A similar argument can prove the Pareto inefficiency of the (much less natural) class of Chip-Hour mechanisms that instead prioritize agents who have spent more of their credits. In this case, facing the same instance as above, agent 1 would report their true demand, but agent 2 would prefer to lie by requesting the units in the first round (although he has no value for them). This way, he would be allocated one of them (by symmetry) and he would ensure that he is also allocated one unit in the second round (by symmetry). However, this is clearly not Pareto efficient since one of the first-round units that agent 1 has positive value for is allocated to agent 2 who has no value for it.

Finally, we conclude with the class of Chip-Hour mechanisms that would split the second round units equally among the agents irrespective of what happened in the previous round (i.e., they are independent of how many credits each agent has left). For these mechanisms, we consider the same instance that we used for the truthful reporting case above. In this case, no agent has any incentive to misreport (since the mechanism essentially disregards history), so the Pareto inefficient outcome that arises is the same as the one in the truthful case. □

Theorem 3 (Pareto Efficiency)**.** *The market mechanism achieves Pareto efficiency for general heterogeneous valuations, irrespective of how much the prices may vary.*

Proof. Given some instance, let p be the market clearing prices computed by the market mechanism and x be the corresponding allocation that it yields. Assume that the allocation x returned by the market mechanism is Pareto dominated by some other allocation x', i.e., there exists some agent i who strictly prefers their allocation in x' over the one in x. This must mean that the total price, according to p, of the units that i is allocated in x' must be greater than the units allocated to i in x, i.e., $\sum_{t\in[T]} x'_t[i]p_t > \sum_{t\in[T]} x_t[i]p_t$, otherwise i could just buy them and strictly increase their value (this is due to the common assumption that i spends their budget optimally given the price vector p). Also, since x' Pareto dominates x, it must be the case that every other agent $j \neq i$ is at least as happy in x'. Similarly, this implies that $\sum_{t\in[T]} x'_t[j]p_t \geq \sum_{t\in[T]} x_t[j]p_t$, otherwise j must be spending their budget sub-optimally in x; specifically, they could instead buy their x' units by spending less than their budget and then spend the remaining budget on some additional units and strictly increase their value. This uses the common assumption that no agent receives everything that they have positive value for, so there are always additional (fractions of) units that they can buy. Summing the aforementioned inequalities over all agents k (both i and $j \neq i$), we get

$$\sum_{k\in N}\sum_{t\in[T]} x'_t[k]p_t > \sum_{k\in N}\sum_{t\in[T]} x_t[k]p_t$$
$$\sum_{t\in[T]}\sum_{k\in N} x'_t[k]p_t > \sum_{t\in[T]}\sum_{k\in N} x_t[k]p_t$$
$$\sum_{t\in[T]} s\cdot p_t > \sum_{t\in[T]} s\cdot p_t,$$

which is a contradiction. This result can also be seen as an implication of the First Welfare Theorem. □

Theorem 4 (Fairness)**.** *Let $\tilde{p}$ be the average price of a resource over time. If the average price paid by some agent i is at most $f_i \cdot \tilde{p}$, then the resulting allocation is* $\min_{i\in N} \frac{1}{f_i}$*-fair, even for general heterogeneous valuations.*

Proof. Since each agent i is allotted a budget of $T \cdot w_i$ credits, the total number of allotted credits is $T \cdot s$. Also, the total number of units allocated per round is s, so $T \cdot s$ units allocated overall. Therefore, the average price per unit is $\tilde{p} = 1$, and the average price paid by any agent i is at most f_i. Also, since agent i has a total budget of $w_i \cdot T$, this means that the number of units that they were able to buy using this budget is at least $\frac{w_i T}{f_i}$ overall, which is a $\frac{w_i}{s\cdot f_i}$ fraction of all available units. This implies that every agent receives at least a $\min_{i\in N} \frac{1}{f_i} \cdot \frac{w_i}{\sum_{i\in N} w_i}$ fraction of the $T \cdot s$ available units, so the resulting allocation is $\min_{i\in N} \frac{1}{f_i}$ -fair. □

B Gaming Strategies

Gaming: Currency Conversion. When designing QM, we made the conscious decision of letting each business unit mint their own currency. All the business-unit-local credits get converted to a global currency when the market clears. The local-to-global currency exchange rate is a function of both the number of credits minted by that business unit, and the market weight assigned to that business unit by the company. This freedom to mint credits has ergonomic benefits: for example, credits minted per hour, can be maintained in proportion to the number of engineers in the team. However, this freedom also comes with an ability to game the system. Consider a scenario where a team mints a lot of credits per hour for a while, accumulates a substantial number of credits in its savings, and then dramatically reduces the rate at which it mints credits per hour. The newly minted credits are worth much more because the currency's value had significantly risen. But if the system were to value the accumulated old credits also at the same level as the new credits, the team would have successfully managed to mint credits out of thin air. If we value these credits differently, we introduce complexity.

An inelegant solution for this problem is to declare that each credit comes with the exchange rate at which it was minted, and therefore different credits are worth differently to a team. This creates too much complexity and the meaning of a credit is lost when different credits are worth differently. Another solution with jarring optics is to say that the bank accounts of teams will get depleted by a certain amount (that depends on how much the business unit decided to raise its currency's value), thereby maintaining the same value for all the credits, old and new. But a team's credits vanishing for no choice of theirs (income rate decisions are made by the head of the business unit) is a recipe for many escalations and confusions. Designing good mechanisms that balance simplicity+usability with robustness to manipulations is a useful problem to solve. We consider this as a UX problem and indeed as [21] notes, the interface has the biggest influence on user perception.

Gaming: Adversarially Depleting Other Teams' Credits. Teams bid for demanded resources, but are only charged credits for jobs that run. A bad actor could launch a job which is unlikely to schedule and is set to immediately fail if it does. For example, this job may require all the resources of a specific type in a specific location to start. The bad actor is thus able to inflate prices for all other market participants without paying any credits to do so.

One approach to disincentivize this behavior is to charge for resource allocations, not usage. However, potentially conflicting scheduling outcomes later in the stack can lead to significant charges for teams that did not get to run their workloads. This becomes less probable as the market becomes more deeply integrated with the scheduler.

Another approach is to use the Vickrey-Clarke-Groves (VCG) mechanism. This would enable the system to price each workload's resources based on the externality it imposes. In other words, each workload's cost would be the difference between the value of the other workloads that would have run in this workload's absence and the value of the other workloads that ran in this workload's presence. A small job which has no measurable effect on the system would be more or less free. A large or hard-to-schedule job, like the one described above, would not be directly displaced by any single workload, so it would not affect their prices. But VCG has its own complications, like having to price each workload differently, as opposed to uniformly pricing every workload that ran at any given point of time at a given location or cell. I.e., VCG's pricing is complicated for users to understand, as opposed to the simple price-per-cell concept that the market guarantees.

Abstract

We present Bodega, the first consensus protocol that serves linearizable reads locally from any desired node, regardless of interfering writes. Bodega attains this capability via a new notion of cluster metadata called the *roster*, which is a generalization of leadership; it tracks arbitrary subsets of replicas as *responder* nodes for local reads. A consistent agreement on the roster is established through *roster leases*, an all-to-all leasing mechanism that generalizes existing all-to-one leasing approaches (Leader Leases, Quorum Leases), unlocking a new point in the protocol design space. Bodega further employs *optimistic holding* and *early accept notifications* optimizations to minimize interruption from interfering writes, and *smart roster coverage* and *lightweight heartbeats* to maximize practicality. Bodega is a non-intrusive extension to classic consensus; it imposes no special requirements on writes other than a responder-covering quorum.

We implement Bodega and related works in Summerset, a protocol-generic replicated key-value store written in async Rust. We compare it to previous protocols (Leader Leases, EPaxos, PQR, and Quorum Leases) and two production coordination services (etcd and ZooKeeper). Bodega speeds up average client read requests by 5.6x~13.1x on real WAN clusters versus previous approaches under moderate write interference, and closely matches the performance of sequentially-consistent etcd and ZooKeeper deployments across YCSB workloads. Bodega supports fast proactive roster changes and delivers on-par write performance. Our Summerset codebase is open-sourced at https://github.com/josehu07/summerset/tree/bodega-artifact.

1 Introduction

Paxos-based consensus [60, 61, 65] (and protocols alike [85, 87]) serves as a critical foundation for modern distributed systems infrastructure. Originally used in limited contexts, e.g., for bespoke configuration information as in Petal [67], for critical metadata stores such as etcd [35, 97] and FireScroll [36, 95], and for lock services such as Chubby [21], consensus now forms the foundation of widely used cloud-native databases such as Spanner [30], CockroachDB [107], TiDB [50], ScyllaDB [100], and Physalia [19].

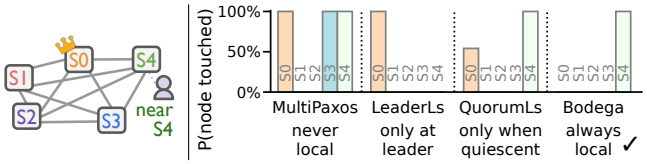

Figure 1. Frequency of touching a node on the critical path of reads *by a client near S4, in a cluster where S0 is the leader, with infrequent writes. Ideal outcome is 100% at S4.*

In these systems, simple access semantics are critical, enabling scalable services to be readily built atop them [4, 15]. In particular, *linearizability* is a strong consistency level they strive to provide: for interrelated requests, clients observe a real-time serial ordering, as if talking to a single node [47, 49].

Local Linearizable Reads. Delivering high performance in linearizable systems remains a daunting challenge. In the cloud era, systems replicate critical data across multiple geographically-distinct availability zones [7, 28, 79], to guard against correlated failures caused by power outage, fire, natural disaster, or operator error [22, 24, 43, 108]. By spreading replicas globally, robustness is achieved, but at the cost of performance due to quorum round trips [66].

The physical distribution of replicas yields an opportunity to serve read requests locally from a client's nearest replica. Reads comprise a majority of the workloads [8, 29, 88, 91]; achieving local reads can greatly reduce read latency and drastically increase overall throughput.

Existing Solutions Fall Short. Existing consensus protocols have demonstrated effective wide-area optimizations, but none, to our knowledge, supports coherently fast linearizable reads for workloads containing even small amounts of interfering writes. Leaderless protocols [27, 56, 62, 76, 80, 98] allow near quorums but not local reads. Others explore flexible quorums [42, 46, 48, 64, 106], utilize special hardware or client validation [5, 32, 40, 69, 93, 101, 112], or exploit API semantics favoring writes [37–39, 74, 86, 90, 96, 114]. Read leases (covered later) [10, 18, 25, 26, 41, 81, 82] are so far the most compelling, but are only effective at the leader or during quiescent periods without interfering writes.

*Work was done when at UW–Madison.

Self-Containment Necessitates Leases. A primary challenge of designing consensus protocols is self-containment: they cannot assume an external oracle. To enable local linearizable reads, the protocol must judge whether replica-local data is the most recent; contacting an external service to obtain this information would defeat the initial purpose. Moreover, having external dependencies would reduce the system's fault tolerance guarantees to those of the external services [57, 95, 107].

Within the design space of self-contained protocols, *leases* are a vital and powerful primitive. They carry timed promises that naturally tolerate faults through expiration [41], while only requiring bounded clock drifts (typical in today's cloud environments [40, 53, 68, 77]). This opens the gateway to local linearizable read protocols.

Leases Were Not Fully Exploited. Existing lease-infused protocols, however, do not employ the most suitable types of promises for local reads, and thus cannot fully realize their potential. As a motivating example, Figure 1 shows a 5-site cluster where S0 is the leader (and S4 is a local-read-enabled replica, if eligible), and reports the frequency of servers being touched by read requests from a client near S4. The workload contains 99% reads and only 1% writes, which favors existing approaches. Classic consensus (MultiPaxos) requires a majority accept quorum around S0. Leader Leases only protect stable leadership, so S0 can reply to reads directly, yet the delay between client and S0 persists. Quorum Leases allow granting leases to followers but use leases to guard against individual writes, rendering them vulnerable to even small amounts of concurrent writes to the key. As a result, a significant portion are redirected to the leader S0.

Our Approach: Roster Leases. We introduce the notion of a *roster*: a generalized form of cluster metadata that dictates not only leadership but also an assignment of local-read-enabled replicas (called *responders*) for arbitrary keys. Accordingly, we introduce *roster leases*, a novel all-to-all generalization of leader leases, deployed off the critical path to protect the agreement on the roster with no observable overhead. Roster leases stay valid in the absence of failures or proactive changes.

We present Bodega, a consensus protocol that uses roster leases to empower local linearizable reads. Bodega assures that writes never commit before reaching all of the key's active responders. A responder that holds a majority of leases can thus serve reads directly from its local state, if it knows the latest value will commit. When unsure, the responder *optimistically holds* the read locally until enough information is gathered, optionally utilizing *early accept notifications* to accelerate the hold. The roster may be changed manually by users, automatically according to runtime statistics, or in reaction to failures.

Our evaluation shows that Bodega speeds up client read requests by 5.6x~13.1x versus previous approaches under slight write interference, delivers comparable write performance, supports proactive roster changes in two message rounds as well as self-contained fault tolerance via leases, and matches the performance of sequentially-consistent etcd [35] and ZooKeeper [52] deployments across all YCSB variants.

Summary of Contributions. ❶ We introduce the notion of roster and propose Bodega, a consensus protocol equipped with a novel all-to-all roster leases algorithm, enabling local linearizable reads from any node at any time. ❷ We provide a thorough qualitative comparison across wide-area linearizable read approaches. ❸ We implement Bodega and related protocols in Summerset, a protocol-generic replicated key-value store, with 25.6k lines of async Rust. ❹ We evaluate Bodega comprehensively against previous works and two production coordination services, etcd and ZooKeeper, on 5-site wide-area clusters, delivering aforementioned evaluation results. ❺ We provide a formal TLA$^+$ specification of the full algorithm in the appendix.

The rest of the paper is organized as follows: §2 provides background and discusses existing solutions; §3 presents the Bodega design; §4 gives a formal comparison and proof; §5 covers the implementation of Bodega in Summerset; §6 presents our evaluation; §7-8 add discussions and related work; §9 concludes.

2 Background and Motivation

We provide background on consensus and linearizable reads, discuss existing solutions, and derive our goals for Bodega.

2.1 Consensus & Linearizable Reads

We consider the typical consensus problem of reaching agreement across message-passing server nodes, where nodes can be fail-slow/stop and the network is asynchronous [60].

Following well-established practice, nodes agree upon an ordered *log* of commands to behave as a replicated state machine (RSM) [61, 99]. For clarity, we use key-value `Put`/`Get` commands. In practice, `Get`s map to read-only requests that only query but do not update state (hereby referred to as *reads*), and `Put`s map to all other requests (*writes*). We restrict our discussion to non-transactional commands [17]; these are out of the scope of this paper.

Linearizable Reads. The consistency level dictates what results are allowed to be observed by clients [49]. *Linearizability* is the strongest non-transactional consistency level, where clients expect a serial ordering of commands with the real-time property: a command on key k issued at physical time t must be ordered after all the interfering writes on k acknowledged before t, and observe its latest value [6, 47, 80]. This semantic is mandatory for critical use cases such as metadata storage and coordination [19, 21, 35, 36], and is generally desirable as clients would otherwise get stale reads from the past (*sequential consistency*) [6, 59] or weaker guarantees [102, 109], complicating development. Linearizable reads are the primary focus of this paper.

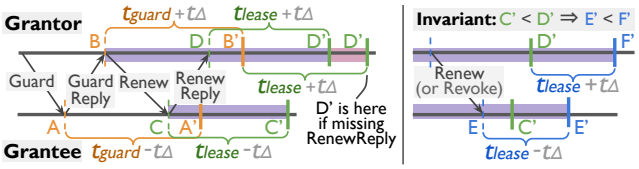

Figure 2. Demonstration of standard leasing. *Left: the guard phase helps establish the first iteration of promise coverage safely; grantee welcomes the first* `Renew` *only if it is received within the guarded period (C < A'). This allows the grantor to derive a safe expiration D' = B'+t_{lease}+t_Δ even if the* `RenewReply` *is lost, such that C' < D'. Right: grantor attempts to extend the promise with a* `Renew` *(or to actively revoke it with a* `Revoke`*), but has not received the grantee's reply. The leasing logic assures that E' < F'; therefore, if the grantee indeed failed, after F' the grantor can safely assert lease expiration. The purple-colored ranges depict when the lease is considered granted/held by the corresponding party.*

Availability Requirements. A practical protocol must also offer *availability* for fault tolerance, allowing client requests to proceed under any minority number of node/network faults, and retaining consistency in all circumstances [49, 61].

2.2 Distributed Lease

Leases are a common distributed system technique [41]. They may be deployed as user-facing APIs through locks [21] and TTL-tagged objects [35], or as protocol-internal optimizations; we focus on the latter.

A lease is, conceptually, a directional limited-time *promise* that a *grantor* node makes to a *grantee*. It relies on bounded clock speed drift between the two ends, that is, over a given physical expiration time t_{lease} elapsed, the two nodes' clocks do not deviate more than a small t_Δ (no clock drift). This is typically true in today's distributed system environments [40, 53, 68, 77]; note that it does not assume synchronized clock timestamps [10, 30, 70] (no clock skew).

Standard One-to-One Leasing. The procedure of activating one lease between two nodes consists of an initial *guard* phase and repeated *renew* phases, depicted in Figure 2. The guard phase (left half) helps establish the first iteration in the presence of clock skew assuming bounded clock drift, and the renew phases (right half) keep it refreshed periodically [41, 81, 82]. Grantor starts to consider the lease granted when the first `Renew` is sent out (not when the `Guard` is sent), and grantee starts to consider the lease held when the first `Renew` is received (not when the `Guard` is received), using carefully designed timer durations as shown in Figure 2. The goal is to maintain this invariant: the grantor-side expiration time is *never earlier than* the grantee-side. A lease is considered held by the grantee when its clock has not surpassed $t_{\text{lease}}-t_\Delta$ after the last renewal received. The grantor can proactively deactivate the lease with a `Revoke` or, in the case of unresponsiveness, wait for $t_{\text{lease}}+t_\Delta$ without granting to let it safely expire.

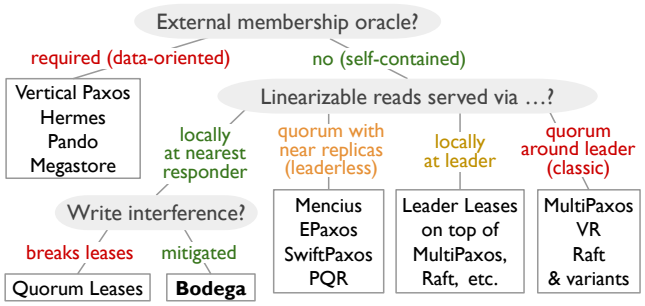

Figure 3. Categorization chart of relevant protocols. *Ideal properties for local reads are marked in green. See §2.3.*

2.3 Previous Work on Read Optimizations

Figure 3 presents a coarse-grained categorization of previous approaches to linearizable reads. The following sections discuss them in the general order from right to left.

2.3.1 Classic Protocols & Leader Leases

Protocols such as **MultiPaxos** [61], **VR** [85], and **Raft** [87] are the de-facto standards implemented in the wild [30, 35, 50, 103, 107]. While stale read options exist [25, 86], normal reads are treated obliviously just like other commands.

With MultiPaxos terminology, a typical protocol is as follows. A node S first makes a "covering-all" `Prepare` phase to settle a unique, higher *ballot* number for all non-committed *instances* (i.e., *slots*) in the log, effectively stepping up as a leader. Without competing leaders, S takes a client command, assigns the next vacant log slot, broadcasts `Accept` messages, and waits for $\geqslant m = \lceil \frac{n}{2} \rceil$ `AcceptReplys` with matching ballot including self (where n is an odd cluster size), after which the slot is marked committed and `Commit` notifications are broadcast asynchronously as announcement. S executes the commands in contiguously-committed slots in order and replies to their clients.

Leader Leases [25] are a commonly deployed optimization to establish *stable leadership*. All nodes grant lease to the most recent leader they are aware of (including self) after invalidating any old lease given out. If a leader S is holding $\geqslant m$ leases, it can safely assert that it is the only such leader in the cluster, i.e., the stable leader. Therefore, S (and only S) can reply to read requests locally using the latest committed value, knowing that no newer values could have committed.

2.3.2 Leaderless or Multi-Leader Approaches

Leaderless (or multi-leader) protocols distribute the responsibilities of a leader onto all nodes, improving scalability and latency under wide-area settings by allowing a fast-path quorum nearer to the clients. However, they are sensitive to command interference and often make local reads infeasible without degrading back to a leader-based protocol.

Mencius [76] assigns the leader role Round-Robin across nodes based on slot index. This mainly benefits scalability.

EPaxos [80, 104] absorbs the idea of inter-command dependencies from **Generalized Paxos** [62] and lets any node to act as the *command leader* for nearby clients. Nodes attach to each command its dependency set; without concurrent conflicting proposals, consensus can be reached on the fast path of `PreAccepts` by a (super-)majority quorum. Conflicts in dependencies require a second phase to resolve. Local reads are inherently hard to achieve in such a protocol without degrading to a leader-based protocol on keys of interest [104].

SwiftPaxos [98] improves EPaxos slow path to 1.5 RTTs (vs. 2) by re-introducing a leader in the slow phase.

PQR [27, 42] applies EPaxos-like leaderless optimization to only reads and not writes. Clients broadcast read requests directly to the nearest majority of servers. If all replies contain the same latest-seen value, all in committed status, then this value must be a valid linearizable read result. Otherwise, the client starts a *rinse* phase where it repeatedly polls arbitrary servers for commit confirmation of the value.

WPaxos [1] is a multi-leader design that partitions the key space and assigns a different leader per partition, improving locality of regional hot keys. However, it expects workload concentration and does not offer local reads at multiple replicas. Its adaptive partitioning approach can be applied orthogonally to consensus protocols including Bodega.

2.3.3 Enhanced Read Leases

Several works explored enhancements to *read leases* beyond stable leadership, enabling broader local reads.

Megastore [10] grants read leases to all replicas by a standalone coordinator. These leases carry the promise of not permitting any writes to covered keys. When writes arrive, leases are actively revoked (requiring an extra round-trip to all replicas) and local reads at followers are disabled until leases are re-granted. Megastore leases cover either all replicas or none; they also require external coordination and experience long downtimes during concurrent writes.

Quorum Leases [81, 82] extend read leases to configurable subsets of replicas. Leases are granted by replicas themselves, removing the need for an external coordinator. Upon writes, revocations are merged with the natural `Accept` messages and their replies, avoiding extra round-trips for writes in failure-free cases. Quorum Leases improve the configurability and write performance aspects of Megastore, but three insufficiencies with reads remain. ❶ Lease actions remain on the critical path, leading to frequent interruptions from writes. ❷ When fast-path local reads fail during lease downtimes, they are redirected to the leader or retried indefinitely by clients, leading to suboptimal slow-path latency. ❸ Assignment of grantees is configured with normal consensus commands, making failure cases hard to reason about and implement. Bodega eliminates all three insufficiencies via the powerful mechanism of background roster leases, as will become clear in §3.

2.3.4 With External Coordination

Protocols below assume external coordination.

Hermes [56] is a primary-backup replication protocol inspired by cache coherence protocols. It allows reads to be completed by individual nodes assuming that writes reach all nodes and are resolved synchronously with respect to each other (similar to CPU shared cache invalidation). Hermes inherits its architectural assumption from **Vertical Paxos** [64], requiring an external membership manager for reconfigurations upon failures.

Pando [106] is a WAN-aware, erasure-coded protocol that emphasizes cost efficiency. It allows statically tunable read-write quorums, which are settable ahead-of-time before deployment, and assumes a network topology with frontends and an external service for membership management.

2.4 Summary of Goals

After reviewing existing solutions, we summarize the desired properties of a linearizable read protocol as our design goals:

- *Self-contained*: no external metadata oracle dependencies.
- *Local reads anywhere*: enable local linearizable reads at arbitrary subsets of replicas as appropriate.
- *Local reads at anytime*: keep reads localized during concurrent interfering writes, minimizing degradation time and maintaining good slow-case latency.
- *Configurable*: tunable against arbitrary ranges of keys.
- *Non-intrusive*: designed atop classic consensus, introducing marginal performance impacts on writes and retaining availability under any minority number of failures.

Via these goals, Bodega delivers superior performance characteristics compared to aforementioned approaches. We will show them both theoretically (§4) and experimentally (§6).

3 Design

In this section, we present the core design of Bodega.

Design Outline. We derive the complete design in three steps: ❶ define the roster, ❷ design optimal normal case operations assuming replicas agree on the same stable roster, and ❸ introduce all-to-all roster leases, the enabler behind the fault-resilient agreement on the roster.

For clarity, we adhere to Paxos-style terminology throughout this paper. All the optimizations are applicable to Raft-style protocols due to their fundamental duality [110].

3.1 The Roster

We start by introducing the core concepts behind Bodega: responder status and the roster. A node is a *responder* for a key if it is expected to serve read requests on that key locally without actively contacting other nodes. A *roster* is the collection of each node's desired capabilities at a certain time; specifically, it dictates:

- The node ID of the current leader node.
- For each (range of) key(s): the node IDs of its responders.

The roster is a generalization of leadership from classic protocols: besides the one special leader role, we now have special responder roles for selected keys. The leader can be implicitly treated as a responder for all keys, and different keys can additionally mark different nodes as responders.

The optimal choice of responders for each key depends on various factors: ❶ client locations and proximity, ❷ workload read-heaviness and skewness, and ❸ cluster topology and status. This paper focuses on the mechanisms supporting the roster rather than the policies for tuning it; we recognize that the latter could be an intriguing study on its own.

The system starts from an empty roster with a null leader ID and an empty responder set for the entire keyspace. Every newly-proposed roster is associated with (and identified by) a unique ballot number, forming a $\langle bal, ros \rangle$ pair, where *bal* is the ballot number formed by concatenating a monotonically increasing integer b with the proposing node's ID r to ensure uniqueness. Rosters of different ballots may contain the same content but are still considered different. Roster changes may happen due to explicit requests by users, automatic tuning from statistics, or mandatorily in reaction to failures.

3.2 Normal Case Operations

We first describe normal case operations, using Figure 4 as a demonstrative example. In a 5-node cluster, S0 is the leader (depicted by the crown) and S2,3,4 are additional responders (depicted by the red star symbols) for a specific key k. Assume, in this section, that this is the latest roster all nodes know and consider stable according to leases. Nodes use their known roster to assure that writes to k would never commit before reaching all of its active responders. A responder can therefore serve reads directly if it knows the latest value of k will commit; when unsure, optimizations exist.

3.2.1 Writes

Writes follow the same leader-based process as in MultiPaxos (Figure 4 blue arrows), except for an updated commit condition. Normally, a write to key k can be marked as committed and acknowledged once $\geqslant m$ `AcceptReplys` are received. We impose an additional constraint that it must also have received replies from all the responders for k, according to the leader's current roster.

Requiring a write quorum that covers all responders is an unavoidable penalty that any local linearizable read algorithm must pay. Luckily, without far-off responders, this penalty is marginal as the system usually picks a leader with relatively uniform distances to other replicas, and the write must anyway reach a majority. This aligns with previous observations [81] and our evaluation results (§6). Distant responders could still be appropriate for certain workloads.

3.2.2 Reads

Clients send read requests on key k to the closest responder server for k (Figure 4 green arrows). It is common for clients of wide-area systems to be co-located with some replica; for example, consensus is usually part of an outer system, e.g., a database, where requests come directly from participating sites, but this is not a requirement.

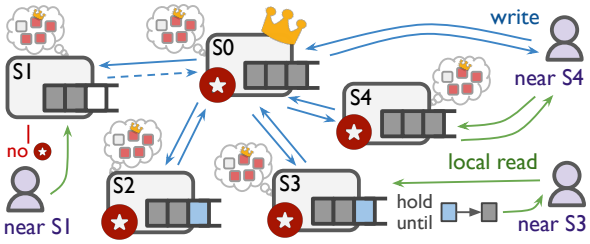

Figure 4. Normal case operations of Bodega. *Assume all nodes agree on the same example roster: S0 is the leader and S0,2-4 are responders for a key while S1 is not. See §3.2.*

When a server S (with a stable roster) takes a read, there are three cases. ❶ S is the leader, in which case S simply finds the highest committed slot in its log that contains a write to k and returns the value. The leader does not need to worry about in-progress writes [25]. ❷ S is neither a leader nor a responder for k (e.g., S1 in Fig. 4), in which case S rejects the read and promptly redirects the client to another server, preferably a close-by responder or the leader. ❸ S is a non-leader responder. In this case, S looks up the highest slot in its log that contains any write to k. If the slot is in committed status, S immediately replies with the value (e.g., the read at S4 in Fig. 4); otherwise, S cannot yet determine whether that value will surely commit or will be overwritten due to impending failures (e.g., the read at S3), in which case S optimistically *holds* the read.

Optimistic Holding. S expects its connection with the leader to be normally healthy, hence anticipates quick commitment for in-flight writes. It is usually faster and more efficient for S to withhold local reads that depend on an in-flight write and to reply as soon as commitment is known, than rejecting the reads and letting clients redirect or retry. In failure-free cases, the commit notification for an interfering write arrives in at most one RTT (from when S receives the `Accept` from the leader and replies to it). Note that even with a constant stream of writes, held reads are not blocked indefinitely: they are released as soon as their associated slot turns committed.

A responder S optimistically holds a local read by adding it to a *pending set* attached to the corresponding slot. Upon receiving the commit notification for a slot, S releases the pending reads and replies with the committed value. To handle cases where the leader fails to notify S promptly, clients start an *unhold* timeout when sending local read requests; if the timeout is reached, clients proactively issue the same request to another responder or the leader (with the same req ID, which is safe since reads are idempotent) and use the earliest reply. A good timeout length is longer than the usual RTT between S and the current leader.

Early Accept Notifications. Bodega can optionally incorporate a further optimization that reduces average holding time when under low load: followers not only reply to `Accepts` on key k to the leader, but also broadcast notifications to k's responders. Once a responder S has received m notifications (counting self), it can assert that a pending slot will surely commit even across minority failures. A similar optimization exists for BFT writes [23]. On average, this halves the expected holding time for interfered local reads. This optimization is optional and can be turned off when write traffic increases.

3.3 Roster Leases

So far, we have assumed a consistent roster across the cluster without showing how it is achieved. The idea is to exchange roster leases in an all-to-all manner, between at least a majority of nodes and all nodes that may be responders for some key. When holding a majority number of leases, responders know that the roster is stable, and the leader (as an implicit responder) also knows the identity of all responders and will not commit writes without notifying them.

	Lease Primitive	Leader Leases	Roster Leases
Pattern	one-to-one	all-to-one	all-to-all
Safe #grantors	1	m	m
Must to whom	-	leader	responders

We present how Bodega deploys off-the-critical-path *roster leases* to establish a stable roster elegantly and efficiently. We use Figure 5 as an illustration when needed.

Lease-related States. Besides the SMR log and the $\langle bal, ros \rangle$ pair, we let every node S act as both a lease grantor and a grantee (recall §2.2 for how a standard lease grant primitive works). This means S maintains the following additional data structures: ❶ two lists of grantor-side timers $T_{\text{guardTo},\,p}$ and $T_{\text{renewTo},\,p}$ per peer node P; ❷ two corresponding sets $\{\}_{\text{guardTo}}$ and $\{\}_{\text{renewTo}}$ for tracking which peers are S currently guarding/renewing to; ❸ two lists of grantee-side timers $T_{\text{guardBy},\,p}$ and $T_{\text{renewBy},\,p}$ per peer P; ❹ two sets $\{\}_{\text{guardBy}}$ and $\{\}_{\text{renewBy}}$ for tracking the guards/renewals S currently holds; ❺ a list of safety slot numbers $thresh_p$, that specifies the highest slot S has accepted from each peer P.

3.3.1 Roster Leases Activation

We first describe how roster leases are activated. Consider node X wants to announce a new roster ros'; this could be due to, e.g., stepping up as new leader (by setting X as the leader in ros') or other reasons covered in §3.3.2. X composes a unique, higher ballot bal' by concatenating $(b+1)$ with its node ID, where b is the higher part of the current bal. X then broadcasts the $\langle bal', ros' \rangle$ pair to all nodes including self.

For any node S upon receiving a ballot bal' higher than ever seen, it first ensures all old leases are safely revoked or expired (discussed later in §3.3.2). Then, it moves on to $\langle bal', ros' \rangle$ and starts a `initiate_leases(`bal'`)` procedure, where it begins granting leases for the new roster to all peers asynchronously in parallel.

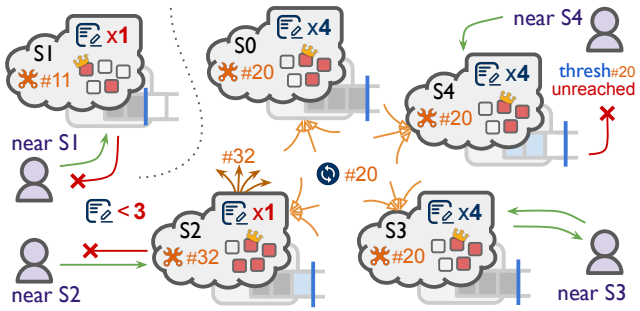

Figure 5. All-to-all roster leases demonstrated. *S0,3,4 are each holding ≥ majority grants of roster #20; S4 has not seen all slots up to #20's safety threshold. S1 is stuck with an older roster of #11. S2 is initiating a new roster of #32. See §3.3.*

To each peer P, the procedure obeys standard lease granting: S and P first complete the guard phase, exchanging a sequence of `Guard`, `GuardReply`, `Renew`, and `RenewReply`, and utilizing proper timers along the way. If all goes well, S should have P in its $\{\}_{\text{renewTo}}$ and have T_{renewTo} properly extended; it repeats renewals periodically to keep the S-to-P lease refreshed. Similarly, P should have S in its $\{\}_{\text{renewBy}}$ and have T_{renewBy} kicked off properly. Whenever a $T_{\text{intent},\,p}$ times out for any intent among the four, the peer is removed from the corresponding set $\{\}_{\text{intent}}$, leading to a retry of the guard phase or a proposal of a new roster.

After transitioning to ros', if S sees itself being the leader of ros', it does the usual step-up routine of redoing the `Prepare` phase for non-committed slots of its log.

Stable Condition & Safety Thresholds. As shown in §2.2 and above, a node P is considered granted a lease by S when S ∈ P's $\{\}_{\text{renewBy}}$ set. Assume P itself is always in the set. The size of this set, $|\{\}_{\text{renewBy}}|$, indicates the number of lease grants P currently holds. When $|\{\}_{\text{renewBy}}| \geqslant m$, then P knows at least a majority number of nodes in the cluster has the same latest $\langle bal, ros \rangle$ as P and that at most one such roster exists; this is called the *stable* roster of the cluster and is a necessary precondition for all optimizations described in §3.2. For example, in Figure 5, the local reads at S1 and S2 are rejected due to an insufficient lease count.

This condition alone is not enough, though. When a node directly inspects its log and uses the highest slot index for local reads, it is assuming that its log is up to date and contains all the recently committed instances; this is usually true, but could be violated during the short period of time when a node that has fallen behind joins a new roster. To address this, a node should be informed of other peers' acceptance progress when transitioning to a new roster.

We let `Guard` messages from S to P carry an extra number, which is the highest slot number that S has ever accepted. P stores the number in its *thresh* list. A node permits local reads only if it has committed all the slots up to the m-th smallest slot number in its *thresh* list; otherwise, it might not have observed the latest committed writes yet. S4 in Figure 5,

for example, has not reached this condition and thus cannot start serving reads locally yet.

In summary, all the stable leader and local read operations of §3.2 are preceded by the following stable condition check:

$$|\{\}_{\text{renewBy}}| \geqslant m \quad (1)$$
$$\wedge \ \exists \text{ size-}m \text{ subset } E \subseteq \{\}_{\text{renewBy}} :$$
$$\text{committed all slots up to } \mathit{thresh}_p, \forall p \in E$$

If the check fails, the operation falls back to classic consensus as if it is a write, which does not require this check.

3.3.2 Revocation & Expiration

Most roster lease activations happen when there are ongoing old leases in the system. Broadly speaking, a roster change may be triggered by one of the following reasons.

- Node initiates a new roster in reaction to suspected failures, removing failed nodes from special responder roles.
- Node autonomously proposes a new, more optimized roster according to collected workload statistics.
- Node receives an explicit roster change request from user.

In either case, before `initiate_leases()`, a node S always invokes the `revoke_leases(`*bal*`)` procedure synchronously to ensure that all the leases it is granting or holding with the older ballot *bal* are safely revoked and removed. To do so, S clears its $\{\}_{\text{guardTo}}$ set and broadcasts `Revoke` messages carrying the old ballot. Whenever a node P receives a `Revoke` with matching ballot from S, it removes S from the $\{\}_{\text{guardBy}}$ and $\{\}_{\text{renewBy}}$ sets and replies with `RevokeReply`.

S either receives a `RevokeReply` from P promptly (common fast case) or has to wait for expiration timeout (failure case), after which it removes P from $\{\}_{\text{renewTo}}$. Note that, unless failures occur and force a wait on expiration, a roster change completes swiftly within two message rounds: one for the revocation and the other for the initiation guards.

3.3.3 Piggybacking on Heartbeats

Distributed systems already deploy heartbeats for tasks such as health tracking [35, 52, 80, 94]. This opens the opportunity to enable roster leases without common-case overheads, by piggybacking lease messages onto existing periodic heartbeats. Bodega piggybacks all the `Renew` and `RenewReply` messages onto heartbeats, and uses a proper heartbeat interval $t_{\text{hb_send}}$ such that leases are refreshed in time. Heartbeat messages also carry the sender's $\langle \mathit{bal}, \mathit{ros} \rangle$ pair to let receivers discover roster changes.

Each node has per-peer timers $T_{\text{heartbeat},\,p}$ which are used for promptly detecting failures from peers; a peer is considered down if no heartbeats were received from it for $t_{\text{hb_fail}}$. A rule of thumb for choosing good timeout lengths for a cluster is:

$$\text{avg. RTT} < t_{\text{hb_send}} \ll t_{\text{hb_fail}} < t_{\text{guard}} = t_{\text{lease}} \quad (2)$$

Bodega uses the following defaults for wide-area replication: $t_{\text{hb_send}} = 120\text{ms}$, $t_{\text{hb_fail}} \approx 1200\text{ms}$, $t_{\text{guard}} = t_{\text{lease}} = 2500\text{ms}$.

Cell is shaded darker if value is higher.*

4 Formal Presentation and Proof

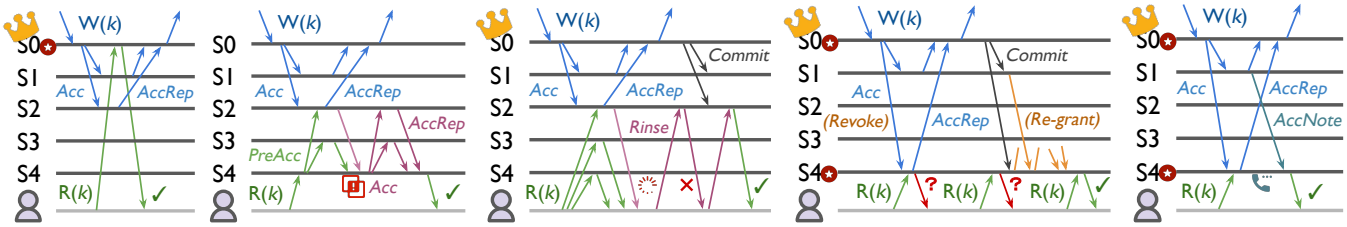
We provide a qualitative comparison across notable protocols (Figure 6, Table 1), a formal presentation of the Bodega algorithm (Figure 7), and a concise proof of correctness.

4.1 Comparison Across Protocols

In Table 1, we model the normal-case write and read latency, degraded read latency under write interference, and degradation period length of related protocols. Cells are shaded according to example values from the Figure 8(b) GEO setting (lighter is better). We also indicate whether a protocol retains the fault tolerance of classic protocols and whether it allows tunable configs. If tunable, we use its most read-optimized config that tolerates $f = \lfloor \frac{n}{2} \rfloor$ faults. Assume only one interfering write.

The following symbols are used to model performance. $\underline{l}$: RTT between client and the leader, $\underline{c}$: RTT between client and its nearest server, $\underline{m}$: time to establish a simple majority quorum (i.e., to reach majority nodes from some server and receive replies), $\underline{M}$: time to establish a super majority quorum (as in EPaxos [80]), $\underline{N}$: time to form a quorum composed of all nodes. For an average client in typical WAN-scale settings, one should expect $c \ll l \approx m < M < N$.

Most results are derived naturally from Figure 6, §2.3, and §3.1-3.3. We provide supplementary explanations. **PQR (+ Ldr Ls)** is a straightforward variant of PQR combined with Leader Leases; if a near quorum read attempt fails, the client contacts the stable leader directly, bounding slow-path latency by $c + m + l$. We assume Quorum Leases always incorporate Leader Leases. **Qrm Ls (passive)** is a variant of Quorum Leases where we deliberately let grantees keep



(a) Leader Leases **(b)** EPaxos **(c)** PQR **(d)** Quorum Leases **(e)** Bodega

the leases upon accept to show the upper bound of Quorum Leases performance, saving one re-granting RTT from the degradation time. Doing so risks blocking fault-induced roster change commands as described in §3.3. Hermes uses primary-backup broadcast and thus requires external coordination for fault tolerance; Megastore is similar. Pando uses a pre-deployment planner to dictate erasure coding and quorum composition. Bodega achieves the best across all metrics and retains fault tolerance and configurability.

4.2 Formal Presentation

Figure 7 presents a complete, code-oblivious summary of the Bodega algorithm, which can be used as a reference for implementors. We also provide a formal, model-checked TLA$^+$ specification in Appendix A.

4.3 Proof

We provide a proof of Bodega's local read linearizability and write liveness, assuming well-established results of the safety and liveness of leases [41]. For linearizability, only locally-served reads need proof, as Bodega behaves the same as classic consensus otherwise.

Linearizability. A local read R served by server S observes any write W acknowledged cluster-wise before R was issued.

Proof. R is served locally only if S is a responder that passes the stable roster check (1). Let the stable roster be $\langle bal, ros \rangle$.

Case #1: W was committed on a ballot $> bal$. It is impossible because the latest ballot on at least a majority is bal.

Case #2: W was committed on a ballot $= bal$. By the injective ballot-roster mapping and the commit condition of writes, S must be in W's write quorum and have W in its log.

Case #3: W was committed on a ballot $< bal$. By majority intersection, for any size-m subset $E \in$ S's $\{\}_{\text{renewBy}}$, at least one of the lease grantors $P \in E$ accepted W at its committed slot x before granting to S. This implies $thresh_p \geqslant x$. □

Liveness of Writes. A write W can always eventually make progress if retried on a majority group G of healthy servers.

Proof. By the property of leases, after old leases expire, a roster change can eventually be made on all servers $\in G$ to restrict the leader and all the responders to be contained in G. Then, normal consensus applies. □

5 Implementation

The Summerset KV-store. We develop Summerset, a distributed, replicated, protocol-generic key-value store. Summerset is written in async Rust/`tokio` using a lock-less architecture and serves as a fair codebase for evaluating consensus and replication protocols.

The codebase has 13.6k lines of infrastructure code and covers five protocols of interest: MultiPaxos w/ Leader Leases (2.5k), EPaxos (3.1k), PQR & variant (2.8k), Quorum Leases & variant (3.2k), and Bodega (3.0k). All protocol implementations have passed extensive tests. The full Summerset codebase is open-sourced at https://github.com/josehu07/summerset/tree/bodega-artifact.

5.1 Smart Roster Coverage

In cases where users desire local reads but cannot observe workload patterns externally, Bodega servers can collect statistics and automatically propose roster changes to mark servers as responders for proper keys. Our default implementation traces per-key read/write request counts grouped by clients' preferred nearby server IDs. For a key, if > 95% requests are reads at a periodic check, then servers near > 20% of the reads are added as responders. More sophisticated strategies exist; for example, straggler detection can help remove fail-slow nodes from responders promptly [51, 54].

5.2 Lightweight Heartbeats

In §3.3, we described roster leases as if all heartbeats carry the complete roster data structure. In practice, rosters with fine-grained key ranges can get large (tens of KBs). Luckily, most heartbeats in Bodega are *lightweight heartbeats*: the sender puts in only the ballot number to indicate that the roster has not changed from previous heartbeats. Full-sized heartbeats are sent when changes occur.

Similarly, clients may request a server to send the roster along with a command reply, and then cache this roster as a heuristic for choosing the best responder for local reads.

5.3 Other Practical Details

Request Batching. As is common practice, Bodega deploys request batching at servers (at 1 ms intervals) for non-local-read commands. Each log slot contains a batch of requests

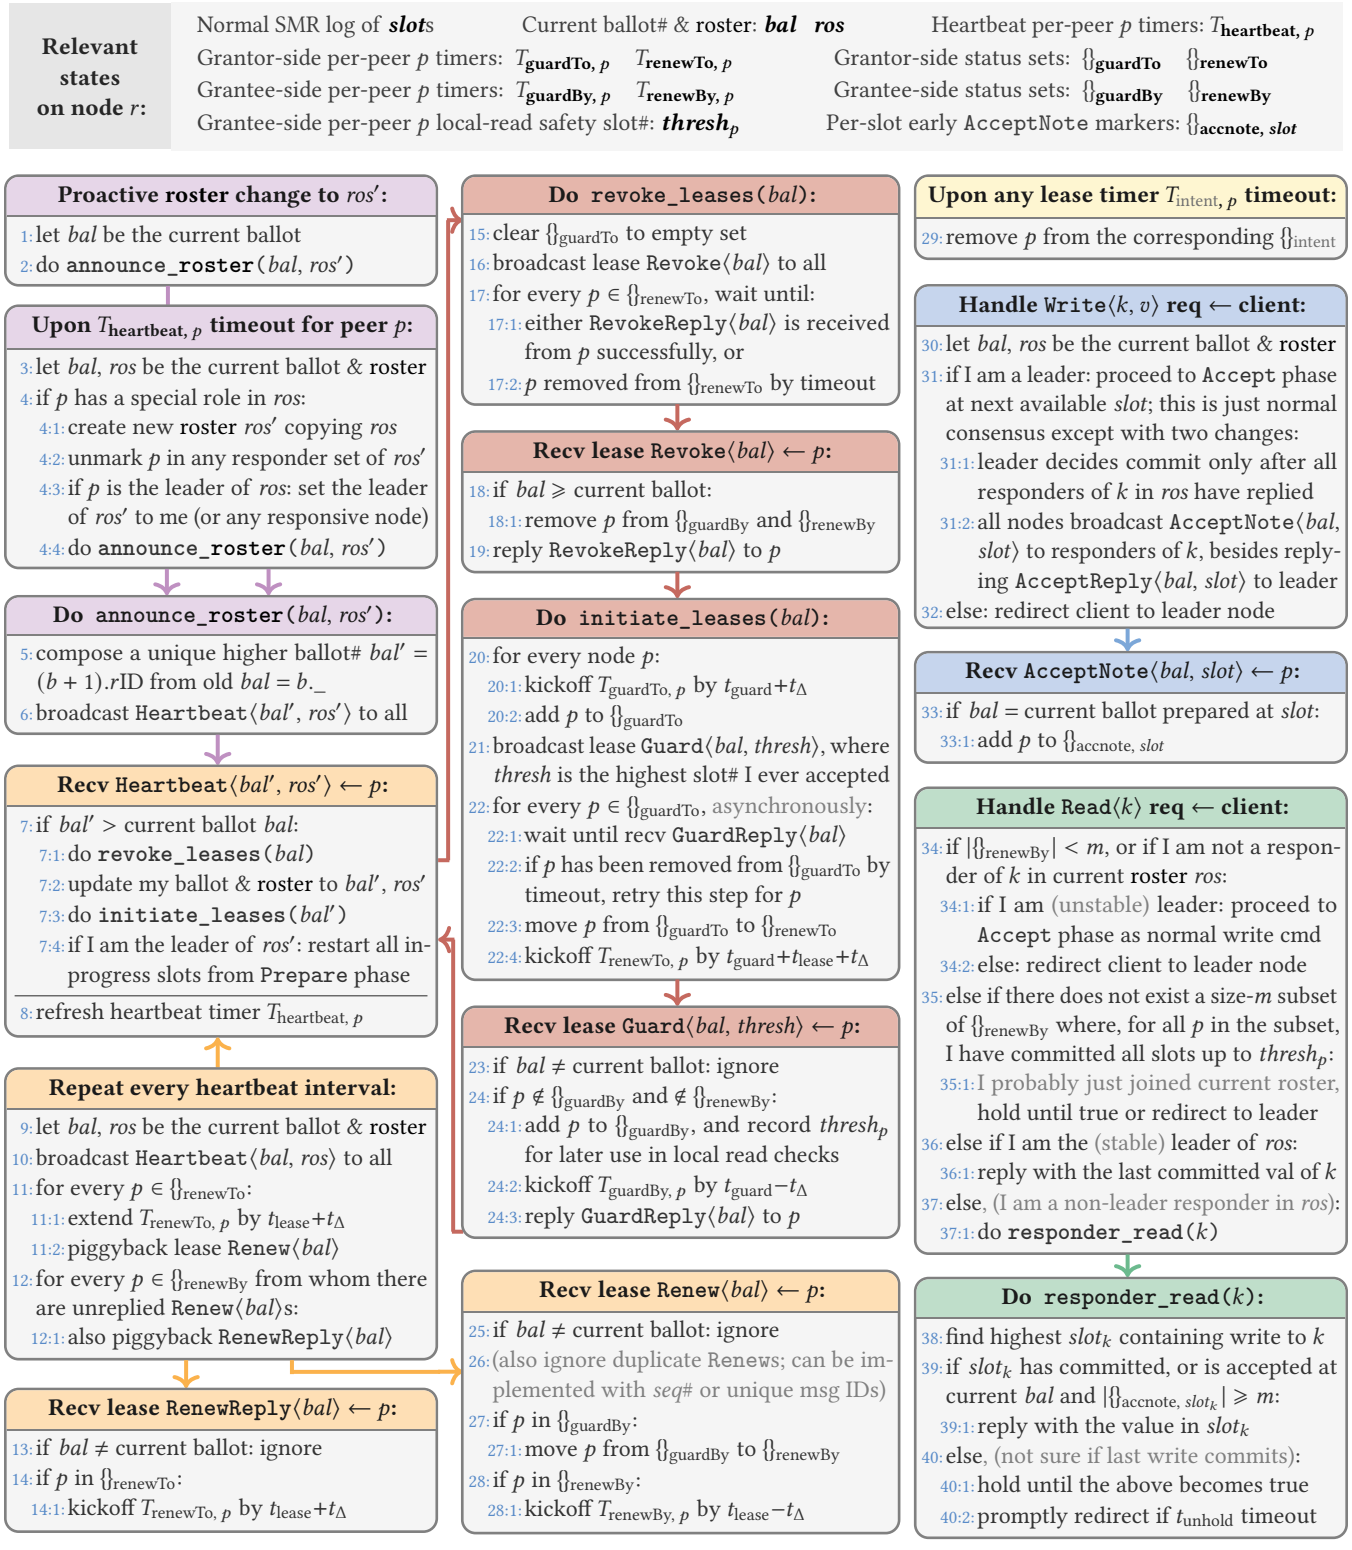

Figure 7. Complete Summary of the Bodega algorithm. *Lists all actions a node r would take upon certain conditions, grouped by purposes for clarity: triggers for a new roster, granting procedure of new roster leases, heartbeats and lease renewals, handling client write requests, handling client read requests. The description is based on a regular key-value API. Nodes implicitly retransmit non-acked messages. Broadcast msg receivers include the sender itself. Clock drift between nodes is assumed to be bounded by t_Δ, as is required by any distributed lease algorithm; clock skews are irrelevant thanks to Guards. The arrows annotate a natural reading order that follows the usual flow of the protocol.*

and the commit condition is checked for all writes contained.

Snapshots. Bodega servers take periodic snapshots of the executed prefix of the log [87]. Local reads past the beginning of truncated log look up the latest snapshot directly.

Membership Management. Membership changes are handled identically to *reconfigurations* in other protocols [25, 80, 85], just with an extra step of proposing and stabilizing an empty roster with no responders ahead of the change.

6 Evaluation

We do comprehensive evaluations to answer these questions:

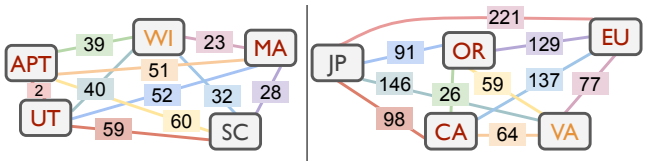
- How does Bodega perform compared to other protocols under microbenchmarks of various write intensities? (§6.1)
- What do the request latency distributions look like? (§6.2)
- What are the impacts of write interference, and how does performance change with write ratios & value sizes? (§6.2)
- How do roster changes impact performance? (§6.3)
- How does Bodega behave with different choices of responders and different coverages of keys? (§6.3)
- How does Bodega compare with production coordination services, etcd & ZooKeeper, under YCSB workloads? (§6.4)

Experimental Setup. All experiments are run on two CloudLab [33] clusters, hereafter called WAN and GEO, shown in Figure 8. WAN is a wide-area cluster spanning five CloudLab sites with nodes of similar hardware types: WI-`c220g5`, UT-`xl170`, SC-`c6320`, MA-`rs620`, and APT-`r320`. §6.1 also includes a GEO cluster of five `c220g5` nodes emulated with Google Cloud RTTs reported in previous work [104] using Linux kernel `netem` [71]. All nodes' public NICs have 1Gbps bandwidth. The orange-colored site in Figure 8 denotes the leader and the red-colored sites denote responders.

Clients are launched on machines evenly distributed across all datacenters, each marking the nearby server as their preferred server for local reads when eligible. All machines run Linux kernel v6.1.64 and pin processes to disjoint cores. All protocols use 120 ms heartbeat interval, 1200±300 ms randomized heartbeat timeout, and 2500±100 ms lease expiration (if applicable). All protocols send immediate `Commit` notifications: whenever a commit decision is made, `Commits` are broadcast to other servers promptly.

6.1 Normal Case Performance

We run microbenchmarks on both cluster settings and compare: ordinary MultiPaxos, Leader Leases, EPaxos, PQR, PQR (+ Leader Leases) variant, Quorum Leases, Quorum Leases (passive) variant, and Bodega. We spawn 50 closed-loop clients with 10 near each server and let all clients run a microbenchmark with 1k 8B-size keys and 128B values; keys are chosen uniformly. We test three write percentages in the workload mix: 0%, 1%, and 10%. Figure 9 shows the normalized throughput (w.r.t. Leader Leases), avg. read latency, and avg. write latency perceived by clients at different locations. Leader and responders are set as depicted in Figure 8. The



(a) WAN (CloudLab sites) **(b)** GEO (GCP [104], emulated)

Figure 8. Evaluation settings. *Orange denotes designated leader node and Red denotes other responders, if relevant. The edges mark per-pair RTT values in milliseconds. See §6.*

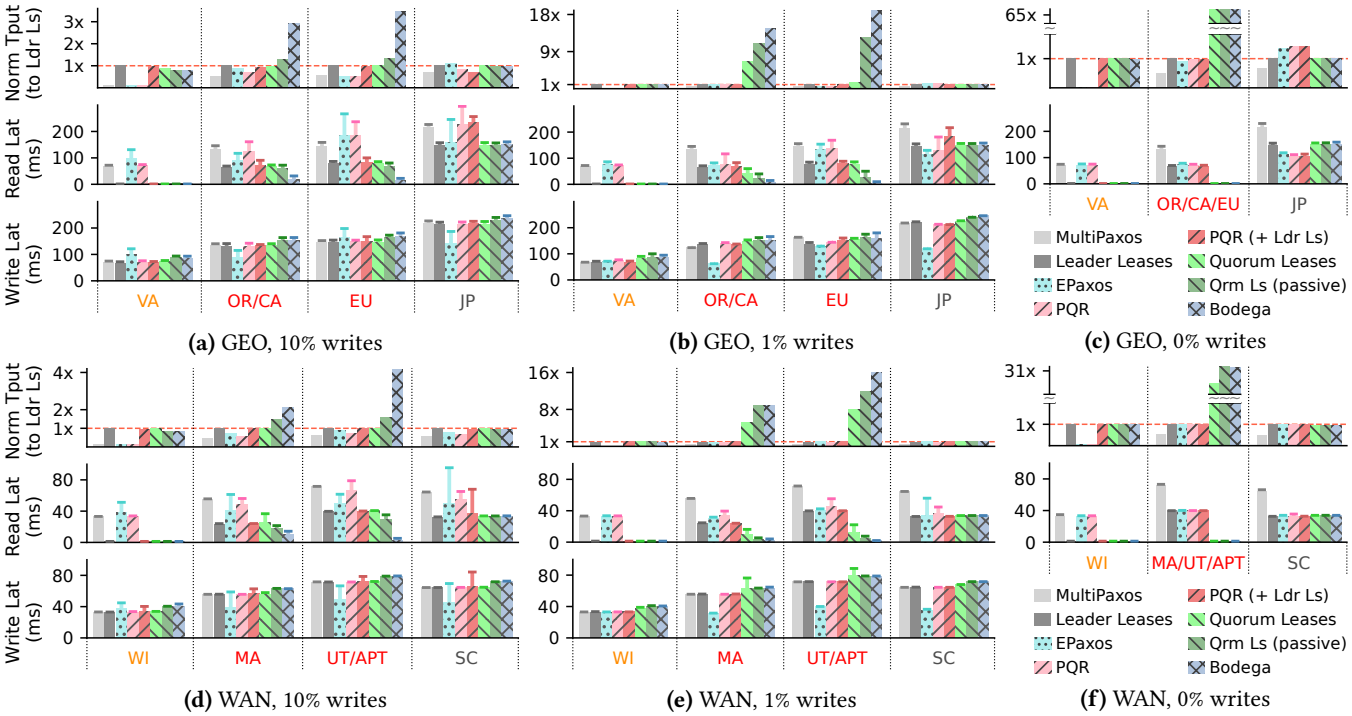
red dashed lines indicate baseline Leader Leases throughput, and the top Ts on latency bars indicate P99 latency.

The results yield the following observations. First, except for a few datapoints (which we soon discuss), both GEO and WAN clusters exhibit similar performance patterns, just with different absolute values due to RTT differences.

Second, for writes, all protocols except EPaxos exhibit similar performance. Quorum Leases and Bodega have higher write latency due to the requirement of writes reaching responders; this explains the small throughput gap between them and Leader Leases for near-leader clients with 10% writes. EPaxos delivers better average (but not P99) write latency due to its leaderless write protocol design.

Third, we observe coherent patterns for read performance. ❶ Compared to ordinary MultiPaxos, Leader Leases cut read latency for near-leader clients to nearly zero, but other clients still pay an RTT to the leader for reads. ❷ PQR (and its Leader Leases variant) show worse (or identical) performance compared to Leader Leases. The only exception is in the GEO, 0% writes setting for the JP clients; they are so far away from the leader that a nearer majority quorum actually helps, letting them outperform local read protocols (since JP is not marked as a responder). ❸ EPaxos has similar read performance as PQR but with higher P99 latency when there are writes. ❹ Both Quorum Leases variants and Bodega show the same performance as Leader Leases for clients near the leader or a non-responder. ❺ Quorum Leases and Bodega both deliver extraordinary read performance for clients near responders when with 0% writes. ❻ Bodega sustains this read performance advantage and keeps read latency close to zero for higher write intensities. In contrast, Quorum Leases performance quickly drops and almost degrades back to Leader Leases for 10% writes. This shows Bodega's resilience to write interference, a crucial advantage.

Throughput to Read Latency Curves. We take the 10% writes WAN setting of Figure 9(d) and run open-loop clients with varying request concurrency up to 100 reqs/sec to profile the throughput-latency curves, which we plot in Figure 10. The x-axis is aggregated throughput and the y-axis is average latency of all requests. The never-local-read protocols (MultiPaxos, PQR, EPaxos) form a cluster at the upper left as expected, due to unavoidable network traffic per read. Leader Leases reveal a throughput upper bound at ~1.8k where the leader node starts to overload; this bound



(a) GEO, 10% writes **(b)** GEO, 1% writes **(c)** GEO, 0% writes

(d) WAN, 10% writes **(e)** WAN, 1% writes **(f)** WAN, 0% writes

Figure 9. Normalized throughput and latency at different client locations *across different write intensities. See §6.1.*

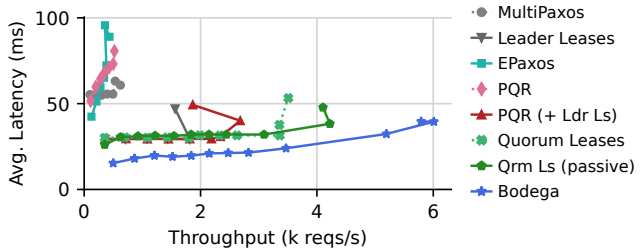


Figure 10. Tput to avg. latency curves *on WAN. See §6.1.*

is slightly higher for PQR + Leader Leases at ~2.2k. Quorum Leases see similar latency under low load and a higher throughput bound at ~3.4k, matching Figure 9. Bodega sustains 1.5x better latency because of most reads being served locally without fallbacks; throughput limit is accordingly higher at ~6k.

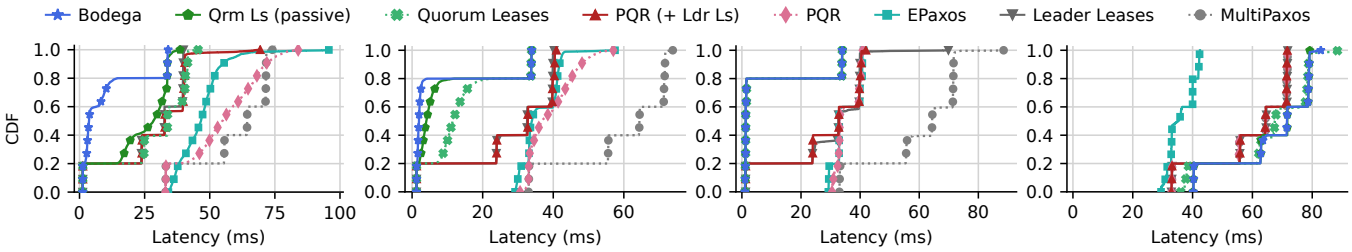
6.2 Detailed Performance Anatomy

We conduct a zoomed-in study across various workloads and metric dimensions.

