fellow (ARF) program.

Abstract

Dynamic memory allocators provide memory allocation and release functionality to languages such as C, C++, and Rust. Existing allocators have been primarily optimized for performance and timely memory release. However, emerging mobile workloads also emphasize CPU, energy, and memory usage under soft real-time constraints.

We present jwmalloc, a novel memory allocator built from the ground up to address these mobile-specific challenges. It is based on three key innovations: a *uniform slab size with pooling* that enables immediate cross-size-class reuse of any emptied slab; the *closed sibling tree*, a new data structure for efficiently managing fragments; and a *two-buffer lifetime tracker* that categorizes short- and long-lived objects to guide memory reclamation. For timely response in soft real-time and oversubscription scenarios, all operations are non-blocking. We verified jwmalloc with a bounded model checker under weak memory models. Replacing jemalloc on a flagship smartphone running real-world workloads, jwmalloc reduces whole-system instructions by 10% and cuts allocator-side instruction counts by 3.84×, while lowering CPU power consumption by 5–11%, all at a comparable memory footprint. jwmalloc has been deployed in production on 12 million commercial mobile devices, operating stably for over 30 billion user hours.

1 Introduction

Dynamic memory allocation is a cornerstone of modern operating systems, with a direct and profound impact on overall performance, from warehouse-scale datacenters to personal mobile devices [40–44, 63, 65, 66, 68–71, 76, 86]. For example, recent Google studies report that allocator activity consumes roughly 7% of all CPU cycles in datacenters, noting that *"even a single percent CPU or memory improvement translates to significant savings in server costs"* [53, 87]. On mobile devices, the stakes are even higher: a few gigabytes of DRAM are intensely shared among dozens of applications and system services, making memory a constantly scarce resource [9, 15, 17]. Each component must minimize reserved memory, or the system resorts to aggressive paging and background app termination, visibly degrading user experience [26, 49]. Under this pressure, allocation activity is enormous: allocator instructions account for 8.2% and 12.4% of all executed instructions in real-world mobile workloads on Android and HarmonyOS, respectively (Fig. 1).

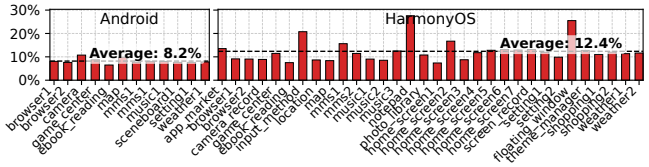

Figure 1: Fraction of CPU instructions spent in dynamic memory allocation with jemalloc under real-world mobile workloads on Android [3] and HarmonyOS [22].

Additionally, mobile workloads have unique challenges, of which we identify four: to avoid reserving new memory, allocations must frequently reuse memory that had been formatted for the prior object size, causing reformatting ❶; foreground and background phases [2], together with bursty user interactions and screen-off idle periods, induce large peak–trough memory swings ❷; short-lived objects [52] causing fragmentation during aggressive memory reclamation ❸; and heavy oversubscription ❹ on a few cores creating potentially high latency with traditional lock-based synchronization [36, 46].

An effective mobile allocator must account for these challenges while achieving the following objectives: (i) *low CPU and energy overhead* to avoid stealing cycles from application logic or triggering thermal throttling [82]; (ii) *bounded memory footprint* to ensure the fluidity of foreground apps and the residency of background processes [23]; (iii) *low tail latency* to prevent visible stuttering on high-refresh-rate displays [39]; and (iv) *correctness guarantees*, ensuring the allocator neither causes crashes nor corrupts memory.

However, despite widespread use of mobile devices [30],

✉ Ming Fu (ming.fu@huawei.com) is the corresponding author.

existing allocator designs do not adequately address these mobile-specific challenges, compromising some of these objectives. Allocators typically employ a two-level architecture: a small-object *slab* frontend [45] and a backend that manages virtual-memory ranges obtained from the OS at page granularity (hereafter, *ranges*). We analyze several allocators, including jemalloc [47], a *performance-oriented* allocator (Sec. 2.2) widely adopted on mobile devices, as well as other mature industrial allocators such as tcmalloc [67] and mimalloc [64], and identify several systematic mismatches.

First, existing frontends mishandle the trade-off between CPU cost and memory footprint for slabs. For example, jemalloc uses heterogeneous slab sizes (i.e., different slab sizes for different *size classes*) to reduce per-slab tail memory waste. However, this incurs high CPU overhead, as the backend must repeatedly subdivide and coalesce ranges to satisfy slabs of varying sizes when demand shifts across size classes (❶).

Second, existing backends contain *intermediate ranges* whose sizes do not match any slab size or large-object size class. These ranges cannot directly satisfy allocation requests but must first be subdivided or coalesced into usably-sized ranges, thereby increasing management and usage costs. In addition, the metadata used to manage ranges is effectively grow-only; under large peak–trough memory swings (❷), it is sized to the historical peak, forcing the allocator to carry substantial dead metadata even at steady state.

Third, existing memory reclamation policies (i.e., returning unused pages to the OS) are not lifetime-aware, leading to suboptimal decisions during aggressive memory reclamation (❸): neighbors of short-lived ranges may be reclaimed too early, missing opportunities to merge with soon-to-be-freed adjacent ranges, incurring extra overhead (e.g., system calls), while neighbors of long-lived ranges may be held too long, leaving memory unreclaimed with little benefit.

Finally, existing allocator data structures are commonly protected by coarse-grained locks, which leads to noticeable latency spikes under heavy oversubscription (❹).

This paper introduces jwmalloc, a new allocator designed from the ground up for mobile devices that addresses these core challenges. Our contributions are as follows:

(i) **Uniform and Pooled Slab Frontend** (Sec. 3.1): All slabs have the same size, allowing immediate reformatting for any frontend size class. We pool empty slabs in the frontend, skipping expensive coalescing of heterogeneous slabs and greatly reducing CPU during frequent slab reformatting (❶).

(ii) **Size-Class-Exact Range Backend** (Sec. 3.2): The set of maintained range sizes in the backend exactly matches the size-class set, eliminating inefficient intermediate ranges. This is realized with a *closed sibling tree*, a generalization of the buddy tree [54,75] in which each node can have more than two children, while maintaining the property that any contiguous subset of siblings can coalesce into a valid size class (hence "closed"). Additionally, we employ a size-friendly range subdivision and coalescing algorithm that tends to preserve large ranges, along with a metadata scheme that grows and shrinks with in-use ranges, keeping metadata overhead low during peak–trough memory swings (❷).

(iii) **Lifetime-Based Reclamation** (Sec. 3.3): jwmalloc employs *lifetime-based reclamation* that allows making good decisions while aggressively reclaiming memory (❸). This is realized with a *two-buffer lifetime tracker* emulating old and young generations in garbage collectors [52]. Short- and long-lived ranges are predicted efficiently without costly per-range timestamps or range scans. Memory neighboring long-lived ranges is reclaimed first, giving short-lived ranges time to be freed and coalesced with their neighbors.

(iv) **Non-Blocking Interface** (Sec. 3.4): jwmalloc's interface is designed to be non-blocking, avoiding high tail latency for operations under heavy thread oversubscription (❹). This is achieved by converting rare but potentially catastrophic blocking into brief, far less harmful memory waste.

(v) **Verification under WMMs** (Sec. 5): We employed bounded formal verification of jwmalloc's functional correctness (e.g., no memory corruption) and general properties (e.g., its memory safety, absence of data races, loop termination) under weak memory models (WMMs) [6,60] using the VSync toolchain [72].

We implemented jwmalloc as a drop-in replacement for state-of-the-art allocators and evaluated it extensively (Sec. 6). On microbenchmarks, jwmalloc improves performance by 74% over jemalloc on average and reduces allocator-side instruction counts by 82%. On a flagship smartphone running real-world workloads, jwmalloc keeps memory usage comparable to that of jemalloc, while reducing overall system instructions by 10% and cutting allocator-side instruction counts by 3.84×. In two representative workloads, it lowers CPU power consumption by roughly 5–11% across different core clusters. Finally, jwmalloc has been deployed in production and is in large-scale commercial use on 12 million mobile devices, including smartphones, tablets, and smartwatches, and has operated stably for more than 30 billion user hours.

2 Background

2.1 Dynamic Memory Allocators

Many modern memory allocators are organized into a *frontend* and a *backend* with distinct responsibilities [47, 64, 67]. The frontend is optimized for fast allocation and deallocation of small *objects*. It typically employs a *slab*-style allocator [45] and maintains per-thread structures to reduce contention in multithreaded workloads. The backend handles large allocations, manages the frontend's memory supply, interacts with the operating system via page-granularity interfaces, and implements caching and reclamation policies for free pages (i.e., returning them to the OS). Allocators maintain a set of *size classes*: predefined standardized allocation

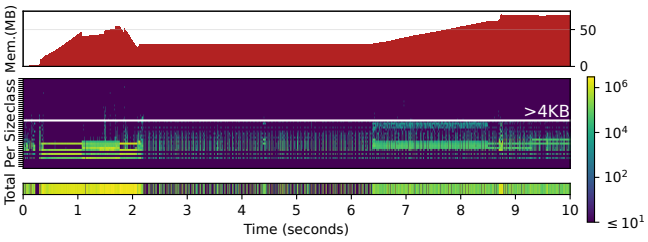

Figure 2: Allocation statistics for the system graphics service of a smartphone over a 10s interval. The first ∼2s correspond to service startup, and the last ∼3s to screen unlock and scrolling. Top: time series of allocator-managed memory in use. Middle: time–size heatmap of per-size-class allocation/free rates. Visually, size classes increase from 8B at the bottom to 16MB at the top; the white horizontal line marks 4KB, and each time slice is 1ms. Bottom: time–size heatmap of total allocation/free rates.

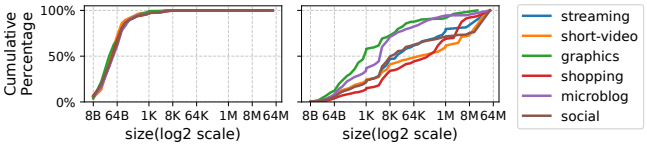

Figure 3: Cumulative distributions by allocation size for services and applications. Left: allocation **operations**. Right: allocated **bytes**.

sizes (e.g., 16B, 32B, 64B, 128B, ...) to which requests are rounded up to reduce fragmentation.

Consider a 100B allocation request. The slab frontend rounds this up to the corresponding size class (e.g., 128B) and serves it from a slab of that class (e.g., an 8KB slab). If no such slab is available, the frontend requests an 8KB range from the backend. If no such free range exists in the backend's cached ranges, the backend instead obtains a larger cached range (e.g., 24KB), carves out 8KB for the slab, and leaves the remaining 16KB available to serve other requests. When all objects in a slab are freed, the slab is returned to the backend as a free range; if its adjacent range (e.g., the 16KB remainder) is also free, the backend coalesces them into a larger range.

2.2 Performance-Oriented Allocators

There is a long-standing trade-off between performance and memory safety in memory allocator design. Performance-oriented allocators such as jemalloc, tcmalloc, and mimalloc prioritize performance over memory safety, making them susceptible to memory-safety issues like use-after-free [7] when the memory user contains bugs. In response, hardened allocators [24, 29, 76] like Scudo and PartitionAlloc emerged, introducing mitigations such as checksums and quarantines. However, these hardening mechanisms come at a significant performance cost; for instance, Bionic's tests show jemalloc

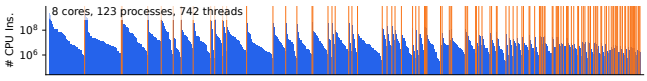

Figure 4: Statistics of processes and threads on a smartphone during the app_market benchmark. Each full-height vertical line (spanning the entire plot) marks a process boundary; within each region, the threads of that process are shown as vertical bars and ordered by executed CPU instruction count in descending order.

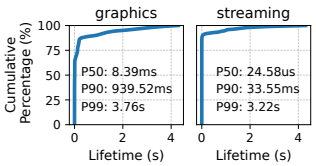

Figure 5: Cumulative percentage of page-granularity allocation lifetimes for the system graphics service and the streaming app.

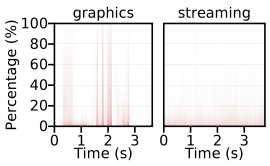

Figure 6: Proportion of cross-thread frees in the system graphics service and the streaming app over a ∼3s interval.

performing up to 4× faster than Scudo [25]. Consequently, the most expensive hardening features, such as Scudo's quarantine, are often disabled by default [29].

This landscape is now being reshaped by emerging technologies that address memory safety at the language and hardware levels. Newly written Android platform code is increasingly written in Rust as the next-generation solution for memory safety [28], and Google reports a 1000× reduction in memory-safety vulnerability density in Android's Rust code compared to C/C++ [38]. In the meantime, ARM's Memory Tagging Extension (MTE) [5] provides hardware-level memory safety checking with only ∼2% performance overhead [37].

Given these observations, as well as our own production-deployment experience (e.g., using large-scale hardware-assisted address sanitizer (HWASAN) deployments [12, 13] to detect memory-safety issues), this paper focuses on the design of a performance-oriented allocator and compares it against other performance-oriented allocators. How to integrate our design with existing memory-safety mechanisms is orthogonal to this work and left out of scope.

2.3 Mobile Allocation Workloads

We profile dynamic allocations across several high-frequency smartphone workloads. Due to space constraints, we show a subset of services and apps; the remaining workloads behave similarly. In general, allocation rates are high in all scenarios, especially during bursty interactions. For example, the bottom panel of Fig. 2 reports that the *system graphics service* (graphics) [10] reaches a peak allocation rate of roughly 3 million ops/s across all threads. Below, we summarize our

detailed observations.

❶ **Frequent memory reformatting.** The per-size-class panel (Fig. 2, middle) shows that activity is dominated by different size classes at different times, while total in-use memory (Fig. 2, top) remains roughly stable. Combined with the size distribution, where allocation counts are strongly skewed toward small sizes (Fig. 3, left) but the fraction of allocated *bytes* is much flatter (Fig. 3, right), this indicates frequent memory reformatting over time.

❷ **Large peak–trough memory swings.** Mobile applications switch between foreground and background phases [2], with bursty user interactions and screen-off idle periods [34]. Consequently, memory usage often exhibits large peak–trough swings. For example, in our measurements of graphics, peak memory usage exceeds 5× the steady-state usage.

❸ **Aggressive Reclamation.** Memory reclamation delays reach 5 to 15 seconds in server loads [19], but are often configured to 1 second or less in mobile [4]. Such short reclamation delays prevent page swapping, but may increase load if ranges are hastily reclaimed before they can be coalesced with neighboring ranges. Only memory near ranges that will anyways not be freed for a long time should be reclaimed immediately. The classical generational hypothesis [80] states that objects that survive for some time are likely to be long-lived. We observe the same in mobile workloads, indicating that a page with old objects is unlikely to be freed in the near future. Fig. 5 reports page-granularity allocation lifetimes. Most pages are freed shortly after allocation: in streaming, 90% of pages become unused within 33.55ms. Beyond this knee point, a small fraction remains allocated for much longer; for example, over 1% of streaming pages live longer than 3.22s.

❹ **High Oversubscription.** Fig. 4 illustrates an app-market installation scenario in which up to 742 threads are time-sliced on an 8-core device. In practice, big.LITTLE asymmetry [59] and power management can further reduce the number of effective cores [46], leading to high thread oversubscription and long delays between timeslices of the same thread. If the thread holds a lock, the delay is propagated to all threads contending on the lock. In existing allocators, this mostly affects *cross-thread frees*, where an object is allocated by one thread and freed by another. The free and further allocations on the same range contend on a lock protecting the range's metadata. Unfortunately, cross-thread frees are frequent in mobile workloads. Fig. 6 reports, for each 1ms time slice, the fraction of cross-thread frees. In the streaming app, most slices remain below 20% cross-thread frees, though short bursts can reach up to 80%. In mobile-typical producer-consumer architectures like graphics [11, 83] and event-driven architectures [48, 79], some slices approach nearly 100% cross-thread deallocation.

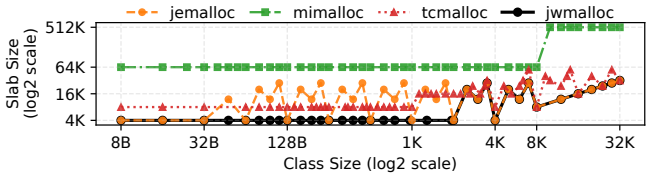

Figure 7: Slab sizes selected for each object size class up to 32KB (default allocator configuration; 4KB OS pages).

3 Our Approaches

3.1 Uniform and Pooled Slab Frontend

Slab-based allocators pack many equal-sized objects into each slab, creating a trade-off: too few objects make in-slab allocations infrequent and reduce performance, while *tail fragmentation* grows due to unused space at the page-aligned slab end. Conversely, any in-use object pins its slab, preventing it from being freed; having many objects per slab amplifies partial-slab persistence, defying reclamation (❸) and thereby inflating both peak and steady-state memory footprints in workloads with frequent memory reformatting and large peak–trough swings (❶ and ❷).

However, this trade-off is often ignored or mishandled by existing allocators. Fig. 7 shows each allocator's *slab size* per size class. mimalloc uses only two large slabs (64KB and 512KB) for simplicity and performance, allowing many objects per slab (e.g., 8192 for an 8B object) and negligible tail fragmentation, but at the cost of a high footprint on mobile workloads (Sec. 6). tcmalloc balances slab sizes to avoid excessive pinning or low performance. jemalloc aggressively reduces footprint by setting a tail-fragmentation threshold and selecting, for each size class, the smallest OS-page-aligned slab size that meets it, yielding heterogeneous slab sizes. This reduces tail waste but increases backend churn when demand shifts across sizes (❶), as more frequent subdivision and coalescing are required, raising CPU overhead (Sec. 6).

To maintain a memory footprint comparable to jemalloc while avoiding its drawbacks, we introduce two changes: (i) *Uniform slab size*: instead of fixing size classes and adjusting slab sizes for each to reduce tail fragmentation as in jemalloc, we fix the slab size and adjust the size classes to keep tail fragmentation below a target cap. In our setting, we use a uniform slab size of one OS page for all size classes of at most half a page. For example, for a 4KB slab containing 128B of metadata, a 512B size class leaves 384B wasted at the slab tail (`(4096-128) mod 512 = 384`), whereas tuning the size class to 560B reduces tail waste to 48B (`(4096-128) mod 560 = 48`). (ii) *Slab pooling*: freed slabs of this uniform size are cached as per-thread plain memory and can later be reinitialized as slabs for any frontend size class. Such pooling is impractical with heterogeneous slab sizes due to memory-footprint constraints.

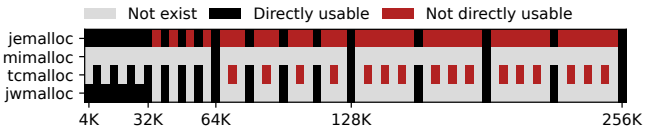

Figure 8: Ranges managed by each allocator. Subdivided ranges are shown in non-gray; directly usable ranges appear in black, intermediate ranges in red.

3.2 Size-Class-Exact Range Backend

3.2.1 Eager Subdivision and On-demand Coalescing

Allocator backends subdivide and coalesce memory ranges to supply slabs and large objects. mimalloc's backend is slab-style: each range is divided into equal-size subranges serving only a single size class. Memory of a range can be reformatted for another size class only once all its subranges are freed. By contrast, tcmalloc and jemalloc manage memory at finer granularity (8KB in tcmalloc; 4KB in jemalloc), allowing subranges to be reformatted independently. For example, a 40KB range can first serve a 16KB object and a 24KB object, and, after the latter is freed, its memory can be immediately reassigned to an 8KB object.

However, their range subdivision method introduces additional CPU overhead. On an allocation demand, they first search for a range of the requested size; if none exists, they select a larger range, split off the required portion, and manage the remainder for further requests. This process produces many intermediate ranges at multiples of the granularity that often do not match any size class (Fig. 8), which increases management and lookup costs. For example, tcmalloc maintains hundreds of size-indexed entries for such ranges. To serve a 224KB request, it probes sizes in ascending order: 224KB, 232KB, 240KB, and so on, leading to higher overhead.

Moreover, they use an eager range coalescing strategy that immediately merges adjacent free ranges, which can be inefficient if the merge produces an intermediate range. For instance, freeing a 224KB range that merges with an adjacent 24KB range yields 248KB. If no size class exists between 224KB and 256KB, the resulting 248KB range cannot be used directly; a subsequent 224KB request will subdivide it again, creating churn and wasting CPU cycles.

To address this, we adopt *size-class-exact ranges* and the following approach: (i) *Eager subdivision*: each range can be subdivided into multiple subranges, one matching the requested size class and the remaining subranges each matching some size class; (ii) *On-demand coalescing*: ranges are coalesced only when the merged size matches a size class. Consequently, the maintained range sizes exactly match the size-class set, greatly reducing these costs.

Table 1: Examples of resolution-R size-class sets for $R \in \{1,2,3\}$ with 8B object alignment. For each R, we list the first eight size classes along with their binary representations.

R	First eight size classes (bytes)							
1	8B 1000_2	16B 10000_2	32B 100000_2	64B 1000000_2	128B $100\ldots0_2$	256B $100\ldots0_2$	512B $100\ldots0_2$	1024B $100\ldots0_2$
2	8B 1000_2	16B 10000_2	24B 11000_2	32B 100000_2	48B 110000_2	64B 1000000_2	96B 1100000_2	128B 10000000_2
3	8B 1000_2	16B 10000_2	24B 11000_2	32B 100000_2	40B 101000_2	48B 110000_2	56B 111000_2	64B 1000000_2

3.2.2 Closed Sibling Tree

The above policy requires a range-management scheme that maintains these size-class-exact ranges. Modern allocators carefully choose size classes to balance internal fragmentation and range reuse: if the size-class set is too sparse, rounding up causes large internal fragmentation (e.g., 9KB to 16KB); if it is too dense, allocations cannot effectively reuse freed ranges from nearby sizes (e.g., a 9KB request rounded up to 12KB cannot satisfy a subsequent 14KB request, but rounding it up to 16KB would work), which is particularly important under frequent memory reformatting (❶). To balance this trade-off, allocators usually use a fixed *resolution-R size-class set*, which bounds the worst-case roundup-induced internal fragmentation rate to at most $1/2^{R-1}$. An allocation request of size n rounds up to the smallest size class $s \geq n$ in which only the R most significant bits of s's binary representation may be non-zero. For example, for $n = 21$ and $R = 3$, 10101_2 is rounded to 11000_2, i.e., $s = 24$. Table 1 shows the first eight size classes for $R \in \{1,2,3\}$ with 8-byte object alignment, along with their binary representations. Most modern allocators [47, 64, 67] use $R = 3$, which corresponds to a worst-case roundup-induced internal fragmentation of 25%.

However, existing range-management schemes cannot maintain a set of range sizes that exactly matches a resolution-R size-class set for arbitrary R. mimalloc's backend manages only two range sizes (64KB and 512KB), while jemalloc's and tcmalloc's backends operate at fixed granularities of 4KB and 8KB, respectively. Classical buddy allocators [54, 75] manage ranges whose sizes are powers of two (2^k), which corresponds to a resolution-1 size-class set. Weighted buddy [78], dual buddy [74], and tertiary buddy [85] extend this by also supporting sizes of the form 3×2^k, and thus can realize a resolution-2 size-class set. Other buddy variants, such as Fibonacci buddy [51, 55], produce range sizes that only partially overlap a given resolution-R size-class set.

We propose the *closed sibling tree*, whose range set can realize any resolution-R size-class set. Each node of the tree represents a range whose size is a size-class size. Subdivision creates two or more child nodes that partition the parent range; each child again has a size-class size. Any contiguous sequence of siblings coalesces into a range whose size is also a size-class size. A formal definition appears in Sec. 4.2.2. In practice, we use the tree to manage a resolution-3 size-class

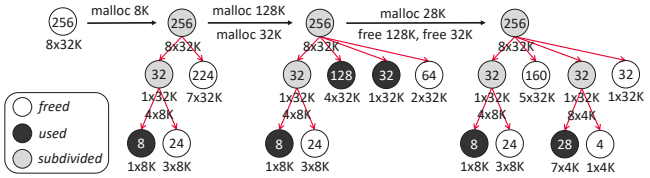

Figure 9: Example of a closed sibling tree on a 256KB range.

set, consistent with modern allocators. We also provide efficient subdivision and coalescing algorithms on this tree. For eager subdivision, we use a size-friendly scheme that tends to preserve large ranges. On-demand coalescing is straightforward: we coalesce adjacent siblings under the same parent.

As an example in Fig. 9, consider a closed sibling tree whose root represents a 256KB range. An 8KB allocation would split it into 8KB and 248KB, but 248KB is not a size-class size. Instead, our algorithm (Sec. 4.2) first carves out a 32KB child, leaving a 224KB child that *is* a size-class size, then subdivides the 32KB child to obtain the requested 8KB, with the remaining 24KB also being a size-class size. Subsequent 128KB and 32KB allocations are served by repeatedly subdividing the 224KB child, eventually leaving a 64KB child; all of these ranges are siblings under the 256KB parent. Later, a 28KB allocation cannot simply split the 64KB child into 28KB and 36KB, because 36KB is not a size-class size. Instead, the algorithm first splits 64KB into two 32KB children and then subdivides one 32KB child into 28KB and 4KB, both of which are size-class sizes. When the 128KB and 32KB children are subsequently freed, these two adjacent siblings coalesce into a single 160KB node, which is a size-class size.

3.2.3 Per-Granule Metadata with Metadata Shifting

Allocator backends face a challenge in balancing metadata lookup efficiency with memory overhead. mimalloc leverages a large range granularity (i.e., 64KB) to employ *per-granularity metadata*, which enables fast address-to-metadata lookups via direct array indexing with minimal memory cost. In contrast, finer-granularity allocators such as jemalloc and tcmalloc cannot afford the overhead of per-granularity metadata and instead rely on *per-range metadata* managed by more complex structures like radix trees. This approach, however, suffers from a major limitation beyond its performance drawbacks: to support multi-threaded performance, metadata records are reused across ranges but are never freed. Consequently, during large peak–trough memory swings (❷), metadata capacity grows with peak usage but fails to shrink at steady state, leading to substantial memory bloat.

To overcome this limitation, we compress the tree's metadata significantly, enabling it to afford fast, per-granularity metadata (12B per 4KB granularity) that is fully reclaimable once its managed ranges are all freed. We adopt a novel *metadata shifting* approach, making the tree entirely pointer-free even with irregular node sizes: the conceptual two-dimensional tree is mapped to a one-dimensional array; internal nodes are encoded into leaf nodes to eliminate parent pointers; and movement between siblings at the leaf level is based on address offsets between siblings, computed from range sizes and tree information (e.g., depth, sibling index) rather than explicit pointers. For example, in Fig. 9, a 256KB range contains 64 metadata nodes (256KB/ 4KB). When the 32KB node shown is freed, its left and right siblings have sibling indices 1 and 6, while the current node's index is 5 (first sibling = 0). Each index corresponds to a distance of 8 nodes (32KB/ 4KB), so the left and right siblings are at offsets of (1 - 5) $\times$ 8 and (6 - 5) $\times$ 8 relative to the current node.

3.3 Lifetime-Based Reclamation

When memory ranges are freed, the allocator caches them temporarily to avoid repeated kernel allocation and deallocation, then eventually releases them to the OS if they are not reused. tcmalloc uses an *asynchronous*, *rate-based reclamation* policy: a background reclamation thread returns cached ranges to the OS at a rate that is tuned either by the user or based on recent allocation activity. However, it lacks timing guarantees for when these ranges will be reclaimed, which is undesirable for mobile workloads: during periods of high allocation and free rates, often coinciding with system-wide high load, tcmalloc may defer reclamation even while other components are competing for memory (Sec. 6.1.2).

mimalloc uses a *synchronous*, *time-based reclamation* policy: each freed range is cached for a fixed interval, after which it is returned to the OS. This policy interacts poorly with the foreground/background behavior [2] of mobile applications. Once an app moves to the background and its allocation and free rates drop sharply, reclamation is rarely triggered, allowing cached ranges to remain resident for a long time (Sec. 6.1.2). Moreover, it requires periodically scanning ranges to check for expiry, wasting CPU cycles.

jemalloc uses an asynchronous, time-based reclamation policy: it divides time into epochs and, at the start of each epoch, computes how much cached memory to reclaim and spreads this work across the epoch. If cached memory exceeds a threshold, it may run extra reclamation before the next epoch. This policy has been battle-tested on mobile devices, but it still has drawbacks. Although it imposes an approximate upper bound on reclamation time, it offers no lower bound. A range may be reclaimed shortly after being freed, even when its adjacent range is about to be freed as well. Waiting slightly longer could allow them to coalesce into a larger range that can satisfy future large requests, potentially avoiding an extra system call if these ranges are eventually returned to the OS.

However, blindly delaying reclamation only increases the memory footprint. Instead, we ask: given a fixed reclamation budget, which ranges should we reclaim first and which should we defer to maximize coalescing? Mobile workloads

follow the generational hypothesis: once a range survives past the knee point, it is likely to remain live much longer, so we prefer to reclaim its adjacent range first. For example, consider five contiguous subranges (1–5). Suppose subranges 1, 3, and 5 are cached, subrange 2 is long-lived, and subrange 4 is short-lived; thus, we prefer to reclaim subrange 1 first.

To this end, we propose a *lifetime-based reclamation* policy. A range starts a countdown once it has no mergeable siblings. If, before the timer expires, one of its siblings is freed and coalesces with it, the countdown is reset; otherwise, the range becomes eligible for reclamation.

A naive implementation of this policy would mirror mimalloc's approach and require scanning all cached ranges, which is expensive. Instead, we implement it using a *two-buffer lifetime tracker*, consisting of an *active buffer* and a *standby buffer*. Freed and coalesced ranges are always placed in the active buffer. Allocations first consult the active buffer; if empty, they consult the standby buffer. A reclamation thread repeatedly performs the following steps: (i) swap the roles of the two buffers, (ii) wait for an interval Δ, and (iii) reclaim all ranges in the standby buffer. This avoids per-range timestamps and full-range scans, significantly reducing CPU load.

Under normal conditions, reclamation is handled asynchronously by the reclamation thread. However, under heavy oversubscription (❹), this thread may not be scheduled promptly, as we observed. To address this, we combine asynchronous and synchronous reclamation: when the number of cached ranges exceeds a watermark, newly freed ranges are immediately reclaimed by the freeing thread, and we trigger an early buffer swapping by waking the reclamation thread, thereby reducing Δ. This mixed reclamation scheme continues until the number of cached ranges drops below the watermark.

3.4 Non-blocking Interface

Allocators need to synchronize between threads accessing the same metadata, for example, during cross-thread frees. In mimalloc, this is synchronized via a concurrent bitmap that controls uniform-sized slabs in the backend; however, it pins ranges to their owning thread, preventing them from migrating to other threads until all subranges have been freed. In contrast, jemalloc and tcmalloc use backend structures shared across threads. These structures are more complex and therefore rely on locks for concurrency control. On heavily oversubscribed workloads (❹), such locks can cause priority inversion [36]: a low-priority thread may hold an allocator lock and be preempted, while a high-priority thread (e.g., the UI rendering thread) waits for the lock, stalls on memory allocation, and causes visible stuttering. Although such events are much rarer than the common case, they are highly disruptive when they do occur.

We therefore design allocator interfaces (e.g., malloc and free) to be non-blocking [50]. Our key observation is that we can turn rare but catastrophic blocking into brief and far less harmful memory waste instead. For each allocation or free operation, the corresponding size class first consults a bounded concurrent bitmap as the primary path. When this bitmap is empty or full, it falls back to a locked, unbounded doubly linked list. If acquiring the lock fails, the operation still does not block: instead, an allocation tries to obtain a larger range from another size class and subdivides it, while a free pushes its range onto a concurrent singly linked list and returns; later operations complete the deferred free.

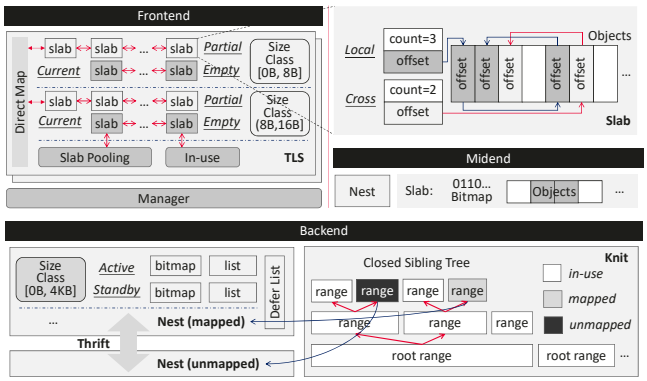

Figure 10: The overall system architecture.

4 Design and Implementation

jwmalloc is organized into three tiers (Fig. 10): frontend, midend, and backend. The frontend is slab-style with a uniform slab size equal to the OS page size (4KB). It maintains *thread-local storage* (TLS) for each thread and a *manager* that creates and destroys TLS. The backend manages virtual memory at OS-page granularity with one instance per process. Allocations smaller than 2KB are served by the frontend (Sec. 4.1). Objects between 2KB and 16KB would incur excessive tail fragmentation if handled by either the frontend or backend (both operate at 4KB granularity), so we introduce a per-process, slab-style midend for these allocations (Sec. 4.3). The backend handles allocations from 16KB up to 4MB and supplies memory for slabs used by both frontend and midend (Sec. 4.2). Allocations larger than 4MB are obtained directly via system calls. These size boundaries are chosen based on observed mobile workloads and are tunable per system configuration.

4.1 Frontend

The TLS manages multiple size classes, each with two doubly linked lists: a *partial list* for slabs with some free objects and an *empty list* for fully free slabs. To accelerate allocation, it uses a *direct map* [64], an array of slab pointers indexed by allocation size (8-byte aligned), each pointing to the *current slab*, i.e., the head of the partial list for that size class. The

TLS also maintains a shared slab pool connecting empty slabs across all size classes. When a size class requires an empty slab, it first checks its empty list and falls back to the shared pool if needed. To bound the pool, a watermark proportional to the total slab count ensures that least-recently-used empty slabs are returned to the backend when exceeded. Finally, the TLS tracks all managed slabs in an *in-use list*, and when a thread is destroyed, its slabs are handed to the reclamation thread (Sec. 4.2) for draining and reuse.

Within each slab, slab metadata resides at the slab head, preceding the objects it manages. Per-object metadata is overlaid on the objects themselves, with freed objects having their memory reinitialized to store the metadata. Cross-thread frees follow mimalloc's design, returning freed objects to the allocating thread. Each slab has an *owner thread* and two *free lists*: a *local list* for objects freed and reused by the owner, and a *cross list* for objects freed by other threads. The owner drains the cross list into the local list either periodically, to check slab reclaimability, or on demand, when allocating from a slab with an empty local list. However, unlike mimalloc's draining, which traverses the entire cross list, we optimize with *batched draining*: each cross list maintains a slab-relative head offset and free-object count (Fig. 10), atomically updatable together. During periodic draining, only the count is consulted, leaving the list intact to avoid expensive singly-linked-list merges; during on-demand draining, both the head and count are moved to the empty local list with a single atomic write.

4.2 Backend

The backend comprises three logical components (Fig. 10): (i) *Nest*, which maintains the search structure used during allocation and deallocation, organizing ranges by size and using fetch() and place() to select suitable ranges for each request (Sec. 4.2.1); (ii) *Knit*, which manages contiguous virtual-memory ranges, providing split() and join() to subdivide and coalesce them (Sec. 4.2.2); and (iii) *Thrift*, which manages cache watermarks and invokes reclaim() to release cached memory when thresholds are exceeded (Sec. 4.2.4).

Figure 11, lines 1–15, illustrates the range fetch() and place() operations, as well as split() and join() during allocation or deallocation. For a fetch(), the backend first attempts to acquire a range (acq_self). If the acquired range exactly matches the requested size, it is returned directly; otherwise, it is subdivided (split) and the remainder is released back (rel). Under eager subdivision (Sec. 3.2), this process may repeat. On a place(), the freed range is released directly if *adjacent* siblings cannot be acquired (acq_sibling); otherwise, it coalesces with the acquired sibling (join) and repeats until no further adjacent siblings can be acquired. Range acquisition and release may be concurrently accessed by multiple threads, requiring concurrency control, which is implemented via ownership transfer [73, 81] (Sec. 4.2.3).

```
1  fetch(sz) {
2    r := acq_self(sz);
3    while (r.size != sz) {
4      r, r' = split(r);
5      rel(r');
6    }
7    return r;
8  }
9
10 place(r) {
11   while(r'=acq_sibling(r)){
12     r = join(r, r');
13   }
14   rel(r);
15 }
16
17 acq_self(sz) {
18   r := nest_acq(sz);
19   if (knit_acq(r))
20     return r;
21   nest_acq_undo(r);
22   retry;
23 }
24
25 acq_sibling(r) {
26   r' := r.sibling;
27   if (!knit_acq(r'))
28     return null;
29   if (nest_acq(r'))
30     return r';
31   knit_rel(r');
32   return null;
33 }
34
35 rel(r) {
36   if (!nest_rel(r)){
37     nest_defer(r);
38   } elif (!knit_rel(r)){
39     nest_rel_undo(r);
40     nest_defer(r);
41   }
42 }
```

Figure 11: Pseudocode of backend operations.

4.2.1 Mapped and Unmapped Ranges

We maintain two Nests: a *mapped* Nest for ranges with physical pages attached, and an *unmapped* Nest for ranges without physical pages. A range allocation request first searches the mapped Nest; if no sufficiently large range is found, it falls back to the unmapped Nest; if that also fails, a 4MB *root range* is requested from the OS. On range free, if synchronous reclamation is not triggered, ranges are first returned to the mapped Nest and later moved to the unmapped Nest by the asynchronous reclamation thread (Sec. 4.2.4) [1]. If synchronous reclamation is triggered, ranges are inserted directly into the unmapped Nest. Before insertion, madvise [20] is called to discard the physical pages of the range.

Each Nest maintains multiple size classes. For each size class, the mapped Nest keeps two buffers of identical structure, an active buffer and a standby buffer, which together support the lifetime-based reclamation policy (Sec. 3.3). The unmapped Nest maintains only an active buffer. Each buffer contains a bounded bitmap and an unbounded linked list for additional ranges. fetch() and place() consult the bitmap first, falling back to the list if necessary. All size classes share a single deferred list to support non-blocking (Sec. 3.4).

4.2.2 Subdivision and Coalescing of Ranges

Knit manages multiple 4MB root ranges, each underlying a closed sibling tree. Range subdivision and coalescing operate on these trees. We formally define the size-class set and the closed sibling tree below. In our setting, a node's weight represents the number of OS pages in the range.

Definition 1 (Resolution-R size-class set)**.** *The resolution-R*

[1] Note that a range in the mapped Nest may not have physical pages if it was originally allocated from the unmapped Nest and then freed into the mapped Nest without triggering paging.

Algorithm 1: MULTI-STEP-SPLIT(X,Y)

Input: a node v of weight X; target weight Y
Precondition: $X \in S(R)$, $Y \in S(R)$, $0 < Y \leq X$
Output: a subtree rooted at v
Postcondition: the subtree is a resolution-R closed sibling tree; some node has weight Y
Begin:
write $X = n_1 \times 2^{m_1}$ with $m_1 \geq 0$ and n_1 the *largest* integer such that $1 \leq n_1 \leq 2^R$
write $Y = n_2 \times 2^{m_2}$ with $m_2 \geq 0$ and n_2 the *smallest* integer such that $1 \leq n_2 \leq 2^R$
if $m_1 \leq m_2$ **then**
  if $X \neq Y$ **then**
    split v into nodes with weights Y and $X - Y$
else
  $Z \leftarrow \lceil Y/2^{m_1} \rceil \times 2^{m_1}$
  split v into nodes with weights Z and $X - Z$
  MULTI-STEP-SPLIT(Z,Y)

size-class set $S(R)$ is defined as

$$S(R) = \{ n \times 2^m \mid m,n \in \mathbb{N},\ 1 \leq n \leq 2^R \}.$$

Definition 2 (Resolution-R closed sibling tree)**.** *A tree T is called a resolution-R closed sibling tree if:*

- *For every node v, its weight $w(v)$ is in $S(R)$.*
- *For any node v with children $c_1, \ldots, c_N$, we have $w(v) = \sum_{i=1}^{N} w(c_i)$, and for all $1 \leq p \leq q \leq N$, $\sum_{i=p}^{q} w(c_i) \in S(R)$.*

Coalescing merges contiguous siblings under the same parent. Once all children of a node have been coalesced, the parent becomes eligible to merge with its own siblings. For subdivision, we introduce the MULTI-STEP-SPLIT algorithm (Alg. 1), which executes the split steps shown in Fig. 11, lines 3–4.

We illustrate MULTI-STEP-SPLIT with an example. Suppose we want to subdivide a 6-page range from a 64-page range under a resolution-3 setting (i.e., $R = 3$, $X = 64$, and $Y = 6$). The max-n decomposition of 64 is 8×2^3, and the min-n decomposition of 6 is 3×2^1. Since $m_1 > m_2$, the recursive case applies: we compute $Z = \lceil 6/8 \rceil \times 8 = 8$, split 64 into two children of weights 8 and 56, and recurse on the child of weight 8. For MULTI-STEP-SPLIT$(8,6)$, we have $8 = 8 \times 2^0$ and $6 = 3 \times 2^1$, so $m_1 \leq m_2$ and $X \neq Y$, which triggers the direct case, splitting 8 into 6 and 2. In this example, the construction obtains the 8-page subrange from the 64-page range in a single step, leaving a contiguous 56-page range available for other large requests. In contrast, a naive binary splitting scheme (e.g., $64 \to 32 \to 16 \to 8$) requires three steps to reach 8, and the intermediate nodes cannot serve the 56-page request.

4.2.3 Ownership Transfer of Ranges

Conceptually, a range allocation transfers ownership of a suitable range from the backend to the requester, while a free operation transfers ownership back to the backend. Within the backend, a range is co-owned by Nest and Knit: acq must obtain ownership from both components, and rel must release it to both. Since these two ownerships cannot be acquired or released atomically, inconsistent states can arise, in which one component succeeds while the other fails. For example, when a free operation attempts to acquire a range's adjacent sibling in Knit to coalesce with it, a concurrent allocation may have already acquired that sibling range from Nest.