Latency CDFs. We collect request latency CDFs across all 50 clients of the WAN setting (Fig.9(d)-9(f)) and plot them in Figure 11. Results are filtered to show a single key for a clean pattern. Each site contributes an equal 20% of datapoints.

We make four observations. ❶ Write latencies across all workloads are similar and are presented as one Figure 11(d). Quorum Leases and Bodega show slightly higher write latencies in favor of responder local reads, while EPaxos delivers the same level of latencies as its reads due to its leaderless design. These results align with §6.1. ❷ At 0% writes, all protocols deliver a read performance close to their theoretical best, though a few outlier datapoints remain. ❸ At 1% writes, slight write interference occurs. Quorum Leases reads deviate from Bodega, with the passive variant delivering roughly half the latency of the original variant. ❹ At 10% writes, differences in read latency distributions are the most obvious. MultiPaxos clients' read latency clearly correlates with their distance to the leader; Leader Leases are similar but with a majority-quorum latency subtracted. PQR and EPaxos exhibit suboptimal latency and have high tail latency of up to 100 ms for a read; this is due to the need for conflict resolution. Quorum Leases variants both degrade to Leader Leases. Bodega delivers outstanding local read performance as expected (except for the 20% non-local SC clients).

Visualizing Write Interference. We use a similar setting to the read-only workload in §6.1 on the WAN cluster, but this time with open-loop clients, each sending reads at a rate of 400 reqs/sec to a key. At ~15 secs, we let one client issue a write command to the key. We monitor the average read latency across the three non-leader responders for the local read protocol variants, and plot them over a time axis in Figure 12. We see that the write introduces an interruption to local reads for all three protocols. Both Quorum Leases variants degrade to 40 ms read latency, which is the average RTT to the stable leader; the passive variant shows a shorter degradation duration. Bodega ❶ shortens the degradation time to ~25 ms; recall Table 1, this corresponds to ~$\frac{m}{2}$, and ❷ allows all reads to be held locally and be released at the end of the degradation, leading to better latencies also for disrupted reads.



(a) Reads w/ 10% writes **(b)** Reads w/ 1% writes **(c)** Reads w/ 0% writes **(d)** Writes

Figure 11. Latency CDFs of requests *in the WAN setting across different write intensities, focusing on one specific key. See §6.2.*

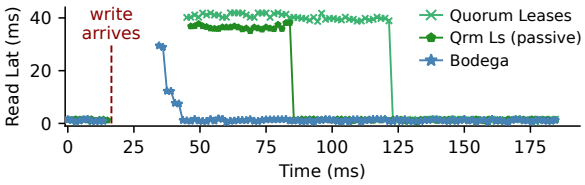


Figure 12. Read latency after an interfering write. *The x-axis is time at which the reads finish. See §6.2.*

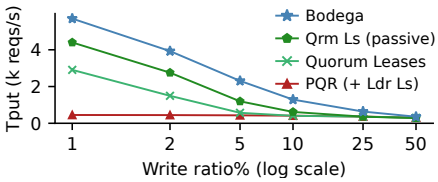

Figure 13. Throughput vs. write ratio. *The x-axis is log-scale (same for Fig. 14).*

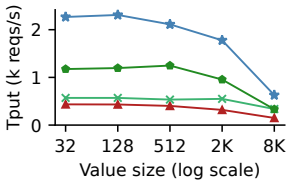

Figure 14. Throughput vs. value size. *See §6.2.*

Varying Write Ratios. We take the same setup as §6.1 on the WAN cluster and vary the write ratios of the workload mix from 1% to 50% while fixing value size to 128B. We report the aggregate throughput in Figure 13. All protocols except the PQR (+ Ldr Ls) baseline show a trend of lower throughput with higher write interference as local reads become less profitable. The results match Figure 9(d)-9(e).

Varying Value Sizes. We repeat the same setup as above and vary the value size while fixing the write ratio at 5%. As expected, Figure 14 shows that smaller values have little impact on performance, but throughput drops with larger values due to slower writes and larger read results to transfer.

6.3 Roster Changes & Composition

We evaluate roster change performance and roster coverage.

Impact of Frequent Failures (Simulation). We first justify roster leases' stability under frequent failures through an exaggerated simulation. We run a 10ms-timeslice-based Monte Carlo simulation with 10% writes using performance numbers measured in Figure 9(d). We apply a failure probability of 0.5% every second–much larger than real-world servers [3]–and a recovery probability of 1% every second. After any failure, the cluster delivers 3 seconds of zero throughput to simulate lease expiration; after any recovery of a responder, the cluster delivers 100ms of zero throughput to simulate a proactive roster change. Figure 15 shows aggregated throughput of 1 million simulated seconds. We can see that, despite these exaggerated conditions, Bodega still delivers up to 2.2x throughput compared to traditional Leader Leases.

Roster Change Duration. On the WAN cluster, we zoom in and compare the duration of two types of roster changes: failure-induced (where waiting for lease expiration is necessary) vs. regular (where revocations complete quickly). Regular roster changes finish in just two message rounds, because they are no more than a lease revocation followed by an initiation. We create an open-loop client near WI and let it issue a 50%-read workload at a rate of 400 reqs/sec to 1k keys. We plot real-time latencies in Figure 16.

At ~800 ms, we crash the UT node, which is one of the responders for the full key range. Writes are immediately blocked since UT as a responder is unreachable. Reads are still served locally without interruption until ~1.1 secs later, when some healthy server in the cluster raises a heartbeat timeout and initiates a change to a new roster where UT is removed from all responder roles. After waiting 2.6 secs for expiration, normal operations continue.

At ~7.2 secs, we make an explicit roster change request to a server. In contrast to the failure case, this roster change completes in just ~75 ms, which is ~2x cluster-wise RTTs as expected. Impacts on client requests are minor.

Choice of Responders. We run a 10%-write workload on all clients in the WAN setting, while using an increasing set of responders for all keys; WI node is still the leader. We report the cluster-wide average read/write latency and their standard deviation in Figure 17. With more nodes added as responders, read latency tends to zero while write latency increases, revealing the expected tradeoff. This demonstrates the importance of allowing adjustable rosters to help avoid unnecessary taxes on writes.

Coverage of Keys. We repeat the same experiment, but vary the percentage of local-read-enabled keys while fixing the choice of responders to Figure 8(a). The cluster-wide average latencies and their standard deviation across the coverage spectrum are plotted in Figure 18. Results show an expected decrease in read latency and a corresponding increase in write latency as local reads are enabled on more keys. This implies the general strategy of enabling local reads for read-heavy keys while avoiding local reads for write-heavy keys.

(b) Zipfian, top-20%-coverage roster

Figure 19. YCSB workloads on Summerset, etcd, & ZooKeeper. *etcd (stale) & ZK (both modes) are not linearizable. See §6.4.*

6.4 Macrobenchmark vs. etcd & ZooKeeper

To evaluate the protocols in a more realistic setup, we compare Summerset protocols with two widely-used coordination services, etcd [35] and ZooKeeper [52], on the WAN cluster. We drive all systems with YCSB [29], the standard KV macrobenchmark. Workloads have the following approximate write ratios (we treat insertions as updates). A: 50% w, B: 5% w, C: 0% w, D: 5% w, F: 25% w.

YCSB Request Distributions. We use 10k keys and construct two scenarios corresponding to two request distributions. ❶ For the Uniform distribution, clients at all locations choose keys uniformly randomly across the key space. Since there are no site-specific preferences for keys, all sites are added as responders for all keys to secure local reads. ❷ For Zipfian, clients at each location choose keys according to a Zipfian-0.99 distribution, skewed towards different sets of keys at different sites; this creates per-site preferences for keys. We then add each site as a responder only for its top-20% accessed keys to derive an asymmetric roster that imposes unnoticeable impacts on write performance.

etcd Modes. We deploy etcd in two modes, both with 120 ms heartbeat intervals. The default mode showcases a standard implementation of vanilla Raft [87]. The *stale* mode turns on the serializable member-local read option for all read requests, delivering sequential consistency by always serving reads locally with past committed values at any server; this represents the ideal upper bound for Bodega.

ZooKeeper Modes. Similarly, we deploy ZooKeeper in two modes, though both are non-linearizable. The default mode is a standard implementation of the ZAB primary-backup protocol [52] that pushes writes to all servers and serves reads locally from anywhere. The *sync* mode is the closest mode to linearizable reads that ZooKeeper clients can get: every read request is preceded by a `sync` API call to force flush all the in-progress writes from the leader to its endpoint server, but all writes that may have completed after the start of the flush are not guaranteed to be seen by the read.

Results. We present the performance results in Figure 19, grouped by workload type and with PQR (+ Ldr Ls) as the normalized throughput baseline. We make the following observations. ❶ Bodega matches (and sometimes surpasses) the performance of sequentially-consistent default ZooKeeper, and is able to keep up with stale etcd across all workloads. This illustrates Bodega's powerful local linearizable read capabilities. The advantage over ZK is due to avoiding Java runtime overheads. ❷ In workload C, both non-linearizable services deliver ~0.3 ms read latency and over 10x throughput gain, while Bodega and Quorum Leases deliver ~1.2 ms latency due to the 1 ms request batching applied. ❸ EPaxos, PQR (+ Ldr Ls), Quorum Leases, and Bodega all show similar patterns coherent to §6.1. With no writes (C), both local read protocols deliver excellent performance. With higher write ratios, Bodega sustains this advantage better than Quorum Leases. ❹ Default etcd and sync ZK have high read latencies of >50 ms because they are classic consensus without leases. ❺ Comparing the Uniform scenario with Zipfian, the only notable difference is that Bodega exhibits higher write latencies close to ZK in Uniform. This is expected because Bodega writes need to reach all nodes as they are all responders.

7 Discussion

We discuss topics that are out of the scope of this paper but are interesting directions for future work. We also clarify non-goals of Bodega.

Partial Network Partitioning. Using heartbeat timeout-based failure detection for leader step-up is known to risk liveness under partial network partitioning [86], and the same holds true for roster lease activations. Common techniques such as pre-votes [86] and transparent re-routing [2] can be deployed to easily eliminate this issue.

Generalization of Roster Leases. We observe that the activation procedure of roster leases shares similarities with *broadcast-based* (randomized) consensus [16, 83, 89]. It is a practical application of all-to-all broadcast in a non-adversarial setting for one-off agreements on the roster ballot. Combined with leases, this technique can be used to establish fault-tolerant agreement on any general "roster metadata" that change infrequently, not limited to leadership and assignment of responders as in Bodega. Possible extensions may include cluster membership, asymmetric quorum sizes, and node-specific performance and reliability hints.

Bounded Staleness Support. With simple modifications, Bodega can extend beyond linearizability and support fast local reads that can tolerate (but require) bounded staleness measured in the maximum version difference with the latest committed write. When a non-leader responder receives a read that allows up to x versions stale, it can traverse the tail of its log in reverse and search for at most x occurrences of the key, returning the latest committed version if found.

Non-Goals of Bodega. Bodega is primarily designed for wide-area linearizable read workloads; its improvements become less pronounced in other consensus use cases outside of this regime. These include: ❶ intra-datacenter replication where locality isn't significant, ❷ write-dominant workloads (see Figure 13 showing diminishing throughput improvement at 50% writes), and ❸ weaker consistency models where arbitrarily stale reads or inconsistent reads are tolerable. They may still leverage Bodega's roster leases as a mechanism to share cluster-wise information at negligible overhead (see the paragraph on generalization above), but would not observe the most immediate gains from localized linearizable reads.

8 Related Work

We list additional notable related work in this section.

Consensus & Read Optimizations. §2.3 and §4.1 have covered in detail the most essential related work, including classic consensus algorithms [60, 61, 65, 85–87], leaderless or multi-leader approaches [1, 27, 34, 56, 62, 63, 76, 80, 98, 104, 106], and read leases [10, 25, 41, 81, 82, 105].

Flexible quorum sizes have been discussed in classic literature [46] as well as in recent proposals such as Flexible Paxos [42, 48, 84, 111], where quorum shapes other than majority are explored to establish asymmetric performance between commands; Bodega is a modern manifestation of fault-tolerant, asymmetric read/write quorums leveraging leases. Optimistic holding shares similarity to wait-vs.-abort in database concurrency control [44, 58] and spin-then-park mutex locks [55]; we wait when waiting is expected to be faster.

Shared Logs & Lazy Ordering for Writes. Shared logs are a common abstraction found in cloud systems and are usually backed by primary-backup-style protocols [11–14, 20, 31, 73]. CAD [38], Skyros [39], and LazyLog [74] are a series of work on a *lazy ordering* optimization for writes and shared log appends. It hides a significant portion of write latency but could hurt read performance in contended cases.

Synchronized Clocks. Recent works demonstrate production-ready implementations of synchronized clocks [30, 70] and designs that take advantage of them through timestamp heuristics [32, 40]. Chandra et al. presented a formal, optimal lease algorithm that assumes synchronized clocks [18, 26].

Weaker Consistency Models. While this paper focuses on linearizable solutions, services may choose to provide weaker consistency models, which are less intuitive to reason about and harder to program against, but usually offer better performance. Common choices include sequential consistency that allows time-traveling reads [6, 45, 59], causal consistency that focuses on client session-local properties [9, 72, 78], and eventual consistency with bounded staleness [92, 109]. There are also studies that explore supporting a mixture of consistency models in one system [75, 113].

9 Conclusion

We present Bodega, a wide-area consensus protocol that enables localized linearizable reads at anywhere, anytime. Bodega achieves this via all-to-all roster leases off the critical path to establish responder assignment without compromising fault tolerance, delivering extreme read performance comparable to sequentially-consistent production systems. We believe Bodega is a valuable step towards performance-optimal wide-area replication for critical workloads of the modern cloud.

A Formal TLA$^+$ Specification of Bodega

We also present a formal specification of Bodega written as a PlusCal algorithm that can be auto-translated into TLA$^+$. The specification builds on top of MultiPaxos and introduces all-to-all roster lease actions to support local reads, faithful to the presentation in Figure 7. Please refer to the inlined comments for specification details.

The specification has been model-checked for both *linearizability* and *fault-tolerance* properties on symbolic inputs of 3 nodes (thus 1 allowed failure), 3 ballot numbers, 2 distinct write requests plus 2 distinct read requests, 3 lease time ticks, and all possible choices of responders. These inputs should be large enough to explore the distinct, interesting execution paths of the protocol. Model checking took 43 hours on a single machine with 96 cores and 768GiB memory, and generated 4,274,883,464 distinct states.

B Artifact Evaluation Instructions

Bodega's source code (as part of the Summerset key-value store) is publicly available on GitHub at https://github.com/josehu07/summerset/tree/bodega-artifact.

Artifact evaluation instructions can be found at https://github.com/josehu07/summerset/blob/bodega-artifact/publish/bodega/ARTIFACT.md. The document contains detailed instructions on setting up a distributed consensus system environment and reproducing all the figures presented in this paper.

MODULE *Bodega*

EXTENDS *FiniteSets*, *Sequences*, *Integers*, *TLC*

Model inputs & assumptions.

CONSTANT *Replicas*, *symmetric set of server nodes*
Writes, *symmetric set of write commands(each w/unique value)*
Reads, *symmetric set of read commands*
MaxBallot, *maximum ballot pickable for leader preemption*
TGuard, *lease guard phase window length(in abstract ticks)*
TLease, *lease renewal extend window length(in abstract ticks)*
MaxTime, *upper bound on abstract time for model checking*
NodeFailuresOn *if true, turn on node failures injection*

$$ReplicasAssumption \triangleq \land IsFiniteSet(Replicas) \land Cardinality(Replicas) \geq 1 \land \text{“none”} \notin Replicas$$

$$Population \triangleq Cardinality(Replicas)$$

$$MajorityNum \triangleq (Population \div 2) + 1$$

$$WritesAssumption \triangleq \land IsFiniteSet(Writes) \land Cardinality(Writes) \geq 1 \land \text{“nil”} \notin Writes$$

$$ReadsAssumption \triangleq \land IsFiniteSet(Reads) \land Cardinality(Reads) \geq 0 \land \text{“nil”} \notin Writes$$

$$MaxBallotAssumption \triangleq \land MaxBallot \in Nat \land MaxBallot \geq 2$$

$$TGuardAssumption \triangleq \land TGuard \in Nat \land TGuard \geq 1$$

$$TLeaseAssumption \triangleq \land TLease \in Nat \land TLease \geq 1$$

$$MaxTimeAssumption \triangleq \land MaxTime \in Nat \land MaxTime \geq TGuard + TLease$$

$$NodeFailuresOnAssumption \triangleq NodeFailuresOn \in \text{BOOLEAN}$$

ASSUME $\land ReplicasAssumption \land WritesAssumption \land ReadsAssumption \land MaxBallotAssumption \land TGuardAssumption \land TLeaseAssumption \land MaxTimeAssumption \land NodeFailuresOnAssumption$

Useful constants & typedefs.

$$Commands \triangleq Writes \cup Reads$$

$$NumWrites \triangleq Cardinality(Writes)$$

$NumReads \triangleq Cardinality(Reads)$

$NumCommands \triangleq Cardinality(Commands)$

$Range(seq) \triangleq \{seq[i] : i \in 1 \,..\, Len(seq)\}$

Client observable events.

$$\begin{aligned} ClientEvents \triangleq\ & [type : \{\text{“Req”}\},\ cmd : Commands] \\ \cup\ & [type : \{\text{“Ack”}\},\ cmd : Commands, \\ & \qquad val\ : \{\text{“nil”}\} \cup Writes, \\ & \qquad by : Replicas] \end{aligned}$$

$ReqEvent(c) \triangleq [type \mapsto \text{“Req”},\ cmd \mapsto c]$

$AckEvent(c, v, n) \triangleq [type \mapsto \text{“Ack”},\ cmd \mapsto c,\ val \mapsto v,\ by \mapsto n]$

val is the old value for a write command

$$\begin{aligned} InitPending \triangleq\ & (\text{CHOOSE } ws \in [1 \,..\, Cardinality(Writes) \to Writes] \\ & \qquad : Range(ws) = Writes) \\ \circ\ & (\text{CHOOSE } rs \in [1 \,..\, Cardinality(Reads) \to Reads] \\ & \qquad : Range(rs) = Reads) \end{aligned}$$

Server – side consensus constants & states.

$Ballots \triangleq 1 \,..\, MaxBallot$

$Slots \triangleq 1 \,..\, NumWrites$

$InfinitySlot \triangleq NumWrites + 1$

sentinel “infinitely-high” *slot, used as commitPrev s*

safe “haven’t learned yet” marker

$$\begin{aligned} Rosters \triangleq\ & \{ros \in [bal : Ballots, \\ & \qquad leader : Replicas, \\ & \qquad responders : \text{SUBSET } Replicas] : \\ & ros.leader \notin ros.responders\} \end{aligned}$$

for a smaller state space we exclude leader from the literal set of *responders* (but always treating it as a responder)

$Roster(b, l, resps) \triangleq [bal \mapsto b,\ leader \mapsto l,\ responders \mapsto resps]$

each new ballot number maps to a new roster; this includes the change of leader (as in classic *MultiPaxos*) and/or the change of who’re *responders*

$NullRoster \triangleq [bal \mapsto 0,\ leader \mapsto \text{“none”},\ responders \mapsto \{\}]$

$Statuses \triangleq \{\text{“Preparing”}, \text{“Accepting”}, \text{“Committed”}\}$

$$\begin{aligned} InstStates \triangleq\ & [status : \{\text{“Empty”}\} \cup Statuses, \\ & \quad write : \{\text{“nil”}\} \cup Writes, \\ & \quad voted : [bal : \{0\} \cup Ballots, \\ & \qquad write : \{\text{“nil”}\} \cup Writes]] \end{aligned}$$

$$\begin{aligned} NullInst \triangleq\ & [status \mapsto \text{“Empty”}, \\ & \quad write \mapsto \text{“nil”}, \\ & \quad voted \mapsto [bal \mapsto 0,\ write \mapsto \text{“nil”}]] \end{aligned}$$

Lease-side constants & typedefs.

$Times \triangleq 1 \,..\, MaxTime$

$ExpireTimes \triangleq 0 \,..\, (MaxTime + TGuard + TLease)$

stored expiration / guard deadlines; 0 is the "null" time

$SeqNums \triangleq Nat$

per-pair monotone *seq* nums on lease messages for dedup

$GrantorStatuses \triangleq \{\text{“None”}, \text{“Guarding”}, \text{“Renewing”}, \text{“Revoking”}\}$
$GranteeStatuses \triangleq \{\text{“None”}, \text{“Guarded”}, \text{“Renewed”}\}$

$$\begin{aligned} GrantorState \triangleq [&status : GrantorStatuses,\\ &guardExpire : ExpireTimes,\\ &leaseExpire\ \ : ExpireTimes,\\ &ros : \{NullRoster\} \cup Rosters,\\ &seq : SeqNums] \end{aligned}$$

$$\begin{aligned} GranteeState \triangleq [&status : GranteeStatuses,\\ &guardExpire : ExpireTimes,\\ &leaseExpire\ \ : ExpireTimes,\\ &ros : \{NullRoster\} \cup Rosters,\\ &seq : SeqNums] \end{aligned}$$

$$\begin{aligned} NullGrantorState \triangleq [&status \mapsto \text{“None”},\\ &guardExpire \mapsto 0,\\ &leaseExpire\ \ \mapsto 0,\\ &ros \mapsto NullRoster,\\ &seq \mapsto 0] \end{aligned}$$

$$\begin{aligned} NullGranteeState \triangleq [&status \mapsto \text{“None”},\\ &guardExpire \mapsto 0,\\ &leaseExpire\ \ \mapsto 0,\\ &ros \mapsto NullRoster,\\ &seq \mapsto 0] \end{aligned}$$

Merged per-node state: consensus *fields* + lease *fields*.

$$\begin{aligned} NodeStates \triangleq [&leader : \{\text{“none”}\} \cup Replicas,\\ &commitUpTo : \{0\} \cup Slots,\\ &commitPrev\ \ : \{0\} \cup Slots \cup \{InfinitySlot\},\\ &balPrepared\ \ \ \ : \{0\} \cup Ballots,\\ &balMaxKnown : \{0\} \cup Ballots,\\ &rosMaxKnown : \{NullRoster\} \cup Rosters,\\ &insts : [Slots \to InstStates],\\ &asGrantor : [Replicas \to GrantorState],\\ &asGrantee : [Replicas \to GranteeState]] \end{aligned}$$

$$\begin{aligned} NullNode \triangleq [&leader \mapsto \text{“none”},\\ &commitUpTo \mapsto 0,\\ &commitPrev\ \ \mapsto 0,\\ &balPrepared\ \ \ \ \mapsto 0,\\ &balMaxKnown \mapsto 0,\\ &rosMaxKnown \mapsto NullRoster,\\ &insts \mapsto [s \in Slots \mapsto NullInst],\\ &asGrantor \mapsto [p \in Replicas \mapsto NullGrantorState],\\ &asGrantee \mapsto [f \in Replicas \mapsto NullGranteeState]] \end{aligned}$$

commitPrev is the last slot which might have been committed by an old leader; a newly joined node can safely serve reads locally only after its log has been committed up to this slot

rosMaxKnown is the roster that came with *balMaxKnown*

$asGrantor[p]$ is the grantor-side lease state & timers toward grantee p; $asGrantee[f]$ is the grantee-side state for grantor f

$$FirstEmptySlot(insts) \triangleq$$
IF $\forall s \in Slots : insts[s].status \neq$ "Empty"
THEN $InfinitySlot$
ELSE CHOOSE $s \in Slots :$
$\wedge\, insts[s].status =$ "Empty"
$\wedge \forall t \in 1 \,..\, (s-1) : insts[t].status \neq$ "Empty"

$$LastNonEmptySlot(insts) \triangleq$$
IF $\forall s \in Slots : insts[s].status =$ "Empty"
THEN 0
ELSE CHOOSE $s \in Slots :$
$\wedge\, insts[s].status \neq$ "Empty"
$\wedge \forall t \in (s+1) \,..\, NumWrites : insts[t].status =$ "Empty"

Service-internal consensus messages.

$$PrepareMsgs \triangleq [type : \{\text{"Prepare"}\}, src : Replicas, bal : Ballots]$$

algorithm *Bodega*

variable $msgs = \{\}$, messages in the network
$node = [r \in Replicas \mapsto NullNode]$, replica merged state
$pending = InitPending$, sequence of pending reqs
$observed = \langle\rangle$, client observed events
$crashed = [r \in Replicas \mapsto \text{FALSE}]$, replica crashed flag
$time = [r \in Replicas \mapsto 1]$; per-node monotone clock

define

A lease from grantee p's perspective is "active" iff p's $asGrantee[f]$ is in *Renewed* status, un-expired, and recording roster ros.

$$FGrantsPWithRos(f, p, ros) \triangleq \begin{array}{l} \land\, node[p].asGrantee[f].status = \text{"Renewed"} \\ \land\, node[p].asGrantee[f].leaseExpire > time[p] \\ \land\, node[p].asGrantee[f].ros = ros \end{array}$$

True if a node r thinks of itself as leader of the latest roster.

$$\begin{array}{l} ThinkAmLeader(r) \triangleq \\ \quad \textsc{let}\ ros \triangleq node[r].rosMaxKnown \\ \quad \textsc{in}\ \ \land\, node[r].leader = r \\ \qquad \land\, node[r].balPrepared = node[r].balMaxKnown \\ \qquad \land\, ros.bal = node[r].balMaxKnown \\ \qquad \land\, ros.leader = r \\ \qquad \land\, Cardinality(\{f \in Replicas : \\ \qquad\qquad FGrantsPWithRos(f, r, ros)\}) \\ \qquad\quad \geq MajorityNum \end{array}$$

True if a node r thinks of itself as a follower of the latest roster.

$$\begin{array}{l} ThinkAmFollower(r) \triangleq \\ \quad \textsc{let}\ ros \triangleq node[r].rosMaxKnown \\ \quad \textsc{in}\ \ \land\, node[r].leader \neq r \\ \qquad \land\, ros.bal = node[r].balMaxKnown \\ \qquad \land\, ros.leader \neq r \\ \qquad \land\, ros.leader \neq \text{"none"} \\ \qquad \land\, Cardinality(\{f \in Replicas : \\ \qquad\qquad FGrantsPWithRos(f, ros.leader, ros)\}) \\ \qquad\quad \geq MajorityNum \end{array}$$

True if a node r thinks of itself as a responder of the latest roster.

$$\begin{array}{l} ThinkAmResponder(r) \triangleq \\ \quad \land\, ThinkAmFollower(r) \\ \quad \land\, r \in node[r].rosMaxKnown.responders \end{array}$$

The "safety threshold" condition: a node serves a read locally only if it has committed up to where previous leaders could have committed.

$$BallotTransferred(r) \triangleq node[r].commitUpTo \geq node[r].commitPrev$$

Given caller node r (a leader or a responder) and a set of $AcceptReplies$, decide whether the write is committable: majority quorum AND the caller's known roster's *responders* all voted.

$$\begin{array}{l} WriteCommittable(r, ars) \triangleq \\ \quad \textsc{let}\ acceptors \triangleq \{ar.src : ar \in ars\} \\ \quad \textsc{in}\ \ \land\, Cardinality(acceptors) \geq MajorityNum \\ \qquad \land\, node[r].rosMaxKnown.responders \subseteq acceptors \end{array}$$

When node r's ballot rises to nb, any live outgoing grant whose roster is at an older ballot must be revoked: *Guarding* grants reset locally, *Renewing* grants move to *Revoking* with *seq* bumped. Expired grants are untouched (cleared later by $TimeTick$).

$$\begin{array}{l} RevokeStaleAsGrantor(r, nb) \triangleq \\ \quad [p \in Replicas \mapsto \\ \qquad \textsc{let}\ g \triangleq node[r].asGrantor[p] \\ \qquad \textsc{in}\ \ \textsc{if}\ \ \land\, g.ros.bal < nb \\ \qquad\qquad\qquad\ \ \land\, g.status = \text{"Guarding"} \\ \qquad\qquad\qquad\ \ \land\, g.guardExpire > time[r] \end{array}$$

```

Abstract

In proof-of-stake blockchains based on State Machine Replication (SMR), the order of transactions directly affects client-visible financial outcomes. *Ordered consensus* augments the SMR specification by imposing correctness conditions on transaction ordering, with a focus on limiting Byzantine influence. However, real-world ordering attacks can occur even when these conditions hold, often enabled by advantages such as faster networks or proximity to the blockchain infrastructure that allow an adversary to systematically bias outcomes without violating the conditions. To address this gap, we extend ordered consensus with a new model and correctness condition based on *equal opportunity*, a notion of fairness widely used in legal contexts. Equal opportunity requires that candidates who are equally qualified—according to criteria deemed *relevant*—have equal chances of being selected (here, for a given position in the total order). We show how carefully introduced randomness can bound ordering bias, and we introduce the Secret Random Oracle (SRO), a fault-tolerant abstraction for generating such randomness. We present two SRO constructions, based on trusted hardware and threshold verifiable random functions, respectively, and use them to build Pompē-SRO, a new ordered consensus protocol that mitigates well-known ordering attacks. Our evaluation shows that Pompē-SRO effectively mitigates front-running and sandwich attacks at a moderate cost to latency.

1 Introduction

This paper extends *ordered consensus* [81] by motivating, expressing, and enforcing *equal opportunity*, a correctness condition governing how a state machine replication (SMR) [72] protocol orders client requests.

At its core, SMR requires a set of replicas to agree on a single, totally ordered sequence of client requests (*i.e.,* a ledger). When SMR is used for fault tolerance, this order serves only to ensure that all correct replicas process requests consistently. As long as all requests from correct clients eventually appear in the ledger, their relative order does not affect correctness. In blockchains, however, the specific order matters, as it can directly impact the financial rewards associated with the transactions recorded in the ledger.

Ordered consensus [81] formalizes correctness conditions on this order. Each replica associates an *ordering indicator* (*e.g.,* a timestamp) with every client request, expressing how it prefers to order requests relative to one another. Using these indicators, one can show that while Byzantine influence over the ledger order cannot be eliminated, it can be curtailed. In particular, ordered consensus can guarantee *ordering linearizability*: if the lowest indicator assigned by any correct node for command c_2 exceeds the highest indicator assigned to c_1, then c_1 appears before c_2 in the ledger. This guarantee is enforced by the Pompē protocol [81].

The starting point of this paper is the observation that limiting Byzantine influence alone is not sufficient: ordering linearizability fails to capture fairness requirements arising in real-world ordering-based attacks with significant financial consequences [68]. Ordering linearizability only constrains the order of requests whose timestamps are unambiguously separated; it says nothing about how to order requests that arrive close together in time, leaving room for network advantages to systematically determine outcomes.

Consider, for example, the unfair practice known in financial markets as *front-running*, in which a party learns of a large pending buy order for a certain stock and submits its own buy order in advance, so it can later profit from the price increase driven by the ensuing large buy order. Such behavior has been widely documented in both traditional financial markets [57] and decentralized ones [37, 75], often enabled by advantages such as lower network latency. While financial regulations prohibit these practices, Pompē does not prevent them: requests from clients with faster network access are likely to appear earlier in the output ledger.

Our first contribution is a model of fairness grounded in real-world concerns. Drawing on the legal and economic literature on *equal opportunity*, we observe that, whenever items are ranked, their positions depend on their characteristics (or *features*). Some features are deemed *relevant* to the rank-

*The first two authors contributed equally to this work.

ing's purpose, while others are *irrelevant*. For example, U.S. employers and lending agencies are legally forbidden from considering certain irrelevant features (so-called *protected classes*) when making decisions [1, 2]. Intuitively, a fair ranking depends only on relevant features and ignores all others: entries with indistinguishable relevant features should have equal chances of being ranked ahead of one another.

Building on the expressiveness of ordered consensus, we instantiate this notion of equal opportunity for blockchains. In this context, two features are typically considered relevant: the *time* at which clients submit requests and the *fee* they attach to them. Other features, such as geographic location, are irrelevant. Existing ordered consensus protocols, however, do not distinguish between relevant and irrelevant features, nor do they reason about this distinction. As a result, protocols such as Pompē [81], Aequitas [50], and Themis [49] remain vulnerable to adversaries that exploit irrelevant features—for example, faster network connectivity—to perform front-running and related attacks, such as *sandwich attacks*.

Our second contribution is to formalize this notion through two correctness conditions: ε-*Ordering Equality* and Δ-*Ordering Separation*. Informally, ε-Ordering Equality requires that, for requests issued at the same time, the probability of any permutation deviates from the uniform distribution by at most ε. Δ-*Ordering Separation* ensures that, for requests submitted at least Δ time apart, the earlier request precedes the later one in the ledger.

To enforce these conditions, we introduce the Secret Random Oracle (SRO), an abstraction that provides a fault-tolerant and unbiased source of randomness. The SRO is used to inject controlled randomness into the final order derived from replicas' ordering indicators. We present two SRO designs: one based on Trusted Execution Environments (TEEs) and one based on threshold verifiable random functions [30, 40]. Because the profitability of front-running and sandwich attacks depends on obtaining a specific ordering of requests, introducing randomness reduces the likelihood of adversarially preferred outcomes and thereby mitigates them.

Our third contribution is to characterize the trade-off between ε-Ordering Equality and Δ-Ordering Separation. Ideally, both ε and Δ would be small. However, while increasing randomness mitigates the attacks, it can also compromise the role of a request's *relevant* features in determining its position in the ledger: thus, decreasing ε comes at the price of increasing the Δ required to ensure that requests separated in time are ordered correctly despite Byzantine behavior.

Finally, we explore the practical implications of this trade-off by designing, implementing, and evaluating Pompē-SRO, a new ordered consensus protocol for the *partially synchronous* model [38] introduced to circumvent the impossibility of achieving safe, live, and fault-tolerant consensus in fully asynchronous systems [39]. Pompē-SRO is always safe and guarantees liveness during sufficiently long periods of synchrony (formally, after some unknown Global Stabilization Time). During such periods, Pompē-SRO enforces both ε-Ordering Equality and Δ-Ordering Separation. Pompē-SRO extends Pompē by injecting SRO-generated noise into the fault-tolerant timestamps used to order client requests.

Our evaluation shows that Pompē-SRO can be effective in mitigating front-running and sandwich attacks while incurring moderate performance overhead. For example, when adding random noise sampled from $[0, 5\Delta_{net}]$, where Δ_{net} bounds message delay during synchronous periods (*e.g.,* $\Delta_{net} = 400$ms in Solana Alpenglow [51]), Pompē-SRO maintains ε below 5%—a threshold considered acceptable in other equal-opportunity contexts [2, 3]—while matching Pompē's throughput. The added noise increases the median and 99th-percentile latency by $1.12\times$–$1.42\times$ in a geo-distributed deployment spanning 12 cities.

2 Equal opportunity

Consider a system in which clients invoke commands, and nodes (*i.e.,* servers) aim to produce a total order that reflects the time at which commands are invoked—earlier commands should precede later ones.

2.1 Motivating equal opportunity

Informally, if two commands have the same invocation time, equal opportunity requires the two possible orders to be equally likely in the system output. Similarly, if three commands are invoked at the same time, all six possible orders should be equally likely. To illustrate how equal opportunity is violated in practice, we analyze publicly available traces from Ethereum.

Bias under two concurrent invocations. Violations of equal opportunity with two concurrent invocations not only indicate bias but can also enable front-running [37, 75]. Empirical studies show that both phenomena have significantly affected the allocation of $89M over 32 months in the Ethereum blockchain [68]. Although Ethereum has since transitioned from proof-of-work to proof-of-stake [11], the ordering problem we study depends only on the semantics of client requests; we defer a discussion of proof-of-stake to Section 4.

In Ethereum, an invocation originating in Europe is more likely to precede a simultaneous one from Australia because a larger fraction of Ethereum nodes are located in Europe. If the system orders European invocations before Australian ones more than half the time, we say it is *biased* toward Europe. Geographic location is an *irrelevant* feature (a protected characteristic) under equal-opportunity legislation [1], yet such bias has been observed in Ethereum and other blockchains [61].

This bias can lead to significant consequences in applications such as blockchain liquidations. In traditional finance, liquidation occurs when an asset is sold below market value to repay debt, creating profit opportunities for buyers. Similar

Output order	Victim's profit	Attacker's profit
i_2, i_1, i_3	-$500	$800
i_3, i_1, i_2	$700	-$400
other order	$300	$0

Figure 1: An example of a sandwich attack in which a victim invokes i_1 and an attacker invokes i_2 and i_3. The example is drawn from a decentralized exchange; details of the associated values are explained in Section 5.2.

$$I_{gt} = \{\langle c_1, \langle 5\text{pm}\rangle\rangle_{i_1}, \langle c_2, \langle 5\text{pm}\rangle\rangle_{i_2}, \langle c_3, \langle 5{:}01\text{pm}\rangle\rangle_{i_3}\}$$
$$\mathcal{P}_1 = \langle\{\langle i_1, 1\rangle, \langle i_2, 2\rangle, \langle i_3, 3\rangle\}\rangle$$
$$\mathcal{P}_2 = \langle\{\langle i_2, 1\rangle, \langle i_1, 2\rangle, \langle i_3, 3\rangle\}\rangle$$

Figure 2: In a system that uses invocation time as the only relevant feature and sequence numbers as ordering indicators, impartiality requires preference profiles $\mathcal{P}_1$ and $\mathcal{P}_2$ to be equally likely.

mechanisms exist in blockchains, where they provide a common profit mechanism in the stablecoin [6] and lending [9] applications. The buyer whose command is ordered first on the blockchain is typically the one to realize the profit.

Consider two clients, one in Europe and one in Australia, invoking a liquidation simultaneously, trying to secure a $200K profit. If the system orders the European request first with probability 0.75, then the expected profit is $0.2M $\times$ 0.75 = $150K for the European client and $0.2M $\times$ 0.25 = $50K for the Australian client. Thus, irrelevant features can lead to substantial disparities among clients that should be treated equally. Similarly, a client intent on becoming the beneficiary of a liquidation's profits could leverage faster network devices to further bias ordering and front-run other clients.

Three-invocation sandwich attack. Violations of equal opportunity under three simultaneous invocations enable sandwich attacks [82]. Empirical studies estimate such attacks extracted more than $174M over 32 months on Ethereum [68].

Figure 1 illustrates a sandwich attack observed in a decentralized exchange. After a victim submits command i_1, an attacker submits i_2 and i_3. The attacker profits only if the system outputs the order i_2, i_1, i_3. Thus, a successful attack relies on making this particular ordering significantly more likely than equal opportunity would permit. A common strategy is to privately relay i_2 and i_3 to colluding nodes that then exclusively propose blocks containing the order i_2, i_1, i_3 [68]. While attackers are free to choose their trading strategy, and different strategies may lead to different expected profits, the system should not allow them to influence the probabilities of its possible outputs. Under equal opportunity, all six permutations of the three commands should occur with equal (or near-equal) likelihood.

2.2 A model for equal opportunity

We model equal opportunity in terms of two classical principles from the economics literature [79]: *impartiality* and *consistency*. In our setting, impartiality captures the idea that irrelevant features (*e.g.*, client geolocation) should not affect the order of commands, while consistency requires that introducing new commands should not alter the relative ordering of existing ones. Together, these principles suggest a natural mechanism for enforcing equal opportunity: a *point system*.

We now formalize these principles in the client-server setting and the ordered consensus framework [81].

Client invocation. An *invocation* is a pair $\langle c, \vec{f_r}\rangle$, where c is a command and $\vec{f_r}$ is a vector of relevant features, *i.e.,* the only attributes that should influence the command's position in the order. Irrelevant features include, for example, client identity, geographic location, wealth, and network connectivity. In blockchain settings, relevant features typically include invocation time and transaction fee. An *invocation profile*, denoted I, is a set of invocations.

Node preference. Given an invocation profile I, each node observes the invocations and expresses a *preference*. A preference is a set of pairs $\langle i, o\rangle$, where i is an invocation and o is an ordering indicator (*e.g.*, a timestamp or score). Intuitively, ordering indicators encode how a node would rank invocations. A *preference profile*, denoted $\mathcal{P}$, is a vector of preferences from all correct nodes. We say that $\mathcal{P}$ is *well-formed* under I if it references only invocations in I.

Chance relation. In practice, due to nondeterminism (*e.g.*, network delays or scheduling effects), a given set of invocations may result in different preference profiles. We assume a ground-truth invocation profile I_{gt} and model the uncertainty in the preferences of correct nodes through *chance relations*. For two preference profiles $\mathcal{P}_1$ and $\mathcal{P}_2$ well-formed under I_{gt}, $\mathcal{P}_1 \succ_c \mathcal{P}_2$ denotes that $\mathcal{P}_1$ is more likely to occur than $\mathcal{P}_2$, and $\mathcal{P}_1 \sim_c \mathcal{P}_2$ denotes that they occur with equal likelihood. Note that $\mathcal{P}_1 \sim_c \mathcal{P}_2$ is equivalent to $\neg(\mathcal{P}_1 \succ_c \mathcal{P}_2) \wedge \neg(\mathcal{P}_2 \succ_c \mathcal{P}_1)$.

Impartiality. Impartiality requires that invocations with identical relevant features be treated symmetrically. Formally, for any $i_1, i_2 \in I_{gt}$ with identical $\vec{f_r}$, a system is *impartial* if and only if swapping i_1 and i_2 in any preference profile does not change its likelihood. That is, if $\mathcal{P}_2$ is obtained from $\mathcal{P}_1$ by swapping i_1 and i_2, then $\mathcal{P}_1 \sim_c \mathcal{P}_2$.

Impartiality is the first pillar of equal opportunity and it is illustrated in Figure 2. If i_1 and i_2 share the same relevant feature (*e.g.*, invocation time), then their relative order must be independent of irrelevant features and $\mathcal{P}_1$ and $\mathcal{P}_2$ must be equally likely.

Consistency. Consistency, the second pillar of equal opportunity, requires that the relative ordering of invocations depend only on their own features and not on the presence or absence of other invocations. Figure 3 illustrates this principle: the

$$I_{gt} = \{\langle c_1, 1\text{pm}\rangle_{i_1}, \langle c_2, 1{:}01\text{pm}\rangle_{i_2}, \langle c_3, 1{:}05\text{pm}\rangle_{i_3}\}$$
$$\mathcal{P}_1 = \langle\{\langle i_1,1\rangle, \langle i_2,2\rangle\}\rangle \quad \mathcal{P}_3 = \langle\{\langle i_1,1\rangle, \langle i_2,2\rangle, \langle i_3,3\rangle\}\rangle$$
$$\mathcal{P}_2 = \langle\{\langle i_1,2\rangle, \langle i_2,1\rangle\}\rangle \quad \mathcal{P}_4 = \langle\{\langle i_1,2\rangle, \langle i_2,1\rangle, \langle i_3,3\rangle\}\rangle$$

Figure 3: An example of consistency where $I_1 = \{i_1, i_2\}$ and $I_2 = \{i_3\}$. This example originates from real-world legislation on equal opportunity in the context of kidney exchange, as explained in Section 6.

key idea is that the relative ordering of i_1 and i_2 should be unaffected by the presence or absence of a third invocation i_3. Consistency requires $\mathcal{P}_1 \succ_c \mathcal{P}_2 \iff \mathcal{P}_3 \succ_c \mathcal{P}_4$: the order of i_1 and i_2 should depend solely on their *own* relevant features.

Let $\mathcal{P}_1 =_I \mathcal{P}_2$ denote that $\mathcal{P}_1$ and $\mathcal{P}_2$ agree on invocations in I, and let $I_{gt} = \{I_1, I_2\}$ denote a partition. A system is *consistent* if and only if, for all preference profiles $\mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3, \mathcal{P}_4$ well-formed under I_{gt}, whenever $\mathcal{P}_1 =_{I_1} \mathcal{P}_3$, $\mathcal{P}_2 =_{I_1} \mathcal{P}_4$, $\mathcal{P}_1 =_{I_2} \mathcal{P}_2$, and $\mathcal{P}_3 =_{I_2} \mathcal{P}_4$, it holds that $\mathcal{P}_1 \succ_c \mathcal{P}_2 \iff \mathcal{P}_3 \succ_c \mathcal{P}_4$.

Point systems. A natural way to satisfy both principles is through a *point system*. In such a system, each invocation is assigned a score that depends only on its relevant features. Invocations are ordered by their scores, breaking ties uniformly at random.

A point system satisfies impartiality because identical relevant features yield identical scores, leading to symmetric treatment. It satisfies consistency because each score depends only on the invocation itself, and is therefore independent of other invocations.

Indeed, in a different model, point systems have been shown to be the only mechanisms that satisfy both impartiality and consistency [79]. Establishing an analogous result in the ordered consensus model remains an interesting direction for future work.

2.3 Correctness conditions for systems

In computer systems, invocation time is the primary relevant feature: commands are intended to be ordered according to *when* they are invoked. In principle, equal opportunity can be enforced by a point system that uses the invocation time as the score.

In practice, however, invocation time cannot be measured precisely. Nodes can only observe when they receive a command, and these observations are affected not only by the true invocation time but also by irrelevant features such as network latency and geographic location. As a result, a perfect point system based on exact invocation times is unattainable.

To accommodate this uncertainty, we relax the point-system ideal using two parameters, ε and Δ, and define the corresponding correctness conditions: ε-*Ordering Equality* and Δ-*Ordering Separation*. These can be viewed as approximate counterparts of earlier principles: ε-Ordering Equality relaxes impartiality by allowing small deviations from uniform ordering, while Δ-Ordering Separation relaxes consistency by tolerating bounded uncertainty in invocation times.

ε-Ordering Equality. This condition captures approximate fairness among invocations with identical relevant features. For any subset $I \subseteq I_{gt}$ in which all invocations share the same invocation time, let n denote the number of invocations in I. For any total order $\succ$ over I, $|Pr[\succ] - \frac{1}{n!}| \leq \varepsilon(n)$.

Here, $\varepsilon(n)$ bounds how far the distribution over permutations can deviate from uniform. When $\varepsilon = 0$, all permutations are equally likely, recovering impartiality. More generally, smaller values of ε ensure that invocations with identical relevant features have similar chances of appearing in any position, approximating how a point system breaks ties.

Δ-Ordering Separation. This condition captures the ability to respect differences in invocation time. It requires that for any invocations $i_1, i_2 \in I_{gt}$, if i_1 is invoked at least Δ time units before i_2, then i_1 precedes i_2 in the system output.

Intuitively, Δ represents the minimum separation required for the system to reliably distinguish between two invocations despite noise in timing observations. Smaller values of Δ correspond to stronger guarantees that earlier invocations appear earlier in the output.

Ideally, one would like $\varepsilon = 0$ and $\Delta = 0$, in which case both perfect fairness and perfect temporal ordering are achieved. This ideal is attainable (alas, only) in an idealized setting where all nodes are correct and observe invocation times without error, as captured by the following theorem.

Theorem 2.1. *If all nodes are correct and accurately measure the invocation time of all invocations, ordering equality and ordering separation with $\varepsilon = \Delta = 0$ can be achieved using a point system.*

Proof. Assuming all observations are accurate to a certain time unit (*e.g.*, microsecond), a straightforward approach is to assign each invocation a score equal to its observed invocation time. In such a point system, we have: (1) all invocations are sorted by this score in ascending order; and (2) the order of invocations with the same score is chosen uniformly at random from all permutations. (1) guarantees $\Delta = 0$ because invocations with different observed invocation times are guaranteed to be ordered in the order they are invoked. (2) guarantees $\varepsilon = 0$ because any two total orders have the same probability when chosen uniformly at random. □

2.4 Mitigating ordering-based attacks

A system that enforces equal opportunity can significantly mitigate ordering-based attacks, though it does not necessarily make them completely unprofitable. In existing systems, victims of front-running attacks are likely to incur losses because the system is biased toward clients with lower network

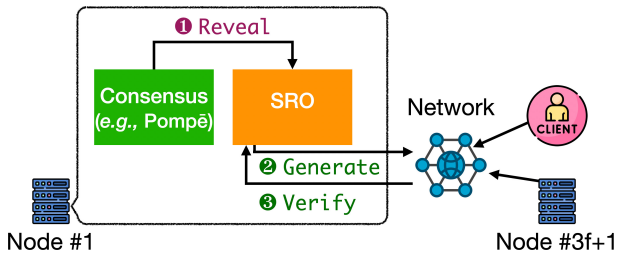

Figure 4: The protocol design overview of Pompē-SRO. The consensus component invokes the `Reveal` interface, which returns a random number. The TEE-based SRO returns the random number immediately. The TVRF-based SRO sends a message generated by the `Generate` interface and verifies messages received from other nodes. After receiving enough valid messages, the SRO will construct and return a random number to the consensus component.

latency. Under equal opportunity, this advantage is reduced: the gap between an attacker (who may have superior network access) and a victim narrows, as the system treats competing requests more uniformly. The ideal case of equal opportunity, with $\varepsilon = \Delta = 0$, provides the strongest possible mitigation that is agnostic to the semantics of client commands. Further reducing an attacker's advantage would require identifying and treating certain commands as adversarial, which risks introducing new sources of bias.

3 Secret Random Oracle

The point-system abstraction suggests that randomness is essential for achieving ordering equality. Crucially, this randomness must remain hidden until after other system components commit to their outputs; otherwise, adversaries could exploit it to bias ordering. We address this requirement with the *Secret Random Oracle* (SRO), a system component that generates random values and reveals them only after a coordinated commit, preventing ordering decisions from depending on them.

Design overview. Figure 4 shows how the SRO integrates with a consensus system. We consider a BFT system with $n = 3f + 1$ nodes running a protocol such as Pompē [81]. When using a point-system approach, the consensus component invokes the SRO to obtain randomness via the `Reveal` interface.

We present two realizations of the SRO abstraction. A TEE-based design generates and reveals randomness locally without network communication. A cryptographic design based on Threshold Verifiable Random Functions (TVRF) requires communication: nodes invoke `Generate` to produce messages, use `Verify` to validate them, and combine sufficiently many valid messages to recover the random value.

The remainder of this section details the SRO interface and its guarantees (§3.1), presents two concrete realizations

```
Reveal(Int k, Set<Signature> s) → Int | Error
Generate(Int k) → Proof
Verify(Int k, Proof p, Int r) → Bool
```

Figure 5: The interface of a Secret Random Oracle (SRO).

based on trusted hardware (§3.2) and cryptography (§3.3), shows how SRO integrates into Pompē-SRO to enforce the desired ordering properties(§3.4), and quantifies the fundamental trade-off that exists in trying to achieve both ε-Ordering Equality and Δ-Ordering Separation(§ 3.5).

3.1 SRO interface and guarantees

The SRO provides a simple abstraction for generating and revealing random values in a coordinated and adversary-resistant manner.

We consider a system with n nodes, at most f of which may be Byzantine. Each node holds a private key and knows the public keys of all others. A function (not shown) maps an integer k to a pseudorandom number. The SRO interface, shown in Figure 5, consists of three operations:

- `Reveal(k, s)` returns the output of the pseudorandom function evaluated at k, once s distinct signatures indicate a quorum of nodes wishes to disclose it.
- `Generate(k)` takes in k and produces a cryptographic proof.
- `Verify(k, p, r)` given a proof p, checks whether the value r returned when invoking `Reveal` on k is correct.

`Reveal(k)` returns its output only after enough nodes signal their readiness to do so. This ensures that randomness remains hidden until it can no longer influence earlier decisions.

The SRO provides the following guarantees.

Uniqueness. All valid invocations of `Reveal(k)` return the same value. A set of signatures is valid if it contains valid signatures on k from at least $n-f$ distinct nodes. Invalid inputs cause `Reveal` to return an error.

Secrecy. For any k, let r be the value returned by `Reveal(k)`. If an adversary does not obtain valid signatures from $n-f$ nodes, it is computationally infeasible to distinguish with non-negligible probability r from a uniform random value.

Randomness. For all k, the value r returned by `Reveal(k)` is a non-error uniform random sample from its codomain.

Validity. If `Generate(k)` outputs proof p and `Reveal(k)` returns r, then `Verify(k, p, r)` returns `True`, and it is computationally infeasible to find some integer $r' \neq r$ such that `Verify(k, p, r')` also returns `True`.

3.2 An SRO design using trusted hardware

Trusted Execution Environments (TEEs) provide secure enclaves that protect the integrity and confidentiality of code and data. They have already been used in blockchain systems such as Ethereum's Sepolia testnet [12] and Solana's Block Assembly Marketplace [21]. Here, we show how they can be used to implement an SRO.

Initialization. Each node hosts a TEE running the SRO logic. During initialization, TEEs generate candidate random values (*e.g.*, via `RDRAND` in x86) and run a consensus protocol to agree on a shared secret one. This number remains confined within the TEEs and will be used as the `seed` of a pseudorandom function denoted as `RAND`.

Reveal, Generate and Verify. To invoke `Reveal`, a node forwards an integer and a set of signatures to its local TEE, which returns `RAND(seed, k)` if enough valid signatures are present; otherwise, it returns an error. Similarly, `Generate` forwards `k` to the TEE, which returns `HASH(RAND(seed, k))` where `HASH` is a one-way function. Lastly, `Verify` checks that its parameter `p` equals `HASH(r)`.

Correctness. Determinism of `RAND` ensures uniqueness, while its pseudorandomness guarantees randomness. Secrecy follows from TEE confidentiality, and validity from the collision resistance of the hash function.

We assume that initialization (*i.e.,* consensus on the random seed) eventually completes, thereby ensuring liveness: all invocations of SRO operations on correct nodes eventually terminate.

3.3 An SRO design using threshold VRF

A Threshold Verifiable Random Function (TVRF) is a cryptographic primitive that enables a set of nodes to jointly evaluate a pseudorandom function in a distributed and fault-tolerant manner [30,40]. Such constructions have been widely used in Byzantine agreement protocols for tasks such as committee selection and randomized consensus.

In our setting, a TVRF provides a natural way to implement the SRO abstraction: random values are generated collaboratively and remain unpredictable until sufficiently many nodes agree to disclose them.

Let `TVRF` denote a pseudorandom function mapping an integer k to a pseudorandom value. Figure 6 shows the interface for evaluating `TVRF(k)`. Each node invokes `Produce(k)` to generate a *share* using its private key. After collecting enough valid shares, a node invokes `Combine` to recover `TVRF(k)`. To handle Byzantine behavior, `Valid` checks the correctness of each share. TVRFs provide the following guarantees [30].

Robustness. For all integers `k`, it is computationally infeasible for an adversary to produce enough valid shares such that the integer output of `Combine` is not `TVRF(k)`.

Unpredictability. Without enough valid shares for `TVRF(k)`, an adversary cannot distinguish `TVRF(k)` from a uniform random sample with non-negligible probability.

```
Threshold VRF node-side function
Produce(Int k) → Share
Threshold VRF client-side functions
Combine(Set<Share> s) → Int | Error
Valid(Int k, Int node_id, Share s) → Bool
Modified node-side function for SRO
Produce(Int k, Set<Signature> s) → Share | Error
```

Figure 6: The interface of (modified) threshold VRF.

We make a slight modification to threshold VRF. For the `Produce` interface, we add a parameter: a set of signatures of `k` to be verified. If verification fails, correct nodes must return an error instead of a share. We can now design an SRO as follows: `Reveal` forwards the two parameters to all nodes, collects enough valid shares, and invokes `Combine`. `Generate` returns the set of public keys. `Verify` takes all the public keys and a set of shares as input and returns whether all the shares are valid (using the `Valid` interface).

Correctness. Under the random oracle model, a threshold VRF outputs cryptographically secure pseudorandom numbers. Robustness implies uniqueness and validity: for all integers `k`, combining enough valid shares can only produce `TVRF(k)`, since an adversary cannot create valid shares leading to a combined value different from `TVRF(k)`. Unpredictability implies secrecy because an adversary cannot obtain enough valid shares without valid signatures of `k` out of $n-f$ nodes, and without enough valid shares, it has no information about `TVRF(k)`. Liveness is ensured, assuming all network messages are eventually delivered.

3.4 Integrating an SRO with Pompē

We now introduce Pompē-SRO, which integrates an SRO with Pompē [81], a state-of-the-art ordered consensus protocol. The goal is to enforce the conditions in Section 2.3.

The Pompē protocol. Pompē employs any standard leader-based BFT SMR protocol (*e.g.,* [32]) that offers a primitive to agree on a value for each slot in a sequence of consensus decisions. Pompē transforms such a protocol into a new one that enforces correctness conditions on ordering.

Specifically, Pompē associates the slots with consecutive time intervals. For example, one slot may be associated with time interval $[t,\ t+500ms)$, and the next slot could be associated with interval $[t+500ms,\ t+1000ms)$. For simplicity, Pompē assumes that such a mapping from slots to time intervals is common knowledge. Within each consensus slot, the value to agree on is a set of $\langle c,\ ats\rangle$ pairs where c is a command and *ats* is called an *assigned timestamp*. Pompē provides two guarantees for this assigned timestamp: (1) *ats* falls in the time interval associated with the slot; (2) *ats* is

bounded by the lowest and highest timestamps provided by correct nodes. The commands are then ordered by their assigned timestamps.

Pompē requires $3f+1$ nodes and ensures guarantee (2) by collecting $2f+1$ timestamps from different nodes for each command c. The *median* of the $2f+1$ timestamps is chosen as the assigned timestamp *ats* for command c. Since there are at most f faulty nodes, the median of any $2f+1$ timestamps is upper-bounded and lower-bounded by timestamps provided by correct nodes.

Integrating Pompē with an SRO. Pompē-SRO augments Pompē by adding controlled randomness to the assigned timestamps of each command. After consensus is reached for slot `k`, a node obtains a quorum of signatures certifying the decision. Using `k` and these signatures, a correct node invokes `Reveal` and obtains a random seed to be used by the pseudorandom number generator. Crucially, this seed remains unknown until consensus is finalized, ensuring that it is independent of the consensus decision.

The pseudorandom number generator assigns an independent value r to each command, which is used to sample from a distribution D over $[0,\ \Delta_{noise}]$. Commands are then ordered by $ats + \texttt{sample}(D,r)$ instead of *ats* alone. Section 3.5 discusses how to select the distribution and Δ_{noise}.

Stability. A command is *stable* (or finalized) when it appears in the output ledger. In Pompē, stability coincides with reaching consensus. In Pompē-SRO, the added random noise may delay stability. Let the latest finalized slot correspond to interval $[ts, ts')$. A command c becomes stable when $ats + \texttt{sample}(D,r) < ts'$, ensuring that c and all preceding commands can be safely added to the output ledger.

Safety and liveness. Pompē guarantees the same safety and liveness properties as classic SMR protocols [32, 55]. Pompē-SRO inherits these guarantees and differs only in how commands are ordered. We now turn to proving the corresponding correctness conditions on ordering.

3.5 A trade-off between ε-Ordering Equality and Δ-Ordering Separation

The key question is how to choose the noise range Δ_{noise} and the distribution D used for random perturbation. We first derive a lower bound on $\varepsilon(2)$ for any fixed Δ, as a function of Δ_{noise} and the system parameter Δ_{net}, which bounds message delay, processing time, and clock drift under partial synchrony [38].

Partial synchrony model. One variant of the partial synchrony model introduces the *Global Stabilization Time* (GST) [38]. Specifically, there is an unknown time GST such that, after this time, there is a known bound Δ_{net} on network latency and processing time. The safety and liveness of Pompē are proven under this model. We now analyze the ordering properties of Pompē-SRO in the same model. More precisely:

Assumption 3.1. *After GST, if a command is invoked at time T, correct nodes will provide timestamps in the range $[T, T+\Delta_{net})$ for this command.*

Note that a simple clock synchronization protocol has been given as part of the Pompē protocol.

We now prove that any probability distribution D on $[0,\Delta_{noise}]$ achieves Δ-Ordering Separation with $\Delta = \Delta_{net} + \Delta_{noise}$ and, in the best case, provides ε-Ordering Equality with $\varepsilon(2) \geq \frac{1}{2(k+1)}$ (k is the natural number such that $k\Delta_{net} \leq \Delta_{noise} < (k+1)\Delta_{net}$). We also construct a discrete probability distribution that achieves this lower bound. These results establish a fundamental trade-off: improving ordering equality (reducing ε) necessarily worsens ordering separation (increasing Δ).

Lemma 3.1. *The assigned timestamp of a command is bounded by timestamps provided by correct nodes.*

Proof. See [81].

Theorem 3.1. *(Δ-Ordering Separation) After GST, for all invocations i_1 and i_2, if i_1 is invoked more than $\Delta_{net}+\Delta_{noise}$ time units earlier than i_2, then i_1 is guaranteed to appear before i_2 in the output.*

Proof. Suppose i_1 and i_2 are invoked at time T_1 and T_2. By Assumption 3.1 and Lemma 3.1, the assigned timestamp of i_1 is in the range $[T_1, T_1+\Delta_{net})$. After adding the random noise, the resulting timestamp is in the range $[T_1, T_1+\Delta_{net}+\Delta_{noise})$. Similarly, the resulting timestamp for i_2 is in the range $[T_2, T_2+\Delta_{net}+\Delta_{noise})$. Therefore, if $T_2 > T_1+\Delta_{net}+\Delta_{noise}$, i_2 will appear after i_1 in the output. □

Theorem 3.2. *($\varepsilon(2)$-Ordering Equality lower bound) After GST, for any probability distribution D on $[0,\Delta_{noise}]$, for all invocations i_1 and i_2 invoked at the same time, $|Pr[i_1 \prec i_2] - \frac{1}{2}| \geq \frac{1}{2(k+1)}$ where k is the natural number such that $k\Delta_{net} \leq \Delta_{noise} < (k+1)\Delta_{net}$.*

Proof. The key idea is that if two random samples fall within the same Δ_{net}-sized interval, their relative order can be determined by adversarially chosen timestamp differences.

Suppose i_1 and i_2 are both invoked at time T. By Assumption 3.1 and Lemma 3.1, the assigned timestamps are in the range $[T, T+\Delta_{net})$, which the adversary may pick. Let the two samples from D be $s_1, s_2 \in [0,\Delta_{noise}]$. Let k be the natural number defined above. We split the interval $[0,\Delta_{noise}]$ into $k+1$ buckets: $B_0 = [0,\Delta_{net}), B_1 = [\Delta_{net}, 2\Delta_{net}), \ldots, B_k = [k\Delta_{net}, \Delta_{noise}]$. If s_1 and s_2 fall into the same bucket, then $|s_1 - s_2| < \Delta_{net}$, and the adversary can decide the ordering of the two commands. Let the probability mass of D in those $k+1$ buckets be $pb_0, pb_1, \ldots, pb_k$. We know $\sum_i pb_i = 1$ and the probability that s_1 and s_2 fall into the same bucket is $\sum_i pb_i^2$. By the relation between the arithmetic mean and the quadratic mean, $\sum_i pb_i^2 \geq \frac{1}{k+1}$. Thus, the adversary can decide the ordering with at least a probability of $\frac{1}{k+1}$. This gives the lower bound $\varepsilon(2) \geq \frac{1}{2(k+1)}$. □

Theorem 3.3. *(Discrete distribution optimality) The above lower bound on* $\varepsilon(2)$ *can be achieved by setting D to be a discrete distribution that is uniformly random across the discrete points of* $0, \Delta_{net}, 2\Delta_{net}, \ldots, k\Delta_{net}$.

Proof. The proof of the lower bound above also shows us how to achieve Pareto-optimality, as the arithmetic mean only equals the quadratic mean if all elements are equal. This discrete distribution guarantees this lower bound of $\frac{1}{2(k+1)}$ for $\varepsilon(2)$, as two commands can only be ordered arbitrarily if they happen to get the same noise, which has a probability of exactly $\frac{1}{k+1}$ happening as the distribution has $k+1$ equally weighted outcomes. □

We defer the full proof of the general case $n > 2$ to the extended technical report [80]. As suggested in Section 2.1, real-world concerns about ordering could also arise due to violating ordering equality with three invocations (*i.e.,* enforcing $\varepsilon(3)$-Ordering Equality is necessary to mitigate sandwich attacks).

Theorem 3.4. *($\varepsilon(n)$-Ordering Equality) After GST, for all invocations $i_1..i_n$ invoked at the same time, for the discrete distribution constructed as above, for any total order $\succ$ of $i_1..i_n$,* $|Pr[\succ] - \frac{1}{n!}]| \leq \frac{\binom{k+n}{n}}{(k+1)^n} - \frac{1}{n!}$.

Proof. See [80].

Choosing the Δ_{noise} parameter. In practice, system designers already tune Δ_{net} in Pompē and similar protocols. To mitigate ordering bias (*e.g.*, front-running and sandwich attacks), they can instead tune Δ_{noise} to achieve a target ε.

For example, when considering attacks involving two or three invocations, designers may focus on $\varepsilon(2)$ and $\varepsilon(3)$. In legal contexts, $\varepsilon(2) \approx 0.05$ is often considered acceptable. The four-fifths rule [2,3] requires that selection probabilities differ by no more than 45% versus 55%, corresponding to $\varepsilon(2) = 0.05$. Similar thresholds have influenced fairness definitions in machine learning (*e.g.*, demographic parity [27]).

4 Implementation

We implement two SRO variants corresponding to the designs in Section 3.2 and Section 3.3.

For the TEE-based variant, we use Intel SGX [17]. Random values are computed as `SHA256(seed + k)`, where `seed` is established during initialization and `k` is the input to `Reveal`. The SGX SDK provides an optimized `SHA256` implementation for Linux [16]. We note that larger hash outputs (*e.g.*, `SHA512`) could provide stronger security, but are not supported in this environment. In practice, the integer type used by the SRO need not be limited to the standard 4-byte size: blockchain systems commonly use 32-byte or 64-byte values, which we also support.

For the TVRF-based variant, we build on an existing C++ implementation of threshold VRF [10, 40] and extend the `Produce` interface with signature verification. Random values are computed as `SHA512` hashes of a combined threshold of shares. The default configuration of this implementation uses the `mcl` cryptographic library [18] and the BN256 curve. Unlike in many BFT systems, cryptographic operations do not dominate the performance overhead in Pompē-SRO. As we show in Section 5, the overhead is primarily driven by the added randomness required to balance ε and Δ. Since cryptographic operations are not the bottleneck, we prioritize implementation simplicity when selecting cryptographic libraries.

In both variants, signature verification in `Reveal` relies on the `secp256k1` library [19], consistent with the Pompē implementation.

Discussion Permissionless blockchains, pioneered by Bitcoin [65], require nodes to know neither the system size nor the identities of the participants. In contrast, Pompē-SRO follows the standard BFT SMR model, where nodes know n, f, and participant public keys. In this sense, Pompē-SRO is not permissionless. Similarly, systems such as Ethereum and Solana are no longer permissionless after switching from proof-of-work to proof-of-stake. Pompē-SRO is well-suited for such proof-of-stake blockchains.

There is, however, a minor difference between the models used in proof-of-stake and traditional BFT SMR systems. With proof-of-stake, different nodes can *stake* different amounts of native currency (*e.g.,* ETH tokens). In this setting, the BFT condition $n = 3f + 1$ maps to a bound of at most 33% adversarial stake, while quorums correspond to 67% of total stake. We incorporate this interpretation in our evaluation by adapting baseline protocols accordingly.

Finally, our current Pompē-SRO prototype does not support the possibility that nodes may join or leave the blockchain. However, Pompē-SRO could easily be extended to support such dynamic participation by integrating standard techniques used for membership changes in traditional SMR protocols.

5 Experimental evaluation

We ask three main questions in our evaluation: (1) Do the state-of-the-art protocols and Pompē-SRO address real-world problems like front-running or sandwich attacks? (2) What do the correctness conditions mean to attackers who try to launch ordering attacks? (3) What is the end-to-end performance of Pompē-SRO? Figure 7 shows the answers.

We choose three baselines: HotStuff [78], Pompē [81], and Themis [49] representing the state-of-the-art fairness notions. HotStuff adopts the *rotating leadership* notion. Themis guarantees a fairness property called γ-*batch-order-fairness*, and we choose $\gamma = 1$, which means that if all correct nodes receive i_1 before i_2, then i_1 should be ordered no later than i_2 in the output. Pompē adopts the fairness notion of *removing oligarchy*, meaning that the output order cannot be dictated by

State-of-the-art systems trying to provide fairness are all vulnerable to bias and front-running.	§5.1
Among all possible financial rewards, an attacker gets the *mean* reward in Pompē-SRO and the *max* in baselines.	§5.2
Pompē-SRO maintains the same end-to-end throughput as Pompē, and the latency increases by 1.12x-1.42x.	§5.3, 5.4

Figure 7: Table of evaluation results.

a single leader. In contrast, Pompē-SRO enforces the *equal opportunity* notion of fairness.

Setup and metrics. We run the three baselines and Pompē-SRO on 12 machines in CloudLab [13] (ds430, Intel Xeon E5-2630, 64GB memory, Ubuntu Linux 24.04 LTS). Since Intel Xeon E5-2630 does not support SGX, we run the TEE-based SRO on a separate machine with the Intel Xeon Silver 4410Y processor. We provide detailed instructions on running the experiments in an open-source artifact [22].

Statistics show that the top countries running Ethereum nodes are: US (33%), Germany (15%), France (6%), Finland (6%), Singapore (4%), UK (4%), Canada (3%), Japan (3%), Netherlands (3%), and Australia (3%) [14]. We thus start with a setup of 80 nodes where each node represents 1% in the statistics. For the US, we assume 11 nodes in Austin, 11 in San Francisco, and 11 in Washington, representing the central, western, and eastern US. For the other countries, we assume that all the nodes are in one of their major cities. There are thus 12 cities in this setup, and we map these 12 cities to the 12 machines in CloudLab, emulating the latency between different cities with the Linux traffic control (`tc`) utility. The latency information is from WonderNetwork [15]. We assume $\Delta_{net} = 400ms$ in the partial synchrony model: $400ms$ is used in Solana's latest consensus protocol [51], and $400ms$ is higher than the maximum latency in this setup (*i.e.,* $296ms$ from Canberra in Australia to Oulu in Finland).

We then introduce proof-of-stake, which reduces resource contention on the machines. Specifically, instead of running 11 instances of the server-side software on one machine (*e.g.,* the machine mapped to Washington), we run only one instance with $11/80$ of the total stake. As explained in Section 4, this is essentially the same as the standard SMR model with 80 nodes that we just described. Moreover, similar to real-world blockchains like Solana, we assign slot leaders based on their stake. For example, in HotStuff, this machine will be the leader for $11/80$ of all the consensus slots.

Given a set of commands, the key metric for fairness is the difference between the probabilities of two permutations in the output. For example, given two commands invoked at the same time in Washington and London, the probability of the London one appearing first in the output is 0.475 (denoted as $Pr[L \prec W] = 0.475$) in our measurement of HotStuff. Therefore, $Pr[L \prec W] - Pr[W \prec L] = 0.475 - 0.525 = -0.05$ is shown in the first row of Figure 8. Since $|Pr[L \prec W] - 1/2| = 0.025$ is lower than 0.05, HotStuff treats the two clients from London and Washington equally if we target $\varepsilon(2) = 0.05$. We will show that HotStuff is biased when considering clients from some other cities.

To answer the question about end-to-end performance, we measure the latency and throughput of HotStuff, Pompē and Pompē-SRO in the 12-city setup. We assume that clients are evenly distributed across the 12 cities, and we increase the number of clients until the system is saturated. Every client invokes commands in a closed loop (*i.e.,* it waits for enough responses of its currently outstanding command before invoking the next one), and before saturation, the throughput increases as the number of clients increases. We aim to measure the overhead of Pompē-SRO over Pompē and compare their performance with HotStuff. As for batching, we use $2000ms$ as the time interval associated with each consensus slot in Pompē and Pompē-SRO. We disabled batching in HotStuff and in the ordering phase of Pompē and Pompē-SRO.

5.1 Bias and front-running

Figure 8 shows that geographical bias could be significant in the baselines. The output order produced by Pompē and Themis is deterministic. When commands are invoked at the same time, Pompē always produces London $\prec$ Munich $\prec$ Washington $\prec$ Tokyo, reflecting the order of the median timestamps obtained by clients from these cities. Themis produces Washington $\prec$ London because more than half (42/80) of the total stake receives the Washington command before a simultaneous one from London. Since 42/80 is close to one half, the γ-batch-order-fairness property of Themis does not require Themis to order the Washington command first. In contrast, 62/80 of the total stake receives the London command before a simultaneous one from Munich, and γ-batch-order-fairness requires Themis to be biased towards London because 62/80 is higher than a threshold derived from the γ parameter. While γ-batch-order-fairness sometimes requires the system to be biased, the notion of removing oligarchy does not require bias despite the fact that Pompē is significantly biased.

HotStuff rotates leadership, and the invocation from Tokyo would have a chance to appear first in the ledger when a Tokyo node serves as the leader. However, this chance is still low compared to Munich invocations. Specifically, we find that $Pr[\mathrm{M} \prec \mathrm{T}] = 0.74$, leading to the $0.74 - 0.26 = 0.48$ in the last row of Figure 8. This difference increases to 0.83 when compared to Washington. While Tokyo and Washington are geographically distant, bias can happen between nearby cities. London and Munich are both in Europe, but HotStuff is still biased towards London, as shown in the third row.

Figure 9 shows how Pompē-SRO reduces geographical bias. After adding a random noise sampled uniformly from

Baselines	HotStuff	Pompē	Themis
$Pr[L \prec W] - Pr[W \prec L]$	-0.05 ✓	1	-1
$Pr[W \prec T] - Pr[T \prec W]$	0.83	1	1
$Pr[L \prec M] - Pr[M \prec L]$	0.48	1	1
$Pr[M \prec T] - Pr[T \prec M]$	0.48	1	1

Figure 8: Geographical bias in HotStuff, Pompē, and Themis. W, L, M, and T stand for Washington, London, Munich, and Tokyo. For two simultaneous invocations from two cities, $Pr[\text{A} \prec \text{B}]$ stands for the probability of the invocation from city A being the first in the system output. The checkmark for HotStuff means that bias is controlled by $\varepsilon(2) = 0.05$.

Pompē-SRO	$\Delta_{noise} = \Delta_{net}$	$\Delta_{noise} = 5 * \Delta_{net}$
$Pr[L \prec W] - Pr[W \prec L]$	0.24	0.05 ✓
$Pr[W \prec T] - Pr[T \prec W]$	0.31	0.07 ✓
$Pr[L \prec M] - Pr[M \prec L]$	0.07 ✓	0.01 ✓
$Pr[M \prec T] - Pr[T \prec M]$	0.46	0.10 ✓

Figure 9: Geographical bias measured in Pompē-SRO with $\Delta_{noise} = \Delta_{net}$ (*i.e.,* 400ms) and $\Delta_{noise} = 5 * \Delta_{net}$ (*i.e.,* 2000ms).

$[0, \Delta_{net}]$ (*i.e.,* $[0, 400ms]$) to the median timestamp of Pompē, clients from London and Munich will be treated equally. With a target $\varepsilon(2) = 0.05$, system designers could choose $\Delta_{noise} = 5 * \Delta_{net}$ (*i.e.,* $2000ms$), and the worst-case bias across these four cities will be effectively controlled. Specifically, given the definition of ε-Ordering Equality, $\varepsilon(2) = 0.05$ means that $|Pr[M \prec T] - 1/2|$ should be at most 0.05. Therefore, the 0.10 in Figure 9 means that $Pr[M \prec T] = 0.55$ and $Pr[T \prec M] = 0.45$, satisfying the constraint put by $\varepsilon(2) = 0.05$. In real-world deployments, Δ_{noise} can be chosen by considering clients with the highest network latency. Pompē-SRO does not provide equal opportunity to clients with unbounded network latency to the system. Indeed, even liveness cannot be guaranteed without a bound on network latency [39], and equal opportunity is meaningless without liveness.

Front-running typically occurs when one client has lower network latencies to a majority of the nodes than the other clients, as London or Washington do in this experiment. By adding randomness, Pompē-SRO could give clients more even chances of obtaining the $89M profit in the liquidation events (explained in Section 2.1). Equal opportunity also plays an important role in mitigating sandwich attacks, which is closely related to front-running.

5.2 Sandwich attacks

To explain sandwich attacks, we start with some background on decentralized exchange. An exchange maintains a pool of some token A (*e.g.,* USD) and some token B (*e.g.,* CNY). For example, people traveling from the US to China may put some USD into the pool and take some CNY away. Similar pools exist on blockchains, and the trading volume of Uniswap, a decentralized exchange application running on Ethereum, has exceeded one trillion dollars [7].

Financial impact	Victim	Attacker
HotStuff / Pompē / Themis	-$500	$800
Pompē-SRO	$233	$67

Figure 10: The expected financial rewards to the attacker and victim within the example sandwich attack shown in Figure 1.

Pools in these exchanges follow a constraint: *amount of tokenA* $*$ *amount of tokenB* $=$ *constant*, which is called the automated market maker (AMM) approach [20]. Suppose the constant is 1800; the number of tokens A and B in the pool could be, for instance, $\langle 45, 40\rangle$, $\langle 60, 30\rangle$, or $\langle 75, 24\rangle$. Say $\langle 75, 24\rangle$ is the current status, and Alice needs 15 token A. Alice can put 6 token B into the pool and take 15 token A away so that the pool state moves to $\langle 60, 30\rangle$.

The sandwich attack works as follows. After seeing Alice's transaction, an attacker, Bob, first buys 15 token A, moving the pool status to $\langle 60, 30\rangle$. Alice now needs to pay 10 (instead of 6) token B to exchange for 15 token A, moving the pool status to $\langle 45, 40\rangle$. Bob can then exchange 15 token A back to 10 token B, making a profit of 4 token B. The three steps reflect the three invocations in Figure 1. If the market value of the tokens are $100 and $200, respectively, we will get the dollar values in Figure 1. Specifically, if the attack succeeds, the victim will pay 10 token B (*i.e.,* $2000) in exchange for 15 token A (*i.e.,* $1500), losing $500 as shown in the first row of Figure 1. Without the attack, the victim will pay 6 token B in exchange for 15 token A, making a profit of $300.

A common way of conducting such sandwich attacks is to use faster network connections [57]. The attacker is typically co-located with the victim and, after observing a trading command from the victim (i_1 in Figure 1), the attacker uses faster network connections to send its own command (i_2 in Figure 1) to the nodes. Figure 10 shows the expected financial rewards in different systems.

In this experiment, we assume that an attacker co-located with the victim could deliver its command to all nodes in the system $10ms$ earlier than the victim. The attack deterministically succeeds in all state-of-the-art systems because they all follow the order in which nodes receive commands. In contrast, all 6 permutations are equally likely in Pompē-SRO, lowering the attacker's expected reward by an order of magnitude. Specifically, $\$233 = (-\$500 + \$700 + \$300 * 4)/6$ is the victim's expected reward, and $\$67 = (\$800 - \$400)/6$ is the attacker's expected reward. Given a much lower expected reward and a caveat of losing $400, Pompē-SRO effectively disincentivizes sandwich attacks.

5.3 Latency of the two SRO designs

Figure 12 shows the latency of the two SRO designs. We show two cases of |s|=0 and |s|=200, where |s| denotes the number of signatures to be verified in the second parameter of `Reveal`. When |s|=0, `Reveal` does not verify signatures,

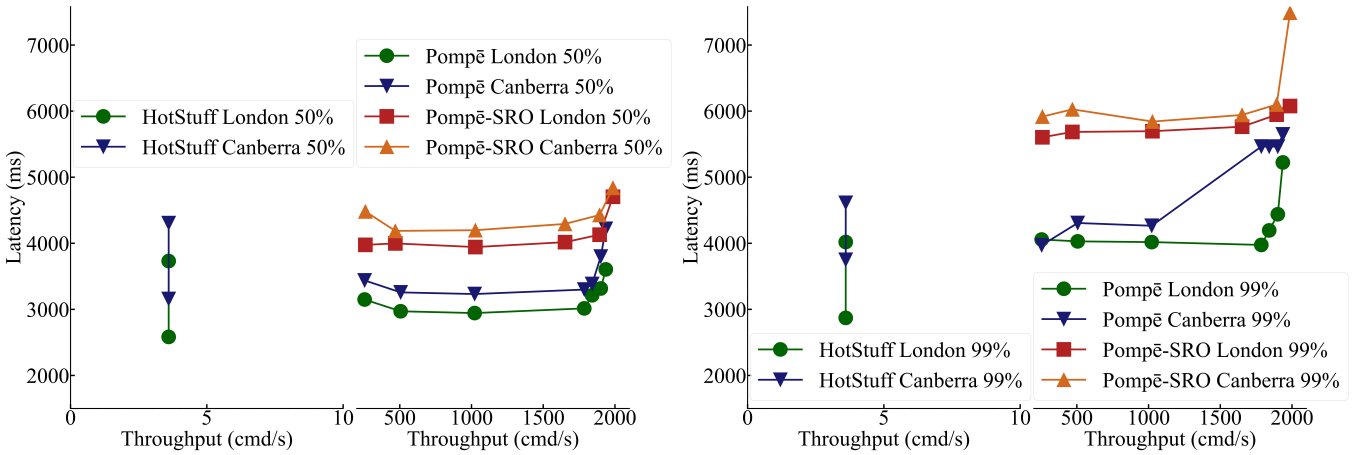

Figure 11: End-to-end performance of HotStuff, Pompē, and Pompē-SRO with $\Delta_{noise} = 5 * \Delta_{net}$ (*i.e.,* 2000*ms*) in the 12-city setup. Batching is disabled in HotStuff and in the ordering phase of Pompē or Pompē-SRO. For example, HotStuff handles 3.6 consensus slots per second, and if we enable a batch of 1000 commands for each slot, the throughput of HotStuff will become 3600 commands per second. Disabling batching is useful because, in practice, protocols only reach consensus on the slot hashes.

	|s|=0 (`base`)	|s|=200
TEE	3us	`base`+20.2ms
TVRF (67/100)	416+6346us	`base`+19.9ms
TVRF (133/200)	394+12330us	`base`+19.9ms

Figure 12: Latency of the `Reveal` interface in different SRO implementations. |s| denotes the number of signatures to be verified in the second parameter of `Reveal`. The numbers in the parentheses are the threshold and total number of nodes for TVRF. The `base` case of TVRF consists of two latency results for generating and combining shares.

and the latency is solely for generating random numbers. For the TEE variant, the latency consists of entering an SGX enclave and computing a `SHA256` function, which takes only 3*us*. For the threshold VRF variant, the latency consists of three parts: (1) generating shares, (2) collecting the shares over the network, (3) combining a threshold of shares. The results in Figure 12 show (1) and (3). Under a setup of 100 nodes and 67 as the threshold, the latency of generating a share is 0.4*ms*, and the latency of combining 67 shares is 6.3*ms*. When moving to a setup of 200 nodes with 133 as the threshold, the latency of generating a share stays at 0.4*ms*, while the latency of combining the shares doubles to 12*ms*. Lastly, when $|s| = 200$, the latency of verifying the 200 signatures is about 20*ms*, both within and outside an SGX enclave.

These results show a trade-off between performance and decentralization. The SRO based on SGX has a much lower latency, making it more practical, but it requires trusting Intel, a centralized party. In the following experiments, we choose performance in this trade-off and use the TEE variant of SRO, since TEE has been used in Ethereum's Sepolia testnet [12] and Solana's Block Assembly Marketplace [21].

5.4 End-to-end performance of Pompē-SRO

Figure 11 shows the end-to-end performance of HotStuff, Pompē, and Pompē-SRO. We made three observations.

- Pompē-SRO keeps the same throughput as Pompē, and the latency increases by 1.12x-1.42x.
- Pompē and Pompē-SRO achieve a significantly higher throughput than HotStuff in the geo-distributed setup.
- The 99% latency of HotStuff is 287-592*ms* higher than its 50% latency, while the 99% latency of Pompē-SRO is 1672-1816*ms* higher than its 50% latency.

When deploying 120 clients in each city (*i.e.,* $120 * 12 = 1440$ clients in total), Pompē and Pompē-SRO reach their peak throughput: 1842 cmd/s for Pompē and 1893 cmd/s for Pompē-SRO. When considering clients from London, the 50% latency in Pompē-SRO is *1.29*x of the 50% latency in Pompē, and the 99% latency is *1.42*x of the 99% latency in Pompē. For Canberra clients, the increase ratios are *1.31*x and *1.12*x for the 50% and 99% latencies, respectively. This is how we derive the last statement in Figure 7.

HotStuff's performance issue in a geo-distributed setup has already been reported in prior work [81]. Specifically, with rotating leadership in HotStuff, the leader of the current slot needs to wait for enough votes on the previous slot before proposing for the current slot. Such waiting results in a low frequency of consensus proposals in HotStuff. Pompē and Pompē-SRO do not suffer from such waiting, although they reuse HotStuff for consensus. Specifically, their leaderless ordering phase proposes commands continuously without waiting, and consensus only happens every 2000*ms* for all commands proposed by the leaderless ordering phase in a 2000*ms* time window.

Lastly, the gap between the 50% and 99% latencies in Pompē-SRO is obviously larger than that gap in HotStuff, and two factors cause such a larger gap. First, since consensus happens every 2000*ms*, there is a delay between the time when a client invokes a command and the time when consensus happens. Second, due to random noise, it takes longer for a command to become stable in Pompē-SRO, as explained in Section 3.4. Both factors enlarge the gap between the 50% and 99% latencies in Pompē-SRO.

6 Related work

Traditional BFT SMR systems. There is a long line of work on traditional BFT SMR systems, including [28, 32, 33, 35, 36, 43, 44, 46, 52, 53, 58–62, 67, 73, 74, 77]. These works focus on enforcing safety and liveness, removing or constraining Byzantine influence, and improving performance or theoretical complexity, among other goals. Our work focuses on how to choose the output order in SMR, which is not considered by the traditional specification. Some works [28, 34, 47, 56] use trusted hardware to increase the ratio of Byzantine nodes that the system can tolerate. Other works [30, 40, 42] use randomness to elect a committee or achieve safety and liveness in a fully asynchronous model. Unlike these works, our work uses trusted hardware to provide a fault-tolerant source of randomness and applies it to ensure equal opportunity.

Rotating leadership. Some works adopt a leader and rotate the leadership frequently, but they focus on reducing theoretical complexity or preventing faulty leaders from degrading performance. Aardvark [36] employs periodic leader changes to ensure a certain degree of performance in the presence of faulty leaders. Aardvark sets an expectation on the minimal throughput a leader must ensure and triggers a leader change if the current leader fails to meet this expectation. Unlike Aardvark, HotStuff [78] employs leader rotation and optimizes the communication complexity. Specifically, HotStuff's communication complexity is linear in the number of nodes, which makes it more suitable for blockchains. Adopted by Diem [8], rotating leadership in HotStuff aims to provide some sense of fairness in a permissioned blockchain. Our work instead specifies and enforces a concrete notion of fairness, and our evaluation results show that rotating leadership could cause significant bias in a real-world deployment.

Removing oligarchy. *Leaderless* protocols argue against having a leader node who can unilaterally decide the output order. EPaxos [63], or Egalitarian Paxos, is an SMR protocol that attempts to make the system egalitarian. While the concept of egalitarianism is closely related to equal opportunity, EPaxos does not specify or enforce egalitarian ideals except being a leaderless protocol. Byzantine oligarchy [81] is the first attempt to specify the goal of leaderless protocols in the context of ordering, and Pompē is the first leaderless protocol that provably removes a Byzantine oligarchy. To achieve this, Pompē requires a client to collect timestamps from a quorum of nodes, and the median is used to order a command. However, our evaluation shows that using such a median timestamp could make the system even more biased than prior approaches such as HotStuff.

Decentralized first-come-first-served. Some recent works define and enforce fairness concepts related to first-come-first-served [31, 48–50, 64, 69]. Specifically, these protocols enforce variants of the receive-order-fairness property [50], which essentially says that if a majority of the nodes receive an invocation first, it should be ordered first in the output. We argue that this property can be unfair because, without distinguishing relevant features from irrelevant ones, it can amplify systemic bias in real-world blockchains, as shown in the evaluation section.

While these works enforce specific properties related to first-come-first-served, the framework of ordered consensus makes it possible to prove that it is impossible, in general, to prevent Byzantine replicas from manipulating the order (*e.g.,* from conducting front-running) [81]. This result is inspired by Arrow's impossibility theorem [26] and the Gibbard-Satterthwaite impossibility theorem [41, 70] from the field of social choice theory. In the past two decades, computer scientists became interested in social choice, leading to the creation of the field of computational social choice [29].

Game theory. The BAR model [23, 24] explores how to connect Byzantine fault tolerance to game theory. The core of the connection is adopting the Nash theorem [66], which states that every normal-form game must have an equilibrium. The Nash theorem connects the rationality model [71, 76] with the Brouwer fixed-point theorem (*i.e.,* a fixed point is interpreted as an equilibrium). We find the concept of equal opportunity and its violations more prevalent in real-life scenarios than the Nash equilibrium. We reuse the key concept of expected value from the rationality model when explaining violations of equal opportunity in Section 2.1. We are also inspired by one of the axioms at the core of the rationality model [71] when defining consistency in Section 2.2. However, unlike BAR, we do not reuse the concept of Nash equilibrium in this work.

Another line of work studies how to eliminate sandwich attacks in blockchains within a game-theoretic model [25]. Similar to our work, this work also argues that randomness is the key to addressing the problem. The proposed solution only randomizes commands within a block, making it vulnerable to destructive front-running attacks described in an empirical study [68]. Destructive front-running means that, in leader-based protocols, the leader of a slot could front-run a command by excluding it from this slot, so this victim command can only be included in a later slot.

Equal opportunity in real-life scenarios. The principles of impartiality and consistency have been scrutinized in the context of how society allocates resources. In his book [79],

Young studies the two principles in a variety of contexts, from employment to kidney exchange, and discusses how they are embodied in key pieces of legislation [1, 2, 4, 5]. The book includes a proof that a point system is the only mechanism that satisfies both impartiality and consistency. Our work adopts this book's approach: we use the invocation time as the score for ordering and use a Secret Random Oracle to break ties.

Kidneys for transplant used to be exchanged through a free market, and wealthy patients had a better chance of getting kidneys. This raised fairness concerns and led to legislation that transferred the operation to the government to overcome such bias towards wealthy patients [4]. While this law enforced *impartiality* between the rich and poor, *consistency* became a concern. The first algorithm proposed was inconsistent, and the order of two patients getting kidneys could be switched due to a third patient joining the system. As a result, a new algorithm was proposed as an amendment that enforces the consistency principle [5]. Details of the relevant features and the point system in this case have been discussed in Chapter 2 of Young's book [79].

Financial regulation laws require financial exchanges to be impartial to all traders. A recent exposé [57], however, has concluded that high-frequency traders have routinely engaged in market-exploiting behaviors, such as aggressive latency optimizations and front-running by exploiting their location or the availability of fast network connections—which our framework would classify as irrelevant features.

In the Olympic Games, the order of athletes is decided, and equal opportunity is required. The Olympic rules specify which relevant features should be measured. Similar to geolocation, a key irrelevant feature is national origin, and judgments should not be biased toward any nation. Besides, due to cognitive bias, a judge may make correlated decisions when judging a sequence of observations. For example, in diving, athletes dive alternately, and an athlete's performance may impact the scores given to the next athlete [54]. Judges typically need professional training to combat such implicit bias and follow the consistency principle.

7 Conclusion

This paper introduces a model for equal opportunity, a notion of fairness based on the distinction between relevant and irrelevant features. Existing protocols—including ones attempting to provide some fairness—can be significantly biased and vulnerable to ordering-based attacks.

We design, implement, and evaluate Pompē-SRO, a new ordered consensus protocol that guarantees two correctness conditions for equal opportunity, ε-Ordering Equality and Δ-Ordering Separation. Pompē-SRO effectively mitigates the well-known ordering-based attacks, given that eliminating such attacks in the presence of Byzantine influence has been proved impossible by prior work.

Acknowledgments

We thank the anonymous shepherd and OSDI reviewers for their insightful and constructive comments. The initial steps towards a theory model for equal opportunity benefited from conversations with Joseph Halpern and his book on theories of uncertainty [45]. Roger Wattenhofer helped us confirm our understanding of Solana's new consensus protocol. This work was supported in part by a Facebook Fellowship.

Jetpack: Consensus Made Generally Fast

Ze Tang[1], Zihao Zhang[1,†], Weihai Shen[1], Jicheng Shi[2], Shuai Mu[1]
[1]*Stony Brook University* [2]*DatenLord*

Abstract

Classic consensus protocols such as Raft require 2 round-trip times (RTTs) for a client to commit a command. Recent protocols reduce this latency to 1 RTT through a carefully designed fast path, but these fast paths are tightly coupled to their host protocols and cannot be retrofitted to existing systems. This paper presents Jetpack, a plugin framework that adds a 1-RTT fast path to existing consensus protocols with minimal modifications.

Jetpack issues commands concurrently to both a fast path and the original path, committing when the fast path succeeds while ensuring the original path honors the same decision. The key challenge is maintaining this guarantee across view changes: we identify the *view change hazard*, a subtle correctness issue where promises made during stable operation can become invalid after leader elections. Jetpack captures this in two structural requirements and two design principles that a fast-path layer can apply across consensus environments, conditions that are easy to overlook when a fast-path idea is adapted to a new setting, as we illustrate with prior designs and a deployed system.

We evaluate Jetpack on six consensus systems across 10 AWS datacenters. Results show that Jetpack achieves 1-RTT latency, reducing average commit latency by as much as 60%, while preserving the original path's performance and properties when the fast path is not used.

1 Introduction

State machine replication and consensus protocols are the backbone of highly reliable distributed systems [55, 23, 41, 27, 54, 39, 61, 38, 68, 67, 30]. These protocols maintain consistency and availability despite machine failures, but achieving low latency remains challenging because consensus fundamentally requires replica synchronization. Classic protocols like Viewstamped Replication [54], MultiPaxos [23, 26] and Raft [55] require 2 round-trip times (RTTs) to commit a command—one RTT from client to leader and back, another for the leader to replicate to followers. This latency is particularly costly in geo-replicated deployments.

To address this, recent consensus protocols offer a "fast path" that allows clients to replicate commands directly to all replicas, bypassing leader serialization and reducing latency to 1 RTT for common cases. Fast Paxos [42] established the theoretical foundation: correctness is maintained by increasing the fast-path quorum size from a simple majority to a supermajority. Subsequent systems such as EPaxos [49], Tapir [65], and SwiftPaxos [59] realize this 1-RTT fast path in complete system designs.

However, the fast paths in these systems are tightly coupled to their protocol designs. They are neither intended nor designed to be generalized to other systems. One cannot extract the fast path from these protocols and apply it to existing systems without adopting the entire design. Yet replacing the consensus layer of a mature system is practically impossible. Even new systems tend to choose reliable, widely adopted protocols. For example, most recent consensus systems [38, 61, 68, 7, 2, 12] in industry are Raft-based.

Given this gap between state-of-the-art and practice, this paper asks: can we develop a universal fast-path framework applicable to a broad range of consensus protocols and systems? We answer this question with Jetpack, a plugin approach that layers fast-path optimization on top of existing protocols without requiring extensive protocol redesign or code modification.

Jetpack aims to achieve a transparent fast path, but a transparent fast path alone is not sufficient in practice. Consider a strawman: implement a Fast Paxos-like fast path as a "gateway" that all requests pass through before reaching the original path, or even skip the original path entirely. While this could apply to almost any consensus protocol, it is impractical: in production systems such as databases, such a gateway disables the original system's optimizations and features (e.g., request batching and slow replica tolerance).

We therefore set three goals for Jetpack beyond achieving 1-RTT latency. First, the fast path and original path must coexist: clients can dynamically choose either path, regardless of other clients' choices. Second, Jetpack must not add overhead to the original path—if all clients use the original path, performance should match the unmodified system. Third, Jetpack must not disable features of the original protocol. For example, Copilot [53] tolerates slow leaders. Copilot enhanced by Jetpack retains this property on its original path while also offering a 1-RTT fast path (which is not slow-tolerant).

To meet these goals, Jetpack runs the fast path and the original protocol path in parallel: each client request travels both paths simultaneously. The fast path exploits commutativity to commit in 1 RTT when concurrent commands do not conflict. The original path proceeds independently to handle conflicts and failures, preserving the original protocol's properties. A client commits as soon as either path returns, and the two paths are designed to converge on the same outcome.

The key safety mechanism is a *promise* from the original

[†]Corresponding author.

path: when the fast path commits a command, the original path promises not to commit any conflicting command before eventually committing the same one. Enforcing this promise is straightforward during stable operation: the original path typically has one or a few leaders responsible for proposing commands, so only those leaders need to acknowledge the promise. However, this promise can become invalid after a view change (e.g., leader re-election due to failure). A new leader may not know about the promise, leading to potential safety violations. We identify this problem as the *view change hazard*, and capture it in two structural requirements that a fast-path layer must meet when paired with a consensus protocol. These requirements are easy to overlook when a fast-path idea is adapted from one environment to another. We illustrate this with three examples whose treatment of view changes leaves these requirements incompletely addressed: an appendix-level sketch in CURP [57] that extends its primary-backup fast path to Raft, a deployed system built on that sketch (Xline [11]), and Carousel [64]. In each case the gap is subtle, and Jetpack's two design principles close it.

We implemented Jetpack on six consensus systems: Raft [55], the most widely used protocol; Mencius [48], a round-robin multi-leader protocol; Copilot [53], which provides fail-slow fault tolerance; MongoDB [68], a production database with customized consensus; etcd [2], a widely used Raft-based key-value store; and ZooKeeper [39], a coordination service built on Zab. All integrations are specified in TLA+ and model-checked with no safety violations across view changes [3]. We evaluated these systems on AWS EC2 across 10 datacenters. Results show that Jetpack achieves 1-RTT latency in common workloads, reducing average latency by as much as 60%. The enhanced systems match original performance when fast paths are not used (§6.4), demonstrating that Jetpack achieves its goals.

Limitation. Jetpack essentially trades throughput for latency: additional protocol overhead on the critical path reduces latency. This tradeoff is fundamental to any fast-path design. For Jetpack specifically, overhead scales with the number of leaders in the original protocol; we demonstrate this with multi-leader protocols like Mencius, which incur higher overhead. However, this is a theoretical bound rather than a design flaw. As a mitigation, we show that a simple adaptive strategy helps the system achieve the same maximum throughput as the original when saturated.

2 Background, Related Works, and Goals

Consensus. Consensus is a fundamental problem in distributed systems and the core building block for replicated state machines. A group of replicas, each with its own input value, must agree on the same output value. In state machine replication, this value is typically a command to execute; by running a sequence of consensus instances, the system ensures all replicas execute the same commands in the same order, maintaining identical state. We use "value" when discussing consensus abstractions and "command" when discussing practical state machine replication.

What makes consensus exceptionally challenging is that replicas must reach agreement by exchanging messages in an asynchronous environment where messages can be delayed arbitrarily. Replicas can crash, slow down, or become isolated by network partitions. No perfect failure detector can distinguish crashed replicas from slow or partitioned ones. The system must make progress as long as a majority of replicas remain responsive.

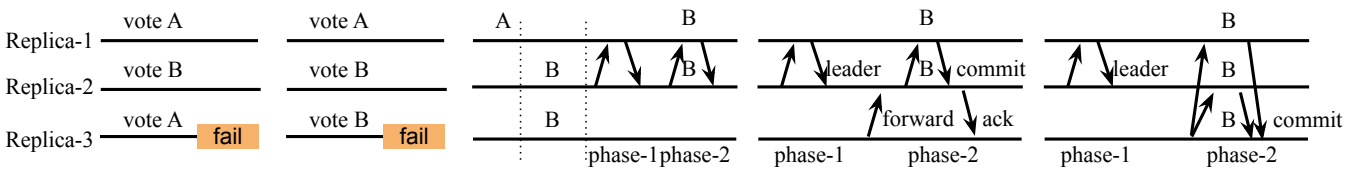
Intuitively, consensus proceeds by replicas voting on values; the value receiving a majority of votes (a quorum) becomes the output. This process is difficult given asynchrony and failures. Figure 1(a) shows a typical scenario. In one case, two replicas vote for A and one for B; A is chosen by majority. In another case, B is chosen. If Replica-3 then fails, the two cases become indistinguishable—one replica voted for A and one for B. Recovery faces a dilemma: either A or B could have been chosen before the failure, and without knowing the failed replica's state, the system gets stuck.

Classic solutions. Three classic solutions are Viewstamped Replication [54], Paxos [40], and Raft [55]. Despite differing in details, they share the same key idea, illustrated in Figure 1(b). Votes are divided into rounds, where only one value can be proposed per round, and all future rounds must adopt any value already chosen. To enforce this, each round is divided into two phases. In the first phase, a replica (e.g., Replica-2) tries to recover any possibly chosen values from past rounds (e.g., B), and makes other replicas promise not to vote for previous rounds anymore. In the second phase, this replica, often serving as a leader, can propose its value, either a previously chosen value or a new one.

In practice, the first phase is usually performed collectively for many consensus instances by the leader, before any commands are ready to propose. When a command arrives, the leader directly enters phase-2 for the appropriate consensus instance. Hence, phase-1 is often called leader election, or a view change. This leader-based structure means only the leader can commit a command in 1 RTT; other replicas require 2 RTTs to commit: 0.5 RTT to forward the command, 1 RTT for the leader to complete phase-2, and 0.5 RTT for the leader to acknowledge the result, as shown in Figure 1(c).

From the client's perspective, latency is higher since clients are not always co-located with replicas [17, 19, 27]. A client needs at least 2 RTTs to commit a request: 1 RTT to send to the leader and receive a reply, in between which the leader takes another RTT to reach consensus.

Reducing latency. The 2-RTT latency is a bottleneck, especially in geo-replicated systems. Some protocols reduce this without modifying the 2-phase structure. Mencius [48] shards consensus instances so each replica leads a subset, achieving amortized 1.5 RTT for co-located clients. However, remote clients still face 2.5 RTT.



(a) A challenging case in consensus

(b) A common structure in classic consensus protocols

(c) 2RTT, with follower forwarding to the leader

(d) Fast path optimization with a super-quorum (>3/4)

Figure 1: Literature review of consensus protocols. From left to right, the figures demonstrate a key challenge in consensus protocols, its common two-phase solution, the 2-RTT latency nature dictated by the solution, and the superquorum-based fast-path optimization. Figure (a) shows two cases illustrating the challenge of split votes in consensus. The two cases are indistinguishable after the failure, despite having achieved a majority vote on different values. Figure (b) shows the common solution in classic consensus protocols, dividing votes into rounds. Rounds are divided by the dotted line in the figure. Figure (c) shows the 2-RTT with follower to leader forwarding. Figure (d) shows the fast path with a superquorum. With 3 replicas, the quorum size is 3.

Further reducing latency is difficult within the 2-phase structure. Doing so requires allowing multiple clients to directly enter phase-2 without phase-1, which returns us to the problem in Figure 1(a): a decided value may be lost after failures. Lamport's Fast Paxos [43] provides the theory to address this problem. The key idea is to enlarge the quorum size to ∼3/4 of replicas for the "fast round," allowing requests to be proposed directly without going through the leader. During recovery, a value that might have been chosen in the fast round dominates by count in the recovery phase of the next round. Figure 1(d) illustrates this: in phase-2, a value is proposed directly to all replicas rather than forwarded to the leader.

Fast Paxos inspired many subsequent works [42, 49, 65, 50, 18, 57, 59, 22, 58, 35, 44, 66] that adopt fast-path optimization to achieve 1 RTT for common workloads. EPaxos [49] and SwiftPaxos [59] use the fast path to reach consensus on command dependencies. CURP [57] uses the fast path to directly commit commands. Tapir [65] and Janus [50] use the fast path for transaction commit.

Question: can we make fast-path optimization universal? Despite these advances, all fast-path protocols are designed from scratch. What if one wants to add fast-path optimization to an existing system? Can we build on top of existing protocols rather than replacing them entirely?

From a research perspective, generalizing fast-path optimization would fill many gaps in the consensus design space. Many protocols have specialized goals: Copilot tolerates slow leaders; Mencius and MultiRaft [38] distribute load evenly among replicas; SAUCR [14] reduces disk write latency by leveraging the time between replica failures. A general fast-path framework could apply to these protocols directly, without redesign.

From a practical perspective, many systems use customized consensus protocols where drastic changes are not an option. For example, MongoDB uses heavily modified Raft [68] to fit its architecture. Even if adding a fast path were possible, it would require significant effort. A generalized approach would be valuable for such systems.

Our goal is to provide a universal fast-path framework applicable to existing consensus protocols, targeting geo-distributed deployments where cross-datacenter round trips dominate commit latency. The framework should provide:

- **1-RTT fast path:** A 1-RTT fast path for clients to commit requests in common cases.
- **Low overhead for the original path:** The framework must not impair the original protocol. This has two aspects: (i) if no requests use the fast path, performance (throughput and latency) should match the unmodified system; (ii) if the original protocol has special properties, like Copilot's slowdown tolerance, the framework preserves them.

We also aim to minimize integration effort. The framework should not drastically change the original protocol. Some modifications are unavoidable, but they should remain minimal, localized, and not require additional correctness proofs. Critically, such changes must never alter the original protocol's outcomes, such as turning a rejected command into an accepted one.

Non-goals. We do not target BFT protocols [33, 15, 63] such as PBFT [25]. We also assume every command is independent, i.e., we do not support interactive transactions, such as Tapir [65]. These are promising directions for future work.

3 Main Idea and Normal Operation

Although our goals may seem ambitious, the underlying rationale is straightforward. This section presents the core idea in the simplified setting of single-decree consensus (§3.1), extends it to multi-decree consensus (§3.2), and concludes with Jetpack's normal-case workflow (§3.3).

3.1 Main idea with single-decree consensus

In single-decree consensus, the system reaches agreement on a single value. This abstraction has been widely used to illustrate the core principles of consensus, most notably in Paxos. Multi-decree protocols used in practice, such as Multi-Paxos, can be viewed as repeated instances of single-decree consensus, each corresponding to a particular log index.

Specializing the framework goals from §2 (a 1-RTT fast path with no impact on the original path) to single-decree

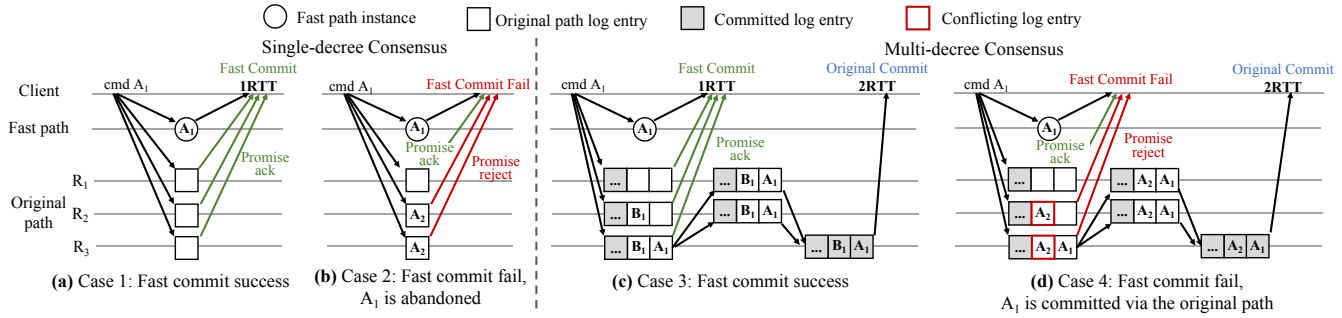


Figure 2: Illustration of the core idea. A_i, B_i denote commands on data A and B. The client sends each command in parallel to the fast path and to three replicas R_1, R_2, R_3 on the original path. The client accepts whichever path commits first (fast: 1 RTT; original: 2 RTT). For simplicity, we show the fast path only by its overall outcome (A_1 is always chosen) and focus the per-replica state on the original path; the overall fast commit succeeds only if the original path also acks the promise. **(a,b)** show the single-decree setting, in which an original replica can ack the promise when it has not proposed or accepted a different command than A_1. In (a), all instances are empty, and fast commit succeeds; in (b), R_2, R_3 hold a different command A_2, so A_1 is abandoned, since A_2 has already been chosen by the original path for the single instance. **(c,d)** show the multi-decree setting, in which an original replica can ack the promise when its log has no uncommitted command conflicting with A_1. In (c), no replica has a conflict, and fast commit succeeds; in (d), R_2, R_3 have a conflicting command A_2, so fast commit fails, R_3 then proposes and commits A_1 via the original path in 2 RTT.

consensus, our goals are twofold: 1) The system can commit the fast-path value in 1 RTT. 2) The original path still operates independently from the fast path.

Consider an arbitrary single-decree protocol serving as the original path, and Fast Paxos as the fast path. The two paths run *in parallel*: a client sends each command to both paths, and each path attempts to commit independently—neither waits for the other. The fast path uses a Fast Paxos-style superquorum to commit in 1 RTT when no conflict arises; the original path runs its own 2 RTT consensus. For correctness, the two paths must agree on the *same* committed value.

Since the fast path finishes earlier (1 RTT vs. 2 RTTs), for the fast-path commit to take effect while keeping the two paths in agreement on the same value, we require the original path to make a *promise* that constrains its future commit value. Only when the original path makes such a promise can the fast-path value be safely considered committed in 1 RTT. Concretely:

Definition 1 (Original Path Commit Promise, Single-decree)**.** *If the fast path commits a value v, the original path guarantees that it will not commit a different value w ($w \neq v$).*

This promise can be realized through a stronger, easier-to-implement variant:

Definition 2 (Original Path Proposal Promise, Single-decree)**.** *If the fast path commits a value v, the original path guarantees that it will not propose a different value w ($w \neq v$).*

As shown in Figure 2(a,b), whenever a value is proposed on the fast path, it is also sent to the original path to request a promise. If the original path has not chosen a different value, it can issue the promise, enabling the fast path to win (Case 1); otherwise, the promise is rejected, and fast commitment fails (Case 2).

This variant is easier to implement because it only requires modifying the proposal logic, which in most protocols is simple logic that sends a value in a message e.g., Accept in Paxos. A brute-force way to implement this promise is to forbid all original-path proposers from proposing any value other than the fast-path value, but this effectively disables the original path, so this does not fit our goals.

A more practical way to implement the promise and fit our goals is to involve only the original path's *initial proposer(s)*: the replicas designated to drive proposals in the system's initial state. In most consensus protocols, these are the replicas that have completed phase-1 of the original protocol before the system begins serving client requests (see §2). Other replicas are not yet proposers; they may only propose after explicitly running phase-1 themselves. This restriction is what makes the promise tractable: only the small set of initial proposers needs to acknowledge it. Most consensus protocols already maintain this distinction, so adopting it adds no new machinery.

With this distinction in place, the protocol works as follows. An initial proposer may propose any value in the original path; if it commits, the value is considered committed for the entire system. This fulfills the goal of the original path still operating and being unaware of the fast path. To integrate with the fast path, we modify the Fast Paxos protocol as follows. When a client attempts to fast-commit a value, it sends the value to both the fast path and the initial proposers (i.e., the Fast Accept quorum includes all initial proposers in the original path). Each initial proposer checks whether it has already proposed any value; if not, it promises not to propose a different value in the future. The client considers the fast-path value committed only if all initial proposers make this promise; otherwise, the fast path fails.

If the system subsequently crashes, a newly elected leader runs a recovery step on the fast path before becoming a proposer. If the fast path has committed a value, the recovery step restores that value and proposes it on the original path, honoring the promise that the original path will match the fast-path value. Otherwise, the recovery step commits a no-op on the fast path, closing it so that no later fast-path commit can occur for this consensus instance, and the system then honors whatever value the original path will commit.

3.2 From single-decree to multi-decree

The single-decree model in §3.1 captures the core insight, but practical systems require multi-decree consensus to build a replicated state machine. In multi-decree consensus, clients continuously send commands to replicas, and replicas agree on which commands to accept and in what order to execute them. A common realization is for replicas to maintain a log of commands, where each log position corresponds to a consensus instance. This is logically equivalent to running many single-decree consensus instances, one per log index. Replicas typically execute commands sequentially in log order to maintain consistent state.

This multi-decree model introduces a key challenge for fast commitment: how do instances in the two paths correspond? In the single-decree setting, the fast path and the original path naturally operate on the same (only) instance, yielding a one-to-one mapping as shown in Figure 2(a). In multi-decree consensus, however, the mapping is no longer naturally one-to-one. The original path can have multiple concurrent consensus instances running, e.g., in Raft, a new leader may propose a new command while the previous command is still pending, and these commands could be modifying the same data item. The system must also allow multiple fast-path instances to run. Therefore, we are looking for a many-to-many mapping between the fast path and the original path.

To simplify the discussion, assume the system runs only one fast-path consensus instance at a time. This reduces the problem to a one-to-many mapping between the fast path and the original path, as illustrated in Figure 2(c,d): a single fast-path command (e.g., A_1) maps to a "window" of candidate instances on the original path (e.g., B_1 and A_1 in (c), A_1 and A_2 in (d)).

To make this one-to-many mapping work, we introduce a refinement:

Leveraging commutativity. In a replicated state machine, correctness (maintaining consistent states among replicas) depends only on the execution order of *conflicting* commands. Non-conflicting commands commute and may execute in any order without affecting the final state. This observation simplifies the problem: we need only ensure that conflicting commands appear in the same order across replicas; non-conflicting commands can be handled independently.

Conflict detection. Jetpack requires the application to provide a predicate $\mathsf{Conflict}(c_1, c_2)$ that returns true when the order of c_1 and c_2 can affect application state or response. For common workloads such as key-value stores, this is straightforward (e.g., two commands conflict if they access the same key and at least one is a write); we discuss application-specific considerations and our key-value implementation in §5.

Refining the original path promise. Following the idea from §3.1, we require the original path to make a promise. But the promise must be refined for the multi-decree setting:

Definition 3 (Original Path Proposal Promise, Multi-decree)**.** *If the fast path commits a command c, the original path guarantees that it will not propose any concurrent conflicting command before c in the log.*

We first observe that most multi-decree consensus systems operate in *views*: stable periods during which the set of replicas authorized to propose is fixed. This stable-view proposer set plays the same role as the initial proposers in single-decree (§3.1): controlling its inputs constrains the command order in the log. From this point on, we use *proposer* to refer to a member of this stable-view proposer set. Concretely, when a client issues a fast-path command, it sends the request to both the fast path *and* the original path (which must include all proposers). Each replica receiving the fast-path request checks for conflicts with all uncommitted commands in its log. If the command is conflict-free, the replica promises not to propose any concurrent conflicting command before this command in the log.

If a superquorum of fast-path replicas acknowledge the command *and* all proposers make the promise, the command can be safely fast-committed. The command will still eventually commit on the original path as well, but the client need not wait for that. For example, in Figure 2(c), command A_1 can obtain the promise, whereas A_1 in (d) cannot because the original path already contains a conflicting command A_2 ahead of it. As a result, A_1 in (c) succeeds in fast commitment, while A_1 in (d) fails and needs to be committed via the original path.

Note that the logic above is discussed in the context of a stable proposer set. View changes are subtle: promises made in the old view must survive into the new one, even though the newly elected proposer was not party to them. We defer this case to §4, where we identify the structural requirements every fast-path layer must meet, derive Jetpack's two design principles, and present the recovery procedure. We first describe how Jetpack processes commands during stable operation.

3.3 Workflow without failures

Jetpack runs on $2f+1$ replicas to tolerate f crash failures. Each replica serves both the original and fast path. A client library routes each command: fast-path commands are broadcast to all replicas while original-path commands are sent only

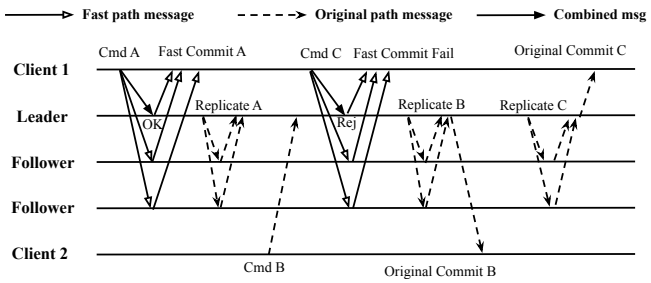

Figure 3: Example workflow of Jetpack integrated with Raft.

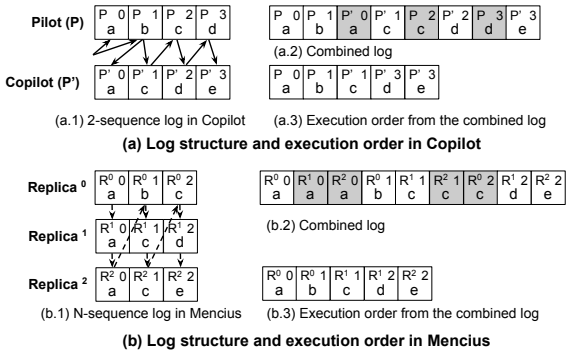

Figure 4: Command execution examples. Each box represents a log entry storing a command, with gray boxes indicating duplicate commands. In (a), the solid arrows show the dependency execution order in Copilot, while in (b), the dashed arrows illustrate the round-robin execution order in Mencius.

to the original path. Clients can select the path explicitly or rely on an adaptive policy (§5). Both clients and replicas track the current original-path view, and every message carries the sender's view so receivers can detect stale operations.

Fast-path processing. Upon receiving a fast-path command, a replica checks for conflicts with uncommitted commands, in both the fast path and the original path. If the command is conflict-free and its view matches the replica's current view, the replica inserts the command into its fast-path log and returns a fast-path acknowledgment. If this replica is a proposer on the original path, it also proposes the command in the original path, regardless of conflicts.

Once the client collects acknowledgments from a superquorum which is at least $(f + \lceil f/2 \rceil + 1)$ replicas and includes all replicas that are original path proposers, the command is fast-committed.

Conflict handling. When conflicts occur, the client may be unable to collect sufficient acknowledgments and promises, causing fast commitment to fail. Jetpack resolves conflicts via the original path, relying on the underlying consensus protocol to order and commit conflicting commands. This design is sound: all commands, fast or not, are eventually handled by the original path. When a fast-path command conflicts with other commands, it can still proceed with the original path as a regular command. From the client's perspective, when fast commitment fails, it waits for the command to commit through the original path.

Figure 3 shows Jetpack integrated with Raft. Commands A, B, and C are conflicting. Command A is fast-committed and also committed on the original path. Command B, intended for the original path only, is committed by the Raft leader without fast-path messages. Fast commitment of command C fails due to conflict with ongoing command B; the leader later commits C via the original path and notifies the client.

Execution correctness. The workflow above places every fast-committed command ahead of any concurrent conflicting commands in the original path log. To ensure the original path produces the same state as the speculative execution on the fast path, execution must respect this log ordering. We require the following prerequisite for the original path:

PR 1. *For two conflicting commands A and B proposed by the same proposer, if A is proposed before B, then A precedes B in the log and is guaranteed to execute before B.*

Although this requirement may appear strict, it is commonly satisfied in practice. The proposer proposes commands by inserting them into its log sequence in an append-only manner, ensuring that any command proposed earlier will always precede those proposed later. Consensus protocols then typically enforce that commit and execution follow the same order as the log. For example, Raft commits and executes log entries strictly in log-index order, meeting this prerequisite. For protocols with multiple log sequences, such as Mencius (Figure 4(b)), a log entry commits only after all earlier entries across all sequences have committed. Copilot, which maintains two log sequences, enforces execution according to dependency order. As shown in Figure 4(a), as long as each proposer inserts command *a* before command *b* in its own sequence, the merged global execution order (Figure 4(a.3)) places *a* before *b*.

To demonstrate generality, we conducted a compatibility study across 16 consensus systems published in OSDI and SOSP since 2000, excluding BFT systems [36, 29, 52, 37] and transactional consensus systems [50, 65, 27]. Figure 5 shows the results. Of these, 6 already have a built-in fast path. Of the remaining 10, 9 satisfy this prerequisite. This indicates that PR 1 captures properties already common in modern consensus protocol design.

Only EPaxos [49] violates PR 1. EPaxos enforces execution according to dependency order, constructed from dependency graphs that may reorder commands through topological sorting. Whether EPaxos can be adapted to work with Jetpack remains open; a promising direction is forcing the topological sort to respect command insertion order.

4 Handling View Changes

The workflow of §3.3 assumed a stable proposer set. We now turn to the harder case: failures and reconfigurations that change the proposer set. We first identify the structural

Protocol(s)	Compatibility
NOPaxos [44], SWARM [51], QuePaxa [62], SKYROS [31], SwiftPaxos [59], LazyLog [46]	already have 1 RTT fast path
Delos [20], Mu [13], Rabia [56] Copilot [53], SAUCR [14], Scatter [34], Mencius [48], Chubby [23], CRANE [28],	compatible with Jetpack (i.e., satisfy PR 1 and PR 2)
EPaxos [49]	violates PR 1

Figure 5: Jetpack compatibility across consensus papers from OSDI/SOSP since 2000.

requirements that any fast-path layer must meet across a view change (§4.1), then derive Jetpack's two design principles from those requirements (§4.2) and describe the recovery procedure (§4.3). Finally, we use prior fast-path designs as evidence that the requirements are real and easy to miss (§4.4).

4.1 The view change hazard

Recall the promise from §3.2: when a fast-path command c is acknowledged, the original path's proposers cannot commit a conflicting command before c. This promise was made by a specific set of proposers in a specific view. The promise itself is *not* durable state in the original protocol—it lives in the fast-path replicas' acknowledgments and in the old proposer's local state. After a view change, none of that is guaranteed to survive: fast-path replicas may have advanced their views, the old proposer may have crashed, and the new proposer was not party to the promise at all.

For the system to remain correct across view changes, the new proposer must do two things on behalf of the old one:

- **(R1) Recover every fast-committed command from the previous view**. A command that was fast-committed before the view change must remain visible—clients have already received acknowledgments based on it.
- **(R2) Place each recovered command before any conflicting uncommitted command in the new view's log.** The fast-path promise was specifically about ordering: the recovered command must execute before any conflicting command the new proposer might propose.

We call the failure of either requirement the *view change hazard*. Both requirements are subtle:

- **R1 is harder than it appears** because the "previous view" is itself ambiguous. Different fast-path replicas may have advanced to different views, and acknowledgments for a single command may straddle multiple views. A naive implementation that simply collects logs from a quorum of survivors can miss commands the client believed were committed.
- **R2 conflicts with standard view-change behavior** in many consensus protocols. Many systems tend to let new proposers carry uncommitted entries forward from prior views (e.g., MongoDB). This is safe in the original protocol, since those entries carry no ordering promise, but it directly violates R2 once a fast path is added: a stale uncommitted entry from an old view can land *before* a recovered fast-committed command.

R1 and R2 are the structural requirements every fast-path layer must meet. We next derive two principles that together guarantee R1 and R2.

4.2 Design principles

As R1 suggests, each time the original path enters a new view, it must recover fast-committed commands and commit them on the original path. For recovery to be tractable, fast-path commands must be cleanly partitioned by view, with each recovery restoring only commands from the previous view. This partitioning requires the fast path to track its own view, separate from the original path's: if a fast-path command's view drifted whenever its co-located original-path replica advanced, the partition would blur and recovery could not identify which commands belong to which view.

Therefore, we propose Principle 1 to address R1:

Principle 1. *The fast path maintains its own view, independent of the original path's view. A command is fast-committed only when both paths are in the same view, and it then belongs to that view in the fast-path log.*

Recoverability requires a fast-committed command to be acknowledged by a superquorum on the fast path, as in most fast-path protocols [42, 49, 65, 50, 57, 59]. But when two paths coexist, this is not sufficient: if acknowledgments come from different views, the recovery quorum for any specific view can be broken. A fast-path acknowledgment issued in an old view cannot contribute to the new view's superquorum, and recovery may miss the fast-committed command. Principle 1 prevents this by requiring same-view acknowledgments, ensuring that any fast-committed value remains recoverable.

With Principle 1 addressing R1, we still need to address R2: every fast-committed command must appear before any conflicting uncommitted command in the new view's log. We achieve this by giving fast-path recovery a higher priority than other commands. We capture this priority as Principle 2:

Principle 2. *On entering a new view v, the new proposers must complete recovery of the previous view's fast-committed commands before committing any other command in v.*

Jetpack achieves this without intrusive changes to the original protocol's recovery procedure: the new proposers commit all recovered fast-committed commands before they propose other commands. This entry serves as the *stability marker* for v: a log position that all future proposers must include and that future view changes use as the recovery boundary. The marker prevents stale uncommitted commands from older views from being committed in v before the recovered fast-path commands.

This priority is not naturally provided by some consensus protocols. Protocols without a fast path, such as MongoDB's pull-based Raft, may commit uncommitted commands from older views during a view change. This is safe in the original protocol (which makes no ordering promise), but once a fast path is added without the stability marker, a stale uncommitted entry could land ahead of a recovered fast-committed command, violating the principle.

Together, these principles guarantee correctness: Principle 1 satisfies R1, ensuring fast-committed commands remain recoverable, while Principle 2 satisfies R2, ensuring consistent ordering of recovered commands across views. §4.3 turns these principles into a concrete recovery protocol. Readers interested in examples of the consequences of violating these principles may jump to §4.4.

4.3 Recovery procedure

Jetpack leverages the original protocol for failure detection and view changes, adding only the synchronization needed to preserve fast-path promises across views.

Two events trigger a view change: proposer reelection changes the proposer set, and membership reconfiguration changes the replica set. Jetpack handles both uniformly by tapping into an interface the original protocol already exposes: a *Propose*() entry point invoked once per command, and a *view* value carrying the current proposer set, membership, and a monotonic identifier.

The proposer maintains the view in which it last called *Propose*(). On each *Propose*() call, it compares the current *view* against this stored view; a mismatch triggers the Jetpack recovery procedure, which carries any fast-committed commands from the old view into the new one.

The entire recovery procedure has three phases:

Phase 1: Detect view change and pause. When a replica detects the view has changed to v, it probes the original path for the most recent committed recovery set (see Phase 3). That set belongs to v_n, the *last normal view*: all views before v_n have already been recovered, so the system could process commands normally in v_n. The replica then acts as the recovery coordinator for v_n. The coordinator broadcasts BEGINRECOVERY to the replica set of v_n, instructing them to stop processing client requests and enter recovery mode. It retries until a majority of replicas acknowledge.

Phase 2: Determine the recovery set. Jetpack runs a Paxos-like procedure to agree on the *recovery set*—the fast-path commands issued in v_n. The coordinator broadcasts PREPARE($v_n \to v$), requesting stored commands from the replica set of v_n.

Each replica returns its previously accepted recovery set for v_n if it has one, otherwise returns its acknowledged commands in v_n (which may be empty). If it already has the consensus result on v_n's recovery set, it can return that instead. By Principle 1, all fast-committed commands in v_n appear on a superquorum and are therefore recoverable.

Once the coordinator collects replies from a majority, it builds the recovery set: if any reply carries an accepted set, it adopts that set; otherwise, it aggregates the returned commands—a command is included if it appears in at least $\lceil f/2 \rceil + 1$ replies, indicating possible fast commitment. Two conflicting commands may both reach $\lceil f/2 \rceil + 1$; in such cases, neither was fast committed, so recovering either is safe.

The coordinator broadcasts ACCEPT($v_n \to v$) containing the recovery set. The set is finalized once at least $f+1$ replicas store and acknowledge it. If recovery fails, any replica that previously accepted a recovery set for a given view includes it in future PREPARE replies; the coordinator simply reuses the attached set. This guarantees all recoveries for the same view recover the same command set. The same mechanism extends to cascading failures across views: by Principle 2, a new view cannot become normal until recovery of the last normal view completes, so all coordinators in successive failed views target the same last normal view and converge to the same recovery set via the accepted-set carry-forward.

Phase 3: Resubmit and resume. The coordinator resubmits the recovery set to the original protocol by sending the set to the new proposer and waiting for it to commit. By committing the recovery set in the new view, the proposer enforces Principle 2. If the recovery set is empty, the coordinator resubmits a single no-op. This commit of the recovery set (or the no-op) serves as the marker that future recoveries use to identify the last normal view in Phase 1.

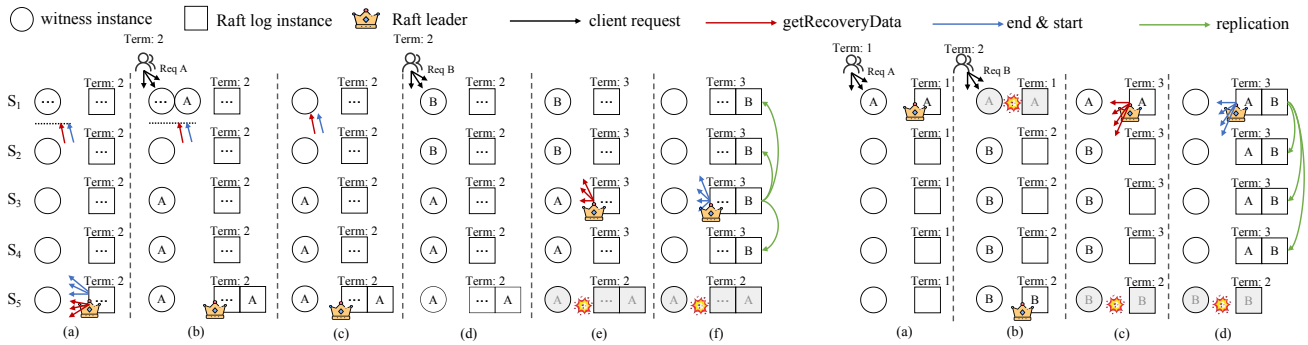
Once these entries commit, the coordinator broadcasts FINISHRECOVERY with the new view v to the replica set of v. Each replica updates to the new view, switches back to normal mode, and begins accepting client commands.

Appendix B provides the full recovery algorithm and optimizations to reduce latency and communication cost.

4.4 The hazard in prior fast-path designs