To handle this, ownership transfer follows a staged protocol with rollback (Fig. 11). acq_self first locates a suitable range and acquires its Nest ownership (nest_acq), then attempts to acquire its Knit ownership (knit_acq). If the Knit acquisition fails, it rolls back the Nest acquire (nest_acq_undo) and retries a bounded number of times at the same size; if these retries fail, it falls back to a larger range, ensuring a non-blocking path. acq_sibling first acquires the adjacent sibling in Knit, then in Nest; if the Nest acquisition fails, it releases the Knit ownership (knit_rel) and returns null. rel first attempts to release Nest ownership. If this fails, the range is placed on the deferred list (nest_defer) and the operation returns. Otherwise, it releases Knit ownership. If the Knit release fails, it rolls back the Nest release (nest_rel_undo), places the range on the deferred list, and returns. Deferred ranges are later drained either by the asynchronous reclamation thread (Sec. 4.2.4) or synchronously on demand when a nest_acq fails to find a suitable range (e.g., at line 18 when r.size $>$ sz); draining simply re-invokes place() on all deferred ranges.

Each range has three states: inuse (currently in use or on the deferred list), mapped (present in the mapped Nest), and unmapped (present in the unmapped Nest). In Knit, knit_acq for a range r requires that r is not inuse, preventing it from being acquired twice. When releasing a range r to the mapped Nest, Knit must ensure that none of r's adjacent siblings is already mapped; similarly, when releasing to the unmapped Nest, none of them is unmapped. This guarantees that free adjacent siblings can always be coalesced if they are in the same state. The states of all siblings under the same parent are packed into a single atomic variable. If any of these conditions fail, knit_acq or knit_rel returns false; otherwise, it atomically updates r's state via compare-and-swap [50]. In Nest, nest_acq and nest_rel acquire and release ownership in the underlying generic structures, i.e., bitmaps and lists.

4.2.4 Asynchronous Reclamation

The reclamation thread repeatedly performs the following steps: (i) drain slabs handed off from TLS instances whose threads have been destroyed (Sec. 4.1); (ii) traverse the deferred list of each size class in both the mapped and unmapped Nests and call place() on each range to complete deferred re-

leases (Sec. 4.2.3); (iii) swap the ready and standby buffers (Sec. 3.3); (iv) perform a futex wait [8] with a timeout (500ms in our setting), possibly being woken early by synchronous reclamation (Sec. 3.3); and (v) for each size class in the mapped Nest, apply madvise to all ranges in the standby buffer to discard their physical pages, then move those ranges to the corresponding size class in the unmapped Nest.

4.3 Midend

The midend uses a Nest similar to the backend's mapped Nest, but with only the active buffer. It manages *midend slabs*, each containing multiple objects of size 2KB–16KB. An allocation selects a corresponding slab from the Nest; if this turns the slab from partial to full, it is removed from the Nest. On object free, if the object's slab changes from full to partial, it is reinserted into the Nest; if it changes from partial to empty, it is returned to the backend as a free range. Each slab uses a bitmap with atomic bit operations to track its objects and implement these state transitions (Fig. 10). The midend shares metadata with the backend: when a range is initialized as a midend slab, the backend Nest's fields for that range become unused, and the memory is repurposed to hold the midend Nest's metadata, such as list links and the slab's bitmap.

5 Verification under Weak Memory Models

jwmalloc is a complex allocator that lies on the critical path of virtually all system services and applications on the device. Any bug can cause severe failures, such as memory corruption that may only manifest far from the point where it actually occurs. In concurrent settings, especially under weak-memory models, such bugs are particularly difficult to reproduce and diagnose. To mitigate this risk, we employ bounded formal verification to increase confidence in jwmalloc's correctness.

Traditional approaches based on manual, machine-checked proofs (e.g., large Coq developments [84]) are prohibitively labor-intensive for a production allocator of this complexity. More recent frameworks such as RefinedC [77] and Verus [61, 62] reduce the proof burden but reason only under sequential consistency, leaving executions arising from weak-memory behaviors, which are often more error-prone, unchecked. For mobile allocators, this limitation is particularly relevant, as mobile hardware is dominated by architectures like ARM that implement weak memory models.

To balance verification coverage against engineering effort, we adopt the VSync bounded model-checking approach [56–58] that automatically verifies a library (here: jwmalloc) against small multi-threaded test cases under weak-memory models. In this approach, like in testing, the test cases act as functional specifications of the library by means of assertions; unlike testing, *all* weak-memory executions of the library on the test cases are explored, and generic properties such as memory safety, absence of data races, and loop termination, are also verified on each execution. Therefore, verification is complete within the bounds set by the tests, while corner cases not covered by tests are not verified.

Note that the number of executions grows rapidly with the complexity of the test cases, such as the number of threads and library API calls. Since all these executions are explored, the test cases need to be engineered to achieve a good balance between verification time and coverage. We achieve this in the following ways:

First, we fully decouple jwmalloc's components. The frontend, midend, and backend each provide a standard malloc/free-style interface and interact with other components only through these interfaces. During verification, each component is treated as a conventional C library rather than an allocator. For example, the frontend exports *frontend_malloc* and, in production, obtains its slabs via *backend_malloc*; during verification, it uses the system allocator's standard *malloc*, treated by the verifier as a standard library with verification deliberately skipped. This modularity allows verification of components both in isolation and in combination.

Second, we partition the client program into multiple specialized clients, each targeting specific edge cases. For example, the frontend exposes concurrency scenarios such as cross-thread frees, on-demand draining, periodic draining, and thread creation and destruction. We construct multi-threaded clients where each thread invokes the relevant API operations a bounded number of times, triggering these scenarios while keeping verification time manageable.

Finally, we shrink jwmalloc's configuration by scaling down certain constants, for example, reducing the backend bitmap from 64 to 2 entries, without changing the code logic.

With the mechanisms described above, we ensure that verification of each client completes within 10 minutes. This verification uncovered a previously unknown bug during the development of jwmalloc. The bug originates from the backend's closed sibling tree, which employs a metadata-shifting design. For the root node, which has no siblings, this design mistakenly assumes a sibling exists and attempts to access its state along one code path, causing out-of-bounds reads in the data area and resulting in a crash only when the data area contains specific values. Using a client targeting the backend, the model checker can expose this bug in roughly ten seconds and reports an error due to accessing uninitialized memory.

6 Evaluation

We compare jwmalloc against widely-used industrial allocators, including mimalloc [21] v2.1.8, jemalloc [18] v5.3.0, and tcmalloc [33] from gperftools-2.16, across various workloads. All allocators were run with their default configurations and profiling disabled.

Hardware instruction counts. We first analyze hardware instruction and conditional-branch counts for in-slab operations

Table 2: Instruction and branch counts on x86 for in-slab operations. Each cell reports "instructions & branches".

Operation	**jwmalloc**	jemalloc	mimalloc	tcmalloc
alloc	**16 & 1**	27 & 3	17 & 2	36 & 6
local free	**22 & 3**	38 & 4	26 & 4	36 & 5
cross-thread free	**29 & 5**	>100 & >10	72 & 9	>100 & >10

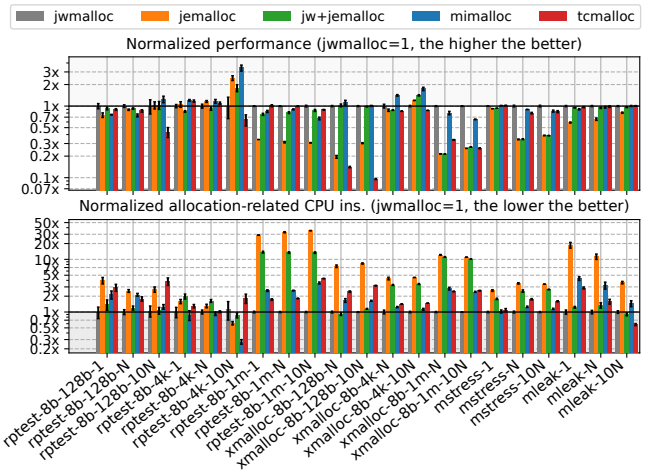

Figure 12: Comparison of performance (top) and CPU instruction counts (bottom).

in each allocator. As shown in Table 2, jwmalloc executes fewer instructions than the other allocators, particularly for cross-thread frees, where it reduces the instruction count by over 70% compared to jemalloc. This low instruction cost contributes to jwmalloc's performance and load advantages.

6.1 Micro-benchmarks

Admittedly, microbenchmarks cannot fully capture the complexity of real-world workloads, but they do reveal how allocators behave under simple synthetic workloads. We select four open-source benchmarks, namely rptest, xmalloc, mstress, and mleak, to exercise four scenarios: predominantly thread-local allocate/free, cross-thread frees, diverse object lifetimes, and frequent thread creation and destruction [27, 31, 32]. To avoid noise from background services on smartphones, we run these benchmarks on a server [16] using 4 cores and different thread counts to emulate mobile behavior. We vary each benchmark's allocation-size range while keeping its default size distribution. For example, rptest-8B-128B-10N denotes rptest with allocation sizes in [8B, 128B] and 10N threads, where N is the number of cores. To better isolate the effect of jwmalloc's frontend, we also pair it with jemalloc's backend; we denote this variant as jw+jemalloc.

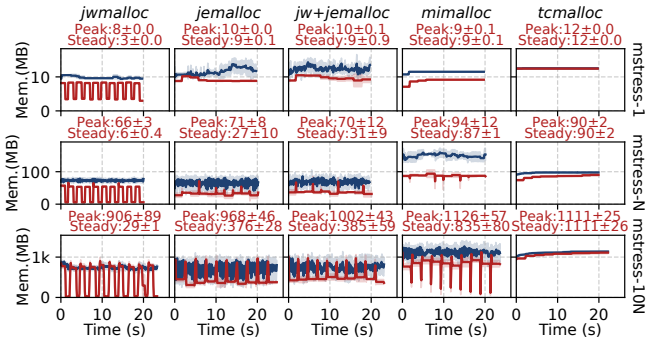

Figure 13: Memory footprint comparison for the original (blue) and sleep-augmented (red) mstress workloads. Shading indicates the standard error.

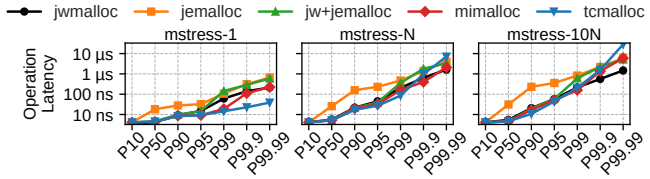

Figure 14: Operation latency comparison (lower is better).

6.1.1 Overall Performance and CPU Overhead

As shown in Fig. 12, even with only the frontend, jwmalloc substantially outperforms jemalloc. For instance, jw+jemalloc is 24% and 4.1× faster than jemalloc on rptest-8B-128B-1 and xmalloc-8B-128B-N, respectively, highlighting the benefits of our frontend. With both frontend and backend enabled, jwmalloc leads the other allocators in nearly all workloads, especially in reducing instruction counts. On average, it improves performance by 74% over jemalloc and reduces allocator-side instructions by about 82%. On rptest-8B-128B-1, jwmalloc outperforms jemalloc, mimalloc, and tcmalloc by 25%, 24%, and 10%, respectively. On rptest-8B-1MB-N, allocator-side instruction counts for jemalloc, mimalloc, and tcmalloc are 32.8×, 2.55×, and 1.81× those of jwmalloc, underscoring the strength of our backend design.

There are a few scenarios where jwmalloc shows modest regressions in performance or load, notably the rptest and xmalloc workloads with the 8B-4KB-10N configuration. One reason is that a nontrivial fraction of the allocation-size distribution lies near 4KB; for these sizes, jwmalloc's unified slab-size design deliberately trades some performance. Another reason is that 10N represents a heavy oversubscription in microbenchmarks; under such workloads, jwmalloc remains non-blocking but incurs additional work, resulting in some performance loss.

6.1.2 Memory Footprint

We use mstress to study allocator memory behavior. In each round, every thread allocates several objects, exchanges some with other threads, and frees a subset, closely resembling mobile workloads. We run both the original configuration and a modified version that inserts a 2-second sleep between rounds to emulate smartphone foreground and background behavior, recording peak and steady-state memory usage for the modified version.

As shown in Fig. 13, under the sleep-augmented workload (the red line), jwmalloc consistently uses less memory than the other allocators across all thread counts. For example, in mstress-10N, jwmalloc's peak and steady-state footprints are 906MB and 29MB, whereas jemalloc's are 968MB and 376MB. In addition, jw+jemalloc and jemalloc exhibit similar peak and steady-state footprints. This demonstrates the effectiveness of our backend for workloads with large peak-trough swings (❷). In contrast, with its default settings, tcmalloc rarely triggers reclamation in this workload. We also observe that mimalloc's reclamation mostly occurs after the sleep period ends rather than shortly after it begins, confirming the delayed effect of synchronous reclamation discussed in Sec. 3.3.

Under the original workload (the blue line), jw+jemalloc exhibits smaller memory fluctuations than jemalloc, especially when there is a larger number of threads, which indicates the effectiveness of slab pooling (Sec. 3.1). In contrast, mimalloc and tcmalloc show higher memory usage, due respectively to a partial inability to reformat memory and a lack of memory reclamation mechanisms.

Taken together across both workloads, we find that under continuous allocation demand (the original workload), jwmalloc exhibits smaller memory fluctuations than jemalloc and jw+jemalloc (the blue line). When demand drops during the inserted sleep, jwmalloc returns more memory to the OS (the red line). This demonstrates the effectiveness of our lifetime-based reclamation policy for workloads requiring aggressive reclamation (❸): it reduces OS-side overhead from repeated allocation and deallocation while maintaining lower peak and steady-state memory footprints.

6.1.3 Operation Latency

We then measure allocator operation latency under the original mstress workload, as shown in Fig. 14. With a single thread, tcmalloc exhibits the lowest latency since it retains memory and rarely requests it from the OS. However, as the thread count increases, particularly under oversubscription, tcmalloc's tail latency rises sharply due to its lock-based design. In contrast, jwmalloc's non-blocking design maintains lower latency than the other allocators. For instance, in mstress-10N, jwmalloc's P99.99 latency is 1.5μs, compared to 5.9μs for the best competing allocator. This demonstrates that jwmalloc ensures low-latency memory operations even under heavy oversubscription (❹).

Table 3: Percentage energy-consumption reduction of jwmalloc relative to jemalloc under selected workloads. CPU_B, CPU_M, and CPU_L denote the big, middle, and little CPU clusters, respectively, and LPDDR denotes DRAM power.

	CPU_B	CPU_M	CPU_L	LPDDR	CPU Ins.
article_reading	7.3 ± 5.2	4.7 ± 0.53	7.2 ± 4.6	2.8 ± 1.1	21.0 ± 3.0
video_playing	11.0 ± 3.9	6.5 ± 0.78	5.8 ± 0.78	2.2 ± 0.41	6.7 ± 3.4

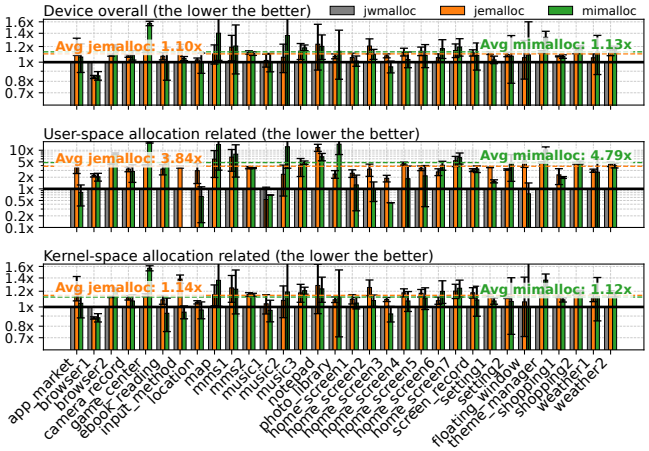

Figure 15: Normalized total CPU instruction counts and user- and kernel-space allocation related instructions.

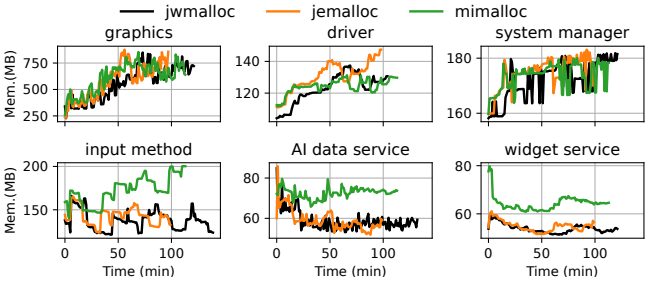

Figure 16: Proportional set size (PSS) over time for the top memory-consuming system services.

A closer comparison with jw+jemalloc further reveals a division of responsibility within jwmalloc's components. The frontend primarily determines non-tail latency, while the backend dominates tail latency. This highlights the effectiveness of the two components in jointly reducing operation latency.

6.2 Real-World Mobile Scenarios

We evaluate jwmalloc in a realistic mobile setting on a flagship smartphone, the Huawei Mate 70 Pro [14], running HarmonyOS 5.1 [22]. We replace the system's default jemalloc with either jwmalloc or mimalloc. We omit tcmalloc, which is implemented in C++ and thus incompatible with the phone's libc and toolchain [1, 35]. The device uses eight ARMv8-A

Benchmark ID	Action
app_market	Open the app market, search for and install a specific app, then uninstall the app.
browser1	Open a browser app, enter a URL, and stay on the page.
browser2	Open a browser app, enter a URL, and scroll the web page.
camera_record	Open the camera app, switch to video mode, and start recording.
game_center	Open the game center app, browse its home screen, then exit the app.
ebook_reading	Open a reader app, open the first book, and turn pages.
input_method	Swipe down from the home screen, tap the search box, and search for a keyword.
location	Open the device-finding app and refresh the location.
map	Open a map app, search for a keyword, and start navigation.
mms1	Open the messages app, enter the message list, view the first message, and scroll back.
mms2	Open the messages app, enter the message list, and scroll.
music1	Open a music app and play a local audio file.
music2	Open a music app and play local music with the screen off.
music3	Open a music app, enter the local song list, and scroll the list.
notepad	Open the notepad app, create a new note, and switch between tabs.
photo_library	Open the photo library, tap “Albums”, tap “Photos”, enter the thumbnail view, and scroll.
home_screen1	Enter an enlarged folder, swipe once, and exit.
home_screen2	Launch the settings app and swipe up to send it to the background.
home_screen3	Continuously launch Settings, Notepad, Messages, Phone, and Calendar; enter the multitasking interface and repeatedly swipe.
home_screen4	Repeatedly increase and decrease the volume.
home_screen5	Repeatedly pull down the control center and then exit it.
home_screen6	Enter the minus-one screen (leftmost panel) and repeatedly swipe.
home_screen7	Enter an enlarged folder, then repeatedly open and exit it.
screen_record	From the home screen, pull down the control center, tap screen recording, record a clip, then stop and return to the home screen.
setting1	Open the settings app and repeatedly swipe.
setting2	Open the settings app, log in to the account, tap “Scan”, select a QR code from Photos, and scan.
floating_window	Open the settings app, swipe up to the floating-window area, and release to create a floating window.
theme_manager	Open the theme app and repeatedly swipe on the home page.
shopping1	Open a shopping app and scroll down to browse products.
shopping2	Open a shopping app, enter the “Me” page, and swipe.
weather1	Open the weather app and send it to the background.
weather2	Open the weather app and swipe left to switch cities.

Figure 17: Detailed description of actions in real-world mobile benchmarks.

CPU cores [6] and 12GB of RAM. We run a suite of common smartphone scenarios for approximately two hours, covering core system interactions (e.g., home-screen scrolling, volume adjustment) and high-frequency app workloads (e.g., map navigation, music playback); the scenarios are detailed in Fig. 17. Each benchmark was executed five times, and we report the mean and standard error.

Figure 15 presents normalized CPU instruction counts from three perspectives: overall device instructions, user-space allocation-related instructions, and kernel-space allocation-related instructions. jwmalloc achieves substantial reductions across all three. On average, jemalloc and mimalloc execute 10% and 13% more overall instructions than jwmalloc, respectively. Broken down by source, in user space, their allocation-related instruction counts are 3.84× and 4.79× those of jwmalloc; in kernel space, they are 14% and 12% higher. These results show that jwmalloc effectively reduces allocation overhead and overall system load.

To further analyze how instruction reduction translates into power savings, we focus on two representative and relatively power-stable benchmark steps: article reading and video playback. For each step, we measure both instruction counts and the power consumption of major hardware components. As shown in Table 3, compared with jemalloc, jwmalloc reduces instruction counts by 7%–21%, lowers CPU-cluster power by 5–11%, and reduces LPDDR power by 2–3%. The CPU power reduction mainly results from shifts to lower voltage-frequency points and the migration of threads from big cores to small cores.

During the benchmark, we sample each process’s proportional set size (PSS), including swapped-out pages, once per minute. We then select the top system services by memory usage and plot their memory footprints over time in Fig. 16. For most services, jwmalloc’s memory usage is comparable to or

lower than that of jemalloc, whereas mimalloc often consumes more memory.

7 Conclusion and Future Work

We presented jwmalloc, a mobile-first memory allocator that significantly improves performance by addressing the mismatch between existing designs and mobile workloads. It has been successfully deployed on over 12 million devices. As future work, we plan to extend its core principles, such as the closed sibling tree, to server environments to enhance datacenter performance.

Acknowledgments

We thank our shepherd and the anonymous reviewers for their insightful comments. We also thank our colleagues and interns at Huawei Fields Lab for their invaluable support in the commercial deployment of jwmalloc.

Abstract

Formal verification via interactive theorem proving is increasingly used to ensure the correctness of critical systems, yet constructing large proof scripts remains highly manual and limits scalability. Advances in large language models (LLMs), especially in mathematical reasoning, make their integration into software verification increasingly promising. This paper introduces a neuro-symbolic proof generation framework designed to automate proof search for system-level verification projects. The framework performs a best-first tree search over proof states, repeatedly querying an LLM for the next candidate proof step. On the neural side, we fine-tune LLMs using datasets of proof state–step pairs; on the symbolic side, we incorporate a range of ITP tools to repair rejected steps, filter and rank proof states, and automatically discharge subgoals when search progress stalls. This synergy enables data-efficient LLM adaptation and semantics-informed pruning of the search space. We implement the framework on a new Isabelle REPL that exposes fine-grained proof states and automation tools, and evaluate it on the FVEL seL4 benchmark and additional Isabelle developments. On seL4, the system proves up to 77.6% of the theorems, substantially surpassing previous LLM-based approaches and standalone Sledgehammer, while solving significantly more multi-step proofs. Results across further Isabelle benchmarks demonstrate strong generalization, indicating a viable path toward scalable automated software verification.

1 Introduction

Formal verification plays a vital role in ensuring the correctness and reliability of software systems, especially in safety- and security-critical domains where failures can be catastrophic [1, 2, 3]. Interactive theorem proving (ITP) stands out for its expressiveness and ability to provide the strongest assurance. With ITPs, landmark projects such as CompCert (a formally verified optimizing C compiler whose correctness is mechanically proven in Rocq [4]) and seL4 (a formally verified OS microkernel whose functional correctness, security properties and reliability guarantees are proven in Isabelle/HOL [5]) have been successfully delivered, which demonstrate that formally verified systems can achieve both practical usability and rigorous correctness.

While ITP offers unparalleled assurance, it also incurs substantial costs, preventing its wide adoption, especially in large-scale, system-level software [6]. Specifically, a typical software verification workflow involves 1) writing precise formal *specifications* to be proved and 2) constructing rigorous *proofs* for these specifications, both of which demand immense human effort. For example, the seL4 verification project required approximately 20 person-years of work, and produced over 100K lines of proof scripts, compared to only about 10K lines of C implementation and merely 3K lines in its simplest abstract specification in Isabelle [5]. Moreover, developing such specifications and proofs necessitates specialized expertise in both theorem proving and the target domain, a combination that is challenging to acquire.

In this work, we focus on the proof generation step in system-level software verification projects. Recently, large language models (LLMs) have demonstrated encouraging mathematical reasoning capabilities, which inspire research into their application for software verification, particularly for proof generation [7, 8, 9, 10]. Unfortunately, both prior studies and our initial experiments show that, even when theorem statements are well formalized and relevant libraries are fully provided in advance, current LLMs still struggle to generate complete, correct proofs. We summarize two challenges as follows.

❶ *Lack of specialized expertise*. The first challenge lies in that software verification often relies on numerous domain-specific lemmas and specialized proof tactics. Although modern LLMs perform well in general reasoning tasks, they are not well-versed in these specialized domains, leading to limited effectiveness when applied to proving corresponding theorems. For example, LLM4FSCQ [7] evaluated models such

*These authors contributed equally to this work.
†Corresponding authors.

as GPT-4o and Gemini 1.5 Flash on FSCQ (a Rocq-based file system verification project [11]) and achieved only 38% proof coverage. Moreover, in the larger seL4 project, which involves extensive lemma libraries and customized tactics, Selene [9] found that GPT-4 succeeded on only 20% of a benchmark theorem set, despite the fact that nearly 40% of them require one-line proofs.

❷ *Paucity of usable data*. The second challenge, which is closely related to the first, is the shortage of high-quality (training) data for software verification. For instance, the seL4 project contains only around 20K theorems and lemmas, and most proofs are written in a procedural style, where much of the reasoning is implicit and encoded in the interaction with the theorem prover. This substantially limits their usefulness in effective LLM training/fine-tuning. Among existing seL4 benchmarks, Selene [9] extracts a small subset of the project, targeting relatively easy theorems with proof lengths of one to five. FVEL [10] is more comprehensive and challenging, as it extracts all theorems to be proved from seL4. Yet even with systematic fine-tuning of Mistral-7B-Instruct [12] and Llama-3-8B-Instruct [13], FVEL reported a success rate below 10% (88 out of 1,077 theorems in the test set).

Approach. In this paper, we propose a proof generation framework that synergistically combines LLMs and ITPs, aiming for automated system-level software verification. Our approach adopts a proof step-based tree-search pipeline that iteratively queries a fine-tuned LLM to predict the next proof step until the target theorem is successfully proved.

To address the first challenge, our framework adopts a neuro-symbolic approach tailored to the nature of software verification. First, to address challenges posed by domain-specific lemmas and tactics, we incorporate a proof-step revision module that repairs or refines LLM-generated steps whenever they fail to compile or make no progress. Second, to efficiently prune unpromising branches, we utilize Nitpick [14] and QuickCheck [15] to "test" each candidate proof state and discard those that admit counterexamples; the remaining candidates are then ranked by the LLM according to their plausibility. Finally, if the tree search still fails to resolve the goal, Sledgehammer [16] acts as a backstop that scans the local library for potentially relevant lemmas and attempts to complete the current proof.

To address the second challenge, we construct our training data by extracting internal proof states from existing theorems. For example, a five-step proof yields five distinct training instances, which are subsequently used for fine-tuning. During inference, our tree-search pipeline leverages this state extraction to facilitate direct interaction between the LLM and the prover, informing step predictions. While we currently train on existing human-authored proofs, this pipeline also enables future "bootstrapping", where new training data could be extracted on-the-fly from successful search paths [17, 18].

Experiments. We evaluate our framework on seL4 [5] proof construction. The results show that, with a fine-tuned language model, our approach achieves a total proof success rate of up to 77.6%, significantly surpassing prior automated proof-generation approaches for seL4. Notably, it excels, compared to the two preceding systems, at successfully handling a larger number of multi-step proofs, a challenge that has not been addressed by prior work. Moreover, our framework substantially alleviates manual proof-engineering effort, reducing expert proof-writing effort by 79.8% on average in an AI–human collaboration setting. Finally, experimental results on benchmarks from Archive of Formal Proofs projects (e.g., X86 Semantics , IEEE Floating Point, and SATSolverVerification), as well as the code verification benchmark Code2Inv (by translating its loop invariants into Isabelle theorems) confirm the strong generalizability of our approach.

Summary of main contributions. (1) We provide a neuro-symbolic framework based on LLM-enabled tree search, tailored for real-world, system-level software verification projects. (2) We implement concrete integration of LLMs and a broad range of symbolic, logic-based tools, substantially enhancing the efficacy of proof-tree search; (3) We curate training datasets and benchmarks, and carry out thorough empirical evaluations. Our work advances a new frontier of AI4Verification, an emerging area focused on applying cutting-edge AI techniques to hardware/software verification, especially to support large-scale proof engineering for safety-critical systems and architectures.

2 Problem

To demonstrate why existing LLMs struggle to synthesize proofs in real-world software verification tasks, we present a representative theorem from seL4. We choose seL4 as it is one of the most widely recognized formally verified systems, with machine-checked proofs of both functional correctness and security properties in Isabelle/HOL.

An example from seL4's verification is demonstrated in Figure 1, where the *theorem* `cap_swap_valid_objs` is drawn from the invariant proofs of the abstract specification of the seL4 microkernel, and similar proof patterns recur throughout the project. To prove this theorem, human experts write down (in Isabelle) three *proof steps*, each comprising one *tactic* (e.g., `simp` and `wp`) and some used *lemmas* (e.g., `cap_swap_def` and `set_cap_valid_objs`; cf. the left panel in Figure 1).

Unlike formal mathematics, theorems in software verification are often formulated as Hoare triples `{P} C {Q}`, where `P` and `Q` are the pre- and post-conditions, and `C` denotes the program being executed. In seL4, the abstract behavior of kernel operations is modeled in a monadic style that yields imperative-like programs; the corresponding Hoare rules capture the semantics of these monadic computations.

Intuitively, the targeted theorem states that if the address space of the seL4 microkernel contains no dangling pointers (`valid_objs`), then swapping the contents of two valid capa-

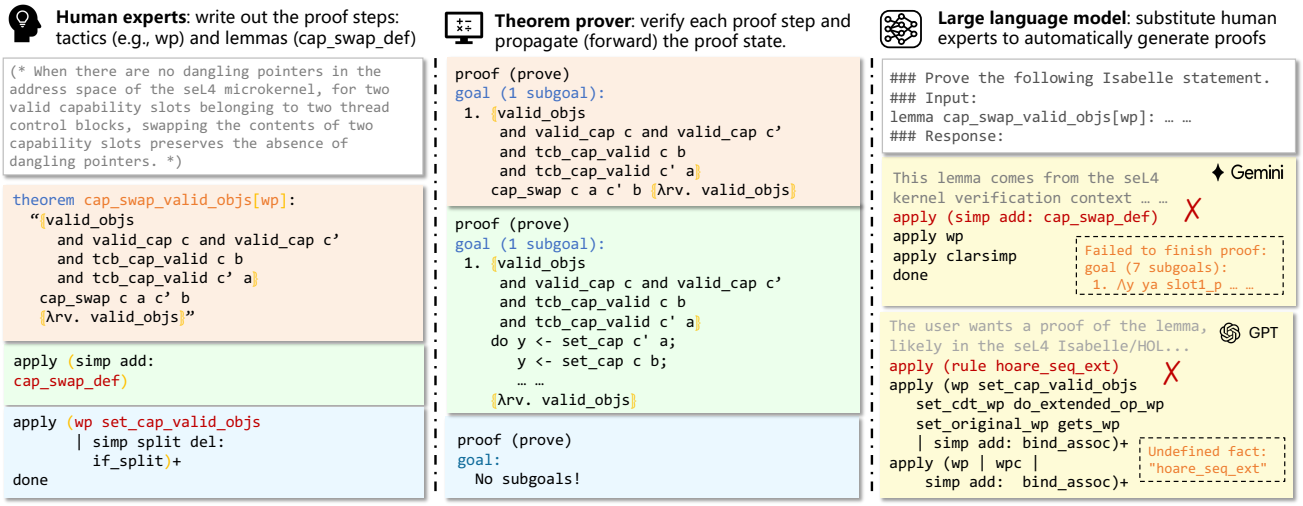

Figure 1: An example theorem and its human-written proof from the seL4 project, shown alongside LLM-generated attempts. The human-written Isabelle proof illustrates the procedural, tactic-driven reasoning style that is common in software verification. We prompted two state-of-the-art LLMs, Gemini 3 Pro and GPT-5.1, to synthesize the same proof under controlled conditions, with web search disabled to avoid any leakage of the original script. Although both models correctly recognized the proof context and invoked some relevant tactics, neither succeeded in producing a valid proof even after roughly one minute of internal reasoning. Their attempts frequently misuse the domain-specific `wp` tactic, or hallucinate nonexistent lemmas.

bility slots `c` and `c'`, which belong to two thread control blocks (`tcb_cap_valid c b` and `tcb_cap_valid c' a`), remains dangling pointers free. Namely, after the operation `cap_swap c a c' b` which exchanges the capabilities stored in these two slots, the resulting program state still satisfies `valid_objs` expressed by the postcondition `λrv. valid_objs` where `rv` denotes the return value of `cap_swap`.

To reduce the burden of manually constructing proofs, developers typically prepare a collection of broadly applicable tactics and lemmas, dedicated to software verification. For example, the `wp` tactic, short for weakest precondition, generates the verification conditions associated with a given Hoare triple. During this process, `wp` systematically applies a suite of previously proved lemmas, each of which encodes a weakest-precondition characterization for a specific construct or monadic computation. After a routine use of `simp` to unfold `cap_swap`, human experts can then easily invoke the pre-defined tactic `wp` together with the lemma `set_cap_valid_objs`.

In this example, the target theorem is discharged by combining the tactics `wp` and `simp`. The simplification step performs splitting, but the usual splitting rule for `if` is disabled to avoid unnecessary case distinction. In the proof script, the symbol `|` indicates that the tactic may apply either branch (or both), while the trailing `+` instructs it to repeat this process until no further progress is possible. This interleaving enables `wp` to generate obligations that `simp` can reduce, while `simp` reshapes the goals to facilitate subsequent `wp` reasoning. In this case, the combined step eliminates the goal entirely, and the proof concludes with `done`.

To assess LLMs in generating this proof automatically, we experiment with two state-of-the-art proprietary models, i.e., Gemini 3 Pro [19] and GPT-5.1 [20]; their results are shown on the right panel of the figure. While both deep-thinking models successfully recognize the seL4 proof context, they are unable to apply the domain-specific tactic `wp` correctly. They also hallucinate lemmas that do not exist in the library (e.g., `hoare_seq_ext`). We further attempted several rounds of iterative repair by feeding back the ITP's error messages, but the regenerated proofs continued to fail verification. An analysis of the models' reasoning traces shows that they frequently misinterpret the functionality and performance characteristics of the `wp` tactic and related lemmas (such as `set_cap_valid_objs`).

There are two potential approaches to addressing this issue. The first is to use retrieval-augmented generation [8, 21]. In this paradigm, given a target theorem, a retrieval module searches for relevant or structurally similar theorems and proofs, which are then supplied to the LLM as contextual guidance. However, this strategy depends on both a high-quality proof corpus and an effective retrieval model: requirements that are difficult to satisfy in our setting. For example, in seL4, when developers introduce a new module (such as SysInit, as shown in our evaluation) together with its accompanying proofs, comparable proofs are often absent from existing libraries. Moreover, even when analogous theorems do exist, neither model-agnostic nor model-dependent retrieval techniques reliably identify them within a large verification codebase [21, 22]. In such cases, weak retrieval can degrade, rather than improve, the quality of generated proofs.

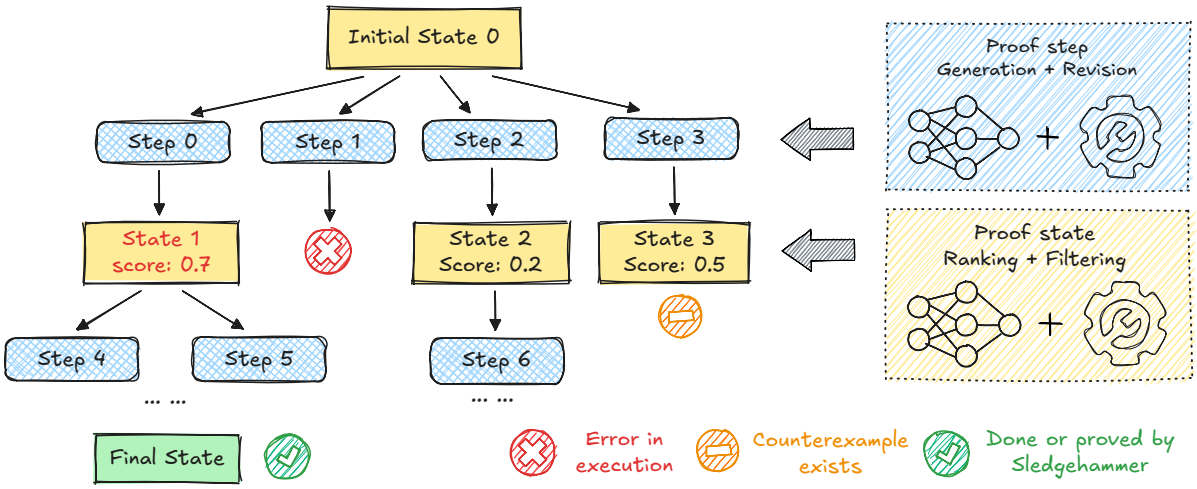

Figure 2: Overview of our neuro-symbolic proof-search framework. Starting from the initial proof state, the system repeatedly generates candidate proof steps using a fine-tuned LLM, followed by rule-based symbolic revision to repair syntactic or semantic issues in the proposed steps. Each accepted step is executed by Isabelle/HOL to derive new proof states, which are then filtered by symbolic tools to prune states containing counterexamples or duplicates. The remaining states are ranked using cumulative LLM log-probabilities, and the highest-scoring ones are selected for further expansion in a best-first search. If the search cannot complete the proof, the framework finally invokes Sledgehammer to attempt to resolve the remaining goals.

Another approach is to fine-tune LLMs on collected proof data. This method is considerably easier to implement and has already demonstrated promising results in formal mathematical proving. However, fine-tuning a model to directly generate complete proofs for software verification remains highly challenging.

First, even in seL4, the available corpus consists of only about 20K theorems, which severely limits the effectiveness of fine-tuning. Second, unlike formal mathematics, most proofs in systems like seL4 are procedural: as our example illustrates, their true semantics reside implicitly in the theorem prover's internal proof states rather than in the proof scripts themselves. As a result, LLMs struggle to acquire the necessary reasoning signal from surface-level proof text alone, making this approach impractical for now.

3 Methodology

We propose a neuro-symbolic approach for proof step search on system-level theorems. The overall procedure is illustrated in Figure 2. Starting from the root node, which represents the initial proof state, the search alternates between proposing new steps and deriving new proof states by executing those steps within the ITP.

To construct the next set of candidate proof steps for the current proof state, we first prompt a fine-tuned LLM to generate potential steps, and then apply a rule-based revision to refine or fix any imprecise suggestions. After executing these steps and obtaining a collection of new proof states, we introduce a hybrid mechanism to identify the most promising ones for further exploration. Specifically, we apply QuickCheck [15] and Nitpick [14], which serve as counterexample generators that help detect false conjectures or invalid intermediate proof states in Isabelle/HOL, to discard any proof state that contains a counterexample. We then use the LLM's prediction score (cumulative perplexity) to rank the remaining states and select the most promising one. Finally, if the search for the proof fails, we invoke an automated tool, i.e., Sledgehammer, to attempt to complete the proof. Putting all the above together, we establish the framework in Algorithm 1.

3.1 Proof Step Generation & Revision

3.1.1 Proof Step Generation

Our approach begins by generating candidate proof steps through prompting a fine-tuned LLM. Given the current proof state, which encapsulates the available hypotheses and the target goal, we query the model to propose the next proof step using a simple instruction template:

```
### Given the following Isabelle proof state,
suggest the next proof step.
### Input:
<current_proof_state>
### Response:
<next_proof_step>
```

The rationale for focusing on the current proof state is

Algorithm 1 Proof Search Framework

Require: initial state s_0, neural generator $\mathcal{G}$, symbolic checker $\mathcal{C}$, max iterations $I_{\max}$

initialize tree T with root containing s_0
for each iteration $i \in [1, I_{\max}]$ **do**
  $n \leftarrow$ highest_score_unexplored(T)
  succStates $\leftarrow []$; failStates $\leftarrow []$
  candidates $\leftarrow \mathcal{G}(n.state)$ ▷ step generation
  for each step $\delta \in$ candidates **do**
    $s \leftarrow$ apply(δ, $n.state$) ▷ ITP execute
    if s is error state **then**
      failStates.add($(s, \delta, \log p_\delta)$)
    else
      succStates.add($(s, \delta, \log p_\delta)$)
  for each $(s, \delta, \log p_\delta)$ in REVISE(failStates) **do**
    $s \leftarrow$ apply(δ, $n.state$)
    succStates.add($(s, \delta, \log p_\delta)$)
  for each $(s, \delta, \log p_\delta)$ in succStates **do**
    if s has no subgoals **then**
      return proof script ▷ proof completed
    if $\mathcal{C}(s)$ detects duplicate or counterexample **then**
      continue ▷ state filtering
    score $\leftarrow$ combine($n.score$, $\log p_\delta$) ▷ scoring
    insert_node(T, $(s, score)$)
return FAIL

twofold. First, proof search can be modeled as a Markov decision process, in which the next step depends solely on the present state; this is also common practice in proof search and is critical for efficiency [23, 24, 25]. Second, the structure and vocabulary of the proof state provide strong cues regarding which tactics are applicable and which premises are likely to be relevant [26, 27]. Additionally, we predict a single step at a time, as one-step prediction empirically yields more reliable results than multi-step prediction.

To fine-tune the model to predict such next steps, we construct a dataset of state–step pairs extracted from existing theorems and their complete proofs. Each proof is decomposed into individual proof steps and replayed in the ITP, allowing us to record the intermediate proof state preceding every step. Using these aligned pairs, we fine-tune the LLM to generate outputs that are not only syntactically correct but also semantically sensible. Finally, since proof search demands efficient generation, we employ relatively small LLMs (e.g., 1.7B or 7B size), which are nevertheless sufficient for our specific tasks.