R1 and R2 are easy to overlook when adapting a fast-path idea to a new consensus environment. To see where the hazard tends to appear in practice, we examine three fast-path designs whose treatment of view changes leaves R1 or R2 incompletely addressed: CURP's sketched Raft extension, a production system that builds on this sketch, and Carousel.

CURP is the protocol most closely related to Jetpack. Both share the high-level idea of running a fast path alongside the original path, but they sit at different abstraction levels. CURP is principally a primary-backup fast-path design; its extension to Raft appears as a brief sketch in the paper's appendix and is not the focus of CURP's main contribution. Jetpack works at a different level: it tries to articulate the structural conditions a fast-path layer must satisfy when paired with a consensus protocol, so they can be reused across consensus environments rather than re-derived for each combination. The two cases below illustrate gaps in the appendix-level Raft sketch, not



Case 1: In (a), S_5 becomes the new leader and all replicas advance to term 2. S_5 sends getRecoveryData to freeze all witnesses, and then sends end & start messages to reset all witnesses after recovery, but S_1 doesn't receive them due to network delay. In (b), the client issues command A at term 2. S_5 and four witnesses, including S_1's stale witness, ack the command. In (c), S_1 later receives the delayed end & start messages and clears its witness state. In (d), the client issues command B at term 2, only two witnesses acknowledge it, so fast commitment fails. In (e), S_5 crashes and S_3 is elected as the leader. S_3 collects commands from witnesses. In (f), S_3 collects commands from a quorum of S_1, S_2, and S_3, and observes that B appears in a majority of 3 servers. S_3 therefore recovers command B and commits it through Raft replication, causing the true fast-committed command A to be lost permanently.

Case 2: In (a), S_1 is the leader when Client issues command A. Command A only gets ack from S_1, so fast commitment fails. In (b), S_1 crashes and S_5 becomes the leader. Command B receives acks from S_5 and four witnesses, to be fast committed. In (c), S5 crashes, S1 recovers and is re-elected. It retains uncommitted command A in its local log and collects fast-committed commands. In (d), S_1 recovers command B and appends it after A in its log, then commits both in that order. This violates the ordering guarantee made in previous term, where command B is committed without any conflicting before it.

Figure 6: Time sequence illustrating two view-change scenarios in CURP+Raft with conflicting commands A and B.

flaws in CURP's primary-backup design. They show why such structural conditions are useful: even careful sketches can leave subtle conditions unaddressed when extended to a new environment.

The CURP recovery procedure proceeds through four phases when a view change occurs: ① the consensus protocol elects a new leader; ② the new leader broadcasts `getRecoveryData` to all witnesses (the term CURP uses for fast-path replicas), stopping them and collecting stored commands; ③ it determines the set of fast-committed commands and replicates them; ④ it sends an `end` message to clear witness state, then `start` to resume normal processing.

Figure 6 illustrates two scenarios that this procedure does not fully cover, one for each of R1 and R2.

Case 1: a gap related to R1, where a fast-committed command can be silently lost. In Figure 6 Case 1(b), command *A* is fast-committed after being acknowledged by a superquorum of witnesses, including the witness at S_1, which is still in the old term. Later, when S_1 receives a delayed `end` message, it erases all stored commands, including *A*. As a result, *A* no longer has superquorum durable storage, and a subsequent leader failure can lose it.

The cause is subtle: in the appendix sketch, CURP uses the corresponding replica's term as the witness term, so a witness lagging in term 1 can approve a command in term 2 based on stale view information. When S_1 later clears its state during recovery, the fast-committed command is gone, and the new leader can insert a different command *B* where *A* should appear. This corresponds to the situation R1 calls out (acknowledgments straddling views), and Principle 1 closes the gap.

Case 2: a gap related to R2, where the promised order can be broken. In Figure 6 Case 2(b), command *B* is fast-committed after S_5 (the old leader) acknowledges that no conflicting command exists. However, when S_1 is elected as the new leader, its log contains an earlier uncommitted command *A*. When the system recovers, command *A* appears *before* the recovered command *B* in the log. This corresponds to the situation R2 calls out (uncommitted entries from prior views landing ahead of recovered fast-committed commands), and Principle 2 (the stability marker) closes the gap.

Production system. To see how the gap manifests in deployed code, we examined a production system that implements CURP-on-Raft, namely Xline [11]. As a production system, Xline is engineered conservatively, with extensive safety checks: it pauses the entire system when a view change occurs and only resumes the fast path after the original path has committed many commands in the new view. This conservatism happens to cover Case 1, but Case 2 still occurs and can lead to data inconsistency. We reported the issue and filed a patch.

Our own implementation with MongoDB tells a similar story: integrating a CURP-style fast path directly into MongoDB ran into a similar gap, because MongoDB's pull-based optimizations are correct under Raft alone but no longer satisfy R2 once a fast path is added (§6.6).

Carousel. A third example appears in Carousel [64], a transactional protocol whose new-leader procedure replicates uncommitted log entries before recovering fast-path transactions; this corresponds to the same R2 situation as Case 2. The full scenario is in Appendix A.

Takeaway. Across these three examples, the same gaps appear because each fast-path integration rediscovers the structural conditions for view changes. Spelling them out once at the framework level allows future fast-path integrations to avoid these gaps by construction.

5 Implementation: Jetpack as a shim layer

Directly extending the original consensus protocol with conflict checking and promise making would require intrusive modifications. To keep changes minimal, we implement Jetpack as a shim layer which we refer to as Jetpack replicas. A Jetpack replica is a process colocated with the originl replica and it sits between clients and the original path. All commands are first sent to Jetpack replicas. Upon receiving a command, each Jetpack replica: (i) forwards it to the paired original replica if this replica is a proposer, and (ii) inserts the command into Jetpack replica's own log. For fast-path commands, a Jetpack replica checks for conflicts and, if conflict-free, issues a promise on behalf of its paired original replica.

A command is fast-committed once the client receives promises from a supermajority of Jetpack replicas, including all those paired with original proposers. If insufficient promises are collected (e.g., due to conflicts), the client waits for the original path to commit the command (§3.3).

Correctness requirement. This shim-layer design preserves correctness by ensuring proposers receive commands in an order consistent with the promise order made by Jetpack. However, this relies on a crucial assumption: the arrival order of commands at each proposer must match their insertion order in the log. Under this condition, a supermajority promise guarantees all proposers place a fast-committed command ahead of any uncommitted conflicting commands, enforcing the promise defined in §3.2. With PR 1 ensuring that the proposed order matches the log order, we also require the following prerequisite to guarantee that commands' arrival order on the proposer matches their proposal order:

PR 2. *For any two commands A and B, if a proposer receives A before B, it will propose A before B.*

Most consensus protocols naturally satisfy this property. However, protocols with additional buffering layers for performance may violate it. For example, Nezha [32] from VLDB employs two intermediate buffers where commands may reside before being appended to the log, breaking equivalence between arrival and log order. As shown in Figure 5, each consensus protocol we surveyed satisfies this prerequisite.

Fast paths beyond PR1 and PR2. When PR2 is violated, arrival order no longer matches proposal order, so the fast-path reply must wait until the command is proposed into the original log. When PR1 is violated (e.g., EPaxos), neither arrival nor proposal order matches execution order; the fast path has no latency advantage and Jetpack cannot meaningfully apply.

Conflict detection. Jetpack replicas detect conflicts based on the key-value interface against in-flight commands stored in command pool, which is a hash map from keys to lists of in-flight commands; the replica reports a conflict on key k if either the new command or any in-flight command on k is a write. A Jetpack replica returns a fast-path acknowledgment only if no conflict is detected; otherwise, the command commits via the original path. All commands, both fast-path and original-path, are inserted into the list, ensuring future fast-path commands detect potential conflicts with all in-flight commands. Other applications can replace this data structure with one matching their detection needs, e.g., interval indexes for ranges or coarser table/namespace-level tracking.

Richer workloads (range queries, SQL predicates, aliased objects, etc.) would need support through the application-provided Conflict interface, e.g., with interval indexes for ranges or coarser scope-based detection (tables, namespaces) for opaque dependencies. Jetpack follows other fast-path protocols in delegating this conflict logic to the application [50, 57, 59, 49, 64].

Garbage collection. To avoid unnecessary promise rejections from stale entries in the command pool, Jetpack replicas must promptly remove completed commands. Once a command is finalized by the original protocol (committed and executed), the result is sent back to the client. Jetpack, as the shim layer, observes these replies and initiates garbage collection: (i) the Jetpack replica that receives the reply removes the command from its own command pool and forwards the result to the client; (ii) it notifies other Jetpack replicas to evict the command from their command pools.

Command execution. After commands commit on the original path, they are executed and applied to the state machine. Since Jetpack proposes fast-path commands to all proposers, multi-sequence protocols like Copilot and Mencius may insert the same command into multiple sequences, resulting in duplicates (e.g., commands a, c, and d in Figure 4).

Copilot naturally tolerates such duplication because a command can be proposed by both pilot and copilot. After merging the two sequences, Copilot executes each command only at its first position (Figure 4(a)). Protocols like Mencius can apply a similar strategy. After ordering log entries round-robin, as shown in Figure 4(b.2), a replica skips duplicate commands (highlighted in gray) and executes only the first occurrence, yielding the final execution order in Figure 4(b.3).

Adaptive path selection. Although the fast path reduces latency, it is not always beneficial. It sends each command to all proposers, increasing CPU load and lowering throughput under saturation. Server locality also matters: when a client is close to the original proposer, replicating to a majority may be faster than obtaining a superquorum for fast commitment.

Jetpack supports adaptive path selection to balance these trade-offs. When CPU load is low, latency dominates, so the fast path is preferred if it is faster; when the system is heavily loaded or the fast path offers no advantage, the client backs off to protect throughput. Each client monitors recent latencies and CPU usage and adjusts its fast-path attempt rate accordingly. Appendix C details the policy, which §6.4 shows preserves original-path performance.

6 Case Studies and Evaluation

We apply Jetpack to six representative systems: Raft, a widely deployed single-leader protocol; Copilot, a dual-leader proto-

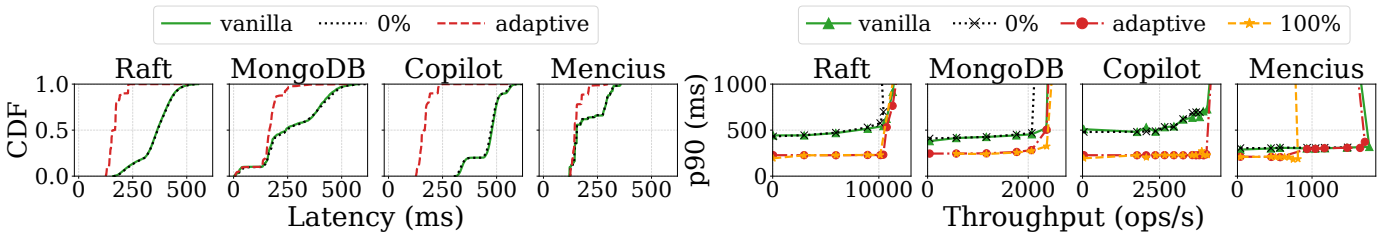


Figure 7: Latency CDF (left) and throughput–latency (right) for Raft, MongoDB, Copilot, and Mencius under a uniform 50/50 read/write workload, comparing the vanilla protocol, Jetpack with fixed attempt rates, and Jetpack in adaptive mode.

col that tolerates fail-slow behavior; Mencius, a classic multi-leader protocol; and MongoDB, a production system with a customized Raft variant. Two additional production case studies on etcd and ZooKeeper appear in Appendix E. In addition to the empirical results below, we model-check each integration in TLA+ for view-change correctness; the specs and artifacts are available at [3].

6.1 Integration

Applying Jetpack requires only minimal modifications to the normal execution path, leaving core protocol logic unchanged. The primary effort lies in handling recovery and view changes through a few lightweight hooks.

On the client side, we assume the original protocol exposes a *Submit*(*cmd*) function. This function is invoked when the client receives either a combined message or an original-path message, and it may also be invoked to resubmit commands during Jetpack recovery.

On the server side, the assumptions and hooks are described in §4.3. The MongoDB integration required 60 lines of code on the original protocol server side; the etcd and ZooKeeper integrations required 68 and 52 lines, respectively.

To prevent Case 2 (§4.4), a new proposer must commit at least one log entry in the new view before acknowledging fast-path commands (§4.2). This requires no modification to the original protocol: Jetpack ensures it by resubmitting recovered commands during recovery. If the recovery set is empty, Jetpack resubmits a no-op and waits for it to commit.

6.2 Experimental setup

Implementation. We implemented Jetpack in C++. For Raft and Copilot, we built on DepFast [47]. For Mencius, we implemented it in the same codebase. For MongoDB, we built on the open-source 8.2.0 release.

Testbed. Experiments ran on AWS EC2 across 10 geo-distributed datacenters (latencies in Appendix D): replicas in datacenters 0–4, clients in all 10. Each 8-vCPU / 16 GB-RAM instance places Raft, etcd, and ZooKeeper's leader in datacenter 0, and Copilot's pilot and copilot in datacenters 0 and 1.

Workload. We use a YCSB-inspired workload similar to CURP: 50% reads and 50% writes over 1M Zipfian-distributed keys by default; we sweep skew 0.5–1.0 and key range 100–1M to vary contention. 60 open-loop clients with multi-threaded request issuance drive load.

6.3 Raft

Integration with Raft follows the standard workflow in §6.1. In Raft, a newly elected leader may contain stale uncommitted entries, potentially triggering Case 2 (Figure 6). With Principle 2 enforced, replicas carrying stale commands are never eligible for election, preventing this case by construction.

Figure 7 shows the latency CDF for vanilla Raft and Jetpack-integrated Raft. With adaptive path selection, Jetpack reduces latency by 53.39% on average, achieving the first design goal (§2). When the fast-path attempt rate is zero—all commands use the original path—the Jetpack curve nearly overlaps with vanilla Raft (Figure 7), confirming no performance degradation when the fast path is unused.

Figure 7 shows behavior under varying load. At low concurrency, adaptive mode aggressively uses the fast path, yielding substantially lower latency. As load grows, the adaptive policy reduces the fast-path attempt rate, causing Jetpack to converge smoothly to vanilla Raft. This demonstrates that Jetpack captures fast-path benefits when available while preserving original performance under saturation. Past the knee, some curves bend back due to queuing at oversaturated replicas—an overload effect rather than a measurement artifact.

Figure 8 shows results under high contention (increased Zipfian skew, smaller key range). The latency benefit diminishes as contention grows due to more conflicts, yet Jetpack consistently outperforms vanilla Raft on both average and p99 latency across all contention levels.

During view changes, Jetpack must recover fast-path commands, introducing additional latency. Figure 9 shows this effect: we trigger a view change by shutting down the leader. After the 10-second timeout, both systems begin recovery. Vanilla Raft completes recovery almost immediately after electing a new leader (orange line). Raft+Jetpack incurs an additional ∼1 second, the time to recover fast-path commands.

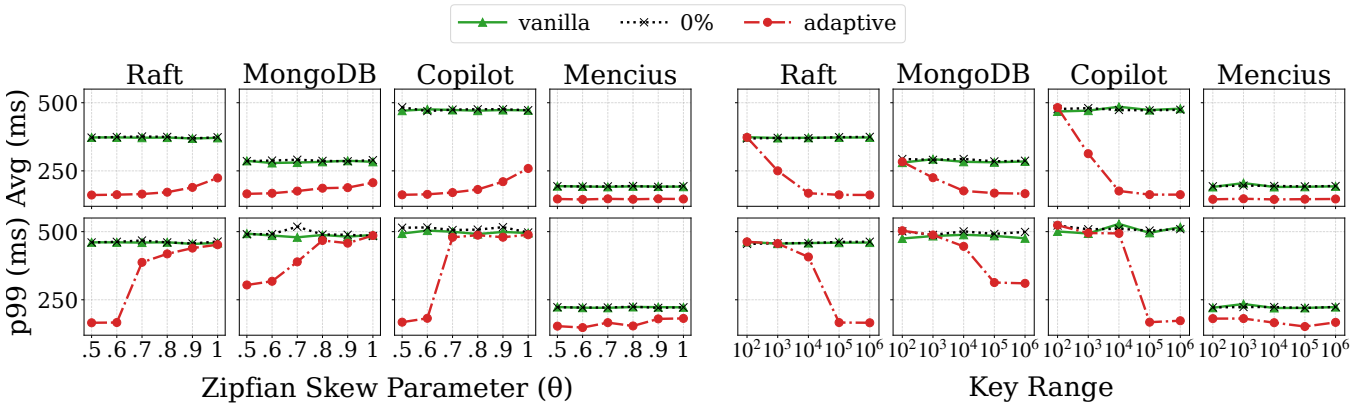

Figure 8: Average and p99 latency for Raft, MongoDB, Copilot, and Mencius under a 50% read / 50% write workload with varied contention.

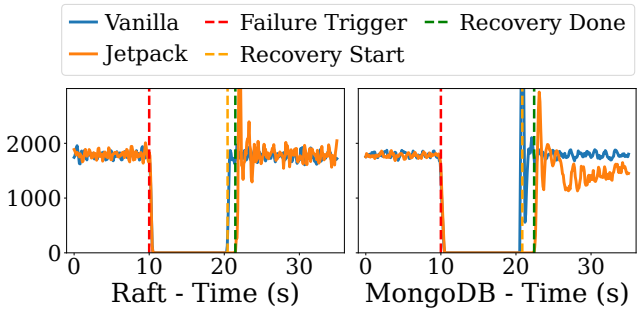

Figure 9: Failure recovery of Raft and MongoDB.

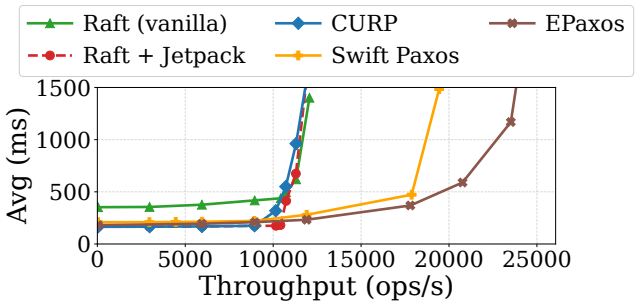

Figure 10: Throughput-latency comparison across Raft, Jetpack, CURP, SwiftPaxos, and EPaxos.

6.3.1 Comparison with native fast-path protocols

We compare Jetpack-Raft against three protocols that achieve a 1-RTT critical path natively: CURP [57] (a witness-based fast path layered on Raft with the view-change hazard fixed), SwiftPaxos [59] (clients broadcast directly to all replicas), and EPaxos [49] (a leaderless protocol where any replica proposes). Vanilla Raft serves as the 2-RTT baseline. All five share a common codebase and run on the testbed of §6.2; for a fair comparison, each replica's consensus thread is pinned to one core and we use a uniform 50/50 read/write workload over 1 M keys to isolate protocol overhead from contention.

Figure 10 shows the throughput–latency curves. At low load, the four 1-RTT protocols (Jetpack-Raft, CURP, SwiftPaxos, EPaxos) commit at 165–210 ms, while vanilla Raft commits at ∼355 ms. Jetpack's plug-in fast path therefore matches the latency of native fast-path designs.

Throughput differentiates the five: Raft, Jetpack-Raft, and CURP saturate at 12 k; SwiftPaxos peaks at ∼19 k; EPaxos at ∼25 k. This gap reflects the tradeoff between generality and deep integration: SwiftPaxos integrates the fast-path broadcast into consensus so the leader skips replicating, and EPaxos makes every replica a command leader to distribute replication across replicas; Jetpack's plug-in design keeps the original path unaware of the fast path and so inherits its throughput envelope, trading throughput for broad applicability.

6.3.2 Composing with production latency mitigations

We further examine whether Jetpack composes with latency mitigations already used in production. Modern geo-distributed deployments often combine two latency mitigations: *leader locality*, which places the leader near the dominant client population, and *lease-based local reads*, which let the leader serve linearizable reads from local state under a quorum-anchored lease. A natural question is whether these techniques subsume Jetpack's fast path, or whether Jetpack remains complementary.

We answer this with a 5-region AWS deployment driven by Facebook's Akkio traces [16]. Akkio migrates each microshard of data toward its dominant access region but cannot perfectly co-locate every client with its shard's leader; the residual steady-state access distribution is roughly 73/8/9/7/3% across the five regions, with 73% of requests accessing the local shard. We mirror this directly: each shard's leader pins to one region, and clients access the five shards in this ratio. Other workload knobs follow Facebook production measurements: 50-byte keys from ZippyDB [24] (a primary Akkio workload), Zipfian skew $\theta = 0.8$ from TAO [21], and a 50/50 read/write ratio from ViewState [45]. We compare five variants: a random-access baseline (Raft on a uniformly random workload); vanilla Raft (Raft on the Akkio distribution, achieving leader locality); Raft+Lease (adds a quorum-

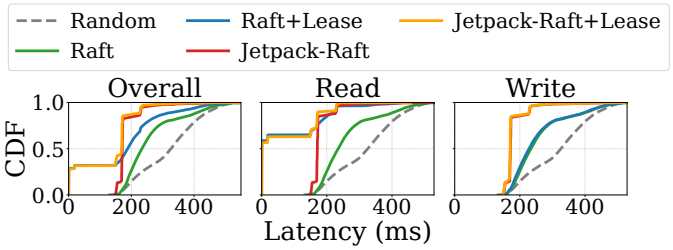

Figure 11: End-to-end latency CDFs (overall, reads, writes) on an Akkio-style simulated workload, comparing random leader placement, vanilla Raft, Raft with read leases, Jetpack-integrated Raft, and Jetpack-integrated Raft with read leases.

anchored read lease on top); and the corresponding Jetpack-Raft and Jetpack-Raft+Lease that integrate Jetpack's 1-RTT fast path.

Figure 11 plots the resulting latency CDFs, with reads and writes shown separately. Leader locality is already effective for the dominant 73% of requests, which reach the local leader within an intra-region hop; the remaining 27%, however, reach a remote shard's leader, paying 2 RTTs. Adding a quorum-anchored read lease lowers latency further, but only on the read side: lease reads complete sub-millisecond when served by the local leader, whereas writes still traverse the entire consensus path. Together, these two limits leave the upper half of Raft+Lease's overall CDF above 300 ms. In contrast, Jetpack's 1-RTT fast path is general, applying to reads and writes uniformly. Its advantage therefore emerges across the entire upper half of Raft+Lease's overall CDF, dominated by writes that the read lease cannot accelerate.

Jetpack is also orthogonal to leader locality and the read lease, composing naturally with both. With locality alone, the 27% remote-shard requests pay 2 RTTs under vanilla Raft. Jetpack's fast path absorbs this overhead, so Jetpack-Raft outperforms vanilla Raft. Adding the read lease on top yields the best regime in Figure 11: local reads complete sub-millisecond through the lease, every write commits in 1 RTT through Jetpack's fast path, and remote-shard reads complete in 1 RTT through either Jetpack's fast path or the read lease. No single mechanism attains this regime in isolation.

6.4 Copilot

Copilot is a dual-leader protocol: a pilot and copilot commit commands independently in separate logs. This provides 1-slowdown tolerance—if one leader becomes slow, the other continues committing. After commitment, the two leaders reconcile logs by establishing cross-log dependencies; this dependency-based ordering preserves per-log order, so Copilot satisfies PR 1.

Despite having its own fast path, Copilot still takes 2 RTTs to commit. Applying Jetpack remains beneficial: Figure 7 shows Jetpack reduces Copilot's latency by 63.90% on average because Copilot frequently fails its `FastAccept` phase

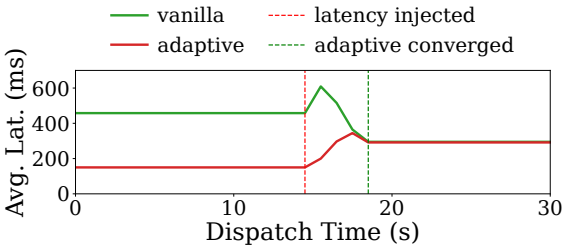

Figure 12: Copilot slowdown tolerance preservation

in geo-distributed deployments and falls back to its 3-RTT slow path. Jetpack's 1-RTT fast path yields large gains even under high contention (Figure 8).

The integration preserves Copilot's slowdown tolerance (Figure 12). We compare vanilla Copilot against Jetpack-integrated Copilot under a simulated pilot slowdown, injecting 300 ms one-way latency using `tc`. The results unfold in three phases: (i) Baseline: Jetpack-integrated Copilot achieves lower latency via its fast path. (ii) Slowdown: when the pilot slows, latency rises for both systems. (iii) Adaptation: vanilla Copilot's copilot performs a takeover; Jetpack's adaptive mechanism detects the slower fast path and reduces its attempt rate, falling back to vanilla Copilot with nearly identical latency.

6.5 Mencius

Mencius is a multi-leader protocol with an N-sequence log for N replicas; each replica leads one dimension. A client normally takes 2.5 amortized RTTs to commit in Mencius.

Integration follows §6.1. With Jetpack, a client can commit in 1 RTT. However, as Figure 7 shows, the fastest 50% of requests show no improvement—vanilla Mencius and Jetpack nearly overlap. Clients co-located with a proposer (5 of 10) already pay only one cross-datacenter RTT; the intra-datacenter hop is negligible, so the fast path yields little benefit. Remote clients incur two cross-datacenter RTTs and see improvement, visible in the slower half of the distribution.

Because all replicas are leaders, each command must be broadcast to every replica, causing each command to be processed multiple times with substantial CPU overhead. As Figure 7 shows, at 100% fast-path rate, Jetpack-integrated Mencius saturates quickly. Adaptive mode mitigates this by dynamically choosing paths: under saturation, it backs off automatically, matching the original protocol's throughput.

Overall, Jetpack's benefit on Mencius is smaller than that in other case studies; moreover, the fast path becomes unavailable upon any replica failure, since fast commitment requires all leaders.

6.6 MongoDB

MongoDB uses a pull-based Raft variant: followers pull entries from a sync source rather than the leader actively repli-

	Memory		CPU	
	Base (MB)	Extra (MB)	Base (%)	Extra (%)
Raft	618.69	30.16	54.26	9.57
Copilot	630.22	28.45	54.52	5.45
Mencius	560.37	5.61	16.70	36.83
MongoDB	919.43	38.86	73.47	3.30
etcd	727.04	27.12	61.22	4.76
ZooKeeper	774.18	5.81	95.96	3.03

Figure 13: Jetpack overhead

cating. During leader election, the new leader may pull uncommitted entries from other replicas, and such stale entries can be inserted ahead of fast-committed commands. We modified the catch-up procedure to skip those uncommitted entries (safe because they were either never acknowledged to clients or acknowledged under weak consistency without durability promises), preventing the case in §4.4.

With Jetpack, MongoDB achieves 39.06% average latency reduction (Figure 7). Approximately 5% of requests show near-zero reduction because reads from clients co-located with the leader are served locally without replication. Under contention (Figure 8), the benefit decreases due to higher conflict rates, yet Jetpack consistently outperforms vanilla MongoDB.

Figure 9 shows recovery performance: once a new leader is elected, Jetpack incurs an additional 1.5 seconds compared to vanilla MongoDB, the time to recover fast-path commands.

6.7 Jetpack overhead

Jetpack reduces latency at the cost of additional resources. We measure CPU and memory overhead across all systems using a uniform workload with 50% reads and 50% writes, with adaptive mode enabled. Figure 13 summarizes baseline consumption and Jetpack's additional overhead.

Across all systems, Jetpack introduces low CPU overhead and modest command pool memory overhead. Mencius is the exception, incurring substantially higher CPU overhead.

Mencius's high CPU overhead explains its limited improvement (§6.5): the extra load saturates the system early, leaving little headroom for the fast path to translate into client-visible gains. This is structural rather than an implementation artifact: Theorem 4 (Appendix G) shows that non-intrusive integration of a client-side 1-RTT fast path with a multi-leader protocol incurs per-command CPU overhead that grows linearly with the number of leaders.

6.8 Discussion of Jetpack's applicability

The empirical results above motivate where Jetpack fits in practice. Jetpack targets geo-distributed settings, where cross-datacenter round trips dominate commit latency. The benefit is largest in single-leader protocols, as remote clients pay a 2-RTT penalty. Production systems therefore commonly adopt multi-leader designs to spread leaders across regions for client-leader co-location. Jetpack still provides improvement on top of these designs, though the magnitude depends on the specific multi-leader pattern, as we discuss below.

One common multi-leader design is the *sharded multi-leader* pattern: data is sharded, each shard runs an independent consensus group with a single leader, and clients co-locate with the leader of the shard they access. Jetpack fits particularly well here. Production traces show that no sharding strategy is perfect [16, 60]: some clients inevitably access shards whose leaders are remote, reaching up to 53% in Facebook's Akkio trace. Jetpack's 1-RTT fast path delivers substantial latency reduction precisely on these remote-shard accesses with low overhead, as our Akkio results show (§6.3.2).

Another design is the *shared-log multi-leader* design (e.g., Mencius), where multiple leaders propose to a single log. Applying Jetpack here incurs structural per-command CPU overhead linear in the number of leaders. Although clients still see latency benefit, this overhead causes the system to saturate sooner, as our Mencius case study shows (§6.5).

A survey of the top 10 DB-Engines databases [1] confirms this: six support multi-shard deployment with leader-based per-shard replication [5, 10, 8, 6, 9, 4]; none use shared-log multi-leader. Mainstream geo-distributed NewSQL systems show the same pattern [38, 61, 12, 27]. Together, these show that the *sharded multi-leader* pattern is the common practice, where Jetpack naturally applies.

7 Conclusion

This paper presents Jetpack, a general approach for adding a 1-RTT fast path to existing consensus systems. The central technical insight is the *view change hazard*: promises made by the original path during stable operation can become invalid after a leader election, breaking the fast path's safety guarantee. Jetpack captures the hazard in two structural requirements that a fast-path layer must meet when paired with a consensus protocol, and addresses them with two design principles. We integrated Jetpack with six representative consensus systems. Across these integrations, Jetpack reduces average commit latency by up to 60% on the fast path and matches the original system's performance when the fast path is not used. We see Jetpack as a step toward making fast-path optimization a reusable layer across consensus systems.

Acknowledgments

We are grateful to our shepherd, Manos Kapritsos, as well as the anonymous reviewers of OSDI '25 and OSDI '26 for their thorough and insightful feedback. We thank Ye Tian for his work in the early stage of the project, and Chenyu Wang for taking charge of running AWS experiments for the first submission. A View change hazard in Carousel

Carousel [64] is a transactional protocol that integrates consensus with distributed transaction processing. Within each data shard, Carousel relies on Raft to replicate transaction results among replicas. To reduce replication latency, Carousel adds a fast-path optimization that exhibits the Case 2 hazard pattern (§4.4).

For clarity, we peel the cross-shard distributed transaction coordination from the complete Carousel protocol and focus on the replication within a single shard. To enable fast replication, each transaction is broadcast to all replicas. Upon receiving a transaction, a replica places it into a local *pending list* and checks whether it conflicts with any earlier transaction. If no conflict is found, the replica responds with PREPARED. Once a coordinator collects PREPARED responses from a superquorum of replicas in the same view, the transaction is considered PREPARED on that shard, and the coordinator replies to the client if all shards are PREPARED. The transaction still goes through the normal Raft replication to complete, but the coordinator does not need to wait for it.

When the leader fails, Carousel runs the standard Raft leader election procedure to elect a new leader. During the election, each replica includes its pending list in its vote, allowing the new leader to identify transactions that have succeeded on the fast path.

After a new leader is elected, however, the recovery procedure creates a subtle ordering issue. As specified in §4.3.3 of the Carousel paper [64], the *new leader first completes replicating any uncommitted log entries in its log to followers*, before recovering the fast-path transactions stored in pending lists. If the new leader's log contains uncommitted entries from an earlier term, those entries will be replicated and committed *before* the recovered fast-path transactions.

This ordering does not preserve the fast-path promise from the previous term: once a transaction is fast-PREPARED as non-conflicting, no conflicting transaction should appear ahead of it in the committed order. Committing earlier-term entries ahead of recovered fast-path transactions can invalidate a previously fast-prepared transaction.

An example. Consider two transactions, tx_1 and tx_2, issued by clients C_1 and C_2, respectively. Initially, both data items a and b are 0. Transaction tx_1 writes $a \rightarrow 5$. Transaction tx_2 reads a (obtaining v_a) and then writes $b \rightarrow v_a + 5$. Assume a and b reside on the same shard with five replicas R_1–R_5, and R_1 is the leader in term 1. Carousel processes two transactions in the following order:

1. C_1 starts tx_1.
2. C_1 sends tx_1's Prepare message to all replicas. Due to a network partition, only R_1 receives it.
3. R_1 validates tx_1 (conflict-free), marks it PREPARED, and appends tx_1 to its log.
4. Before replicating tx_1, R_1 crashes.
5. The remaining replicas elect R_3 as the leader for term 2.
6. C_2 starts tx_2, reads a on R_3 obtaining $v_a = 0$, and writes $b = 5$.
7. C_2 sends tx_2's Prepare message to all replicas.
8. R_2, R_3, R_4, and R_5 validate tx_2 (conflict-free), insert it into their pending lists, and reply PREPARED to the coordinator.
9. As the leader, R_3 adds tx_2 into its log.
10. The coordinator collects PREPARED from four replicas, which form a superquorum, and therefore considers tx_2 PREPARED and committed (since tx_2 involves only one shard).
11. R_1 recovers; then, before tx_2 is replicated, R_3 and R_2 crash, leaving R_1, R_4, and R_5 alive.
12. R_1 is elected leader in term 3 (since R_3 crashed before replicating tx_2, the logs of R_4 and R_5 are empty, while R_1's log still carries tx_1 from term 1, so R_1's log is more up-to-date). During the election, replicas R_4 and R_5 send their pending lists, both containing tx_2.
13. R_1 has an uncommitted tx_1 in its log; it first replicates and commits tx_1.
14. R_1 attempts to recover fast-path transactions from the pending lists and discovers tx_2.
15. R_1 validates tx_2, detects a conflict with tx_1. According to §4.3.3 step 4 of the Carousel paper, it considers that tx_2 cannot succeed on the fast path and discards tx_2.

As a result, tx_2 is dropped during recovery and its fast-path completion guarantee is violated, even though the client has already been notified that tx_2 is committed. This example is an instance of violating R2 (§4.1).

We would like to note that our analysis is based solely on the specification available in the paper. We appreciate the Carousel authors' helpful clarification, through personal communication, that Carousel includes additional mechanisms that may address some of the issues discussed here.

B Recovery and correctness

B.1 Recovery protocol

This appendix provides the complete pseudocode (Figure 14) for the recovery procedure described in §4.3.

The recovery protocol proceeds in three phases.

Phase 1 (fast-path freeze). When a coordinator receives a new view from the original protocol's proposer, it first broadcasts BEGINRECOVERY to all replicas in the old view, and instructs these replicas to freeze the fast path so that no fast path can succeed during recovery.

Phase 2 (recovery-set agreement via Paxos). The coordinator then runs a standard Paxos instance to agree on a *recovery set*. The Paxos value is this recovery set, which is computed from the logs returned by the old set and includes all commands that may have succeeded on the fast path.

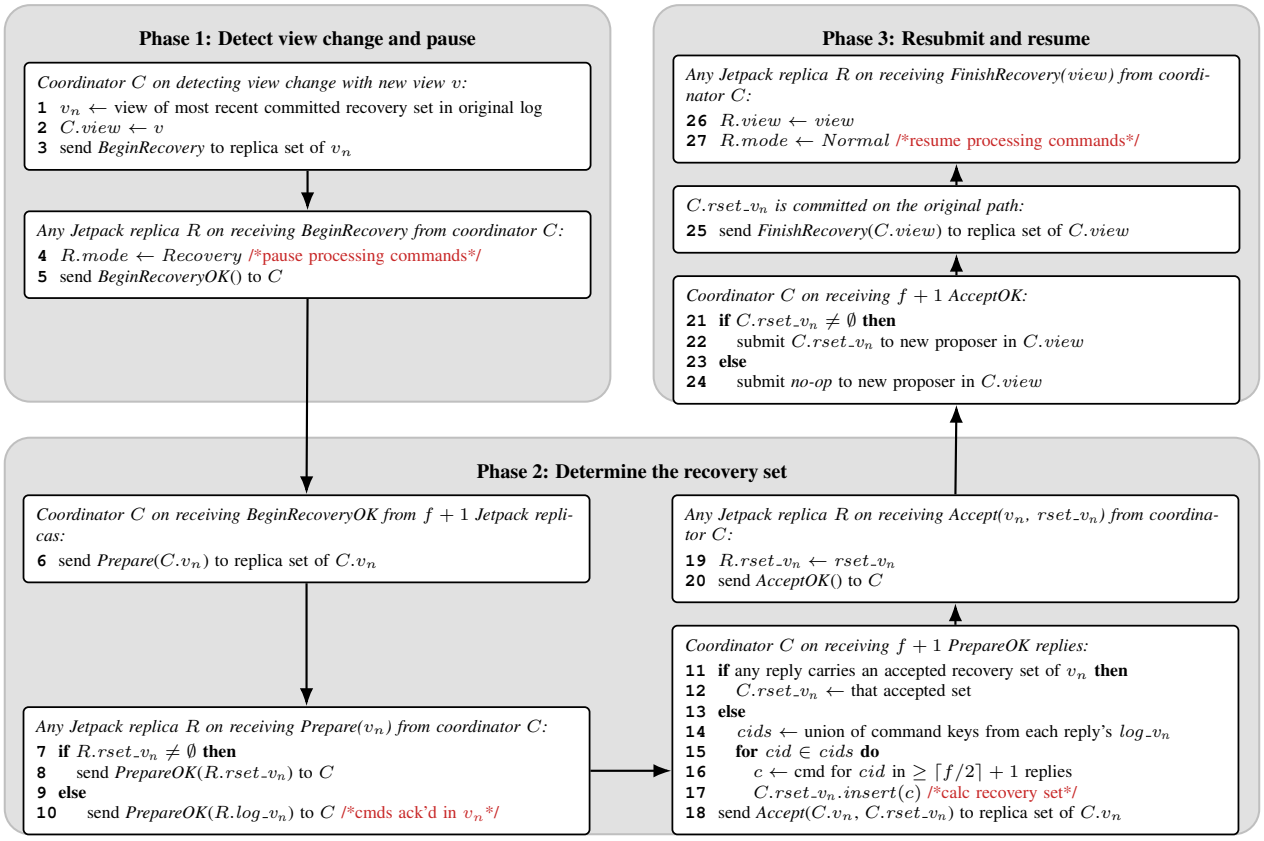

Figure 14: The recovery protocol of Jetpack.

Phase 3 (resubmit and resume the fast path). Finally, the coordinator resubmits the agreed recovery set to the original protocol, or a no-op if the recovery set is empty. The commit of this entry serves as the stability marker that future recoveries use to identify the last normal view in Phase 1. After the entry commits, the coordinator broadcasts a FINISHRECOVERY message to the new replica set, enabling the fast path in the new view.

B.2 Recovery optimizations

Naively, this protocol requires 3 RTT exchanges before any command can be resubmitted: BEGINRECOVERY, PREPARE, and ACCEPT. Moreover, two of these messages carry the entire recovery set or full logs, which can be very large.

We consider two potential optimizations. First, to avoid transmitting the full recovery set or logs, we try to transmit metadata when possible: (1) one RPC to pull log metadata from replicas and compute the recovery set; (2) one RPC to record the metadata and a recovery-set identifier; and (3) one RPC to fetch any command that the current coordinator does not already hold. This optimization replaces large, log-sized messages with smaller metadata messages plus on-demand fetching of missing commands.

However, this refinement increases the total number of RPCs to six. Our second optimization reduces downtime by merging independent steps and thereby reducing the number of round-trips. Concretely, we merge them into two RPCs: one RPC that performs BEGINRECOVERY, pulls log metadata, and executes PREPARE, and a second RPC that records the metadata and recovery-set identifier, pulls missing commands, and executes ACCEPT. The three operations combined in each RPC do not depend on one another, so they can be executed together without changing the protocol's semantics while reducing the number of network round-trips from six to two.

B.3 Correctness proof

We prove that Jetpack preserves correctness when integrated with any original consensus protocol. The proof is structured as follows: we first state our assumptions about the original protocol and define key concepts, then prove three properties—durability, execution consistency, and linearizability.

B.3.1 Assumptions and definitions

We assume the original protocol satisfies the following properties; the *in-order execution* is also enforced in PR 1:

A1. Durability. Once a command is committed on the original path, it will not be lost across view changes.

A2. Consistent ordering. Once a command is committed on the original path at a log position, its position never changes.

A3. In-order execution. The original protocol executes and replies to commands in log order. A command at position j is not executed until all commands at positions $i < j$ are committed.

A4. Linearizability. If command A is committed on the original path before command B is proposed, then B will be executed after A in the log.

In addition, Jetpack enforces the following design principles (from §4.2):

- **Principle 1** (Same-view acknowledgment): A command is fast-committed only when all acknowledgments from both paths are in the same view.
- **Principle 2** (Stability marker): Before activating command processing in a new view v, the new proposers must finish recovering the last normal view v_n and commit at least one entry via the original path in v.

Definition 4 (Fast-path invariant)**.** *If a command A is fast-committed in view v', then during v', no concurrent conflicting command can be committed on the original path at a position before A.*

Justification. This is exactly the fast-path promise made by all original proposers. A fast-committed command A is stored on $f + \lceil f/2 \rceil + 1$ replicas, which includes all proposers. Since every proposer has already received A, any conflicting command B arriving later will be inserted after A in the original log (by PR 2).

We then prove three correctness properties. For each, Cases 1 and 2 (original-path and fast-path-fail commands) follow directly from the original protocol's guarantees. The nontrivial case is always Case 3: a fast-committed command that has not yet been committed on the original path when a view change occurs.

B.3.2 C1: Durability

Any command that has been replied to the client, whether through the fast path or the original path, will not be lost.

Case 1: Original-path command. The command is replied only after it is committed on the original path. Durability follows from **A1.**.

Case 2: Fast-path command, fast commitment fails. The command is replied only after being committed through the original path. Durability follows from **A1.**.

Case 3: Fast-path command, fast commitment succeeds. Once this command is eventually committed on the original path, durability follows from **A1.**. The nontrivial case is when a view change occurs before the command is committed on the original path.

Let v be the new view and v_n be the last normal view. We show that any command fast-committed in v_n is recovered in v.

The command has been stored on $f + \lceil f/2 \rceil + 1$ replicas in v_n's membership (by Principle 1), and by design, these replicas retain fast-path entries until the recovery of v_n completes. Among any $f+1$ replicas of v_n's membership participating in recovery, at least $\lceil f/2 \rceil + 1$ contain the command. Since recovery selects exactly the commands that appear in at least $\lceil f/2 \rceil + 1$ replies (lines 16–17 in Figure 14), the command is included in the recovery set and recommitted on the original path. Once recommitted, durability follows from **A1.**.

Commands from older views. When entering view v_n, the proposers of v_n have already recovered and committed all fast-committed commands from the previous normal view v'' (the normal view immediately before v_n). By induction, every fast-committed command from any earlier view is already committed on the original path. Durability of these commands follows from **A1.**.

B.3.3 C2: Execution consistency

If a command is executed and replied to the client with result r, then in any subsequent execution (including after view changes), the command produces the same result r.

A command's execution result is determined by its position relative to all conflicting commands in the log. Therefore, it suffices to show that a command's position (relative to conflicting commands) never changes after it is replied.

Case 1: Original-path command. The command is executed only after being committed on the original path. By **A2.**, its log position never changes. Therefore, its execution result is stable.

Case 2: Fast-path command, fast commitment fails. The command is executed only after being committed via the original path. Same as Case 1.

Case 3: Fast-path command, fast commitment succeeds. The command A is speculatively executed under the fast-path invariant (Definition 4): the proposer guarantees that no conflicting command will be committed before A on the original path. Once A is committed on the original path, its position is fixed by **A2.**, and all future executions produce the same result.

The nontrivial case is when a view change occurs before A is committed on the original path. Let v be the new view and v_n be the last normal view. We must show that after recovery, no conflicting command appears before A. We prove this in two steps.

Lemma 1 (Original-path recovery safety)**.** *During original-path recovery in view v, no uncommitted conflicting command is recovered at a position before A.*

The original path finishes its own recovery before the fast-path command recovery starts. By Principle 2, the new proposer in view v recovers only uncommitted commands belonging to v_n and does not introduce uncommitted commands from other views.

All commands in v_n were proposed by the proposers of v_n, and by the fast-path invariant (Definition 4), they either:

1. do not conflict with A (recovery of these commands does not affect A's execution result), or
2. conflict with A and appear *after* A in the original log (i.e., at index $j > i$ where A is at index i).

For case (2), consider a conflicting command B at index $j > i$. By PR 1, A at index i will be replicated before B at index j, and therefore be recovered before B. Even in a protocol that allows out-of-order replication (where B could reach a majority while A does not), the recovery may miss A and leave a log hole at index i. Since B at index $j > i$ has not been executed or replied to the client (by **A3.**, it cannot execute while position i is uncommitted), the new leader can safely discard all entries after a log hole. Therefore, original-path recovery never introduces an uncommitted conflicting command before A's position.

Lemma 2 (Fast-path recovery completeness and safety)**.** *Every fast-committed command in v_n is included in the recovery set, and no command in the recovery set conflicts with it.*

Proof. Completeness. By the same quorum argument as C1 Case 3, a fast-committed command appears in at least $\lceil f/2 \rceil + 1$ of the $f+1$ replies during view change, and is therefore included in the recovery set.

Safety. Any conflicting fast-path command C would have failed fast commitment, because A already occupies the superquorum: C cannot obtain a superquorum of conflict-free acknowledgments. Therefore, C cannot appear in $\lceil f/2 \rceil + 1$ fast-path logs, and is excluded from the recovery set. □

By Lemmas 1 and 2, after recovery in view v, the fast-path invariant still holds: no conflicting command appears before A. Therefore, A's execution result remains consistent with its speculative execution.

B.3.4 C3: Linearizability

For any two conflicting commands A and B, if B is issued after A is replied to the client, then A must always be executed before B.

Case 1: A is an original-path command. A is replied only after it is committed on the original path. Since A is committed before B is proposed, by **A4.**, B will be placed and executed after A.

Case 2: A is a fast-path command, fast commitment fails. A is replied only after being committed through the original path. Same as Case 1.

Case 3: A is a fast-path command, fast commitment succeeds. Once A is committed on the original path, A is committed before B is proposed, and by **A4.**, B will be placed and executed after A.

The nontrivial case is when A is fast-committed but not yet committed on the original path when B is issued.

Case 3a: B is issued in the same view as A. If B is a fast-path command, it will fail fast commitment: since A is stored on a superquorum, B cannot obtain conflict-free acknowledgments from a superquorum. Therefore, regardless of whether B is a fast-path or original-path command, B is handled by the proposers and inserted into the original log after A (by the fast-path invariant, Definition 4).

If no view change occurs, B is committed after A and executed after A. If a view change occurs, by Lemmas 1 and 2, A's position is preserved and no conflicting command appears before A. Therefore, B is still executed after A.

Case 3b: B is issued in a higher view than A. A view change occurs before B is issued. By Principle 2, the recovery of v_n (including A) must complete before the new view accepts client commands. Therefore, B can only be processed after A has been recovered and committed on the original path. At that point, A is committed, and by **A4.**, B will be placed after A and executed after A.

C Adaptive path selection strategy

This appendix presents the detailed strategy used by Jetpack to adjust its fast-path attempt rate. §5 introduced the intuition; here we specify the concrete mechanism.

Each client maintains a circular buffer of the most recent 100 requests, recording for each request: (i) whether the fast path was attempted, (ii) its end-to-end latency, and (iii) CPU utilization at issuance time. From this buffer, the client computes running averages: the fast-path latency $\bar{L}_{\text{fast}}$, the original-path latency $\bar{L}_{\text{orig}}$, the recent attempt rate $\bar{A}$, and the current CPU load.

Using these measurements, the client updates its future fast-path attempt rate according to the following rule:

$$\text{AttemptRate} = \begin{cases} \min(\bar{A} + 20\%,\ 100\%) & \bar{L}_{\text{fast}} < \bar{L}_{\text{orig}} \wedge \text{CPU} \le 80\% \\ \max(\bar{A} - 20\%,\ 5\%) & \bar{L}_{\text{fast}} < \bar{L}_{\text{orig}} \wedge \text{CPU} > 80\% \\ 5\% & \bar{L}_{\text{fast}} \ge \bar{L}_{\text{orig}} \end{cases}$$

This rule captures three behaviors: (1) When the fast path is faster and CPU usage is modest, the attempt rate gradually increases. (2) When CPU load is high, even a faster fast path is throttled to protect throughput. (3) When the fast path is slower, it is effectively disabled except for a minimum 5% probing rate, which allows the system to detect future improvements.

During cold start, the client enables the fast path for the first 5 requests to gather baseline measurements; afterward,

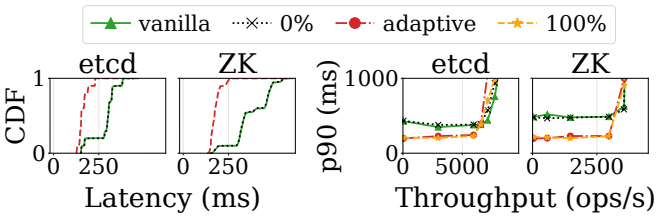

Figure 16: Latency CDF (left) and throughput–latency (right) for etcd and ZooKeeper under a uniform 50% read / 50% write workload, comparing the vanilla protocol, Jetpack with fixed fast-path attempt rates, and Jetpack in adaptive mode.

the adaptive rule takes control. This mechanism enables Jetpack to automatically exploit the fast path when beneficial, while avoiding performance degradation when system load or contention makes the fast path ineffective.

D Network latency between datacenters

We measured round-trip time (ms) between datacenters. These datacenters spanned North America (California, ID 0; Oregon, ID 1), Europe (Frankfurt, ID 3; Stockholm, ID 4; London, ID 5; Ireland, ID 8; Paris, ID 9), and Asia Pacific (Mumbai, ID 2; Hong Kong, ID 6; Singapore, ID 7).

E Additional case studies: etcd and ZooKeeper

In addition to the systems evaluated in §6.6, we also integrated Jetpack with etcd and ZooKeeper. The integration methodology is identical to §6.1, so we report only the performance results here; the latency CDFs and throughput–latency curves appear in Figure 16, and the workload-axis sweeps appear in Figure 17.

etcd. We built on etcd 3.7.0-alpha.0, a widely deployed Raft-based key-value store using a standard Raft implementation. With Jetpack, etcd reduces average commit latency by 42.36% (Figure 16).

ZooKeeper. We built on ZooKeeper 3.9.4, which uses Zab (ZooKeeper Atomic Broadcast), a leader-based atomic broadcast in which a designated leader assigns a total order to write

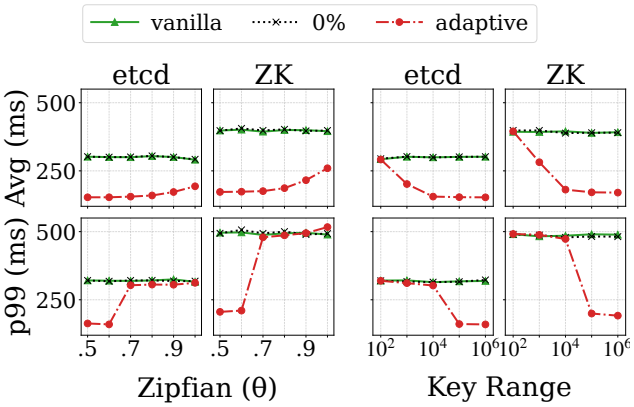

Figure 17: Average and p99 latency for etcd and ZooKeeper under a 50% read / 50% write workload with varied contention (Zipfian skew and key-range size).

requests and replicates them to followers via a propose-ack-commit broadcast. Like Raft, Zab is leader-based and satisfies Jetpack's prerequisites. With Jetpack, ZooKeeper reduces average commit latency by 52.59% (Figure 16).

F Benefit rate of fast path in Jetpack

In the adaptive mode, Jetpack's effectiveness depends on three conditions being met for any given request: (1) the fast path must be attempted, (2) the attempt must succeed, and (3) the resulting latency must be lower than the original path's latency. We define the *fast-path benefit rate* as the percentage of total requests that satisfy all three conditions. This metric quantifies the practical advantage delivered by Jetpack.

Figure 18 shows this benefit rate under two scenarios: a balanced (50% read / 50% write) and a read-intensive (95% read/5% write) workload, with varying Zipfian skewness (θ). In the balanced workload, the benefit rate for all four systems gradually decreases as θ increases. This is because a higher skew leads to greater data contention, which in turn increases the failure rate of fast-path attempts. In the read-intensive workload, Raft and Copilot integration exhibit higher true benefit rates than those in the read-write balanced workload, as read operations do not conflict in Jetpack's fast path, increasing the likelihood of a successful fast path. MongoDB's benefit rate is capped at 5%, since 95% of operations are reads that will complete in 1 RTT without replication.

To further analyze the true benefit rate, we examined a read-write balanced workload (50% read / 50% write) with high contention ($\theta = 1$). For Raft and Copilot, the benefit rates are 65.91% and 64.53%, respectively. In these systems, the fast path is faster than the original path in most datacenters, leading to a high attempt rate ($90-100\%$). This, combined with a success rate of around 60% under high contention, yields the final benefit rate. The rate for Mencius (18.87%)

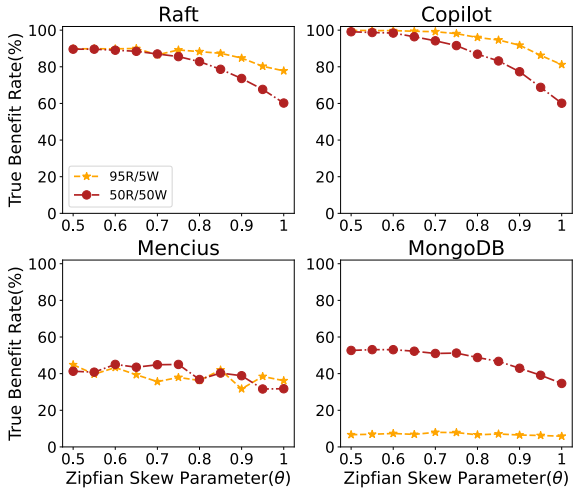

Figure 18: Fast-path benefit rate in a geo-distributed environment

is roughly half of that, as clients co-located with a proposing replica do not gain a latency advantage from the fast path. Similarly, MongoDB's benefit rate (34.66%) is also halved because 50% of its read requests are non-replicated and are already served in a single RTT, receiving no additional benefit from Jetpack.

Even under extreme contention (Zipfian $\theta = 1.0$, 50% read / 50% write), Jetpack benefits between 18.87% and 65.91% of requests, demonstrating substantial fast-path gains across all systems.

G Multi-leader fast-path overhead

This appendix formalizes the argument referenced in the main text: in multi-leader settings with rotating leaders, Jetpack's per-command processing overhead is a structural consequence of its design goals, not an artifact of the particular integration.

G.1 Model and design goals

We consider a *shared-log multi-leader* consensus protocol with $M \geq 2$ leaders $\mathcal{L} = \{l_1, \ldots, l_M\}$, where multiple leaders concurrently propose to a single global log Λ and conflicting commands may be issued to different leaders. Each leader l_i maintains a log sequence Seq_i, and Λ is obtained as

$$\Lambda \;=\; \text{merge}(Seq_1, \ldots, Seq_M)$$

under a fixed deterministic merge rule (e.g., round-robin slot interleaving in Mencius). Replicas execute commands in Λ-order, deduplicating any command that appears in multiple Seq_i (executed only at its first occurrence in Λ). For any command c appearing in Λ, we write p_c for the position of its first occurrence; this is the position that determines execution order.

We adopt the standard asynchronous distributed system model: leader progress depends on incoming commands and message delays, both of which can vary independently. As a consequence, no leader can be perpetually ahead of every other leader; over time, any leader can be transiently the slowest-progressing one.

Lemma 3 (Existence of a min-position leader)**.** *At any time T, the next available slots of the M leaders correspond to M distinct positions in Λ. Hence some leader has a strictly minimum next-slot position in Λ among all leaders.*

Proof. Each leader owns a disjoint subset of Λ's slot positions, so the next-slot Λ-positions of distinct leaders are distinct. The minimum of M distinct values exists. □

Jetpack's three design goals are restated in this model as follows.

- **G1 (Client-side 1-RTT fast path).** For every fast-path command c, the client receives the commit acknowledgment within one round-trip of the request.
- **G2 (Order consistency).** For any fast-path-committed command c and any command d that conflicts with c and has not yet been committed at the time of c's fast-path commit acknowledgment, whenever both c and d appear in Λ they satisfy $p_c < p_d$. That is, the order established by a fast-path commit must be honored by the original protocol's eventual placement in Λ.
- **G3 (Non-intrusive integration).** Jetpack is layered atop the original protocol, whose logic remains unchanged. As a consequence, on any given replica the original protocol cannot observe the fast-path acknowledgment order produced by Jetpack.

G.2 Each command must be proposed by every leader

Theorem 4. *Under **G1**, **G2**, and **G3**, every fast-path-committed command c must appear in every leader's local sequence: $c \in Seq_i$ for all $i \in \{1, \ldots, M\}$.*

Proof sketch. Suppose for contradiction that there exists an execution in which c is fast-path committed but $c \notin Seq_j$ for some leader l_j.

Construction. Let T_0 denote the time the client issues c. By Lemma 3 and the flexibility of the asynchronous model, choose an execution in which l_j is the strictly min-position leader throughout $[T_0, T_d]$, with constant next-slot Λ-position p_j^*, and c has not propagated to Seq_j during this interval.

Deriving the contradiction.

1. By **G1**, the client receives a fast-path commit acknowledgment for c at some $T_c > T_0$.
2. At time $T_d > T_c$, the client issues a command d conflicting with c and routes d to l_j. Since d is issued after c's fast-path commit acknowledgment, the fast-path order is $p_c < p_d$.

3. By **G3**, l_j's decision of which slot in Seq_j to assign to d depends only on l_j's local log state. Since $c \notin Seq_j$ by construction, l_j has no record of c and proposes d at p_j^*.
4. Meanwhile, l_i proposes c on the original path at some time $T_c' \in (T_0, T_d]$. Since l_j is strictly min throughout $[T_0, T_d]$ (Lemma 3 + construction), l_i's next-slot at T_c' exceeds p_j^*, so $p_c > p_j^*$.
5. Combining steps 3 and 4: $p_d = p_j^* < p_c$, contradicting the fast-path order $p_c < p_d$ from step 2 and violating **G2**.

Therefore the supposition fails: $c \in Seq_j$ for every l_j. □

Corollary 5. *Any integration satisfying **G1**, **G2**, and **G3** with a multi-leader protocol incurs per-command processing cost $\Omega(M)$, where M is the number of leaders.*

This corollary directly explains the empirical CPU overhead observed for Mencius+Jetpack in §6.5: with $M = 5$ leaders, each fast-path command is processed five times, matching the observed high CPU increase.

Ambulance: saving BFT through racing

Abstract

Today's practical Byzantine Fault Tolerant (BFT) state machine replication deployments are vulnerable to slowdowns [70, 71]. The main culprit is timeouts. Aggressive timeouts spuriously trigger expensive leader changes, while conservative timeouts leave the system idle and let slowdowns severely inflate latency. Two main alternatives exist: hedging [37, 80], which improves recovery from slow leaders but still incurs a time-based hedging delay, and cooperative asynchronous protocols [19, 66], which recover quickly from slowdowns but suffer from high common-case latency and low throughput. This paper presents Ambulance: a BFT state machine replication protocol that sidesteps this trade-off through *protocol-rigged races*, where replicas, rather than race against the clock, race against each other by executing protocol steps. This enables Ambulance to achieve high throughput and low latency comparable to state-of-the-art timeout-based BFT, while matching the robustness of cooperative approaches.

1 Introduction

This paper presents Ambulance, a Byzantine Fault Tolerant (BFT) state machine replication (SMR) protocol that achieves low latency, high throughput, and robustness to slowdowns (including failures and network blips).

Distributed trust systems allow multiple mutually distrustful parties to secure data even when a subset of them are compromised or misbehave. These systems have been used for secure key recovery [35], code transparency [4], securing land records [57], and stablecoins [8]. Signal [35], for instance, distributes its key recovery logic across three clouds for better security. At the core of these systems lies a BFT SMR protocol, which implements the abstraction of a totally ordered log. This log can then be materialized into application state that is consistent across all parties, even when a subset crashes or misbehaves. These protocols must (*i*) sustain high throughput, (*ii*) ensure low latency, and (*iii*) remain robust to actual failures and network events.

Much of the focus on robustness has been on tolerating discrete events: a replica failure [34] or network events in which messages are dropped [45]. Much less attention has been given to slowdowns [71]. Slowdowns are events such as network misconfigurations, partial hardware failures, etc. [23, 53, 59] that cause a replica to respond more slowly than normal. While slowdowns of course encapsulate machine crashes or network failures (a crashed node is infinitely slow), they also include events that cause latency spikes over longer time periods, without necessarily triggering timeouts.

These events are of major concern to real distributed system deployments. Sei [65], a blockchain company running the Autobahn [45] protocol, as well as Etcd and Neo4j (both Raft-based production datastores) report slowdowns of over seven seconds as a result of data synchronization issues, I/O contention, and garbage collection [7, 65, 69].

Although there exist crash-fault-tolerant protocols robust to slowdowns [70], most existing state-of-the-art BFT protocols are vulnerable to this issue. Even systems like Autobahn [45], which explicitly target recovering from network events, are vulnerable. Because they rely on a leader to drive protocol execution, tail latency can spike when that leader is slow. Techniques such as monitoring leader performance [34] can detect some slowdowns, but are not comprehensive and offer only partial protection [70].

This paper argues that *timeout-triggered fault-detection is fundamentally the wrong mechanism for detecting slowdowns in an SMR protocol*, for two reasons. First, it is a *destructive* process. If timeouts are configured too aggressively, the system might unfairly accuse a leader of being down, unnecessarily triggering an expensive recovery process to elect a new leader. Moreover, trying to elect a new leader while the old leader is still alive can lead to concurrent proposals from both replicas. These proposals will interfere with each other, precluding either from making progress. Second, timeout-triggered fault detection is a *blocking* process. Setting the timeout too conservatively causes the system to wait idle for long periods of time prior to detecting a failure. This is especially problematic as production deployments today recommend setting timeouts to at least ten times the network round-trip time [9]. Timeouts are thus almost always configured to be on the order of seconds for geo-distributed deployments, with some production deployment choosing upwards of 30 seconds [13, 27]! As a result, slowdowns often remain undetected, while truly failed leaders cause the system to stall for seconds [45].

To gracefully handle slowdowns, we need a new fault-detection mechanism that is instead *guaranteed to make forward progress*. It should 1) be *cooperative* rather than *destructive*: it should not destructively interfere with ongoing proposal invocations from existing leaders; and 2) be *productive*: it should contribute useful work towards committing operations. Together, these properties minimize the system's recovery time when there is a slow or failed leader.

Hedging [80] recognizes the issues of timeout-based approaches and offers a promising avenue for better handling of slowdown events. It replaces the traditional competitive leader-based proposal process with a novel cooperative multi-

proposer approach. Each replica proposes in a staggered fashion, according to a known delay schedule. Concurrent proposals contribute to faster termination when there are slowdowns or faults. Consequently, hedging delays can be set much smaller than timeouts. Hedging, unfortunately, still relies on time-based delays. If the first proposer (leader) is slow, then the next replica must stall for the full hedging delay before it can propose. As such, hedging remains a blocking process that is not productive: stalling does not contribute to the protocol's forward progress.

Fundamentally, timeout-based approaches detect slowdowns by having the leader *race against the clock*. The leader is given a fixed deadline to finish its work. If it fails to finish before that deadline, it loses the race and is deemed faulty or slow. Hedging, on the other hand, replaces this fixed deadline with a *rigged race*. Instead of racing against the clock, the leader races against other replicas that are also proposing. Time is used only to give the leader a head start, ensuring that when the leader is not slow, it comfortably wins the race.

In this work, we argue that *rigged racing* is indeed the correct mechanism for handling slowdowns. But racing against the clock or using time to rig the race 1) causes replicas to wait idle 2) requires precise knowledge of what value to set the clock to. Replicas should instead *race against each other*, using protocol messages to rig the race. We purposely design the leader's proposing protocol to take fewer steps than the other replicas' proposing protocol, so that the leader finishes proposing first in the absence of slowdowns. Unlike time-based rigging, non-leader replicas stay productive as they do work that can be used to commit an operation *if they happen to win the race*.

To instantiate this idea, we propose Ambulance, a new consensus protocol that achieves low latency, high throughput, and better robustness to slowdowns through *protocol rigged races*. In the absence of a slowdown, the leader always wins the race, matching the latency of traditional leader-based BFT. In the presence of slowdowns, the leader will lose the race, but the other replicas will quickly recover using the work they did during the race.

Naturally, realizing this in practice requires addressing two key challenges: (*i*) replicas may disagree on whether the leader won the race, and (*ii*) replicas may commit at different stages, with some committing the leader's value during the race and others committing only after the race's dust settles.

Our results are promising. Ambulance matches the common-case performance of Autobahn [45], a state-of-the-art timeout-based BFT protocol, while outperforming it under slowdowns, achieving 1.6–3.0x lower peak latency for 1–2 second slowdowns and up to 10.8x lower latency for more severe cases. Compared to ParBFT2 [37], a leading hedging-based BFT protocol, Ambulance delivers 1.3x higher throughput and 1.9x lower common-case latency, along with 1.7–3.1x lower peak latency during slowdowns.

This paper makes three core contributions:

- We identify the two necessary conditions for slowdown-detection mechanisms to be precise and efficient: being cooperative and productive.
- We introduce a new slowdown-detection mechanism, protocol-rigged racing, the first to satisfy both conditions.
- We implement and evaluate Ambulance, a novel BFT protocol that uses protocol-rigged racing to offer high throughput, low latency, and robustness to slowdowns. Ambulance is deployed in production at a leading distributed trust company.

2 Background

We first survey the slowdowns observed in real deployments, and then examine the mechanisms used to detect them.

2.1 Slowdowns in practice

In production, distributed systems often experience *slowdowns*: periods when a replica remains correct and available, yet its service rate falls below its usual baseline. Even brief slowdowns can cause end-to-end latency spikes and trigger timeouts.

Slowdowns arise from a mix of hardware, software, and network effects. Fail-slow behavior is prevalent across the hardware stack: disks may suffer throughput degradation from vibrations, memory cards from loose connections, CPUs from power loss. Even NICs can drop packets because of firmware or driver bugs [48, 63]. Software slowdowns arise because of I/O contention, slow data syncs, or garbage collection pauses. I/O contention in etcd, for instance, can induce long `fsync` latencies [7]; since proposals must be persisted to disk, these stalls directly translate into large latency spikes. Data synchronization likewise causes sufficiently long latency spikes in HBase that developers have added a dedicated feature to detect slow syncs [5]. Sui [15], a production blockchain system, similarly observes that slow data synchronization can trigger slowdowns lasting up to 5 seconds [13]. Elasticsearch and Neo4j both report that rapid heap allocation can trigger stop-the-world garbage collection pauses lasting seconds to minutes, inadvertently causing leader election timeouts [11, 69]. Finally, network pathologies, including misconfigurations and flaky links have been shown to cause partial network partitions in several production data stores [22].

2.2 Slowdown detection mechanisms

Slowdowns are managed in a variety of ways today.

Timeouts. The most common way to detect slowdowns is to use timeouts. Timeouts effectively make the leader race against the clock to finish committing its proposal. If the leader loses, the timeout fires, triggering a leader election process to replace it.

Tuning timeouts is notoriously difficult [80]. It requires significant administrative effort, and a poorly chosen value can degrade performance or compromise availability. Aggressive timeouts risk frequent leader elections, in which new leaders

override the progress of old leaders, hurting liveness. Conservative timeouts give leaders plenty of time to win the race, but cause the system to stall in the process. This is especially problematic when the leader fails, as other replicas must wait out the full timeout to detect that failure. Moreover, timeouts are typically set statically, which makes them adapt poorly to changing conditions, such as network latency fluctuations or replicas that become gradually slower over time. Taken together, these limitations make clear that timeouts are an overly coarse heuristic for detecting slowdowns.

Production systems recommend setting timeouts to be at least ten times the network RTT, though in practice they are even more conservative. Default timeout values include 2 seconds for Sei [65], 5 s for Microsoft CCF [10], 7 s for Neo4j [69], and 30 s for Diem [13, 79].

Cooperative Proposing. Timeout-based protocols make progress only if the leader "beats the clock". When it cannot, the system stalls until the replicas elect a new leader. Effectively, these protocols are built around the assumption that, in the typical case, the leader usually wins this race [20, 34].

Asynchronous consensus protocols [19, 60, 66, 73] instead start from a different premise: *all* leaders may consistently lose the race against the clock. This can be a result of poorly configured timeouts or because the network is controlled by an adversary that selectively delays the leader's messages. Thus, to avoid blocking on a single leader, asynchronous protocols let all replicas propose cooperatively. During slowdowns, this approach achieves low latency and remains robust up to f slow replicas, since $n-f$ correct replicas are guaranteed to eventually respond. However, this approach is more expensive in the common case, since extra coordination is required to handle multiple proposers. Asynchronous protocols thus have significantly higher latency in the absence of slowdowns.

Hedging. The most recent slowdown detection mechanism, hedging [37, 80], takes a middle-ground between the timeout and cooperative proposing approaches. With hedging, all replicas cooperatively propose (like in asynchronous protocols), but they do so in a staggered fashion according to a known delay schedule. This creates a race between the leader (the first proposer) and the remaining replicas to finish proposing. If the leader wins the race, the latency matches that of traditional leader-based BFT. Otherwise, the other proposers cooperatively work together to terminate the protocol. Hedging preserves the efficiency of timeout-based protocols in the absence of slowdowns. Unfortunately, during a slowdown, recovery is unnecessarily delayed until after the leader's head start. Furthermore, extra coordination is needed to reconcile the leader-based and cooperative mechanisms. During slowdowns, ParBFT2 [37], the state-of-the-art hedging BFT protocol, has a consensus latency of 22 message delays on top of the hedging delay, compared to only 10 message delays for SMVBA [49], the state-of-the-art cooperative BFT protocol.

Toward Rigged Racing. In short, current detection mechanisms are inadequate. Timeouts are too slow to react to slowdowns, as the system stalls until the timeout triggers. Cooperative approaches are not practical, as they unnecessarily pay the cost of higher latency always. Hedging, while an improvement, still stalls until the hedging delay is over.

A better slowdown detection mechanism should meet three requirements. First, it must be *cooperative*: concurrent proposals should not destructively interfere with each other. Second, it must be *productive*: the work done during detection should directly accelerate commitment once the slowdown is detected. Third, it must detect real slowdowns quickly without mislabeling a healthy replica as slow.

These requirements rule out timeouts and hedging, since both rely on time-based delays that fundamentally do not contribute to useful protocol progress. A more promising direction instead quantifies slowness by measuring how quickly replicas advance through protocol steps that replicas must anyway execute. Truly slow replicas will consistently lag behind. However, raw relative progress is noisy: routine jitter can briefly make a healthy replica look slow. To satisfy the third requirement, we need a mechanism that separates genuine delay from benign variation. Our solution, *protocol-rigged racing*, meets all three requirements by racing replicas while carefully adding sufficient bias to prevent false accusations.

3 System Model

Ambulance adopts the assumptions of prior BFT protocols. We assume $n=3f+1$ replicas, of which at most f are faulty, as well as a PKI for digital signatures, and a trusted setup for threshold signatures. We consider a replica correct if it adheres to the protocol specification; a replica that deviates is considered faulty (or Byzantine). We make no assumptions about the number of faulty clients. We assume the existence of a strong, yet static adversary, that can corrupt and coordinate all faulty participants' actions but cannot break standard cryptographic primitives. Replicas communicate through reliable, authenticated, point-to-point channels; we write $\langle M \rangle_p$ for messages signed by replica p. We assume all signatures and quorums are validated and omit the check in protocol descriptions. Ambulance operates under the asynchronous network model: it makes no synchrony assumptions for safety or liveness.

4 Ambulance: Overview

Ambulance seeks to achieve two goals: (*i*) match the high performance of timeout-based BFT protocols in the absence of slowdowns, and (*ii*) provide stronger robustness to slowdowns than both hedging-based and timeout-based BFT protocols.

Timeout-based BFT protocols enjoy low latency by relying heavily on a designated leader: they assume the leader will beat the clock most of the time. When that happens, the leader becomes the sole replica authorized to propose new operations, and agreement can be reached quickly, with only three message delays [30]. Unfortunately, these protocols pay

a steep price when the leader loses the race. Hedging-based protocols improve robustness by having all replicas propose concurrently when the leader falls behind, but they still pay both the hedging delay and additional coordination needed to reconcile all proposals. Ambulance overcomes these limitations and achieves both objectives through a new technique called *protocol-rigged racing*.

In Ambulance, a designated leader drives commitment of its proposal in its *proposal lane*. Additionally, each replica has a proposal lane of its own, where it proposes operations and votes in the lanes of others.

Ambulance consists of two components: a race, in which replicas try to beat the leader (but assume that they won't), and a recovery path in which the replicas try to commit their own proposal if they believe that the leader lost. During the race, the leader runs a faster protocol that ensures that it will win if it is not slow. If the leader loses, replicas do not have to turn back and start over. Instead, the steps taken to beat the leader are directly useful towards committing.

Race. Replicas race with the leader by submitting their own proposals. Rather than having replicas perform meaningless busy work during the race, Ambulance's key insight is to have them execute required protocol operations during this time, shortening the amount of work left post-race. *All* consensus protocols fundamentally consist of two phases: a *non-equivocation* phase and a *persistence* phase. Non-equivocation guarantees that malicious replicas cannot cause conflicting operations to commit; persistence ensures committed operations survive. Ambulance uses the non-equivocation phase as the race itself! Both leaders and replicas need it *anyways* to commit.

To ensure a non-slow leader will win the race, the race is rigged in the leader's favor in two ways. First, the leader completes the two-step, quadratic message exchange of PBFT's non-equivocation phase while the other replicas instead perform a slower three-way linear message exchange. Second, the leader does not have to finish first to win; it only has to beat the cutoff. This cutoff is chosen to maximize the leader's chances of winning, while still allowing replicas to recover quickly if the leader is slow. When the cutoff is reached locally, the race outcome is determined. The key challenge is that replicas may disagree on the race outcome. One replica might observe the leader winning, while another sees the leader losing. Despite this divergence, Ambulance ensures agreement across all participants.

Recovery Path. If a replica failed to commit the leader's proposal, it moves to the recovery path. Unfortunately, there is no longer a dedicated leader from which to choose a proposal. Instead, all replicas potentially have formed a distinct non-equivocation certificate for their lane. To make matters worse, the leader lane could have committed with only some replicas knowing. The recovery path addresses each issue in turn and proceeds in three steps. First, a replica chooses a value to recover for its lane. Second, it persists this value. And third, a lane is randomly selected to be committed.

Step 1. Replicas must recover any potential proposal that *could* have committed from the leader. If a leader proposal could have committed, replicas must select that value as input to the recovery path. If no leader proposal was committed, replicas recover their proposal from the race to ensure that the progress made during the race was productive.

Step 2. Replicas then persist the recovered value, so that it is safe to commit it. This step has two parts. The first is an optional *race exclusion phase* that addresses a subtle issue. If a leader non-equivocation certificate forms but the leader does not successfully commit, a malicious replica may successfully obtain both a non-equivocation certificate from the leader and for its own lane. It cannot equivocate on any proposal, but it still can equivocate between the leader's proposal and its own lane proposal. Thankfully, we find that, in most cases, the leader is slow enough that replicas can directly generate a proof that the leader's non-equivocation certificate *cannot exist*. Most of the time, replicas thus safely omit this phase. Only when they cannot generate this proof must they proceed to run this additional exclusion phase to guarantee uniqueness between the leader's non-equivocation certificate and the replica's. The second part is the *persistence phase*, which performs the same role as in traditional BFT. It guarantees that if the lane proposal is committed, then it survives despite failures.

Step 3. The third and final step is that a lane is *randomly* selected for commitment. Note that this election process is run *after* each replica has completed all the steps required to commit a proposal in its lane. This is by design: if the winner were chosen deterministically, a network adversary, could intentionally delay messages necessary for the anointed winner to commit the operation, defeating the point of not having a leader. If the randomly selected lane does not have a proposal ready for commit, the protocol simply retries the recovery path.

Performance Summary Using these techniques, Ambulance achieves a latency of three message delays under normal conditions, matching the performance of latency-optimal PBFT [30]. When the leader experiences a slowdown, the expected latency is comparable with state-of-the-art pessimistic (asynchronous) protocols [19, 49]: 9.5 message delays if the leader fails to propose during the race, and 10.5 message delays otherwise. These results meet our goal of delivering state-of-the-art latency in both normal and slowdown scenarios.

5 Ambulance: The Protocol

We now describe the protocol in more detail. We first focus on how the protocol works for a single slot, before expanding it to support efficient agreement across multiple slots. For ease of exposition, we omit the standard checks performed by all replicas—*i.e.*, whether messages are well-formed and from the correct view, and signatures are valid. Replica state is summarized in Algorithm 1. We defer formal proofs of

correctness to Appendix §B (Theorems 1 and 2).

Execution in Ambulance is organized into a sequence of views. Within a view, replicas try to commit a proposal. The protocol consists of two components: a *race*, in which replicas determine whether the leader is fast enough to commit, and a *recovery path*, in which they try to commit their own proposal if the leader is deemed slow. As previously stated, each replica in Ambulance has its own proposal lane. Replicas drive commitment for their own lane, but additionally vote in other replicas' proposal lanes. Note that the leader runs both a leader lane and a replica lane.

Algorithm 1 Replica state cheat sheet for a given slot s.

```
1: v                          ▷ replica's current view
2: sc-prep                    ▷ SC-PREPARE from the leader or ⟨⊥_prep⟩
3: sportscar-cert             ▷ sports car certificate or ⟨⊥_sc⟩
4: truck-cert                 ▷ truck certificate
5: race-cutoff cert           ▷ race-cutoff certificate from race
```

5.1 The Race

The protocol begins with a race whose purpose is two-fold: (*i*) correctly and quickly identify whether the leader is slow and (*ii*) allow a non-slow leader to commit.

To achieve this, the leader and replicas simultaneously issue proposals in their own lanes and race to form non-equivocation certificates for their lane. Such certificates guarantee that, in any view, only a single value can be proposed in the corresponding lane. We call the leader's non-equivocation certificate a *sports car certificate*, and a replica's non-equivocation certificate a *truck certificate*[1]. Non-equivocation is a necessary step in essentially all BFT protocols, so replicas make progress toward commitment while participating in the race.

We ensure that leaders progressing normally are not accidentally identified as slow by rigging the race in the leader's favor in two ways. First, the leader runs a faster non-equivocation procedure that produces a sports car certificate in only two message delays, whereas each replica lane requires three message delays to produce a truck certificate. This structural asymmetry naturally biases the race toward a non-slow leader. Second, the leader does not need to finish first overall to avoid being detected as slow. It only needs to finish prior to a *cutoff*, which occurs when a quorum of truck certificates has formed. If a sports car certificate forms prior to the cutoff, the leader wins the race and replicas continue toward committing the leader's value. Otherwise, the leader loses the race and replicas proceed to the recovery path.

5.1.1 Leader Lane: Sports Car Certificate

Ambulance structures the leader lane to guarantee that a non-slow leader will beat the cutoff while still making useful progress toward commitment. The leader lane implements the standard non-equivocation step required for commitment with a two-step all-to-all communication pattern, enabling a non-slow leader to produce a *sports car certificate* in only two message delays (illustrated in Figure 1).

1: L → R: Leader L sends SC-PREPARE to all.

The leader broadcasts a SC-PREPARE $:= \langle v, val \rangle_L$ message, where v is the view number and val is the value proposed by L.

2: R → R: Replica R processes SC-PREPARE and sends vote to all replicas.

On receiving a SC-PREPARE message $prep$ from the leader, R checks that $prep$ is valid and stores it in $sc\text{-}prep = prep$. It then broadcasts a SC-PREP-VOTE $:= \langle v, dig = h(prep.val) \rangle_R$ message to all replicas, where h is a cryptographic hash function.

3: R: Replica R assembles a sports car certificate.

R waits for at least $n - f = 2f + 1$ matching SC-PREP-VOTE messages and aggregates them into a *sports car certificate*. It sets *sportscar-cert* $:= (v, dig, \{\text{SC-PREP-VOTE}\})$.

This certificate has two purposes. First, it guarantees non-equivocation—the uniqueness of the leader's proposal within a view—since correct replicas vote only once and any two quorums of size $n - f$ intersect in at least one correct replica. Second, as we are about to see, it serves to determine whether the leader beat the cutoff. R stores this certificate in *sportscar-cert* for potential use during recovery.

5.1.2 Replica Lanes: Truck Certificate

Each replica lane similarly produces a non-equivocation certificate, called a *truck certificate*. Unlike the leader lane, a replica lane uses a three-step linear communication pattern, so truck certificates form more slowly than a sports car certificate by design (illustrated in Figure 2).

We describe the protocol from the perspective of a single proposer replica P, which drives one such lane to completion. In practice, all replicas concurrently act as proposers in their own lanes, and they all contribute to each other's lanes.

1: P → R: Replica P sends TRUCK-PREPARE to all replicas.

A proposer P broadcasts a message TRUCK-PREPARE $:= \langle v, val \rangle_P$, where v is the view number and val is the value proposed by P.

2: R → P: Replica R processes TRUCK-PREPARE and sends vote to P.

Upon receiving a TRUCK-PREPARE message $prep$ from P, R verifies its validity and, if valid, replies to P with a TRUCK-PREP-VOTE $:= \langle v, dig = h(prep.val) \rangle_R$ message.

3a: P: Replica P assembles a truck certificate.

P aggregates $n - f$ distinct matching TRUCK-PREP-VOTE messages into a truck certificate, and sets *truck-cert* $:= (v, dig, \{\text{TRUCK-PREP-VOTE}\})$.

[1] Sports cars are optimized for speed but are fragile, whereas trucks are slower but more reliable.

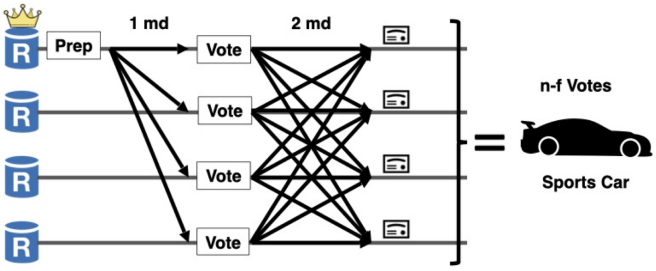

Figure 1: Leader lane protocol pattern.

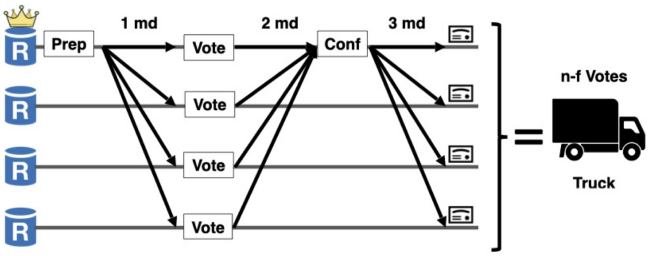

Figure 2: Replica lane protocol pattern.

3b: P → R: Replica P broadcasts TRUCK-CONFIRM.

After forming a truck certificate for that lane, P sends a TRUCK-CONFIRM $:= \langle v, \textit{truck-cert} \rangle_P$ message to all replicas.

5.1.3 Race Cutoff

The race ends locally at a replica once it has received $n-f$ truck certificates. This cutoff is chosen to give the leader as much room as possible to win the race. Since up to f replicas may be faulty, no correct replica can wait for more than $n-f$ truck certificates. At the same time, setting the cutoff below $n-f$ would shorten the race unnecessarily, increasing the chance that the leader is falsely detected as slow even when it is not. Once the cutoff is reached, the replica either continues toward committing the leader's proposal, if it observed the leader win the race, or enters the recovery path, if it observed the leader lose.

1: R: Replica R assembles a race-cutoff certificate.

Upon receiving $n-f$ matching valid TRUCK-CONFIRM messages from distinct replicas for this proposal lane, R assembles a *race-cutoff cert* $:=$ {TRUCK-CONFIRM} certificate. This certifies that the $(n-f)$th certificate has formed and hence cutoff is reached.

After the cutoff, each replica is in one of two cases: either (*i*) it received a sports car certificate prior to the cutoff (Figure 3) or (*ii*) the leader missed the cutoff (Figure 4). As replicas can receive certificates in a different order, their belief about who won the race may diverge. The sports car certificate forming prior to cutoff indicates that the leader is making progress at the expected speed. If instead a cutoff forms first, the leader is behaving unexpectedly slowly. We describe each case in turn.

Case 1: The leader beat the cutoff. Suppose replica R receives the sports car certificate before $n-f$ truck certificates. Then R concludes locally that the leader is behaving as expected, and therefore its proposal should be committed. The protocol then moves toward committing the leader's value.

1: R → R: Replica R broadcasts SC-COMMIT.

R broadcasts SC-COMMIT $:= \langle v, dig \rangle_R$. The SC-COMMIT message serves two purposes: (*i*) it tells other replicas that R locally observed the leader beating the cutoff and that the leader's proposal should therefore be committed; and (*ii*) it ensures that R has persisted the leader's proposal for use in recovery, in case recovery begins before R commits the leader proposal. This is equivalent to the commit phase of traditional BFT protocols.

2: R → R: Replica R assembles and forwards a leader commit certificate.

Replica R aggregates $n-f$ matching SC-COMMIT messages into a leader commit certificate. It then locally commits the leader's value and forwards the commit certificate to all replicas so that they can commit as well. Because the leader lane has a single designated leader, a quorum of SC-COMMIT messages suffices to commit the leader's proposal. Conflicting leader proposals cannot arise in the same view because the truck certificate guarantees non-equivocation. Note that even if R saw the leader missing the cutoff locally, it can still commit the leader's proposal if it receives a quorum of SC-COMMIT messages from other replicas.

Case 2: The leader missed the cutoff. Suppose replica R observes $n-f$ truck certificates before the sports car certificate, then it concludes the leader is slow. It therefore abandons participation in the leader lane and stops sending SC-PREP-VOTE or SC-COMMIT messages. However, it continues processing SC-COMMIT messages from other replicas, since those messages may still certify that the leader's proposal has committed.

5.2 Recovery Path

Once a replica locally reaches the cutoff, it enters the recovery path. The goal of the recovery path is to guarantee commitment of *some* proposal across all replicas. This may be the leader's proposal if some replica committed it during the race, or it may be some other replica's proposal.

In traditional BFT protocols, recovery proceeds in three steps: (*i*) replicas elect a new leader, (*ii*) that leader chooses a value to recover, and (*iii*) the protocol then runs the usual non-equivocation and persistence phases for that value. However, this ordering of steps is problematic in our setting, where liveness does not rely on any synchrony assumptions. If the new leader is identified at the start of recovery, a network adversary can repeatedly target that replica and prevent progress. To avoid this vulnerability, we reverse the usual order of steps. Rather than electing a leader first, every replica initially acts as a potential leader by advancing its own recovery value

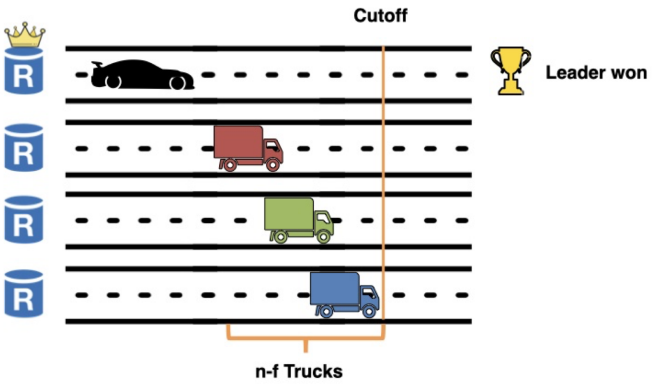

Figure 3: Leader beating the cutoff.

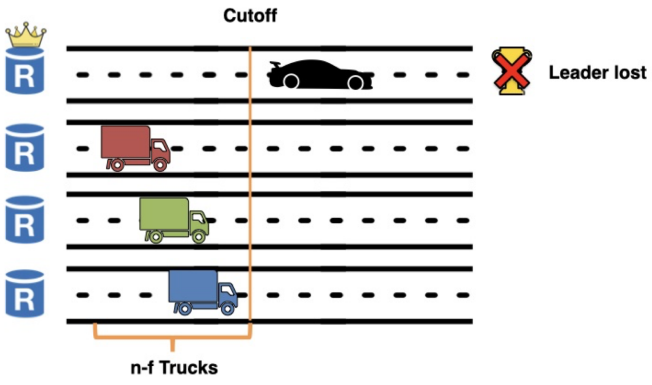

Figure 4: Leader missing the cutoff.

through the consensus steps needed for commitment, namely non-equivocation and persistence. Leader election is deferred until a quorum has completed these steps, so the adversary learns whom to target only at the very end, when it is too late to interfere. This makes it likely that the election selects a replica from that quorum, at which point the protocol can terminate because that value has already been persisted.

Algorithm 2 Replica state cheat sheet for recovery path.