3.1.2 Proof Step Revision

Writing syntactically and semantically valid proof steps in an ITP (such as Isabelle) is challenging, particularly in system verification tasks that depend on numerous domain-specific

Algorithm 2 Proof-step revision and execution

Require: Failed proof state set failStates

revisedSteps $\leftarrow []$
premiseSet $\leftarrow$ established from trainingCorpora
tacticSet $\leftarrow$ established from trainingCorpora
for each $(s, \delta, \log p_\delta) \in$ failStates **do**
  if s.error is w.r.t. tactic **then** ▷ tactic repair
    $p \leftarrow$ extract referred premises in δ
    revisedSteps.add(combine(tacticSet, p))
  if s.error is w.r.t. premise **then** ▷ premise repair
    $t/p \leftarrow$ extract referred tactic/premises in δ
    $p' \leftarrow$ retrieve similar premises from premiseSet
    revisedSteps.add(combine(t, p'))
return revisedSteps

lemmas and tactics. Consequently, even a well-trained LLM may generate steps that either refer to premises or tactics absent from the current proof context, or cannot be applied to the current goals due to syntactic errors or lack of progress. Such failures substantially degrade the effectiveness and efficiency of the proof search.

Despite their incorrectness, these failed attempts often contain useful information. Continuing our running example, an LLM might identify relevant premises `cap_swap_def` but pair them with an inapplicable tactic `by`; or it may propose a promising tactic `wp` while selecting premises `hoare_seq_ext` that do not precisely fit the context.

To fully exploit these incorrect but reasonable responses from LLMs, we employ a best-effort repair procedure. Whenever the ITP rejects an LLM-generated step, we record it for post-processing and re-evaluate the revised version. After examining all proposed steps for a given proof state, we systematically transform the failed ones in two ways: (1) tactic repair: we extract the premises referenced by misused tactics and recombine them with a curated set of frequently used tactics; and (2) premise repair: we search the proof context for similar premises and substitute them where appropriate. By synthesizing additional candidate steps, these symbolic revisions help reveal prover-accepted steps, thereby strengthening the overall proof search.

For the tactic repair, we first extract all tactics from the training corpus. Given a proof step rejected by the ITP, we attempt to rewrite it by identifying the premises referenced in the failed step and recombining them with the pre-built tactic set. As to the premise repair, which explicitly targets proof steps that fail with an "undefined fact" error, we attempt to correct every LLM-generated undefined premise using an available version from the proof context. Concretely, we compare the undefined fact with all candidate premises using edit distance and select the closest matches (e.g., the top three). The failed step is then revised by substituting the matched premises for the undefined ones.

The procedure of proof-step revision is summarized in Algorithm 2. However, the revision can produce a large number of candidate steps. To alleviate this, we impose constraints to keep the search space manageable. For tactic repair, we limit the tactic set (e.g., to the 12 most frequently used tactics). For premise repair, we pre-select a compact subset of premises from the library. In particular, we use MePo (a heuristic module in Isabelle's Sledgehammer that ranks and selects premises relevant to a given goal) as a lightweight relevance filter to retrieve the 128 facts most related to the current subgoal.

3.2 Proof State Filtering & Ranking

3.2.1 Proof State Filtering

To alleviate state explosion in tree-search approaches, we reorganize the accumulated proof states before further exploration. Particularly, after generating new proof states by executing the newly produced proof steps, we first invoke two complementary symbolic tools, QuickCheck [15] and Nitpick [14], to detect potential counterexamples in the candidate states. QuickCheck performs random property-based testing on executable parts of the proof state, whereas Nitpick translates higher-order formulas into finite relational models and searches for counterexamples using Kodkod, which is a SAT-based first-order relational model finder.

Additionally, we adapt the tool SolveDirect [28] to detect potentially duplicate proof states. Initially, SolveDirect determines whether a newly stated theorem can be solved directly using an existing one. In our setting, we formalize two proof states as theorems and apply SolveDirect in both directions to determine whether they are semantically equivalent.

We use a basic theorem in seL4 as an example to illustrate proof state filtering. Consider the "signed overflow" theorem, whose formal statement is as follows.

```
theorem sofl_test:
  ‹ sint x + sint y = sint (x + y) ⟷
      drop_bit (size x - 1)
          ((x + y XOR x) AND (x + y XOR y)) = 0 ›
  for x y :: ‹ 'a::len word ›
```

The theorem claims that for two signed machine words, the value of their machine-level sum matches the sum of the mathematical values they represent. This property guarantees the correctness of the machine-word definitions on which the low-level kernel specifications depend. To prove this theorem, the LLM proposes a total of 8,445 candidate proof steps, rendering exhaustive exploration prohibitively time-consuming. Nevertheless, our filtering reveals that 44.2% of these steps lead to duplicate proof states, and 52.3% of the remaining states are unprovable due to existing counterexamples. Thus, the state-filtering process effectively eliminates unproductive effort and conserves the search budget, enabling the proof to be found much earlier.

3.2.2 Proof State Ranking

To guide the proof search efficiently, we rank all proof states and always expand the most promising ones first. To score a given proof state, we rely on the log probabilities predicted by the fine-tuned LLM. The LLM is trained to predict the next proof step; its log probability directly reflects the model's confidence in applying that step to the current proof state.

Consider a candidate proof state s_L, obtained by applying a sequence of proof steps $(a_1, \ldots, a_{L-1})$. We define its cumulative log-probability score as

$$\text{score}(s_L) = \frac{\sum_{t=0}^{L-1} \log p(a_t \mid s_t)}{L^{\alpha}},$$

where $s_1, \ldots, s_{L-1}$ are the intermediate states produced by the corresponding steps. The normalization term L^{α} mitigates the inherent bias against longer proof sequences, with the exponent α specifying the degree of mitigation [18], which we set to 1 by default. After computing the score for each proof state, we select the top-k states for further expansion where k is a hyperparameter.

3.3 Hammer Integration

Hammers are tools designed to discharge proof goals in ITPs automatically. In Isabelle, the primary hammer is Sledgehammer [16], which applies ATPs and SMT solvers (e.g., Z3, CVC5, E, SPASS, Vampire, etc) to the current goal and synthesizes corresponding Isabelle proofs. When invoked, it first retrieves a fixed number of potentially relevant premises that may aid in solving the goal. These premises, together with the goal, are translated into a form suitable for backend ATP and SMT solvers. If a backend solver succeeds, Sledgehammer attempts to reconstruct a corresponding Isabelle proof step, and, when this reconstruction succeeds, a complete proof for the current goal is returned to the prover.

Although Sledgehammer's performance is far from satisfactory for our tasks, it plays a mutually beneficial role in the tree search process. In particular, while tree search may fail to solve the original problem within a limited search budget, it often reduces the problem to a simpler form that Sledgehammer can solve, even though it cannot solve the initial goal on its own. This makes it natural to integrate the hammer into our framework. Because invoking the hammer at every search step is prohibitively expensive, we only call it when tree search fails. Specifically, upon search failure, we rank all proof states in the currently expanded tree, select a small subset with the highest scores, and pass them to Sledgehammer for a final attempt at solving the goal.

4 Evaluation

This section presents our experimental results. We use seL4 as a system-level evaluation testbed to demonstrate both the

effectiveness and efficiency of our proposed method. In addition, we introduce four additional repository-level benchmarks to further assess its generalizability. Specifically, our study aims to address the following research questions (**RQ**s):

- **RQ1 – Effectiveness**: Does our proposed method outperform existing techniques in generating proofs for seL4?
- **RQ2 – Efficiency**: How much human effort in proving seL4 can be saved using our proposed method?
- **RQ3 – Generalizability**: Can our method perform well on the verification of other software projects?
- **RQ4 – Ablation**: What is the contribution of each component within our framework?

All evaluations were carried out within a dedicated Docker environment on a Linux server with an AMD EPYC 9654 96-core processor and six high-end GPUs.

4.1 Isabelle REPL

To enable efficient interaction with Isabelle from Python, we implement a new Isabelle REPL (Read-Eval-Print Loop), whose logic builds on scala-isabelle [29] and Py4J [30]. The REPL provides a Gateway Server that exposes Isabelle components to Python clients through a unified API. This design enables programmatic interaction with Isabelle, allowing users to parse Isabelle theories, extract run-time context information, and execute proof steps incrementally.

Compared to the previously developed Isabelle REPL, PISA [31], our REPL supports more recent Isabelle versions and provides extended ML-level capabilities. A wide range of Isabelle's proof-automation tools, including Sledgehammer, Nitpick, QuickCheck, and other integrated methods, can be accessed directly through our interface. It also improves the extraction of information from proof contexts, such as variables and assumptions in proof goals, dependencies of proved theorems, and facts selected by Sledgehammer.

In addition, our REPL provides improved management of the Isabelle process, top-level state, and theories. It allows users to safely impose strict time limits on Isabelle processes, as well as to clone, restore, and switch between different proof states. Theory management is also strengthened: in large verification projects, complex theory dependencies can heavily degrade compilation efficiency. For example, in the CRefine theory of seL4, a single proof step takes more than one minute to process. To address this, we implement a caching mechanism that avoids redundant execution of unrelated theorems and proofs, significantly reducing unnecessary recomputation.

4.2 Experimental Setup

Dataset. We use the FVELER dataset [10], which comprises 29,125 theorems from seL4. The dataset is split into four subsets, i.e., training, validation, test, and test-hard, containing 26,081, 1,115, 1,077, and 852 theorems, respectively. Following the FVEL criteria, the training, validation, and test sets are randomly partitioned. In contrast, the test-hard set consists of theorems drawn from three specific and independent sessions, i.e., SysInit, SysInitExamples, and LibTest, that do not appear in any of the other splits. Note that *sessions* are the way Isabelle organizes theory files, which resemble the relationship between code files and libraries in other programming languages. A theory can import other theories, and a session can depend on other sessions by declaring dependencies in the Isabelle ROOT file. These sessions are typically selected based on the depth of their session-level dependency graphs, and the theorems they contain exhibit more complex dependencies, making them considerably more challenging to prove.

In our experiments, we use the training set as the corpus for fine-tuning LLMs, and adopt validation, test, and test-hard sets to evaluate our proposed framework. From the training set, we further extract all proof state–step pairs, yielding a total of 181,887 pairs. On average, each theorem contributes to about seven pairs, substantially increasing the amount of supervised data available for model training.

Training. We fine-tuned two small models, Qwen3-1.7B [32] and Mistral-7B [12], to predict and score each proof step. We carried out the full-parameter supervised fine-tuning (SFT) using the Llama-Factory framework [33]. We use DeepSpeed ZeRO-2 optimization to enable memory-efficient distributed training. The training used an effective global batch size of 16 and ran 3 epochs using bfloat16 mixed precision. The learning rate was set to 1e-5 and followed a cosine decay schedule with a warmup ratio of 0.1.

Proving. For the LLM inference, we adopt a high temperature of 1.0 and a top-p value of 0.95 to explore the proof space sufficiently. The maximum generation length is fixed at 2,048 tokens. In each search iteration, at most five proof states are selected; for each proof state, the model is prompted to generate 128 candidate proof steps. In our framework, we disable LLMs' internal thinking to improve inference efficiency.

When proof search fails, we select the 16 highest-scoring proof states and invoke Sledgehammer for assistance. We run Sledgehammer with its default premise-selection strategy: it first selects 2,048 most relevant premises for the current proof goal using MeSh, which combines MePo [34] and MaSh [35] to gauge relevance between the proof goal and available facts in the context. With these retrieved results, Sledgehammer then attempts to discharge the current subgoal using the built-in SMT/ATP solvers Z3, CVC5, E, SPASS, and Vampire, with a 60s time limit.

Baseline. We select four neural or symbolic proof-generation methods as baselines. Selene prompts GPT-4o with the target problem and several examples to generate a candidate

Table 1: Proof success rates (%) across validation (Val), test (Test), and test-hard (TsHd) splits. Compared to existing neural and symbolic provers, our framework delivers substantial improvements: Qwen3-1.7B achieves 70.4% overall success, and Mistral-7B reaches 77.6%, exceeding the strongest baseline by 30.0 and 37.3 percentage points, respectively.

Method		Val	Test	TsHd	Total
Neural	Selene	6.1	7.0	3.3	5.6
	FVEL	8.9	9.5	4.5	7.8
Symbolic	Auto	4.9	6.7	6.1	5.9
	Hammer	40.5	39.5	40.9	40.3
Ours	Qwen3	73.6	74.9	61.1	70.4
	Δ	↑33.1	↑35.4	↑20.2	↑30.0
	Mistral	**79.8**	**89.0**	**69.8**	**77.6**
	Δ	**↑39.3**	**↑49.5**	**↑28.9**	**↑37.3**

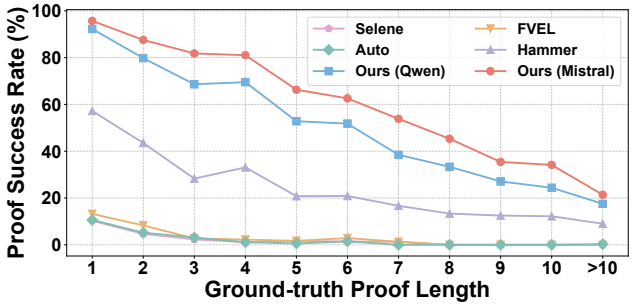

Figure 3: Proof success rate across ground-truth proof lengths. Our approach consistently outperforms existing methods. In particular, the success rate decreases as proofs grow longer, but our approach still maintains non-negligible performance even on proofs exceeding 10 lines.

proof. FVEL follows a similar paradigm but also fine-tunes a Mistral-7B-Instruct model on the training data to produce complete proofs, rather than using in-context learning. We also include two symbolic methods, Auto and Sledgehammer, which operate purely symbolically to prove the target theorem. Here, Auto is a collection of common symbolic automatic proving methods in Isabelle, such as `by simp`, `by auto`, and `by fastforce`. The time limit for all methods is set to 120 minutes, as we observed no noticeable improvement when increasing it further.

4.3 Experimental Results

4.3.1 RQ1: Effectiveness Comparison

Table 1 summarizes the performance of our approach compared to both neural and symbolic baselines. Among neural methods, Selene achieved 156 successful proofs, while FVEL improved this to 219. As for symbolic baselines, Auto proved 164 theorems, whereas Sledgehammer reached 1,124. In contrast, our framework substantially outperforms all these baselines across different splits. Using the fine-tuned Mistral-7B model, our approach produces a total of 2,167 successful proofs, of which 788 are on the validation set, 811 are on the test set, and 568 are on the test-hard set. This accounts for 77.6% of all still valid theorems across the three evaluated sets, 37.3 percentage points higher than the best baseline, Sledgehammer. It is also encouraging that, on a relatively small model, Qwen3-1.7B, our approach manages to complete the proof of 1,965 theorems, which amounts to 70.4% of the total theorems. This demonstrates that in a real environment where new proofs need to be crafted, a deployed small model can already help with the development of verification.

We further evaluate the performance of our automated proving approach in two aspects. First, prior work struggled to generate nontrivial proofs. Since the proofs in seL4 are largely procedural, we use the proof length as a proxy for proving difficulty. We compute the proof success rate across different proof lengths and present the results in Figure 3. The results show that our approach is more capable of proving longer theorems than previous baselines. Although the success rate naturally decreases as proof length increases, it remains around 20% even for the 393 theorems whose proofs exceed 10 lines. We leave it as future work to investigate more effective strategies for constructing longer proofs.

Second, we examine the performance across different proof sessions. We group the seL4 theorems into six major categories w.r.t. the functionality [5, 36, 37]: Base Libraries & Tools (Base), Specifications (Spec), Abstract-Level (A-Level) Properties, Refinement from Abstract-Level to Executable C (A→C), Security/Information Flow Control (IFC), and System Initialization Group (SysInitGroup). Figure 4 presents the results across these categories, demonstrating that our approach delivers superior performance compared with all baselines across all sessions. Notably, under the test-hard set division strategy, SysInitGroup is derived from a completely distinct session and is isolated from the training data, yet our approach still achieves a success rate of 67.6%.

Response to RQ1

Our approach substantially outperforms baselines, achieving a success rate 37.3 percentage points higher than the (symbolic) ATP tool Sledgehammer and 69.8 percentage points higher than the state-of-the-art neural method. It remains reliably effective across different proof difficulty levels and session categories. Further, it demonstrates good generalizability, successfully discharging 67.6% of the theorems from unseen sessions during training.

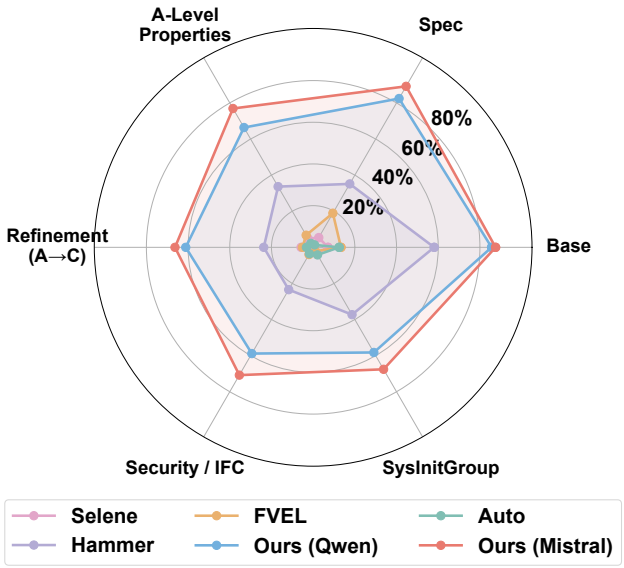

Figure 4: Proof success rates across the six seL4 session categories. Our approach yields stronger performance than all baselines in all sessions. Notably, it achieves high accuracy even on the challenging SysInitGroup category, which is entirely unseen during training.

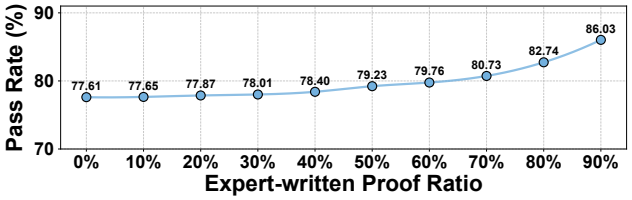

Figure 5: Proof completion rate under varying proportions of provided proof lines. Our method is increasingly effective as more human-written lines are supplied. Overall, the method reduces human effort by 79.8% on average.

4.3.2 RQ2: Proving Efficiency in Saving Human Efforts

To evaluate how effectively our approach reduces manual effort in developing proof scripts, we adopt a standard metric: the coverage of the entire library that can be automatically generated [38]. As summarized in Table 2, our method successfully proves theorems whose corresponding proofs account for 6,235 lines in the seL4 proof corpus, achieving 36.2% coverage across all evaluated theorems. Under this metric, our approach yields more than a one-fold improvement over existing baseline methods.

The coverage metric above credits only fully automated proofs. To also capture partial assistance, we simulate an AI–human collaborative workflow, where our framework completes proofs after several proof lines have been written by human. This experiment depicts a scenario where human experts can initially provide some reliable proof directions, and

Table 2: Coverage results of automatically generated proof lines. Our method attains the highest coverage, proving theorems whose existing proofs amount to over one-third of all proof lines and substantially outperforming existing baselines in reducing manual proof-script development effort.

Method	# of proof lines	% of coverage
Selene	197	1.1
FVEL	271	1.6
Auto	204	1.2
Hammer	2,581	15.0
Ours	**6,235**	**36.2**

then AI attempts to complete the subsequent proof tasks. In practice, for each theorem, we provide a prefix taken from the ground-truth proof (the first σ fraction of expert-written lines from the dataset) and ask our approach to complete the remaining steps, starting from the resulting proof state reached after executing the provided lines.

We then define an effort saving metric η for this experiment. Specifically, if our approach proves a theorem with at least the first σ fraction proofs provided, the effort saving is then $1-\sigma$. For instance, consider a theorem whose ground-truth proof consists of 10 lines: if our framework cannot complete the proof when the first two lines are provided, but succeeds when the first three lines are provided ($\sigma = 0.3$), the effort saving for this theorem is 0.7. We compute the average effort saving under this setting as:

$$\eta = \sum_{i=1}^{k} (p_i - p_{i-1}) \cdot (1 - \sigma_i), \quad p_0 = 0,$$

where $(\sigma_1, \ldots, \sigma_k)$ are the prefix fractions in ascending order, and p_i is the fraction of theorems whose remaining proof can be completed automatically given a σ_i-prefix; theorems unsolved at every evaluated σ_i contribute zero saving.

Figure 5 plots the proof completion rate over the prefix fraction σ. Consistent to the intuition, as the prefix size grows, more theorems become completable. This yields $\eta = 79.8\%$, meaning our approach reduces human proof-writing effort by roughly 80% on average in this setting.

We also record the time consumption of our framework as a reference; the average time to generate a successful proof is 139.1 minutes. However, it is worth noting that this average is skewed upward by a small number of theorems that take extremely long to prove. In our experiment, we find that 58.4% of the theorems are proved within 10 minutes, 73.4% within 30 minutes, and 80.8% within 2 hours. Therefore, the majority of proofs are obtained within minutes to tens of minutes—substantially faster than manual proof development, which often requires hours to days per theorem for complex system properties.

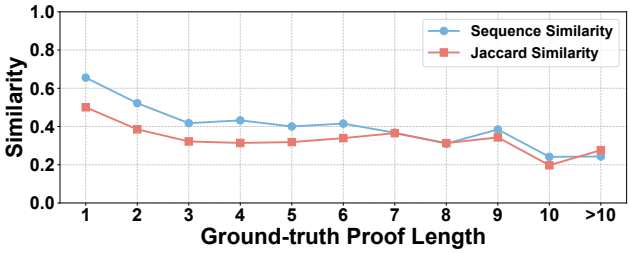

Figure 6: Sequence and Jaccard similarity between generated and ground-truth proofs across proof lengths. Both metrics remain low and decrease as proofs grow longer, suggesting the model synthesizes novel strategies rather than recalling memorized proofs.

Response to RQ2

Our approach alleviates much of the burden of interactive theorem proving, automatically completing proofs that correspond to 36.2% of the proof lines in the evaluated corpus and reducing expert effort by approximately 79.8% in an AI–human collaboration setting. Moreover, it is able to synthesize the majority of proofs within a practical time budget.

4.3.3 RQ3: Generalizability to Other Projects

A major concern with training-based methods is their generalizability, namely, whether the approach is only applicable to a specific domain due to potential data leakage or overfitting.

To investigate possible leakage, given that the seL4 proofs are publicly available and that the pre-trained model may have already incorporated some of the knowledge, we compute the similarity between the ground-truth proofs and the proofs generated by our approach using sequence similarity [39] and Jaccard similarity [40]. As shown in Figure 6, both metrics remain low and, crucially, decrease as proof length grows. If the model were memorizing ground-truth proofs, we would expect similarity to remain high regardless of length; the observed downward trend instead suggests the model is synthesizing novel proof strategies rather than recalling memorized ones. The only exceptions are one- or two-line proofs, where the solution space is inherently small—yet even among these, only 16.7% are identical to the ground truth.

We further explore the generalizability of our approach and the fine-tuned LLM. We select three projects from the Archive of Formal Proofs (AFP*), i.e., X86 Semantics [41], IEEE Floating Point [42], and SATSolverVerification [43], to directly apply proof search on the theorems therein. In addition, we include the code verification benchmark Code2Inv and translate its loop invariants into Isabelle theorems.

*https://www.isa-afp.org/

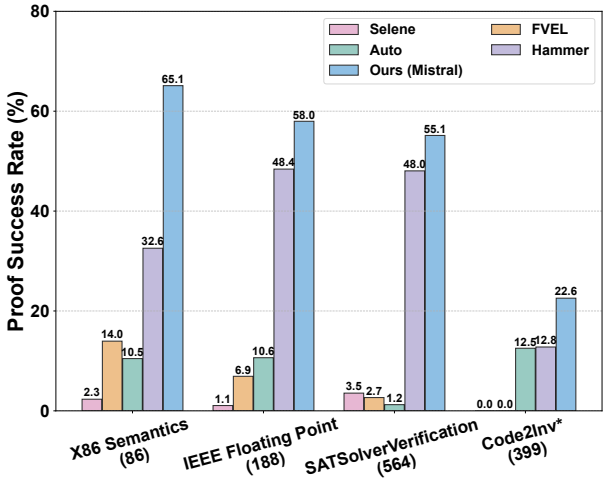

Figure 7: Performance of our proof search framework on additional benchmarks. The x-axis lists the benchmarks, where entries in brackets denote the number of theorems included in each benchmark. Our approach consistently achieves higher proof success rates across all benchmarks, demonstrating strong generalizability and robustness.

The performance of our approach and baselines is shown in Figure 7. Because the X86 semantics benchmark is more relevant to the seL4 project, the fine-tuned LLM performs particularly well on it, yielding a 32.5% higher success rate than the baselines. The other three benchmarks are hammer-friendly because of their SMT-oriented nature. Even in this setting, our framework demonstrates superior effectiveness, achieving an average relative improvement of 36.9%.

Response to RQ3

The knowledge acquired by the fine-tuned LLM, together with our proof search framework, generalizes well across domains. In particular, the approach can be effectively leveraged to assist proof construction in a wide range of formal verification tasks beyond the seL4 setting.

4.3.4 RQ4: Ablation study

Since our approach integrates several components, namely LLMs, hammer, as well as proof-step revision and proof-state filtering mechanisms, we conduct ablation studies to evaluate the contribution of each part of the framework. To assess the impact of our fine-tuned model, we replace it with off-the-shelf LLMs such as GPT-4o or DeepSeek. Due to budget constraints (running tree search costs approximately $4.1 per theorem on average when using the DeepSeek or GPT-4o APIs), we randomly sample 200 theorems from the benchmark and use the DeepSeek API to propose proof steps.

In addition, inspired by Rango [8], we implement a retrieval-augmented generation (RAG) mechanism. The retrieval module fetches both similar proof steps and potentially relevant premises. Similar steps are retrieved from the training set based on the similarity between their associated proof states and the current proof state, where these states are tokenized into sequences of identifiers, and relevance is measured using BM25 [44]. For premises retrieval, we continue to rely on Sledgehammer's MePo heuristic for efficiency. The final prompt for LLMs includes the retrieved steps and premises along with their statements, and we restrict the total lengths of steps and premises to 1024 and 512 tokens, respectively.

The results for all method variations are reported in Table 3. Overall, although adding tree search and RAG steadily improves DeepSeek's performance, these variants still fall significantly short of our full framework. This confirms that the combination of the fine-tuned model, structured search, and hammer integration is essential for achieving high proof success rates, and highlights the importance of each major component in our design.

We also evaluate the impact of the fine-tuning process by adopting a hammer-free tree search setting to focus on the quality of proof steps generated by the model itself. As shown in Table 4, vanilla base models such as Mistral-7B and Qwen3-1.7B struggle with formal proof tasks, yielding negligible success rates even when augmented with tree search. This underscores the necessity of our domain-specific fine-tuning.

To evaluate the impact of the step revision mechanism, we analyze the theorems that become difficult to prove when the revision is disabled. We observe that revision is most beneficial when the LLM fails to generate enough effective proof steps. In particular, for the most challenging 77 theorems where the model initially proposed no valid steps and therefore failed immediately, the revision procedure is highly effective, enabling 24.7% of these theorems to be proved. For a broader set of 220 theorems where the LLM proposed fewer than 5% valid steps, the revision mechanism still provides substantial gains, allowing 11.8% of them to succeed.

Regarding the necessity of proof state filtering, particularly the counterexample detection, our experiments show that incorporating this component allows the system to identify an average of 1.3 counterexamples per evaluated theorem. For the subset of search traces that contain counterexamples, the average number rises to 11.1. These results indicate that counterexample detection is valuable for identifying unprovable states early and preventing unproductive search efforts, although it does not directly increase the overall success rate.

Table 3: Proof success rate (%) on several variants of our framework. The proof success rate increases progressively as tree search, retrieval augmentation, and hammer are incorporated, indicating the necessity of each component. The comparison highlights that our full approach, which replaces the off-the-shelf model with a fine-tuned LLM, achieves substantially stronger performance.

Method Variation	**Rate**
DeepSeek (DpSk) v3.2	5.5
DpSk + Tree Search	12.5
DpSk + RAG + Tree Search	33.0
DpSk + RAG + Tree Search + Hammer	52.0
Ours (Trained LLM+Tree Search+Hammer)	**70.0**

Table 4: Effect of supervised fine-tuning under the same tree-search configuration. Without fine-tuning, the base models solve almost no theorems; in contrast, after supervised fine-tuning, both models reach around 60% proof success.

Method Variation	**Rate**
Mistral-7B + Tree Search	0.0
Qwen3-1.7B + Tree Search	0.1
Mistral-7B SFT + Tree Search	**59.8**
Qwen3-1.7B SFT + Tree Search	**57.1**

Response to RQ4

Each of the symbolic and neural components in our framework plays an essential role, and their synergy substantially strengthens the overall theorem-proving capability for software verification.

5 Further Analysis

Beyond aggregate accuracy, we examine how our proposed framework actually constructs successful proofs and what causes the remaining failures.

5.1 Successful Case Studies

We discuss two successful proofs that exhibit complementary patterns: a short symmetry lemma closed by an LLM-proposed case analysis combined with the symbolic tool Sledgehammer (C1), and a long Hoare-triple proof for an seL4 fault handler built entirely from LLM-generated steps (C2). For each, we show the theorem, the proof our framework discovered, and the search behavior behind it.

C1. A symmetry lemma in CSpace. The seL4 lemma `same_object_as_commute`, from the CSpace invariant de-

velopment, states that the capability-equivalence relation `same_object_as` is symmetric. The seL4 proof reduces the equality to a one-way implication via `subgoal_tac` and closes both directions with a single `auto` call. Our framework takes a different route: it splits on `c'` first and lets Sledgehammer discharge each constructor case independently.

```
lemma same_object_as_commute:
  "same_object_as c' c = same_object_as c c'"
apply (case_tac c')
apply (simp_all add: same_object_as_def split:
cap.splits)
apply blast
apply meson
apply blast
using bits_of_def apply force
apply blast
apply blast
using same_aobject_as_commute by blast
```

What the framework did. At depth 0, the LLM proposed several decompositions. Tree search explored seven of them, including `case_tac c` with various simp-set expansions, before settling on `case_tac c'` followed by `simp_all (split: cap.splits)`, which left a small frontier of constructor cases. Sledgehammer then closed the leaves with single-line `blast`, `meson`, and `force` calls, together with the previously proved `same_aobject_as_commute`.

C2. Invariance under VM-fault handling. The lemma `hv_inv_ex`, from the ARM `ArchSyscall_AI` session, is a top-level Hoare triple for seL4's VM-fault handler: it asserts that an arbitrary precondition P is preserved along the exceptional return path. The seL4 proof is a single composite tactic that relies on dedicated `*_inv` weakest-precondition lemmas:

```
lemma hv_inv_ex:
  "{|P|} handle_vm_fault t vp {|λ_ _. True|}, {|λ_. P|}"
  by (cases vp;
      wpsimp wp: dmo_inv getDFSR_inv getFAR_inv
                 getIFSR_inv getRestartPC_inv)
```

Our framework arrives at a substantially different proof. It does not use any of the `*_inv` lemmas; instead, it rebuilds the argument as a 29-step script of `wp`/`wpsimp` calls, `clarsimp` unfoldings, and four explicit postcondition weakenings via `hoare_post_imp`. Sledgehammer is never invoked: every step is produced by the LLM and validated by the Isabelle kernel. The proof below is abridged.

What the framework did. After the initial `cases vp` split, the proof unfolds along three near-parallel branches, one per fault sub-handler (`getDFSR`, `getFAR`, `getIFSR`). Tree search repeatedly favored `wp`/`wpsimp` steps interleaved with `clarsimp` unfoldings as the symbolic state became exposed. At four points, the LLM proposed intermediate postconditions through `rule_tac P=... + hoare_post_imp`, which were essential to keep the proof state tractable. None of the 29 steps required Sledgehammer.

```
lemma hv_inv_ex:
  "{|P|} handle_vm_fault t vp {|λ_ _. True|}, {|λ_. P|}"
apply (cases vp, simp_all)
apply wp
apply (clarsimp simp: do_machine_op_def getDFSR_def)
apply wp
apply (case_tac rv)
apply clarsimp
apply (rule_tac P="P and (λx. snd (aa,ba) =
       machine_state x)" in hoare_post_imp)
(* ... 20 proof lines omitted ... *)
apply clarsimp
apply (drule in_inv_by_hoareD [OF gets_inv])
by simp
```

Summary of successful cases. In both cases, the framework reaches the theorem through a proof structure that differs from the seL4 script: decomposing the equality on the opposite side in C1, and expanding a one-line composite tactic into a 29-step derivation in C2. These examples show that the system genuinely composes LLM generation, symbolic validation, and Sledgehammer integration on non-trivial seL4 goals, rather than replaying memorized scripts. Further examples are available in our GitHub repository.

5.2 Failure Analysis

We next turn to the failures. Across the three evaluation splits, 692 theorems remain unsolved (validation: 241, test: 199, test-hard: 252). We study them at two different granularities. At the step level, our *tactic-error* analysis draws on the 7.77M individual tactic attempts logged for the 241 failed theorems on the validation split, where each rejected step records the underlying Isabelle kernel error. At the run level, our *search-outcome* analysis draws on the 451 failed runs from the test and test-hard splits, whose logs record the maximum search depth reached before the budget was exhausted.

Step-level error categories. Of the 7.77M tactic attempts on the validation failures, 30.1% advance or duplicate the proof state, while 69.8% raise a kernel error. Table 5 groups these errors into 12 categories, two of which dominate. The first is *lemma hallucination*, which combines the `undefined-fact`, `undefined-method`, and `undefined-constant` categories and accounts for 61.1% of all errors. The second is *shape mismatch*, captured by `tactic-inapplicable`, which contributes another 17.9%. Together, these two patterns explain 79% of rejected tactics: the model most often cites premises absent from the active context, and otherwise produces well-formed tactics that do not fit the current goal shape. The remaining categories, including schematic-variable mistakes, syntax errors, type errors, tactic timeouts, and unfinished `by` closures, each contribute under 3%.

Search-level outcomes. Table 6 shows how far search gets before exhausting its budget. Only 3.7% of failures stall by depth 10. Most failures therefore make real multi-step progress (≥ 11 depth in 96% of cases) but run out of the 128-

Table 5: Step-level error breakdown over all tactic attempts on the validation failures (241 theorems, 7.77M attempts). Undefined-fact alone accounts for nearly two-thirds of all errors: the LLM repeatedly cites premises that do not exist in the active context.

Error category	Count	%	Error category	Count	%
Undefined fact	3,263,494	60.1	Bad method args.	65,430	1.2
Tactic inapplicable	976,398	17.9	Inner syntax error	50,033	0.9
Multi-line / other	423,982	7.8	Undefined method	47,163	0.8
Unknown variable	161,842	2.9	Proof unfinished	37,100	0.6
Outer syntax error	153,037	2.8	THM exc.	26,750	0.4
Type unification	110,717	2.0	Undefined constant	8,852	0.1
Tactic timeout	102,099	1.8			
			All errors	5,427,419	100

Table 6: Search-depth distribution for failures on the test and test-hard splits (the validation log format does not record depth markers). Only 3.7% of failures stall before depth 10; most failures make substantial multi-step progress and run out of budget later in the search.

Max search depth reached	Theorems	%
0 (no progress past initial state)	11	2.4
1–10 (early stall)	6	1.3
11–30 (medium-depth stall)	109	24.2
31–60 (deep stall)	181	40.1
>60 (very deep)	145	32.0
Total	451	100

attempt budget later in the search. On the validation split, where QuickCheck signals are logged, 23 of 241 failed theorems (9.5%) contain at least one search node with a genuine counterexample. These cases suggest that the extracted obligation is unprovable in the active context, typically because an essential assumption is dropped when proof states are sliced from the original seL4 scripts to form the benchmark; we treat them as benchmark-side issues rather than framework failures. Sledgehammer was invoked on all 241 validation failures that still had a residual goal but closed none of them, indicating that the remaining goals lie outside the reach of off-the-shelf SMT/superposition.

Summary of failure modes. The two analyses converge on the same bottlenecks. At the step level, wasted budget is dominated by missing premises ($\sim$61% of errors) and goal-shape mismatches ($\sim$18%). At the run level, most failed runs do not stall early; they reach substantial depth and then exhaust the budget on residual goals that Sledgehammer cannot close either. We therefore see two clear directions for future work: better premise grounding to reduce lemma hallucination, and longer-horizon planning to prevent late-search collapse on deep proofs.

6 Related Work

6.1 Software System Verification via ITP

Formal methods have successfully verified critical software systems including operating system kernels, hypervisors, file systems and compilers. Interactive theorem proving (ITP) provides strong formal assurance by allowing engineers to encode specifications and build proofs in ITP systems such as Rocq or Isabelle/HOL. Notable examples include CertiKOS [45], which employs a compositional refinement framework to verify a layered OS kernel; CompCert [4], an optimizing C compiler whose translation passes are all verified to preserve semantics; FSCQ [11], a crash-safe file system proven correct under all failure scenarios using Crash Hoare Logic; SeKVM hypervisor [46], a reduced KVM core with enforced confidentiality and integrity of guest memory; seL4 [5], an OS microkernel with machine-checked proofs of functional correctness and security properties. These efforts demonstrate that ITP enables high-assurance proofs for critical systems, albeit at a significant engineering cost.

Another line of work seeks to reduce this cost by automating more of the verification pipeline itself. AutoCorres [47] synthesizes high-level Isabelle specifications from C to ease low-level proof writing within the seL4 verification effort. More recently, Spoq [48] automates the derivation of layered specifications and refinement proofs from unmodified C code, reducing manual Coq effort by around 70% on the SeKVM hypervisor [46]. Spoq 2 [49] extends this direction to security properties, reducing them to inductive invariants over a transition system that Z3 can discharge automatically, and reports up to 80% reduction in manual effort across four real-world systems.

6.2 Automated Theorem Proving

Automated theorem proving (ATP) has long served as a benchmark for machine reasoning. Classical ATP systems rely on symbolic methods, such as resolution-based first-order provers (e.g., Vampire [50], E [51]) and SMT solvers (e.g., Z3 [52], CVC5 [53]) with built-in theories. These solvers are also integrated into interactive theorem provers via hammers (e.g., Sledgehammer [16] in Isabelle), enabling automated discharge of proof goals [54]. Related to ATP, several works (e.g., Ironclad Apps [55] and Verve [56]) leverage verification-aware languages (e.g., Dafny [57] and Boogie [58]) to prove memory and control-flow safety of system components, including kernels and device drivers.

In recent years, machine learning has been increasingly applied to ATP [59]. Early efforts focused on premise selection and tactic prediction using classical learning methods (e.g., Holophrasm [60], TacticToe [26], Proverbot9001 [61], Diva [62]), showing improved success rates in Metamath, HOL4, and Coq. More recently, large language models

(LLMs) have been used to generate complete proofs or sketches [63, 64], achieving near-superhuman results on mathematical problems [65]. Notably, AlphaProof [66] combines Monte Carlo tree search with reinforcement learning to solve IMO-level competition problems in Lean, representing the state of the art in search-based mathematical theorem proving.

Closer to our setting, prior efforts have attempted to bring such techniques to software verification, including Baldur [67], PALM [68], Guided Proof Search [69], and Goedel-Code-Prover [70]. However, these approaches remain limited to textbook-scale problems and do not address the challenges of real-world system-level verification projects such as seL4.

Complementary to whole-proof generation, the proof-step prediction paradigm harnesses LLMs to propose the next tactic or lemma, guided by proof-state feedback. Systems such as GPT-f [71], LISA [31], HTPS [72] and LeanDojo [21] demonstrate the potential of this paradigm across Metamath, Isabelle and Lean, but again primarily on isolated mathematical problems. Our method fills this gap by integrating a fine-tuned LLM for proof search with symbolic techniques, namely proof-step revision and proof-state filtering, making large-scale verification both effective and efficient.

Hybrid approaches such as Thor [73], ProofAug [74], Strat2Rocq [75], and LIPS [76] couple LLM-generated reasoning with ATPs or hammers. However, hammer-only proofs grow brittle on long obligations and place additional trust in the external solver. In contrast, our framework invokes ATP only as a final-stage closer for residual subgoals, keeping the bulk of the proof inside the kernel-checked workflow.

7 Limitations and Future Work

Despite strong empirical performance, our framework has several limitations that suggest directions for future research.

Computational cost. The tree-search procedure remains expensive, as each iteration invokes Isabelle for proof-step execution and state checking. Future work includes state caching, parallel expansion, and cost-aware search policies to improve throughput.

Performance degradation for longer proofs. While our method successfully constructs longer proofs than prior methods, its performance indeed degrades as proof length increases. The current tree-search procedure adopts one-step prediction and bounded search, making it challenging to uncover deeper reasoning chains. Future improvements could involve hierarchical planning, subgoal decomposition, or reinforcement learning from bootstrapped trajectories.

Rigid rule-driven step revision. The step revision modules rely on heuristic tactic-premise recombination and lightweight premise retrieval, which are imperfect and may introduce misleading candidates. Future improvements may learn premise relevance directly from the proof state or integrate stronger semantic filters.

Leveraging frontier models. As frontier LLMs advance in reasoning, an important direction is whether agentic workflows—where a large model autonomously invokes tools, inspects proof states, and iterates—can complement or replace parts of our pipeline. Our use of fine-tuned small models is motivated by lower cost and higher inference throughput, both critical for generating and scoring large candidate pools. A promising hybrid would delegate high-level planning and subgoal decomposition to a frontier model, directly addressing the degradation on longer proofs, while relying on lightweight models for intensive step generation and ranking.