```
1: cert-data   ▷ elected recovery-non-equiv-cert or ⟨⊥_elect⟩
2: qcs         ▷ map: replica ID → recovery path certificate
3: finish      ▷ set of FINISH messages received
```

5.2.1 Step 1: Choosing a value to recover per lane

In Step 1, each replica selects, for its lane, a value to recover based on the evidence gathered during the race. The key safety requirement is that if some value was already committed (via the sports car certificate), then replicas must recover that value.

Replicas first share with each other any messages they received from the leader during the race. This evidence will be used to determine what proposal should be recovered.

1: R → R: Replica R broadcasts STATUS.

The replica broadcasts all state received from the leader during the race, including any proposal received from the leader (*sc-prep*). If a replica did not receive a *sc-prep* it sets $sc\text{-}prep = \langle \perp_{prep} \rangle_R$. Similarly, it sends any sports car certificate it received. If a replica did not receive a sports car certificate it sets $sportscar\text{-}cert = \langle \perp_{sc} \rangle_R$.

R broadcasts this information to all other replicas as part of a STATUS $:= \langle sc\text{-}prep, sportscar\text{-}cert \rangle_R$ message.

2: P receives quorum of STATUS messages

A replica P selects a value to recover for its lane based on a quorum of $n-f$ STATUS messages. P considers three cases:

Case 1: P receives a sports car certificate.

If a sports car certificate exists as part of any received STATUS message, then some replica may have formed a leader commit certificate (follows from quorum intersection). To preserve safety, P therefore sets its recovery input to the leader's value: $r\text{-}input = sportscar\text{-}cert$.

The next two cases handle the situation where P does not receive a sports car certificate. In both cases, P chooses the same recovery input; however, in the latter case P can safely skip the race exclusion phase.

Case 2a: P receives $n-f$ $\langle \perp_{sc} \rangle$ and a SC-PREPARE.

Receiving $n-f$ $\langle \perp_{sc} \rangle$ messages definitively indicates that no correct replica committed on the leader's lane. This also follows from quorum intersection: if a leader commit certificate existed, P would be guaranteed to receive a *sportscar-cert*, which it did not. In principle, P could now safely recover any value, since no leader commit occurred. However, we require P to recover its own truck certificate from the race, thereby preserving the progress already achieved on its lane.

In this case, P sets its recovery input to $r\text{-}input = truck\text{-}cert$, aggregates the $n-f$ signatures on $\langle \perp_{sc} \rangle$ into a no-commit certificate *nc-cert*, which proves that a leader commit could not have occurred, and proceeds to the next step.

Case 2b: P receives $n-f$ $\langle \perp_{sc} \rangle$ and $n-f$ $\langle \perp_{prep} \rangle$.

Receiving $n-f$ $\langle \perp_{prep} \rangle$ messages definitively indicates that no sports car certificate exists. This follows from quorum intersection: if a sports car certificate existed, P would be guaranteed to receive a corresponding SC-PREPARE, which it did not. Since there is no possible sports car certificate to equivocate with, P can safely skip the race exclusion phase (see section 5.2.2): its own racing truck certificate (*truck-cert*) already ensures non-equivocation within its lane. P aggregates the $n-f$ signatures on $\langle \perp_{prep} \rangle$ into a no-lock certificate *nl-cert*, which proves that no sports car certificate exists, and sets its recovery input to $r\text{-}input = (truck\text{-}cert, nl\text{-}cert)$.

5.2.2 Step 2: Persisting the recovered value per lane

In Step 2, each replica persists its recovered value so that its value can be safely committed in Step 3. This step has two parts: the aforementioned optional race exclusion phase followed by a persistence phase that mirrors the familiar two-phase structure of traditional BFT. The optional race exclusion phase is needed because, although the racing path already guarantees non-equivocation within each lane, a Byzantine replica could still try to equivocate between a possible sports car certificate and its own truck certificate. The race exclusion phase prevents this. The persistence phase then plays the usual role from traditional BFT: it records the recovered value so that subsequent protocol steps treat it as the lane's durable candidate.

Race Exclusion Phase. The race exclusion phase prevents a Byzantine replica from equivocating across lanes between its own truck certificate and a possible sports car certificate. By the end of this phase, at most one of these values can advance in P's lane: either P's truck certificate or the sports car certificate, but not both.

1: P → R: Replica P broadcasts REC-PREPARE.

P broadcasts REC-PREPARE $:= \langle v, r\text{-}input, nc\text{-}cert \rangle_P$ where v is the view, *r-input* is the selected recovery input (from step 1), and *nc-cert* is the no-commit certificate formed from case 2a if it exists.

2: R → P: Replica R processes REC-PREPARE and votes.

R checks whether the received REC-PREPARE is valid. If so, R replies by sending REC-PREP-VOTE $:= \langle v, dig = h(r\text{-}input) \rangle_R$ back to the proposer.

3: P: Replica P assembles a quorum of REC-PREP-VOTE.

P waits for at least $n - f$ matching REC-PREP-VOTE messages, and aggregates these votes into a recovery non-equivocation certificate, *recovery-non-equiv-cert* $:= (v, P, dig, \{$REC-PREP-VOTE $\})$ No two recovery non-equivocation certificate can exist for the same lane because the necessary quorums intersect in at least one correct replica (which votes only once). For P's lane, all replicas will either have a recovery non-equivocation certificate for the leader's value or P's value from the racing path but not both.

Persistence Phase.

1: P → R: Replica P broadcasts REC-CONFIRM.

If P could skip the race exclusion phase, P sets *recovery-non-equiv-cert* $=$ *r-input*. This effectively upgrades its truck certificate into a recovery non-equivocation certificate. Otherwise, P uses the recovery non-equivocation certificate it formed in the race exclusion phase. P broadcasts a message REC-CONFIRM $:= \langle v, recovery\text{-}non\text{-}equiv\text{-}cert \rangle_P$ where v is the view, and *recovery-non-equiv-cert* is the recovery non-equivocation certificate P is proposing.

2: R → P: R receives and acknowledges REC-CONFIRM.

R checks whether the received REC-CONFIRM is valid. If the validity checks pass, R stores a copy of the recovery non-equivocation certificate in $qcs[P] =$ *recovery-non-equiv-cert*. Then, it replies by sending REC-CONFIRM-VOTE $:= \langle v, dig = h(recovery\text{-}non\text{-}equiv\text{-}cert\ ) \rangle_R$ back to the proposer.

3: P → R: Replica P broadcasts FINISH.

P waits for at least $n-f$ REC-CONFIRM messages with matching digests, and aggregates these votes into a recovery confirm certificate, *rec-confirm-cert* $:= (v, dig, \{$REC-CONFIRM-VOTE $\})$. It then forwards the recovery confirm certificate it formed in a FINISH $:= \langle v, rec\text{-}confirm\text{-}cert \rangle_P$ message.

4: R: Replica R receives quorum of FINISH messages.

For each FINISH message, R stores a copy of the recovery confirm certificate in $qcs[R_i] =$ *rec-confirm-cert*, where R_i is the replica who proposed *rec-confirm-cert*. Once R receives $n-f$ FINISH messages, it starts the lane election step.

5.2.3 Step 3: Selecting a lane to commit

Unlike traditional BFT, which has a single dedicated proposal lane from the leader, Ambulance has multiple lanes, so it is not immediately clear which lane to commit. To mirror traditional BFT's single-lane behavior, once $n-f$ lanes have completed the persistence phase, Ambulance randomly elects a single lane and checks whether to commit its proposal. If the elected lane has completed the persistence phase, the election succeeds and replicas commit the proposal in that lane. Otherwise, replicas move to the next view and rerun the recovery path. The lane election process must satisfy two properties: (*i*) all correct replicas must agree on who won the election—this is necessary for safety; and (*ii*) more surprisingly, the lucky winner cannot be predicted prior to running the protocol. The latter requirement originates from the potentially adversarial nature of slowdowns: if the "eventual" winner is known prior to its committing, a network adversary could systematically target it. Ambulance achieves both properties by leveraging threshold signatures to elect the winning lane.

Lane Election. Each replica R produces a threshold-signature share on the view number, v, and broadcasts it. After collecting $2f + 1$ valid shares for view v, a replica combines them into a single unique threshold signature σ and computes the elected lane proposer as $E := h(\sigma) \bmod n$, where h is a cryptographic hash function. Agreement follows because σ is unique, so all correct replicas compute the same E; unpredictability follows because E cannot be determined before the shares are revealed.

Commit rule. Replica R commits if it completed the persistence phase for the elected lane ($qcs[E]$ contains a recovery confirm certificate). Otherwise, R stops participating in view v, advances to the next view, and forwards σ to help other replicas derive the same election outcome.

Table 1: RTTs between regions (ms)

RTT	us-east1	us-east2	us-west1	us-west2
us-east1	-	20	72	67
us-east2	21	-	57	55
us-west1	69	53	-	23
us-west2	66	49	24	-

5.3 Retry Protocol

If a replica fails to commit in view 0, it advances to the next view. In all views >0, replicas execute only the recovery path (there is no racing path). The recovery path is identical to the recovery path of view 0, with one small (but key) difference: the race-exclusion phase is always executed as there could be multiple valid lane inputs to recover. We defer the details of the retry protocol to Appendix A.

5.4 Multi-Shot Agreement

For multi-shot agreement, Ambulance constructs a totally ordered log of slots, where each slot runs an independent instance of the single-shot protocol. To avoid sequential delays, Ambulance pipelines these instances, so that a slot can begin without waiting on the previous slot to finish. We adopt the same pipelining strategy as Autobahn [45], where we start a new slot upon receiving a proposal from the previous slot, and cap the number of concurrent uncommitted slots to a pipelining parameter, k.

5.5 Motorization

Autobahn [45] introduced the concept of motorization, which allows any consensus protocol to achieve higher throughput by adopting Autobahn's data layer. Ambulance can use Autobahn's data layer to parallelize the data dissemination process and efficiently utilize all replicas' bandwidth, leading to high throughput.

5.6 Implementation Notes

Leader message sharing. For liveness, the leader needs to run both a fast-track lane and a replica lane. Instead of sending separate messages for each lane, a single message can be used with a boolean flag indicating the lane it belongs to.

All-to-all communication. The recovery path utilizes linear style communication, where replicas forward their votes to the proposer instead of broadcasting them to all replicas. This reduces communication complexity at the trade-off of increasing latency. To reduce recovery path latency further, Ambulance supports an all-to-all voting strategy to shave off extra message delays.

Signature aggregation. Ambulance uses threshold signatures, but only for the lane election phase. We can also adopt threshold signatures for protocol votes to reduce the communication complexity of Ambulance by a factor of n. In practice, this is only necessary for large values of n.

6 Evaluation

Our evaluation seeks to answer three questions:

Table 2: Default timeout values used in production systems

System	Timeout
CockroachDB [3]	2 s
Microsoft CCF [10]	5 s
Neo4j [69]	7 s
TiKV [16]	10 s
HotShot [12]	12 s

1. **Performance**: How well does Ambulance perform in the absence of slowdowns? (§6.1)
2. **Slowdown Robustness**: How well does Ambulance tolerate slowdowns? (§6.2)
3. **Real-world Performance**: How well does Ambulance perform in production under realistic conditions? (§6.3)

We implemented a prototype of Ambulance[2] in Rust, using the same codebase as the open source implementation of Autobahn [45]. We implement all the notes in §5.6 except for signature aggregation. We use Tokio's TCP [17] for networking, and RocksDB [14] for persistent storage of payload data to disk. Finally, we use ed25519-dalek [6] signatures for authentication.

Baseline systems. We compare Ambulance against several state-of-the-art BFT protocols: 1) Autobahn [45], a leading timeout-based BFT protocol, 2) ParBFT2 [37], a state-of-the-art hedging-based protocol, as well as 3) SMVBA (Speeding Dumbo) [49], a state-of-the-art pessimistic (asynchronous) protocol. ParBFT2 uses HotStuff [83] as its optimistic path, and after a hedging delay, it launches its pessimistic path, which runs SMVBA combined with an asynchronous binary agreement protocol [18]. We use the available open-source codebase each time[3]. Ambulance and Autobahn share the same data layer design, where all replicas disseminate batches through structured data lanes, enabling parallelized data dissemination. In contrast, ParBFT2 and SMVBA adopt the Batched HotStuff data layer [38], where replicas optimistically stream batches and consensus leaders propose hashes of any batches they have received.

Ambulance and Autobahn use a PBFT-style multi-shot consensus with a totally ordered log, allowing multiple consensus instances to be pipelined in parallel. This eliminates sequential delays and reduces end-to-end latency. ParBFT2 and SMVBA instead follow the HotStuff [83] chaining approach, which introduces inherent sequential latency. In ParBFT2's optimistic path, a new consensus instance begins only after the leader collects a quorum of votes for the previous one. In its pessimistic path-and in SMVBA—there is no pipelining at all; consensus instances run strictly sequentially. As a result, requests must wait for the next consensus instance to start, adding further end-to-end latency.

Evaluation Setup. We evaluate all systems on AWS EC2. For sections §6.1 and 6.2, we evenly distributed nodes in `us-west1`, `us-west2`, `us-east1` and `us-east2`.

[2] https://github.com/neilgiri/ambulance-artifact

[3] We validated our Autobahn and ParBFT2 results with respective authors

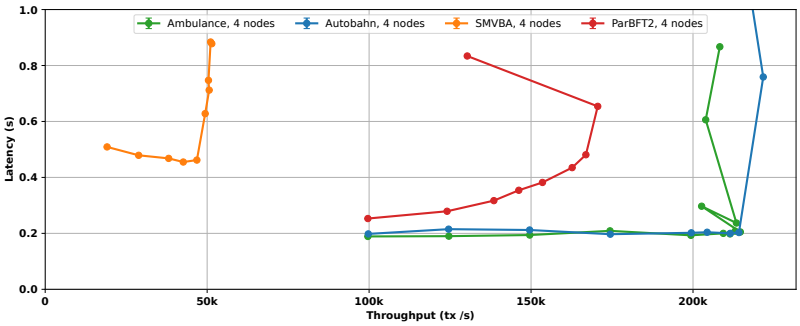

Figure 5: Throughput and Latency under increasing load.

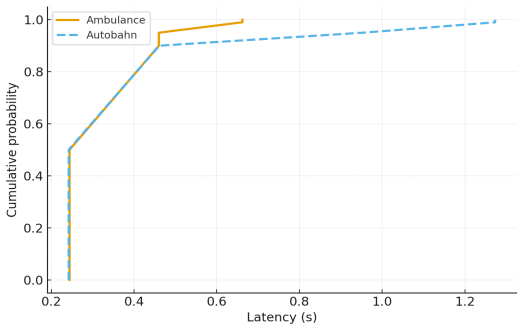

Figure 6: Production Latency CDF

We summarize RTTs between regions in Table 1. We use machine type `m6a.4xlarge` [1] (16 vCPUs and 64GB RAM) with 30GB gp3 disk (SSD) and 12.5GB/s network bandwidth. Clients are co-located in the same region as the replica, and issue a constant stream of no-op transactions (tx), consisting of 512 random bytes [38, 75]; no-op transactions allow us to stress the consensus system, without risking being bottlenecked on execution. We set a batch size of 500KB (1000 transactions) for all baselines, but allow consensus proposals to include/reference more than one batch if available; this *mini-batching* design [40, 41] allows replicas to organically reach larger effective batch sizes with reduced latency trade-off. For the systems that use leaders, they are elected using a deterministic round-robin scheme.

6.1 Common Case Performance

Figure 5 presents performance in a fault-free, synchronous setting with $n=4$ nodes. Each experiment runs for 60 seconds under increasing client load. Ambulance reaches a peak throughput of 214k tx/s, matching Autobahn's peak throughput of 214k tx/s. This high throughput stems from motorization as Ambulance adopts Autobahn's data layer. Ambulance makes efficient use of network bandwidth, which dominates overall cost, as consensus messages are small compared to large batched proposals. Although Ambulance introduces multiple consensus lanes, the metadata overhead is negligible in practice, and both Ambulance and Autobahn ultimately bottleneck on data layer work (serializing/deserializing).

Ambulance achieves a latency of 205 ms compared to Autobahn's 203 ms. In the absence of failures and synchrony, both systems essentially run PBFT, leading to similar latency.

ParBFT2 reaches a peak throughput of 167k tx/s, substantially higher than SMVBA but 1.3x lower than Ambulance. This gap is primarily due to its weaker data layer, which incurs substantial data-synchronization overhead at high load [38, 45], limiting throughput even when consensus is not the bottleneck. In the good case, ParBFT2's consensus latency is five message delays, compared to three for Ambulance, contributing to its 382 ms latency (1.9x higher than Ambulance).

SMVBA achieves only 50.6k tx/s peak throughput and exhibits the highest latency of 462 ms (2.3x higher than Ambulance). It shares the same data layer as ParBFT2, but its low throughput follows directly from its sequential consensus design: consensus instances run strictly one after another, so throughput is constrained by consensus latency. In the good case, SMVBA's consensus latency is six message delays, more than ParBFT2 (five) and Ambulance (three). Together with the additional inclusion latency introduced by this sequential design, these extra message delays yield higher end-to-end latency than Ambulance.

Overall, Ambulance matches the common-case throughput and latency of state-of-the-art timeout-based BFT (Autobahn) while outperforming pessimistic and hedging-based systems.

6.2 Slowdown Robustness

The previous section demonstrated that Ambulance performs well under ideal conditions. We now examine Ambulance's tolerance to slowdowns of varying severity in an $n=4$ deployment. At time $t=3$ seconds, we inject a transient slowdown whose duration we vary across experiments. The slowdown is introduced by pausing all processing (i.e., sleeping) on a single replica. For ParBFT2, we run only the pessimistic path and do not inject slowdowns, due to bugs in the optimistic–pessimistic path switching logic.[4] This configuration still captures slowdown latency but does not reflect ParBFT2's common-case latency, which should closely match Figure 5 (382 ms).

We plot latency over time for slowdown durations of 1, 2, 5, 7, and 10 seconds, where each point is the median latency over a 500 ms window across 5 runs. For Autobahn, we use the timeout values from Table 2, which are taken from production deployments of major reliable datastores.

In the slowdown experiments, we run Autobahn with two different leader-election timeout values. One timeout value is set above the injected slowdown (timeouts of 2, 5, 7, 10, and 12 seconds for slowdowns of 1, 2, 5, 7, and 10 seconds, respectively) so that the plots capture the full effect of the slowdown. The other timeout value is set below the slowdown duration, so that the timeout detects the slowdown. Using a more aggressive timeout for a given slowdown duration caps the peak latency at the timeout value, making it closely match the peak latency of a smaller slowdown. For ParBFT2, we use

[4] We are working with the authors of [37] to resolve these issues.

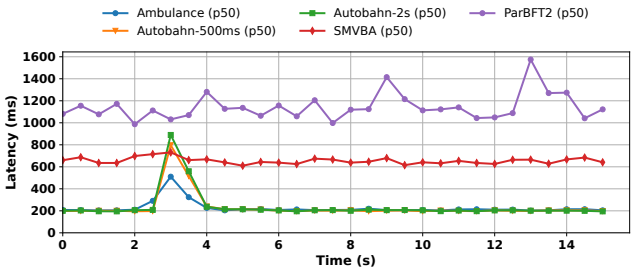

Figure 7: 1s slowdown

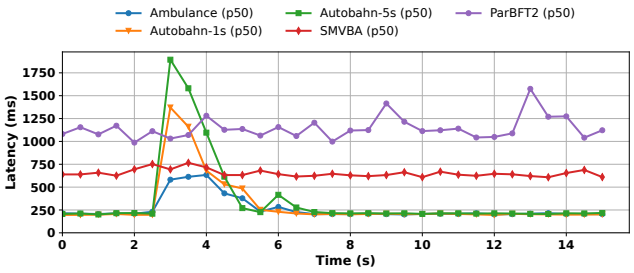

Figure 8: 2s slowdown

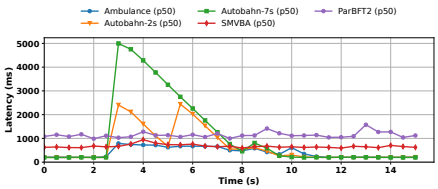

Figure 9: 5s slowdown

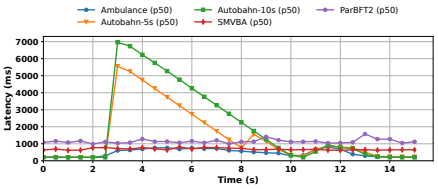

Figure 10: 7s slowdown

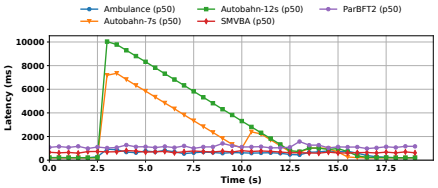

Figure 11: 10s slowdown

an aggressive 75 ms hedging delay to minimize slowdown latency, consistent with the maximum RTT in Table 1 ([37] specifies a hedging delay of 2Δ, equal to the maximum RTT).

1 second slowdown (Figure 7). All systems are evaluated under a conservative load ([70]) to minimize queuing effects (Ambulance and Autobahn at 100k, and ParBFT2 and SMVBA at 10k). Ambulance has the lowest peak latency at 510.4 ms. This is 1.6x better than Autobahn with a 500 ms timeout (796.1 ms), 1.7x better latency than Autobahn with a 2 s timeout (889.5 ms), 1.4x better than SMVBA (731 ms), and 3.1x better than ParBFT2 (1.58 s). Ambulance promptly detects the slowdown and switches to the recovery path, which takes 7 message delays for the first view. Autobahn, configured with a 2 s timeout (from Table 2), does not detect the slowdown, causing latency to rise proportionally to the slowdown duration as replicas block on the slow leader. Autobahn with a 500 ms timeout detects the slowdown; however, it must elect a new leader and pay the consensus latency cost, so the overall latency ends up being similar to Autobahn with a 2 s timeout. SMVBA's consensus latency is similar to Ambulance's, but its lack of pipelining increases end-to-end inclusion latency. ParBFT2 exhibits the highest latency due to the hedging delay and the requirement to run both SMVBA and an asynchronous binary agreement protocol for its pessimistic path.

2 second slowdown (Figure 8). With a 2 second slowdown, Ambulance's peak latency increases mildly to 633.4 ms, but is still 2.2x better than Autobahn with a 1 s timeout (1.37 s), 3.0x better than Autobahn with a 5 s timeout (1.89 s), 1.2x better than SMVBA (766 ms), and 2.5x better than ParBFT2 (1.58s). Longer slowdowns increase the probability that multiple recovery views are needed, raising Ambulance and SMVBA's latency. Autobahn with a 5 s timeout again fails to detect the slowdown, resulting in latency degradation proportional to the slowdown duration. Autobahn with a 1 s timeout detects the slowdown after 1 second, but must also pay the consensus latency afterwards, so the latency is still higher compared to Ambulance. ParBFT2 behaves similarly to the 1 s case. Figures 9–11.

5-10 second slowdowns (Figures 9-11) The same trend holds. Ambulance reaches peak latencies of 787.7 ms, 810 ms, and 932 ms for 5, 7, and 10 second slowdowns, respectively, increasing only modestly due to additional failed views. These are still 3.1-6.3x, 6.9-8.6x, and 7.9-10.8x better than Autobahn for 5, 7, and 10 second slowdowns, respectively. SMVBA closely tracks Ambulance at these longer slowdowns (with peak latencies of 812 ms and 945 ms), while ParBFT2 remains at 1.58 s (1.7x worse than Ambulance).

Across all slowdown durations, Ambulance consistently delivers lower peak latency than Autobahn—1.6x–3.0x better for short (1–2 second) slowdowns and up to 10.8x better for more severe (5–10 second) slowdowns. Ambulance also closely matches SMVBA, the state-of-the-art pessimistic protocol, while achieving 1.7x–3.1x lower latency than ParBFT2, the state-of-the-art hedging protocol.

6.3 Production Performance

We evaluate the performance of Ambulance as deployed in Sei [65], a production-grade distributed ledger system, and compare it to their current implementation of Autobahn. The deployment consists of $n = 40$ replicas distributed across 20 AWS EC2 regions in North America, South America, Asia, and Europe. Each replica runs on an `m6i.12xlarge` [2] instance (48 vCPUs, 192 GB RAM, 18.75 GB/s network bandwidth).

Figure 6 reports latency over a 24-hour production run. The system experiences slowdowns approximately once every thousand slots, consistent with rates observed in deployed distributed ledger systems [12, 13, 65]. Both Ambulance and the production Autobahn implementation operate at 180k load (with a peak throughput of 220k) on the same workload;

Autobahn uses 2-second timeouts. Ambulance matches the median latency of Autobahn (244ms vs 242ms), while significantly improving tail performance: its p99 latency of 662 ms represents a 1.92x reduction compared to Autobahn's 1.27 s. Because the slowdown events dominate the p99, these results show that Ambulance maintains Autobahn's common-case latency in production while substantially reducing latency during slowdowns.

7 Related Work

Ambulance is inspired by several prior works. Ambulance's leader racing path draws from traditional BFT protocols, in particular, PBFT [30]. The recovery path draws from the VABA (MVBA) family of asynchronous protocols, in particular, 2PAC [73]. Ambulance directly adopts Autobahn's [45] data layer and pipelining strategy to achieve high throughput and reduce end-to-end latency.

Slowdown tolerance and failure detectors The most common failure detectors [32, 33, 55] rely on heartbeats or timeouts. These mechanisms are slow to react to failures, and are fundamentally not cooperative nor productive. Other failure detection mechanisms [21, 52, 58, 61] are less generic and inspect the actual processes themselves. These mechanisms can detect more types of failures, including gray failures, but do not easily extend to Byzantine environments. PeerReview [51] does detect provably faulty behavior but can neither detect nor correct slow behavior. Copilot [70] is the first SMR protocol to introduce slowdown tolerance, limited to the CFT setting. It defines and satisfies the *s*-slowdown-tolerance property, which guarantees performance similar to the no-slowdown case even with *s* slow replicas. We instead assess slowdown robustness by measuring each protocol's latency under slowdown, since even Copilot can suffer performance degradation in certain slowdown scenarios [62].

Partially synchronous BFT These protocols [25, 26, 30, 31, 44, 46, 47, 50, 56, 68, 74, 76, 78, 83] are optimized for the failure-free case, minimizing latency when there are no slowdowns. Because they rely on timeouts to detect failures, a slow leader causes latency to spike by an amount proportional to the leader timeout or the duration of the slowdown.

Robust BFT Aardvark [34] monitors leader performance and invokes view changes if the leader does not meet performance thresholds. The system offers only partial protection against slowdowns [70] as it cannot easily detect transient slowdowns. Autobahn [45] is robust to blips, a subset of slowdowns that includes network events such as partial partitions or replica failures that trigger timeouts. It ensures that latency returns to baseline immediately after a blip but allows latency to spike during the blip.

Asynchronous BFT protocols [19, 38, 54, 66] are pessimistic: they assume the leader always loses the race against the clock. There are two main families of asynchronous BFT protocols: the HoneyBadger (BKR) family [24, 60, 66, 82] and the VABA family [19, 42, 49, 73, 77]. HoneyBadger-style protocols typically run *n* instances of reliable broadcast [29] and *n* instances of binary agreement to decide which broadcasts completed, while VABA-style protocols run *n* instances of a leader-based BFT protocol and use a common coin to randomly select one instance to commit. Asynchronous protocols have lower latency than traditional BFT during slowdowns, since they do not require a failure detection mechanism such as timeouts. However, they have much higher common-case latency than traditional BFT protocols, limiting their adoption in practice.

Hybrid BFT protocols [28, 36, 37, 43, 64, 72, 75] aim to combine the advantages of traditional and asynchronous BFT. Ditto [43] and BDT [64] run a traditional BFT protocol first and fall back to an asynchronous one when a timeout fires. Relying on timeouts causes them to suffer high latency during slowdowns, particularly when switching protocols. ParBFT [37], Abraxas [28], and Ipotane [36] instead run one or more asynchronous protocol instances to detect failures of the traditional BFT protocol. Unfortunately, commitment during a slowdown requires still requires completing multiple asynchronous instances. Hedging [37, 80] detects failures by having the leader race against other replicas, but giving the leader a time-based head start. This mechanism is cooperative, but not productive; it stalls recovery until the hedging delay is over.

Leaderless SMR protocols [39, 67, 81] distribute the ordering task across multiple replicas instead of relying on a single leader. Because no single leader orders all requests, replicas commit dependency graphs that induce an order among instances. This design avoids stalling on a single slow leader, but slowdowns still harm performance: replicas can depend on commands proposed by slow replicas and must wait for those commands to commit before executing. In the worst case, they must invoke an expensive recovery procedure for those commands.

8 Conclusion

This paper introduces Ambulance, a novel BFT protocol, that uses a novel *protocol-rigged racing* mechanism to detect slowdowns. This allows Ambulance to offer the best of both worlds: the good-interval performance of timeout-based systems and slowdown performance comparable to asynchronous protocols.

A Retry Protocol

Recovery Input Selection. To determine whether a value may have been committed in prior views, replicas broadcast their local state to others.

1: P → R: Replica *P* broadcasts START-VIEW.

When *P* enters view *v*, it broadcasts its local understanding of whether the previously elected lane committed (it sets $cert\text{-}data = qcs[E]$ or $\langle \perp_{elect} \rangle_P$ if it did not receive an *elected* recovery non-equivocation certificate): if $cert\text{-}data = \langle \perp_{elect} \rangle_P$, no operation committed in view $v-1$ according to *P* (note that, unlike traditional BFT protocols, this says nothing about whether a value committed in a prior view). Otherwise, it forwards $cert\text{-}data = qcs[E]$ to all other replicas as part of a START-VIEW $:= \langle v, cert\text{-}data \rangle$ message.

2: P: *P* receives a quorum of valid START-VIEW messages.

Replica *P* decides what input to recover based on the $n-f$ valid START-VIEW messages it has received. From these, *P* distinguishes between two cases: 1) a value could have been committed in view $v-1$ 2) a value definitely did not commit in view $v-1$, but may have committed in a prior view.

Case 1: *P* receives a recovery non-equivocation certificate in view $v-1$.

Upon receiving a recovery non-equivocation certificate (*recovery-non-equiv-cert*), *P* checks that is well-formed and from the elected lane in view $v-1$. Receiving an recovery non-equivocation certificate signals that a correct replica *may have committed* on the recovery path for view $v-1$. This follows from quorum intersection: if an *elected* recovery confirm certificate exists, *P* is guaranteed to receive at least one corresponding recovery non-equivocation certificate. To preserve safety, *P* must therefore set its recovery input to the *elected* recovery non-equivocation certificate: $r\text{-}input = recovery\text{-}non\text{-}equiv\text{-}cert$.

Case 2: *P* receives $n-f$ $\langle \perp_{elect} \rangle$.

Receiving $n-f$ $\langle \perp_{elect} \rangle$ messages definitively indicates that no correct replica committed on the recovery path in view $v-1$. By quorum intersection, if an *elected* recovery confirm certificate had existed, *P* would necessarily have received an recovery non-equivocation certificate.

However, *P* still cannot safely recover an arbitrary value. Receiving $n-f$ $\langle \perp_{elect} \rangle$ says nothing about what was decided in *prior views*. If a value was previously committed, *P* must recover the value and set it as its recovery input. We distinguish between two cases. A correct replica may have committed a value 1) on the racing path 2) on the recovery path in any earlier view $v' < v-1$.

If a value *x* committed on the racing path, all replicas would have received a sports car certificate in view 0, and thus set this as their recovery input. From then onwards, all recovery confirm certificate exchanged as part of higher views will always be for value *x*. All recovery confirm certificate received as part of view $v-1$ will thus necessarily be for value *x*. *P* can select any as its recovery input.

If a value *x* instead committed in view $v' < v-1$, all replicas would have received a REC-PREPARE for *x* in view $v'+1$, and would have thus set their recovery input to *x*. From then onwards, all recovery confirm certificate exchanged as part of higher views will always be for value *x*. In both cases, *P* can thus set its recovery input to any recovery confirm certificate from $v-1$: $r\text{-}input = rec\text{-}confirm\text{-}cert$, and aggregates the $n-f$ signatures on $\langle \perp_{elect} \rangle$ into a no-elected commit certificate, *nec-cert*.

After selecting its recovery input, *P* enters the race exclusion phase, using the no-elected commit certificate in place of the no-commit certificate (if it exists). From this point forward, *P* executes the persistence and lane-election phases exactly as in view 0, with no further differences.

B Proofs

B.1 Safety

For safety, correct replicas enforce the following validity rules for messages for a given slot.

Protocol validity rules. All rules below are for a fixed consensus instance/slot. Correct replicas only sign or vote for messages that are valid according to the rules below.

1. **Fast-prepare uniqueness.** A correct replica sends at most one SC-PREP-VOTE message.
2. **No-leader-proposal exclusion.** A correct replica never both signs $\langle \perp_{prep} \rangle$ and sends a SC-PREP-VOTE message.
3. **Fast-commit validity.** A correct replica sends SC-COMMIT for digest *d* only after verifying and storing a valid sports car certificate for the same digest *d*.
4. **No-leader-lock exclusion.** A correct replica never both sends SC-COMMIT and signs $\langle \perp_{sc} \rangle$. This exclusion is permanent in both directions.
5. **Slow-prepare uniqueness.** For each proposer *i* in view 0, a correct replica sends at most one TRUCK-PREP-VOTE message.
6. **Recovery-prepare vote uniqueness.** For each proposer *i* and view *v*, a correct replica sends at most one REC-PREP-VOTE message.
7. **Recovery-prepare vote validity.** A correct replica sends a REC-PREP-VOTE for digest *d* only after verifying a valid REC-PREPARE message for the same proposer, view, and digest *d*.
8. **View-0 recovery-prepare validity.** In view 0, a REC-PREPARE message from proposer *i* for digest *d* is valid only if it contains one of the following:

   (a) a valid sports car certificate for digest *d*; or

(b) a valid truck certificate from proposer i for digest d together with a valid no-commit certificate.

In particular, the digest of the REC-PREPARE must match the digest of the supporting certificate.

9. **Later-view recovery-prepare validity.** For view $v>0$, a REC-PREPARE message for digest d is valid only if it adopts one of the following certificates from view $v-1$:
   (a) an *elected* recovery non-equivocation certificate from view $v-1$ with digest d; or
   (b) a non-*elected* recovery confirm certificate from view $v-1$ with digest d together with a valid no-elected commit certificate for view v.

   Thus, the digest proposed in view v must equal the digest of the certificate adopted from view $v-1$.
10. **Recovery-confirm validity.** A correct replica sends a REC-CONFIRM-VOTE for digest d only after verifying a valid REC-CONFIRM message containing a valid recovery non-equivocation certificate for the same proposer, view, and digest d.
11. **Recovery-confirm vote uniqueness.** For each proposer i and view v, a correct replica sends at most one REC-CONFIRM-VOTE message.
12. **Election uniqueness.** In every view v, all correct replicas agree on at most one elected proposer. A certificate is *elected* in view v only if it originates from that proposer.
13. **No-election exclusion.** A correct replica never both sends a REC-CONFIRM-VOTE for an *elected* recovery non-equivocation certificate in view v and signs $\langle\perp_{elect}\rangle f$or view $v+1$. This exclusion is permanent in both directions.
14. **Commit validity.** A correct replica commits on the fast path only after receiving a valid leader commit certificate. A correct replica commits on the recovery path only after receiving a valid *elected* recovery confirm certificate.
15. **Embedded validity.** Whenever a correct replica verifies a message containing an embedded certificate, the embedded certificate must be valid and must match the same consensus instance, proposer where applicable, view, and digest claimed by the outer message.

Lemma 1. *For any two sports car certificate, P and P', $P.dig=P'.dig$*

Proof. Suppose for the sake of contradiction, $P.dig\neq P'.dig$. P and P' consist of $n-f$ SC-PREP-VOTE messages. Two quorums of size $n-f$ intersect in at least one correct replica, which means at least one correct replica sent conflicting SC-PREP-VOTE messages with different digests, a contradiction since correct replicas only send one SC-PREP-VOTE message. □

Lemma 2. *For any two leader commit certificate, C and C', $C.dig=C'.dig$*

Proof. Suppose for the sake of contradiction, $C.dig\neq C'.dig$. C and C' consist of $n-f$ SC-COMMIT messages. Two quorums of size $n-f$ intersect in at least one correct replica, which means at least one correct replica sent conflicting SC-COMMIT messages for different digests. A correct replica only sends a SC-COMMIT message for digest, dig, if it receives a sports car certificate also for dig, meaning it received two conflicting sports car certificate, a contradiction to lemma 1. □

Lemma 3. *For any sports car certificate, L, and any leader commit certificate, C, $L.dig=C.dig$.*

Proof. Suppose for the sake of contradiction, $L.dig\neq C.dig$. By lemma 1 any two sports car certificate must have the same digest, $L.dig$. C consists of $n-f$ SC-COMMIT messages, of which at least $n-2f$ are from correct replicas. This means that $n-2f$ correct replicas sent a SC-COMMIT message for a digest that does not correspond to a valid sports car certificate, a contradiction. □

Lemma 4. *For any two truck certificate, P and P', from proposer i in view 0, $P.dig=P'.dig$*

Proof. Suppose for the sake of contradiction, $P.dig\neq P'.dig$. P and P' consist of $n-f$ TRUCK-PREP-VOTE messages. Two quorums of size $n-f$ intersect in at least one correct replica, which means at least one correct replica sent conflicting TRUCK-PREP-VOTE messages with different digests, a contradiction since correct replicas only send one TRUCK-PREP-VOTE message for a given proposer in view 0. □

Lemma 5. *If a no-lock certificate forms, then no sports car certificate can exist.*

Proof. Suppose for the sake of contradiction there exists both a no-lock certificateand a sports car certificate. This means a quorum Q_1 of size at least $n-f$ signed $\langle\perp_{prep}\rangle$. And a quorum Q_2 of size at least $n-f$ sent a SC-PREP-VOTE message. Q_1 and Q_2 intersect in at least one correct replica, which signed $\langle\perp_{prep}\rangle a$nd sent a SC-PREP-VOTE message. A correct replica will not do both, a contradiction. □

We say that a recovery non-equivocation certificate is either $n-f$ REC-PREP-VOTE messages, or a tuple consisting of $n-f$ TRUCK-PREP-VOTE messages and a no-lock certificate (upgraded).

Lemma 6. *For any two recovery non-equivocation certificate, P and P', in view 0 from proposer i, $P.dig=P'.dig$*

Proof. Suppose for the sake of contradiction, $P.dig\neq P'.dig$. There are three cases: (*i*) P and P' consist of $n-f$ REC-PREP-VOTE messages (*ii*) P and P' consist of $n-f$ TRUCK-PREP-VOTE messages and a no-lock certificate or (*iii*) WLOG P consists of $n-f$ REC-PREP-VOTE messages and P' consists of $n-f$ TRUCK-PREP-VOTE messages and a no-lock certificate.

Case (*i*). P and P' consist of $n-f$ REC-PREP-VOTE messages. Two quorums of size $n-f$ intersect in at least one correct replica, which means at least one correct replica sent conflicting REC-PREP-VOTE messages with different digests, a contradiction since correct replicas only send one REC-PREP-VOTE message for a given proposer in view 0.

Case (*ii*). By lemma 4 any two truck certificate must be for the same digest, a contradiction.

Case (*iii*). By lemma 4, any truck certificate from proposer i must have digest = $P'.dig$, and by lemma 5, there does not exist a sports car certificate. This means that at least $n-2f$ correct replicas sent a REC-PREP-VOTE for a REC-PREPARE that did not contain a supporting truck certificate or a sports car certificate, a contradiction since a valid REC-PREPARE must contain either a truck certificate or a sports car certificate. □

Lemma 7. *For any two recovery confirm certificate, C and C′, in view* 0 *from proposer i, C.dig* $= C'.dig$

Proof. Suppose for the sake of contradiction, $C.dig \neq C'.dig$. C and C' consist of $n-f$ REC-CONFIRM-VOTE messages. Two quorums of size $n-f$ intersect in at least one correct replica, which means at least one correct replica sent conflicting REC-CONFIRM-VOTE messages for different digests. A correct replica only sends a REC-CONFIRM-VOTE message for digest, *dig*, if it receives a recovery non-equivocation certificate also for *dig* (contained in a REC-CONFIRM message), meaning it received two conflicting recovery non-equivocation certificate, a contradiction to lemma 6. □

Lemma 8. *For any recovery non-equivocation certificate, P, and recovery confirm certificate, C in view* 0 *from proposer i, P.dig* $= C.dig$.

Proof. Suppose for the sake of contradiction, $P.dig \neq C.dig$. By lemma 6 any recovery non-equivocation certificate must have digest equal to $P.dig$. This means that $n-2f$ correct replicas sent a REC-CONFIRM-VOTE message for a digest not corresponding to a valid recovery non-equivocation certificate, a contradiction. □

Lemma 9. *For any two recovery non-equivocation certificate P and P′, from proposer i in view* $v > 0$, $P.dig = P'.dig$.

Proof. Suppose for the sake of contradiction, $P.dig \neq P'.dig$. P and P' consist of $n-f$ REC-PREP-VOTE messages. Two quorums of size $n-f$ intersect in at least one correct replica, which means at least one correct replica sent conflicting REC-PREP-VOTE messages with different digests, a contradiction since correct replicas only send one REC-PREP-VOTE message per proposer per view. □

Lemma 10. *For any recovery non-equivocation certificate, P, and recovery confirm certificate, C in view* $v > 0$ *from proposer i, P.dig* $= C.dig$.

Proof. Suppose for the sake of contradiction, $P.dig \neq C.dig$. By lemma 9 any recovery non-equivocation certificate from proposer i in view v must have digest equal to $P.dig$. This means that $n-2f$ correct replicas sent a REC-CONFIRM-VOTE message for a digest that does not correspond to a valid recovery non-equivocation certificate, a contradiction. □

Lemma 11. *If there exists a leader commit certificate, C, then a no-commit certificate cannot exist.*

Proof. Suppose for the sake of contradiction, there exists both a leader commit certificate and a no-commit certificate. The existence of C implies that at least $n-2f$ correct replicas sent a SC-COMMIT message. These correct replicas must have stored a sports car certificate locally (in *sportscar-cert*) before sending a SC-COMMIT message. However, the existence of a no-commit certificate implies that at least $n-f$ replicas signed the message $\langle \perp_{sc} \rangle$. A quorum of $n-2f$ correct replicas intersects any quorum of $n-f$ replicas, in at least one correct replica. This correct replica must have sent a SC-COMMIT message and signed the message $\langle \perp_{sc} \rangle$, a contradiction since correct replicas never both send SC-COMMIT and sign the message $\langle \perp_{sc} \rangle$. □

Lemma 12. *If there exists a leader commit certificate, C, then any recovery non-equivocation certificate, P, from any proposer in view* 0 *must have P.dig* $= C.dig$

Proof. Suppose for the sake of contradiction, $P.dig \neq C.dig$. There are two cases: (*i*) P is a tuple consisting of a truck certificate and a no-lock certificate (upgraded) or (*ii*) P consists of $n-f$ REC-PREP-VOTE messages.

Case (*i*). The existence of C implies that at least $n-2f$ correct replicas sent a SC-COMMIT message. A correct replica only sends a SC-COMMIT message if it received a sports car certificate, thus a sports car certificate exists. By lemma 5, there cannot exist a sports car certificate since P contains a no-lock certificate, a contradiction.

Case (*ii*). By lemma 11 there cannot exist a no-commit certificate and by lemma 3, any sports car certificate must have the same digest as a leader commit certificate. However, the existence of P implies that at least $n-2f$ correct replicas sent a REC-PREP-VOTE message for $P.dig \neq C.dig$. A correct replica will only send a REC-PREP-VOTE message for $P.dig \neq C.dig$ if the REC-PREPARE message contains a no-commit certificate, a contradiction. □

We say an *elected* certificate in view v is a certificate originating from the randomly elected proposer in view v. We say a no-elected commit certificate is $n-f$ $\langle \perp_{elect} \rangle$*m*essages.

Lemma 13. *If there exists an elected recovery confirm certificate in view v, then there cannot exist a no-elected commit certificate in view* $v+1$.

Proof. Suppose for the sake of contradiction there exists both an *elected* recovery confirm certificate in view v and a no-elected commit certificate in view $v+1$. The existence of an *elected* recovery confirm certificate, means that at least $n-2f$ correct replicas sent a REC-CONFIRM-VOTE message for an *elected* recovery non-equivocation certificate. However, the existence of a no-elected commit certificate implies that at least $n-f$ replicas signed $\langle \perp_{elect} \rangle$. $n-2f$ correct replicas intersects a quorum of $n-f$ replicas in at least one correct replica. This means that a correct replica sent both a REC-CONFIRM-VOTE message indicating it received an *elected* recovery non-equivocation certificate in view v, and also signed $\langle \perp_{elect} \rangle$, a contradiction, since correct replicas never do both. □

Lemma 14. *If a correct replica commits dig in view v (recovery path), then any recovery non-equivocation certificate, P, in view $v' > v$ must have $P.dig = dig$*

Proof. We prove the lemma by induction.

Base Case: $v' = v+1$**.** Suppose for the sake of contradiction $P.dig \neq dig$. The existence of a recovery non-equivocation certificate in view $v+1$ implies that at least $n-2f$ correct replicas sent a REC-PREP-VOTE message for a REC-PREPARE message containing either (*i*) an *elected* recovery non-equivocation certificate from view v or (*ii*) a non-*elected* recovery confirm certificate and a no-elected commit certificate for view $v+1$. For case (*i*), by lemmas 10 and 8 any *elected* recovery non-equivocation certificate in view v must have a digest of dig, a contradiction since the recovery non-equivocation certificate must also be for digest dig. For case (*ii*), by lemma 13, a no-elected commit certificate cannot exist, a contradiction.

Induction Step. Assume the lemma holds for all $v'-1$, now consider view v'. Suppose for the sake of contradiction $P.dig \neq dig$. The existence of a recovery non-equivocation certificate in view v' implies that at least $n-2f$ correct replicas sent a REC-PREP-VOTE message for a REC-PREPARE message containing either (*i*) an *elected* recovery non-equivocation certificate from view $v'-1$ or (*ii*) a non-*elected* recovery confirm certificate from view $v'-1$ and a no-elected commit certificate for view v'. For case (*i*), by the induction assumption any recovery non-equivocation certificate in view $v'-1$ must have $P.dig = dig$, a contradiction. For case (*ii*), by the induction assumption and lemma 10 any recovery confirm certificate in view $v'-1$ must have digest $= dig$, a contradiction. □

Lemma 15. *If there exists a leader commit certificate for digest dig, then any recovery non-equivocation certificate, P, in view $v' > 0$ must have $P.dig = dig$.*

Proof. We prove the lemma by induction.

Base Case: $v' = 1$**.** Suppose for the sake of contradiction $P.dig \neq dig$. The existence of a recovery non-equivocation certificate in view 1 implies that at least $n-2f$ correct replicas sent a REC-PREP-VOTE message for a REC-PREPARE message containing either (*i*) an *elected* recovery non-equivocation certificate from view 0 or (*ii*) a non-*elected* recovery confirm certificate from view 0 and a no-elected commit certificate. By lemma 12 any recovery non-equivocation certificate (including *elected*) in view 0 must have digest $= dig$. By lemma 8 any recovery confirm certificate must have digest $= dig$. Thus a correct replica sent a REC-PREP-VOTE for neither (*i*) or (*ii*), a contradiction.

Induction Step. Assume the lemma holds for all $v'-1$, now consider view v'. Suppose for the sake of contradiction $P.dig \neq dig$. The existence of a recovery non-equivocation certificate in view v' implies that at least $n-2f$ correct replicas sent a REC-PREP-VOTE message for a REC-PREPARE message containing either (*i*) an *elected* recovery non-equivocation certificate from view $v'-1$ or (*ii*) a non-*elected* recovery confirm certificate from view $v'-1$ and a no-elected commit certificate for view v'. For case (*i*), by the induction assumption any recovery non-equivocation certificate in view $v'-1$ must have $P.dig = dig$, a contradiction, since the REC-PREPARE must adopt the same digest dig. For case (*ii*), by the induction assumption and lemma 10 any recovery confirm certificate in view $v'-1$ must have digest $= dig$, a contradiction, since the REC-PREPARE must adopt the same digest dig. □

Theorem 1 (Safety)**.** *No two correct replicas commit different values.*

Proof. Suppose for the sake of contradiction there exists two correct replicas, R and R', which commit dig and dig', where $dig \neq dig'$ respectively. There are three cases: (*i*) R and R' both committed from receiving a leader commit certificate, (*ii*) R and R' both committed from receiving an *elected* recovery confirm certificate, and (*iii*) WLOG R committed from receiving a leader commit certificate while R' committed from receiving an *elected* recovery confirm certificate.

For case (*i*), by lemma 2 any leader commit certificate must be for the same value, a contradiction. For case (*ii*), let view v and view v' be the views in which R and R' committed respectively. If $v = v'$ and $v = 0$, then by lemma 7, $dig = dig'$, a contradiction. If $v = v'$ but $v \neq 0$ then by lemmas 9 and 10, $dig = dig'$. Otherwise, WLOG let $v < v'$. By lemma 14, any recovery non-equivocation certificate in view v' must have digest $= dig$, and by lemma 10 any *elected* recovery confirm certificate must have digest $= dig$, a contradiction. For case (*iii*), let view v' be the view in which R' committed. If $v' > 0$ by lemma 15, any recovery non-equivocation certificate certificate in view v' must have digest $= dig$, and by lemma 10 any *elected* recovery confirm certificate in view v' must also have digest $= dig$, a contradiction. Otherwise, if $v' = 0$, the by lemmas 12 and 8 have digest $= dig$, a contradiction. □

B.2 Liveness

The elected lane in each view is produced by a common coin. For any set S of lanes fixed before the election output

is known, $\Pr[elected(v) \in S] = |S|/n$. In particular, if a replica has recovery confirm certificate certificates for $n-f$ distinct lanes before the elected lane is known, then the elected lane is among those lanes with probability $(n-f)/n > 2/3$.

Termination certificates are globally verifiable. If a correct replica terminates after receiving either a leader commit certificate or an elected recovery confirm certificate, then before terminating it forwards that certificate to all replicas. Any correct replica that receives a valid termination certificate terminates, regardless of its current view. We also assume eventual delivery of messages between correct replicas.

Lemma 16. *If no correct replica ever terminates and a correct replica, R is in view v, then all correct replicas will eventually advance to view $v+1$.*

Proof. We prove the lemma by induction on v.

Base Case: $v = 0$**.** Suppose for the sake of contradiction some correct replica never enters view 1. All correct replicas must have entered view 0 and started the race. Since there are at least $n-f$ correct replicas, and correct replicas only propose valid values, eventually all correct replicas will form a *race-cutoff cert*. This will trigger sending a STATUS message, so all correct replicas will eventually receive $n-f$ STATUS messages. After receiving $n-f$ STATUS messages, a correct replica either obtains a no-lock certificate and skips race exclusion, or enters race exclusion and eventually receives at least $n-f$ REC-PREP-VOTE messages. It then proceeds to persistence phase. It will eventually receive $n-f$ REC-CONFIRM-VOTE messages and complete the persistence phase. All correct replicas will eventually complete the persistence phase, so all correct replicas will eventually receive $n-f$ recovery confirm certificate and send an ELECT-LANE message. Thus every correct replica eventually receives at least $n-f \geq 2f+1$ ELECT-LANE messages. Since no correct replica ever terminates, every correct replica advances to view 1, a contradiction.

Induction Step. Assume the lemma holds for all views up to $v-1$, and consider view v. Since R is in view v, it previously entered view $v-1$. By the induction hypothesis applied to view $v-1$, all correct replicas eventually advance to view v. All correct replicas will send a START-VIEW message at the start of view v and eventually receive $n-f$ START-VIEW messages. All correct replicas will then eventually complete the race exclusion and persistence phases in view v since there are at least $n-f$ correct replicas. All correct replicas will thus receive $n-f$ recovery confirm certificate and send an ELECT-LANE message. Thus every correct replica eventually receives at least $n-f \geq 2f+1$ ELECT-LANE messages. Since no correct replica ever terminates, every correct replica advances to view $v+1$. □

Lemma 17. *If no correct replica terminates before view v and some correct replica enters view v, then some correct replica terminates in view v with probability at least $(n-f)/n > 2/3$.*

Proof. If some correct replica terminates in view v before the election step, then the claim already holds. Otherwise, no correct replica terminates before the election step of view v.

By the same progress argument as in Lemma 16, unless some correct replica terminates earlier in view v, correct replicas eventually complete the required phases of view v. Hence, some correct replica R eventually receives $n-f$ recovery confirm certificate certificates for $n-f$ distinct lanes before the elected lane is known. Let S be this set of lanes.

By the common-coin assumption, $\Pr[elected(v) \in S] = (n-f)/n > 2/3$. If $elected(v) \in S$, then R has a valid recovery confirm certificate for the elected lane, so R terminates in view v. Therefore, some correct replica terminates in view v with probability at least $(n-f)/n > 2/3$. □

Lemma 18. *If a correct replica, R, terminates in view v, then all correct replicas eventually terminate.*

Proof. Suppose for contradiction, a correct replica R' never terminates. If R received a leader commit certificate it forwards it to all correct replicas before terminating. R' will thus receive it and also terminate, a contradiction. If R received an *elected* recovery confirm certificate in view v, it will also forward it to all correct replicas before terminating. R' will thus receive it and also terminate, a contradiction. □

Theorem 2 (Liveness)**.** *Ambulance terminates with probability* 1.

Proof. By Lemma 16, if no correct replica terminates, then correct replicas keep entering higher views. Let $p = (n-f)/n > 2/3$. By Lemma 17, conditioned on no correct replica terminating before a view, if no correct replica has terminated before that view, some correct replica terminates in that view with probability at least p. Therefore, by a geometric tail bound, the probability that no correct replica terminates in the first k views is at most $(1-p)^k$, which converges to 0 as $k \to \infty$. Hence some correct replica terminates with probability 1. By Lemma 18, once one correct replica terminates, all correct replicas eventually terminate. Therefore, Ambulance terminates with probability 1. □

C Additional Technical Discussion

By default, the race gives the leader a one-message-delay advantage over the other replicas: the leader can commit in two message delays, whereas non-leader replicas require three. In some deployments, such as LAN environments, this advantage may be insufficient because communication delays between replicas are extremely small. As a result, a non-slow leader may be mistakenly classified as slow, causing replicas to trigger recovery more often than necessary.

To increase the leader's advantage, Ambulance can insert a configurable number of dummy phases before non-leader replicas enter the race. In each dummy phase, replicas send

a message containing the phase number and wait for $n - f$ matching messages before advancing to the next phase. Alternatively, Ambulance can introduce a time-based delay, similar to a hedging delay, to further bias the race in favor of the leader. Although dummy phases or time-based delays may may seem at odds with our productivity requirement, replicas still use this time to generate non-equivocation certificates for recovery. By contrast, traditional timeouts and hedging delays do not perform useful protocol work while waiting.

Dummy phases are particularly useful when motorizing Ambulance. Since coverage (new data layer proposals) to start a slot may be achieved at different times across replicas, the leader may begin a slot later than other replicas, and therefore be detected as slow even when it is not. To mitigate this, replicas can forward their proposals to the leader, allowing the leader to satisfy coverage as well. Because this forwarding step takes one message delay, Ambulance can add one corresponding dummy phase to compensate for the added delay.

SDCs in the Wild: Characterizing and Diagnosing SDC-defective GPUs in Production LLM Training (Operational Systems)

Abstract

Silent Data Corruption (SDC) has emerged as a critical reliability bottleneck in Large Language Model (LLM) training, where hardware faults are frequently indistinguishable from software anomalies. While standard industry practice relies on synthetic microbenchmarks for fault isolation, our experience shows these methods miss over 60% of defective devices. To understand this gap, we present a comprehensive characterization of 23 SDC-defective GPUs harvested from a large-scale production cluster. Our analysis reveals three key insights: (1) SDCs are not confined to new hardware but often arise later due to aging; (2) SDCs are highly data-dependent and unit-specific, meaning devices that pass general stress tests often fail under specific training input data; and (3) standard ECC and thermal protections fail to capture these logic-level bit flips. Driven by these findings, we propose SDCHUNTER, an automated diagnosis system for detecting SDC-defective GPUs in a large-scale training cluster. Instead of relying on generic benchmarks, SDCHUNTER employs execution replay with the exact training workload and input data that triggered the failure. Deployed at ByteDance, SDCHUNTER successfully mitigated 40 SDC incidents in production.

1 Introduction

Silent Data Corruption (SDC), the unintended alteration of data without error signals, is a persistent reliability challenge in large-scale computing [17, 20, 27, 75]. Although SDC events are statistically rare on one device, the massive scale of training Large Language Model (LLM) amplifies their impact, making them a visible and frequent disruption. With training clusters scaling to tens of thousands of GPUs running for months, low-probability hardware faults become inevitable. Recent reports highlight the frequency of hardware faults in large-scale training environments. Meta reports that during training runs on 16,000 GPUs, hardware failures occur approximately every 2.78 hours, with roughly 1.4% of these attributed to GPU SDC [1]. Similarly, Google observes SDC events every one to two weeks within their TPU clusters [3], while ByteDance records 6,096 implicit errors over a three-month operational period in their GPU clusters [73].

However, the most agonizing challenge for training engineers is not the frequency of these errors, but their *ambiguity*. GPU SDCs typically manifest as computational anomalies such as an unexpected fail-stop error or sudden loss spikes that appear identical to software bugs or numerical instabilities. This creates a costly dilemma: engineers often waste weeks debugging phantom code issues, unaware that the root cause is a silent hardware defect. Prior research has primarily focused on detecting and mitigating CPU-side SDCs [16, 18, 29, 40, 44]. On GPUs, numerous studies have investigated SDC detection and fault tolerance in model inference workloads [35, 36, 42, 82]. Other lines of work propose more reliable algorithms, such as self-check GEMM variants [47, 48], or techniques that monitor specific numerical ranges during training to detect SDCs [21, 26]. However, these approaches are not effective for large-scale LLM training, as the increased numerical robustness of LLM models and the significantly more complex software stack make SDCs harder to detect and localize.

In our production environment at ByteDance, we find that most SDC incidents stem from **SDC-defective GPUs**. These devices contain subtle hardware faults that intermittently corrupt computation. Although we occasionally observe SDCs originating from CPUs, they can be diagnosed with the same approach. In these cases, both CPU and GPU memory are protected by ECC and are not the source of SDCs. Unlike transient soft errors, SDC-defective GPUs pose a persistent risk because the same device can repeatedly corrupt training jobs. When engineers observe suspicious behavior during LLM training, such as unexpected errors, the key challenge is to identify which GPU or GPUs in the cluster caused the corruption. The common industry practice is to run hardware diagnostic tools and synthetic stress tests, such as intensive GEMM loops across all GPUs [52, 54, 77]. However, in our experience, these synthetic tests miss more than 60% of defective GPUs, leaving a substantial detection gap.

*Work done while interning at ByteDance.

Insights from Real-World GPU SDCs. To understand why standard benchmarks fail, we experimentally analyzed 23 SDC-defective GPUs harvested from our production fleet. Our characterization reveals three critical insights. First, SDCs are not limited to new hardware. They often appear later due to aging, requiring continuous lifecycle monitoring. Second, SDCs depend heavily on the specific hardware units (e.g., complex math units fail more often than Tensor Cores) and data inputs. A GPU might pass a general test but fail on specific training tasks. Third, these errors are missed by standard protections like ECC or thermal sensors. Consequently, effective diagnosis requires execution replay with the exact production model, checkpoint, workload, and data distribution that triggered the failure. Despite its promise, production replay faces two fundamental challenges.

Challenge 1: Training Replay Determinism. To identify a defective GPU, we compare its output against a "gold standard" from healthy hardware. Because no single GPU can be assumed reliable, this comparison must span replicas and requires identical inputs to produce bit-wise identical outputs. Yet LLM training is rife with non-determinism [25, 79]. System-level noise, such as non-deterministic reduction orders in AllReduce [62] or random operators, prevents direct cross-replica comparison and makes hardware SDCs indistinguishable from normal stochasticity. Our production measurements show that deterministic training has no measurable throughput loss (within 0.01% step-time difference) and reduces normalized debug time by 70% through bit-wise replay.

Challenge 2: Diagnosis Efficiency. Localizing an SDC requires capturing the corruption before it is masked by nonlinear operators or normalization layers [43]. Theoretically, this requires monitoring every intermediate tensor, but global full-state inspection across thousands of GPUs is prohibitively slow. Because intermittent SDCs may take hours to reproduce, such instrumentation would extend downtime from hours to days and delay the critical training job. We therefore need to isolate the fault quickly without paying the cost of full-state monitoring everywhere.

To address these challenges, we propose SDCHUNTER, an automated diagnosis system that uses hierarchical replay to balance speed and precision. SDCHUNTER first screens the cluster to isolate a small faulty GPU group, then investigates that group to pinpoint the defective device.

Phase 1: Lightweight Grouping via Homogeneous Replay. Upon detecting an anomaly, SDCHUNTER partitions the cluster along the Data Parallel (DP)[1] dimension into two logical replicas that consume the identical input batch. In this controlled "dual-replica" setting, outputs should be bit-wise identical. SDCHUNTER verifies this by hashing tensors only at the Pipeline Parallel (PP)[2] boundaries, incurring only 3% runtime overhead and a few extra training steps. Comparing these signatures across DP groups identifies the divergent stage within hours, which is enough to remove the affected replica and resume training while device-level localization continues offline.

Phase 2: Precise Localization via Full-State Comparison. Once the anomaly is confined to a parallel group[3], SDCHUNTER deterministically replays the problematic iteration on the *suspicious* group and a *healthy* reference group. It collects layer-wise signatures for all intermediate tensors, finds the first divergent tensor and kernel through differential analysis, and maps the error back to the defective GPU.

After the training job resumes on healthy machines, SDCHUNTER confirms the localized device offline by repeatedly replaying the alert-triggering trace and checking the result with hardware tools. This verification does not block the online job and provides a hardware-actionable decision within one hour in our production cases.

Both phases rely on system-wide determinism. SDCHUNTER eliminates noise by locking RNG seeds, enforcing deterministic GPU kernels, and standardizing communication order, so discrepancies across DP groups (Phase 1) or against the reference (Phase 2) indicate hardware defects.

We deployed SDCHUNTER in ByteDance's production environment managing a large GPU cluster. It has mitigated 40 SDC incidents to date. Most importantly, SDCHUNTER decouples cluster recovery from hardware debugging: training resumes within an hour after isolating the faulty stage, while the defective GPU is later pinpointed and confirmed offline within one hour for hardware repair.

Our contributions can be summarized as follows:

- We share our first-hand experience managing SDC incidents in large-scale production clusters at ByteDance, showcasing the problem of SDCs in real-world systems.
- We present a characterization study of 23 SDC-defective GPUs, revealing key insights about their manifestation.
- We quantitatively identify the critical challenges in reproducing SDCs in LLM training.
- We propose SDCHUNTER, an automated diagnosis system for localizing SDC-defective GPUs and have identified 40 SDC incidents in production, reducing diagnosis time from days to under one hour.

To the best of our knowledge, this is the first large-scale study of GPU SDCs in production-level LLM training workloads.

[1]The data-parallel dimension is the axis of the training layout where workers run replicated model copies on different input shards. A DP group denotes one set of workers that participate in this replicated computation and synchronize updates.

[2]Pipeline parallelism splits model layers into sequential stages placed on different workers. PP boundaries are the interfaces between adjacent stages where activation or gradient tensors are exchanged.

[3]A parallel group is a subset of distributed workers that cooperate along one parallelism axis, such as data, pipeline, tensor, or expert parallelism.

2 GPU Silent Data Corruption in Production

2.1 Silent Data Corruption

The correctness of large model training is very important. In practice, training can yield incorrect data in three characteristic ways: crash [73], detected unrecoverable error (DUE) [6, 13, 14, 18, 24, 49], and silent data corruption (SDC) [24, 26, 43, 44]. The crash indicates that the program terminates abnormally due to an unrecoverable error, such as segmentation faults or illegal instructions. DUE refers to errors that are detected by the hardware or software, leading to the termination of the program to prevent further propagation of errors. Both crash and DUE provide immediate feedback to developers, allowing them to identify and address issues promptly.

Different from the crash and DUE, SDC does not produce any general immediate indication of an error. It refers to errors that occur silently without any immediate indication, leading to incorrect results or data corruption. SDC can manifest in various ways, such as bit flips in memory, or incorrect computations. The typical reasons for SDC include environmental factors, hardware bugs, and hardware degradation. Environmental factors such as cosmic rays and radiation can induce transient faults in hardware components [56, 74, 78, 82]. Hardware bugs, such as design flaws or manufacturing defects, can also lead to SDC [44]. Over time, hardware components can degrade due to circuit wear-out and aging [44]. All these factors can contribute to the occurrence of SDC, making it a significant concern in large-scale computing systems.

2.2 SDC-Induced Failures in LLM Training

In this paper, we analyze 23 GPUs with confirmed SDCs identified in our production clusters. Figure 1 classifies the detection sources of these defective devices. Specifically, 10 GPUs were identified during offline stress test using online workloads where they failed numerical validation checks. The remaining 13 GPUs surfaced during active LLM training tasks, causing task interruptions. These production failures manifest in two primary ways: (1) fail-stop errors, where the SDC triggers a system exception (e.g., shape mismatch or out-of-bound access) causing an immediate crash; and (2) implicit anomalies, where the training continues but exhibits incorrect behavior (e.g., loss spikes), leading engineers to manually halt the job.

Confronted with these interruptions, developers instinctively prioritize software debugging over hardware verification. Given the rarity of hardware faults, engineers typically attribute these anomalies to logical bugs in the training software framework or numerical instabilities inherent to the model architecture [30]. Consequently, engineers often invest days or weeks isolating pipeline components and attempting to reproduce the error, but these efforts are frequently wasted. The identification of a hardware fault usually emerges only as a diagnosis of exclusion after all software hypotheses have been exhausted. This characterizes the insidious nature of SDCs: while their probability of occurrence is low, the incurred cost in engineering productivity and wasted computing resources is disproportionately high. We share two detailed cases derived from our real-world production experience to illustrate these deceptive patterns of SDC-induced failures.

Case 1: Explicit Fail-stop Error (Shape Mismatch or Out-of-bound Access). Megatron [69] decouples capacity planning from tensor dispatching in its implementation of MoE operators to maximize device utilization. Under this pipeline, the framework first aggregates token counts to pre-allocate contiguous memory buffers, and subsequently invokes a scatter kernel to populate these buffers. We observed a case in our production environment where an SDC occurred during the token count aggregation, silently corrupting the buffer size calculation. As shown in Figure 2, the error comes from the corrupted `scatter` operation (line 6) and eventually triggers a shape mismatch error at line 9. As shown in Figure 3, the out-of-bound access is caused by the corrupted modulo operation (line 1) and eventually triggers a segmentation fault at line 6. This manifested error creates a debugging trap: the exception did not trigger immediately, but it indicates a fail-stop error, causing developers to suspect a bug in the code. However, the

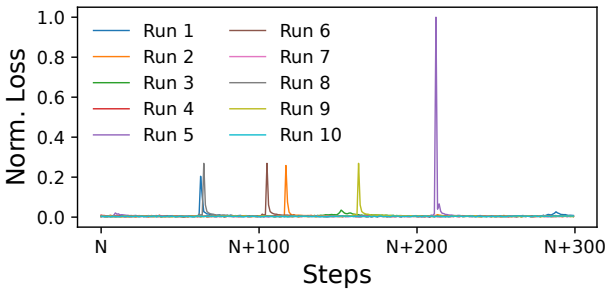

Figure 4: Loss spike caused by SDC during model training with different runs. *The loss spike is confirmed to be caused by SDC, but the spike is not always the same.*

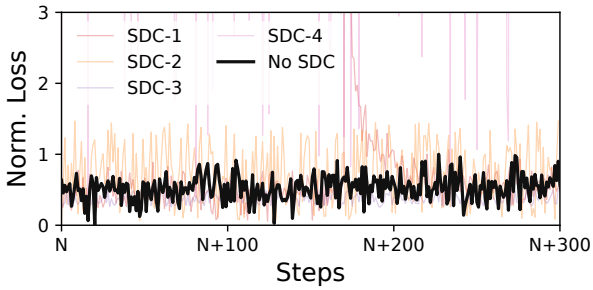

Figure 5: Loss curves of training runs with and without SDC collected from the same checkpoint in production. The spike problem observed in production is shown in Figure 4.

code at the crash site is correct. The SDC had already altered the program state in a previous kernel, rendering the error message a misleading indicator of the true failure source.

Case 2: Implicit Performance Degradation (Anomalous Loss Spikes). In contrast to fail-stop errors, SDCs can manifest as implicit model degradation where the training process continues but produces corrupted checkpoints. The loss comparison in Figure 5 shows the practical consequence: without SDC, the training loss remains within the expected narrow range, while SDC-affected executions create visible excursions that can invalidate subsequent checkpoints. The spike problem is shown in Figure 4. We encountered this scenario in 10 independent training runs executed on the same cluster and initiated from the identical checkpoint. The anomaly first surfaced in Run 1, where the loss spiked dramatically. A distinct re-run, Run 2, reproduced the failure, exhibiting a similar spike. However, when engineers attempted Runs 3 and 4, the training proceeded without incident, showing no anomalies. This led engineers to suspect the occurrence of SDCs. Continued monitoring validated this hypothesis: Runs 5 and 6 (and subsequently Runs 8 and 9) exhibited loss spikes again, but crucially, these occurred at completely different steps compared to the earlier failures. Unlike a code error that would typically fail at a consistent logical point, these random, high-magnitude gradient values indicated underlying hardware malfunctions in the floating-point units. Consequently, the training was halted, and the affected nodes were taken offline to confirm the existence of a defective GPU.

2.3 SDC Impact in LLM Training

Both failure modes impose substantial operational cost in production-level LLM training. Fail-stop errors (Case 1) immediately interrupt the job, leaving allocated GPUs idle until the training state is restored from a valid checkpoint and the defective hardware is isolated. Implicit anomalies (Case 2) are more difficult to handle because the training job may continue to produce invalid checkpoints. Engineers must then determine whether the observed loss spike originates from software bugs, numerical instability, or hardware corruption since the loss spike can degrade the model performance [5, 37, 60, 71, 72]. Without deterministic execution, rerunning the same checkpoint cannot guarantee bit-wise alignment, which further obscures the boundary between benign training variance and SDC-induced model corruption.

The difficulty of mitigation is amplified by the large variation in how frequently a defective GPU manifests an error. We define the *observed SDC occurrence rate* as the fraction of deterministic replays of an alert-triggering workload that produce an incorrect tensor. Across the confirmed defective GPUs, this replay occurrence rate ranges from 100% down to 10^{-6}%. This variation explains why generic hardware stress tests frequently miss SDC-defective GPUs and why diagnosis must replay the production workload that exposed the anomaly. To quantify the practical impact, we measure the optimistic estimation of retraining overhead and the debugging and diagnosis time observed in our production workflow in Table 1. **Actually, the overhead is a lot higher than the estimation in our production workflow.**

Table 1: Overhead over a full training run across varying SDC occurrence rates. *The **SDC Rate** means the visible difference in the loss curve. This trace is collected from manual oncall services with round-the-clock coverage.*

SDC Rate	Expected Steps	Polluted Ckpts	Overhead	
			Retrain	Debug
100%	~ 1	≤ 1	0.011%	0.029%
10%	~ 10	≤ 1	0.020%	0.29%
1%	~ 100	~ 1	0.110%	2.90%
0.1%	$\sim 1,000$	≥ 1	1.510%	29.0%
0.01%	$\sim 10,000$	≥ 10	1.510%	2.9×

Utilizing the industry-standard software diagnostic method [73], the required validation compute scales inversely with p. At $p = 0.01\%$, diagnosing a single defective GPU consumes parallel compute equivalent to training approxi-

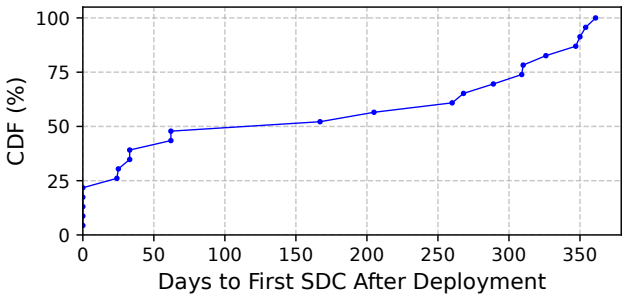

Figure 6: Temporal distribution of SDC emergence across hardware lifecycle.

mately three full LLM models (≈ 290%). This mathematically negates the viability of purely software-replay-based debugging for low-frequency SDCs in hyperscale clusters. This motivates a system to diagnose SDC-defective GPUs at scale.

3 Characterizing SDC-defective GPUs

Silent data corruption originates from hardware degradation that manifests in ways fundamentally different from hard failures. To characterize these differences, we first analyze hardware fault behaviors across four dimensions: temporal patterns, observability, triggering conditions, and visibility.