8 Conclusion

In this paper, we present a neuro-symbolic proof-generation framework that automates proof search for large-scale software verification projects in interactive theorem provers. Instead of attempting whole-proof synthesis, our approach performs a best-first tree search over fine-grained proof states, repeatedly querying a lightweight, fine-tuned LLM for the next proof step. This paradigm not only substantially improves data efficiency, but also enables a seamless integration of symbolic reasoning tools with LLM-based step generation and scoring, forming an effective and efficient pipeline for proof-step construction as well as proof-state filtering and ranking. The experiments on the seL4 verification corpus show that our approach significantly outperforms prior baselines. Notably, our method succeeds on a considerably higher proportion of multi-step, nontrivial theorems, addressing a long-standing limitation of LLM-based provers. Additional experiments on AFP projects and translated program-verification benchmarks further showcase strong cross-project generalizability.

Our work provides evidence that proof-step–centric neuro-symbolic search is a practical path toward scalable, automated software verification at the systems level. While challenges remain, our results represent promising progress toward AI-enabled, rigorous engineering methods for real-world computer systems.

Availability. The tool, experimental data, and source code are available at the seL4-proof-search GitHub repository. Additionally, a prebuilt Docker image containing the seL4 verification environment and all required dependencies is available at Docker Hub.

Spain: Succinct proofs for numerical computations

Zachary DeStefano, Noah Golub, Zile Huang, Julius Zhang, Sam Frank, Michael Walfish

Courant Institute, NYU

Abstract. In a succinct proof protocol, a *verifier* gets assurance that an untrusted *prover* executed an agreed computation, without requiring the verifier to re-execute the computation itself. In little more than a decade, this area has undergone a remarkable transformation from theory to implemented systems. This activity is extremely exciting. But there is a catch. To apply succinct proofs, one needs to translate one's computation to a set of equations, or *constraints*. The required translation has so far completely blocked systematic support for *numerical* computations, namely those for which the bulk of the computation uses approximations of real numbers. This paper fills that void with the design, implementation, and evaluation of a system called Spain. The starting insight of Spain is that since numerical computations inherently have approximation error, the constraint formalism should likewise allow for *approximate* satisfiability. Based on this insight, Spain introduces a new proof protocol and new ways to translate computations to constraints. Spain's implementation improves over natural baselines by multiple orders of magnitude.

1 Introduction

A *succinct proof protocol* provides execution integrity: one party (the *verifier*) gets assurance that another party (the *prover*) executed an agreed computation, without requiring the verifier to redo the computation or trust the prover. A variant of this setup is zero-knowledge, which additionally hides sensitive inputs from the verifier. Note that execution integrity is orthogonal to program verification. Program verification is about ensuring that a given program meets a specification; here, the question is whether the alleged outputs of a program, verified or otherwise, truly came from running that program.

Succinct proofs have undergone a remarkable transformation. These constructs were known to theorists, based on foundational results in interactive proofs, zero-knowledge proofs, arguments, and probabilistically checkable proofs (PCPs) in the 1980s and 1990s [13, 14, 16, 17, 34, 65, 80, 89, 91, 120]. At the time, they were considered to be wildly impractical. However, over the past 15 years, these constructs have been refined and implemented (see [130, 140] for surveys). They have even been deployed [69, 126], mostly in cryptocurrency [54, 55, 72, 73, 84, 88, 103]. For example, in a traditional blockchain, every node re-executes all transactions to check the validity of state transitions; with succinct proofs, by contrast, a prover generates a proof once and records it on the blockchain, and other nodes need only verify the proof [133].

Despite all of the progress, there is an inescapable awkwardness in applying succinct proofs. One must *arithmetize* one's computation, which means translating it to equations, or *constraints*; roughly speaking, a solution to the constraints corresponds to a valid program trace. Unfortunately, this process does not match how software developers write programs. Control flow, for example, is unnatural to represent as constraints. Making matters worse, the constraints are expressed over a finite field (such as the integers mod a given prime q), yet finite fields have no notion of negative numbers or even order relationships. Consequently, a simple program operation like conditionally branching based on a comparison between two numbers has a very verbose expression in constraints (§2).

Still, researchers and practitioners manage to get around the semantic gap for certain small-scale computations (like validating blockchain transactions). The verifier is truly fast, and the prover's overhead is "only" $10^6\times$ relative to executing the computation natively (§7, §8).

However, the semantic gap becomes a yawning chasm for *numerical* computations: those for which the bulk of the computation uses fixed-point or floating-point approximations of real numbers. The core issue is that numerical computations don't map naturally to equations over finite fields, not even with the kinds of gymnastics used for non-numerical computations. Not to mention, researchers have no hope of competing with the decades of investment in optimizing FPUs and GPUs.

Yet, numerical computations were one of the primary motivations for the invention of computers, and continue to be of intense interest. In the modern era, LLM training and inference, physics simulations, cyberphysical systems, and far more all compute over approximations of real numbers. Succinct proofs applied to numerical computations would thus allow such computations to run on untrusted infrastructure. For example, a user of an LLM could get a proof that the produced tokens truly came from running inference on a given model. Or someone could run a fluid simulation and then prove to others that the simulation ran as specified, without anyone having to redo the computation.

The purpose of this paper is to produce a system that applies succinct proofs to numerical computations, with three goals:

1. *The system should be general-purpose.* This means that the core proving machinery should not be specialized to the computation itself; in particular, if the computation changes, the core protocol should not have to change, nor should the pencil-and-paper mathematics that undergird the correctness of the succinct proof protocol.
2. *The verifier should be less expensive computationally than native execution.* Otherwise, the verifier could simply run the computation itself. Note that in zero-knowledge setups, this requirement does not arise, as the verifier

is not expected to be able to run the computation itself. However, zero-knowledge is a non-goal for us.

3. *The prover's overhead is no more than three orders of magnitude versus natively executing the computation.* While in ordinary computing contexts, overhead of 1000× would be preposterous, in this research area, the state of the art, including in deployed systems, is $10^5\times$ or $10^6\times$.

Prior works encoding numerical computations in proof systems do one of two things (§8). Some works give standalone encodings of specific numerical operations, embedded in general-purpose proof systems; these arguably meet goal 1 but at the cost of goal 3 [9, 50, 51, 59, 82, 115, 124]. Other works build end-to-end special-purpose protocols for specific numerical computations, sacrificing goal 1 – and in most cases goal 3, too [19, 63, 77, 78, 86, 127, 128, 151]. In fact, only one work that we are aware of has achieved goal 3 [105], but at severe compromise of goals 1 and 2.

This paper describes a system, *Spain*, that achieves all three goals in certain regimes. Spain makes several contributions:

A succinct proof framework for approximate rational arithmetic (§3). Spain's idea here is to reflect existing numerical notions of accuracy by using constraints but having the proving machinery establish that each constraint holds *approximately*.

A new proving protocol (§4). To actually prove that the constraints hold approximately, Spain introduces a new proof protocol. It is built on and inspired by prior work, specifically Spartan [116], Zaratan [42], and DARK [40].

Highly compact arithmetizations (§5). Rather than paying a number of constraints proportional to the number of bits in numerical operations, Spain translates individual numerical operations to *single constraints*; for example, division and square root become one constraint each. This in turn enables highly efficient comparisons, range checks, and piecewise functions. Spain also uses division to create efficient translations of transcendental operations, such as e^x. These encodings could be of independent interest.

Rigorous proof (Apps. B, E, F). We prove correctness of Spain's proof protocol and its arithmetizations.

Implementation of Spain (§6, Appx. G). We have implemented Spain. It includes several *front-ends* that translate numerical computations to constraints and a common *back-end* that implements the Spain prover and verifier.

Experimental evaluation (§7). We evaluate Spain and baseline systems on various applications, including linear programming problems; machine learning primitives and an end-to-end application (GPT-2); fluid simulations; and geospatial calculations. We find that Spain has the fastest (general-purpose) numerical prover in the literature. Additionally, Spain's verifier is the first that we are aware of to beat native execution for reasonably-sized numerical computations.

Like all succinct proof systems, Spain must pay high overheads. However, in exhibiting a new kind of arithmetization, Spain has substantially expanded what is possible.

2 Background

2.1 Numerical computations

People want to perform computations that involve real-numbered arithmetic. However, doing so exactly is often intractable. Instead, numerical programs are implemented with *approximate arithmetic*, which comes in two flavors: fixed-point and floating-point. Both have some rounding, or *error*. *Numerical analysis* studies how to ensure that the final result is meaningful.

Fixed-point arithmetic encodes a subset of the rational numbers (denoted $\mathbb{Q}$), specifically those expressible as an integer divided by a fixed denominator (normally a power of two). Real numbers outside of fixed-point are mapped to nearby fixed-point numbers via rounding, prior to entering fixed-point operations. Operations obey absolute error bounds. For any two fixed-point numbers x and y and primitive operation op (for example, $+$, $-$, $\times$, or $\div$), the fixed-point operation op_δ is defined (ignoring overflow) as:

$$(x \ \text{op}_\delta \ y) = (x \ \text{op} \ y) + \widehat{\delta_\pm},$$

where $|\widehat{\delta_\pm}| \leq \delta$ for some fixed δ that depends on the operation and the fixed-point format.

With floating-point representations and arithmetic, operations obey relative error bounds. Then with op as above, x, y as floating-point numbers, and op_δ now denoting the floating-point operation:

$$(x \ \text{op}_\delta \ y) = (x \ \text{op} \ y) \cdot (1 + \widehat{\delta_\pm}).$$

Where $|\widehat{\delta_\pm}| \leq \delta$. Even simple operations introduce errors. For example, when using single-precision IEEE 754 [2] floating point, $(2 \div_\delta 5) \approx 0.400000006$ rather than exactly 0.4.

2.2 Succinct and probabilistic proofs

A *succinct proof* (or *probabilistic proof*) is a cryptographic protocol between a *prover* and a *verifier* (typically thought of as probabilistic algorithms) about a *statement* that the prover wants to persuade the verifier of [64, 130]. We will in this work consider statements of the form: "(in, out) is a valid input-output pair for some procedure F." That is, the succinct proof is aimed at establishing that the alleged *out* is truly the output when F is run on *in*.

Astonishingly, the data flowing from prover to verifier, and the work required by the verifier, is (at least in principle) much smaller than the work to execute F. Yet, a verifier is unlikely to be fooled by a false claim from the prover.

Succinct proof implementations typically have a *front-end* and a *back-end*. The front-end compiles F into a set of *constraints*. The back-end is the proving and verifying algorithms. We elaborate on both below.

Front-end: Arithmetization and R1CS. Various proof back-ends require statements to be compiled, by the front-end, to a *rank-one constraint system* (R1CS), which we often

refer to as *constraints*. An R1CS *structure* is a system of m equations and n variables over a finite field (typically $\mathbb{F}_q$, the integers mod a prime q) with a subset of the variables designated as *in* and a subset designated as *out* [118]. These equations are represented by three matrices A, B, C, each of dimension $m \times n$. An R1CS *instance* for a given structure is (A, B, C, in, out); we say that an instance is *satisfiable* if there exists some *witness* w such that, for $z := (in, out, 1, w)$, we have: $(A \cdot z) \circ (B \cdot z) - (C \cdot z) = \vec{0}$, with $\circ$ denoting entry-wise multiplication. Unpacking the algebra, each constraint $i \in \{1, \ldots, m\}$ restricts any *assignment*, that is any valuation of the variables $z = (z_1, \ldots, z_n)$, as follows: $(A_{i,1}z_1 + \cdots + A_{i,n}z_n) \cdot (B_{i,1}z_1 + \cdots + B_{i,n}z_n) - (C_{i,1}z_1 + \cdots + C_{i,n}z_n) = 0$.

As a simple example, take the computation

function $F(z_1, z_2, z_3)$
  $z_4 \leftarrow (z_1^2 - 4) \cdot (z_2 + 3z_3) - 2$
  return z_4

Here *in* is (z_1, z_2, z_3) and *out* is z_4. The first step in translation to R1CS is to unroll the computation so that each line of code is written as a product of linear combinations of variables, minus another linear combination of variables:

function $F(z_1, z_2, z_3)$
  $z_6 \leftarrow z_1 \cdot z_1 - 4$ // z_6 is a new var, part of the witness
  $z_4 \leftarrow z_6 \cdot (z_2 + 3z_3) - 2$
  return z_4

Next, these lines are translated to constraints, each of which becomes a row in the A, B, C matrices. These constraints are:

$$(1 \cdot z_1) \cdot (1 \cdot z_1) - (1 \cdot z_6 + 4 \cdot 1) = 0$$
$$(1 \cdot z_6) \cdot (1 \cdot z_2 + 3 \cdot z_3) - (1 \cdot z_4 + 2 \cdot 1) = 0.$$

In matrix form, the constraints are:

$$A = \begin{array}{c} \begin{matrix} z_1 & z_2 & z_3 & z_4 & z_5 & z_6 \end{matrix} \\ \left[\begin{array}{ccc|c|c|c} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{array}\right] \end{array}$$

$$B = \left[\begin{array}{ccc|c|c|c} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 3 & 0 & 0 & 0 \end{array}\right]$$

$$C = \begin{array}{c} \left[\begin{array}{ccc|c|c|c} 0 & 0 & 0 & 0 & 4 & 1 \\ 0 & 0 & 0 & 1 & 2 & 0 \end{array}\right] \\ \begin{matrix} \multicolumn{3}{c}{in} & out & 1 & w \end{matrix} \end{array}$$

Now, consider this valuation of the *in* variables: z_1=3, z_2=2, z_3=−1 (these quantities are in $\mathbb{F}_q$, so −1 is shorthand for $q - 1$), and the corresponding *out* valuation: $z_4 = -7$ (shorthand for $q - 7$). In this case, the full assignment is $z = [3, 2, -1, -7, 1, 5]^\intercal$. When subsequently giving example constraints, we drop the explicit "1·", add the "C piece" to both sides, and use semantically appropriate variables to refer to elements of z.

One can translate an entire unrolled computation to a set of constraints, in the sense that some z satisfies the constraints only if z respects the original semantics of the computation. This translation is called *arithmetization* [7, 17, 18, 24, 35, 36, 49, 75, 81, 96, 97, 115, 118, 138, 146, 147]. It is typically accompanied by a *witness generator*, which either executes the computation and thereby obtains the assignment to z [15, 24, 26, 76, 81, 102], or else solves the constraints using annotations provided by the translation process [35, 75, 96, 100, 114, 115].

Modern proof systems also translate computations into *lookup tables* [31, 33, 41, 57, 71, 119, 119], often in combination with constraints. However, lookup tables outperform constraints only when the table is small (for example, 2^8 elements) or has algebraic structure [119]. Numerical operations do not generally fit into either of these categories.

Back-end: Proving R1CS satisfiability. The job of the back-end is, given an R1CS structure and instance (A, B, C, in, out), to prove that a satisfying assignment exists. The back-end provides the following properties, which we state informally.

- *Back-end soundness:* If there does not exist a w such that $z := (in, out, 1, w)$ makes $(A \cdot z) \circ (B \cdot z) - (C \cdot z) = 0$, then the probability (over the verifier's random choices) that the verifier accepts is negligible.
- *Back-end completeness:* If a prover has access to w such that $z := (in, out, 1, w)$ makes $(A \cdot z) \circ (B \cdot z) - (C \cdot z) = 0$, then the prover can make the verifier accept with probability 1, over the prover's and verifier's random choices.

For our work, the relevant strand of back-end protocols is based on the *sum-check* primitive [89]. We defer justifying this choice until we have established the necessary context (§4.1, §4.2.2). The sum-check primitive is an interactive proof [16, 65] by which the prover persuades the verifier that the sum of a given multi-variate polynomial's evaluations over all Boolean combinations that its variables can take is a given value. (Appendix A reviews this primitive.) Succinct proofs that use the sum-check primitive typically do so multiple times within the same protocol; for example, GKR [66, 67] invokes the sum-check primitive once per layer in a layered circuit while Spartan [116] invokes the primitive twice (loosely speaking, one invocation is over the rows of the R1CS instance and one is over the columns). We call proofs built on the sum-check primitive *sum-check protocols* [30, 42, 44–46, 48, 60, 66–68, 116, 117, 119, 123, 129, 135–137, 139, 143, 147, 148].

Modern works in this strand [131] rely on *polynomial commitment*. The idea is that w is encoded as a polynomial by the prover; a small *commitment* (far smaller than w) is sent to the verifier; this commitment binds the prover to that polynomial; and one or more invocations of the sum-check primitive prove that an additional polynomial (formed from the prover's committed polynomial, from *in* and *out*, and from the R1CS structure itself) has a certain property that is equivalent to $z = (in, out, 1, w)$ satisfying the instance.

The costs of the back-end are driven by the *number of constraints*, m and the *number of witness elements*, $|w|$. Specifically, the prover's costs are roughly $O(m + |w|)$. The verifier's costs vary based on the protocol. Our work follows Spartan [92, 116] (without its SPARK module), where the verifier

has an $O(m)$ *fixed cost* that is specific to the structure (the constraints); this cost amortizes over synchronized instances, with each instance adding cost that is $O(\log(|w|))$. There is also an $O(\log(|w|))$ *setup cost*, reusable across all future invocations, including different R1CS structures. See elsewhere [38, 116, 117, 119] for techniques that asymptotically lower the verifier's work at the prover's expense.

To quantify, running the prover on a single machine is generally considered unreasonable when m and $|w|$ are above 2^{29} (unless one possesses terabytes of RAM and hundreds of cores) [108], owing to memory bottlenecks. There are techniques for scaling across a fleet [87, 108, 142, 144], and reducing memory requirements at the cost of increased prover time [20, 93, 99], but neither approach mitigates the sheer amount of work required to prove large computations.

Arithmetization poses a semantic challenge. A salient cost is translating from ordinary computations to R1CS; this appears in the values of m and $|w|$. Indeed, there is a massive semantic gap in this research area: ordinary computations do not map to equations over finite fields in a natural way. To highlight the challenge, consider the division of two positive k-bit integers. Checking this computation, $z \leftarrow x/y$, in R1CS involves two steps. First, the prover supplies the purported quotient z and remainder r and the following constraint is added: $y \cdot z = x - r$, where r is a witness variable. Second, constraints are required to assert that $x \geq (z+1)$ and $y \geq (r+1)$.

But finite fields have no native notion of order, so a typical arithmetization of assert$(x \geq (z+1))$, where x and z are k-bit numbers, introduces witness variables $b_0, \ldots, b_{k-1}$ representing the bits of $x - (z+1)$. Then, for all i, constraints are added to enforce that each variable b_i is a bit: $b_i \cdot (1 - b_i) = 0$. Finally, a constraint is added to enforce the relationship among x, z, and the bits: $\sum_{i=0}^{k-1} b_i 2^i = x - z - 1$. This set of constraints is satisfiable only if $x - z - 1$ is itself a k-bit number. This assert alone requires k additional variables and $k+1$ constraints.

This blowup is not isolated to division. Researchers in succinct proofs often perform contortions to represent computations. While there are, for example, more succinct encodings of certain kinds of conditional operations [115], arbitrary low-level operations of the kind that would ordinarily be accelerated in hardware are not well-handled. In particular, representing a single numerical operation in R1CS typically involves explicitly expressing the digital logic of the operation. This results in a number of auxiliary variables and constraints that is a multiple of the *number of bits of the numbers being represented* in each operation [9, 50, 51, 82, 124] (§7, §8), rather than the *number of machine instructions that would be required in an ordinary computing context*.

3 Problem statement and overview of Spain

Problem statement. A prover and a verifier agree on a single numerical computation, F. The verifier sends input *in*, the prover executes F on that input, and claims that the output is *out*. The prover then wants to persuade the verifier that *out* indeed could have been produced by $F(in)$, given the kinds of approximation that are inherent in fixed- or floating-point numerical computation. The verifier should spend fewer computational resources than if it ran $F(in)$ itself; otherwise, the verifier could disregard *out*, and simply use the result of executing F on *in*. We will sometimes work in an amortized setting where multiple instances of F are outsourced on $in_1, \ldots, in_L$ different inputs, getting different outputs $out_1, \ldots, out_L$.

The core conflict. On the one hand, existing proof machinery ensures that an execution proceeded *exactly* as it was supposed to. On the other hand, in the numerical context "supposed to" means "certain *error*". To resolve this conflict between exactness and error, any protocol must reject truly wrong executions, namely those that include any operations with more than δ error (§2.1). At the same time, the protocol must not be too much of a scold: if all operations do obey the δ error bound, then the given execution should be accepted.

As noted in Section 2.2, some works handle this tension by representing the digital logic of the approximate computation in the arithmetization (the R1CS instance). A related approach is for the prover to embed in the R1CS instance variables that capture each operation's error, thereby making the error incurred by each operation part of the statement to be validated [59]. Both approaches bring expense.

Overview of Spain. In contrast to existing work, Spain's arithmetizations are agnostic to the error in each operation, yet the prover is forced to adhere to the bounds. Spain combines several new techniques, in the front-end and back-end. Figure 1 depicts Spain, contrasting it with the most natural baseline.

Front-end (§5): Spain introduces a new kind of arithmetization; it translates F to a set of constraints over the *rational numbers* $\mathbb{Q}$ (rather than a finite field $\mathbb{F}_q$) in way that satisfying all constraints up to some ϵ corresponds to error up to δ in each operation. Each constraint $i \in \{1, \ldots, m\}$ enforces: $\left|\left(A_{i,1}z_1 + \cdots + A_{i,n}z_n\right) \cdot \left(B_{i,1}z_1 + \cdots + B_{i,n}z_n\right) - \left(C_{i,1}z_1 + \cdots + C_{i,n}z_n\right)\right| \leq \epsilon$. We call such constraints *approximate constraints*; compare to the constraints in §2.2 that enforce equality, which we call *traditional constraints*.

Approximate constraints are dramatically more concise than the alternative; in fact, each low-level operation in F generally corresponds to one or a small number of constraints. The intuition is that constraints in Spain are freed from operating on the bits of operands, being expressed over $\mathbb{Q}$, and are freed from explicitly encoding approximation error, as "$\leq \epsilon$" encodes slackness directly. The trade-off is that a user of Spain must perform certain analyses not needed when working with traditional constraints. This requirement is a manifestation of the conflict stated earlier: the user must show that satisfying the constraints means the prover adhered to "$\leq \delta$" error, and also show that if the prover does execute the operation with bounded error, then it *can* satisfy the approximate constraints.

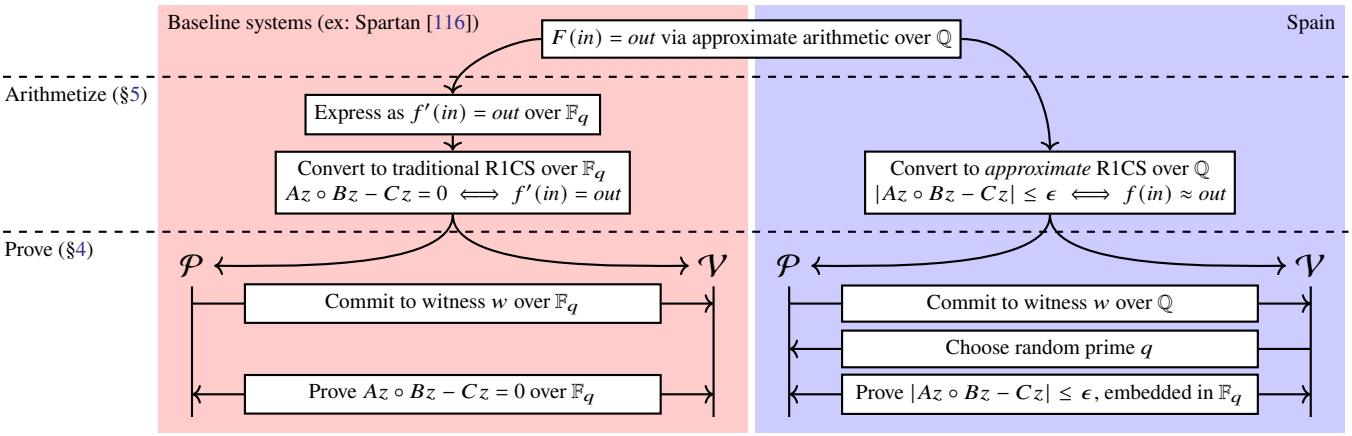

Figure 1: High-level comparison between existing proof systems (left) and Spain (right). Given an initial claim, the protocol is divided into two phases: arithmetization and proving. Similar steps are vertically aligned to facilitate comparison.

Back-end (§4): Spain's back-end enables a prover to establish that a given assignment (to a given set of constraints) meets the ϵ bounds. We call such an assignment ϵ-*accurate*.

Compared to prior work, Spain's back-end has three interlocked aspects. First, Spain maps the constraints over $\mathbb{Q}$ to a finite field, which is the kind of domain typically used in sum-check protocols (§2.2). However, preserving the semantics of the constraints in the finite field requires care; a key mechanism is that the verifier chooses the finite field (via prime q) only after the prover commits to the assignment.

Second, Spain establishes a statement that implies ϵ-accuracy. Specifically, Spain modifies Spartan [116] to prove a statement about the sum of each constraint's squared error, for a given assignment; this sum will be notated as $\|E_{\mathbb{X},z}\|_2^2$. As we argue later, by proving that $\|E_{\mathbb{X},z}\|_2^2$ is small, the protocol guarantees that the assignment obeyed the required ϵ bounds. Third, Spain uses a polynomial commitment protocol (§2.2) that is geared to integers, but makes several technical adjustments, as naive use of this primitive in our context would be prohibitive.

4 Spain's approximation-friendly back-end

This section presents the core statement that Spain's back-end proves (§4.1) and the techniques that it uses to do so (§4.2–§4.3). First, though, we must define what it means for a back-end to be correct in Spain's context. We do so by modifying the existing back-end notions of soundness and completeness (§2.2). The modified properties are as follows, with respect to an R1CS instance $\mathbb{X} = (A, B, C, in, out)$:

- *Back-end ϵ-soundness.* If there does not exist a w such that $z := (in, out, 1, w)$ is ϵ-accurate for $\mathbb{X}$, then the probability κ (over the verifier's random choices) that the verifier accepts is negligible. κ is known as *soundness error*.
- *Back-end ϵ_C-completeness.* A prover with access to w such that $z := (in, out, 1, w)$ is ϵ_C-accurate for $\mathbb{X}$ can make the verifier accept with probability 1, over the prover's and verifier's random choices in the protocol.

These definitions embed two different levels of ϵ-accuracy; at the end of Section 4.1 below, we will see that $\epsilon_C < \epsilon$. To preview the practical consequence, an honest prover will have to execute with greater precision (for completeness) than what the protocol guarantees to the verifier (via soundness).

4.1 What claim about error should be proved?

Spain's back-end must establish the ϵ-accuracy of an assignment z. Before highlighting the challenges, we give a compact notation for ϵ-accuracy. Define the *error vector* $E_{\mathbb{X},z}$ for an R1CS instance $\mathbb{X} = (A, B, C, in, out)$ and an assignment $z = (in, out, 1, w)$ as:

$$E_{\mathbb{X},z} := (A \cdot z) \circ (B \cdot z) - (C \cdot z).$$

This error vector has m components. Its ith component is $(A_i \cdot z) \cdot (B_i \cdot z) - (C_i \cdot z)$, where A_i, B_i, and C_i are the ith rows of A, B, and C. Notice that if the component with maximum absolute value is upper-bounded by ϵ, that is equivalent to saying that the assignment z for the instance $\mathbb{X}$ is ϵ-accurate (§3). Meanwhile, the maximum absolute value over all components of $E_{\mathbb{X},z}$ is, by definition, the ℓ^∞ norm of $E_{\mathbb{X},z}$, denoted $\|E_{\mathbb{X},z}\|_\infty$. Thus, ϵ-accuracy can be written:

$$\|E_{\mathbb{X},z}\|_\infty \leq \epsilon.$$

One challenge is that we don't know how to apply proving machinery to this inequality directly. Sum-check protocols (§2.2), for example, work over polynomial expressions. Although Spartan [116] shows how to cast R1CS satisfiability as suitable polynomial expressions, the ℓ^∞ norm cannot be turned into polynomial expressions, because of the absolute value and maximum operations.

Instead, our insight here is that *the square of the ℓ^2 norm* is compatible with sum-check protocols, and this quantity upper-bounds the square of the ℓ^∞ norm. Specifically, for a vector v,

the square of the ℓ^2 norm, $\|v\|_2^2$, is $\sum_{i=1}^{m} v_i^2$. Also, the definitions of the norms imply that for any vector v, $\|v\|_\infty^2 \leq \|v\|_2^2$. So, if the prover could persuade the verifier that

$$\|E_{\mathbb{X},z}\|_2^2 = J, \tag{1}$$

for some J, and if the verifier then checked that $J \leq \epsilon^2$, that would suffice to establish that $\|E_{\mathbb{X},z}\|_\infty \leq \epsilon$.

However, there is another difficulty. While $\|E_{\mathbb{X},z}\|_2^2 \leq \epsilon^2$ implies $\|E_{\mathbb{X},z}\|_\infty \leq \epsilon$, the converse is not true. Consequently, an assignment z could well satisfy $\|E_{\mathbb{X},z}\|_\infty \leq \epsilon$, but Equation (1) would not hold for any $J \leq \epsilon^2$. In a full protocol, an honest prover would then have no way to convince the verifier.

To address this, the execution by the prover has to be more accurate than ϵ. Specifically, while Spain must meet Back-end ϵ-soundness, it must meet Back-end ϵ_C-completeness, where $\epsilon_C = \epsilon/\sqrt{m}$. (The gap between ϵ and ϵ_C can be narrowed; §D.3.) Under these conditions, there does exist $J \leq \epsilon^2$ with $\|E_{\mathbb{X},z}\|_2^2 = J$. To see this, notice that the definitions of the norms imply that for any vector v, $\|v\|_2^2 \leq m \cdot \|v\|_\infty^2$. Consequently, requiring that the prover produces an ϵ_C-accurate z yields $\|E_{\mathbb{X},z}\|_\infty \leq \epsilon_C = \epsilon/\sqrt{m}$ and thus:

$$\|E_{\mathbb{X},z}\|_2^2 \leq m \cdot \|E_{\mathbb{X},z}\|_\infty^2 \leq m \cdot \epsilon_C^2 \leq \epsilon^2.$$

4.2 Main protocol

Spain's back-end aims to establish Equation (1). Spain adapts three existing tools, specifically *Spartan* [116], which is a sum-check protocol (§2.2) that targets R1CS instances, and forms the core of Spain's back-end; *DARK* [40], which is a polynomial commitment protocol (§2.2) with the ability to bind the prover to a polynomial over $\mathbb{Q}$; and *Zaratan* [42], which is a framework for proving traditional R1CS satisfiability over the integers, as opposed to over a finite field.

One of the configurations explicitly considered by Zaratan is combining Spartan and DARK, and we will do likewise. Specifically, whereas Spartan assumes that an R1CS structure is defined over a finite field (typically $\mathbb{F}_q$; §2.2), Zaratan observes that q can be chosen at run-time by the verifier, after the prover commits to an encoded version of w via DARK.

Spain's full protocol is given in Appendix B. Figure 2 provides an overview. This protocol embeds three major changes compared to prior work, as outlined below.

4.2.1 Proving statements over $\mathbb{Q}$

Constraints in Spain are expressed over the rational numbers, $\mathbb{Q}$. However, the sum-check primitive is typically applied over a finite field (§1, §2.2). Accordingly, Spain maps Equation (1) into a corresponding claim over a finite field, namely $\mathbb{F}_q$. But, this mapping is fraught; to highlight the challenge, we introduce some mathematical language.

Define $\mathbb{Q}^{(q)}$ as $\{(a, b) \in \mathbb{Q} \mid q \nmid b\}$. This set is the rational numbers without multiples of q in the denominator.[1] Spain

[1]Mathematically, this set is known as a localization [141], and could be written $(\mathbb{Z} \setminus q\mathbb{Z})^{-1}\mathbb{Z}$, or $\mathbb{Z}_{(q)}$.

1. The prover runs an agreed-upon computation F, thereby producing w.
2. Using DARK, the prover encodes w as a polynomial, $\widetilde{w}$; *commits* (§2.2) to that polynomial; and sends this commitment to the verifier, effectively binding itself to the value of $E_{\mathbb{X},z}$.
3. The prover computes and sends J to the verifier; J is purportedly $\|E_{\mathbb{X},z}\|_2^2$.
4. The verifier checks that J is less than ϵ^2.
5. The verifier sends a prime q to the prover randomly chosen from a set of large primes.
6. The prover and verifier map all rationals to elements of $\mathbb{F}_q$ and apply the sum-check protocol to the claim $\rho_q(\|E_{\mathbb{X},z}\|_2^2) = \rho_q(J)$, reducing it to a claim about $\widetilde{w}$.
7. The verifier checks consistency between the claim in Step 6 and the commitment to $\widetilde{w}$ in Step 2.

Figure 2: Spain's back-end protocol (simplified).

maps these numbers into a finite field, via:

$$\rho_q : \mathbb{Q}^{(q)} \longrightarrow \mathbb{F}_q$$
$$(a, b) \longmapsto (a \bmod q)(b \bmod q)^{-1},$$

and the Spain prover and verifier apply a sum-check protocol to the claim:

$$\rho_q(\|E_{\mathbb{X},z}\|_2^2) = \rho_q(J). \tag{2}$$

However, for this approach to make sense, there are two requirements. First, arithmetic must stay in $\mathbb{Q}^{(q)}$, otherwise ρ_q is undefined. Second, unequal quantities in $\mathbb{Q}^{(q)}$ should stay unequal after the mapping. That is, if $\|E_{\mathbb{X},z}\|_2^2 \neq J$, then $\rho_q(\|E_{\mathbb{X},z}\|_2^2) = \rho_q(J)$ should not occur, except with negligible probability (over the verifier's choice of q).

Spain achieves both requirements through a combination of convention, DARK, and the verifier's checks. The starting convention is that all rational numbers in the A, B, C matrices that define an R1CS instance $\mathbb{X}$ are presumed to have a denominator D that is a power of two; thus q does not divide D. Furthermore, the assignment z is supposed to follow this convention as well. DARK partially preserves the convention, by ensuring that all committed rationals (Step 2) have the same denominator but not necessarily that it is exactly D. Surprisingly, this partial preservation does not give the prover room to cheat without detection (§B). For simplicity, our description below assumes that DARK preserves the convention fully.

One consequence is that arithmetic begins in $\mathbb{Q}^{(q)}$, and stays there. Thus, ρ_q is defined on all intermediate values and the result. To see this, notice that the convention ensures that the entries of $A \cdot z$, $B \cdot z$, and $C \cdot z$ have denominator D^2; the entries of $(A \cdot z) \circ (B \cdot z)$ have denominator D^4, and the values of $((A_i \cdot z) \cdot (B_i \cdot z) - (C_i \cdot z))^2$, and hence $\|E_{\mathbb{X},z}\|_2^2$, have denominator D^8. The verifier completes the enforcement by requiring J to have denominator D^8.

Another consequence is that this approach avoids collisions. If $\|E_{\mathbb{X},z}\|_2^2$ and J are not equal, then given that they have the same denominator, $\rho_q(\|E_{\mathbb{X},z}\|_2^2) = \rho_q(J)$ only if the numerator N of $\|E_{\mathbb{X},z}\|_2^2 - J$ is a multiple of q. Analysis shows that by limiting the numerators of the entries of A, B, C, and z, N can be kept small enough that the probability of a randomly chosen large prime, like q, dividing N is low (Appx. B.5).

Both Spain and Zaratan [42] map a claim from a larger domain (in their case $\mathbb{Z}$, in Spain's case $\mathbb{Q}$) to some $\mathbb{F}_q$. However, the introduction of a denominator in Spain significantly complicates the analysis of collisions.

The bottom line is that Spain ensures that if the prover sends a $J \neq \|E_{\mathbb{X},z}\|_2^2$ (Step 3, Figure 2), then with overwhelming probability over the choice of q in Step 5, $\rho_q(\|E_{\mathbb{X},z}\|_2^2) \neq \rho_q(J)$. Consequently, if the prover did lie in Step 3, it would be stuck trying to prove a false statement in Step 6.

4.2.2 Proving a new type of claim

To prove that $\rho_q(\|E_{\mathbb{X},z}\|_2^2) = \rho_q(J)$, Spain observes that an adaptation of Spartan can directly prove statements about the squared ℓ^2 norm of the errors in an R1CS instance.

To explain how Spain both borrows and diverges from Spartan, we must present some further mathematical detail. One can view $A, B, C \in \mathbb{F}_q^{m \times n}$, and $z \in \mathbb{F}_q^n$ as *functions*. Specifically, letting $s = \lceil \log m \rceil$ and $k = \lceil \log n \rceil$, we view the matrices as functions $\{0,1\}^s \times \{0,1\}^k \to \mathbb{F}_q$. For example, $A(r, c)$ is the entry of A at the row given by the binary representation of r and the column given by the binary representation of c. We do the same for z, viewing it as a function $\{0,1\}^k \to \mathbb{F}_q$.

An important concept is a polynomial *extension* of a discrete function. The polynomial extension of a function agrees with that function everywhere the function is defined, but the polynomial is defined over a larger domain. A polynomial extension can be thought of as an *encoding* of that function. As a simple example, imagine defining a function f at points 0 and 1, and drawing a line (a first-degree polynomial) through $f(0)$ and $f(1)$. The entire line – its description, or any two points on it – encodes the values of $f(0)$ and $f(1)$. We denote *multilinear extensions* with tildes. For example, for a function $f(\cdot)$ defined over $x \in \{0,1\}^s$, the multilinear extension of f is $\tilde{f} : \mathbb{F}_q^s \to \mathbb{F}_q$, which is a polynomial that equals f on $\{0,1\}^s$, with degree no more than 1 in each variable.

Now, let M stand in for A, B, or C, and let $\widetilde{g_M}(t) := \sum_{c \in \{0,1\}^k} \widetilde{M}(t, c) \cdot \widetilde{z}(c)$, where $\widetilde{M}$ and $\widetilde{z}$ are the multilinear extensions of M and z, respectively (when mapped to $\mathbb{F}_q$). Also, let $Eq(\cdot,\cdot)$ return 1 if its two arguments, viewed as s-bit strings, are the same and 0 otherwise; denote the multilinear extension of Eq as $\widetilde{Eq}$.

In Spartan (and Zaratan), the prover aims to persuade the verifier of the following, where τ is chosen randomly [116, §4]:

$$\sum_{r \in \{0,1\}^s} (\widetilde{g_A}(r) \cdot \widetilde{g_B}(r) - \widetilde{g_C}(r)) \cdot \widetilde{Eq}(\tau, r) = 0. \qquad (3)$$

In Spain, by contrast, the prover aims to persuade the verifier (in Step 6) that the following holds:

$$\sum_{r \in \{0,1\}^s} (\widetilde{g_A}(r) \cdot \widetilde{g_B}(r) - \widetilde{g_C}(r))^2 = \rho_q(J). \qquad (4)$$

Notice from the definition of extension that the left-hand side above sums the squared error for each constraint, given assignment z, when the constraints and z are mapped to $\mathbb{F}_q$. That sum is $\rho_q(\|E_{\mathbb{X},z}\|_2^2)$. Thus, the protocol is indeed establishing Equation (2). After this step, Spain follows Spartan.

4.2.3 Accelerating and adapting DARK

Spain makes two sets of modifications to DARK. First, whereas DARK normally works over a group of order unknown to both prover and verifier, Spain exploits interactivity to have the verifier generate a group for which it alone knows the order. Appendix C details this technique.

Second, DARK as originally proposed had an error: it provided only a weak binding property, namely it ensured only that the committed-to polynomial had *rational* coefficients [29]. This was problematic for Zaratan and other uses of DARK (for example, in combination with Spartan), as those uses require a polynomial with *integer* coefficients. Thus, Zaratan (and other protocols) layer techniques [29, 42] atop DARK, which have extra costs. However, in our context, the original (weaker) form of DARK suffices. Appendix B gives details.

4.3 Support for batching and "just in time" R1CS

Spain supports two variants of R1CS. The first is a *SIMD-R1CS instance* [134], which is a combination of L R1CS instances with the same structure (that is, multiple executions of the same program on different inputs). The second is an *I-R1CS instance* [97], where the prover and verifier interact to construct the full instance. Given a partial R1CS instance (one with some variables missing), the prover and verifier take turns filling it in. In round i, the prover commits to w_i, and the verifier sends additional in_i. The final R1CS instance has assignment $z := (in_1, \ldots, in_R, out, 1, w_1, \ldots, w_R)$.

Spain extends I-R1CS in a natural way: in Spain, the verifier may also supply *constraints*. Thus, the prover and verifier start with a partial structure, and as the prover commits to w_i in round i, the verifier submits in_i or new constraints. Further details of Spain's support for R1CS variants are in Appendix D.

5 Encoding numerical operations in R1CS

This section describes how, by taking advantage of the backend claim of ϵ-accuracy (§4), Spain produces dramatically more concise arithmetizations versus the traditional approach.

Using approximate constraints (§3) requires a new kind of correspondence between a numerical function F and an

R1CS structure that allegedly arithmetizes F. Roughly speaking, (a) any assignment that is ϵ-accurate (§3) for the constraints should correspond to an execution of F with operations bounded by δ (§2.1), and (b) for every execution of F with operations bounded by δ_{wg} (where δ_{wg} is a constant smaller than δ) there should be an ϵ_C-accurate assignment. The need for separate δ and δ_{wg} reflects the same asymmetry that leads to $\epsilon_C < \epsilon$ (§4). Appendix E formalizes (a) and (b) as *translation fidelity*, and proves that the constraints described in this section meet these properties.

Note that translation fidelity concerns the error in *each* operation, not the accumulated error in the output of a computation. This is analogous to how the IEEE floating-point specification [2] bounds the error in each operation and relies on numerical analysis to derive bounds on the accumulated error.

Below we present arithmetizations using approximate constraints, notating them with $\approx_\epsilon$. For example, $z_1 \cdot z_2 \approx_\epsilon z_3$ enforces $|z_1 \cdot z_2 - z_3| \leq \epsilon$.

Division and square root. Recall that checking $z \leftarrow x/y$ traditionally requires dozens of constraints (§2.2). Spain uses *one* constraint: $y \cdot z \approx_\epsilon x$.

In traditional constraints, the square root operation ($y \leftarrow \sqrt{x}$) is encoded as $y \cdot y = x - r$ plus dozens of constraints to bound r in terms of x and y. Spain again requires only one constraint: $y \cdot y \approx_\epsilon x$. This takes advantage of the fact that all real square roots have arbitrarily close rational approximations. If one wants a specifically positive or negative root, one applies the square root operation again! For example, suppose we want y to be the negative square root of x. Then we use an additional constraint: $t \cdot t \approx_\epsilon -y$, exploiting the fact that $-y$ must be non-negative to have a real square root.

Note that this encoding of the square root operation can be satisfied when x is a small negative number, in contrast to usual numerical computations, where Not a Number (NaN) would arise. If this is problematic, the constraints and/or numerical analysis should ensure that the function's input is strictly non-negative.

The power of approximate square roots. In traditional arithmetization, bottlenecks include range checks, branching, max, and min. As we show next, Spain arithmetizes approximate versions of these operations orders of magnitude more efficiently, using square roots.

assert ($\mathbf{x} \geq \mathbf{y}$). Recall from Section 2.2 that this operation required k additional variables and $k+1$ constraints. Spain requires only 1 constraint and 1 additional variable, regardless of bit width: $t \cdot t \approx_\epsilon x - y$, for some witness variable t. This is not a strict translation of assert but instead an approximate version that allows x to be ϵ smaller than y but no smaller.

$\mathbf{b} \leftarrow (\mathbf{x} \geq \mathbf{y})$. Spain requires only 3 constraints and 2 auxiliary variables: $b \cdot (1-b) \approx_\epsilon 0$, $(2b-1) \cdot (x-y) \approx_\epsilon t$, and $s \cdot s \approx_\epsilon t$. The first constraint ensures that b is Boolean. The second ensures that t is non-negative only when b correctly reflects the comparison. The third ensures that t is indeed non-negative. As with square root and assert, this comparison is an approximate version; Appendix E.2 delves into the semantics.

max. Consider $z \leftarrow \max(v)$ for an array $v = [v_1, \ldots, v_L]$. Spain's approach here is inspired by Distiller [76], which encodes a *checker* for min, rather than embedding logic to identify the minimum. However, Distiller requires $L \cdot (k+3)+1$ constraints and $L \cdot (k+2)$ witness variables, where k is the bit-widths of the elements in the array. Spain's are far more concise because it pays so little for comparison operations:

- for all $i \in \{1, \ldots, L\}$: $t_i \cdot t_i \approx_\epsilon z - v_i$
- for all $i \in \{1, \ldots, L\}$: $b_i \cdot (1 - b_i) \approx_\epsilon 0$
- for all $i \in \{1, \ldots, L\}$: $b_i \cdot (z - v_i) \approx_\epsilon 0$
- $\sum_{i=1}^{L} b_i \approx_\epsilon 1$

The first set ensures that z is greater than or equal to all elements in the array. The next two sets ensure that b_i is Boolean and that b_i can be 1 only if $v_i = z$ (to support multiple equal maxima, b_i is allowed to be 0 even when $v_i = z$). The last ensures that exactly one of the b_i is 1. This requires $3 \cdot L + 1$ constraints and $2 \cdot L$ auxiliary variables.

Piecewise functions, sorting, and beyond. The encoding of comparisons naturally leads to efficient translations of piecewise functions; ReLU will demonstrate this below. Similarly, the previous best solutions for sorting or for string manipulation paid relative to the number of bits in their inputs due to comparisons, while Spain's approach more closely matches the number of instructions in a typical CPU execution.

ReLU is a primitive in machine learning contexts. The operation is $z \leftarrow \max(0, x)$. This function can be represented in constraints as $s \cdot s \approx_\epsilon z - x$, $t \cdot t \approx_\epsilon z$, and $(z - x) \cdot z \approx_\epsilon 0$. The first two ensure that $z \geq \max(0, x)$. The last one ensures that $z = 0$ or $z = x$.

Transcendental functions. Arithmetizing transcendental functions, such as e^x or $\tanh(x)$, over some interval traditionally uses *polynomial approximation* [50, 51, 78, 82, 105, 124, 128, 151]. Specifically, for a function $f(x)$ to be approximated, one identifies a polynomial $P(x)$ such that $|P(x) - f(x)| \leq \delta$ for x in the given interval. The motivation is that add and multiply, which are the operations that polynomials require, are the easiest to represent in traditional constraints.

However, there is an additional issue (besides the overhead from traditional enforcement of numerical operations in constraints): polynomials require many terms to converge. Drawing on its support for division, Spain uses *rational approximations*: a ratio of polynomials $P(x)/Q(x)$ such that $|P(x)/Q(x) - f(x)| \leq \delta$ for x in the interval. In Spain, rational approximations cost nearly nothing extra over polynomial approximations, but rational approximations converge faster. To illustrate, compare the degree-4 Taylor series for e^x:

$$g(x) = 1 + x + \frac{x^2}{2} + \frac{x^3}{6} + \frac{x^4}{24}$$

to the degree-$[4/4]$ Padé approximant [98]:

$$h(x) = \frac{1 + \frac{x}{2} + \frac{x^2}{10} + \frac{x^3}{120} + \frac{x^4}{1680}}{1 - \frac{x}{2} + \frac{x^2}{10} - \frac{x^3}{120} + \frac{x^4}{1680}}.$$

Note that the number of constraints for the two approaches is the same (for translating $h(x)$, Spain memoizes the powers of x). One can compare accuracy (using a computer algebra system or a large piece of paper), and consider the size of the intervals for which $|g(x) - e^x| \leq \delta$ and $|h(x) - e^x| \leq \delta$ respectively. In this example, take $\delta = 0.01$. The Taylor Series (g) has error at most 0.01 over the interval $[-1.07, 1.00]$ and larger errors outside this interval. The Padé approximant (h) has error at most 0.01 over $[-8.11, 2.84]$. In fact, the degree $[2/2]$ Padé approximant has error at most 0.01 over $[-2.18, 1.16]$: better than the degree-4 Taylor series.

Better approximations (more accuracy, wider interval) for the same number of terms also translates to fewer variables and hence fewer constraints to achieve the same accuracy. Going beyond exponentials, the technique of rational approximation works for a large class of functions.

Concurrent work [124] makes a similar observation; they find that for highly precise approximations, arithmetizations (of high-degree polynomials) can be even more expensive than traditional arithmetizations of division. These authors then incorporate Padé approximations to existing proof pipelines, obtaining a small speedup. Their paper contains many intriguing examples of approximation using this technique. All of these examples can be used in Spain directly, only with lower cost, because division is so inexpensive in Spain.

6 Implementation of Spain

6.1 Back-end implementation

Spain's back-end implements the protocol described in Section 4.2. It also supports SIMD-R1CS and I-R1CS (§4.3).

Spain implements fixed-size large integer arithmetic with inline limb storage; this avoids the performance cost of existing large integer libraries' [3–5] heap allocation of limb arrays. This functionality is used to compute and check J (Steps 3 and 4 in Fig. 2). Spain also implements 64- and 128-bit finite field arithmetic, with support for fast type conversion from large integers (Step 6); Spain does not use existing finite field libraries [11] because they optimize at compile time for a specific field, whereas in Spain, the finite field is determined only at run time. Finally, Spain implements fixed-size RSA group arithmetic, to do fast modular arithmetic for moduli not known at compile time (Steps 2 and 7).

Spain's back-end is implemented in 12,135 lines of Rust, including the new libraries.

6.2 Front-end implementation

We implemented three front-ends for Spain.

Gadget front-end. This front-end provides a library of gadgets [113, 150] (pairs of functions where the first generates constraints and the second generates witness values satisfying them), including the primitives in Section 5. The framework is modular and extensible.

ONNX front-end. ONNX [95, 132] is a specification for machine learning models. In ordinary use, one describes a model in ONNX's format (a collection of nodes), and then a highly optimized run-time executes the model on the available hardware. Spain's ONNX front-end translates from the ONNX format to approximate constraints. For the accompanying witness generator (§2.2), we had hoped to reuse ONNX-compatible run-times and tools; however, existing run-times neither produce satisfying assignments to auxiliary variables of the kind that arise in arithmetization (§5) nor run with the high-precision floating-point types that Spain uses (§6.3).

Spain solves this challenge with two sub-components. The first is a *model translator* that converts an ONNX model to a verbose version of the model, whose nodes produce output that includes the auxiliary information. In the process, the model translator rewrites transcendental functions to use rational approximations (§5), using the textbook implementation of the Remez algorithm [104]. The translator also modifies the operations in the model to specify higher-precision data types (for example, double- or quadruple-precision floating point instead of single-precision floating point). The second sub-component is a from-scratch ONNX executor that supports these high-precision data types. This executor implements each ONNX operator that appears in Spain's benchmarks (§7).

Linear programming front-end. This front-end is specialized to linear programming problems for comparison with prior work (§7), specifically Otti [9].

Spain's front-ends are implemented in, respectively, 2898 lines of Rust; 4747 lines of Python and 2025 lines of Rust; and 1524 lines of Rust.

6.3 Numerical considerations

A user of Spain begins with a particular computation F and desired error δ. Note that the choice of δ is exogenous to Spain, and should be driven by numerical considerations (§2.1). The user must then determine: (a) ϵ, to inform the verifier's check of J (§4), (b) δ_{wg}, the precision at which the prover must run F (§5, Appx. E), and (c) D, the denominator used in the arithmetization of F (§4.2.1, Appx. B). The general recipe for doing so is as follows. First, translate F to R1CS. Next, perform numerical analysis on each operation in the translation and compose the analyses to obtain an upper bound on ϵ in terms of δ (Appx. E.2). This ϵ, along with the number of constraints, m, upper-bounds ϵ_C (§4). Finally, returning to the numerical analysis, ϵ_C enforces an upper bound on δ_{wg} and on $1/D$, and thus a lower bound on D (Appx. E.2).

One could perform this last step analytically; essentially one would determine the maximum magnitude of values in the computation over all possible inputs, and then choose small-

enough δ_{wg} and $1/D$ to ensure each constraint has error upper-bounded by ϵ_C. For convenience, we instead guess (by running the witness generator at an estimated high precision) and check (by observing that it produces a witness for which $\|E_{\mathbb{X},z}\|_2^2 \leq \epsilon$). This approach is not dangerous: choosing δ_{wg} and $1/D$ too large – meaning underestimating the required precision – cannot affect soundness (which holds regardless of the prover's behavior). Furthermore, if there were such an underestimate, the prover could recalibrate and run witness generation at higher precision for all subsequent proof generations; witness generation is not the primary bottleneck for the prover (§7.2). For the same reason, accidentally overestimating precision does not unduly increase costs.

In Section 7, we provide values of δ, ϵ, ϵ_C, and D for the benchmarks in our experiments. Here, we work through their derivation for one example, a fluid simulation with $\delta = 2^{-32}$.

By analyzing the translation to R1CS (Appx. E), we get that $\epsilon = \delta/4$ suffices: an ϵ-accurate assignment to the constraints ensures absolute error of $\delta = 2^{-32}$. Supposing that $m \leq 2^{26}$, the prover needs a witness with error $\epsilon_C \leq \epsilon/\sqrt{2^{26}} = 2^{-47}$ (§4.1). For witness generation, this example uses double-precision floating-point arithmetic, which has *relative* error about 2^{-53}. In this application, the magnitude of intermediate values is sufficiently small that this relative error keeps the absolute error of each operation (δ_{wg}) below 2^{-47}. Note that the next choice up, quadruple-precision floating-point arithmetic, has relative error 2^{-112}, and would suffice if the intermediate values were larger.

Furthermore, most constraints are satisfied with error far smaller than ϵ_C, so the "closeness" of δ_{wg} and the floating-point relative error is not a concern in practice, and one can even run witness generation in a way where *some* constraints violate ϵ_C provided their totality satisfies $\|E_{\mathbb{X},z}\|_2^2 \leq \epsilon$. To counterbalance δ_{wg} being close to ϵ_C, this example chooses $1/D$ to be significantly smaller than ϵ_C: 2^{-70}.

Spain's back-end scales these floating-point values and converts them to large fixed-width integers to commit via DARK and to compute J exactly (Steps 2 and 3, Figure 2). For these steps, Spain combines 256-, 512-, and 786-bit integer arithmetic. Spain then maps these integers to field elements to execute the sum-check protocol steps (Step 6, Figure 2).

7 Experimental evaluation

We aim to answer the following questions experimentally:

1. How does Spain perform compared to the best proof systems for numerical computations?
2. What are the contributions to Spain's costs?
3. In what regimes does Spain meet the performance goals stated in Section 1?

Baselines. We compare Spain to five baselines, listed below. Two are end-to-end general-purpose systems, two are synthetic general-purpose systems with back-ends very similar to Spain's (for isolating the effect of Spain's front-end), and one is a special-purpose system.

Otti [9]: This is a general-purpose proof system in which fixed-point numerical computations are translated to finite field operations (§2.2). Otti aims at linear programming and semi-definite programming. Otti's back-end is a non-interactive and zero-knowledge variant of Spartan [116] so Otti offers qualitative properties that Spain does not (§7.4). Our experiments run Otti's released code [10].

ZKLP [51]: This general-purpose proof system encodes IEEE 754 floating-point logic in I-R1CS (§4.3, §D.2). ZKLP's back-end is the gnark [32] implementation of Groth16 [70], which (like Otti's back-end) is non-interactive and zero-knowledge. Our experiments run ZKLP's released code [52].

Otti-FE: This baseline uses Otti's front-end, meaning the same constraints as in Otti, and couples it with Spain's back-end implementation (including DARK), adjusted to prove a statement in the form of Equation (3) (§4.2.2). This setup results in a small fraction of Otti's constraints not being satisfied, because they rely on inverses over Otti's original finite field, rather than the one that Spain uses for sum-check, which is smaller. To be pessimistic to Spain, we filter out these constraints in our measurements.

ZKLP-FE: This baseline uses the same back-end as Otti-FE. For the front-end, we adopt a synthetic approach because ZKLP's front-end is not compatible with Spain's back-end, and making it so would have been a significant engineering effort. To apply this baseline to a benchmark, we count the operation types in the benchmark; for each operation type, we borrow constraint counts from ZKLP, and use the total number of constraints to construct an R1CS structure. Although this structure is semantically meaningless, its *size* (which is what drives performance) reflects the expected number of constraints that would be produced by using ZKLP's arithmetization of single-precision floating-point computations.

zkGPT [105]: This baseline is a special-purpose proof system for GPT-2 inference (described below). We choose it because it is, to our knowledge, the fastest application-specific prover for any numerical computation in the literature; however, the proof system itself mirrors the structure of GPT-2 inference, so it cannot be adapted to other computations.

Benchmarks. Our benchmarks are in four families:

Linear Programming. This family includes several linear programming instances from the Netlib library [61] that are used by Otti [9] (specifically, adlittle, afiro, sc105, scagr7, and scsd8).

Machine Learning. This family includes common machine learning primitives (Softmax, LayerNorm, and GELU) as well as the inference phase of GPT-2 [106].

Softmax maps $x = [x_1, \ldots, x_L]$ to $y = [y_1, \ldots, y_L]$ as follows: $y_i \leftarrow e^{x_i}/(\sum_{j=1}^{L} e^{x_j})$, for $i \in \{1, \ldots, L\}$. Spain arithmetizes this computation with Remez approximations of $e^{x_1}, \ldots, e^{x_L}$ (§5). This microbenchmark runs on each row of a 32×32 tensor.

F	δ	ϵ	ϵ_C	D
Linear Programming	2^{-32}	2^{-32}	$2^{-38.26}$	2^{50}
Machine Learning	2^{-20}	2^{-40}	$2^{-46.75}$	2^{75}
Fluid Simulation	2^{-32}	2^{-34}	$2^{-44.27}$	2^{70}
Geolocation	2^{-13}	2^{-26}	$2^{-35.10}$	2^{70}

Figure 3: Numerical parameters for benchmark families. ϵ_C varies within a family as it depends on the number of constraints m (§4.1) and batch size L (§4.3, §D.1) for the particular instance(s). We report the minimum ϵ_C across the family. δ_{wg} is omitted because all witness generation is performed using double- or quadruple-precision floating point, which has relative rather than absolute error guarantees (§6.3). Specifically, the Linear Programming, Fluid Simulation, and Geolocation families use double-precision, and the Machine Learning family uses quadruple-precision.

LayerNorm involves computing the mean and variance of a vector and then normalizing the vector. Specifically, $x = [x_1, \ldots, x_L]$ is transformed to $y = [y_1, \ldots, y_L]$ via $y_i \leftarrow \frac{x_i - \mu}{\sqrt{v+\delta}}$, where μ and v are the mean and variance of the inputs x, and δ provides numerical stability. Spain arithmetizes this benchmark with square root, division, and multiplication operations. We run this microbenchmark on a 32×768 tensor.

GELU is a popular activation function used in GPTs, defined as $x \cdot \Phi(x)$, where $\Phi(x)$ is the Gaussian CDF. Spain arithmetizes this with a piecewise linear approximation (§5). We run this microbenchmark on a 32×3072 tensor.

GPT-2 [106] is an open source LLM that uses several machine learning primitives, including Softmax, LayerNorm, GELU, and matrix multiplication (MatMul). For MatMul, Spain includes an optimization not described earlier: Spain translates to a *checker* that uses the Freivalds algorithm [56]. This requires an approximate version of Freivalds [74] together with Spain's extension to I-R1CS (§4.3, Appx. D.2). This benchmark runs the inference phase of GPT-2, and is parameterized by a length of input tokens (*seq*), and a number of iterations, *passes*.

Fluid Simulation. This family is a Stable-Fluids-style [125] incompressible fluid simulation that approximately solves the 2D Navier-Stokes equations over square grids. Spain arithmetizes this benchmark with multiplication, max, and min operations. We benchmark 8×8 and 16×16 grids, each simulated for 10 timesteps, denoted *small* and *large* respectively. Even at such small sizes, these benchmarks are computationally intensive; simulations of this form often run on GPUs in practice.

Geolocation. This family includes the geospatial computation in ZKLP [51], which checks consistency between spherical coordinates (latitude, longitude) and coordinates in a hierarchical Discrete Global Grid System [110] called Uber H3 [37]. This benchmark required simulating modular arithmetic, by arithmetizing the $\lfloor \cdot \rfloor$ operation.

Figure 3 gives the numerical parameters for each family.

Metrics, measurement, and method. We report the proving time, verification time, constraint counts (m, from §2.2), and proof size of Spain and baseline systems on the benchmarks above. We also report the cost of native execution. In addition, we measure the memory usage of Spain's prover, and fixed and setup costs for the Spain verifier.

We run all experiments in single-threaded configurations, on CPUs. We measure time based on the wall clock, with a harness that runs and times all phases of Spain. The exception is witness generation. That is timed differently depending on the benchmark. For the Linear Programming benchmarks, we time a custom Rust program that solves the linear program and uses the solution to generate the witness values. For ONNX benchmarks, we time the execution of the transformed ONNX model on Spain's high-precision ONNX executor (§6.2). For Fluid Simulation, similar to the Linear Programming benchmarks, we time a custom Rust program that generates witness values.

We report the average of at least 5 runs for each experiment. The standard deviations are within 11% of the means.

Testbed. For all experiments, we run the verifier on a 2.1 GHz 64-Core AMD Opteron 6272 with 256 GB RAM, running Red Hat Enterprise Linux 9.8. To reflect the motivation for succinct proofs, we run the prover on a more powerful machine: a 64-Core Intel Xeon Platnium 8592+ with 3 TB RAM, running Red Hat Enterprise Linux 9.6. When running Otti and ZKLP on our hardware, we use the artifacts provided by the authors.

7.1 Spain versus baselines

To compare Spain to the baselines, we run the aforementioned benchmarks. For ZKLP-FE run on GPT-2, the constraint counts are too large to run the back-end. Instead, we estimate prover and verifier time, as well as proof size, by executing ZKLP-FE on synthetic instances of various sizes and extrapolating times linearly ($R^2 > 0.99$ for both).

Figure 4 depicts the results. Spain shows dramatic improvement in number of constraints (m). This owes to the techniques in Section 5; for example, with the Linear Programming benchmarks, the baseline needs verbose constraints to represent comparisons ($\geq$, $\leq$, and so on) whereas Spain does not.

The lowered m for Spain yields prover speedups of 8–2700×, bringing the prover's overhead down in some cases to our goal of 3 orders of magnitude (§1). In fact, notice that Spain's back-end is *worse* than the baselines on a per-constraint basis; for example, Otti outperforms Otti-FE (which has a Spain-like backend) when running with substantially the same constraints. Yet, the reduction in m is more than enough to compensate. Indeed, the only baseline that Spain's prover does not exceed is zkGPT. But zkGPT does not apply beyond that one benchmark, and it has qualitative disadvantages, described later (§7.3).

Similarly, Spain's verifier improves on all baselines except zkGPT (see above) and ZKLP. ZKLP's back-end is specifically aimed at verifier performance, but it has high setup cost (§7.3, §7.4). Spain's improvement over all other baselines

Figure 4: Constraint counts, native execution time, prover time, verifier time, proof sizes, and overhead of proving (ratio of prover:native) for baselines and benchmarks. "Native time" refers to the verifier's hardware while the Spain/native ratio is measured on the prover's hardware. Times, proof sizes, and ratios are displayed with two significant figures. Constraints are displayed with three significant figures. The italicized numbers for ZKLP-FE mean that the times and proof sizes are extrapolated (see text); the back-end could not run at that scale. zkGPT does not support a batched configuration, so we scale zkGPT's measurements by *passes* where appropriate. Spain improves over baselines in constraint counts (from 32× to 4 orders of magnitude). With two exceptions, Spain improves over baselines in prover and verifier time, by at least an order of magnitude. The first exception is zkGPT, which outperforms Spain on all metrics, except for verifier time when *passes* = 16, where Spain's verifier is slightly better. The second exception is ZKLP, whose verifier outperforms Spain's verifier by 4–5×.

stems from substantial reduction in the number of auxiliary variables in the arithmetizations, making the witness w correspondingly smaller. Meanwhile, recall that one contribution to the verifier's costs is a component logarithmic in $|w|$ (§2.2).

7.2 Costs of Spain

We examine the relative costs of the protocol phases, for the prover and verifier. Figures 5 and 6 depict the results. For most benchmarks, DARK is the dominant cost. For GPT-2, witness generation (compute w) has a larger share of prover time, due almost entirely to the difference in complexity between executing matrix multiplication (which must happen to generate the witness) and checking matrix multiplication with the Freivalds algorithm (which is what the constraints enforce, as described in the GPT-2 benchmark earlier).

The prover's primary resource bottleneck is memory. For example, with GPT-2, our largest benchmark, the prover requires ≈41 GB for *seq*=32, *passes*=1, and ≈267 GB for *seq*=32, *passes*=16. The verifier's bottleneck for small computations (small m) is DARK evaluation. The bottleneck for larger computations is evaluating $\widetilde{A}$, $\widetilde{B}$, and $\widetilde{C}$ at a random point.

7.3 Breaking even and batching

Recall that to justify outsourcing on performance grounds, the verifier must be cheaper than native execution (§1). For the largest linear program, scsd8, Figure 4 shows that Spain's verifier *does* meet this condition. However, for most of the other benchmarks, this condition is not met.

In these cases, Spain must amortize fixed costs (§2.2) via *batching*. This is the SIMD-R1CS model (§4.3, Appx. D.1): the same computation repeated on different input/output pairs. This structure is natural for many numerical computations. For example, when running an LLM, people don't just want one token; they want a whole paragraph (or more...).

Spain's verifier indeed benefits from batching; notice that for the rows in Figure 4 featuring GPT-2 with various *passes*, the verifier's work grows less than linearly in batch size. Indeed, Figure 6 shows that the fixed costs – namely fixed work in DARK (§4.2.3, Appx. C) and evaluating $\widetilde{A}$, $\widetilde{B}$, $\widetilde{C}$ at a random point (Step 6, Figure 2) – are the dominant contribution when verifying single instances, and thus amortization is beneficial. These results agree with the theory. Specifically, Spain's fixed-cost is $O(m)$ for the entire batch (§2.2). Meanwhile, Spain's variable costs comprise a component logarithmic in the total witness size across all instances in the batch and a component linear in the number of variables in *in* and *out* across all instances. Given this cost profile, there is usually a batch size for which, in principle, Spain's verifier breaks even once the batch size crosses a threshold. We say *usually* because, for very small computations with very large *in* and/or *out*, the

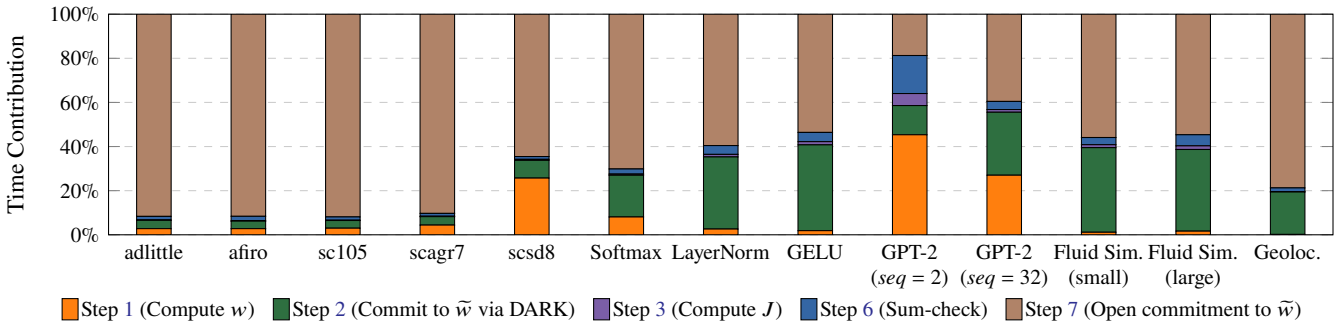

Figure 5: Prover phase breakdown for Spain. Steps refer to those in Figure 2. Steps 4 and 5 are omitted as they incur no cost for the prover.

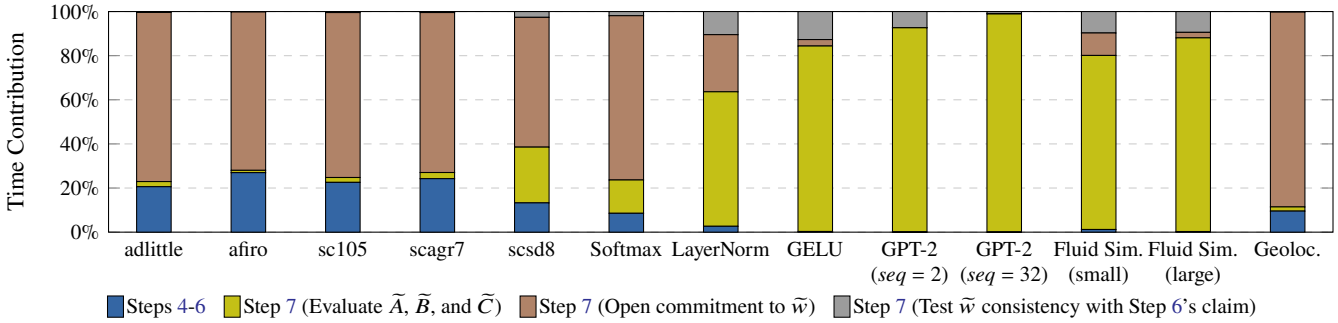

Figure 6: Verifier phase breakdown for Spain. Steps refer to those in Figure 2. Steps 1-3 are omitted as they incur no cost for the verifier. The majority of the verifier's time is spent in Step 7, which decomposes into three sub-steps: evaluating $\widetilde{A}$, $\widetilde{B}$, $\widetilde{C}$; opening the commitment to $\widetilde{w}$; and checking consistency between the claim in Step 6 about $\widetilde{w}$ and the opening of $\widetilde{w}$, using *in* and *out*.

variable costs alone may exceed the cost of native execution.

In contrast to Spain, zkGPT does not amortize with *passes*; as shown in Figure 4 (the GPT-2 rows), zkGPT's verifier is more expensive than Spain's verifier at *seq*=32, *passes*=16. For ZKLP, the comparison is equivocal. On the one hand, ZKLP's fixed costs (which are not included in Figure 4) amortize over all future uses of an R1CS structure, not merely a synchronized batch as in Spain; on the other hand, ZKLP's fixed costs are dramatically higher (over 50 thousand times larger than the verifier's work on a single instance [112]).

A loose end is *setup costs*, as distinct from fixed costs (§2.2); these are not depicted. However, on our benchmarks, Spain's setup costs range from negligible to 5× the verifier's work to check a single instance, so this cost quickly amortizes.

7.4 Summary and discussion

We believe that Spain meets the goal of being general-purpose (§1): it easily handled an array of natural benchmarks, and we did not have to discard any benchmarks because Spain lacked sufficient expressiveness.

At its core, Spain bakes approximation into the constraints themselves, eliminating the need to enforce numerical semantics explicitly, which in turn improves on the number of constraints (m) in an arithmetization, by 32× to 17,000× (§7.1).

This reduction lowers the prover overhead versus natural baselines by 1–3 orders of magnitude, down to 3–5 orders of magnitude versus native execution (§7.1). Spain's prover isn't the fastest in the literature; that honor belongs to zkGPT [105], but as we have noted, zkGPT is specialized to a specific machine learning model architecture, and its verifier neither breaks even nor benefits from amortization (§7.3).

Spain's verifier beats native execution for some reasonably-sized numerical problems (§7.3), and is the only system we experimented with to do so. Given their cost profiles (§7.2), Spain's verifier and prover would directly benefit from improvements in integer polynomial commitment protocols or rational ones [6, 121]. There are additional avenues for improving the verifier's costs. Most saliently, the verifier could shift some work to the prover using SPARK [116] or one of its descendants [38, 117, 119].

A structural disadvantage of Spain is that, for the time being, its new arithmetizations *require* its back-end. Traditional constraints are more portable; they can be combined with back-ends that provide different properties. Otti's back-end, for example, provides zero-knowledge and non-interactivity. ZKLP's back-end does too, and it inherits from Groth16 [70] an extremely fast verifier (albeit with high fixed costs; §7.3). If Spain's arithmetizations could be ported to alternative back-ends (§9), Spain could derive end-to-end speedups and enhanced properties.

8 Other related work

We have described Spain's intellectual antecedents throughout. Here we focus on the intersection of proof systems and numerical computations; we divide the work into two strands.

General-purpose (§1) proof systems. The first attempt to represent numerical operations in succinct proofs was Ginger [115], which supported fixed-point and primitive floating-point operations, by mapping them to operations in a finite field $\mathbb{F}_q$. Ginger used static analysis, bit-wise decompositions of values, and a large field (large q) to ensure a unique representation of each rational encountered during execution.

Subsequent works applied variations on this encoding to specific numerical problems, for example Otti [9] to linear programs, zkQMC [50] to Monte Carlo simulations, and KL24 [82] to transcendental functions. All of these works target general-purpose back-ends [8, 21–24, 46, 47, 49, 58, 62, 70, 85, 90, 100, 116, 117] and express computations as traditional constraints over a finite field.

A few recent works have explored alternative approaches, focusing on arithmetizing floating-point arithmetic. The works in this vein range between strict IEEE 754 compliance with support for all rounding modes and exceptions [51] (see §7) and more relaxed semantics [59]. All such works translate numerical operations using more constraints than Spain; however, they offer relative error guarantees that Spain does not.

Recently, interest has renewed in a class of proof systems known as *zkVMs* [15, 25, 26, 53, 83, 145]. These proof systems allow for proving the correct execution of any programs written in a given instruction set, typically RISC-V [107]. Although RISC-V includes numerical operations via floating-point instructions in an extension, we do not know of any zkVMs that currently support this extension.

Like Spain, some works have back-ends that work over domains other than finite fields. Chen et al. [45] arithmetize numerical computations as arithmetic circuits (addition and multiplication gates) over Galois rings, by encoding a rounding operation as a sequence of additions and multiplications within the ring. They then run GKR [66, 67] (§2.2) over the Galois ring. Bitan et al. [27] observe that some sum-check protocols can be modified so that the protocol messages themselves become approximate. Although we have yet to do a detailed analysis, we estimate that the costs of these approaches would be in between Spain's and the approaches derived from Ginger.

Finally, concurrent with this work, others have refined Zaratan [42] (discussed in §4.2), which is geared to integer computations. These works design polynomial commitment protocols over rational numbers that are significantly faster than DARK [6, 121].[2] While these works apply their faster polynomial commitments to general-purpose proof systems for exact integer and rational arithmetic, rather than approximate computations, we observe that the polynomial commitments themselves are compatible with Spain. We anticipate that replacing DARK with the fastest of them will improve the most expensive components of Spain by at least an order of magnitude (§7.2).

Special-purpose proof systems. Here we consider systems designed around specific applications. These systems rely on the observation that checkers for some numerical computations can be directly represented as sum-check protocols (§2.2).

The first in this line of work is Thaler's protocol for proving matrix multiplication [129]. Some works use Thaler's protocol as a primitive in proof systems for machine learning [19, 63, 77, 78, 86, 105, 127, 128, 151] (see the survey of Peng et. al [101] for a taxonomy). These protocols typically quantize numerical values, and alternate between checking exact operations (such as matrix multiplications, convolutions, and activation functions) and rounding to return to a quantized domain. From our testing, the most efficient of these systems is zkGPT [105], which was discussed and evaluated (§7).

[2] An older work in this family, Zinc [60], relies on results from another paper [28]. However, under scrutiny, it turned out that the latter paper's performance claims are about a protocol without any provable guarantees.

9 Conclusion

Spain meets the goal of proving numerical computations in a general-purpose way, while in some regimes meeting the goals (§1) of a prover with 3 orders of magnitude overhead and a verifier less expensive than native (§7.4).

Spain also introduces a new form of arithmetization, approximate constraints (§5). We believe this is of independent interest, as efficient arithmetizations are an object of intense study among those interested in succinct proofs. In principle, approximate constraints are usable in conjunction with the two dominant forms of arithmetization: traditional constraints and lookup tables (§E.4, §2.2).

A natural area for future work is adapting other proof back-ends (both those based on sum-check protocols and those *not* based on sum-check protocols) to handle approximate constraints. Other future work includes reducing the cost of polynomial commitment in Spain, slashing the cost of Spain's verifier by shifting work to the prover (§7.4), making Spain zero-knowledge and non-interactive, supporting relative error in constraints, and adding numerical support to zkVMs (§8) [15, 53, 83, 145]. Many of these are separate research efforts, which we hope our work here has motivated.

Acknowledgments

We are grateful to our shepherd, Andi Quinn, who went above and beyond with close readings that fundamentally improved the presentation of this work. In a similar vein, this paper was substantially improved by the thoughtful suggestions of the anonymous OSDI reviewers. Andrew Blumberg gave useful comments. All errors and problems are the fault of the authors. This project used computing resources at the Courant Institute and NYU's HPC organization, and was partially supported by gifts from Google and Stellar.

A Sum-check primitive

Given a prover, $\mathcal{P}$, and a verifier, $\mathcal{V}$, the sum-check primitive of Lund et al. [89] is an interactive protocol for proving that a claimed value H is equal to the sum of evaluations of a v-variate polynomial G over the Boolean hypercube: $\{0,1\}^v$. This primitive is depicted in Figure 7.

Spain relies on the following lemma concerning the soundness and completeness of this primitive [122, Chapter 10.4] [12, Chapter 8.5] [130, Chapter 4.1].

Lemma 1. *The primitive in Figure 7 is an interactive proof (the term is defined in the references above) for the claim that* $H = \sum_{b\in\{0,1\}^v} G(b)$. *If the initial claim is false,* $\mathcal{V}$ *rejects with probability at least* $1 - sd/q$. *If the initial claim is true,* $\mathcal{P}$ *can make* $\mathcal{V}$ *accept with probability* 1.

Setup: $\mathcal{P}$ and $\mathcal{V}$ agree on a field $\mathbb{F}_q$ and a degree d multi-variate polynomial G over $\mathbb{F}_q$ with v variables.
Online phase: If at any point $\mathcal{V}$'s check fails, it rejects.

1. $\mathcal{P}$ sends $\mathcal{V}$ a value H, claimed to equal
$$\sum_{b\in\{0,1\}^v} G(b)$$
and a univariate polynomial $g_1(x)$, claimed to equal
$$\sum_{(b_2,\ldots,b_s)\in\{0,1\}^{v-1}} G(x, b_2, \ldots, b_s).$$
2. $\mathcal{V}$ checks that $H = g_1(0) + g_1(1)$.
3. $\mathcal{V}$ sends $\mathcal{P}$ a random $r_1 \in \mathbb{F}_q$.
4. For $k = 2, \ldots, v$:
   (a) $\mathcal{P}$ sends $\mathcal{V}$ a univariate polynomial $g_k(x)$, claimed to equal
   $$\sum_{(b_{k+1},\ldots,b_s)\in\{0,1\}^{v-k}} G(r_1, \ldots, r_{k-1}, x, b_{k+1}, \ldots, b_s).$$
   (b) $\mathcal{V}$ checks that $g_{k-1}(r_{k-1}) = g_k(0) + g_k(1)$.
   (c) $\mathcal{V}$ sends $\mathcal{P}$ a random $r_k \in \mathbb{F}_q$.
5. Finally, $\mathcal{V}$ checks that $g_s(r_s) = G(r_1, \ldots, r_s)$.

If all checks pass, $\mathcal{V}$ accepts.

Figure 7: The sum-check primitive of Lund et al. [89].

B Spain's full back-end protocol and analysis

Here we provide background on polynomial commitment schemes and define the properties required by Spain (§B.1); provide Spain's full back-end protocol (§B.2) and its correctness proofs (§B.3); quantify the guarantees based on the specific parameters in our implementation and evaluation (§B.4); and finally prove some supporting lemmas (§B.5).

For clarity in exposition, when we mention a polynomial commitment scheme, we are referring to a polynomial commitment scheme for multilinear polynomials. Additionally, when we use the term "coefficients" for a v-variate multilinear polynomial, these refer to the coefficients in the multilinear Lagrange basis [130, §3.5] with the interpolating set being the v-variate Boolean hypercube: $\{0,1\}^v$. These are exactly the *evaluations* of the polynomial over the Boolean hypercube.

B.1 Spain-compatible polynomial commitment schemes

A multilinear polynomial commitment scheme [79, 94] *PC* is a tuple of protocols (*Setup*, *Commit*, *Open*, *Verify*), defined as follows.

- *Setup*: Given security parameter λ and a bound on the number of variables in polynomials to be committed to, produce public parameters *pp*.
- *Commit*: Given public parameters *pp* and a multilinear polynomial $\tilde{f}$, produce a commitment $com_{\tilde{f}}$.
- *Open*: Given public parameters *pp*, a multilinear polynomial $\tilde{f}$, and a point x, produce a result y and a proof π_y that $y = \tilde{f}(x)$. Together, the result and proof are called an *opening* of $com_{\tilde{f}}$ at x.
- *Verify*: Given public parameters *pp*, a commitment $com_{\tilde{f}}$, a point x, and an alleged opening (y, π_y), output "accept" if π_y is a valid proof that $y = \tilde{f}(x)$ and "reject" otherwise.

A polynomial commitment scheme is *binding* if it is intractable for a prover to produce two distinct openings (y, π_y) and $(y', \pi_{y'})$ for the same commitment $com_{\tilde{f}}$ such that the verifier accepts both openings. For Spain, intractable means that a polynomial-time adversary cannot succeed with probability greater than κ_{PC}.

Spain requires, as a building block, a binding polynomial commitment scheme, *PC*, that satisfies an additional property, which we call *Weak Integer Binding*. Weak Integer Binding is parameterized by 2 constants, $N_{\max}$ and $D_{\max}$. Weak Integer Binding has two sub-properties, given below. To state the sub-properties we define *Integer-limited*: a v-variate multilinear polynomial $\tilde{f}$ is called *Integer-limited* if all of its coefficients are integers with magnitude at most $N_{\max}$.

- *Weak Integer Binding, sub-property 1.* It is impossible for a prover to produce a commitment $com_{\tilde{f}}$ unless for some positive integer D' and multilinear polynomial $\tilde{g}$, $\tilde{f} = \tilde{g}/D'$, where $D' \leq D_{\max}$ and $\tilde{g}$ is Integer-limited. (Here $\tilde{g}/D'$

means a polynomial with the same coefficients as $\tilde{g}$ but with an extra D' factor in each coefficient's denominator.)

- *Weak Integer Binding, sub-property 2.* Given an honest (polynomial-time) prover, for any Integer-limited polynomial $\tilde{f}$, invoking *Commit* causes the prover to produce a valid commitment, and for any point x, invoking *Open* causes the prover to produce a corresponding opening that causes *Verify* to accept

Weak Integer Binding is similar to, but weaker than, the notion of a *Relaxed Mod-PCS* introduced by Zinc [60]. A Relaxed Mod-PCS imposes an additional requirement, *extractability* (essentially, that the prover must "know" $\tilde{f}$ of the right form in order to produce $com_{\tilde{f}}$).

Also, note that Weak Integer Binding is an idealized property in that sub-property 1 states that it is *impossible*, rather than computationally *intractable*, for a prover to produce a commitment $com_{\tilde{f}}$ that does not satisfy the stated condition. When instantiating a multilinear commitment primitive (§B.4), we will handle probabilistic deviation from the ideal.

B.2 Spain's back-end protocol

Spain's full protocol is in Figure 8. This protocol is parameterized by a constant ϵ; an R1CS instance, $\mathbb{X}$, containing rationals with unreduced denominator D and unreduced numerators with magnitude at most $N_{\max}$; a polynomial commitment scheme PC satisfying Weak Integer Binding with parameters $N_{\max}$ and $D_{\max}$ (§B.1); and a large set of primes, P. The R1CS structure underlying $\mathbb{X}$ has m constraints and n variables. Recall from Section 4.2.2 that s and k are defined to be $\lceil \log_2 m \rceil$ and $\lceil \log_2 n \rceil$ respectively.

Note that Weak Integer Binding means an honest prover commits to a polynomial $\tilde{f}$ with *integer* coefficients, yet Spain has been described (Fig. 2, §4) as committing to a polynomial $\widetilde{w}$ with *rational* coefficients. In fact, in Step 1 (Fig. 8), Spain's prover obtains $\tilde{f}$ by multiplying $\widetilde{w}$ by D. Meanwhile the elements of w are expected to have unreduced denominator D (§4.2.1) and hence the same holds for the coefficients of $\widetilde{w}$. Thus, $\tilde{f}$ indeed has integer coefficients.