Temporal Patterns. Unlike prior studies that primarily observe CPU SDCs during early stress testing [75], our long-term analysis reveals that GPU SDCs pose a persistent threat throughout the entire hardware lifecycle. By tracking the timelines of all confirmed SDC cases in our production environment, we find that these faults are not limited to the early time of GPUs. Instead, they manifest continuously due to cumulative hardware degradation. Specifically, only 25% of SDCs were detected during pre-deployment burn-in, whereas the remaining incidents surfaced gradually: 25% within the first two months, 10% within six months, and a substantial 40% around one year post-deployment (see Figure 6). Furthermore, once a GPU begins to exhibit SDC, the error rate typically escalates over time, signaling progressive deterioration that can lead to permanent failure. This temporal dispersion indicates cumulative degradation rather than manufacturing defects. Vendor analysis suggests the underlying mechanism involves resistance drift in computational circuits, specifically, repeated intensive computation causes electrical stress that gradually alters resistance values, leading to arithmetic errors. This finding is applicable to all long-running GPU fleets that execute sustained high-utilization training workloads, while the exact timeline depends on GPU generation, cooling conditions, workload intensity, and maintenance policy.

> The emergence of SDC covers the entire life cycle of hardware and is caused by GPU hardware degradation, which is irreversible once it occurs.

Table 2: Distribution of kernels where the first SDC was detected on SDC-defective GPUs. Some SDCs are only triggered by specific kernels.

Kernel	Proportion
GEMM	17.3%
InplaceMoE	17.3%
FlashAttention	13.0%
RMSNorm	8.69%
InplaceLinear	8.69%
Scatter	8.69%
FusedKernel	8.69%
Mean	8.69%
InternalImplemented	8.69%

Table 3: Characterization of SDC sources in μ-archs for GEMM kernels. ✓ *indicates correct computation, while* ✗ *indicates erroneous computation.*

GPU	CUDA Core		Tensor Core			
	FP32	FP64	BF16	FP16	TF32	INT8
1	✗	✓	✓	✓	✓	✓
2	✗	✗	✓	✓	✗	✗
3	✓	✗	✓	✓	✓	✓
4	✗	✗	✓	✓	✗	✗

SDC Sources in μ-archs. Unlike memory errors that can be detected via ECC or execution exceptions triggered by instruction faults, SDCs come from diverse hardware components [44]. We conducted in-depth experiments to find the sources of SDC by replaying the same workload and kernels on victim GPUs and monitoring error rates. Our analysis reveals that SDC comes from diverse hardware components. Some of them may have specific component failures, while others may have unclear failures. We've listed the first-detected SDC kernels and GPUs in Table 2. For those with GEMM kernel SDCs, we conduct a further analysis of different data types and precision in Table 3. The results indicate that FP64 and FP32 CUDA cores exhibit a higher propensity for SDC. A plausible explanation is that high-precision ALUs are substantially larger and more complex than their lower-precision counterparts: they require wider datapaths and more transistors to implement the corresponding logic. The increased physical area correspondingly elevates the likelihood of fault manifestation [8, 65]. Our findings further suggest that certain SDCs are strongly tied to specific microarchitectural features and data types. For other cases, we posit that SDCs arise from intricate and insufficiently understood interactions within the microarchitecture. This finding is applicable to all GPUs because arithmetic units, memory paths, and fused execution units can all become fault sources, while the exact vulnerable unit and precision mode are implementation dependent.

SDCs originate from multiple GPU components, with susceptibility patterns highly specific to microarchitecture implementations and precision modes.

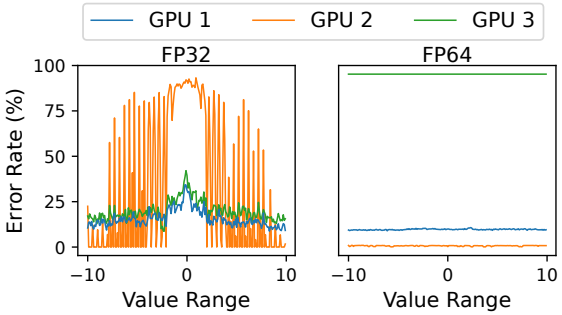

Figure 7: Error rate for a single operator (GEMM) across different input ranges and data types on SDC-affected GPUs.

Triggering Conditions. Triggering SDC is not straightforward. As listed in Table 2, some SDCs become visible only when specific kernels are executed. For these complex cases, errors often manifest as element-wise differences rather than simple numerical errors.

To investigate the triggering patterns of SDC, we executed repeated GEMM kernels on three distinct SDC-defective GPUs, denoted as GPU 1 through GPU 3, varying the input numerical ranges to observe stability boundaries. We define an error as any bit-wise deviation from the standard golden result. Unlike transient soft errors which are stochastic, the errors observed in these devices exhibit strong correlations with input patterns. As shown in Figure 7, the error rate is highly sensitive to both data type and input magnitude. Specifically, GPU 1 and GPU 3 yield incorrect results across all ranges for FP32, whereas GPU 2 exhibits errors only within specific value bands. As for FP64, GPU 3 produces 100% incorrect results with a calculation latency 50× higher than nominal, indicating severe hardware degradation, while GPU 2 maintains an error rate below 1%.

Overall, these findings highlight that SDCs are extremely hard to trigger because they depend on specific operators, data types, and values. Furthermore, even under identical workloads, the error manifests with only a relatively low probability. This finding is applicable to other LLM training workloads that rely on complex fused kernels and data-dependent operators, although the concrete triggering kernels and value ranges must be identified for each model and hardware platform.

SDC occurrence is highly dependent on specific workloads (e.g., kernels, data types and input values), exhibiting strong operator and workload affinity.

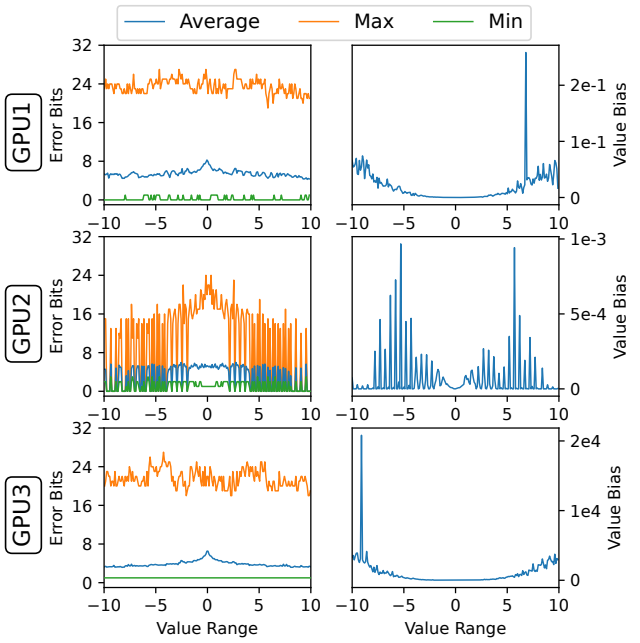

Figure 8: Number of error bits and average value bias for a single operator (GEMM, FP32) across different input ranges on SDC-affected GPUs.

SDC Visibility. We further dissect how SDCs manifest at the numerical level by analyzing the bit-level discrepancies and value biases across different devices. As illustrated in Figure 8, the manifestation of SDCs varies significantly across varying devices. While some defects cause massive deviations, others manifest as sparse bit flips affecting only specific significance levels. For instance, GPU 2 exhibits extremely subtle value biases (magnitude $< 10^{-3}$). Such minor errors are particularly insidious as they are prone to being masked or absorbed by subsequent computational operations (e.g., accumulations or activation functions), propagating silently without triggering obvious outliers.

More importantly, apart from these numerical discrepancies, the hardware faults remain invisible to standard system monitoring metrics. We compared the execution traces between golden hardware and SDC-defective devices. Despite the observable computational errors, standard indicators such as machine check exceptions, performance counters, and device status registers remained indistinguishable from the healthy baseline. Furthermore, the ECC error count shows no correlation with the SDC occurrences, and there are no observable anomalies in clock frequencies or thermal limits between the golden hardware and the defective GPUs. This lack of hardware-level observability implies that error detection must rely solely on verifying the output correctness (e.g., double-checking), as no side-channel signals are available to flag the degradation. This finding is expected to apply to logic-level computational corruptions across all GPUs, while the numerical magnitude and masking behavior depend on

the model architecture and downstream operators.

> SDCs often manifest as subtle value biases without triggering hardware signals, making them difficult to detect through traditional monitoring mechanisms.

4 Challenges of Diagnosing GPU SDCs

Given that SDCs are highly context-sensitive, our characterization reveals that synthetic benchmarks fail because they lack the specific data patterns and instruction sequences required to trigger the faults. This limitation compels us to shift our diagnosis strategy from *simulation* to *reproduction*. Instead of relying on pre-defined test vectors, we adopt an execution replay approach: restoring the training state from a recent checkpoint and re-executing the exact iterations that led to the failure (or loss spikes). By subjecting the suspected GPU to the real production workload, we maximize the probability of recreating the precise micro-architectural state that triggers the silent corruption.

The core principle of this approach is differential testing based on the premise of hardware determinism. Ideally, for a deterministic computational kernel, identical inputs must yield bit-wise identical outputs regardless of the device executing them. Therefore, to confirm a GPU is defective, we can compare its replay output against a golden reference generated by a healthy peer GPU running the same workload. Any discrepancy in the output can be definitively attributed to a hardware fault.

While conceptually straightforward, implementing this replay-based diagnosis in a production LLM training stack is non-trivial. The complexity of distributed training frameworks introduces two fundamental challenges that prevent straightforward comparison and localization: replay determinism and corruption observability. In this section, we quantitatively demonstrate the severity of these two challenges.

4.1 Training Replay Determinism

The prerequisite for differential testing is strict bit-wise reproducibility. Any deviation from the golden reference must stem uniquely from hardware faults. However, achieving such determinism in a distributed training cluster is inherently difficult. The complex interaction between hardware parallelism and software scheduling introduces significant execution noise, which can easily drown out the subtle signals of an SDC. In practice, we identify three primary sources of non-determinism.

Operator Randomness. GPU kernel implementations of some operators often exhibit inherent randomness during execution (e.g., scatter add). Consequently, without explicitly enabling deterministic algorithms, the computation results are inconsistent across runs, as shown in Figure 9. This inconsistency comes from nondeterministic execution order rather than floating-point instability, since a fixed deterministic order produces bit-wise identical results for the same inputs.

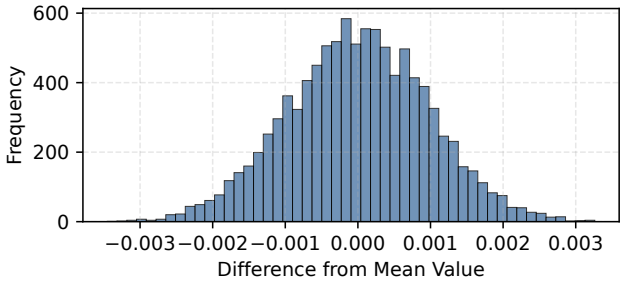

Figure 9: Distribution of output values for the scatter add operator, illustrating the non-determinism on GPU.

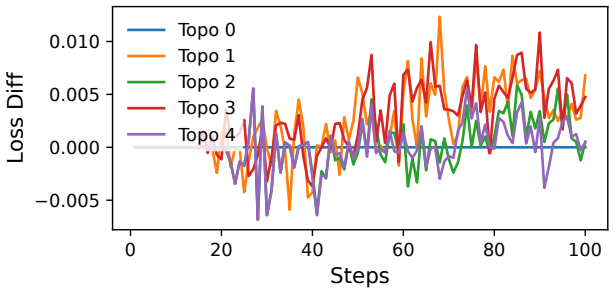

Figure 10: Differences in loss values of different network topologies (Topo 0 to Topo 4) relative to Topo 0.

Network Topology Influence. In distributed training, collective communication operations (e.g., AllReduce) are essential for gradient synchronization. Due to the non-associativity of floating-point arithmetic, ensuring bit-wise reproducibility requires a strictly fixed order of accumulation during reduction. However, the effective network topology in a production cluster is often volatile. NIC failures or bandwidth fluctuations can change the topology observed by communication libraries such as NCCL, causing them to adjust channel counts or algorithms. These changes alter the reduction structure and floating-point addition order, producing numerical divergence even under the same training configuration. To illustrate this effect, we execute the same training configuration across multiple network topologies and collect loss-level metrics. The results, presented in Figure 10, show that the loss variations introduced solely by differing network topologies can be non-trivial. This complicates the diagnosis of SDCs, as it becomes difficult to distinguish whether observed discrepancies stem from actual data corruption or from inherent software-level nondeterminism induced by network topology differences.

Scaling Non-equivalence. GPU resources are extremely precious. When a suspected SDC is detected in a training job involving thousands or even tens of thousands of GPUs, performing a direct replay on a cluster of the same scale is impractical. Doing so would consume a massive amount of

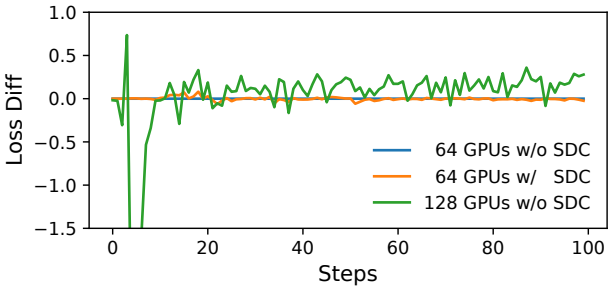

Figure 11: Differences in loss values relative to the setup of 64 GPUs without SDC when scaling down training configurations.

GPU hours and incur huge costs; furthermore, it monopolizes critical resources, blocking other training jobs from being scheduled. Consequently, it is necessary to scale the workload down to a smaller cluster to verify whether a specific GPU is faulty. However, the training result is sensitive to the scale. As stated in previous work [41], keeping consistency between large-scale and small-scale training configurations is challenging. The training framework will select different parallel strategies and kernel fusion strategies for different scales. The training result is different for different scales. To demonstrate this, we use different scales to run the same training configuration on both normal GPUs and SDC GPUs and collect the loss-level training metrics. The results are shown in Figure 11. We observed that the loss difference introduced by scaling down the training configuration is even larger than the deviation caused by a faulty GPU. Consequently, when observing a loss discrepancy in a scaled-down environment, it becomes impossible to distinguish whether the divergence originates from the SDC or the inherent software behavior changes due to scaling.

4.2 Data Corruption Observability

Even if a deterministic replay environment is established, capturing the manifestation of an SDC remains a significant hurdle due to the lack of appropriate observability. We face a fundamental dilemma between *sensitivity* and *efficiency*. High-level metrics (e.g., training loss) are non-intrusive but inherently mask errors due to the robustness of deep learning algorithms. Conversely, low-level inspection (e.g., instruction instrumentation) offers high sensitivity but extremely high overhead, making the SDC reproduction time impractical. We experimentally explore this trade-off in this section.

Loss Observability. Large-model training can mask SDCs in loss-level metrics. To illustrate this, we randomly perturb 10% of tensor values by 1% and 10% during training and compare the resulting loss and gradient-norm differences against an unmodified run as shown in Figure 12. The loss difference is initially small (absolute value below 0.1 and relative value below 5%) and becomes increasingly obscured as training proceeds.

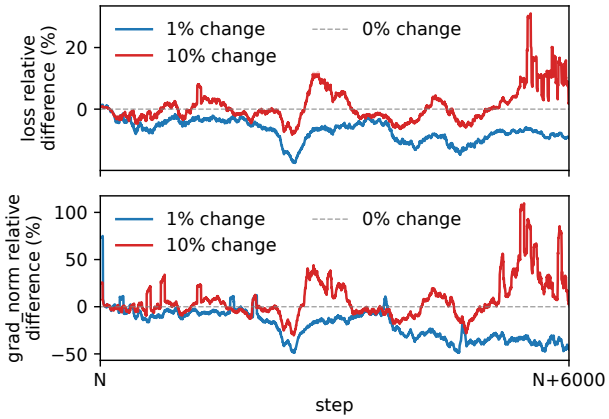

Figure 12: Difference in loss and gradient norm values for changing the value of 10% of tensors by 1% and 10% relative to no value change.

Even if the loss value is different, the first tensor value error appears significantly earlier than the loss value error. To show this lagging effect, we instrumented all tensors on the SDC GPUs and collected the loss-level metrics and tensor-level values. The result is shown in Figure 13. We found that the first tensor value error appears significantly earlier than the loss value error and the loss difference is usually smaller than the value difference. The magnitude of the loss difference and the value difference are related. These conclusions show that even if the loss value is different, it is challenging to determine which step is reliable and which step is caused by the SDC.

Intermediate Result Observability. Since loss values are often insensitive to transient faults, a theoretical alternative is to instrument the execution flow to capture intermediate states. However, deep instrumentation creates a Heisenbug effect: it fundamentally alters the micro-architectural state (e.g., pipeline timing and thread scheduling), potentially masking the very race conditions that trigger SDCs. We observed this phenomenon when applying heavy instrumentation to the defective GPUs identified in Figure 7. As shown in Figure 14, the error rates for GPU 1 and GPU 2 paradoxically decreased compared to the baseline, suggesting that the overhead altered the execution path enough to hide the corruption. Furthermore, we observed new anomalies (e.g., NaNs) absent in the original run, confusing the diagnosis.

A more practical approach involves verifying the checksums (hashes) of tensor outputs at different execution boundaries, yet this introduces a critical trade-off between diagnostic resolution and reproduction cost, as quantified in Table 4. To achieve precise localization, one must perform fine-grained inspection by checksumming outputs after every kernel execution. While this allows us to pinpoint the exact corrupted tensor and its corresponding kernel, it incurs a prohibitive

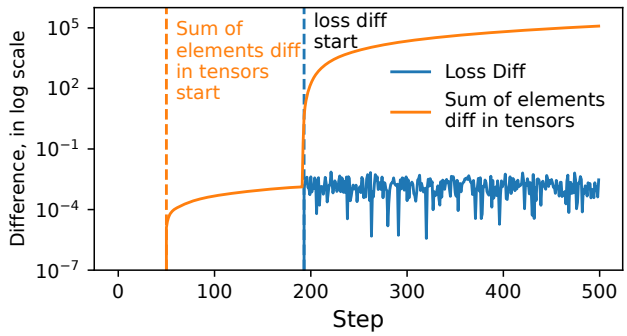

Figure 13: Timestep difference between the loss difference and value difference in log scale.

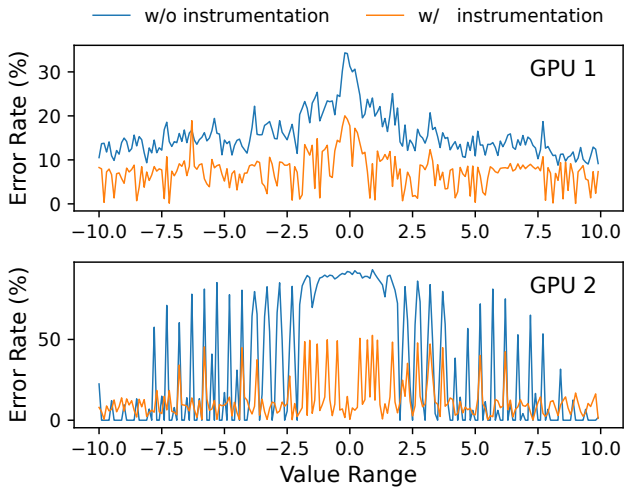

Figure 14: Error rate differences between instrumented and non-instrumented execution.

683.9% overhead. Since diagnosis requires iterative replay, such a 7× slowdown extends the debugging cycle from hours to days, rendering global fine-grained monitoring impractical for production timelines. Conversely, applying coarse-grained checks solely at communication boundaries offers a lightweight alternative with negligible overhead (4.3%). However, this approach suffers from limited resolution: while it can efficiently identify the faulty GPU, it fails to isolate the specific kernel or tensor responsible for the SDC.

5 Diagnosing SDC-defective GPUs at Scale

When an abnormal signal occurs in the online task (e.g., loss decreasing less than expected, Shape Error, etc.), we first determine whether it is a hardware issue. Specifically, we introduce a two-phase diagnosing mechanism. The first phase is a lightweight grouping of all GPUs to identify the suspicious parallel group by replaying the training workload. The second phase is a full tensor comparison within the suspicious GPU groups to pinpoint the specific device. After diagnosis, we confirm the SDC-defective GPUs using offline diagnostics. Before implementing such a two-phase mechanism, we need

Table 4: The overhead and coverage of different instrumentation granularity. ***R**: Rank, **K**: Kernel, **T**: Tensor*. The filled proportion of each circle indicates the coverage achieved by the corresponding instrumentation granularity at the Rank, Kernel, and Tensor levels.

to ensure the training procedure is deterministic.

SDCHUNTER diagnoses the affected job with the exact same model, checkpoint, input shards[4], operator implementations, and communication schedule[5] used by the original training run. The key insight is that deterministic training makes each healthy DP group a bitwise reproducible replica of the same computation, so SDCHUNTER can preserve execution equivalence when it reduces or repartitions DP groups for diagnosis. In the first phase, the parallel configuration[6] is the same as the original training run except that DP groups are organized into replay replicas. In the second phase, SDCHUNTER changes only the DP groups used for comparison while keeping the model, checkpoint, input shards, PP configuration, TP configuration, operator choices, and communication order unchanged. We intentionally avoid a separate lightweight diagnostic model because our characterization shows that GPU SDCs are strongly tied to the production kernel sequence, input value ranges, and communication order. A smaller diagnostic model would improve isolation from the production job, but it would lose the workload fidelity needed to reproduce rare, data-dependent corruptions. Therefore, SDCHUNTER isolates diagnosis by replaying only a bounded window from the latest checkpoint and by moving fine-grained device confirmation off the training critical path, rather than by changing the model under test.

5.1 Pre-requisites: Deterministic Training

To ensure the training procedure is deterministic, we add several deterministic constraints on the computation and communication.

Definition of Deterministic Training. Deterministic training does not eliminate or exclude the numerical randomness in the learning algorithm, such as randomized data order, dropout masks, or other pseudo-random choices. Instead, it

[4]Input shards are partitions of the training data assigned to different workers during distributed training.

[5]A communication schedule specifies the order and grouping of messages exchanged among distributed workers.

[6]A parallel configuration specifies how the training job maps model computation and data across workers, including DP, PP, TP, and EP settings.

makes these sources of randomness reproducible by recording or regenerating the same random sequences from the same checkpoint and configuration. Under this definition, a healthy training system should produce bitwise aligned execution traces when replaying the same checkpoint, input shards, model code, operator implementations, and communication schedule. The purpose is therefore not to eliminate stochastic learning behavior, but to preserve a reproducible training trace.

Such a reproducible training trace is essential for diagnosis. Several industry technical reports indicate that bitwise alignment and deterministic training are becoming standard practice for large-scale model training [1–3]. From the ByteDance production perspective, this property is particularly useful because it separates data issues, model issues, infrastructure issues, operator bugs, and SDC-induced hardware corruption with only several steps of replay under the same replay framework. Our production measurements show that deterministic training preserves normal step time, with less than 0.01% difference from non-deterministic training, while reducing normalized debugging time from 1.00× to 0.30×.

Setup Constraints. To support reproducible training, our training framework setup leverages the deterministic features provided by modern training frameworks and GPU drivers. In practice, we activate every deterministic toggle exposed by the software stack, including disabling `torch.backends.cudnn.benchmark` [10], enabling `torch.backends.cudnn.deterministic` [11] and `torch.use_deterministic_algorithms` [12]. By setting up these configurations, we ensure that computation executes identically in every iteration when the underlying hardware is healthy.

Computation Constraints. The primary source of non-determinism in GPU computation is the non-associativity of floating-point arithmetic, which causes parallel accumulation to vary across executions [7, 25, 68, 79, 80]. To achieve bitwise reproducibility, our framework applies strict constraints to core kernels: we disable optimization heuristics in operator libraries [50, 51, 53], deactivate GEMM autotuning to lock launch configurations, and serialize atomic reductions where needed. Dynamic control flows introduce additional challenges. For elementwise kernels, we enforce a static SM-to-row mapping. For operators with data-dependent routing (e.g., MoE gating), we re-implement kernels to serialize accumulation and scatter steps, ensuring deterministic processing regardless of thread scheduling. For kernels whose outputs can still depend on thread interleavings, we manually implement deterministic kernels whose reduction and write rules produce the same result under any valid execution order. All other standard operators retain their native deterministic behavior to preserve system-wide consistency.

Communication Constraints. As noted regarding network topology influence, the non-associativity of floating-point arithmetic renders collective operations (e.g., AllReduce) sensitive to the underlying reduction structure. Standard communication libraries (e.g., NCCL[7]) typically perform runtime topology detection to optimize bandwidth, dynamically selecting algorithms (e.g., Ring vs. Tree) and adjusting the number of parallel channels based on available hardware health. To eliminate this source of non-determinism, our framework enforces a static communication configuration regardless of the physical topology state. We explicitly lock the collective algorithms and fix the number of communication channels to prevent the library from adapting the reduction tree to hardware fluctuations. Additionally, for dynamic architectures like Mixture-of-Experts (MoE), we enforce a deterministic dispatch order to ensure that gradient aggregation sequences remain invariant across different runs. During training, SDCHUNTER records the communication trace and replays communication according to an immutable deterministic order, so diagnosis uses the same message ordering as the original execution.

These deterministic constraints are enabled during production training, not only during replay. This choice ensures that the communication order and kernel choices in the diagnostic run match those that produced the anomaly. Since the same deterministic configuration is used during both normal execution and diagnosis, SDCHUNTER can replay the alert-triggering window without changing the workload behavior being tested.

5.2 Phase 1: Lightweight Grouping

Figure 15 illustrates the overview of Phase 1. The objective of the first phase is to rapidly narrow the scope of anomalies from the entire cluster to a specific logical group with minimal overhead. This phase should not compromise the SDC characterization. To achieve this, we partition the cluster along the data-parallelism (DP) dimension, forming two replicas, each comprising half of the DP groups. Both replicas are provided with the identical training data used before as input. Because deterministic training fixes random sequences, operator behavior, and communication order, healthy replicas should produce the same signatures even after this DP-level scaling, which preserves the execution equivalence needed to expose SDC-induced divergence.

For each replica, we collect the signatures of the intra-DP-group pipeline parallelism (PP) communication tensors and compare these signatures across the two replicas. Here, the signature refers to a hash of the tensor values designed to satisfy associativity. By aggregating and comparing communication signatures across replicas, we can identify potentially anomalous DP groups. The novelty of this detection step is that it is implemented as a training framework ability, where the framework already knows the checkpoint

[7] NVIDIA Collective Communications Library, a GPU communication library commonly used for collectives such as AllReduce in distributed training.

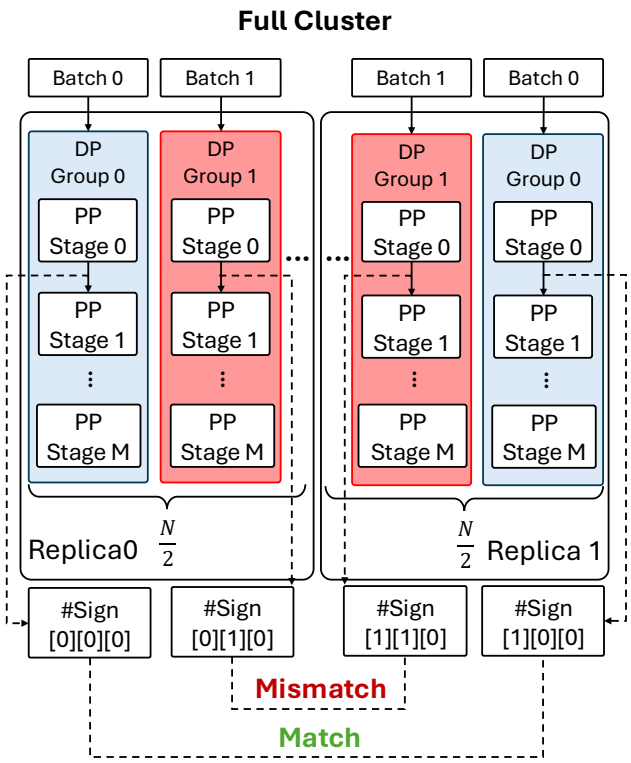

Figure 15: Phase 1: Lightweight Grouping. The indices in the signature label `#Sign [·][·][·]` denote the Replica ID, DP Group ID, and PP Stage ID, respectively.

boundary, DP groups, PP communication tensors, and replay window. As a result, SDCHUNTER only records compact signatures at framework-visible communication boundaries instead of dumping full tensors or inserting external kernel-level monitors, which keeps the online overhead very small. If only one DP group diverges from the majority signature, SDCHUNTER marks the machines in that group as suspicious and removes them from subsequent scheduling. The training job then resumes from the latest verified checkpoint on the remaining healthy machines. This resumption does not wait for the device-level diagnosis in Phase 2 because it only requires isolating the anomalous DP group so that corrupted ranks are removed from the restarted job. The blocking time on the training critical path is therefore the sum of the time to reload the checkpoint, replay the workload, compare the signatures, and restart the scheduler for the next step. Checkpoint reload and scheduler restart are the normal recovery costs, Phase 1 replays fewer than 100 steps in our deployment, and signature comparison takes seconds because only compact communication-boundary hashes are compared.

Ideally, comparing signatures derived from additional parallelism dimensions (e.g., expert parallelism, EP) would further localize the suspicious nodes. However, in modern training architectures that employ EP for Mixture-of-Experts (MoE) models, computation and communication kernels are frequently fused to maximize efficiency [81]. As a result, internal signatures of communication-related tensors within these fused kernels are inaccessible, preventing us from extracting EP-specific signatures.

Fault Model. In our deployment experience, we assume that, within one diagnosis window, at least one replay replica remains healthy and can serve as a reference. When two replicas disagree and no majority exists, SDCHUNTER introduces an additional replay replica on spare healthy machines and compares all three signatures to determine which DP group is faulty. If multiple DP groups are defective, SDCHUNTER can identify multiple outliers as long as they do not all produce the same corrupted signature. The pathological case where every replay replica is simultaneously corrupted in the same way cannot be resolved by consensus. In that case, SDCHUNTER falls back to offline confirmation with known good machines and vendor diagnostics. In practice, this is consistent with the observed production pattern where SDC-defective GPUs are rare and independent, so simultaneous identical corruptions across all DP replicas are unlikely.

5.3 Phase 2: Precise Localization

Once the suspicious parallel group is identified, we perform a comprehensive tensor comparison to pinpoint the specific defective device. This involves collecting tensor signatures from both the suspicious group and a healthy reference group during a deterministic replay of the problematic iteration. By comparing these signatures layer-by-layer, we can detect the exact point of divergence. This process isolates the first corrupted tensor and its producing kernel, allowing us to definitively identify the SDC-defective GPUs. The localization step also relies on framework-level knowledge of tensor ownership, rank[8] placement, and operator order, so SDCHUNTER can map the first divergent tensor back to a physical GPU without globally instrumenting every kernel during normal training. This framework integration is the reason SDCHUNTER can combine accurate device-level localization with much lower overhead than full tensor dumping or always-on fine-grained instrumentation.

5.4 Post-Diagnostic Verification

To verify suspicious GPUs, we employ a hybrid strategy to isolate the minimal reproducible execution trace. First, we utilize Hardware tools [52,55] to screen for permanent hardware faults, any failure triggers immediate repair. However, since SDC often evades standard stress tests, GPUs that pass these hardware tools undergo offline analysis using SDCHUNTER. We subject execution traces from the alert-triggering workload to intensive iterative replay to perform full-scale tensor verification, as extensive repetition of these traces maximizes the likelihood of reproducing the SDC symptoms. Through

[8] A rank is one distributed training process, usually mapped to one accelerator in GPU training.

this process, we progressively isolate the consistently reproducible kernel error, thereby confirming the GPU as SDC-defective.

6 Evaluation

To show the effectiveness of SDCHUNTER, we evaluate it by answering the following questions:

- How much overhead does SDCHUNTER introduce to the training process?
- How does SDCHUNTER perform in alarming SDC?
- How fast does SDCHUNTER perform in locating SDC?

Setup. We evaluate SDCHUNTER on a cluster with 128 and 512 GPUs. Each host contains 168 CPUs, 2TB memory, and 8 GPUs. All the GPUs are connected with high-speed inter-GPU communication and all hosts are connected with high-speed RDMA for inter-host communication.

The evaluation is conducted using ByteDance's production training traces. We use LLM models with 50B and 150B parameters. For baselines, we choose dumping all the tensors and comparing, and dumping all tensors signatures and comparing as our baseline. The dumped tensors will be stored in the GPU memory. If GPU memory is not enough, it will be stored in the host memory. We use the same training configuration as the original training process.

Baseline. We select two types of baselines, offline and online. Offline baselines include offline stress tests and log analysis, including hardware tools [52], GPU-Burn [54, 77] and PEPPA-X [61]. Online baselines include online metrics tracing including loss or gradient norm metric, and He et al. [26]. Also, online baselines contain real-time detection including HWSentinel [18]. Within the online baselines, we add a gold standard, Full Data Dump, which dumps all the tensors and compares them.

6.1 Production Deployment

SDCHUNTER is now deployed in a production GPU-cluster environment and is a part of base infrastructure for large model training in ByteDance. By the time of paper submission, SDCHUNTER has detected 40 SDC-defective GPUs in the production cluster. It has become the first step to check hardware issues when loss spikes occur and the offline debug time is reduced from several days to under one hour. Our investigation revealed that the SDC-defective GPUs detected by SDCHUNTER have occurrence rates ranging from 100% to 0.000001%.

6.2 SDCHUNTER Overhead

We evaluate the end-to-end overhead of SDCHUNTER on the production cluster in Figure 16.

Analysis. For both the 50B and 150B models, SDCHUNTER introduces minimal overhead, which remains below 4% relative to the original training process. In contrast, computing full tensor signatures introduces approximately a

Table 5: The detection ability of SDCHUNTER in detecting SDC GPUs in real-world tracing.

		Coverage (↑ is better)
Offline	Hardware tools [52]	30.0%

4× slowdown, and performing full tensor data comparisons results is totally unacceptable. The substantial overheads of these two baselines arise primarily from transferring tensors from GPU to host due to the limited capacity of GPU memory, and also from the need to perform many of these transfers synchronously because the recorded tensors must remain unmodified before they are saved. In practical large-scale training scenarios, GPU memory is typically close to saturation, which further amplifies the overhead incurred by the baseline methods.

6.3 SDCHUNTER Detection Ability

To evaluate the effectiveness of SDCHUNTER in detecting SDCs, we conduct both real-world trace based and fault injection based evaluations. The fault injection is conducted by changing the input or output tensor values during the training process. For the real-world evaluation, we measure the coverage in detecting SDC-defective GPUs since it is impractical to manually replicate the training process to determine the golden baseline. For the fault injection evaluation, we measure the detection ability of SDCHUNTER in overhead, the percentage of SDC GPUs successfully identified, and the mean gap between the SDC occurrence and its first detection by the system. The real-world trace based evaluation results

are presented in Table 5 and the fault injection based results are shown in Table 6.

In the real-world trace evaluation, SDCHUNTER covers all confirmed SDC-defective GPUs, and it reaches 91% coverage under synthetic fault injection. For the fault injection evaluation, SDCHUNTER localizes SDC-defective GPUs in fewer than 5 steps, with 3 steps on average. For the real-world evaluation, SDCHUNTER only needs to replay fewer than 100 steps of the training process in the first stage, which allows the affected training job to resume within one hour after the suspicious DP group is isolated. The offline debugging stage then pinpoints the defective GPU in under one hour and does not block the online job because the training job has already moved away from the suspicious machines. Naive offline stress tests [52,54,77] can only achieve a coverage lower than 40%. PEPPA-X [61] improves coverage by searching for inputs that maximize SDC vulnerability based on the sensitivity of the input to SDC. Although this approach achieves certain gains compared with simple stress-testing methods, the coverage attainable during offline tests remains fundamentally limited. He et al. [26] detects SDCs by monitoring whether the optimizer's gradient history terms and the normalization moving-variance values exceed mathematically derived bounds. This method maintains a low overhead, but the coverage does not reach 50%, and the number of steps from SDC occurrence to metric out-of-bound is still relatively high. We also apply HWSentinel [18] to GPU SDC detection. However, once GPU logs reflect abnormal behavior, it is already too late to detect SDC.

6.4 SDCHUNTER Locating Ability

We assess the localization capability of device-level identification, which pinpoints the specific faulty accelerator, among all the baselines. We define localization accuracy as the percentage of SDC cases where SDCHUNTER correctly identifies the specific device ID. The result of localization accuracy evaluation is shown in Table 7, also including both real-world trace based and fault injection based evaluations.

SDCHUNTER achieves perfect device-level localization, offering 100% accuracy in attributing the SDC to the specific faulty GPU, even in the presence of complex collective communication primitives. This precise localization enables operators to isolate faulty hardware or numeric instabilities swiftly, significantly reducing the debug turnaround time compared to standard bisection methods.

7 Related Work

Silent Data Corruption on CPU. Extensive research targets CPU hardware defects [15, 22, 24, 31, 38, 39, 66, 67], detection [16, 34, 58, 59], and mitigation [17, 23, 27, 44, 76], particularly in HPC environments where computational density amplifies SDC frequency [9, 19, 20, 29, 46, 61]. Mission-critical systems often employ spatial or temporal redundancy [28, 29, 45, 63, 64], but high overheads frequently necessitate specialized processor support [45, 63, 64]. To reduce validation costs, Orthus [40] exploits control-data path separation, using lightweight checksums for control and versioned-memory re-execution for data. While system-level replication guarantees consistency in databases [57] and has been adapted for broader error detection [19, 20, 70], its utility is often limited by synchronization costs and latency in long-running jobs.

Silent Data Corruption on GPU. Recent studies extensively characterize GPU-induced SDC in AI workloads [4, 14, 21, 26, 32, 43]. Research has largely focused on software-based mitigation for inference: SAVE [82] employs bit-level robustness analysis to shield critical memory, while distribution-based methods [35, 42] detect errors by monitoring activa-

tion value bounds. Additionally, Agarwal et al. [4] analyze how transient faults propagate through LLM architectures to impact final outputs. While SDC in training poses unique challenges. Ma et al. [43] reveal that faults can induce catastrophic parameter drift silently, even when loss curves remain unaffected. To counter this, He et al. [26] propose checking optimizer states against derived statistical bounds and recovering by re-executing recent iterations. In proprietary systems, Google reports using deterministic replay to isolate incorrect computations [2, 3], though specific implementation details remain undisclosed.

GPU Determinism. Achieving determinism is critical for debugging and reliability [7, 25, 68, 79, 80]. Nondeterminism often stems from floating-point non-associativity in atomic operations; while some approaches focus on request-level batch invariance [25], they often overlook distributed communication noise. Although newer hardware supports deterministic in-switch reductions [62], communication over RDMA remains inherently non-deterministic. TBIK [80] bridges this gap by designing fully deterministic MatMul and AllReduce kernels for different tensor-parallel configurations.

8 Discussion

Deployment Experience. SDCHUNTER has been deployed as part of the production training infrastructure at ByteDance in cooperation with SDC detection tools [33] and OpGuard [83], where it is used as the first hardware-diagnosis step when training jobs exhibit suspicious symptoms such as loss spikes or unexplained fail-stop errors. By the time of submission, the system had identified 40 SDC-defective GPUs in production. These devices cover a wide range of manifestation frequencies, from faults that reproduce in every replay to faults that appear only rarely, which explains why hardware tools and generic stress tests alone cannot serve as a reliable production gate. In operation, SDCHUNTER first isolates the suspicious DP group so the online training job can move away from the affected machines and resume from a checkpoint. The subsequent offline debugging process pinpoints the defective GPU in under one hour and does not block the online job.

Deployment Lessons. Our experience suggests three practical lessons for operating large-scale LLM training clusters under SDC risk. First, SDC diagnosis must be integrated with the training control plane rather than treated as a standalone hardware test. The most useful action during an incident is to remove suspicious machines from the training path quickly and defer device-level confirmation to offline analysis. Second, exact workload replay is more effective than synthetic stress testing because many defective GPUs only fail for the model kernels, data ranges, and communication schedules that triggered the original anomaly. Third, deterministic training is useful beyond SDC detection. It turns ambiguous symptoms such as loss spikes into reproducible comparisons, which also helps engineers distinguish data issues, model issues, infrastructure problems, operator bugs, and hardware corruption. Finally, SDC occurrence rates vary widely across defective GPUs, so a fixed-duration stress test is not a reliable acceptance criterion. Production systems should retain the alert-triggering trace and replay it when confirming rare faults.

Analysis Ability of Other Problems. The core of SDCHUNTER is to use deterministic operators and instrument the operators to limit the error to within a single GPU, and then locate the faulty GPU by comparing different replicas. SDCHUNTER can be used not only for SDC detection but also for the analysis of other problems. In our production environment, the tool has also helped detect slow nodes, nodes with runtime jitter, and machine issues that cause training jobs to idle.

Towards Real-time Online SDC Detection. While SDCHUNTER currently reacts to explicit anomalies, we envision proactive, always-on SDC monitoring. The main bottleneck is the overhead of frequent tensor signature computation. Future work can reduce this cost through operator fusion. By embedding the checksum arithmetic into the memory load/store of the communication primitives (e.g., fusing hash calculation into the communication Send/Recv kernels), we can compute signatures on-the-fly as data flows through the interconnect. This design can mask the computation cost behind the communication latency or memory bandwidth, enabling zero-overhead, real-time SDC shielding for every training iteration.

9 Conclusion

We characterize GPU Silent Data Corruption (SDC) in production LLM training, showing that SDCs often mimic software bugs and evade synthetic benchmarks. We develop SDCHUNTER, which localizes defective devices through bitwise deterministic replay of the triggering workload. In production, SDCHUNTER identified 40 SDC-defective GPUs, reducing job-blocking recovery to under one hour and confirming each device offline within one hour.

Abstract

Silent Data Corruption (SDC) poses a critical threat to large-scale LLM training. Existing offline tests and online detection methods provide solutions for large-scale systems, yet they suffer from high overhead or low detection accuracy in LLM training. This paper presents AEGIS, an online SDC detection framework for large-scale LLM training. We introduce a two-stage cSensor-cVerifier abstraction that decouples SDC detection into lightweight corruption sensing and definitive corruption verification. Based on this abstraction, AEGIS co-designs new detection techniques by integrating the *inherent features* of LLM training with GPU characteristics, enabling practical online SDC detection. In a production deployment spanning 3.5×10^7 GPU-hours, AEGIS identified 18 *real-world* SDC incidents and 13 faulty GPUs while incurring only 0.86% performance overhead, enabling a systematic empirical characterization of SDCs in large-scale LLM training.

1 Introduction

Large language models (LLMs) have demonstrated impressive capabilities across a wide range of domains [2, 9, 15]. To further explore the potential, many efforts have been devoted to scaling model training to hundreds of billions or even trillions of parameters, using datasets with comparable numbers of tokens. While this scaling delivers gains in performance and generalization, it requires extraordinary computational resources, with training often lasting weeks or months on large-scale GPU clusters. For example, Llama 3 405B [15] is trained on up to 16K H100 GPUs. MegaScale [19] reported employing around 10,000 GPUs to train LLMs.

With the continuous scaling-up of LLM training tasks, a class of low-frequency faults, namely silent data corruption (SDC), has emerged as one of the most challenging and devastating system failures. An SDC occurs when hardware produces incorrect results without triggering any hardware or software alarms. Such faults can destabilize training, degrade model quality, and even cause failures in LLM training tasks that cost millions of dollars. Figure 1 provides an example of GPU SDC incident in our in-house LLM training task involving around 10,000 GPUs. It causes pronounced gradient norm and loss spikes, indicating the model degrades significantly under the influence of SDC. Despite the severe consequences of SDC, the current understanding of SDC in LLM training—including its frequency, types, and root causes—remains extremely limited. This knowledge gap persists because the silent, low-frequency, and non-deterministic nature of SDC makes its detection and study exceedingly difficult.

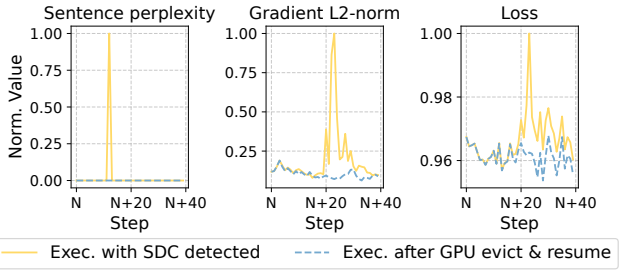

Figure 1: The impact of an SDC incident detected in a training task with around 10,000 GPUs.

Existing approaches fall into three broad categories, none of which is satisfactory for production LLM training. Offline diagnostics suites [3, 32] interrupt training and validate only a limited set of test workloads, leaving correctness during real production runs uncertain. Rerunning-based approaches [41] can provide strong confirmation, but typically require substantial duplicated computation and are therefore too expensive at LLM-training scale. Algorithm-based online detection [5, 6, 8, 21, 45] is attractive in principle, but directly applying it to modern low-precision training [23] is difficult: checksum mismatches can be dominated by ordinary floating-point error, causing false positives or triggering too many costly verifications [27]. As a result, existing methods either demand prohibitive computational resources or achieve unsatisfying detection efficacy. This makes them impractical

[*] Equal contribution.

for LLM training, where correctness is paramount but hardware resources (both computation and memory) are tightly constrained. Consequently, *how to effectively detect SDCs and safeguard large-scale LLM training* remains a significant open problem.

To address this challenge, we design AEGIS, an online SDC detection framework tailored for large-scale LLM training. Our key idea is a two-stage cSensor-cVerifier abstraction that reconciles two conflicting requirements: suspicious computations must be sensed immediately on the critical path, yet definitive confirmation must remain off the critical path. cSensor runs inline with training, performs lightweight detector-specific sensing, captures the minimal verification context needed for later confirmation, and emits compact verification tasks before the training framework releases or overwrites the relevant state. cVerifier then consumes these tasks to perform definitive confirmation. Because replay-based confirmation can be expensive, AEGIS schedules verification into naturally occurring idle periods such as pipeline bubbles [16, 30], improving assurance without perturbing training throughput.

The cSensor-cVerifier abstraction turns online SDC detection into a common system interface rather than a collection of ad hoc detectors. Based on this abstraction, AEGIS instantiates two categories of SDC detection methods that exploit complementary opportunities exposed by modern LLM training systems and accelerator hardware.

Mixed-precision-aware Algorithmic Detection. While low-precision arithmetic undermines classical algorithmic detection, we observe that the tensor processing units in modern GPUs feature high-precision accumulation. Based on this characteristic, AEGIS adopts a mixed-precision checksum method to significantly distinguish SDCs from numerical errors. Beyond protecting `Matmul`, AEGIS leverages the *inherent algebraic property* of attention mechanism to enable a novel, low-overhead algorithmic detection. During cSensor, AEGIS records checksums and a small slice of inputs/outputs; during cVerifier, it lazily replays the highly suspicious computation and performs a bitwise comparison between two outputs, enabling deterministic SDC detection.

Self-equivalence-based Deterministic Detection. AEGIS also exploits *inherently redundant computations* in LLM training to enable low-overhead SDC detection. This self-equivalence arises both at the operator level (e.g., FlashAttention [10, 11, 35] recomputing forward intermediates in backward) and at the framework level (e.g., activation recomputation [42]). During cSensor, AEGIS records a compact fingerprint of outputs for each self-equivalent segment; during cVerifier, it cross-checks fingerprints in the two executions to flag mismatches as SDCs.

We implement AEGIS as a lightweight system on top of our in-house Megatron-LM [36] implementation, requiring minimal changes to the training pipeline. In a deployment spanning 3.5×10^7 GPU-hours on our in-house LLM training jobs, AEGIS identified 18 SDC incidents and 13 faulty GPUs while incurring only 0.86% performance overhead on training tasks of around 10,000 GPUs. After the deployment, only one additional SDC was observed through other methods in training tasks (e.g., periodical task replay test), indicating the effectiveness of AEGIS.

To expedite efforts toward improving the correctness and stability of LLM training, we present a systematic study of SDCs in large-scale LLM training based on AEGIS. Our research yields several intriguing and crucial observations (§3.1 and §8), such as 1) The majority of SDC incidents silently corrupted training correctness and escaped alarms in training frameworks (e.g., `NaN` and `inf` detection). 2) All observed SDC incidents occurred non-deterministically even with the same program. 3) All detected SDCs were identified as permanent SDCs, which stem from GPU faults and recur on the same devices.

In summary, this paper makes the following contributions.

- We propose an online SDC detection system for large-scale LLM training, which decouples detection into time-critical corruption sensor and lazily-executable corruption verifier for both detection efficiency and accuracy.
- We share our experiences in deploying AEGIS in real-world large-scale LLM training and present insights gleaned from 35 million GPU hours, aiming to advance research in safeguarding the scaling of LLM training.
- We identify mathematically equivalent and self-equivalent features inherent to LLM training and leverage them for SDC detection. This substantially reduces the overhead of the primary sensing stage.
- We design and implement AEGIS based on the proposed techniques. We evaluate AEGIS on production-level training jobs over 3.5×10^7 GPU hours and detect 18 real-world SDCs.

2 Background

2.1 LLM Training at Scale

Transformer Architecture. The Transformer architecture serves as the foundational backbone for the majority of LLMs, consisting of stacked layers each with an attention and a feed-forward network (FFN) module. Computation is dominated by matrix multiplications (`Matmul`): the attention block involves six `Matmul` operations (projections, scoring, and aggregation), while the FFN mainly includes two large up- and down-projections.

Distributed Infrastructure. Training state-of-the-art models involves hundreds of billions to trillions of parameters, typically requiring thousands of GPUs operating in parallel for weeks or even months. Such jobs are orchestrated by large-scale distributed training frameworks that employ a variety of parallelism strategies to efficiently utilize cluster resources, including data parallelism [34], tensor parallelism [36], pipeline

parallelism [16, 30, 31, 33], and sequence parallelism [17, 25]. Workloads are dominated by linear algebra kernels, and typically executed in `bfloat16` alongside memory optimizations like activation recomputation [42].

SDCs in LLM Training. Despite the prohibitive cost of LLM training, reliability has received less attention than throughput optimization. SDCs pose a severe threat at scale; rare hardware faults can happen frequently in a large cluster and then cause catastrophic loss spikes or `NaN` values. However, SDCs can be masked by normal loss fluctuations, making loss monitoring unreliable. Moreover, distributed collective communication can rapidly propagate a single corrupted value across the cluster, jeopardizing the training run. In this work, we focus on detecting such infrequent, hardware-induced errors within large-scale GPU clusters.

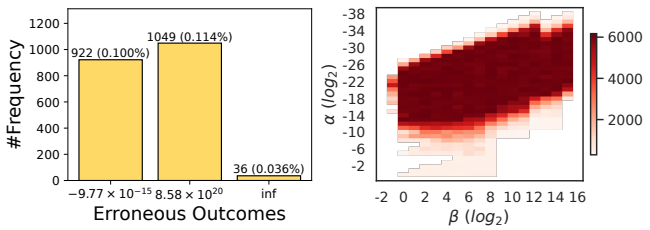
2.2 Existing Approaches to Detect SDCs

Hardware Diagnostic Suites. One primary approach to fault localization is hardware diagnostic suites [3, 32], which relies on offline stress testing. This approach involves running expert-designed, stop-time test suites, such as NVIDIA Extended Utility Diagnostics (EUD) [32], to validate hardware health. However, this method has critical limitations for SDC detection. These test suites often miss non-deterministic SDCs, yielding low recall (about 70% in production [41]), and are costly and slow, taking over 8 hours and substantial cluster resources to identify a single faulty GPU.

Rerunning-based Testing. Another approach is rerunning-based testing, which attempts to locate faults within the real training environment [41]. The core idea is to compare two identical, deterministic executions. ByteRobust [41] proposes a dual-phase replay mechanism. This approach partitions the cluster into two dimensions (horizontally and vertically), and replays the deterministic workloads on each set to locate the faulty machine via intersection. While these methods are more efficient at reproducing live faults, they still incur significant extra overhead at scale.

Algorithm-based Online Detection. As an alternative to the offline approach, algorithm-based online detection [5, 6, 8, 21, 45] is a prominent online detection technique that utilizes algorithm-specific properties (e.g., checksums) for online SDC detection in matrix multiplication. Specifically, prior work [6] proposes adding a checksum to matrix multiplication to flag whether SDCs have occurred during computation by comparing the results of two equivalent computation paths, e.g., $C\mathbf{1} = (AB)\mathbf{1} = A(B\mathbf{1})$, where $\mathbf{1} = [1, 1, \ldots, 1]^{\mathrm{T}}$, A, B are matrices. However, these classical techniques face a significant challenge in LLM training. As low-precision data types like `bfloat16` are common to LLM training, accumulated floating-point errors can easily exceed the error bound E designed for `float32`, resulting in a high rate of false positives [27] or requiring prohibitively many computation replays for verification.

As a result, existing approaches either require prohibitive computational resources or deliver unsatisfying detection accuracy. This limits their practicality in LLM training, where correctness is crucial but hardware resources—especially compute and memory—are severely constrained.



(a) (b)

Figure 2: Some observations on SDC incidents. (a) Frequency of erroneous outcomes when replaying a faulty `Matmul` workload (9.2×10^5 replays; expected correct result -8.58×10^{20}); and (b) SDC occurrence probability in matrix multiplication with varying inputs, simulated as $C = \alpha A \times \beta B$.

3 Observations and Motivation

3.1 Observations on SDC Incidents

Observation 1: Non-deterministic Reproducibility. In all SDC incidents we observed, their behavior was inherently non-deterministic: executing the same workload on the same faulty hardware did not always result in SDC. For instance, on a GPU where SDC had previously been observed, we repeatedly executed the nanoGPT [1] 50 times under identical settings; only one run showed divergent loss. Moreover, the numerical errors induced by SDC are also non-deterministic. By investigating this incident, we traced the fault to the `Matmul` operator. We re-executed this `Matmul` kernel 9.2×10^5 times and observed only three distinct erroneous outcomes, corresponding to an overall estimated error rate of 2×10^{-9}. Figure 2(a) summarizes these erroneous outcomes. When the correct result should have been -8.58×10^{20}, the faulty GPU instead returned either a near-zero value, a large but incorrect value with flipped sign, or `inf`. These observations indicate that a single execution of stress testing is insufficient to uncover all faulty GPUs, as SDCs may not be deterministically reproducible.

Observation 2: Workload Sensitivity. We observe that many SDC incidents are also input-sensitive, depending on both workload and numerical values, and often appearing only under specific conditions. For the SDC reported in Observation 1, we adjusted the input tensors A and B of the `Matmul` operation. Specifically, by introducing scaling factors α and β, we measured the probability of triggering SDC under different inputs of $C = \alpha A \times \beta B$. As shown in Figure 2(b), SDCs occur only within certain numerical ranges, while

other ranges remain unaffected. Consequently, standardized diagnostic tools such as EUD and NCCL tests, or even bitwise alignment tests tailored to match the structure of the target training job, cannot exhaustively cover all input conditions and may therefore fail to identify all faulty GPUs. As a result, machines that pass offline stress testing may still exhibit SDC during training.

Observation 3: Diverse Fault Patterns. Our analysis of production data (Table 2) shows that SDC incidents do not expose a uniform signature across faulty GPUs. Different incidents can surface in different computations and expose different observable evidence, making it difficult for any single checker to cover them all reliably. Although offline diagnostic tools (e.g., NVIDIA EUD) achieve a recall of approximately 70%, each run typically requires several hours for a GPU. Moreover, the inherent non-determinism and input-sensitive nature of SDC make it impossible for offline stress testing to exhaustively cover the computations and input regimes that arise in production. Consequently, neither offline pre-screening nor any single online checker can reliably preclude SDCs in large-scale GPU clusters.

3.2 Motivation

The three observations above have an important implication for system design. Observation 1 and Observation 2 show that SDCs cannot be reliably excluded by offline pre-screening, because whether a fault manifests depends on the exact execution and numerical regime encountered during real training. Observation 3 further shows that no single online checker can cover all incidents, because different faults surface in different computations and expose different forms of evidence.

Practical SDC detection therefore must satisfy three requirements. First, it must perform *lightweight in-situ sensing* on the critical path, because only online monitoring can observe the real computations and inputs that trigger SDCs. Second, it must support *multiple complementary sensing mechanisms* under a common interface, because different parts of the training stack expose different low-cost checking opportunities and produce different evidence. Third, it must provide *definitive confirmation* before reporting incidents, because lightweight online signals alone are not trustworthy enough in low-precision training. Together, these requirements suggest a sense-then-verify architecture that separates fast sensing from definitive confirmation while allowing multiple sensing strategies to share the same detection workflow. Realizing such a design in modern LLM training raises the following key challenges:

Challenge 1: Reliable Sensing under Low Precision. Low-precision data types such as `bfloat16` [20, 29] and even `float8` [23] are now standard in modern LLM training. In these regimes, ordinary floating-point round-off can obscure SDC-induced perturbations [27], causing naive checksum-based sensing to either flag too many benign computations as

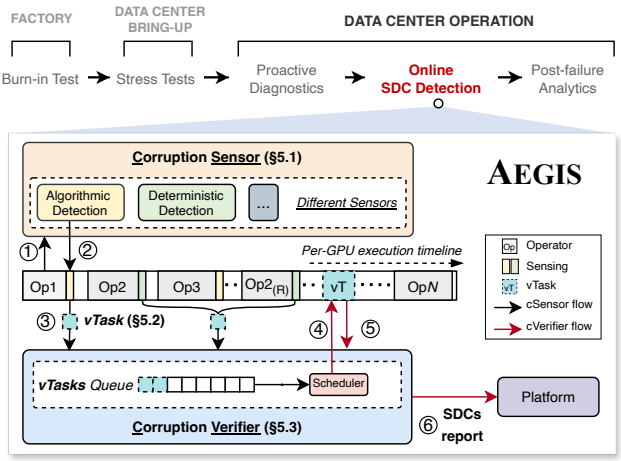


Figure 3: AEGIS Overview.

suspicious or miss real corruptions. The challenge is therefore to generate trustworthy online signals while keeping sensing lightweight on the critical path. The key question is whether modern training systems and hardware expose opportunities for reliable, low-cost sensing.

Challenge 2: Unifying Diverse Detection Mechanisms. Large-scale LLM training does not expose a single reusable checking pattern [21, 26]. Practical detection must instead combine multiple mechanism-specific sensing strategies that produce evidence with different semantics and confidence. The challenge is to unify these heterogeneous signals under a common abstraction so they can share the same buffering, scheduling, and confirmation workflow, rather than requiring custom system support for each new mechanism.

Challenge 3: Efficient Verification. Definitive confirmation is expensive in large-scale LLM training because establishing a trusted reference often requires replaying suspicious computations. Such replay consumes GPU cycles, can accumulate backlog, and may introduce stragglers [22] unless its cost is carefully bounded and scheduled. The challenge is therefore to keep verification off the critical path and scale it with suspicious-event volume without degrading end-to-end training throughput.

4 Overview

To address the above challenges, we propose AEGIS, a two-stage online SDC detection system for large-scale LLM training. As shown at the top of Figure 3, SDC detection is performed throughout the entire production and operational lifecycle of a GPU. AEGIS therefore targets the online stage with a sense-then-verify architecture that meets the three requirements identified in §3.2. Its *lightweight corruption Sensor* **cSensor** (§5.1) performs lightweight in-situ sensing on the critical path and unifies heterogeneous sensing outputs through the vTask abstraction (§5.2). Its *lazy corruption*

Verifier **cVerifier** (§5.3) performs definitive confirmation off the critical path. By decoupling fast sensing from expensive verification, AEGIS achieves low-overhead, high-coverage online protection without compromising training efficiency.

Workflow. Figure 3 illustrates AEGIS's workflow using a snapshot of the operator timeline on one GPU during an LLM training run. AEGIS instruments selected computations with cSensor (step ①). Immediately after a protected computation completes, cSensor applies the corresponding sensing strategy and records compact sensing evidence together with the minimal metadata needed for later verification (step ②). If cSensor flags a computation as potentially corrupted, it creates a verification task (vTask) and enqueues it into cVerifier 's vTask queue (step ③). cVerifier 's scheduler then dispatches vTasks to GPUs during naturally occurring idle periods to perform verification (step ④). cVerifier then performs definitive confirmation: depending on the vTask type, it either compares fingerprints from self-equivalent executions or replays the suspicious computation and checks it against the recorded evidence (step ⑤). When verification confirms an SDC, AEGIS reports the incident, together with the associated device and execution context, to the platform and users, enabling rapid restart and rollback to the previous checkpoint so training can resume with minimal wasted computation (step ⑥).

5 AEGIS Design

This section details how AEGIS realizes the cSensor-cVerifier architecture introduced in §4. The design relies on a system-level prerequisite: a protected computation must be deterministic, producing the same result under the same inputs and execution configuration. This prerequisite gives cVerifier a deterministic reference for confirmation, obtained either by deferred replay or by self-equivalent execution. cSensor therefore focuses on capturing compact evidence immediately after protected computations, while cVerifier performs definitive confirmation off the critical path. We first describe the inline sensing mechanisms, then the vTask interface, and finally the verifier and its scheduling policy.

5.1 cSensor: Corruption Sensor

cSensor is the inline sensing stage of the cSensor-cVerifier framework. Its goal is to observe real training computations at the moment SDCs can manifest, while retaining only the evidence needed for later confirmation. To address the reliable-sensing challenge under low precision, AEGIS exploits opportunities exposed by modern LLM training systems and accelerator hardware. Based on this idea, AEGIS instantiates cSensor with two complementary strategies: (1) mixed-precision-aware algorithmic detection and (2) self-equivalence-based deterministic detection. cSensor also applies sensing-control policies that decide when an inline signal becomes a vTask and bound the resulting verification load.

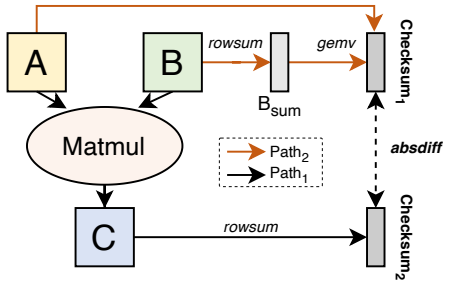

Figure 4: Classic matrix multiplication checksum workflow.

5.1.1 Mixed-precision-aware Algorithmic Detection

Algorithmic detection is AEGIS's answer to the low-precision reliability challenge: it keeps algebraic checks cheap enough for inline use by exploiting precision already present inside modern accelerator kernels. These sensors compress high-dimensional tensors into compact checksum values and compute a checksum difference Δ that indicates potential corruption. When Δ exceeds the current runtime tolerance estimate $\widehat{E}_t$, cSensor packages the suspicious computation into a vTask for later confirmation by cVerifier. We instantiate this approach for two dominant operators in LLM training. The key design point is to leverage *the mixed-precision design feature of modern accelerators* to overcome the floating-point error barrier in low-precision arithmetic.

Matrix Multiplication Checksum. AEGIS adopts the classic algorithmic scheme for matrix multiplication (`Matmul`), a key operation in LLM training. Specifically, this scheme validates `Matmul` by comparing two computationally equivalent paths encoded via checksums. As a simple example, we use a row checksum. Let $\mathbf{1}$ be a column vector of ones $[1,1,\ldots,1]^{\mathrm{T}}$; right-multiplying by $\mathbf{1}$ performs a row-wise sum. We obtain two checksum values: $C\mathbf{1} = (AB)\mathbf{1}$ and $A(B\mathbf{1})$. In the classic formulation, a significant mismatch is indicated when $\Delta_{\texttt{Matmul}} = \|(AB)\mathbf{1} - A(B\mathbf{1})\| > E$, where E is the theoretical round-off error bound [5]. A concrete example is illustrated in Figure 4.

However, algorithmic detection for `Matmul` has been deemed unreliable for low-precision LLM training (e.g., `bfloat16`) [27], as this method often suffers from large checksum differences caused by floating-point round-off noise. To better understand this issue, we conduct a fault injection study on a healthy machine. We consider a `Matmul` with `bfloat16` inputs and `bfloat16` outputs, and apply a row checksum over output C. Specifically, we inject faults by randomly flipping a single bit of the `bfloat16` input A.

Figure 5(a) shows the checksum differences obtained when checksums are accumulated from the final `bfloat16` outputs. Here, a checksum difference is the absolute difference between the two checksums, and the max discrepancy

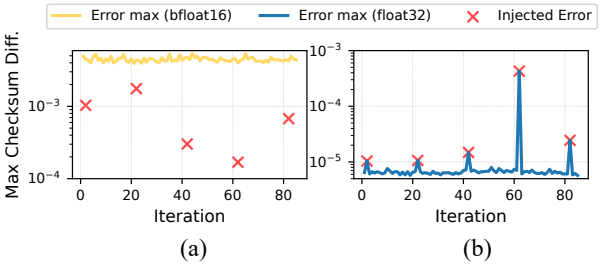

Figure 5: Fault injection study of checksum accumulation using `bfloat16` outputs versus `float32` accumulators.

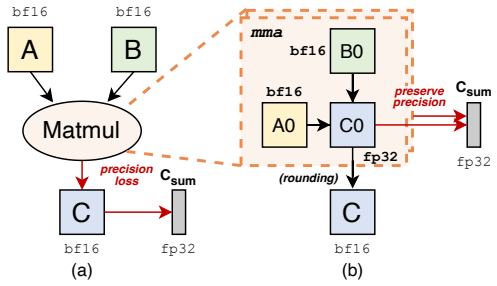

Figure 6: (a) Directly accumulating the final `bfloat16` output inherently introduces precision loss through truncation. (b) Accumulating directly from the `float32` accumulator preserves precision.

is the maximum over all such values. The red cross in the figure marks the fault-induced discrepancy caused by the injected fault. In Figure 5(a), it is clear that the fault-induced discrepancy is masked by larger round-off-induced discrepancies from `bfloat16` floating-point noise, making it difficult to distinguish a genuine fault from ordinary round-off noise.

To address this issue, our key insight is that `Matmul` operations in LLM training are typically executed using mixed-precision kernels (e.g., `bfloat16` compute paired with `float32` accumulation), a pattern inherent in modern accelerators (e.g., NVIDIA Tensor Core units). This creates an opportunity to compute the checksum of C in the `float32` accumulator, preserving higher precision and avoiding the final `bfloat16` truncation. In this way, we repeat the same fault injection experiment using the `float32` accumulator to validate this idea, as shown in Figure 5(b). The difference in checksum difference between (a) and (b) stems solely from round-off effects. Figure 5(b) clearly shows that using `float32` accumulator significantly reduces round-off-induced discrepancy, allowing each injected fault to produce a clear, pronounced peak that is easy to distinguish from the background numerical noise.

Based on this insight, AEGIS proposes a novel matrix multiplication checksum scheme tailored to low-precision computation. Specifically, AEGIS does not accumulate the result directly from the final `bfloat16` outputs, which would

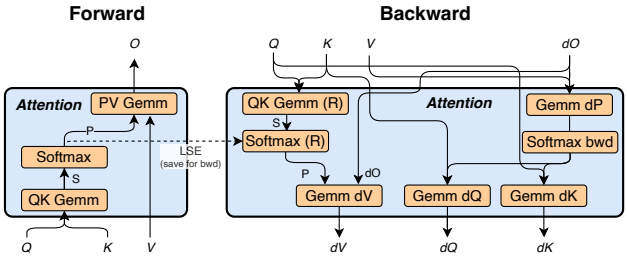

Figure 7: The forward and backward pass of FlashAttention.

inherently introduce precision loss through truncation from the kernel, as depicted in Figure 6(a). Instead, it leverages the mixed-precision execution provided by modern accelerators to accumulate checksums on-chip in `float32`, as shown in Figure 6(b). This higher precision accumulation significantly improves robustness to numerical noise, enabling reliable SDC detection for matrix multiplication in LLM training. In this case, the resulting vTask records the suspicious checksum together with the minimal replay context needed to re-execute the flagged computation during verification. The implementation details of the matrix multiplication checksum in AEGIS are described in §6.

FlashAttention Checksum. AEGIS proposes a novel algorithmic detection method for the attention operation, tailored to FlashAttention [10, 11, 35]. This method is grounded in an inherent algebraic property in the backward computation of dV. By exploiting this property, AEGIS can verify the correctness of the attention operation without performing checksum checks within each internal matrix multiplication. The forward and backward passes of FlashAttention are illustrated in Figure 7.

Specifically, the backward pass computes dV as:

$$\mathrm{d}V = P^{\mathrm{T}}\mathrm{d}O$$

Each row of the attention matrix P sums to 1 since it is the output of a row-wise softmax function, thus representing the attention distribution for each token. Consequently, its transpose P^T has columns that sum to 1.

Let $\mathbf{1}^T$ be a row vector of ones. By left-multiplying by $\mathbf{1}^T$ (which performs a column-wise sum), we observe:

$$\mathbf{1}^T\mathrm{d}V = \mathbf{1}^T(P^{\mathrm{T}}\mathrm{d}O) = (\mathbf{1}^T P^{\mathrm{T}})\mathrm{d}O$$

Given that P^T has columns that sum to 1, the identity $\mathbf{1}^T P^{\mathrm{T}} = \mathbf{1}^T$ holds. Therefore, we derive the mathematical invariant:

$$\mathbf{1}^T\mathrm{d}V = \mathbf{1}^T\mathrm{d}O$$

This relation asserts that the column-wise sum of the input gradient dO must equal the column-wise sum of the output gradient dV, and computing these sums incurs very low computational cost.

Furthermore, this novel checksum approach offers broad detection coverage. Beyond directly checking the invariant

itself, the invariant implicitly protects a larger portion of the computation. Because it is conditional on $\mathbf{1}^{\mathrm{T}}P^{\mathrm{T}} = \mathbf{1}^{\mathrm{T}}$, any error that violates this condition will, in turn, cause the assertion to fail. Specifically, the matrix P in the backward pass is recomputed within the `Softmax(R)` operator using a recomputed S (which is calculated by the `QKGemm(R)`) and the LSE saved from the forward pass. The LSE itself is computed across the forward `QKGemm` and `Softmax` operators. Therefore, an error in any of these preceding computations will violate the condition $\mathbf{1}^{\mathrm{T}}P^{\mathrm{T}} = \mathbf{1}^{\mathrm{T}}$ and consequently invalidate the invariant. Accordingly, AEGIS flags a potential SDC whenever $\Delta_{\text{attn}} = \|\mathbf{1}^{\mathrm{T}}\mathrm{d}V - \mathbf{1}^{\mathrm{T}}\mathrm{d}O\| > \widehat{E}_t$. In particular, the checksum in FlashAttention is also accumulated from the `float32` accumulators enabled by the mixed-precision feature of modern accelerators. As with `Matmul`, a violated invariant is converted into a vTask that carries the compact evidence and replay metadata required by cVerifier.

5.1.2 Self-equivalence-based Deterministic Detection

Self-equivalence-based deterministic detection exploits redundancy that already exists in LLM training. When a computation is executed twice deterministically, such as an original execution and a later recomputation, the two outputs should be bitwise identical. AEGIS captures this property by recording a compact xorsum fingerprint over each output during cSensor and attaching the fingerprints to vTasks. cVerifier then verifies the task by comparing the fingerprints from the two executions; any mismatch indicates an SDC. This differs from algorithmic detection, which reasons about approximate arithmetic through algebraic invariants, whereas deterministic detection relies on exact equality created by inherent recomputation.

Framework-level. Deterministic redundant computations are common in LLM training frameworks. For instance, activation recomputation [7, 37] mitigates the heavy memory footprint of activations by trading additional computation for memory footprint. These optimization techniques, while essential for the efficiency of large-scale LLM training, naturally create a detection opportunity.

Specifically, AEGIS computes each fingerprint by applying an xorsum reduction to compress high-dimensional tensors. As illustrated in Figure 8, the `Input` is processed by the operator (`Op`) during the forward pass to produce the initial output (`Output`), which is later recomputed as the recomputed output (`Output(R)`) in the backward pass. The detection mechanism computes two fingerprints, $\texttt{xorsum}_1$ and $\texttt{xorsum}_2$, by applying the `xorsum_reduce` function to the forward output `Output` and the recomputed output `Output(R)`, respectively. cVerifier (§5.3) subsequently compares $\texttt{xorsum}_1$ and $\texttt{xorsum}_2$, and any mismatch between the two fingerprints is confirmed by cVerifier as an SDC incident. Furthermore, this approach is applicable to a wide range of operators, extending beyond common operations such as `Matmul` and attention

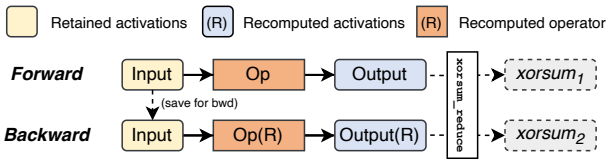

Figure 8: The mechanism of deterministic detection.

to fault-prone operators such as RMSNorm and GeLU, as detailed in §7.

Operator-level. Moreover, we identify and exploit similar inherent opportunities within individual operators. In AEGIS, we instantiate this detection mechanism in FlashAttention, and use it as a concrete example:

In FlashAttention, one primary optimization is selective recomputation in the backward pass, which avoids storing large intermediate matrices (S and P of size $N \times N$) from the forward pass, thereby reducing activation memory usage and I/O overhead (Figure 7). Specifically, S and P are recomputed when input blocks (Q, K, V) are loaded into SRAM. While this technique is fundamentally an optimization to improve computational efficiency and minimize memory footprint, it also creates a natural opportunity for deterministic self-checking. Under deterministic execution, the recomputed values (e.g., S) in backward must be bitwise identical to the original forward results. Accordingly, AEGIS applies an xorsum reduction in both the forward and backward passes to obtain two fingerprints for later comparison.

Deterministic detection complements algorithmic detection for attention. While it does not cover the $\mathrm{d}V = P^{\mathrm{T}}\mathrm{d}O$ path protected by our algorithmic method, it provides coverage for other self-equivalent segments. Together, the two methods offer complementary coverage for FlashAttention.

5.1.3 Sensing Control

Sensing control keeps cSensor useful as an online component rather than an unbounded generator of verification work. It decides when an inline signal is strong enough to become a vTask and how much evidence cSensor should retain for later confirmation. These policies bound verification workload while leaving the confirmation semantics of cVerifier unchanged.