B.3 Correctness of Spain's back-end protocol

In this section, we prove the correctness, meaning completeness and soundness (§4), of Spain's back-end, specifically the protocol in Figure 8. The figure depicts, and the proof is about, an idealized version of Spain in which the polynomial commitment scheme meets the properties in Appendix B.1. In addition to quantifying parameters, Appendix B.4 instantiates the polynomial commitment scheme with a concrete protocol, namely DARK [40], and handles the deviation from the ideal.

En route to the proof, we define $U_{m,n,N_{\max},D,D_{\max}}$ (written as U for brevity) to be

$$U := m \cdot n^2 \cdot N_{\max}^4 \cdot D_{\max}^4 \cdot (n \cdot N_{\max}^2 + D^2)^2 + D^8 \cdot D_{\max}^4.$$

Additionally, we use $\min P$ to denote the smallest prime in P, and $|P|$ to denote the number of primes in P.

The definitions of completeness and soundness (§4) reference ϵ-accuracy, which was described informally in Section 3. Below, we state ϵ-accuracy more formally. Let M_i denote row i of matrix M.

Definition (ϵ-accuracy)**.** *An assignment z for an R1CS structure $\mathbb{S} = (A, B, C)$ is* ϵ-accurate *if*

$$|(A_i \cdot z) \cdot (B_i \cdot z) - (C_i \cdot z)| \leq \epsilon, \text{ for all } i \in \{1, \ldots, m\}.$$

We are now ready to state the central correctness theorem for Spain.

Theorem 1. *The protocol in Figure 8 satisfies Back-end $(\epsilon/\sqrt{m})$-completeness. The protocol also satisfies Back-end ϵ-soundness, with soundness error κ upper-bounded by*

$$\frac{\lfloor \log_{\min P} D_{max} \rfloor + \lfloor \log_{\min P} U \rfloor}{|P|} + \frac{4s + 2 + 2k}{\min P} + \kappa_{PC}.$$

Proof. We use two facts about ρ_q, both proved in Appendix B.5.

Lemma 2 (ρ_q ill-defined)**.** *Let $\mathbb{X}$, z, and $\widetilde{w}$ be as in Figure 8, and let q be sampled uniformly from P. Then*

$$\Pr_{q \sim P}\left[\rho_q \text{ is undefined on } \|E_{\mathbb{X},z}\|_2^2\right] \leq \frac{\lfloor \log_{\min P} D_{max} \rfloor}{|P|}.$$

Lemma 3 (ρ_q collision)**.** *Let $\mathbb{X}$, z, $\widetilde{w}$, and J be as in Figure 8 with $J \neq \|E_{\mathbb{X},z}\|_2^2$, and let q be sampled uniformly from P. Conditioned on ρ_q being defined for $\|E_{\mathbb{X},z}\|_2^2$, we have*

$$\Pr_{q \sim P}\left[\rho_q(J) = \rho_q(\|E_{\mathbb{X},z}\|_2^2)\right] \leq \frac{\lfloor \log_{\min P} U \rfloor}{|P|}.$$

Back-end $(\epsilon/\sqrt{m})$-completeness. If $\mathcal{P}$ has an assignment z that is $(\epsilon/\sqrt{m})$-accurate for the instance $\mathbb{X}$, by the argument of Section 4.1, $\|E_{\mathbb{X},z}\|_2^2 \leq \epsilon^2$. Thus if $\mathcal{P}$ sends messages prescribed by the protocol, every check by $\mathcal{V}$ passes, and $\mathcal{V}$ accepts with probability 1.

Back-end ϵ-soundness. Suppose that there does not exist an ϵ-accurate assignment for $\mathbb{X}$. We bound the probability that $\mathcal{V}$ accepts.

First, an adversarial prover need not use *Commit* in Step 1 to produce $com_{\tilde{f}}$ nor use *Open* in Step 8 to produce an alleged opening (y, π_y) of $com_{\tilde{f}}$ at $\hat{\beta}$. To handle all adversarial prover behavior involving the polynomial commitment, we define $\mathsf{E}_{\mathsf{bind}}$ to capture the event that $\mathcal{V}$ accepts the opening in Step 8 but this opening is inconsistent with the commitment provided in Step 1. By inconsistent, we mean that $y \neq \tilde{f}(\hat{\beta})$. By the binding property of the polynomial commitment scheme,

$$\Pr[\mathsf{E}_{\mathsf{bind}}] \leq \kappa_{\mathrm{PC}}.$$

We now consider the case where $\mathsf{E}_{\mathsf{bind}}$ does not occur, so the binding property of the polynomial commitment scheme fixes a unique $\tilde{f}$ and thus a unique w (and unique z).

Setup: Prover $\mathcal{P}$ and Verifier $\mathcal{V}$ agree on the parameters of the protocol, which are as follows:

- a small constant $\epsilon \ll 1$
- an instance, $\mathbb{X} = (A, B, C, in, out)$, consisting of rationals with unreduced denominator D (a power of 2).
- a polynomial commitment scheme PC satisfying Weak Integer Binding with parameters $N_{\max}$ and $D_{\max}$.
- a large set of primes, P, from which $\mathcal{V}$ will sample in the protocol.

Preprocessing: $\mathcal{P}$ and $\mathcal{V}$ performs the setup required by PC.
Online phase: If at any point $\mathcal{V}$'s check fails, it rejects.

1. Using PC, $\mathcal{P}$ commits to a multilinear polynomial $\tilde{f}$ whose coefficients are purportedly integers. $\mathcal{P}$ sends this commitment to $\mathcal{V}$.
   - Define $\widetilde{w} := \tilde{f}/D$. Define w as the coefficients of $\widetilde{w}$, and define $z := (in, out, 1, w)$. If $\mathcal{P}$ is honest, then w is chosen to make z an ϵ-accurate assignment to $\mathbb{X}$.
2. $\mathcal{P}$ computes $\|E_{\mathbb{X},z}\|_2^2$ (over $\mathbb{Q}$), and sends $S := \|E_{\mathbb{X},z}\|_2^2 \cdot D^8$ to $\mathcal{V}$.
3. $\mathcal{V}$ checks that S is an integer, computes $J := S/D^8$, and checks that $0 \le J \le \epsilon^2$.
4. $\mathcal{V}$ samples a random prime $q \sim P$, sends it to $\mathcal{P}$, and $\mathcal{P}$ and $\mathcal{V}$ map all quantities in $\mathbb{Q}$ into $\mathbb{F}_q$ via ρ_q.
5. $\mathcal{V}$ and $\mathcal{P}$ run a degree-4 sum-check primitive on
$$\rho_q(J) = \sum_{r \in \{0,1\}^s} (\widetilde{g_A}(r) \cdot \widetilde{g_B}(r) - \widetilde{g_C}(r))^2,$$
where $\widetilde{g_A}$, $\widetilde{g_B}$, and $\widetilde{g_C}$ are defined as in Section 4.2.2.
The result of this primitive is three purported claims over $\mathbb{F}_q$:
$$v_a = \widetilde{g_A}(\alpha), \quad v_b = \widetilde{g_B}(\alpha), \quad \text{and} \quad v_c = \widetilde{g_C}(\alpha)$$
for a random $\alpha \in \mathbb{F}_q^s$.
6. $\mathcal{V}$ samples a random $\gamma \in \mathbb{F}_q$, sends γ to $\mathcal{P}$, and computes
$$v \leftarrow v_a + v_b \cdot \gamma + v_c \cdot \gamma^2.$$
7. $\mathcal{P}$ and $\mathcal{V}$ run a degree-2 sum-check primitive on
$$v = \sum_{c \in \{0,1\}^k} (\widetilde{A}(\alpha, c) + \widetilde{B}(\alpha, c) \cdot \gamma + \widetilde{C}(\alpha, c) \cdot \gamma^2) \cdot \widetilde{z}(c).$$
This results in the following four purported claims over $\mathbb{F}_q$:
$$u_a = \widetilde{A}(\alpha, \beta), \quad u_b = \widetilde{B}(\alpha, \beta), \quad u_c = \widetilde{C}(\alpha, \beta), \quad \text{and} \quad u_z = \widetilde{z}(\beta)$$
for a random $\beta \in \mathbb{F}_q^k$.
8. $\mathcal{P}$ maps the point β into $\mathbb{Z}$ as $\hat{\beta}$, opens the commitment to $\tilde{f}$ at $\hat{\beta}$, and sends the result y (and accompanying proof π_y) to $\mathcal{V}$.
9. $\mathcal{V}$ uses π_y to check that the result y is a valid opening; if it is, $y = \tilde{f}(\hat{\beta})$ over the rationals. $\mathcal{V}$ computes $\widetilde{in}(\beta)$ and $\widetilde{out}(\beta)$ (over $\mathbb{F}_q$), and combines them with $y/D = \tilde{f}(\hat{\beta})/D = \widetilde{w}(\hat{\beta})$ (mapped to $\mathbb{F}_q$ via ρ_q) to produce $\tilde{z}(\beta)$. $\mathcal{V}$ then checks the purported claims from the end of Step 7.

If all checks pass, $\mathcal{V}$ accepts.

Figure 8: Spain's back-end protocol for proving that an R1CS instance has an ϵ-accurate assignment.

Because $\mathbb{X}$ has no ϵ-accurate assignment, $\|E_{\mathbb{X},z}\|_\infty > \epsilon$ and thus $\|E_{\mathbb{X},z}\|_2^2 > \epsilon^2$. However, in Step 3, $\mathcal{V}$ accepts only if $J \le \epsilon^2$. Consequently, $J \ne \|E_{\mathbb{X},z}\|_2^2$.

For $\mathcal{V}$ to accept the final check in Step 9, it must be the case that, in some step of the protocol, a false claim is transformed into a true claim. We define one bad event per step that captures this transformation.

- E_{ρ_q}: the event that, in Step 4, $J \ne \|E_{\mathbb{X},z}\|_2^2$, but either ρ_q is undefined on $\|E_{\mathbb{X},z}\|_2^2$ or $\rho_q(J) = \rho_q(\|E_{\mathbb{X},z}\|_2^2)$.
- $\mathsf{E}_{\mathsf{sc1}}$: the event that, in Step 5, $\rho_q(J) \ne \rho_q(\|E_{\mathbb{X},z}\|_2^2)$, but after the first sum-check primitive, the claims $v_a = \widetilde{g_A}(\alpha)$, $v_b = \widetilde{g_B}(\alpha)$, and $v_c = \widetilde{g_C}(\alpha)$ are all true.
- $\mathsf{E}_{\mathsf{agg}}$: the event that, in Step 6, $v_a \ne \widetilde{g_A}(\alpha)$, $v_b \ne \widetilde{g_B}(\alpha)$, or $v_c \ne \widetilde{g_C}(\alpha)$, but the aggregated claim $v = v_a + v_b \cdot \gamma + v_c \cdot \gamma^2$ is true.

- $\mathsf{E}_{\mathsf{sc2}}$: the event that, in Step 7,

$$v \neq \sum_{c \in \{0,1\}^k} (\widetilde{A}(\alpha, c) + \widetilde{B}(\alpha, c) \cdot \gamma + \widetilde{C}(\alpha, c) \cdot \gamma^2) \cdot \widetilde{z}(c),$$

but after the second sum-check primitive, the claims $u_a = \widetilde{A}(\alpha, \beta)$, $u_b = \widetilde{B}(\alpha, \beta)$, $u_c = \widetilde{C}(\alpha, \beta)$, and $u_z = \widetilde{z}(\beta)$ are all true.

If none of these occur, then ρ_q is defined on $\|E_{\mathbb{X},z}\|_2^2$, $\rho_q(J) \neq \rho_q(\|E_{\mathbb{X},z}\|_2^2)$, and each step of the protocol transforms a false claim into a false claim. As a result, in the final step, at least one of the following must be false:

$$u_a = \widetilde{A}(\alpha, \beta)$$
$$u_b = \widetilde{B}(\alpha, \beta)$$
$$u_c = \widetilde{C}(\alpha, \beta)$$
$$u_z = \widetilde{z}(\beta)$$

Either the verifier's explicit evaluation of $\widetilde{A}$, $\widetilde{B}$, or $\widetilde{C}$ at (α, β) will expose a false claim, or the opening of the commitment to $\widetilde{w}$ will expose a false claim about $\widetilde{z}(\beta)$. Hence $\mathcal{V}$ rejects if none of the bad events occur.

By a union bound, the probability that $\mathcal{V}$ accepts is at most the sum of the probabilities of these bad events, plus $\Pr[\mathsf{E}_{\mathsf{bind}}]$. We now bound the probability of each bad event.

For E_{ρ_q}, by Lemma 2, the probability that ρ_q is undefined on $\|E_{\mathbb{X},z}\|_2^2$ is at most

$$\frac{\lfloor \log_{\min P} D_{\max} \rfloor}{|P|}.$$

By Lemma 3, the probability that $\rho_q(J) = \rho_q(\|E_{\mathbb{X},z}\|_2^2)$, conditioned on $J \neq \|E_{\mathbb{X},z}\|_2^2$ and ρ_q being defined on $\|E_{\mathbb{X},z}\|_2^2$, is at most

$$\frac{\lfloor \log_{\min P} U \rfloor}{|P|}.$$

Thus, by a union bound,

$$\Pr[\mathsf{E}_{\rho_q}] \leq \frac{\lfloor \log_{\min P} D_{\max} \rfloor + \lfloor \log_{\min P} U \rfloor}{|P|}.$$

For $\mathsf{E}_{\mathsf{sc1}}$, this event involves an invocation of the sum-check primitive on a degree-4 polynomial with s variables where the claimed sum is false but the final polynomial evaluation claims are all true. By Lemma 1 and $\min P \leq q$,

$$\Pr[\mathsf{E}_{\mathsf{sc1}}] \leq 4s/q \leq 4s/\min P.$$

For $\mathsf{E}_{\mathsf{agg}}$, this event treats three claims as a degree 2 polynomial and evaluates this polynomial at a random point γ. If at least one constituent claim is false, the resulting polynomial is non-zero, and thus, by the Factor Theorem (a univariate case of the Schwartz-Zippel lemma [111, 149]) and $\min P \leq q$,

$$\Pr[\mathsf{E}_{\mathsf{agg}}] \leq 2/q \leq 2/\min P.$$

For $\mathsf{E}_{\mathsf{sc2}}$, this event involves an invocation of the sum-check primitive on a degree-2 polynomial with k variables where the claimed sum is false but the final polynomial evaluation claims are all true. By Lemma 1 and $\min P \leq q$,

$$\Pr[\mathsf{E}_{\mathsf{sc2}}] \leq 2k/q \leq 2k/\min P.$$

By a union bound over all bad events, we get Back-end ϵ-soundness holds with error at most

$$\frac{\lfloor \log_{\min P} D_{\max} \rfloor + \lfloor \log_{\min P} U \rfloor}{|P|} + \frac{4s + 2 + 2k}{\min P} + \kappa_{\mathrm{PC}}.$$

□

B.4 Quantifying the guarantees of Spain's back-end

The implementation described in Sections 6 and 7 uses specific parameters. The following corollary characterizes the soundness and completeness guarantees of Spain's back-end when instantiated with DARK as the polynomial commitment scheme, and in a regime that covers the aforementioned parameters.

Corollary 1. *When Figure 8 is instantiated with the following parameters:*

- $m \leq 2^{32}$, $n \leq 2^{32}$;
- $D \leq 2^{96}$;
- *PC is the DARK multilinear polynomial commitment scheme [40] with* $N_{max} \leq 2^{96}$; *and*
- P *is the set of* 128*-bit primes,*

the resulting protocol has Back-end $(\epsilon/\sqrt{m})$*-completeness and Back-end* ϵ*-soundness, with soundness error* $\kappa \leq 2^{-40}$.

Proof. Back-end $(\epsilon/\sqrt{m})$*-completeness.* DARK satisfies sub-property 2 of Weak Integer Binding, so the completeness result of Theorem 1 applies directly to this corollary.

Back-end ϵ*-soundness.* For soundness, DARK only satisfies sub-property 1 of Weak Integer Binding *with high probability* (explicitly bounded further below), so we have to modify the soundness analysis of Theorem 1.

Suppose that there does not exist an ϵ-accurate assignment for $\mathbb{X}$. We bound the probability that $\mathcal{V}$ accepts. Define the event $\mathsf{E}_{\mathsf{weak}}$ to be the event that, over randomness internal to DARK's *Verify* function, $\mathcal{V}$ accepts an alleged opening of a commitment $com_{\tilde{f}}$ at $\hat{\beta}$ where $\tilde{f}$ does not satisfy the conditions detailed in sub-property 1 of Weak Integer Binding.

Conditioned on $\mathsf{E}_{\mathsf{weak}}$ not occurring, the verifier's acceptance probability is upper-bounded by the soundness error stated in Theorem 1. Thus, the overall probability that $\mathcal{V}$ accepts is at most

$$\frac{\lfloor \log_{\min P} D_{\max} \rfloor + \lfloor \log_{\min P} U \rfloor}{|P|} + \frac{4s + 2 + 2k}{\min P} + \kappa_{\mathrm{PC}} + \Pr[\mathsf{E}_{\mathsf{weak}}].$$

It remains to fill in the parameters and bound $\Pr[\mathsf{E}_{\mathsf{weak}}]$.

First, we quantify DARK-related parameters. We explicitly set $N_{\max} \leq 2^{96}$ and derive κ_{PC}, $D_{\max}$, and $\Pr[\mathsf{E}_{\text{weak}}]$ using a combination of the analysis in the corrected DARK paper [40] and a subsequent work [39]. In the corrected DARK paper [40], it is proved that κ_{PC} for the DARK polynomial commitment scheme is at most $(3\log|w|)/2^{\lambda}$, where λ is a parameter internal to DARK that introduces a tradeoff between κ_{PC} and $D_{\max}$. By choosing $\lambda = 50$, we get that $\kappa_{\text{PC}} \leq (3\log|w|)/2^{\lambda} = 3 \cdot 32/2^{50} < 2^{-43}$. From the analysis and scripts provided in the subsequent work [39], we get that for $D_{\max} \leq 2^{1422}$, $\Pr[\mathsf{E}_{\text{weak}}] \leq \kappa_{\text{PC}}$. Note that the analysis below is not very sensitive to the magnitude of $D_{\max}$ or $N_{\max}$; however, it is very sensitive to κ_{PC}, and λ is chosen with that in mind.

Next, we need to determine the size of P, the set of 128-bit primes. The number of 128-bit primes is exactly $\pi(2^{128}) - \pi(2^{127})$, where $\pi(x)$ is the prime counting function. By the following standard bound [109]:

$$\pi(2x) - \pi(x) \geq 3x/(5 \cdot \ln x) \quad \forall x \geq 21,$$

we have that

$$|P| \geq \frac{3 \cdot 2^{127}}{5 \cdot 127 \cdot \ln 2} > \frac{3 \cdot 2^{127}}{5 \cdot 128 \cdot \ln 2} = \left(\frac{3}{5 \cdot \ln 2}\right) \cdot 2^{120} > 2^{119}.$$

Additionally, $\min P > 2^{127}$ by definition.

The remainder of the proof proceeds by computing

$$\frac{\lfloor \log_{\min P} D_{\max} \rfloor + \lfloor \log_{\min P} U \rfloor}{|P|} \quad \text{and} \quad \frac{4s + 2 + 2k}{\min P}$$

using the parameters above. This calculation is tedious but mechanical. By definition:

$$\begin{aligned} U &\leq m \cdot n^2 \cdot N_{\max}^4 \cdot D_{\max}^4 \cdot (n \cdot N_{\max}^2 + D^2)^2 + D^8 \cdot D_{\max}^4 \\ &\leq 2^{32+2\cdot 32+4\cdot 96+4\cdot 1422} \cdot (2^{32+2\cdot 96} + 2^{2\cdot 96})^2 + 2^{8\cdot 96+4\cdot 1422} \\ &\leq 2^{32+64+384+5688} \cdot (2^{32+192} + 2^{192})^2 + 2^{768+5688} \\ &\leq 2^{6168} \cdot (2^{224} + 2^{192})^2 + 2^{6456} \\ &< 2^{6168} \cdot 2^{450} + 2^{6456} \\ &< 2^{6619}. \end{aligned}$$

It follows that

$$\frac{\lfloor \log_{\min P} D_{\max} \rfloor + \lfloor \log_{\min P} U \rfloor}{|P|} < \frac{\lfloor \frac{1422}{127} \rfloor + \lfloor \frac{6619}{127} \rfloor}{2^{119}} = \frac{63}{2^{119}}.$$

Additionally, we have the following bound on the second term:

$$\frac{4s + 2 + 2k}{\min P} < \frac{4 \cdot 32 + 2 + 2 \cdot 32}{2^{127}} = \frac{194}{2^{127}}.$$

By summing these two terms, $\kappa_{\text{PC}} < 2^{-43}$, and $\Pr[\mathsf{E}_{\text{weak}}] \leq \kappa_{\text{PC}}$, we get that the probability that the verifier accepts a non-ϵ-accurate assignment is less than 2^{-40}, as claimed. □

B.5 Deferred proofs

Here we prove Lemma 2 and Lemma 3. We start with two counting lemmas that they use.

Lemma 4. *Given an integer x of magnitude at most M and a set P of primes,*

$$\Pr_{q \sim P}[x \equiv 0 \pmod{q}] \leq \frac{\lfloor \log_{\min P} M \rfloor}{|P|}.$$

Proof. For x to be divisible by a prime q, q must be one of the prime factors of x. Suppose by contradiction that x had more than $\lfloor \log_{\min P} M \rfloor$ prime factors from P (counting multiplicity). Then x would have magnitude at least $(\min P)^{\lfloor \log_{\min P} M \rfloor + 1} > M$, a contradiction. Thus, x has at most $\lfloor \log_{\min P} M \rfloor$ prime factors from P, and the probability that a random prime from P divides x is at most $\lfloor \log_{\min P} M \rfloor / |P|$. □

Lemma 5. *Consider instance $\mathbb{X}$, multilinear polynomial $\tilde{f}$, and vector z, as defined in the protocol in Figure 8. Let D' be the unreduced denominator shared by the coefficients of $\tilde{f}$. Then, the denominator of $\|E_{\mathbb{X},z}\|_2^2$ is exactly $D^8 \cdot D'^4$. The numerator of $J - \|E_{\mathbb{X},z}\|_2^2$ is at most U, where U is as defined in Section B.3, and the denominator of this difference has the same denominator as $\|E_{\mathbb{X},z}\|_2^2$.*

Proof. The proof proceeds by bookkeeping: tracking exact denominators and an upper bound on the magnitude of intermediate numerators. The accounting pessimistically assumes that no reduction occurs when performing arithmetic operations. For example, when adding two rationals (N_1, D_1) and (N_2, D_2) where $\gcd(D_1, D_2) = 1$, the numerator of the result is at most $|N_1| \cdot D_2 + |N_2| \cdot D_1$ in magnitude and the denominator is exactly $D_1 \cdot D_2$.

By definition (§4.1),

$$\|E_{\mathbb{X},z}\|_2^2 = \sum_{r=1}^{m} \left(\sum_{c=1}^{n} A_{r,c} z_c \cdot \sum_{c=1}^{n} B_{r,c} z_c - \sum_{c=1}^{n} C_{r,c} z_c \right)^2.$$

Note that these summations are over m and n summands respectively as opposed to 2^s and 2^k summands as described in Section 4.2.2. This is because we are working with A, B, C as matrices, rather than their multilinear extensions.

Now, recall that the entries of A, B, C, *in*, and *out* all have unreduced denominator D; recall also that the numerators of the entries of A, B, C, *in*, and *out* have magnitude at most $N_{\max}$ (§B.2).

z is a concatenation of *in*, *out*, and w (the definition of w is in Figure 8). To bound the components of w, Weak Integer Binding's sub-property 1 (§B.1) implies that, for the coefficients of $\tilde{f}$, their unreduced denominator, D', satisfies $D' \leq D_{\max}$ and their numerators have magnitude at most $N_{\max}$. By definition of $\widetilde{w}$, its coefficients – that is, the components of w – share an unreduced denominator of $D \cdot D'$, and each has

an unreduced numerator of magnitude at most $N_{\max}$. From this, it follows that z, when written with a common unreduced denominator of $D \cdot D'$, has numerators of magnitude at most $N_{\max} \cdot D'$.

For any matrix M, $M_{r,c} z_c$ is a rational with an unreduced numerator of magnitude at most $N_{\max}^2 \cdot D'$ and an unreduced denominator exactly $D^2 \cdot D'$.

Thus, $\sum_{c=1}^{n} M_{r,c} z_c$ is a rational with a numerator of magnitude at most $n \cdot N_{\max}^2 \cdot D'$ and an unreduced denominator exactly $D^2 \cdot D'$.

It follows that $\sum_{c=1}^{n} A_{r,c} z_c \cdot \sum_{c=1}^{n} B_{r,c} z_c$ is a rational with a numerator of magnitude at most $n^2 \cdot N_{\max}^4 \cdot D'^2$ and an unreduced denominator of magnitude exactly $(D^2 \cdot D')^2 = D^4 \cdot D'^2$.

When subtracting $\sum_{c=1}^{n} C_{r,c} z_c$, a rational of the form $(N_1, D^2 \cdot D')$, from $\sum_{c=1}^{n} A_{r,c} z_c \cdot \sum_{c=1}^{n} B_{r,c} z_c$, a rational of the form $(N_2, D^4 \cdot D'^2)$, one needs to multiply the numerator and denominator of the first rational by $D^2 \cdot D'$ to get a common denominator (in the worst case). Thus, after performing the scaling and subtraction, the resulting rational has a numerator of magnitude at most

$$n^2 \cdot N_{\max}^4 \cdot D'^2 + n \cdot N_{\max}^2 \cdot D^2 \cdot D'^2$$

and an unreduced denominator of magnitude exactly $D^4 \cdot D'^2$.

Squaring this rational to get the contribution of row r to $\|E_{\mathbb{X},z}\|_2^2$ results in a rational with a numerator of magnitude at most

$$(n^2 \cdot N_{\max}^4 \cdot D'^2 + n \cdot N_{\max}^2 \cdot D^2 \cdot D'^2)^2$$

and an unreduced denominator of magnitude exactly $D^8 \cdot D'^4$.

Summing over m rows to get $\|E_{\mathbb{X},z}\|_2^2$ does not change the denominator so results in a rational with denominator $D^8 \cdot D'^4$ (as claimed) and a numerator of magnitude at most

$$m \cdot (n^2 \cdot N_{\max}^4 \cdot D'^2 + n \cdot N_{\max}^2 \cdot D^2 \cdot D'^2)^2$$

which simplifies to

$$m \cdot n^2 \cdot N_{\max}^4 \cdot D'^4 \cdot (n \cdot N_{\max}^2 + D^2)^2.$$

To bound the numerator and denominator of $J - \|E_{\mathbb{X},z}\|_2^2$, we first need to characterize the numerator and denominator of J. To do this, we consider $\mathcal{V}$'s checks in Step 3. To pass these checks, J must be a rational of the form (S, D^8) where S is a positive integer bounded above by D^8 (since $0 \le J \le \epsilon^2 \le 1$). To perform the subtraction $J - \|E_{\mathbb{X},z}\|_2^2$, one needs to multiply the numerator and denominator of J by D'^4 to get a common denominator (in the worst case). The resulting rational $J - \|E_{\mathbb{X},z}\|_2^2$ has a numerator of magnitude at most

$$m \cdot n^2 \cdot N_{\max}^4 \cdot D'^4 \cdot (n \cdot N_{\max}^2 + D^2)^2 + S \cdot D'^4$$

and an unreduced denominator of magnitude exactly $D^8 \cdot D'^4$, as claimed.

Given that $D' \le D_{\max}$ and $S \le D^8$, the numerator is upper-bounded by

$$m \cdot n^2 \cdot N_{\max}^4 \cdot D_{\max}^4 \cdot (n \cdot N_{\max}^2 + D^2)^2 + D^8 \cdot D_{\max}^4.$$

This is exactly U, as claimed. □

With the prime-divisibility bound (Lemma 4) and the numerator bound (Lemma 5) in hand, the two ρ_q facts quickly follow.

Proof of Lemma 2 (ρ_q ill-defined). ρ_q is undefined on $\|E_{\mathbb{X},z}\|_2^2$ exactly when q divides the denominator of $\|E_{\mathbb{X},z}\|_2^2$. By Lemma 5, the denominator is a product of powers of D and D' (where $D' \le D_{\max}$). By construction, q does not divide D; thus q divides the denominator of $\|E_{\mathbb{X},z}\|_2^2$ if and only if q divides D'. Applying Lemma 4 with $M = D_{\max}$ gives the bound. □

Proof of Lemma 3 (ρ_q collision). $\rho_q(J) = \rho_q(\|E_{X,z}\|_2^2)$ if and only if q divides the numerator of $J - \|E_{X,z}\|_2^2$, which, by Lemma 5, has magnitude at most U. Applying Lemma 4 with $M = U$ gives the desired bound. □

C DARK with verifier-known group order

This appendix details the technique mentioned in Section 4.2.3.

We consider an RSA group $\mathbb{G}$ with generator g and modulus $M = p_1 \cdot p_2$. The verifier knows p_1 and p_2, while the prover only knows g and M but not its factorization.

DARK requires, as a primitive, a way for the prover to convince the verifier that $g^z = g^x \cdot g^{c \cdot y}$ given g^x, g^y, and g^z and a constant c known to both parties. The problem is computing $(g^y)^c$; the verifier cannot efficiently compute an exponentiation this large, because it requires $\lceil \log c \rceil$ multiplications, which is potentially on the order of a million or a billion (the combined bit-length of all witness elements). DARK solves this with a proof of exponentiation protocol that is burdensome for the prover. In Spain, the verifier borrows an optimization from RSA signing algorithms when the signer knows the factorization of M.

The key observation is that knowledge of the factorization of M allows the verifier to compute $\lambda(M)$, where λ is Carmichael's function [1, 43]. Then the verifier can compute $c' = c \bmod \lambda(M)$, a value on the order of M rather than c itself, and compute $(g^y)^{c'}$ instead of $(g^y)^c$.

The correctness of this substitution is as follows. g^y is a group element and thus is relatively prime to M, so by the definition of Carmichael's function, we have $(g^y)^{\lambda(M)} \equiv 1 \pmod{M}$, and thus $(g^y)^{c'} \equiv (g^y)^c \pmod{M}$.

This substitution is efficient because $\log c' \approx \log M$, which is at worst a few thousand rather than a few billion.

At a high level, replacing the proof of exponentiation in DARK with an explicit exponentiation, independent of how the verifier computes, does not change the security of DARK.

Block et al. [29, Lemma 6.4] formally prove this in the context of a verifier that does not know the factorization of M and opts to compute $(g^y)^c$ directly. Their proof applies to our setting as well, as the verifier's computation of $(g^y)^{c'}$ is functionally equivalent to computing $(g^y)^c$ directly.

D Protocol extensions

Spain can be adapted and extended in various ways.

D.1 SIMD-R1CS

Per Section 4.3, Spain can be adapted to support common variations on R1CS, namely SIMD-R1CS and I-R1CS.

In SIMD-R1CS (§4.3), the prover has L instances, each with its own public input and witness, but sharing the same R1CS structure (A, B, C). That is, there are vectors $z_0, \ldots, z_{L-1}$, corresponding to instances $\mathbb{X}_0, \ldots, \mathbb{X}_{L-1}$, where all instances are the same R1CS structure. To support SIMD-R1CS, define $z(c, j)$ similarly to $z(c)$. Here j selects the particular instance and c selects the variable within that instance (similar to how c functioned earlier). Given the multilinear extension $\widetilde{z}(t_1, t_2)$, define

$$\widetilde{h_M}(t_1, t_2) := \sum_{c \in \{0,1\}^k} \widetilde{M}(t_1, c) \cdot \widetilde{z}(c, t_2),$$

Then there are two options for proving correctness across all L instances.

The first option is for the prover to make a single claim J about the sum of squared errors across all L instances. Then, the verifier can confirm that $J \leq \epsilon^2$ and the two parties can apply the sum-check protocol to prove that

$$\rho_q(J) = \sum_{j \in \{0,1\}^\ell} \sum_{r \in \{0,1\}^s} \left(\widetilde{h_A}(r, j) \cdot \widetilde{h_B}(r, j) - \widetilde{h_C}(r, j) \right)^2$$

where $\ell = \lceil \log_2 L \rceil$. This provides Back-end ϵ-soundness and Back-end $(\epsilon / \sqrt{L \cdot m})$-completeness. Notice that completeness degrades with L here.

The second option is to have the prover make $L - 1$ separate claims, where for $j = \{0, \ldots, L-1\}$, each claim J_j is about $\|E_{\mathbb{X}_j, z_j}\|_2^2$ for the respective instance $\mathbb{X}_j$. The verifier then checks that each J_j is at most ϵ^2. Then, the prover and verifier interpret $\rho_q(J) = [\rho_q(J_0), \ldots, \rho_q(J_{L-1})]$ as a function (from index bits to value) to get its multilinear extension: $\widetilde{J}(t)$. Finally, the verifier chooses a random $\tau \in \mathbb{F}_q^\ell$ and uses polynomial identity testing (similar to Spartan [116]) to prove that $\widetilde{J}(\tau)$ is equal to

$$\sum_{j \in \{0,1\}^\ell} \widetilde{Eq}(\tau, j) \sum_{r \in \{0,1\}^s} \left(\widetilde{h_A}(r, j) \cdot \widetilde{h_B}(r, j) - \widetilde{h_C}(r, j) \right)^2.$$

This provides Back-end ϵ-soundness and Back-end $(\epsilon / \sqrt{m})$-completeness. Compared to the first option, completeness does not degrade with L here; however, the expression is degree 5 in j rather than degree 4, which mildly increases prover and verifier time.

D.2 I-R1CS

For I-R1CS (§4.3), the modification to Spain is simply: at the end of the protocol, rather than opening a single commitment, the prover opens all commitments $\widetilde{w}_1, \ldots, \widetilde{w}_R$.

Recall that Spain introduces an additional optimization: Spain allows for the prover and verifier to collaboratively introduce not only new values for the *assignment* but also new *constraints on the witness* in each round. This allows the verifier to encode random challenges in constraints, or to partially specify constraints that are "filled-in" by the prover. These techniques reduce the cost of performing dot products between the witness and random vectors, which is the core operation in checkers for matrix multiplication [56, 74]

D.3 Different norms for error measurement

Spain can be generalized to have a smaller gap between soundness and completeness versus the one presented in the paper, namely $\epsilon_C = \epsilon / \sqrt{m}$. Doing so lowers the precision required of the prover's witness generation (see §6.3 for the interplay between "precision of witness generation" and ϵ_C) but makes the underlying back-end protocol more costly.

Specifically, by using the ℓ^{2t} norm rather than the ℓ^2 norm of $E_{\mathbb{X},z}$, for integer $t > 1$, Spain will continue to have Back-end ϵ-soundness but now it will have Back-end $(\epsilon / m^{1/(2t)})$-completeness. That is because the following chain of inequalities holds:

$$\|E_{\mathbb{X},z}\|_\infty^{2t} \leq \|E_{\mathbb{X},z}\|_{2t}^{2t} \leq m \cdot \|E_{\mathbb{X},z}\|_\infty^{2t}$$

for any integer $t > 1$. To adapt Spain to use the ℓ^{2t} norm, the prover and verifier start with the following equation in place of Equation (4) in Section 4.2.2 (Step 5 in Figure 8):

$$\rho_q(J) = \sum_{r \in \{0,1\}^s} \left(\widetilde{g_A}(r) \cdot \widetilde{g_B}(r) - \widetilde{g_C}(r) \right)^{2t}.$$

This is a degree-$(4t)$ polynomial in r, so as t increases, so does prover time, verifier time, and communication.

E Translation fidelity

This appendix defines translation fidelity and covers some technical details of this concept. The bulk of the appendix analyzes the translation fidelity of the arithmetizations presented in Section 5.

E.1 Preliminaries

Definitions. Given an R1CS structure $\mathbb{S} = (A, B, C)$, recall that all entries in A, B, C are presumed to have a given denominator D, and likewise with the assignment z (§4.2.1, Appx. B). We call such numbers *η-multiples*, where $\eta = 1/D$.

Let $F_\delta(x)$ denote the possible outputs of function F on input x when its individual operations have error bounded by δ.

Recall the distinction between δ and δ_{wg} (§3). δ is part of the underlying protocol's soundness guarantee: if any operation in an execution has error greater than δ, the verifier is supposed to reject with high probability. On the other hand, δ_{wg} connects to the protocol's *completeness* guarantee: we want to arrange the design and implementation so that if the prover limits the per-operation error to δ_{wg}, then it *can* satisfy all constraints with suitable error, and thereby cause the verifier to accept.

The reason for the asymmetry is technical. It relates to the definitions of soundness and completeness in the front-end (given in the next paragraph), and to the fact that ϵ and ϵ_C are different, which itself stems from the fact that $\|E_{\mathbb{X},z}\|_\infty \leq \epsilon$ does not imply $\|E_{\mathbb{X},z}\|_2^2 \leq \epsilon^2$ (§4.1).

Now, consider a purported translation of F to an R1CS structure $\mathbb{S} = (A, B, C)$. Translation fidelity is two properties:

- The translation is *ϵ-tf-sound* if: for all ϵ-accurate assignments $(in, out, 1, w)$ to $\mathbb{S}$, $out \in F_\delta(in)$.
- The translation is *ϵ_C-tf-complete* if: for all (in, out) such that $out \in F_{\delta_{wg}}(in)$ and (in, out) contains only η-multiples, there exists an accompanying w such that $(in, out, 1, w)$ is an ϵ_C-accurate assignment to $\mathbb{S}$.

It is helpful to keep the following ordering in mind:

$\delta \geq \epsilon$ (will be established in the examples below)
$> \epsilon_C$ (§4.1)
$\geq \delta_{wg}$ (will be established in the examples below)

Per-operation vs per-function translation fidelity. The definitions of tf-soundness and tf-completeness cover translation of an entire *function*. However, the arithmetizations that we present in the next section will be at the level of *individual operations*. For these lower-level translations to be relevant, Spain needs a way to combine the translations of individual operations. The needed concept is *composition* (of operations or functions), and specifically how translations combine under composition. The description below delves into detail; the high-level point is that focusing on the translations of individual operations is justified.

Given two functions F and G, with corresponding R1CS instances $\mathbb{X}_F = (A_F, B_F, C_F, in_F, out_F)$ and $\mathbb{X}_G = (A_G, B_G, C_G, in_G, out_G)$, the corresponding instance for $G \circ F$, $\mathbb{X}_{G\circ F}$, is (A, B, C, in, out) where $in = in_F$, $out = out_G$, and A, B, C contain the constraints of A_F, B_F, C_F and A_G, B_G, C_G, relabeled so that the output variables of $\mathbb{X}_F$ and the input variables of $\mathbb{X}_G$ refer to the same set of variables, which we call *med*; the variables in *med* are not part of either *in* or *out*. The lemma below states that translation fidelity is preserved by the composition of functions.

Lemma 6. *If F and $\mathbb{X}_F$ satisfy ϵ-tf-soundness and ϵ_C-tf-completeness, and if G and $\mathbb{X}_G$ satisfy ϵ'-tf-soundness and ϵ'_C-tf-completeness, then $G \circ F$ and $\mathbb{X}_{G\circ F}$ satisfy* $\min\{\epsilon, \epsilon'\}$*-tf-soundness and* $\max\{\epsilon_C, \epsilon'_C\}$*-tf-completeness.*

Proof. We first establish $\min\{\epsilon, \epsilon'\}$-tf-soundness, where $\epsilon^* := \min\{\epsilon, \epsilon'\}$. The constraints of $\mathbb{X}_{G\circ F}$ are those of $\mathbb{X}_F$ together with those of $\mathbb{X}_G$, sharing only the variables *med*. An ϵ^*-accurate assignment to the composite therefore restricts to an ϵ^*-accurate assignment to each part; as $\epsilon^* \leq \epsilon$ and $\epsilon^* \leq \epsilon'$, these are in particular ϵ- and ϵ'-accurate. Then ϵ-tf-soundness of F gives $med \in F_\delta(in)$, and ϵ'-tf-soundness of G gives $out \in G_\delta(med)$, so $out \in (G \circ F)_\delta(in)$.

For tf-completeness, set $\epsilon^* := \max\{\epsilon_C, \epsilon'_C\}$. Consider (in, out) where *in* and *out* contain η-multiples and $out \in (G \circ F)_{\delta_{wg}}(in)$. By definition of the composite, there must be *med*, consisting of η-multiples, with $med \in F_{\delta_{wg}}(in)$ and $out \in G_{\delta_{wg}}(med)$. Applying ϵ_C-tf-completeness of F, there exists w_F, where $(in, med, 1, w_F)$ is an ϵ_C-accurate assignment to (A_F, B_F, C_F). Likewise, there exists w_G, where $(med, out, 1, w_G)$ is an ϵ'_C-accurate assignment to (A_G, B_G, C_G). Combining w_F, w_G, and *med* into w, the assignment $(in, out, 1, w)$ satisfies each constraint of $\mathbb{X}_{G\circ F}$ with error upper-bounded by ϵ_C or ϵ'_C, hence upper-bounded by ϵ^*. □

E.2 Analysis of arithmetizations

The ϵ and ϵ_C described for the translations below depend on the magnitudes of the inputs to these subfunctions. This is not problematic because Spain enforces a strict bound on the magnitude of rationals in the proof protocol (§B). By considering this maximum magnitude, one derives absolute bounds on ϵ and ϵ_C.

$\mathbf{z \leftarrow x/y}$. Division is a special case where the error bound is inversely proportional to the magnitude of y, and thus one must place restrictions on the domain of y or perform static analysis to ensure y is not too close to 0 when using this operation. Here we will assume that $|y| \geq M$ for some known $M > 0$.

First, we establish ϵ-tf-soundness. Suppose we have an ϵ-accurate assignment to $y \cdot z \approx_\epsilon x$. That means $|y \cdot z - x| \leq \epsilon$. Rearranging, we have that $|z - (x/y)| \leq \epsilon/|y|$. This implies that z is within $\epsilon/|y|$ of x/y, and thus $|z - (x/y)| \leq \epsilon/M$ (using the assumed lower bound on $|y|$). Letting $\delta = \epsilon/M$ completes the proof of ϵ-tf-soundness.

Second, for ϵ_C-tf-completeness, consider all (x, y, z), restricted to η-multiples, such that $z = (x/y) + \widehat{\delta_\pm}$ where $|\widehat{\delta_\pm}| \leq \delta_{wg}$. The constraint has error at most

$$|y \cdot z - x| = |y \cdot ((x/y) + \widehat{\delta_\pm}) - x| = |y \cdot \widehat{\delta_\pm}| \leq \delta_{wg}|y|.$$

This establishes ϵ_C-tf-completeness provided that $\epsilon_C \geq \delta_{wg}|y|$ for all inputs y.

$\mathbf{y} \leftarrow \sqrt{\mathbf{x}}$. First, we establish ϵ-tf-soundness. Suppose we have an ϵ-accurate assignment to $y \cdot y \approx_\epsilon x$. That means $|y^2 - x| \leq \epsilon$. This can be rewritten as $|y - \sqrt{x}| \cdot |y + \sqrt{x}| \leq \epsilon$, where $\sqrt{x}$ is a true square root of x, and assume WLOG that $\sqrt{x}$ is the positive root. This implies that either $|y - \sqrt{x}|$ or $|y + \sqrt{x}|$ is less than or equal to $\sqrt{\epsilon}$. This, in turn, implies that y is within $\sqrt{\epsilon}$ of a true square root of x. Letting $\delta = \sqrt{\epsilon}$ finishes the proof for ϵ-tf-soundness.

Second, for ϵ_C-tf-completeness, consider all (x, y), restricted to η-multiples, such that $y = \sqrt{x} + \widehat{\delta_\pm}$ where $\widehat{\delta_\pm}$ is a real number with $|\widehat{\delta_\pm}| \leq \delta_{wg}$. The constraint $y \cdot y \approx_\epsilon x$ is satisfied with error at most

$$\left|(\sqrt{x} + \widehat{\delta_\pm})^2 - x\right| \leq 2\delta_{wg}|\sqrt{x}| + \delta_{wg}^2.$$

This establishes ϵ_C-tf-completeness provided that $\epsilon_C \geq 2\delta_{wg}|\sqrt{x}| + \delta_{wg}^2$ for all inputs x.

assert $(\mathbf{x} \geq \mathbf{y})$. Recall that this is an assert of the form "greater-than-or-approximately equal" where x and y are allowed (but not required) to be "approximately-equal" when they are within δ of each other.

First, we establish ϵ-tf-soundness. Suppose we have an ϵ-accurate assignment to $t \cdot t \approx_\epsilon x - y$. That means $|t^2 - (x - y)| \leq \epsilon$. By definition, $t^2 \geq 0$. This implies that $x - y \geq -\epsilon$. Letting $\delta = \epsilon$ finishes the proof for ϵ-tf-soundness.

Second, for ϵ_C-tf-completeness, consider all x, y, restricted to η-multiples, such that $x \geq y$. Let t be the nearest η-multiple to $\sqrt{x - y}$. Thus, $t = \sqrt{x - y} + \widehat{\eta_\pm}$ where $|\widehat{\eta_\pm}| \leq \eta/2$. Then the constraint $t \cdot t \approx_\epsilon x - y$ is satisfied with error at most

$$|t^2 - (x - y)| = |2\widehat{\eta_\pm}\sqrt{x - y} + \widehat{\eta_\pm}^2| \leq \eta\sqrt{x - y} + \eta^2/4.$$

This establishes ϵ_C-tf-completeness provided that $\epsilon_C \geq \eta\sqrt{x - y} + \eta^2/4$.

$\mathbf{b} \leftarrow (\mathbf{x} \geq \mathbf{y})$. First, we establish ϵ-tf-soundness for $\epsilon < 1/8$. Suppose we have an ϵ-accurate assignment to the constraints: $b \cdot (1 - b) \approx_\epsilon 0$, $(2b - 1) \cdot (x - y) \approx_\epsilon t$, and $s \cdot s \approx_\epsilon t$. Using the same reasoning as in proving ϵ-tf-soundness for the assert statement, the third constraint implies $t \geq -\epsilon$.

The first constraint implies $|b \cdot (1 - b)| \leq \epsilon$. By our bound on ϵ and the quadratic formula applied to $-\epsilon \leq b \cdot (1 - b) \leq \epsilon$, we have

$$b \in \left[\frac{1 - \sqrt{1 + 4\epsilon}}{2}, \frac{1 - \sqrt{1 - 4\epsilon}}{2}\right]$$

or

$$b \in \left[\frac{1 + \sqrt{1 - 4\epsilon}}{2}, \frac{1 + \sqrt{1 + 4\epsilon}}{2}\right].$$

Given that $\sqrt{1 - 4\epsilon} \geq 1 - 4\epsilon$ for $\epsilon < 1/4$, and $\sqrt{1 + 4\epsilon} \leq 1 + 4\epsilon$ for $\epsilon < 1/4$, this implies that $b \in [-2\epsilon, 2\epsilon] \cup [1 - 2\epsilon, 1 + 2\epsilon]$, namely that b is within 2ϵ of either 0 or 1.

The second constraint requires the most involved analysis. An ϵ-accurate assignment implies $|(2b - 1) \cdot (x - y) - t| \leq \epsilon$. Given that $t \geq -\epsilon$, this implies $(2b - 1) \cdot (x - y) \geq -2\epsilon$. Let $b' := 2b - 1$. From the bounds on b from before

$$b' \in [-1 - 4\epsilon, -1 + 4\epsilon] \cup [1 - 4\epsilon, 1 + 4\epsilon].$$

We also have $b' \cdot (x - y) \geq -2\epsilon$. We consider two cases, depending on which interval b' falls into.

Case 1: $b' \in [-1 - 4\epsilon, -1 + 4\epsilon]$. In this case, we have

$$x - y \leq \frac{2\epsilon}{1 - 4\epsilon}.$$

Given that $\epsilon \leq 1/8$, we have

$$\frac{2\epsilon}{1 - 4\epsilon} \leq \frac{2\epsilon}{1/2} = 4\epsilon.$$

Case 2: $b' \in [1 - 4\epsilon, 1 + 4\epsilon]$. In this case, we have

$$x - y \geq \frac{-2\epsilon}{1 - 4\epsilon}.$$

Given that $\epsilon \leq 1/8$, we have

$$\frac{-2\epsilon}{1 - 4\epsilon} \geq \frac{-2\epsilon}{1/2} = -4\epsilon.$$

Summarizing the two cases: $b \in [-2\epsilon, 2\epsilon]$ (which is case 1) implies $x - y \leq 4\epsilon$, while $b \in [1 - 2\epsilon, 1 + 2\epsilon]$ (which is case 2) implies $x - y \geq -4\epsilon$, or $y - x \leq 4\epsilon$.

Taking the contrapositive of both

$$x - y > 4\epsilon \implies b \in [1 - 2\epsilon, 1 + 2\epsilon]$$
$$y - x > 4\epsilon \implies b \in [-2\epsilon, 2\epsilon].$$

Finally, if $|x - y| \leq 4\epsilon$, no further conclusion can be drawn about b, except that it must remain in the intervals derived above. This means it must be within 2ϵ of either 0 or 1.

By taking $\delta = 4\epsilon$, the relationships among x, y, and b obey the intended semantics of the operation, and thus ϵ-tf-soundness holds.

Second, we establish ϵ_C-tf-completeness, provided that $\delta_{wg} \leq 1/2$. Consider all (x, y, b), restricted to η-multiples, such that $b = 1 + \widehat{\delta_\pm}$ if $x \geq y$ and $b = \widehat{\delta_\pm}$ otherwise, where $\widehat{\delta_\pm}$ is a real number with $|\widehat{\delta_\pm}| \leq \delta_{wg}$.

For the first constraint there are two cases to consider.

Case 1: suppose $x \geq y$ and thus $b = 1 + \widehat{\delta_\pm}$. The constraint is satisfied with error at most

$$|b \cdot (1 - b)| = |(1 + \widehat{\delta_\pm}) \cdot (-\widehat{\delta_\pm})| \leq \delta_{wg} + \delta_{wg}^2.$$

Case 2: suppose $x < y$ and thus $b = \widehat{\delta_\pm}$. The upper bound on error is the same:

$$|b \cdot (1 - b)| = |\widehat{\delta_\pm} \cdot (1 - \widehat{\delta_\pm})| \leq \delta_{wg} + \delta_{wg}^2.$$

For the second constraint, take $t = (2b - 1) \cdot (x - y)$. The constraint is then satisfied with zero error.

For the third constraint, take s to be the nearest η-multiple to $\sqrt{t}$. Thus, $s = \sqrt{t} + \widehat{\eta_\pm}$ where $|\widehat{\eta_\pm}| \leq \eta/2$. Such a square root exists because $t \geq 0$. This follows because $(2b-1)$ and $(x-y)$ have the same sign, as long as $\delta_{wg} \leq 1/2$. Now, we show $t \leq 2 \cdot |x-y|$, as follows. If $x \geq y$, then $b = 1 + \widehat{\delta_\pm}$ and thus

$$t = (2b-1) \cdot (x-y) = (1 + 2\widehat{\delta_\pm}) \cdot |x-y| \leq 2 \cdot |x-y|.$$

If $x < y$, then $b = \widehat{\delta_\pm}$ and thus

$$t = (2b-1) \cdot (x-y) = (1 - 2\widehat{\delta_\pm}) \cdot |x-y| \leq 2 \cdot |x-y|.$$

Given this, the third constraint is satisfied with error at most

$$\begin{aligned} |s^2 - t| &= |(\sqrt{t} + \widehat{\eta_\pm})^2 - t| \\ &= |2\widehat{\eta_\pm}\sqrt{t} + \widehat{\eta_\pm}^2| \\ &\leq \eta\sqrt{t} + \eta^2/4 \\ &\leq \eta\sqrt{2 \cdot |x-y|} + \eta^2/4. \end{aligned}$$

This establishes ϵ_C-tf-completeness provided that $\epsilon_C \geq \max\{\delta_{wg} + \delta_{wg}^2, \eta\sqrt{2 \cdot |x-y|} + \eta^2/4\}$.

$\mathbf{z} \leftarrow \max\{\mathbf{v_1}, \ldots, \mathbf{v_L}\}$. Recall the constraints from Section 5:

- for all $i \in \{1, \ldots, L\}$: $t_i \cdot t_i \approx_\epsilon z - v_i$
- for all $i \in \{1, \ldots, L\}$: $b_i \cdot (1 - b_i) \approx_\epsilon 0$
- for all $i \in \{1, \ldots, L\}$: $b_i \cdot (z - v_i) \approx_\epsilon 0$
- $\sum_{i=1}^{L} b_i \approx_\epsilon 1$

First, we establish ϵ-tf-soundness, for all $\epsilon \leq 1/4$ when $\epsilon \cdot (2L+1) < 1$. Suppose we have an ϵ-accurate assignment to the constraints. For the first set of constraints, we can reuse the results from the assert operation to establish that $z \geq v_i - \epsilon$ for all i. From the second set of constraints, we can use the same reasoning as in $b \leftarrow (x \geq y)$ to establish that each b_i is within 2ϵ of either 0 or 1. Given that $\epsilon \cdot (2L+1) < 1$, the last constraint and the second set together imply that there exists some index j such that b_j is within 2ϵ of 1. This follows by contradiction, suppose this was not the case, then each b_i would be within 2ϵ of 0, and thus $\sum_{i=1}^{L} b_i \leq 2L \cdot \epsilon < 1 - \epsilon$, leaving the final constraint unsatisfied by more than ϵ.

This leaves the third set of constraints to analyze. Let j be the index for which $b_j \geq 1 - 2\epsilon$. Since the assignment is ϵ-accurate, $|b_j \cdot (z - v_j)| \leq \epsilon$. Thus:

$$|z - v_j| \leq \frac{\epsilon}{b_j} \leq \frac{\epsilon}{1-2\epsilon}.$$

In particular:

$$z \leq v_j + \frac{\epsilon}{1-2\epsilon} \leq \max_i v_i + \frac{\epsilon}{1-2\epsilon}.$$

We already have $z \geq v_i - \epsilon$ for all i, which implies

$$z \geq \max_i v_i - \epsilon,$$

and since $\epsilon < \frac{\epsilon}{1-2\epsilon}$ also

$$z \geq \max_i v_i - \frac{\epsilon}{1-2\epsilon}.$$

Thus, $|z - \max_i v_i| \leq \frac{\epsilon}{1-2\epsilon}$. Given that $\epsilon \leq 1/4$, $\frac{\epsilon}{1-2\epsilon} \leq \frac{\epsilon}{1/2} = 2\epsilon$. Setting $\delta = 2\epsilon$ completes the proof of ϵ-tf-soundness.

Second, we establish ϵ_C-tf-completeness. Consider all $(v_1, \ldots, v_L, z)$, restricted to η-multiples, such that $z = \max_i v_i + \widehat{\delta_\pm}$ for some $\widehat{\delta_\pm}$ where $|\widehat{\delta_\pm}| \leq \delta_{wg}$.

Take $b_j = 1$ for the index j corresponding to the maximum value, and set all other b_i to 0.

For the first set of constraints, we use that $z - v_i \geq -\delta_{wg}$. This follows from the fact that $z = \max_i v_i + \widehat{\delta_\pm}$ and thus $z - v_i = \max_i(v_i) + \widehat{\delta_\pm} - v_i \geq \widehat{\delta_\pm} \geq -\delta_{wg}$. Now there are two cases to consider.

Case 1: suppose $z - v_i \geq 0$. In this case, set t_i to be the nearest η-multiple to $\sqrt{z - v_i}$. Thus, $t_i = \sqrt{z - v_i} + \widehat{\eta_{\pm i}}$, where $|\widehat{\eta_{\pm i}}| \leq \eta/2$. These constraints are satisfied with error at most

$$\begin{aligned} |t_i^2 - (z - v_i)| &= |(\sqrt{z - v_i} + \widehat{\eta_{\pm i}})^2 - (z - v_i)| \\ &= |2\widehat{\eta_{\pm i}}\sqrt{z - v_i} + \widehat{\eta_{\pm i}}^2| \\ &\leq \eta\sqrt{\max_i(v_i) - \min_i(v_i) + \delta_{wg}} + \eta^2/4. \end{aligned}$$

Case 2: suppose $z - v_i < 0$. In this case, take $t_i = 0$. These constraints are satisfied with error at most

$$|t_i^2 - (z - v_i)| = |z - v_i| \leq \delta_{wg}.$$

The second and fourth set of constraints are satisfied with zero error, by the choice of b_i above.

The third set of constraints breaks into two cases. When $b_i = 0$, the ith constraint in the set is satisfied with zero error. When $b_i = 1$ (that is, when $i = j$), constraint j in the set is satisfied with error at most δ_{wg}, as $b_j \cdot (z - v_j) = z - v_j = \widehat{\delta_\pm} \leq \delta_{wg}$.

This establishes ϵ_C-tf-completeness provided that

$$\epsilon_C \geq \max\left\{\delta_{wg}, \eta\sqrt{\max_i(v_i) - \min_i(v_i) + \delta_{wg}} + \eta^2/4\right\}.$$

ReLU. First, we establish ϵ-tf-soundness for $\epsilon \leq 1$. Suppose we have an ϵ-accurate assignment to the constraints: $s \cdot s \approx_\epsilon z - x$, $t \cdot t \approx_\epsilon z$, and $(z - x) \cdot z \approx_\epsilon 0$ From the first and second constraints, we have that $z \geq -\epsilon + \max(0, x)$. The third constraint is where things diverge from prior analyses. An ϵ-accurate assignment implies $|(z - x) \cdot z| \leq \epsilon$. This can be decomposed as $|z - x| \cdot |z| \leq \epsilon$. For the product on the left to be at most ϵ, then at least one of the two factors must be at most $\sqrt{\epsilon}$. Thus z is within $\sqrt{\epsilon}$ of either 0 or x.

Now there are two cases to consider.

Case 1: suppose $x \geq 0$. Here z is at least $x - \epsilon$ by the first two constraints, and at most $x + \sqrt{\epsilon}$ by the third constraint. thus, as required, z is within $\sqrt{\epsilon}$ of x.

Case 2: suppose $x < 0$. Here z is at least $-\epsilon$ by the first two constraints, and at most $\sqrt{\epsilon}$ by the third constraint. Thus, as required, z is within $\sqrt{\epsilon}$ of 0.

By combining these cases, we get that z is within $\sqrt{\epsilon}$ of $\max(0, x)$. Setting $\delta = \sqrt{\epsilon}$ completes the proof.

Second, we establish ϵ_C-tf-completeness. Consider all (x, z), restricted to η-multiples, such that $z = \max(0, x) + \widehat{\delta_\pm}$ where $\widehat{\delta_\pm}$ is a real number with $|\widehat{\delta_\pm}| \leq \delta_{wg}$. We consider each constraint individually and take the maximum error across all constraints.

Constraint 1: $s \cdot s \approx_\epsilon z - x$. This constraint has error at most

$$|s^2 + x - (\max(0, x) + \widehat{\delta_\pm})| = |s^2 + \min(x, 0) - \widehat{\delta_\pm}|. = |s^2 + x'|,$$

where $x' := \min(x, 0) - \widehat{\delta_\pm}$. x' is an η-multiple $\leq \delta_{wg}$. There are two cases to consider.

Case 1: suppose $x' > 0$. In this case, setting $s = 0$ satisfies this constraint with error at most δ_{wg}.

Case 2: suppose $x' \leq 0$. In this case, set s to the closest η-multiple to $\sqrt{-x'}$. Thus, $s = \sqrt{-x'} + \widehat{\eta_\pm}$, for some $\widehat{\eta_\pm}$ where $|\widehat{\eta_\pm}| \leq \eta/2$. Then this constraint has error at most

$$\begin{aligned} |(\sqrt{-x'} + \widehat{\eta_\pm})^2 + x'| &= |2\widehat{\eta_\pm}\sqrt{-x'} + \widehat{\eta_\pm}^2| \\ &\leq \eta\sqrt{-x'} + \eta^2/4 \\ &\leq \eta\sqrt{|x| + \delta_{wg}} + \eta^2/4. \end{aligned}$$

Thus the first constraint is satisfied with error at most

$$\max\left\{\delta_{wg}, \eta\sqrt{|x| + \delta_{wg}} + \eta^2/4\right\}.$$

Constraint 2: $t \cdot t \approx_\epsilon z$. This constraint has error at most

$$|t^2 - (\max(0, x) + \widehat{\delta_\pm})|.$$

The analysis is similar to the one for the first constraint. The cases here are $z \leq 0$ (in which case let $t = 0$) and $z > 0$ (in which case let t be the closest η-multiple to $\sqrt{z}$). These settings satisfy this constraint with error at most

$$\max\left\{\delta_{wg}, \eta\sqrt{|x| + \delta_{wg}} + \eta^2/4\right\}.$$

Constraint 3: $(z - x) \cdot z \approx_\epsilon 0$. This constraint is satisfied with error at most

$$\left|(\max(0, x) + \widehat{\delta_\pm} - x) \cdot (\max(0, x) + \widehat{\delta_\pm})\right| \leq \delta_{wg}|x| + \delta_{wg}^2.$$

Combining the above, we have that all constraints are satisfied with error at most

$$\max\left\{\delta_{wg}, \eta\sqrt{|x| + \delta_{wg}} + \eta^2/4, \delta_{wg}|x| + \delta_{wg}^2\right\}.$$

This establishes ϵ_C-tf-completeness provided that

$$\epsilon_C \geq \max\left\{\delta_{wg}, \eta\sqrt{|x| + \delta_{wg}} + \eta^2/4, \delta_{wg}|x| + \delta_{wg}^2\right\}.$$

E.3 On choosing between alternative arithmetizations

When using traditional constraints, the fewer constraints in an arithmetization the better. However, with approximate constraints, this is not always the case. Take ReLU as an example. The ReLU arithmetization in Section E.2 is 3 constraints and satisfies ϵ-tf-soundness with $\delta = \sqrt{\epsilon}$. By contrast, if the following 5 constraints are used (derived from the max primitive):

- $s \cdot s \approx_\epsilon z - x$
- $t \cdot t \approx_\epsilon z$
- $b \cdot (1 - b) \approx_\epsilon 0$
- $b \cdot (z - x) \approx_\epsilon 0$
- $(1 - b) \cdot z \approx_\epsilon 0$

then ϵ-tf-soundness is satisfied with $\delta = 2\epsilon$.

Despite using almost twice as many constraints, the second arithmetization produces a significantly tighter relationship between ϵ and δ. This in turn enables a larger ϵ_C and δ_{wg} (which means lower precision is needed in witness generation). In settings where high-precision witness generation is a bottleneck, the second arithmetization may be preferable, in spite of using a larger number of constraints.

E.4 Hybrid arithmetizations

Spain exclusively handles approximate constraints. Here we sketch a short exploration of a hybrid setting where there are two structures, $\mathbb{S}_\epsilon$ and $\mathbb{S}_{\text{exact}}$, that enforce approximate and traditional constraints respectively on the same assignment z.

By appending to the definition of ϵ-accuracy the requirement that the traditional constraints (those in $\mathbb{S}_{\text{exact}}$) are satisfied with zero error, the notion of translation fidelity can be extended to this hybrid setting. To demonstrate, we step through the analysis of a simple operation, $b \leftarrow_{\text{exact}} (x \geq y)$, where b is exactly 0 or 1 and the comparison is approximate. Consider a hybrid arithmetization of this primitive that has two traditional constraints: $b \cdot (1 - b) = 0$ and $(2b - 1) \cdot (x - y) = t$, and one approximate constraint: $s \cdot s \approx_\epsilon t$.

$\mathbf{b} \leftarrow_{\text{exact}} (\mathbf{x} \geq \mathbf{y})$. First, we establish ϵ-tf-soundness. Suppose we have an ϵ-accurate assignment to the constraints.

From the first constraint, we have that b is either 0 or 1.

From the second constraint, we have that

$$\begin{aligned} b = 0 &\implies t = y - x \\ b = 1 &\implies t = x - y. \end{aligned}$$

Using the same reasoning as in proving ϵ-tf-soundness for the assert statement, the third constraint (the approximate one) implies $t \geq -\epsilon$.

By combining the above, we have that

$$\begin{aligned} x - y > \epsilon &\implies b = 1 \\ y - x > \epsilon &\implies b = 0. \end{aligned}$$

In the case where $|x - y| \leq \epsilon$, b can be either 0 or 1, which is consistent with the semantics of the approximate comparison.

By taking $\delta = \epsilon$, we have that b is consistent with the semantics of the approximate comparison, and thus ϵ-tf-soundness is established.

Second, we establish ϵ_C-tf-completeness. Consider all (x, y, b) restricted to η-multiples such that $b = 1$ if $x \geq y$ and $b = 0$ otherwise. Take t to be exactly $(2b - 1) \cdot (x - y)$ and s to be the nearest η-multiple to $\sqrt{t}$. Thus $s = \sqrt{t} + \hat{\eta}$ for some $\hat{\eta}$ where $|\hat{\eta}| \leq \eta/2$.

The traditional constraints are satisfied with zero error by the choice of t and the definition of b.

Because b is either 0 or 1, $t = (2b - 1) \cdot (x - y) = |x - y|$. Given this, the third constraint is satisfied with error at most

$$\begin{aligned} |s^2 - t| &= |(\sqrt{t} + \widehat{\eta_\pm})^2 - t| \\ &= |2\widehat{\eta_\pm}\sqrt{t} + \widehat{\eta_\pm}^2| \\ &\leq \eta\sqrt{t} + \eta^2/4 \\ &\leq \eta\sqrt{|x - y|} + \eta^2/4. \end{aligned}$$

This establishes ϵ_C-tf-completeness provided that $\epsilon_C \geq \eta\sqrt{|x - y|} + \eta^2/4$.

Note that both the tf-soundness and tf-completeness results here are stronger than those presented in the prior analysis of $b \leftarrow (x \geq y)$ where b is approximately Boolean and no traditional constraints are used.

Also, when exclusively using approximate constraints, it is extremely complex to confine b to be strictly Boolean, while with traditional constraints, doing so is straightforward. This example indicates the potential benefits of hybrid arithmetization, the full exploration of which we leave to future work.

F End-to-end correctness

We derive end-to-end soundness and completeness for Spain in the general case and for the parameters in our implementation. We do so by combining back-end correctness (Theorem 1, §B.3) and translation fidelity (§E.1). The statements below rely on δ and δ_{wg}, which are discussed in Appendix E.1.

Corollary 2. *Let F be a computation and (A, B, C) be an R1CS structure with m constraints and n variables. If (A, B, C) is an ϵ-*tf-sound *and $(\epsilon/\sqrt{m})$-*tf-complete *translation of F, then the protocol in Figure 8 satisfies the following two guarantees:*

1. *If out $\notin F_\delta(in)$, then the verifier accepts with probability at most*

$$\frac{\lfloor \log_{\min P} D_{max} \rfloor + \lfloor \log_{\min P} U \rfloor}{|P|} + \frac{4s + 2 + 2k}{\min P} + \kappa_{PC}.$$

2. *If out $\in F_{\delta'}(in)$, then the prover can always make an honest verifier accept.*

This corollary follows by straightforward combination of Theorem 1 with the definitions of tf-soundness and tf-completeness in Appendix E.1.

Corollary 3. *Let F be a computation from the list of benchmarks in Section 7, and (A, B, C) be an R1CS structure with $m \leq 2^{32}$ constraints and $n \leq 2^{32}$ variables. If (A, B, C) is an ϵ-*tf-sound *and $(\epsilon/\sqrt{m})$-*tf-complete *translation of F, then the protocol in Figure 8 with the parameters in Corollary 1 satisfies the following two guarantees:*

1. *If out $\notin F_\delta(in)$, then the verifier accepts with probability at most 2^{-40}.*
2. *If out $\in F_{\delta'}(in)$, then the prover can always make an honest verifier accept.*

The proof of this corollary follows mechanically from Corollaries 1 and 2.

G Artifact Appendix

Abstract

The purpose of this artifact is to disseminate our implementation of Spain, let others to prove execution of numerical computations using Spain, and enable reproduction of the paper's experimental results.

Scope

The artifact comprises the implementation of Spain described in Section 6 as well as the experimental results and figures in Section 7.

Contents

The artifact includes implementations of Spain's front-ends and back-end (§6), implementations of the ZKLP-FE and Otti-FE baselines, scripts for reproducing experimental results, and ONNX files used for arithmetization.

The artifact is documented with a README that includes further detail and instructions for running numerical computations through Spain.

Hosting

The artifact is publicly available at `https://doi.org/10.5281/zenodo.20090527`.

Requirements

Docker is required to run this artifact. Memory requirements to reproduce results for benchmarks on the prover are as follows:

- For GPT-2, *seq*=2: at least 10 GB RAM
- For GPT-2, *seq*=32: at least 40 GB RAM
- For GPT-2, the largest *passes* with which we experiment, namely *passes*= 16: at least 270 GB RAM
- For ZKLP-FE: at least 92 GB RAM
- For all other benchmarks: experimental results can be reproduced with under 5 GB of RAM for the prover.

Abstract

This paper presents an overlay type system, RT, for statically checking streaming shell programs or fragments *before* their execution. RT's *regular types* offer expressiveness appropriate for capturing a command's standard input and output streams, support computationally tractable and efficient type checking, and provide an interface encoded as regular expressions—*i.e.*, annotations and error messages familiar to developers versed in the Unix environment. RT's extensions around type polymorphism, finite-state transductions, environment concretization, and syntactic primitives offer additional expressiveness and improved precision. Applying RT to hundreds of programs from various sources including StackOverflow, GitHub, and prior literature indicates efficient type checking (0.02*s* on average), effectiveness at discovering serious bugs (91% accuracy), and key benefits from RT's extensions (up to 83% reduction in false negatives).

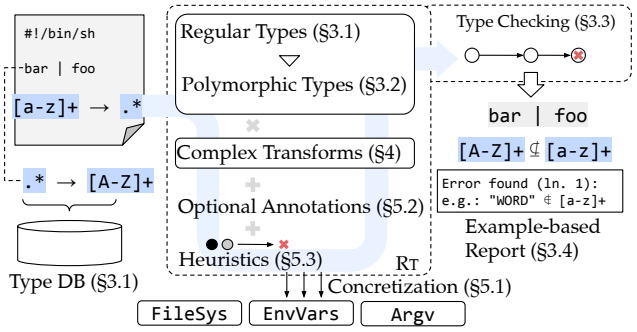

Fig. 1: RT overview. A shell program is parsed into RT, which assigns types to commands from a database of type declarations (§3.1). It models command behavior with simple regular types (§3.1), extends expressiveness through polymorphism (§3.2) and custom regular operations (§4), and detects composition errors with counterexamples (§3.4). Optional extensions—concretization (§5.1), annotations (§5.2), and heuristics (§5.3)—boost precision.

1 Introduction

The type systems of modern programming languages offer significant benefits [28, 37, 39, 54]: fast pre-execution checks for computations that may take days; detection of misbehaviors by a program's developer, not its user; improved error messages, including counter-examples; whole-program optimization opportunities, such as dead-code removal; and elimination of entire classes of bugs.

Unfortunately, these benefits are absent from the Unix shell—a pervasive environment used for a variety of tasks, ranging from system administration to data processing [24, 33, 36, 50, 55, 64]. Shell programs often combine commands developed in a variety of languages, interact in an untyped bytestream fashion, and are composed using the shell's intricate composition primitives. Coupled with the myriad of command flags and options, the implicit assumptions about the structure of certain file contents (*e.g.*, `/etc/passwd`), and the ease by which stream contents are manipulated, these characteristics routinely lead to errors that with current practices can only be discovered *after* the execution of shell programs. Such errors, arising when programming-in-the-large and in-the-small, can have devastating effects—at best crashing the execution of a long-running task and at worst silently, irreversibly corrupting entire filesystems [23, 51, 61, 62].

This paper proposes a new type system and associated implementation, RT, for statically checking shell programs before their execution (Fig. 1). RT's novel *regular types* offer expressiveness appropriate for capturing the structure of a command's input, output, and other streams, support computationally tractable and efficient type checking, and provide an interface encoded as regular expressions—*i.e.*, annotations and error messages familiar to developers versed in the Unix environment. With regular types, RT allows expressing, propagating, and checking constraints over the values of interprocess communication streams and the commands operating on them. RT targets shell fragments and scripts whose cor-

*Equal contribution.

```
1 find . |                          # Find files                    ε                    →   \.(/.+)?
2 grep -E 'book[0-9]+\.txt' |       # Filter by name               .*                   →   .*book[0-9]+\.txt.*
3 xargs cat |                       # Concat files      [^␣\t]+|".+"|'.+'                →   .*
4 tr -cs A-Za-z '\n' |              # Split words                   .*                   →   [A-Za-z]*
5 tr '[:lower:]' '[:upper:]' |      # Normalize                [A-Za-z]*                →   [A-Z]*

7 sort | uniq -c | sort -rn         # Freq sort                ␣*[-+]?[0-9]+.*          →   ␣*[-+]?[0-9]+.*
```

Fig. 2: Left: A shell program with subtle composition mistakes. Right: Regular types for each line in the left script; the last corresponds to `sort -rn`. These are not the only types that could accurately summarize each invocation's behavior—in general, there may be infinitely many possible types for any given invocation, all of which may be correct (if not precise); see §3.

rectness depends on the line-level structure of streams passed between commands. This focus enables RT to catch bugs such as path-shape and argument-splitting mistakes, incompatible record formats between stages, text field mismatches, filters that eliminate output unintentionally, and malformed streams supplied to dangerous side-effectful commands.

These benefits of regular types come with (deliberately) constrained expressiveness: not all command behaviors are directly representable. With carefully designed extensions that maintain regularity, RT demonstrates that regular types are sufficiently expressive to capture many interesting properties of command behavior. It also reasons about many commands via useful approximations and regular subsets of their domains, including handling commands manipulating data such as CSV or JSONL. RT's regular-type reasoning allows it to identify bugs in computations that directly lead to dangerous side effects, such as pipelines computing path names to delete. By identifying bugs in such input-output manipulations, RT can prevent a wide array of bugs relating to dangerous side-effects without reasoning about those effects directly.

RT's type system (§3) and checking algorithm (§3.3) are extended with polymorphic types (§3.2) aimed at improving precision while maintaining tractability. Additional extensions such as compositional regular-type operators and finite-state transducers further improve expressiveness and accuracy (§4). The RT implementation is parameterized over a database of type declarations for every supported command invocation, akin to a typed standard-library in other languages. RT can optionally be configured to leverage developer annotations, additional heuristics, and environment concretization to improve its results (§5).

Evaluated on hundreds of shell programs, including dozens of real-world bugs collected from GitHub and StackOverflow, RT achieves 91% accuracy (864 out of 954) at classifying programs as correct or buggy. It uncovers 87 bugs ignored by state-of-the-art systems, including newly discovered bugs on production shell programs previously considered correct. RT's extensions offer valuable benefits in several cases—for example, finite-state transducers drop RT's false positive rate from 20% to 4%. And it is fast: RT typechecks 954 programs in 20s, averaging 0.02s per program.

The paper starts by exemplifying the kinds of composition problems often found at the streaming core of the shell and how RT exposes them ahead of time (§2). Sections 3–5 highlight RT's key contributions:

- *Regular types*: A type system targeting stream contents and commands operating on them, along with an efficient type checking algorithm that automatically detects composition errors in shell programs (§3).
- *Compositional regular-type operators*: An extended set of regular-type operations for common input-output transformations implemented efficiently via automata constructions (§4).
- *Extensions and optimizations*: Extensions and optimizations improving RT's precision—including a concretization subsystem for probing the current runtime context, a lightweight annotation language for expressing additional constraints, and heuristics for subtle composition errors (§5).

The paper continues with RT's evaluation (§6), discussion of related work (§7), and conclusion (§8). Appendix A contains examples of RT's optional syntax sugar, and Appendix B summarizes the open-source RT artifact:

https://github.com/atlas-brown/rt

2 Motivating Example

Consider the shell script in Fig. 2, a modern equivalent to McIlroy's classic one-liner [6]. It counts frequencies of correctly spelled words across all book files anywhere within the file tree rooted at the user's current directory. This example illustrates RT's target setting: a shell fragment whose behavior depends on whether each stage receives and emits lines in the shape expected by downstream.

Unfortunately, it does not work right: it produces an error saying that some files do not exist, and nothing on standard out. While ShellCheck—a state-of-the-practice linter [22]—reports no warnings, RT uncovers several issues causing the undesired behavior. Applied to `spell.sh`, its output begins:

```
$ rt spell.sh

  Error (ln. 2):
  > grep -E 'book[0-9]+\.txt' | xargs cat ...
        grep -E > (\.(/.+)?)&(.*book[0-9]+\.txt.*)
  maybe incompatible w/
   xargs cat > [^ \t]+|".+"|'.+'
  Counter-example: "./ book0.txt" ...
```

RT reports that the output of `grep` may be incompatible with `xargs cat`. To make the issue concrete for the developer, RT gives an incompatibility witness: `"./ book0.txt"` is a line that the upstream command may produce and cause the downstream command to misbehave because `xargs` splits the path at the space.

Regular types: RT reasons about composition mistakes by specifying the contents of communication channels with regular types. Regular *stream* types describe the language of the *lines* in the stream—*e.g.*, `find .` outputs paths relative to the current directory, one per line, so its output type is `\.(/.+)?`. Regular *command* types describe the languages of input-output streams—*e.g.*, `find .` :: $\varepsilon \rightarrow$ `\.(/.+)?`.

To reason about Fig. 2's pipeline, RT leverages the corresponding command types listed on the right of Fig. 2. By checking that the output language of every stage is included in the expected input of the following, RT reasons that the output language of `grep` (ln. 2) is not included in the expected input of `xargs cat` (ln. 3):

$$\texttt{.*book[0-9]+\.txt.*} \not\subseteq \texttt{[^␣\t]+|".+"|'.+'}$$

This is because filenames with spaces (*e.g.*, `my book1.txt`) are problematic inputs for `xargs cat`, as they are split into multiple arguments leading them to be misinterpreted as separate files (as in `cat my book1.txt`). The fix: `grep`'s pattern should be stricter to eliminate unexpected paths (`grep -E '^\./book[0-9]+\.txt$'`).

Configurability: Unfortunately, RT cannot reason precisely about the output stream type of `grep -fw dict.txt` without the contents of `dict.txt`. Absent that information, RT can only say that the patterns could be anything, therefore the invocation's output could be any subset of its input type (`[A-Z]*`)—not enough information to determine a problem.

However, RT can perform *environment-specific concretization* by reading the contents of `dict.txt` and computing a highly precise type for the command capturing every word in the file. The intersection of the input type of the `grep -fw dict.txt` invocation (`[A-Z]*`) with the disjunction of every word in the file simplifies to the empty type (*i.e.*, the patterns can never match any input lines), thereby identifying another error.

With that information from RT, the problem and corresponding fix are apparent. The arguments of line 5's `tr` are swapped: it should normalize words to lowercase, not upper. The fixed line 5 is: `tr '[:upper:]' '[:lower:]'`.

Extensions: Fig. 2 omits simple regular types for `sort` and `uniq` on purpose. They pose a problem: what are their appropriate types? Consider `sort`, which only reorders lines, and therefore by the definition of stream types, accepts any type and produces output of the same type. Hence, the most precise input type for `sort` would be whatever `grep -fw dict.txt` produces; similarly for its output.

The trouble with `sort` reveals a general concern, shared by `grep`, `uniq`, and others: the most precise type for a particular use of command depends on its context. To enable succinctly expressing types with this property, RT supports two extensions to regular types: *polymorphic command types* and *domain-specific type transformation operations*. With these extensions, RT's type database can provide equivalent or more precise versions of all of the types in Fig. 2 as well as (for the final program): `[a-z]*` $\rightarrow$ `[a-z]*` for `sort`, and `[a-z]*` $\rightarrow$ `␣*[0-9]+ [a-z]*` for `uniq -c`.

Results: RT identifies all composition mistakes in 0.02s. Once corrected, the program triggers no RT warnings.

3 Core Regular Types

RT summarizes stream contents using regular stream types, and command input/output behavior using regular command types. This section details the nature of these types, and how RT uses them to automatically identify composition mistakes.

A regular stream type is a regular language, written as a regular expression, that describes the set of all possible contents of each line in a stream, mirroring the line-oriented nature of most UNIX commands. The regular stream type is therefore line-oriented: it can precisely capture regular structures such as the formats of `/etc/passwd` entries and IPv6 addresses, and can approximate line-delimited formats such as CSV and text search results. For example, a regular stream type describing the output of `find .` is `\.(/.+)?`, capturing that every line of output is a relative path—*i.e.*, either `.` itself, or `./` followed by any non-empty string.

At its core, RT describes commands by combining two stream types: an input and an output stream type. Intuitively, a regular command type describes a transformation from a language of input to the language of output of the command. For example, the regular command type `.*` $\rightarrow$ `[0-9]+` describes how `wc -l` transforms the input language (anything) to the output language (decimal digits).

3.1 Regular Types and Commands

RT summarizes byte-stream contents using stream types—regular languages defined via extended regular expressions (EREs) [63] (*T* defined in Fig. 3). These include standard ERE features such as concatenation, alternation (`|`), repetition (`*`, `+`, `?`), grouping with parentheses, character classes (e.g., `[A-Z]`,

$$
\begin{array}{rcl}
T & ::= & \textit{literal} \mid \textit{character class} \mid \texttt{.} \mid \texttt{\^{}} \mid \texttt{\$} \\
 & \mid & TT \mid T\texttt{*} \mid T\texttt{+} \mid T\texttt{?} \mid \texttt{(}T\texttt{)} \mid T\texttt{|}T \\
 & \mid & T\texttt{\{}n\texttt{\}} \mid T\texttt{\{}n\texttt{,\}} \mid T\texttt{\{}n\texttt{,}m\texttt{\}} \\
 & \mid & \texttt{!}T \mid T\texttt{\&}T \\
n & \in & \mathbb{N} \\
 & & \\
C & ::= & T \to T
\end{array}
$$

Fig. 3: Base regular types accepted by RT. The grammar is a superset of POSIX ERE, with the addition of negation (`!`) and intersection (`&`). Regular stream types T are closed under regular languages. Command types C pair an input and output stream type.

`[:digit:]`), anchors (`^`, `$`), and bounded quantifiers (e.g., `a{2,5}`).

RT does not support lookaround assertions (see, e.g., [12,40,47]). It also does not support non-regular features such as backreferences (found in PCRE [3]) so that language inclusion remains decidable [20]. To improve expressiveness while retaining regularity, RT adds two operators: intersection (`&`) and negation (`!`). For instance, `[a-z]+ & err.*` matches all lowercase words with an "err" prefix, and `!(abc)` matches any string not matching `abc`. All supported operations are closed under regular languages.

RT defines a regular stream type as *sound* if it accepts all possible stream contents, and *precise* if it accepts only those that can actually occur. For example, if the possible lines in a stream are exactly `foo` and `bar`, then the regular stream type `foo` is unsound because it misses `bar`; `.*` is sound but not precise because it also accepts lines such as `baz`; and `foo|bar` is precise.

Command types: RT summarizes a command's input/output behavior using command types (C defined in Fig. 3), which pair stream types for each stream. A command type is *sound* if its input type is a subset of the command's safe domain—the set of inputs guaranteed not to cause crashes and misbehaviors—and its output type is a superset of the command's possible outputs. A command type is *precise* if for every input type satisfying the input constraints, the output type is exactly the language of possible outputs.

Although many UNIX commands do not correspond directly to regular-type transformations, most can be approximated with sufficient accuracy. For instance, `grep`'s output is the intersection of its input with a search-pattern. In contrast, commands such as `sort` exceed the expressiveness of regular types, but can still be usefully approximated—*e.g.*, by assigning identical input-output types that abstract over line contents, as the set of lines remains unchanged.

Commands such as `tee`, `paste`, or `comm` involve multiple streams; RT assigns each a separate type. RT also instantiates a type to the error streams of commands. For simplicity, this paper discusses commands in terms of a single input and single output stream unless otherwise noted.

$$
\begin{array}{rcl}
C & ::= & \ldots \mid \forall\, \alpha \subseteq T\ .\ \alpha \to T \\
T & ::= & \ldots \mid \alpha
\end{array}
$$

Fig. 4: Polymorphic regular type extensions. Polymorphic regular types have an input type constraint, and an input type variable α that may be used anywhere in the range type. This grammar extends the regular types of Fig. 3.

The type database: RT is parameterized over a database of command type declarations for supported invocations, much like how the type system of a typical programming language requires a manually-crafted base type environment declaring the types of primitive runtime functions. In general, RT's type database could be a literal mapping from invocations to command types, or arbitrary functions that produce a command type given an invocation.

RT strikes a middle-ground, with manually-written configuration files that define (1) how to parse relevant invocations and (2) how to construct a command type given an invocation (useful for example for `grep`, whose output type can be constructed from its argument regular expression). The higher-order command constructor `xargs` is not typed individually: an invocation such as `xargs cat` is handled as a single command. For commands not found in the database, RT defaults to the command type that is trivially correct for all command invocations: `.* → .*`. In total, RT's starting database covers 71/106 GNU coreutils (*Cf.*§6).

RT's type database is available for systems and users to inspect and modify the types of individual commands during development and use. It is integrated into the UNIX environment through the `rti` command. To inspect the type of a specific invocation, a user runs:

```
$ rti wc -l
wc -l :: .*  →  [0-9]+
```

Conversely, to add or update the regular type of a command in the type database, a user—or a system synthesizing regular types—runs:

```
$ rti word-stem :: '[A-Za-z]+' → '[A-Za-z]+'
```

3.2 Polymorphic Regular Types

A finite type database that maps each command invocation to a simple type struggles with commands whose most precise type depends on the input type. For example, `cat` copies its input stream, so its precise output type should be exactly the input type. Enumerating every possible `cat` type is impossible, while using a broad type such as `.* → .*` is sound but not precise. RT overcomes this challenge by introducing *polymorphic* command types. In particular, command types may be parameterized over *type variables*, which stand in for arbitrary regular types and may appear as the input type and anywhere within the output type. Fig. 4 defines the syntax

Algorithm 1: RT type checking algorithm. RT iterates over pipeline stages (commands), checking if the output of each stage is compatible with the following stage's input type. An example application is shown in Fig. 5. The algorithm generalizes naturally to directed acyclic command graphs by processing commands in topological order.

```
1  Function CheckPipeline(c_1|c_2|...|c_n, in):
2      input ← in;
3      for i ← 1 to n do
4          type ← GetTypeAnnotation(c_i);
5          if not CheckInput(type, input) then
6              ReportMismatch(type, input);
7          input ← InstantiateOutput(type, input);
8  Function CheckInput(type, input):
9      if type is simple then
10         return IsSubset(input, type.input);
11     else
           // Polymorphic type annotation
12         return IsSubset(input, type.constraint);
13 Function InstantiateOutput(type, input):
14     if type is simple then
15         return type.output;
16     else
17         return type.output[type.var ↦ input];
```

as an extension of simple command and stream types C and T; as a notational convenience, the input bound type can be omitted (equivalent to a bound of `.*`). The polymorphic type of `cat`, for example, can be written $\forall\alpha\,.\,\alpha \to \alpha$—capturing the fact that the output type of `cat` is the same as its input.

While some commands, such as `cat`, impose no expectations on their input, many commands with polymorphic types do: they are polymorphic over a constrained set of regular types (analogous to bounded polymorphism [11]). For instance, `sort -n` copies its input to its output (abstracting across all lines), but its numeric sorting expects each input line to begin with decimal digits. Polymorphic command types can express constraints over polymorphic variables, such as the following type for `sort -n`: $\forall\alpha \subseteq$ `[␣\t]*[-+]?[0-9]+.*` $\,.\,\alpha \to \alpha$.

Polymorphic command types do not introduce any challenges for type checking. RT reasons about polymorphic command types after instantiating them into simple types, so that type compatibility checks are always over simple stream types. For a fixed command invocation and input type, RT uses the unique most-precise instantiation. For example, when the input type is `[0-9]+`, RT instantiates the polymorphic type of `cat`, $\forall\alpha\,.\,\alpha \to \alpha$, by substituting `[0-9]+` for α, yielding the simple type `[0-9]+` $\to$ `[0-9]+`.

3.3 Type Checking with Regular Types

Alg. 1 outlines the core of RT's type checking algorithm. The algorithm is shown for pipelines, but generalizes naturally to directed acyclic command graphs by processing commands in topological order. At a high level, for pipelines, RT iterates over stages (commands), checking if the output of each stage is compatible with the following stage's input type.

In detail, the main `CheckPipeline` procedure accepts the pipeline of commands $c_1|c_2|...|c_n$ and an input stream type for the pipeline *in*. It iterates over each stage (command), keeping track of the intermediate stream types between each stage in the *input* local variable. The initial value of *input* is *in*, the assumed input to the pipeline; absent any specific information, *in* could be either the type that only accepts the empty string ε—assuming the pipeline receives no input—or `.*`—assuming it could receive any input. The choice between these two assumptions is easily configurable alongside other aspects of RT (*Cf.*§5).

For each stage of the pipeline, the algorithm performs four steps. First, it retrieves the command type for the stage's command invocation (c_i) with `GetTypeAnnotation`. Then, it checks if the current intermediate stream type is a valid input according to the input stream type of the command with `CheckInput`; if not, it calls `ReportMismatch` to report an error (see §3.4). Otherwise, the algorithm computes the next intermediate stream type based on the command type and its input using `InstantiateOutput`, and then proceeds with the rest of the pipeline.

The `CheckInput` and `InstantiateOutput` helpers check type compatibility and compute output types respectively. `CheckInput` consists of two cases: (1) if the command type is not polymorphic, then it checks if the input is a subset of the command type's input stream type, *i.e.*, regular language inclusion; (2) if the command type is polymorphic, then it checks if the input is a subset of the constraint bound on the command type's polymorphic input type. Similarly, `InstantiateOutput` mirrors the same structure with two cases: (1) if the command type is simple, then it returns the literal output stream type of the command; (2) if the command type is polymorphic, then it *instantiates* the output of the command type to obtain a simple stream type. Instantiating the polymorphic type means syntactically substituting the type variable with the actual input type. For example, for a polymorphic command type $\forall\alpha.\alpha \to$ `hi␣`α, and input type `[a-z]+`, the substitution in the output type results in the concrete type `hi␣[a-z]+`.

3.4 Error message generation

If the type checking algorithm detects type incompatibility between a stream and the input type of a command consuming it, it generates error messages to help users understand and fix the composition error. The error message includes

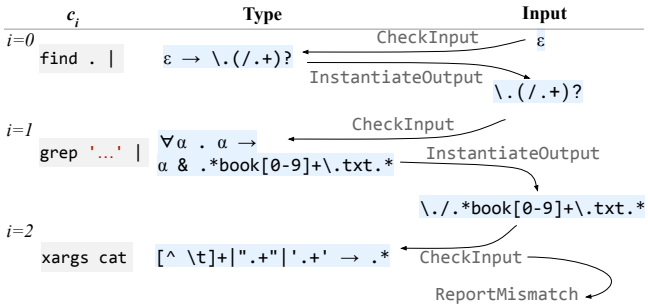

Fig. 5: Type-checking example. Applying Alg. 1 to Fig. 2's pipeline, step by step. Columns (left to right) are the command in the pipeline, the type produced by `GetTypeAnnotation`, and the intermediate stream type assigned to *input* after each iteration. Rows (top to bottom) show iterations 1–3 of the loop in `CheckPipeline`.

a counterexample witness x that demonstrates the type incompatibility, where x belongs to the input type but not to the expected type (for simple annotations) or the constraint type (for polymorphic annotations). Equivalently, RT looks for a string that L_1 accepts and L_2 rejects. By the set-theoretic equivalence $x \in L_1 \wedge x \notin L_2 \leftrightarrow x \in L_1 \backslash L_2$, RT finds such a witness from the automaton for $L_1 \backslash L_2$.

4 Complex Transformations

While simple and polymorphic types suffice to precisely model many commands—and approximate others—some approximated commands perform fine-grained manipulations that are (1) critical for reasoning about program correctness and (2) amenable to precise modeling. To capture such behaviors, RT leverages finite-state transducers to express complex regular-type transformations corresponding to common command semantics.

RT exposes these transformations as new primitive operations that extend regular types beyond standard operations such as union, intersection, and negation. These operations enable precise modeling of commands such as `tr`, `cut`, and `grep -o` whose behaviors are regular but not expressible using standard regular operations alone.

For instance, `grep '[A-Z]'` can be precisely typed using intersection and polymorphism, but `tr A-Z a-z` cannot—its transformation, while regular, lies outside the expressive power of standard operations. Naive approximations using only standard operations can be unsound: modeling `tr -s ' '` as $\forall\alpha.\alpha \to \alpha$ `&!(.*␣␣.*)` underapproximates its output. With input `(␣b␣)*`, this results in `(␣b␣)?`, whereas the actual output is `(␣(b␣)+)?`. Unsound command types can lead to false negatives, since downstream checks then reason about an output type that omits streams the command can actually produce. Imprecise command types can lead to false positives, since downstream checks must also account for streams that the command will never produce.

$$
\begin{array}{rcl}
T & ::= & \ldots \\
 & | & \texttt{reverse}(T) \\
 & | & \texttt{translate-match}(T, T, s, \texttt{global=}b) \\

c & ::= & \textit{literal} \\
N & ::= & n \mid n-n \mid n- \mid N,N \\
n & \in & \mathbb{N}
\end{array}
$$

Fig. 6: The full RT types. The full syntax of regular stream types, extending regular expressions with five new primitive operations (extending Fig. 3 and Fig. 4).

4.1 New Regular-Type Operations

To improve precision while maintaining soundness, RT supports concisely expressing regular types for these kinds of transformations via a novel set of regular-type operations that, alongside standard operations, make up a domain-specific language of regular types. Fig. 6 shows the now-extended language of regular types.

The semantics of each operation is that of a type-level transformation of regular languages. The `reverse(`T_i`)` operator transforms language T_i into the reverse language, as recognized by the reversed DFA. The `translate-match(`T_i`, `T_p`, `s`, global=`b`)` operator transforms input type T_i into a type where all leftmost-longest[1] occurrences of T_p are replaced with s (if b is true, otherwise only the first)—and s may include group references (not to be confused with backreferences in patterns). The `line-extract(`T_i`, `T_p`)` operator transforms T_i into the sublanguage which also matches T_p. The `translate-chars(`T_i`, `C_f`, `C_t`, invert=`b_v`, squeeze=`b_s`)` operator transforms T_i into a type where all characters in C_f are replaced with the same-position character in C_t (where positions beyond the end of C_t translate to the last character of C_t, as in `tr`); if b_v is true, the set of characters to be replaced is the complement of C_f; if b_s is true, the result type also compresses repeated occurrences of each individual character in C_t to a single occurrence. The `field-select(`T_i`, `c`, `N`, invert=`b`)` operator transforms T_i into the type of just fields at indices N (or all other fields, if b is true), separated by c; fields that are absent come out empty in the transformed type.

The `translate-chars` and `field-select` operations are specializations of the more general `translate-match` construct; these specializations correspond to commonly-used commands and admit more precise and efficient modeling than the fully general `translate-match`.

[1] This corresponds to the POSIX disambiguation policy for regular expressions, which differs from the leftmost-greedy policy used by PCRE [41].

Tab. 1: Soundness and precision of operations. Each row describes a regular type operation, whether RT can compute the output type soundly and precisely, and an example command that is described with the operation. The last column describes the type of FST used to compute the output type, which can be a functional non-deterministic FST (FN-FST), a deterministic FST (DFST), or a non-deterministic FST (NFST).

Operation	Instance	*Sound?*	*Precise?*	Example (`Command :: Output Type`, for input type T)	FST Type
`translate-match`	String to string	✓	✓	`sed 's/old/new/' :: translate-match(`T`,old,new)`	FN-FST
	Anch. regex	✓	✓	`sed 's/^a.a*b/new/' :: translate-match(`T`,^a.a*b,new)`	FN-FST
	General case	✓	-	`sed 's/a.*/b/g' :: translate-match(`T`,a.*,b,true)`	NFST
`line-extract`	Cap. string	✓	✓	`grep -o 'pattern' :: line-extract(`T`,pattern)`	FN-FST
	Cap. anch. regex	✓	✓	`rg -o '^a.a*b' :: line-extract(`T`,^a.a*b)`	NFST
	Cap. regex	✓	-	`awk '/a.a*b/' :: line-extract(`T`,a.a*b)`	NFST
`field-select`	General case	✓	✓	`cut -d ' ' -f 2 :: field-select(`T`&(.*␣.*),␣,2)|`T`&[^␣]*`	DFST
`translate-chars`	General case	✓	✓	`tr a-z A-Z :: translate-chars(`T`,a-z,A-Z)`	DFST

To illustrate the operations concretely, Tab. 1 lists example command invocations and corresponding command types demonstrating each operation. For instance, `sed` uses `translate-match`, and `tr` uses `translate-chars`.

The behavior of `cut` has three cases: (1) if the input line lacks the delimiter entirely, it outputs the whole line, (2) if the input line includes the delimiter but fewer fields than those requested, it outputs the empty string for the missing fields, and (3) otherwise it outputs the requested fields separated by the delimiter and in ascending order of index. To capture this complex behavior, `cut`'s type performs field selection according to `field-select`'s stricter semantics for the sublanguage of inputs that contains the delimiter, and then unions with the sublanguage of inputs that do not contain the delimiter.

While some common commands map directly to one operation, others compose multiple. For example, the type of `awk '{print $2}'` in RT's database is:

```
∀α.α →
  field-select(
    translate-chars(
      translate-match(α,"^[␣\t]+", ""),
    "␣,\t", "␣", squeeze=true),
  "␣", 2)
```

4.2 Finite-State Transducers

RT implements the regular type operations shown in Fig. 6 by constructing finite-state transducers (FSTs) and composing them with the input automata representing regular types. An FST is a finite-state machine that not only recognizes input strings but also emits output strings along transitions [48]. This allows RT to define type-level string transformations that preserve regularity: the output of an FST applied to a regular language is itself regular.

Each new regular type operation that RT supports corresponds to its own FST construction. Once constructed, the FST is composed with the input automaton (corresponding to the input stream regular type) to produce a new automaton representing the transformed language (the output regular type). These constructions do not complicate type checking: they essentially contribute one new step to `InstantiateOutput` in Alg. 1, which computes the result of any operations; hence, type checks remain in terms of simple regular languages.

To more concretely understand how RT constructs the FST for a given regular type operation, consider the `translate-chars` operation with `squeeze=true`, which transforms an input type `A` by collapsing consecutive occurrences of characters in the translated-to set into a single instance. At a high level, RT computes the `translate-chars` operation over regular types by constructing the operation's FST for the particular arguments, computing its product with the input language automata, and constructing a resulting NFA. Fig. 7 illustrates this process in detail for the input type `(␣b␣)*`, with space as the character being squeezed. Starting from the DFA of the input (a) and the FST representing the `translate-chars` operation (b), RT computes their product (c) and derives an NFA over the FST's outputs (d), yielding the transformed type.

Different operations require different classes of FSTs depending on their complexity and the structure of their pattern-matching logic. Tab. 1 summarizes the operations supported by RT, including whether their output types are computed soundly and precisely, and the class of FST used. Deterministic FSTs (DFSTs) are transducers with exactly one possible transition per input symbol in each state. They are used for transformations that are positionally local and unambiguous. Functional non-deterministic FSTs (FN-FSTs) allow multiple accepting paths for a given input, but all such paths produce the same output. This enables more expressive transformations while preserving precision. General non-deterministic FSTs (NFSTs) may produce multiple outputs for the same input and are used for the most general forms of pattern-based transformations. These transducers remain sound but may sacrifice precision—the result of computing the corresponding operation may be a larger language than necessary.

Tab. 2: RT heuristics. Each row describes a heuristic that RT uses to identify likely mistakes in command compositions, its description, and an example command composition that triggers the heuristic.

Name	Description	Example
Empty output	Command has empty output type	`cat data.txt | tr a b | grep pattern`
Ignored input	Command that expects no input	`cat data.txt | grep -rHn "word1" $list`
Useless composition	Stage does nothing	`echo "http://www.google.com" | cut -f3`
Lexicographic number sort	Sort numbers with non-numeric `sort`	`cat data.txt | sort | uniq -c | sort -r`

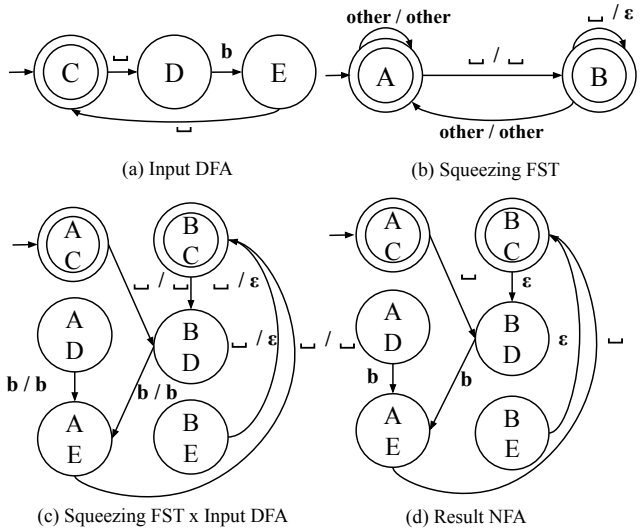

Fig. 7: FST construction example. RT constructs the FST `translate-chars((␣b␣)*, ␣, ␣, squeeze=true)` by constructing the DFA for the regular type `(␣b␣)*` (a) and then taking its product with the `translate-chars` FST (b). Taking the output of each transition of the resulting FST (c) produces the output NFA corresponding to the transformation of the input type (d).

Precision of transformation: Not all operations can be implemented perfectly precisely. Some instantiations of the operations are not regular transformations: consider the invocation `sed -E "s/(.*)/\1\1/"`, corresponding to `translate-match(A, (.*), \1\1)`, which duplicates input strings. The image of input type `.*` under this duplication operation is not a regular language [31]. On the other hand, other instantiations do perform regular transformations, but the transformations do not admit precise modeling. RT supports sound approximations in all such cases, even while supporting precise modeling for simple common cases; Tab. 1 breaks down which cases RT can and cannot support precisely.

RT precisely computes the output type for operations `field-select` and `translate-chars`. They are implemented using deterministic FSTs, which contain no ambiguous transitions. However, `line-extract` and `translate-match` operations are challenging to implement because determining exact match positions often requires nondeterministic guesses. Specific cases of `translate-match`—string matching and anchored patterns—are addressed with special transitions in the FST that recover from failed partial matches, which results in functional non-deterministic FSTs. Similarly, for the precise cases of `line-extract`, such as capturing an anchored regex pattern, RT relies on non-deterministic FSTs. In the general cases of `line-extract` and `translate-match`, however, RT constructs non-deterministic FSTs that over-approximate the actual output type. These non-deterministic structures ensure soundness by covering all possible outputs but sacrifice precision. For instance, RT computes `translate-match("abab", "a.*b", c, global=true)` as `c?c`, an over-approximation of the precise output `c`. If a downstream command expects strictly `c`, this can lead to false positives.

5 Configurability and Concretization

RT optionally performs environment-specific concretization, inferring input types based on the contents of input files at the time of analysis, to provide more precise information (§5.1). Two types of annotations provide a way for developers to describe the specific shape of unknown inputs, or assert expectations about the type of desired outputs (§5.2).

Also configurably, RT can warn about composition mistakes that do not strictly violate any command's input constraints, but rather behave in ways that are almost always undesirable. For instance, a common bug is a pipeline that never produces output due to incorrect command composition. Using regular type information, RT can warn developers about such mistakes ahead-of-time based on a set of heuristics about typical input and output types (§5.3).

5.1 Environment-based Concretization

RT can be configured to leverage information from the environment during analysis to obtain information about actual inputs to reason precisely about program behavior within the local system context. For instance, by analyzing the content of an input file, RT can infer a regular type capturing the current contents, and then use that type to be able to notify developers that a program will certainly be problematic if executed using that particular file. This can help developers stay ahead of typical mistakes that slow down development, such as using `cut` to select fields but forgetting to specify the field delimiter.

RT leverages concretization as part of a secondary specialization pass when type checking programs. After performing normal type checking (*i.e.*, making no assumptions refining the range of possible values) and reporting any general issues with a program, RT then attempts concretization to offer finer-grained information. Specifically, if there are concrete inputs that are accessible at analysis-time on the local machine, including files or environment variables, RT reads the input and uses the entire contents verbatim as the input type in the same way as assumption annotations.

5.2 Type Annotations

Type annotations let developers configure how RT checks command compositions, enabling more precise validation. While some compositions may seem unsafe for arbitrary inputs, they can be valid for specific input formats. For example, using `grep` to filter out `NA` lines before passing data to a command expecting numbers is safe when the input contains only numbers or `NA`. By annotating such expectations, developers help RT suppress irrelevant warnings and provide more accurate feedback.

Annotations also help developers use RT to catch bugs beyond unsafe compositions. For instance, a program's output may need to meet specific correctness properties—*e.g.*, not containing newlines before being sent over the network. With output annotations, developers can encode such expectations, allowing RT to verify them.

Developers can provide annotations using comments in a script's source, such as the following:

```
# @assume "cat $1" --> "[0-9]\t[A-Za-z]"
cat $1 | tr A-Z a-z | cut -f 2 | ...
```

In general, annotations appear as comments that begin with `@` and a keyword identifying the kind of annotation. Corresponding to the different kinds of information developers can offer, there are five distinct kinds of annotations. The first two are assumptions that RT should use while reasoning instead of computing the corresponding information: `assume` assumes the type of an invocation's output, and `input` assumes the type of input to the entire program. The remaining three are assertions that RT checks in addition to confirming input-output type compatibility: `assert` checks that the computed output type of an invocation is a subset of the annotated type, `expect` checks that the input received by an invocation is a subset of the annotated type, and `output` checks that the program's output is a subset of the annotated type.

To help developers write annotations when necessary, RT supports human-friendly definitions for a variety of types that desugar behind the scenes. These definitions capture common patterns such as ip-addresses, numbers in a floating-point decimal format, urls, and more (appendix A lists the full set of definitions RT supports, which is also extendable).

RT incorporates annotations into the type-checking process at different points for each kind of annotation. For assumption annotations, RT simply replaces the corresponding type with the assumed one at the relevant stage of the pipeline. For assertions, RT first computes the actual regular type at the relevant stage, and then checks if that actual type is included in the asserted type—if so, it proceeds with the computed type, and otherwise raises an error reporting the failure.

5.3 Heuristics

RT includes several heuristics identifying compositions that do not strictly violate any command's input constraints, and hence are well-typed, but correspond to likely mistakes. That is, the circumstances identified by the heuristics are not necessarily problematic, but they capture common mistakes and undesirable behavior.

Tab. 2 lists the four heuristics RT considers, each of which describes a criterion for rejecting a program. The first heuristic is command invocations in pipelines that have an empty output type—therefore are guaranteed to have no output. The second is providing input to commands that expect none, such as `echo`. The third is pipeline stages that are guaranteed to have no effect on the pipeline contents. This heuristic applies only to filter-like commands such as `grep`, selector-like commands such as `cut`, and transformer-like commands such as `tr`. The fourth is using the `sort` command in lexicographic mode (without `-n`) on numeric inputs. Critically, the heuristics describe properties of compositions that depend on input and output type information. Hence, the heuristics capture common mistake patterns at a more semantic level than syntactic matching, which is not robust to syntactic variation.

6 Evaluation

We evaluate RT on hundreds of real-world programs, investigating the following questions: **Q1**) What is the effectiveness of RT? and **Q2**) What is the analysis performance of RT?

Overview of Results: RT's overall accuracy across all programs is 91%. Fig. 8 breaks this down into accuracy on buggy programs (72%) and correct ones (96%)—and when programs include extra type annotations to inform RT, its accuracy rises to 94% and 98% respectively. In comparison to state-of-the-art systems, RT is 52% more accurate than LADDERTYPES and ShellCheck on buggy programs. Furthermore, RT provides confidence information indicating whether approximations may lead it to warn about a program, and for programs with definite confidence RT exhibits 100% accuracy (and 86% accuracy for possible-bug reports). RT analyzes every program in the set in under 1s (avg. 0.02s).

Tab. 3: Benchmark summary. Correct (#C) and buggy (#B) columns show the number of programs that are correct or include one or more composition mistakes, respectively.

Set	#C	#B	Description
GitHub	57	57	GitHub bugfix commits
StackOverflow	–	11	StackOverflow
LadderTypes	4	8	Example programs [60]
Koala	478	3	Koala benchmarks [38]
Intercode	188	17	NL synthesis tasks [66]
LLM	–	120	LLM-generated [52]
Handwritten	3	8	Microbenchmarks
Total	730	224	

6.1 Benchmark Suite

We use a comprehensive suite of both correct and buggy programs to answer these research questions. Since no established suite meeting both of these criteria already exists, we have collected and curated a new set of benchmarks.

Tab. 3 summarizes our benchmark suite, consisting of 7 different evaluation sets drawn from a variety of sources. The sets in rows three through five are drawn directly from the literature and community. The first is examples of both buggy and correct programs from Sippel and Schirmeier's pipeline typing system, LadderTypes [60] (*Cf.*§7); second is all scripts in the Koala benchmark suite [38]; and third is the full set of programs from the Intercode evaluation suite for natural-language-to-code-synthesis systems [66]. These three sets come with explicit and implicit labels; some of the LadderTypes programs are provided as buggy examples, and all of the other programs are intended to be correct. However, in the process of collecting these sets, we identified two other bugs in the LadderTypes programs, three in the Koala benchmarks, and 17 in the Intercode suite, and therefore labeled these particular programs buggy.

The remaining benchmark sets focus on buggy programs from four sources: (1) GitHub scripts, extracted from bugfix commits; (2) StackOverflow bugs identified via manual search and inspection; (3) LLM-generated programs, prompted to produce common shell mistakes; (4) Handwritten tests targeting specific composition patterns.

We collected the GitHub programs using a partially automated process. First, we selected the top twenty repositories with shell code on GitHub (according to number of stars) using the GitHub query API. For each such repository, we filtered the history of commits (total 47080) to those which (1) modify a file ending with `.sh|.bash|.zsh` and (2) the modified line contains the pipe character `|`. For every such commit (total 1028), we prompt gpt-4o-mini to identify which commits fix a bug relating to the contents of a pipeline. We manually inspected the resulting 328 commits to check their relevance, discarding commits that do not fix bugs, or for which the bug is unrelated to pipeline contents—ending up with 57 relevant commits. Each such commit provides two programs in our suite: the pre-commit script, which contains a bug (included in the buggy set), and the post-commit script, which fixes the bug (included in the correct set).

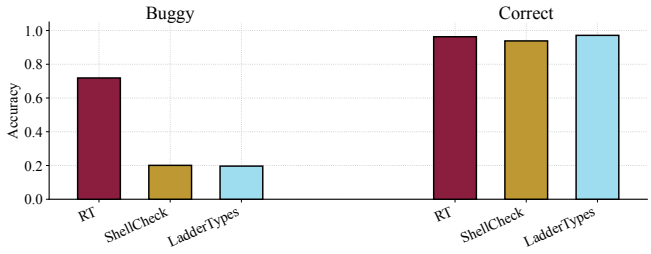

Fig. 8: Accuracy results. The bars depict the accuracy of RT, ShellCheck, and LADDERTYPES on buggy and correct programs.

We collected the StackOverflow scripts manually, using both web search (with phrases such as "shell", "bash", and "pipeline"), and the StackExchange API, filtering for questions containing the keywords "error", "bug", "pipeline", or "unexpected" in the core site and Unix & Linux Stack Exchange sub-domain. We manually reviewed the results and included only buggy programs, as these posts rarely provided corrected versions.

6.2 Q1: Effectiveness

To answer Q1, we calculate RT's accuracy in identifying composition mistakes across all benchmark sets. Accuracy is defined as the proportion of correct categorizations RT makes relative to the whole population; a system that always flags buggy programs and never correct ones is 100% accurate. We evaluate RT configured with its included type database—which covers 71/106 of the GNU coreutil commands and 86% of the command invocations in the GitHub set (*Cf.*§3.1).

Big picture: At a high level, RT has an overall accuracy of 91% (90 false positive/negatives), and identifies 87 bugs that state-of-the-art systems fail to detect. Fig. 8 breaks this down into accuracy on buggy programs (72%) and correct ones (96%)—and for programs with extra type annotations, its accuracy rises to 94% and 98% respectively. Breaking RT's judgments down into definite and possibly-buggy warning levels, RT's definite warnings are 100% accurate, while its possibly-buggy warnings are 86%—the drop in accuracy reflecting the use of approximations and heuristics in its reasoning. In a comparison across RT, ShellCheck, and LADDERTYPES, RT significantly outperforms both baseline systems on buggy programs (by 52 percentage points) while maintaining comparable accuracy on correct programs.

Detailed Analysis: Tab. 4 breaks down RT's accuracy across correct and buggy benchmark subsets, reporting true positives and negatives based on whether RT correctly signals warnings for buggy programs or refrains from warning on correct ones.

Tab. 4: Breakdown of configurations. Each column represents a different configuration of RT. The leftmost is RT with all features enabled, and following columns disable one feature: without heuristics, without FSTs, and without concretization. Rows indicate RT's true result under each configuration on correct and buggy scripts.

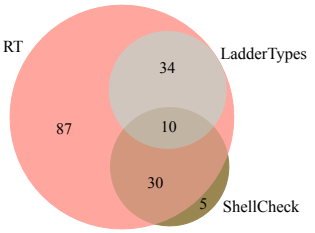
		RT	w/o heus	w/o FSTs	w/o con
w/o Ann.	Correct	703	714	583	702
	Buggy	161	94	176	161
	Acc	91%	85%	80%	90%
w/ Ann.	Correct	716	724	594	708
	Buggy	210	142	200	210
	Acc	97%	91%	83%	96%

The leftmost column reports results for the full configuration of RT. The remaining columns list results for a version of RT with one or more features disabled, thereby quantifying the benefits offered by each feature in isolation or combination. Overall, RT has 91% accuracy in the evaluation suite, with 27 false positives on correct scripts and 63 false negatives on incorrect ones. With annotations, RT has 97% accuracy on the programs, with 14 false positives on correct scripts and 14 false negatives on incorrect ones.

Sources of inaccuracy: To better understand RT's inaccurate results, Tab. 5a breaks down their causes for the maximal configuration without annotations. RT produces 11 false positives due to programs that violate heuristics, but are actually correct (*Cf.*§5.3). RT reports 16 false positives due to over-approximations in type inference. For instance, the file referenced by `${input}` in the pipeline `cat ${input} | sort -n` is unknown ahead of time. Consequently, RT conservatively infers the output of `cat` as `.*`, which is sound but imprecise. RT produces 14 false negatives for programs that are well-typed, but whose behavior is incorrect according to the program's original source (*i.e.*, the bug is not of a nature that RT could detect). RT produces 49 false negatives due to the absence of expected output specifications. Without user-provided assertion annotations to define the required format, the programs are well-typed.

Tab. 5b shows the false results for the full configuration of RT evaluated on the benchmark set with annotations. RT eliminates all false negatives caused by the absence of expected output specifications with annotations. However, RT still produces 6 false positives related to over-approximations. These are invocations that RT models soundly but imprecisely due to inherent complexity of the commands—such as complex uses of `awk` and `sed`. Properly supporting all possible invocations of these commands demands a specialized language analysis (in the case of `awk`); `sed` invocations with complex capture groups, however, pose fundamental challenges (§4.2).

Comparison with state-of-the-art systems: We compare RT's accuracy to that of LADDERTYPES and ShellCheck. Like RT, LADDERTYPES classifies programs as buggy or correct. However, LADDERTYPES by default comes with a smaller set of type declarations than RT. To enable fair comparison we manually add reasonable versions of all RT's simple type declarations and a fallback type declaration mirroring RT's. ShellCheck differs from RT and LADDERTYPES in that it emits a wide range of warnings—many irrelevant. To bring it into parity for comparison, we consider a program buggy under ShellCheck if it produces any warning related to pipelines or output stream contents,[2] and correct otherwise.



The Euler diagram on the right compares the effectiveness of these systems, showing the number of buggy programs each identifies. Overlaps indicate agreement across systems. RT is evaluated without annotations, as neither ShellCheck nor LADDERTYPES benefits from developer-supplied information. RT uniquely detects 87 bugs, compared to 5 unique to ShellCheck and 0 to LADDERTYPES. Notably, 58 bugs remain undetected by all three systems in the absence of type annotations.

Digging into the nature of the buggy programs that ShellCheck identifies but RT does not reveals that all are generic warnings that are not relevant for the particular bug at hand. While the error code ShellCheck issues is potentially relevant for composition mistakes, and hence conservatively counted in the evaluation metrics, manual inspection reveals that in every case, the bug is unrelated to ShellCheck's warning. For example, in several of the cases ShellCheck warns about irrelevant quoting in an unrelated pipeline stage.

6.3 Q2: Analysis Performance

Experimental setup: All evaluations were performed on a single machine running Ubuntu 20.04, equipped with an AMD Ryzen 7 4800H processor (2.9 GHz, 8-core) and 16 GB of RAM, using OpenJDK 17.0.2, Python 3.10, and the automaton package dk.brics.automaton (version 1.12-4).

Results: RT analyzes each program in 0.020s on average (0.009–0.903s), which is comparable to ShellCheck's 0.018s average (0.010–0.038s). In contrast, LADDERTYPES averages 3.081s per program (0.234–14.861s), roughly two orders of magnitude slower than RT; this is primarily due to an inefficient type lookup using an external shell script to search for command invocations in its type database.

[2] Ignored (irrelevant) warnings: SC2012,SC2046,SC2086,SC2018,SC2019, SC2002,SC2006,SC2009,SC2035,SC2060,SC2061,SC2062,SC2063,SC2126, SC2154,SC2185,SC2196,SC2225.

Tab. 5: Breakdown of false results. The tables break down the false results for the full configuration of RT evaluated on the benchmark set with and without annotations.

(a) Without annotations

Category	Group	#	Description	Example
False Positive	Bad heuristics	11	Correct scripts flagged by heuristic	`du -ah /workspace | sort -rh`
	Over-approximation	16	Imprecise command type	`cat ${input} | sort -n`
False Negative	Unexpressible semantics	14	Well-typed, but *e.g.*, unsorted	`... | sort | cut -d',' -f10 | uniq`
	Wrong output format	49	Expected output format is not provided	`echo "$INDEX" | grep '^ D '`

(b) With annotations

Category	Group	#	Description	Example
False Positive	Bad heuristics	8	Correct scripts flagged by heuristic	`du -ah /workspace | sort -rh`
	Over-approximation	6	Imprecise command type	`... | sed -E 's/(.*)/\1\1/'`
False Negative	Unexpressible semantics	14	Well-typed, but *e.g.*, unsorted	`... | sort | cut -d',' -f10 | uniq`

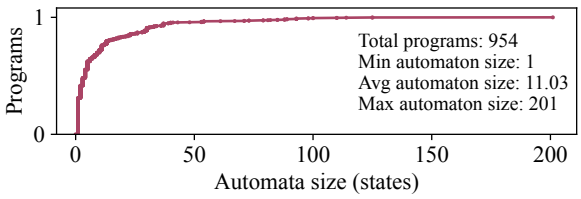


Fig. 9: Automata size across evaluated programs. The CDF plot shows the fraction of evaluated programs where the largest automaton representing a type has at most the number of states on the x-axis. The average automaton size across all programs is 11.03 states, minimum is 1, and maximum is 201.

RT's overall performance is dependent on the complexity of the types it reasons about, one proxy for which is the size of minimal automata representing the types. Fig. 9 shows the cumulative distribution of automata sizes RT constructs for the types in the evaluation suite, where each recorded automaton size corresponds to the largest DFA within a given program. Most programs contain minimal DFAs with fewer than 10 states. However, several programs include large DFAs; this occurs primarily when input or variable annotations involve lengthy regular expressions, resulting in complex DFAs even without additional transformation. Indeed, all but one of the programs taking more than 0.2s to analyze are annotated with relatively complex, large input types. The longest time is for a 5-stage pipeline at 0.90s, which has an input annotation requiring a minimal DFA with 105 states.

7 Related Work

Static analyses for the shell: Other kinds of static analyses have been proposed for the shell. ABash [44] analyzes scripts for expansion and word-splitting-related bugs, with a particular emphasis on code-injection style vulnerabilities. The CoLiS shell [34] includes a static analyzer that identifies dangerous or undesirable filesystem actions. Prior work [56] statically infers filesystem pre-conditions for file manipulation scripts. These analyses target different kinds of bugs and script behaviors than RT.

Semantic models of the shell: Semantic models of the shell provide critical underpinnings for understanding and reasoning about the semantics of shell scripts ahead of execution. Smoosh [26] defines the first mechanized formal semantics for the POSIX shell. The CoLiS language includes a formally verified interpreter [35], thereby defining the semantics of the (similar, but not POSIX shell) language. Such models inform how static analyses like RT should reason about shell programs, but are not analyses themselves.

Regular expressions for stream processing: Prior works [4, 42] have considered the use of unambiguous regular expressions to describe the hierarchical decomposition of streams into finite windows for computing quantitative queries. The restriction of unambiguity is imposed to ensure that streaming queries have a uniquely determined output. In these works, regular expressions are not used to express correctness properties or data invariants for streams.

Types for POSIX shell pipelines: LadderTypes [60] models pipeline contents using types familiar from statically typed programming languages (*e.g.*, `Int` or `Sequence[Byte]`), encoding hierarchies of types (dubbed ladders) connected by a "represented as" relationship. Hence, it is a fundamentally different type system design, with a stricter notion of compatibility: two ladder types are compatible only if the full interpretation of a downstream consumer is included in the representation of the upstream producer's output.

Regular languages for static string reasoning: Regular languages provide a well-known formalism for statically

reasoning about string-like values and their formats. Prior works [7,32] extend XML-oriented type systems with Kleene-algebraic operators. Boomerang uses regular languages to refine the basic `string` type into precise format types [9]. Prior work also uses automata or regular-language abstractions to analyze string expressions in Java [14], jQuery [53] and dynamic languages [5]. String solvers and decision procedures further reason about path feasibility for programs with rich string operations [13]. Prior work [56] also uses an automata-based representation of file paths, and leverages FSTs to manipulate them. RT differs from these analyses in (1) domain—POSIX shell streams—and (2) defining regular languages as the primitive type of its type system.

Shell replacements: Both the literature and open-source community abound with shell-like scripting languages. These include traditional-looking shells with features drawn from typical general-purpose languages [15, 19]; libraries and embeddings in general purpose languages which maintain the essential design of byte-level communication streams [1, 8, 16, 21, 23, 25, 27, 57, 65]; languages that introduce higher level structure in at least some process communication [2, 29, 46, 58]; languages that also feature a type system that can catch some composition mistakes [30, 43, 59]; and languages that offer security monitoring in shell programming [49]. Unlike this direction of work, RT is a static analysis tool for the POSIX shell rather than a new language.

Linters for the shell and shell-wrapping systems: Several shell linting tools have been developed to analyze shell scripts. Checkbashisms [10] mainly focuses on identifying the usage of shell syntax that is exclusive to the bash shell environment. PSScriptAnalyzer [45] specializes in detecting common syntax issues and code smells in PowerShell scripts, while ShellCheck [22] does a similar job for various popular shells such as Bash and zsh. SecureCode [17] extracts shell code embedded in DevOps orchestration frameworks like Ansible in order to analyze them with ShellCheck. DRIVE [67] similarly extracts shell code from Dockerfiles and applies rule-based patterns to identify code-smells and possible bugs. These tools rely on syntax-based pattern matching, which limits their analysis to syntactic issues. In contrast, RT models stream contents, enabling semantic analysis beyond predefined syntactic rules.

Automated program repair for the shell: NoFAQ is a rule-based command-repair tool [18]. It matches the given command and error message with bugfix examples in a database and suggests the corresponding fixes. RT does not aim to suggest fixes, and identifies bugs semantically rather than with rules/patterns over syntax or error messages.

8 Conclusion

RT demonstrates that regular types provide an effective and efficient basis for statically detecting input-output composition mistakes in the UNIX shell. Regular types capture significant structure in stream contents while remaining faithful to the byte-oriented nature of shell communication, leverage the rich literature around regular languages and automata, and lean into the familiarity of regular expressions that are already ubiquitous in UNIX environments.

Availability

RT's implementation, alongside all benchmarks in this paper, is available as MIT-licensed open-source software:

B Artifact Appendix

Abstract

The artifact for RT packages the prototype checker, command specifications, documentation, tests, benchmark inputs, and reproduction scripts used for the evaluation in §6. It is organized to support three tasks: inspecting how the implementation realizes the regular-type analysis described in the paper, running functional checks for the core analyzer, and regenerating the principal evaluation artifacts, including the accuracy summaries, ablation and false-result breakdowns, bug-detection comparison, timing table, and automata-size plots.

Scope

The artifact supports the paper's design and evaluation claims. In particular, it covers: (1) the RT implementation of regular stream and command types from §3, the type-checking procedure in §3.3, and the regular-language operators and FST machinery from §4; (2) the configurable mechanisms in §5, including environment concretization, annotations, and heuristics; (3) the motivating example and the seven benchmark sets discussed in §2 and §6; and (4) the automation for reproducing the main tables and figures reported in §6.

Contents

The artifact includes the following components:

- the RT checker implementation and command type database;
- support code for regular-language operations, finite-state transducers, annotations, concretization, and heuristics;
- documentation, including the top-level README and artifact-evaluation instructions;
- functional tests and smoke-test examples, including the motivating example from §2;
- the benchmark suites used in the paper's evaluation and the configuration needed to run baseline comparisons against ShellCheck and LADDERTYPES; and
- scripts for checking the artifact, reproducing the full evaluation, and generating the resulting tables and plots.

Hosting

The artifact is publicly available as a GitHub repository at `https://github.com/atlas-brown/rt`.