Adaptive Threshold. For algorithmic detection, AEGIS employs a lightweight adaptive thresholding mechanism, rather than relying on the ideal tolerance E, to catch SDCs with small verification overhead, as illustrated in Figure 9. The core idea is to maintain a runtime tolerance estimate $\widehat{E}_t$ for the checksum difference Δ and dynamically calibrate it based on the historical distribution of Δ, which exhibits stability in training tasks. A key reason for this is that Δ, which essentially represents the numerical errors, is tightly correlated to the magnitude of the activations. Moreover, activation magnitudes do not change rapidly during training. Therefore, when the

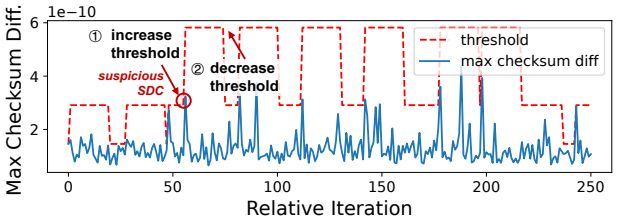

Figure 9: The adaptive thresholding mechanism.

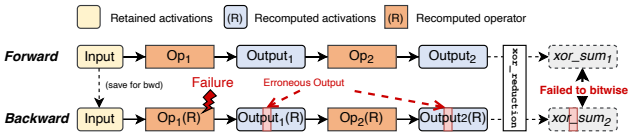

Figure 10: Example of backward recomputation and fingerprint mismatch under an operator fault.

observed Δ exceeds the current $\widehat{E}_t$ (indicating a potential SDC), AEGIS temporarily increases $\widehat{E}_t$ (e.g., by $2\times$) to adapt to the current error variance (step ①). Conversely, if no potential SDCs are detected over a subsequent window of checks, AEGIS decays $\widehat{E}_t$, gradually decreasing it (e.g., by halving) back toward its baseline (step ②). This heuristic yields a practical, low-overhead and adaptive mechanism that tolerates round-off fluctuations while still preserving reliable SDC detection.

Selective Operator Instrumentation. Under deterministic computation, repeated executions of the same computation graph always produce bitwise-identical results. Therefore, on a deterministic computation graph, any computational error in an operator inevitably leads to a different result. As illustrated in Figure 10, we consider a deterministic computation graph with two operators, $\texttt{Op}_1$ and $\texttt{Op}_2$, whose outputs are recomputed during the backward pass (denoted as $\texttt{Op}_1\,\texttt{(R)}$ and $\texttt{Op}_2\,\texttt{(R)}$). A fault in $\texttt{Op}_1\,\texttt{(R)}$ during the backward pass in turn corrupts the output of its successor $\texttt{Op}_2\,\texttt{(R)}$, causing the final fingerprint of $\texttt{Op}_2\,\texttt{(R)}$ to not be bitwise-identical with that of $\texttt{Op}_2$. Based on this insight, AEGIS's deterministic detection only focuses on the final operator in a deterministic computation graph, rather than instrumenting every operator individually. This policy reduces the number of vTasks generated by deterministic detection while preserving coverage of the entire recomputation chain.

5.2 vTask Abstraction

To address the challenge of unifying diverse detection mechanisms, AEGIS uses vTasks as the common contract between heterogeneous cSensor sensors and the shared cVerifier backend. Every suspicious computation that survives cSensor's local control is converted into a vTask that can be queued, scheduled, and processed uniformly by cVerifier. For algorithmic detection, a vTask records the minimal replay context and checksum evidence; for deterministic detection, it records

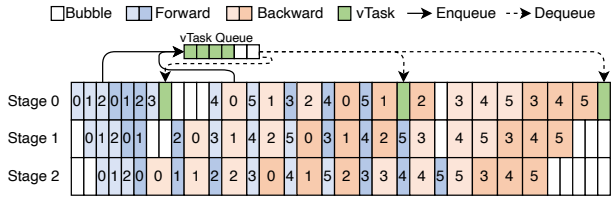

Figure 11: An example of vTask scheduling with interleaved 1F1B pipeline.

the two fingerprints for later cVerifier comparison. This unified abstraction lets AEGIS reuse one shared buffering and scheduling path across detectors. To minimize memory overhead, cSensor retains only the minimal payload required for cVerifier to perform verification, as detailed in §6. In addition to the minimal context required for verification, AEGIS also retains auxiliary metadata such as operator names, row/column indices, and verification type to facilitate scheduling and subsequent diagnosis.

5.3 cVerifier: Corruption Verifier

To address the efficient-verification challenge, AEGIS separates inline sensing from definitive confirmation. cVerifier consumes queued vTasks and turns inline evidence into confirmed SDC reports. Deterministic vTasks are checked by comparing fingerprints from self-equivalent executions, while algorithmic vTasks are checked by replaying the suspicious computation with the saved minimal context. An SDC is reported only after definitive confirmation is obtained, filtering out spurious alarms caused by benign numerical noise.

5.3.1 Lazy Verification and Scheduling

Lazy scheduling is the mechanism that makes definitive confirmation practical in production training. Because verification can be expensive, cVerifier treats vTasks as deferred work and executes them off-path by leveraging existing idle periods such as pipeline bubbles [16, 30].

As illustrated in Figure 11, we consider three-stage pipeline parallelism using the interleaved 1F1B pipeline schedule introduced in [31]. The cSensor creates and enqueues vTasks for both algorithmic and deterministic detection during the forward and backward passes. These vTasks are subsequently dequeued and processed by the cVerifier when workers are stalled waiting for tensor data from preceding or subsequent pipeline stages, i.e., during pipeline bubbles (shown as white cells in Figure 11). This scheduling strategy allows the cVerifier to perform the necessary verification without introducing additional synchronization stalls, thereby preserving the overall throughput of the LLM training process. In practice, scheduling follows a best-effort policy: vTasks are opportunistically executed during idle periods. Therefore, at the end of each training step, AEGIS reserves a small, fixed

time slice to process vTasks that could not be handled during idle time.

5.4 Supplementary Outlier Warning

Outlier warning provides a separate reporting channel for useful signals that would otherwise be ignored, as they are not yet strong enough to trigger a vTask. As discussed earlier, AEGIS uses a set of mechanisms to selectively verify only the most suspicious computations. This design balances coverage and performance, but may leave tiny SDC-induced deviations unconfirmed. To address this gap, AEGIS also performs an outlier-based warning analysis that is intentionally kept separate from definitive confirmation.

Specifically, AEGIS performs a cross-rank statistical analysis of the checksum difference at the end of each training step within each data-parallel (DP) group. The key insight is that, for the same batch and operator, the distribution of checksum differences across DP ranks should be relatively stable; a genuine SDC can manifest as an out-of-distribution deviation. To establish a collective baseline for each operation, AEGIS computes the $P90$ (90th percentile) of the checksum differences across all DP ranks. This statistic is collected via an efficient `allgather` over compact checksum-difference data, incurring only modest communication overhead.

If the checksum difference of a specific operation on a particular DP rank significantly exceeds the $P90$ baseline by a large margin (e.g., 10^6 times), AEGIS raises an outlier warning. Unlike confirmed SDC reports, such warnings are heuristic signals rather than definitive proof; they indicate a high likelihood of genuine SDCs that may have been missed by selective verification. Our production experience further confirms that outlier analysis is a practical and effective complement to the detection pipeline.

6 Implementation

AEGIS is integrated as a lightweight system on top of our in-house Megatron-LM [36] implementation. This integration requires minimal changes to the training pipeline and follows the proposed design to support online SDC detection for large-scale LLM training.

Verification Task Packing. Considering the severe memory constraints of LLM training, AEGIS retains only the minimal context required for verification. Specifically, only algorithm-based detection requires an additional recomputation step. Therefore, we describe the vTask packing design for algorithm-based detection in more detail.

For matrix multiplication, AEGIS adopts two checksum schemes: row checksums and row-and-column checksums. We apply them to different `Matmul` categories in LLM training, namely activation forward (*fwd*), input-gradient backward (*dgrad*), and weight-gradient backward (*wgrad*). For *fwd* and *dgrad*, AEGIS uses row checksums. The packing strategy is shown in Figure 12(a). In these cases, the input B corresponds to model weights that typically persist in GPU memory, whereas A and C are intermediate tensors that may be released before verification. Thus, the cSensor only needs to retain the row of A with the maximum numerical error and the corresponding row of C for later verification. For *wgrad*, AEGIS adopts row-and-column checksums to reduce the saved context, the packing strategy is shown in Figure 12(b). Since both inputs in *wgrad* are activations that may be released later by the framework, the cSensor retains the row of A and the column of B with the maximum numerical error, along with the corresponding elements of C needed for verification. For attention operation, verifying $\mathrm{d}V = P^{\mathrm{T}}\mathrm{d}O$ would require replaying the entire backward kernel and retaining additional intermediates (e.g., LSE, $\mathrm{d}O$, Q, and K).

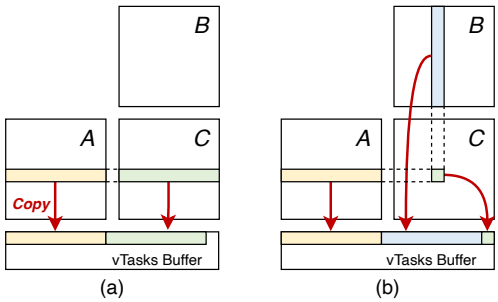

Figure 12: Different matrix multiplication checksum vTask packing strategy (a) row checksum and (b) row-and-column checksum.

Dynamic Sampling Strategy. In addition to the aforementioned mechanisms, we further employ a dynamic sampling strategy during the production deployment to reduce system overhead. Such a strategy is particularly practical for our algorithm-based detection mechanisms, as the computational overhead of checksum calculation in cSensor is non-negligible. Specifically, we assign a sampling rate to an operator, meaning that the operator will execute the checksum validation with a certain probability.

7 Evaluation

7.1 Experimental Setup

TestBed. All experiments are conducted on production GPU clusters. Each node is equipped with 8 GPUs unless otherwise specified.

Model Configurations. The configuration of the models used in our overhead analysis is listed in Table 1, detailing the number of layers, hidden size (h), number of attention heads, FFN intermediate size (h_{ffn}), number of experts, and top-k values.

Name	#layers	h	#heads	h_{ffn}	#experts	top-k
70B	24	4096	32	1024	256	8
268B	32	6144	48	2048	256	8

Table 1: Model configurations in evaluation.

7.2 AEGIS in Production

We first validate AEGIS's effectiveness in production through a deployment in our production clusters. During this time, AEGIS continuously monitors and detects SDCs in online large-scale LLM training jobs.

Detection Effectiveness. We first summarize the online SDC incidents detected by AEGIS. Over a deployment of 3.5×10^7 GPU-hours, AEGIS identified 18 SDC incidents involving 13 distinct faulty GPUs while incurring only 0.86% performance overhead. Among these incidents, only three incidents manifested as observable training failures (e.g., unexpected `NaN` loss); the rest were silent. This low overhead is achieved by enabling the dynamic sampling strategy described in §6, which balances detection coverage and performance in production.

Figure 13 plots the cumulative number of SDC incidents observed in our production environment after deploying AEGIS. For clarity, the figure shows only outlier warnings from GPUs that were repeatedly flagged and later confirmed faulty, reporting only the last warning for each such GPU. Initially, SDC incidents occur more frequently. Quantitatively, 13 SDC incidents were detected in the first half of the deployment period, whereas only 5 incidents occurred in the latter half. As faulty GPUs are detected and removed from the resource pool, the rate of SDC incidents gradually decreases. This marked reduction in SDC rate demonstrates the critical necessity of deploying online SDC detection in large-scale LLM training to protect training reliability and also validates the effectiveness of the AEGIS. Outlier warnings also serve as an early signal of latent risks; for example, a warning from a specific machine in Figure 13 was subsequently confirmed as a genuine SDC by AEGIS. We discuss outlier warning, false negative, and false positive problems in more detail in the discussion section (§8).

Coverage. The deterministic detection method detects more SDC incidents (12 times) than algorithmic detection and its outlier warnings (6 times). This observation can be attributed to two main factors: First, the broad operator coverage of deterministic approaches extends beyond `Matmul` and attention to include other components such as normalizations. Second, algorithmic detection is only sparingly sampled in production tasks to minimize overhead. Crucially, algorithmic detection remains essential as it offers a distinct detection scope and hence targets different SDCs. In particular, in training scenarios where recomputation is limited, algorithmic detection provides effective protection for computationally intensive operators that dominate the overall runtime. This

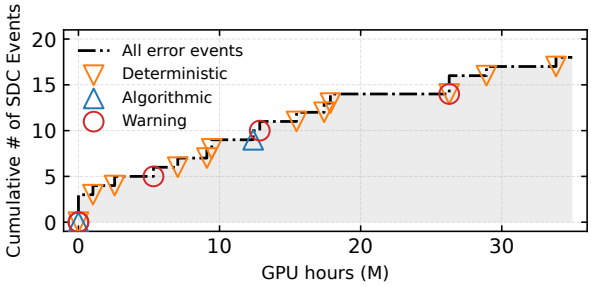

Figure 13: Cumulative SDC count over time (in million GPU-hours) in the production environment, as detected by AEGIS.

complementarity further justifies AEGIS's multi-sensor design for maximizing SDC detection coverage in production.

7.3 Analysis of Detection Capability

We conduct a capability study on eight available machines that had previously exhibited SDCs, as detailed in Table 2. For each machine, we run the training task 10 times to account for the inherent non-determinism of SDC manifestation during LLM training.

Compared with Offline Method. We compare AEGIS against the vendor-provided offline diagnostics tests. As shown in Table 2, AEGIS achieves a recall of 8 out of 8 faulty machines. In contrast, thorough diagnostic tests, which require hours to complete, detect only 25% of them (2 out of 8). We note that this recall is lower than the 70% reported in [41]. We attribute this discrepancy primarily to pre-screening bias in our operational environment. Prior to production training, all GPUs undergo strict offline stress testing to filter out visibly unhealthy machines. These eight GPUs were initially certified as healthy and then admitted into the LLM training cluster. Therefore, the low recall of offline stress testing underscores the difficulty of detecting such silent corruptions with conventional methods. This result highlights the practical value of our online approach in identifying hard-to-detect SDCs that escape offline screening.

Different Method Recall. Table 2 also breaks down the recall of individual methods across the eight faulty machines. A key observation is that no single method achieved 100% recall across all machines, indicating that online SDC detection in large-scale LLM training requires multiple complementary methods. This phenomenon aligns with our analysis in §7.2.

7.4 Overhead

We then evaluate the runtime overhead during training. We conduct experiments using two model sizes, 70B and 268B (as illustrated in Table 1), and scale up to 1,024 GPUs. Unless otherwise stated, the sequence length and global batch size are fixed at 8,192 and 768, respectively. We compare the per-iteration training time of AEGIS against a baseline without

ID	Fault Type / Description	Vendor-provided Diagnostics Tests	Algorithmic Detection		Deterministic Detection	
			Matmul	Attention	Framework	Attention

2	`Matmul` execution fault on EU `id=81`	✓	✓			
3	`wmma` instruction execution fault on EU `id=94`		✓			
4	HBM memory error (single-bit flips)				✓	✓
5	`Matmul` execution fault	✓	✓	✓	✓	✓
6	FlashAttention execution fault				✓	✓
7	FlashAttention execution fault					✓
8	FlashAttention execution fault		✓			✓

Table 2: Summary of SDC detection capability of AEGIS and vendor-provided diagnostics tests on eight real-world faulty machines, with detailed fault descriptions.

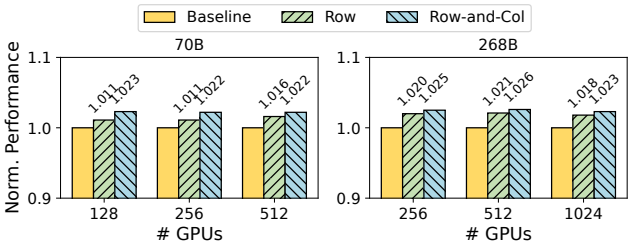

Figure 14: Overhead of AEGIS with different checksum techniques.

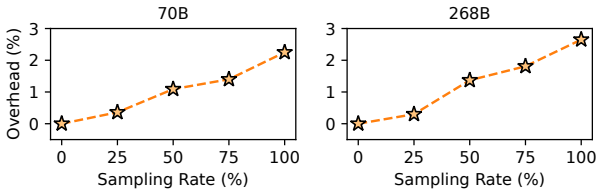

Figure 15: Overhead of different dynamic sampling rate.

SDC detection enabled to demonstrate its efficiency. All reported performance numbers are averaged over 10 stable iterations to ensure measurement reliability.

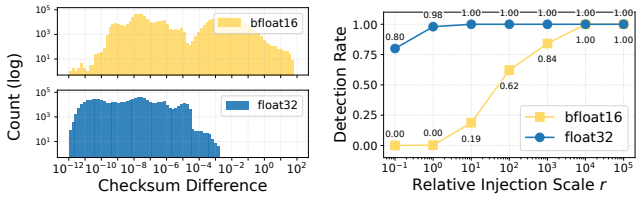
End-to-end Overhead. We evaluate two AEGIS configurations. The first enables only row checksums; in this configuration, *wgrad* is not fully covered. The second enables row-and-column checksums, providing coverage for all `Matmul` categories in LLM training. In both configurations, deterministic detection is enabled. Figure 14 summarizes the runtime overhead of AEGIS. Across all tested workloads, AEGIS incurs low overhead throughout training, averaging below 1.61% with row checksums and 2.35% with row-and-column checksums. The maximum slowdown is 2.1% for row checksums and 2.6% for row-and-column checksums. The primary sources of overhead can be divided into two stages: cSensor and cVerifier. In the cSensor stage, overhead mainly comes from checksum computation and minor memory operations needed to retain the minimal context for potential replay. In the cVerifier stage, overhead comes from executing vTasks to confirm whether it is a genuine SDC. The higher overhead of row-and-column checksums is primarily due to the extra memory copies (the column of input B) required to retain verification context compared to row checksums. In return, this configuration enables SDC verification for *wgrad*, trading minor overhead for broader coverage.

The results also indicate that AEGIS scales well to 1,024 GPUs and to larger model sizes. Because AEGIS does not introduce additional communication, it remains effective as cluster size grows. We expect this design to scale to larger deployments, providing reliable SDC detection for future ultra-large-scale LLM training with minimal impact on throughput.

Dynamic Sampling. To evaluate AEGIS 's dynamic sampling strategy (§6) and its impact on overhead, we conduct an ablation study under settings that mirror our end-to-end evaluation, except that both the 70B and 268B models are run on 128 GPUs. As shown in Figure 15, varying the sampling rate provides a simple and effective way to tune AEGIS 's overhead, which scales approximately linearly with the sampling rate. In our production deployment, we use this strategy to select a sweet spot that balances overhead and online SDC detection capability. Specifically, AEGIS controls the sampling rate of algorithmic detection to meet a target overhead budget (e.g., 0.86% overhead in our production).

7.5 Ablation Study

Checksum Difference. We next evaluate the contribution of algorithmic detection during training, focusing on how checksum accumulation precision affects detection sensitivity. Because operators differ in output scale and numerical-noise profile, we collect checksum-difference distributions for `bfloat16` and `float32` accumulation across operators over 500 training iterations without injected faults. As shown



(a) (b)

Figure 16: Ablation study of checksum precision in algorithmic detection. (a) Checksum difference distribution. (b) Detection rate vs. relative injection scale.

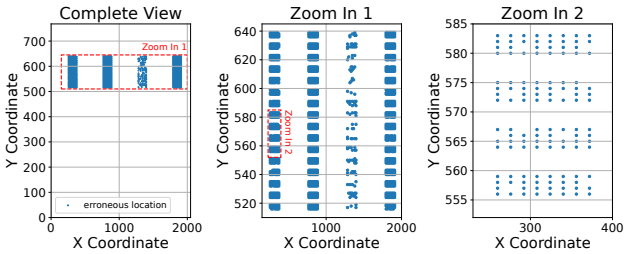


Figure 17: The erroneous locations of output tensor.

in Figure 16(a), `float32` produces substantially smaller checksum differences, making it more sensitive to small SDC-induced deviations.

Detection Rate. We then perform a calibrated fault-injection analysis. Because operators have different checksum-difference scales, injecting the same absolute perturbation, or an uncalibrated random fault such as a bit flip, would confound the comparison across operators. We therefore normalize each injected perturbation by the corresponding operator's `float32` checksum-difference scale. For each operator, we use the median `float32` checksum difference from this 500-iteration run as its reference scale. For a relative injection scale r, we inject a fault into a randomly selected element during the operator computation with probability 0.02%. The faulty element receives a signed perturbation with magnitude $r \cdot m_o$, where m_o is the corresponding operator's median `float32` checksum difference. Each setting is repeated 100 times. Figure 16(b) shows that `float32` checksums detect injected faults at the median reference scale with a near-100% detection rate. In contrast, `bfloat16` checksums remain largely insensitive at this scale and require roughly $10^4\times$ larger perturbations to reach comparable detection. This gap demonstrates that the higher-precision checksum design of our method provides stronger detection capability and enables finer-grained error detection.

7.6 Case Studies

Case 1: Detection of Matrix Unit Fault. In this case, the faulty GPU was detected during a matrix multiplication operation (corresponding to ID 3 in Table 2). We reproduced the SDC fault and analyzed its root cause.

We locate erroneous positions by comparing the faulty GPU's output with the expected results, as shown in Figure 17. The output tensor from the faulty GPU, of size 768×2048, exhibits errors only at specific positions with a regular pattern, as illustrated on the right. Zooming in on this region reveals a clearer structure, with errors recurring at periodic intervals along both the x and y axes (middle). Further zooming in (left) shows that the errors predominantly appear as four consecutive incorrect elements within localized regions.

Given this spatial clustering and regular structure, we hypothesize that the SDC originates from a specific execution unit. By inserting the assembly instruction to retrieve the `id` at erroneous locations, we identify the faulty execution unit (EU), which in our experiments consistently reports `id=94`. For identical inputs, we observe computation errors only when the Matrix Multiply-Accumulate instruction (`mma`, e.g., `wmma_f32_16x16x16_bf16_w32`) is executed on the matrix cores of this EU, whereas the same inputs produce correct results on the vector cores within the same EU. These observations indicate that the SDC is localized to the matrix unit and is specifically triggered by `mma` execution.

This case underscores the importance of integrating SDC detection into matrix multiplication, given the heavy reliance of LLM training on matrix units for efficient acceleration across the execution stack.

Case 2: Detection of HBM Fault. Our second case involves an SDC caused by an HBM fault (corresponding to ID 4 in Table 2). This SDC was detected by our deterministic detection. In this case, a `float32` intermediate value was saved during the forward pass and later read in the backward pass. Its value changed by a one-bit flip, from `10111111`**`0`**`11010100100000111110111` to `10111111`**`1`**`11010100100000111110111`. This single-bit error causes the fingerprint of the recomputed result to be not bitwise-aligned with that of the original forward pass, and is therefore detected by AEGIS. An interesting observation is that this fault does not trigger the ECC protection mechanism, suggesting a potential ECC failure that exposes GPU memory to the risk of undetected errors.

8 Discussions and Experiences

Permanent vs. Transient SDC Incidents. SDC incidents can be categorized as permanent or transient. Permanent SDCs stem from persistent hardware faults, whereas transient SDCs are rare, occasional events on healthy hardware, often attributed to external factors such as cosmic rays [28] and temperature [43]. In our production environment, all SDC incidents detected by AEGIS were reproducible on the corresponding GPUs. The time between re-triggered incidents during training varied widely, ranging from seconds to days. We further performed a reboot experiment on one such GPU. Although the GPU had previously been flagged

for a VRAM fault by the diagnostic tool, it passed all offline test suites immediately after a system reboot, suggesting that rebooting can temporarily mitigate SDC symptoms. However, one month later, the SDC reappeared; AEGIS detected it, and the diagnostic tool again reported the same underlying VRAM fault, indicating that *reboot does not resolve the underlying hardware faults*. These findings are similar with our in-house study [46], indicating that the observed SDC incidents predominantly stem from persistent hardware faults rather than sporadic transient events. Therefore, online SDC detection provides an efficient mechanism to identify and isolate faulty GPUs, preventing long-term degradation of LLM training caused by underlying hardware issues.

Software-induced SDCs. The correctness of AEGIS relies critically on bitwise comparison during computation replay. This property, however, can be violated not only by hardware faults but also by software bugs. During our deployment, AEGIS caught an SDC-like incident caused by a training framework bug. Specifically, the framework read illegal input data, which led to an out-of-bounds write in a kernel and triggered a recomputation mismatch alarm. This failure case highlights an additional benefit of AEGIS integrated into the training framework stack. Beyond hardware-induced SDCs typically targeted by offline testing, AEGIS can also identify software bugs within the training framework that manifest as SDCs, thereby offering further protection for training jobs.

False Negatives. To detect SDCs escaping from AEGIS, we screen for SDCs through several other methods. We periodically performed task-level replays using bitwise-deterministic, cluster-level training tasks to probe for undiscovered SDC issues. Across repeated runs, the losses remained aligned, providing additional confidence that no faulty GPUs were missed during the deployment. We also analyze unexpected task failures, including segmentation faults, `NaN` and `inf` values in the training task. Only one additional faulty GPU is detected, which caused an SDC that occurred outside the backbone of the Transformer network and hence beyond the protection region of AEGIS. This retrospective analysis demonstrates that AEGIS can detect most SDC incidents in LLM training, indicating its effectiveness. Nevertheless, we cannot completely rule out undetected SDCs, given their potentially low frequency and the inherent difficulty of observing silent corruptions in production LLM training.

Operator Coverage. The current AEGIS prototype focuses on dominant compute-intensive Transformer kernels, including `Matmul` and FlashAttention, while some lightweight or outside-backbone patterns, such as standalone element-wise operations, remain uninstrumented. This gap explains the remaining production false negative; extending coverage mainly requires adding the corresponding operator-specific sensor to the existing detection pipeline.

False Positives. Beyond these confirmed SDC reports, we observed 21 warning alerts from the outlier-based analysis (§5.4) during deployment. Among them, 11 alerts were attributed to reproducible faulty GPUs. Six alerts were repeatedly reported by a highly suspicious GPU over one month, yet could not be reproduced by existing offline diagnostic tools, highlighting the limitations of offline testing for identifying hard-to-reproduce faults. Three alerts in the remainder occurred on different GPUs during the model warm-up phase, suggesting that outlier-based numerical checks can be sensitive to out-of-distribution values in early LLM training.

Observing Only Compute- and Memory-Induced SDCs. In our deployment, we reproduced SDC incidents attributable to computation and memory, but did not observe communication-induced SDCs. A plausible explanation is that the communication stack is protected by multiple layers of error detection and correction (e.g., ECC and link-level checks), whereas compute paths on accelerators expose fewer built-in, end-to-end integrity checks. This asymmetry reinforces the importance of integrating lightweight SDC detection into compute-intensive operators in LLM training.

High Precision Accumulation Enables SDC Localization. During deployment, we did not successfully locate SDC incidents using checksums accumulated from `bfloat16` outputs. Instead, all confirmed detections were achieved by accumulating checksums from `float32` accumulators.

9 Related Work

SDC Detection in Training Systems. Existing research has explored various techniques to detect and mitigate the impact of SDC in AI training systems. [27] analyzes the effect of SDC in LLM training. ATTNChecker [21] uses ABFT to provide fault tolerance for the attention mechanism. Dr.DNA [26] proposes early-stage SDC detection and mitigation based on activation distributions. Gemini 2.5 [9] uses numerical analysis and rerun to identify suspicious SDCs. LongCat [38] introduces additional recomputation to verify the correctness of attention backward computation. However, these approaches often suffer from high overhead or limited detection efficacy. In contrast, AEGIS offers practical online SDC detection with low overhead and broad coverage for production-scale LLM training.

Fault-tolerant LLM Training. Some orthogonal efforts enhance the fault-tolerance of LLM training. GEMINI [44] and ByteCheckpoint [40] optimize checkpointing for faster recovery and reduced stall time. Other systems [14, 18, 39] exploit training redundancy to tolerate failures without disrupting training. Yet they do not study or address SDC issues. In contrast, AEGIS provides online SDC detection that promptly flags errors, which can then be combined with these fault-tolerance mechanisms to perform rapid rollbacks when necessary, thereby complementing these techniques.

SDC Detection in Other Applications. In other applications and hardware, [4] provides ultralight, application-agnostic

data dynamic monitoring to detect SDC in extreme-scale MPI. [12] studies SDC incidence and survey hardware/software mitigation strategies; Farron [43] mitigates CPU SDCs via prioritized testing and temperature control; Orthrus [24] detects SDCs in the cloud through resource-adaptive validation; and Hardware Sentinel [13] monitors large data-center fleets using software failure indicators. However, these CPU- and application-centric techniques do not directly address the distinctive computational and communication characteristics of GPU-accelerated LLM training; while AEGIS provides a specialized solution tailored to this setting.

10 Conclusion

We present the online SDC detection system AEGIS for large-scale LLM training, along with insights gleaned from 35 million GPU hours. Our findings demonstrate that online SDC detection should be established as a standard component of training frameworks to safeguard the scaling of LLM training.

Abstract

Large-scale LLM training runs on many GPUs for weeks atop rapidly evolving software stacks. Bugs or hardware glitches can silently corrupt the computation and only surface much later. Debugging becomes finding a needle in a haystack across time. Developers often use another training run and compare their loss, gradient norms, *etc.* But these aggregate signals are noisy and easily diluted across millions of operations, offering little guidance on why the divergence occurs.

This paper introduces *bitwise alignment* as a correctness oracle and debugging primitive for LLM training, and OpGuard, a practical system that realizes it at production scale. OpGuard discovers semantic-stable operator boundaries across heterogeneous training stacks, and wraps them with lightweight fingerprinting. A schedule-tolerant mapper computes the longest prefix where two executions produce bitwise-identical tensors. The first mismatching point becomes a pivot for debugging and is presented with rich context. By carefully controlling benign nondeterminism, OpGuard makes the first mismatch strong evidence of error. OpGuard has been deployed at ByteDance across pre-training and post-training workloads. It diagnosed over twenty production issues, including subtle kernel races and silent data corruptions missed by existing checks, reducing debugging time from days to minutes.

1 Introduction

Large language model (LLM) training runs on a large number of GPUs for weeks [19, 29] on top of a complex software stack composed of user code, compilers, libraries, CUDA kernels, distributed runtime, *etc.* This stack also undergoes frequent updates [28], so bugs and hardware glitches are inevitable [17, 22]. Their symptoms are often subtle, such as loss spikes, gradient-norm drift, degraded model quality [35, 43, 77, 87].

When such an anomaly arises, developers need to determine (1) is the run truly buggy, and if so, (2) what the root cause is. This is challenging for several reasons. First, rerunning a training job consumes substantial resources, limiting the number of diagnostic reruns developers can afford. Second, the observed signals, such as loss and gradient norms, are only composite metrics aggregated over millions of operations and devices, so an error is easily diluted. Third, LLM training is prone to numerical variations [12, 19, 27, 80], so an anomaly may be harmless noise or early sign of a serious fault.

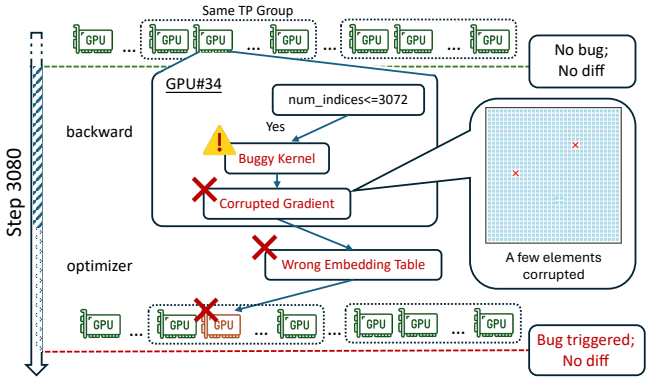

Figure 1. A tiny race in embedding backward affects one GPU's embedding shard. The next forward step reads the corrupt weight and propagates the error through its TP group and downstream layers. By the time the loss diverges, most GPUs already hold bad tensors.

A production incident illustrates the challenge. In one of our thousand-GPU vision-language model training runs, an alert on the gradient-norm curve was raised after over 3,000 steps. Expert developers spent five days running repeated experiments, toggling flags, and swapping kernels, but made no progress. The root cause turned out to lie in an embedding backward kernel, which had a tiny race condition that perturbed a few rows under rare token patterns (Figure 1).

To cope with the challenge, developers often compare a suspect run with a reference run. The reference run may come from an older release, a branch before a suspected feature, with different flags, with an alternative CUDA kernel, or even on another framework. This comparative strategy has been well studied in conventional debugging: delta debugging and related techniques compare executions, changes, or program states to isolate the minimal failure-inducing input or code [38, 95, 96, 99]. However, in LLM training, today's comparisons still rely on composite signals. Thus, they inherit the same ambiguity that can hide real bugs or raise false alarms. Even when two loss curves clearly differ, they offer little guidance on what causes the divergence. In the above case, developers repeatedly compared signals across runs (Figure 2), but this alone was insufficient to localize the bug.

Our insight is that effective comparisons for LLM training must be unambiguous and early enough. Composite signals have high ambiguity because they mix the effects of many operations and surface long after the original error; low-level code execution traces expose irrelevant details, creating many

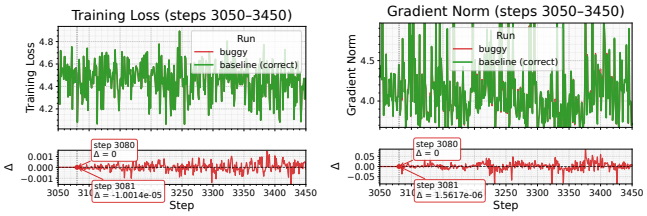

Figure 2. Loss and gradient-norm comparisons between a good run and the buggy run around Steps 3050–3450 for Figure 1. The bottom plot highlights where the buggy run first diverges and by how much.

benign differences when compared; tolerance-based tensor comparisons still leave ambiguity with ad-hoc thresholds.

Based on this insight, this paper proposes **bitwise alignment** as a new correctness oracle and debugging primitive for LLM training. Given two comparable training executions, we view each as a sequence of model-level computation boundaries and compute the *longest prefix* over which the tensors at corresponding boundaries match *bit-for-bit*. The first boundary failing this check is then the earliest point where the two runs diverge, regardless of how similar their aggregate metrics might still appear. This provides precise correctness criterion and the first diff becomes the debugging pivot.

At first glance, bitwise alignment seems infeasible for LLM training, which contains numerous sources of nondeterminism such as multi-threading and non-associative reductions. Production pipelines add further complexity through operator fusion, recomputation, graph capture, and backend-specific rewrites. These behaviors suggest that two training runs would diverge quickly, making bitwise alignment too fragile.

This intuition overlooks an opportunity: modern stacks provide substantial determinism control. Randomness can be seeded; kernel libraries expose deterministic modes [18, 24, 50, 51, 82]; data pipelines can be made reproducible[67, 83]; deterministic algorithms exist [20, 65, 73]. However, current determinism settings are scattered and used ad-hocly to improve *reproducibility*, not to systematically localize bugs.

We design OpGuard, a system that realizes the idea for production LLM training. OpGuard leverages existing determinism but organizes it to support debugging, and adds new mechanisms to make bitwise alignment feasible.

In practice, we find the space of bitwise-alignable runs is much broader than expected. With modest care, we can align runs that are several commits apart, runs that enable new features (*e.g.*, activation recomputation [11]), and even runs from different training stacks (*e.g.*, DeepSpeed vs. our custom runtime), as long as they implement the same model computation. This observation underpins our design of OpGuard and its applicability in complex, evolving LLM training pipelines.

Realizing this versatility requires addressing several challenges. Full-stack determinism is too costly, if not infeasible, for production environments. OpGuard does not seek absolute determinism. Instead, it identifies and neutralizes *avoidable* sources of variation for bitwise comparison to be well-posed.

Even so, unavoidable nondeterminism and complexities in production pipelines still pose problems. *How to make bitwise alignment robust even when the underlying stack is not fully deterministic and contains aggressive optimizations?* Production jobs routinely enable kernel fusion, recomputation, compute–communication overlap, evolving sharding layouts, and graph-captured executions. These optimizations reorder and regroup kernels, so any alignment scheme tied to a particular execution plan is brittle. Large organizations like ByteDance also use multiple training frameworks——PyTorch, DeepSpeed, Megatron, and internal runtimes——whose APIs differ substantially. Correctness checks defined in terms of specific framework APIs are therefore too restrictive and limits available reference runs. Finally, tensors are enormous, making full tensor dumps prohibitively expensive. Their representations can also change under sharding or reshuffling.

To address these challenges, OpGuard identifies and instruments a small set of *semantic-stable* boundaries—the lowest-level Python operators that correspond to model semantics, such as linear projections, layer normalization, and attention blocks. These points represent the same mathematical transformation across frameworks. Because these boundaries sit above kernel choices and scheduler decisions, they also become *execution-stable*: even if one run fuses kernels, overlaps communication differently, or uses a different CUDA Graph capture, the same semantic boundary is still reached and observed. OpGuard uses a short preflight phase that runs each stack to efficiently discovers these stable boundaries.

OpGuard automatically inserts a lightweight device-side *fingerprint kernel* around these boundaries, which emits a constant-size, *scale-stable* fingerprint. During the main run, OpGuard records only these fingerprints. This reduces the trace size and ensures the comparison does not depend on the size, layout, or sharding of the underlying tensor. Afterward, OpGuard uses a *schedule-tolerant mapping* algorithm to reliably align the fingerprint streams from two executions. It computes their longest bitwise-identical prefix, and reports the first boundary that differs, together with its immediate context. OpGuard further includes UI support that presents this boundary as a pivot in a unified timeline so developers can visually inspect how the discrepancy propagates.

OpGuard has been deployed in production in ByteDance for 8 months. It seamlessly supports different pre-training and post-training frameworks and heterogeneous hardware backends. This ease of integration is because OpGuard observes model-level tensors rather than framework APIs or internals.

To date, OpGuard has helped diagnose 20 production bug cases, including resolving 11 long-standing difficult cases like the motivating example. They cover a variety of subtle issues, such as nondeterministic races in communication-overlap paths, one-bit routing errors in MoE routing kernels that later explode into shape mismatches, and long-standing cross-stack mismatches such as different loss masking policies between Megatron and FSDP. Across these cases, OpGuard reduces

diagnosis time *from days to minutes*. In a separate online SDC-detection mode, OpGuard has also detected more than 21 silent-data-corruption (SDC) [44] cases. We also evaluated OpGuard in open-source training ecosystems. It enabled the diagnosis of 4 new reproducible issues and 6 long-standing bugs whose cumulative resolution time exceeded fifteen days.

Besides diagnosis, teams have used OpGuard as a reliable correctness oracle in scenarios where system changes introduce subtle correctness regressions, including new overlap schedules, recompute policies, sharding layouts, heterogeneous backends such as GPUs and NPUs, and compiler-generated execution paths. These workflows routinely alter execution order, precision, kernel fusion, or parallel boundaries—changes that are notoriously hard to validate and historically have caused silent divergences in production training. OpGuard provides a principled way to confirm correctness of low-level optimizations. This allows teams to safely innovate on scheduling, parallelism, and compilation.

In summary, this paper makes the following contributions:

- We formulate bitwise alginment as a new correctness oracle and practical debugging primitive for LLM training.
- We design and implement OpGuard, a system that realizes this primitive into a practical and scalable workflow.
- We evaluate OpGuard across production pre-training and post-training pipelines in ByteDance as well as open-source stacks. The results demonstrate its impact.

2 Background and Motivation

LLM training requires extensive computation distributed across many devices. A single training run traverses layers of software and hardware: user code that defines the model, optimizer, and configuration; distributed framework that implements data, tensor, and pipeline parallelism [79] across accelerators; runtime that schedules operators and manages multiple CUDA streams [52]; compiler and kernel-generation framework that lower operators into fused CUDA kernels [91].

2.1 Correctness Challenges in Large Training Stacks

Our experience in operating large training pipelines suggests that faults can originate from any part of this stack. A small deviation in user code can change the intended computation. Mistakes in the parallelism partitioning, or microbatch ordering can cause different devices to see inconsistent parameters or activations. Races between transfers and computation can corrupt intermediate state. A collective may reuse a stale buffer or misroute a shard. At lower levels, corner-case kernel fusion bugs, nondeterministic kernels, and hardware-level issues such as silent data corruption, can all produce wrong activations or gradients. Even the systems surrounding a ML framework, such as dataloaders and caching service, may supply incorrect or reordered batches that appear valid.

Moreover, these faults seldom produce an observable symptom at the moment they occur. They often initially affect only a single device or a handful of tensor elements. As computation intensifies and training state synchronizes, this local error gradually propagates. Eventually it manifests as some visible anomaly, *e.g.*, a drift in gradient norms. By that time, the original fault is often many layers and operations away. Worse still, the same symptom can be caused by many possible faults.

These characteristics makes correctness debugging in LLM training notoriously challenging. An apparently abnormal signal may turn out to be harmless noise, while a subtle deviation may be the first sign of a serious underlying fault. Localizing the true root cause is akin to finding a needle in a haystack spread across time.

2.2 Existing Solutions and Their Gaps

Substantial tools have been created for debugging individual training components. Framework-level debuggers and anomaly modes (*e.g.*, TensorFlow Debugger [84], PyTorch Autograd Anomaly [69]) focus on the training program and catch obvious mis-specifications. GPU correctness and sanitization tools (*e.g.*, cuCatch, NVIDIA Compute Sanitizer, GPUBurn) target kernel behavior and memory errors [8, 39, 54, 81]; MPI and communication checkers such as MUST [86] focus on collectives; hardware-focused tools like DCGM diagnostics [57] watch for device faults; and cluster monitoring systems track service and data anomalies. These tools are useful for identifying local issues, but each tool focuses on a narrow slice of the system. They do not answer the core questions developers face during correctness incidents of an end-to-end training task: (1) *is this run still performing the computation as intended?* (2) *where in this long execution did the misbehavior first occur?*

In practice, engineers routinely rely on a pragmatic strategy: they run a candidate training job next to a known-good one with the same checkpoint and seed, then compare their loss curves, gradient norms, activations, and related metrics. This approach is popular because it provides a concrete baseline for an otherwise fuzzy notion of correctness, while fitting naturally into existing rollout workflows. When the two runs match, engineers gain confidence; when they differ, there might be a bug that warrants investigation.

However, these comparisons only operate at composite signals that aggregate the effect of millions of operations, masking subtle discrepancies for long periods while amplifying harmless numeric fluctuations. Across real incidents, we observe that they help reveal two runs have diverged, but they offer little insight about why. Debugging remains a tedious trial-and-error by toggling flags, adjusting settings, swapping kernels, *etc.* Each rerun consumes costly cluster resources.

What is missing is a *precise* comparison mechanism to augment this practice. It must surface faults soon as they occur, while pinpointing what causes the divergence. It should remain robust under production training stacks and only reveal true differences in model computation semantics. In addition, it should not require extensive changes to a training pipeline, disable core optimizations, or incur severe slow-down.

3 Abstraction: Bitwise Alignment

To address the challenges and gaps described in §2, we advocate for *bitwise alignment* as a correctness oracle and debugging primitive for LLM training.

Definition 1 (Bitwise alignment)**.** *Consider two training executions E_1 and E_2 that are expected to compute the same model. Each execution produces a sequence of observable boundaries: $E_1 = \langle b_1^1, \ldots, b_m^1 \rangle$ and $E_2 = \langle b_1^2, \ldots, b_n^2 \rangle$. A boundary b has an identifying model-level operator $\sigma(b)$ with an input/output tensor state $T(b)$. An alignment between E_1 and E_2 is an order-preserving partial matching $A = \langle (b_{i_1}^1, b_{j_1}^2), \ldots, (b_{i_k}^1, b_{j_k}^2) \rangle$, where $\sigma(b_{i_r}^1) = \sigma(b_{j_r}^2)$. Bitwise alignment is the longest prefix of A such that every matched pair satisfies $T(b_{i_r}^1) \equiv_{\text{bit}} T(b_{j_r}^2)$.*

3.1 Alignment Spectrum

A useful way to think about correctness in LLM training is to examine it along a spectrum of alignment strengthen.

At the weakest level, *behavior alignment* judges whether the overall behavior of a model, *e.g.*, its accuracy, BLEU score [60], or loss curve, remains statistically consistent across runs. This level suffices for high-level monitoring and regression testing but offers no visibility into internal correctness: two runs can exhibit identical accuracy yet silently diverge in intermediate activations or gradients.

A stronger level is *numerical alignment*, which compares two tensors and treat them as equal if they are close enough, as in `torch.allclose` [68]. This appears robust, since it tolerates small differences, but in practice it is an unreliable oracle. A 10^{-4} difference in logits may be acceptable but may indicate a serious bug for a loss or normalization constant. Choosing a single tolerance that works across layers, data regimes, and models is difficult. In addition, due to floating-point arithmetic's non-associativity, small discrepancies arising from reduction trees, fusion patterns, or accumulation paths will change the results even when the underlying computation is mathematically the same. Raising the tolerance reduces false alarms but will also mask small-but-systematic drifts caused by actual bugs (*e.g.*, losing a few rows in a gradient, missing an update, or corrupting a subset of parameters) [40]. Numerical alignment is inherently ambiguous.

At the strongest level lies *bitwise alignment*, which demands that the tensors match exactly, *bit for bit*, across operations in both forward and backward passes. This *binary predicate* removes ambiguity entirely: two runs are either identical or not. When they differ, the first mismatched operation marks the precise boundary where equivalence breaks, exposing the responsible kernel, reduction order, race, *etc.* Therefore, it provides strong diagnostic power.

3.2 Make Bitwise Alignment a Precise Oracle

For bitwise alignment to serve as a precise oracle, mismatches should indicate a real difference in computation logic rather than incidental noise. This requires three key conditions.

Comparable replay. The two executions should be comparable, *i.e.*, implement the same mathematical logic. They need not be identical binaries. Many useful comparisons intentionally differ in implementation. A related assumption is that an execution can be reproduced given the same data, seeds, and environment. This is often feasible. Unlike conventional systems where reproduction is hard [59, 98], LLM training is fundamentally more reproducible. Its computation follows a mostly static graph of tensor operations, and its inputs are drawn from fixed datasets instead of dynamic, unknown user requests. If two pipelines intentionally read or preprocess data differently, they should first align the input, e.g., using the same checkpoint or captured post-preprocessing tensors. Reproducing a faulty run is generally feasible even when the underlying bug is a data race. LLM training is computation-intensive and repetitive: an operator is often invoked thousands of times per training step and millions of times over a run, which creates abundant opportunities for the race to manifest.

Feasible, however, does not mean cheap. Replaying a large training job consumes substantial resources and time, so a debugging system should require as few reruns as possible. OpGuard uses one captured faulty run and a reference run to expose the first boundary divergence; the faulty execution itself need not be deterministic.

Controlled nondeterminism. LLM training stacks contain various sources of nondeterminism that can introduce variation between runs even when they do not change the intended computation. We distinguish two categories. *Controlled nondeterminism* is benign variation in the execution environment, *e.g.*, RNG streams, data order, library kernel choices, collective topologies, and numeric modes. *Residual nondeterminism* is variation that remains after these controls are fixed, typically because user code, third-party kernels, or hardware behavior is schedule-sensitive. The former should be stabilized so that bitwise comparison is well-posed; the latter is intentionally left visible and treated as a bug signal. §4.2 describes how OpGuard enforces this split.

Model-level boundaries. Bitwise comparison should be applied at a granularity that yields stable and precise outputs. Comparing at full training steps or whole layers would be too coarse to localize faults. Comparing at every Python-level callsite would be too noisy and inconsistent: many functions do not operate on tensors, and those that do may be reordered, fused, or eliminated by tracing and compilation passes. Conversely, if the comparison is too low-level, *e.g.*, framework internals or temporary buffers, it becomes highly sensitive to implementation details. Small changes in heuristics, autotuning, or vendor libraries can add, rename, or remove temporary tensors without affecting the model semantics.

We find the right granularity for bitwise alignment are *model-level operators whose input and output tensors are materialized in every valid execution of the model*, *e.g.*, a linear projection, a layer-normalization call, an attention block,

or an MLP submodule. We call those comparison points **model-level boundaries**. By materialized tensors we mean those that any faithful implementation should produce and pass to the next model-level operator as opposed to transient buffers, which a compiler may create, rename, or eliminate. These tensors define the *contract* between adjacent model components. Backends may change kernel schedules, fusion plans, or temporary buffers, but changing a boundary tensor changes the model computation. A match at such a boundary implies that the proceeding components' transformations are equivalent for that input; a mismatch marks the first component that has divergent transformation. This granularity is stable across framework and backend because different optimizations should preserve model logic; yet it remains fine-grained to localize the divergence to a small region of model code.

4 Design of OpGuard

We design OpGuard, a system to realize the bitwise alignment abstraction. Our goal is to make OpGuard practical for production training pipelines. OpGuard also aims to make bitwise alignment broadly applicable as a general and powerful debugging primitive so it can support comparing executions across frameworks, compilers, libraries, hardware backends, and distributed runtimes, as long as both runs represent the same model computation. Otherwise, bitwise alignment would only be a narrow regression check for nearly identical binaries, which would greatly limit its utility.

Achieving these goals requires turning the insights discussed in §3.2 into concrete mechanisms. Production training pipelines are highly complex and contain aggressive optimizations such as operator fusion, and graph capture and rewriting. These complexities introduce several design challenges for OpGuard. First, the stable comparison points required by bitwise alignment are not directly exposed by single API surface. OpGuard needs to efficiently discover the boundaries without requiring users to rewrite models or disable optimizations. Second, production training runs generate enormous tensors. Dumping full tensors is infeasible. OpGuard should extract lightweight, scale-independent observations that are still informative. Third, even after benign nondeterminism is neutralized, two executions likely will not emit outputs in exactly the same order. OpGuard should align partially ordered observations and recover the longest prefix.

4.1 Overview

OpGuard addresses these challenges with a three-phase workflow that compares a suspect execution against a reference run (Figure 3) for post-failure root cause diagnosis. OpGuard has a separate deployment mode for online SDC detection, which is discussed in §6.4. The Preflight phase (§4.3) runs a few iterations in eager mode to discover model-level boundaries (§3.2) shared by both runs, and produces an alignment plan. The Guarded Execution phase (§4.4) wraps the discovered boundaries with input/output fingerprinting and runs the full

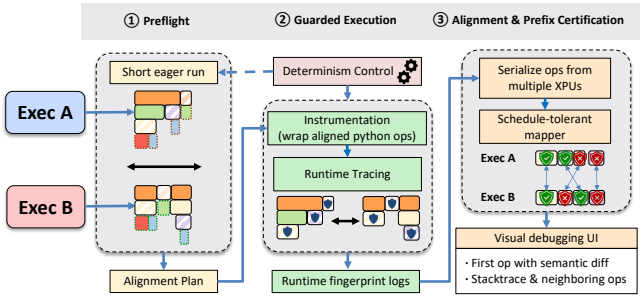

Figure 3. OpGuard workflow.

training job, producing compact fingerprint logs. Determinism control (§4.2) is applied in this phase as well as in Preflight. The Alignment phase (§4.5, §4.6) processes the two logs offline. A schedule-tolerant mapper first identifies anchors to partition each trace into windows; within each window, the mapper pairs the remaining boundaries despite fusion, overlap, and asynchrony. Prefix certification then walks the matched boundary pairs to compute the longest bitwise-identical prefix and report the earliest divergent boundary. A visual debugging UI presents this boundary along with surrounding context for engineers to quickly triage and pinpoint the root cause.

4.2 Determinism Control

As discussed in §3.2, bitwise alignment is only well-defined if nondeterminism is controlled. Conventional deterministic multithreading systems [6, 7, 15, 16, 42, 46, 47] force reproducible execution by controlling thread schedules, system-call results, and external inputs. One extreme for LLM training is full-stack bitwise determinism, exemplified by PaLM [12]. PaLM's training pipeline was engineered so that, starting from any checkpoint, resuming training produces bitwise identical results. Achieving this required carefully constraining the entire hardware and software stack. Outside such bespoke stacks, this level of control is rare. While mainstream frameworks such as PyTorch and TensorFlow offer deterministic modes, they are best-effort and do not eliminate nondeterminism. Enforcing bitwise determinism across heterogeneous fleets (mixed GPU generations, different drivers/compilers, evolving libraries) is also fragile. A single library upgrade or kernel change can break the assumption.

OpGuard's goal differs from deterministic runtimes and from PaLM's full-stack discipline. It does *not* aim to make every run absolutely bitwise deterministic or to impose a deterministic scheduler, which can severely slow down production workloads. Instead, it identifies and fixes *controlled nondeterminism*: avoidable sources of variation that would otherwise make two runs with the same intended computation perform different arithmetic and make bitwise alignment meaningless. Many numerical differences between runs arise from sources that have nothing to do with model correctness: different shuffling orders, RNG streams, collective algorithms or bucketizations, kernel variants, or numeric modes. If these

Surface	Controlled?	What remaining nondeterminism means
Randomness & data order (dropout, shuffling, sampling)	Yes	We fix all RNG seeds and sampler settings so that both executions see the same mini-batch sequence and the same stochastic draws. If runs still diverge here, it reflects data/config drift.
Framework / library kernels (torch ops, cuBLAS/cuDNN, fused kernels)	Yes	We enable deterministic algorithms and pin kernel choices so that, given the same inputs, the library computes in the same arithmetic order. After this, mismatches usually indicate version/flag skew or a latent library bug, not benign nondeterminism.
Hardware collective / reduction order (NCCL tree/ring, chunking, topology)	Yes	We pin NCCL's algorithm and topology so all partial sums follow the same reduction tree. Different trees lead to different FP accumulation orders, so we treat those as different configurations and should not compare them. If the hardware produces different bits despite identical inputs and kernel, this constitutes *silent data corruption (SDC)*.
User / third-party code & scheduling (custom CUDA kernels, host concurrency, warp/SM timing)	**No**	We do not fix CPU thread schedules, warp/SM timing, or user kernel design. Correct kernels must be schedule-invariant. If scheduling changes bits (racy atomics, missing sync, uninitialized memory), that is a bug, not benign nondeterminism, so OpGuard is meant to expose it.

Table 1. OpGuard distinguishes controlled nondeterminism from residual nondeterminism. Controlled nondeterminism inside the stack (RNG, framework kernels, hardware reduction order) is stabilized so bitwise comparison is well-posed. Residual nondeterminism after these controls is treated as a bug signal when it changes output.

choices differ between runs, they no longer perform the same arithmetic, making bitwise comparison meaningless.

As Table 1 lists, these are exactly the categories OpGuard controls. The controls are lightweight and do not disable core optimizations or alter user-visible training logic.

Specifically, OpGuard applies nondeterminism controls at five surfaces. First, it makes randomness and input order replayable by fixing CPU/CUDA RNG state, dropout streams, dataloader workers, sampler state, and distributed initialization, so both executions consume the same mini-batches and stochastic draws. Second, it pins arithmetic choices inside framework and vendor libraries: deterministic algorithm modes, fixed cuDNN/cuBLAS workspace behavior, disabled autotuning, and consistent numeric modes such as TF32 settings keep kernels using the same implementation and accumulation order. Third, it fixes distributed reduction order by pinning collective algorithm, protocol, topology, and bucketization; otherwise two correct runs can differ solely because floating-point partial sums follow different trees. Fourth, when comparing from a checkpoint, it restores all state that affects future execution, including RNG streams, optimizer state, dataloader position, and scheduler counters. Finally, for comparisons across tensor-parallel configurations, OpGuard can use a TP-simulator mode that executes the full unsharded arithmetic while preserving the logical parallel configuration, preventing sharding-induced reduction-order changes from being mistaken for faults.

Importantly, OpGuard does *not* suppress residual nondeterminism in user/third-party code or fix scheduling. Schedule-sensitive custom or third-party kernels (*e.g.*, CUDA/Triton kernels with race conditions or nondeterministic reductions) are treated as part of the system under test rather than stabilized or reasoned about internally. If such a kernel is not schedule-invariant, OpGuard surfaces the effect as a divergence. Thus controlled nondeterminism is noise that OpGuard removes, while residual nondeterminism is evidence that the tested system has a latent correctness problem. The exhaustive knob-level recipe is detailed in Appendix A.5.

4.3 Preflight: Discovering Stable Model Boundaries

OpGuard splits debugging into two phases: a short Preflight phase that determines *where* bitwise comparison should occur and whether the two executions share those points, followed by Guarded Execution that instruments only those points. This separation enables low overhead for long training runs.

Preflight's goal is to discover a shared set of boundaries across two executions that are expected to compute the same model-level transformation. These boundaries should define a stable comparison grid: regardless of differences in compiler passes, fusion strategies, or kernel schedules, the same boundaries in two runs should see the same logical tensors. Thus, same computation is a contract on boundary values, not source code or kernel identity.

We use the MoE block in Figure 4 as a running example throughout the design. The block dispatches tokens with `all_to_all_dispatch`, normalizes activations with `fused_rmsnorm`, runs expert computation with `grouped_gemm_experts`, and combines expert outputs with `moe_combine`. One execution may fuse adjacent kernels or schedule communication on different streams, but if it implements the same MoE block, it should expose the same logical tensors at the boundaries.

Preflight assumes the runs start from equivalent checkpoints, consume the same training examples in the same microbatch order, make the same seeded random choices, and use the same numerical contract for each boundary (*e.g.*, precision policy, normalization formula, optimizer update rule, and collective reduction order). They may still use different kernels, fusion plans, recomputation strategies, graph-capture schedules, or physical sharding layouts, as long as those choices implement the same boundary-to-boundary tensor transformation.

As discussed in §3.2, choosing the right boundary granularity is critical. OpGuard chooses *model-level operators* whose input and output tensors are materialized in every valid

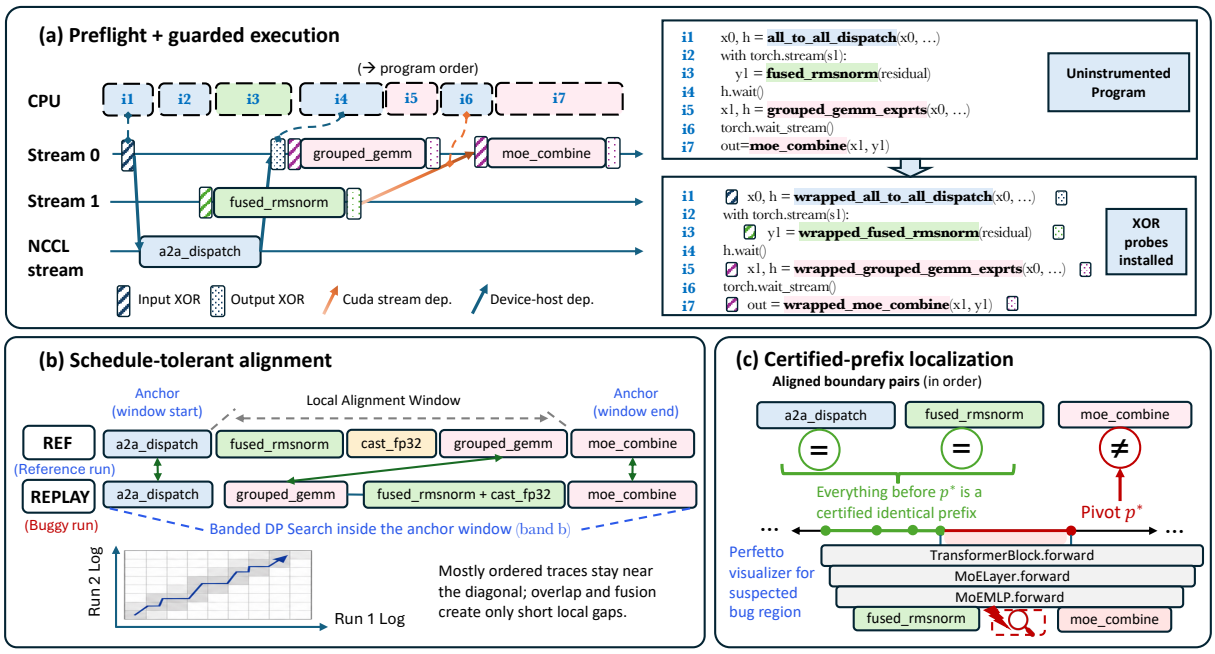

Figure 4. OpGuard components on one running MoE-block example. (a) Preflight discovers stable model-level boundaries and guarded execution installs input/output XOR probes at those boundaries. (b) Schedule-tolerant alignment pairs boundary logs despite fusion, overlap, and local reordering. (c) Prefix certification reports the first mismatching aligned boundary as the debugging pivot.

execution of the model, specifically the lowest Python-level operators that directly initiate device work (through C++/CUDA kernels), *e.g.*, `linear`, `layer_norm`, attention blocks, the four MoE operators in Figure 4. These operators are explicit in model code and define the model computation, while existing in every major training stack. They form a consistent logical order despite backend differences. Bugs must eventually perturb a tensor passed through one boundary.

OpGuard discovers these boundaries automatically. It executes each pipeline for a few iterations, and enables Python- and device-level tracing for tensor-producing operations. It then inspects the stack frames of these operations and filters out frames originating from JIT internals, compilation runtimes, and vendor libraries. From the remaining frames, OpGuard selects the nearest user-defined operator as a candidate.

OpGuard then identifies the device work caused by each candidate operator. This is needed to (1) filter Python callsites to operators that actually launch device work; (2) provide runtime context (streams, launch order, timing, *etc.*) for later stages. This attribution is non-trivial. A single model-level operator may trigger multiple CUDA or Triton kernels, call vendor libraries, issue collectives, or runtime-scheduled launches. The device trace alone cannot name the model operator that caused these launches, while the Python trace alone does not expose their concrete runtime behavior.

OpGuard therefore uses a layered attribution scheme. Its Python tracer records the operator intent (function names, callsite, argument summaries). Device-level tracer records kernel launches, memory operations, collectives, streams, and timestamps using the device profiling interface [55] and kernel-launch interception. OpGuard merges the two views into a unified stream that associates each Python-level operator with the set of device activities it triggers. This provides both the stable operator identifiers for instrumentation and concrete context for attaching fingerprints and later debugging.

4.4 Guarded Execution: Fingerprinting at Boundaries

After preflight identifies the boundaries to observe, OpGuard instruments only those sites during guarded full training execution. The instrumentation is done with framework operators instead of a separate profiling runtime. At each boundary, the original callsite is replaced with a small wrapper that launches a pre-op fingerprint kernel, invokes the original operator, and then launches a post-op fingerprint kernel. All other model code is untouched. Since the wrappers are normal framework operators, they preserve the original execution mode (eager, `torch.compile`, CUDA Graphs). In Figure 4a, the callsites for `all_to_all_dispatch`, `fused_rmsnorm`, `grouped_gemm_experts`, and `moe_combine` are replaced with wrappers.

Each wrapper emits a compact trace entry containing the boundary identifier, tensor metadata (shape, dtype, device, stream), rank id, and a local monotonic timestamp. The fingerprint kernels read the input/output tensors and compute a lightweight XOR hash; they add no tensor copies or control logic. Appendix A.4 analyzes the fingerprint's sensitivity to tensor precision, value distributions, and corruption modes.

Correct placement is essential. Modern training stacks routinely overlap computation and communication across

multiple streams, and many operators execute asynchronously. Fingerprints must run *exactly* where tensors become valid and on the same execution stream as the operator they guard. Thus, each wrapper launches its fingerprint kernels on the operator's own stream and attaches them to the same synchronization points (completion handles, `wait_stream` sites). This placement embeds fingerprinting into the existing stream graph without introducing additional synchronization or reordering.

Figure 4a illustrates this placement rule on the MoE block. The output probe for `all_to_all_dispatch` attaches after the collective handle completes; probes around `fused_rmsnorm` run on its stream; and the probe before `grouped_gemm_experts` respects the wait edge from the collective stream. In each case, the trace records the tensor at the device-time point where the program consumes or produces it, together with the callsite and local stream-order constraints. The runtime appends these entries to one log in device-dependency order, reusing existing handles and streams so logging adds no cross-stream synchronization and does not alter scheduling.

4.5 Schedule-Tolerant Alignment

Even when two executions implement the same computation, their fingerprint logs rarely line up position by position. Stream overlap, fusion, graph rewrites, and backend-specific kernels can introduce local reordering or extra events without changing the boundary values. A positional diff would confuse such schedule skew with real tensor drift.

The mapper looks for high-confidence, order-preserving partial matching. A pair of events are only matched when they share the same boundary identifier, tensor shape and dtype, and rank. A positive score would be given if they have relatively close device-time and operator index. Matching events should preserve relative order: if event a precedes event b in one log, their counterparts should appear in the same order in the other log. Gaps are allowed but penalized. They represent inserted or fused work that remain unmatched.

The mapper's alignment algorithm runs in three stages. First, it constructs anchors from boundaries that are unique in a local region, appear in both logs, and preserve relative order. A boundary is used as an anchor only when its symbolic operator name and tensor metadata are unambiguous among nearby events. These anchors split the logs into small windows, preventing repeated kernels or ambiguous metadata from pulling the mapper into a globally inconsistent alignment.

Second, within each anchor window, OpGuard runs a banded monotone dynamic programming algorithm (listed in Appendix A.3). Production traces are mostly ordered: stream overlap, fusion, and graph rewrites usually create short local displacements rather than arbitrary permutations. The band keeps the search near the diagonal, covering these local skews while avoiding the cost and instability of unconstrained global matching. If a true counterpart falls outside the window or is ambiguous, OpGuard leaves it as a gap.

Third, OpGuard performs a conservative rescue pass for missed matches that move slightly across anchor boundaries, such as repeated reduction events emitted at different times. The pass scans nearby unmatched events using device-time windows and fingerprint metadata, and adds a pair only when it is consistent with the established monotone alignment.

In Figure 4b, for example, one MoE run records `all_to_all_dispatch`, `fused_rmsnorm`, `grouped_gemm`, and `moe_combine`; the other reorders `grouped_gemm` around normalization and fuses `fused_rmsnorm` with a cast. Anchors keep the shared boundaries in order, local DP absorbs the short displacement, and fused work simply remains unmatched.

4.6 Prefix Certification and Fault Localization

Given two aligned traces, what engineers want is not a long list of discrepancies but a single, trustworthy pivot that separates equivalent behavior from a real tensor divergence. In the running example (Figure 4c), the two runs agree through dispatch and normalization, but the first mismatching aligned boundary is `moe_combine`; this boundary becomes the debugging pivot.

OpGuard therefore computes a *certified prefix*: the longest run of matched boundary pairs whose fingerprints agree on both sides. It walks the aligned sequence of boundaries and, at each one, checks whether both executions produced the same tensor. For most boundaries, this is a comparison of the attached fingerprints; suspected mismatches are confirmed with a one-time byte-level tensor comparison. The longest run of successful checks is the certified prefix.

This prefix yields a strong invariant: everything before that point is bitwise identical; everything after is downstream and allowed to differ for benign or faulty reasons. If both runs are supposed to implement the same computation at the reported boundary, a mismatch is strong evidence of a real fault. If instead it reflects an intentional change in the computation (*e.g.*, a different masking convention), the certified prefix still tells engineers exactly how far the two runs behave the same.

OpGuard reports the first divergent boundary together with its context, including the Python operator, stream, tensor metadata, rank, and timing information. Not all boundary differences are important. Some boundaries legitimately disagree on performance or configuration-dependent values, e.g., XPU utilization [10], peak-memory metrics, profiling buffers, RNG state [71], sliced views, padded regions, or scratch workspaces. These differences are difficult to eliminate completely with static rules, but easy for engineers to discard in the visualizer. In one major pre-training framework, engineers found only five such cases: three were padded output tensors allocated inside an operator, where the extra elements were never consumed, and two were RNG-state records whose differences stayed in framework bookkeeping while neighboring model tensors still matched. OpGuard shows the certified prefix as a marker in the timeline, the matching operators around the first divergence, the argument or output that differs, and the corresponding callstack/source location. If the mismatch is isolated

in the middle of otherwise matching neighboring operators, it is usually a false positive rather than a propagated model-state difference. Engineers can then discard the harmless tensor and, when appropriate, add a small filter rule.

5 Implementation

We implement OpGuard with 25.6K lines of code (86.7% Python, 11.3% C++, and 1.1% CUDA).

Identifying Instrumentation Sites in Source Code. Once preflight (§4.3) determines which operators to observe, OpGuard must locate the corresponding source-level sites. This step should tolerate the small, routine edits engineers make during debugging (reordering expressions, inserting print logs, extracting helpers) without new preflight run. OpGuard therefore uses a pattern-driven matcher rather than line-number tracking. For each traced operation, it re-parses the surrounding source using both abstract syntax tree (AST) and concrete syntax tree (CST). The AST captures the operator's program role (receiver, arguments, operation type), while the CST preserves syntactic structure and keeps instrumentation transparent: engineers may inspect the generated patches when desired, but routine use requires no manual confirmation.

This approach reliably identifies tensor-producing sites across diverse syntactic patterns, including fused expressions, helper-function refactorings, triton kernel launches, and in-place indexed writes. Because instrumentation is inserted statically, OpGuard preserves the framework's native dispatch and scheduling behavior, avoiding the perturbations of runtime monkeypatching. The code block in Figure 4a illustrates the resulting code-level transformations. Appendix A.2 details the matching rules and algorithms.

Runtime Trace Batching. During tracing, each rank accumulates trace records in an in-memory buffer that batches thousands of entries before flushing them to disk. This batching amortizes queue synchronization, JSON conversion, and file I/O costs. A background consumer thread on each rank then finalizes and writes each batch, offloading all heavyweight CPU work (serialization, I/O, and tensor-to-bytes conversion) from the critical GPU path. As a result, batching eliminates nearly all GPU–CPU synchronization points and reduces tracing overhead to negligible levels. Keeping `dump_mode="summary"` transfers only XOR signatures, while full tensor dumps are reserved for explicit debugging.

Distributed Trace Collection and Ordering. OpGuard collects traces on each GPU rank independently and should later assemble them into a consistent global order. Each instrumented operator thus carries two ordering metadata:

(1) *Intra-rank ordering*. Operations within rank may execute on multiple CUDA streams are completed out of submission order. OpGuard uses the GPU `%globaltimer` values recorded around each XOR kernel to derive a monotonic device-time order that respects inter-stream dependencies.

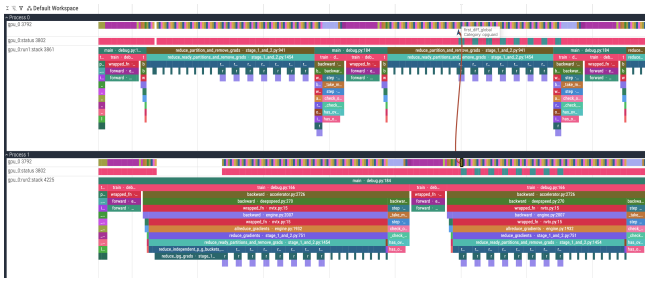

Figure 5. Perfetto visualization for Bug 21.

(2) *Inter-rank ordering*. Device clocks are not synchronized across ranks. OpGuard thus orders operators using their Python-level launch timestamps. These reflect global program order and are consistent across nodes; rank ID and per-rank sequence numbers break ties deterministically.

This lightweight scheme yields a coherent global timeline without clock synchronization or CUDA barriers. It assumes that inter-node clock skew is negligible relative to operator latencies, which in our workloads span 10^{-4}–10^{-1} seconds. Unlike Spanner [13], which uses bounded clock uncertainty to enforce consistency, our goal is diagnosis. A skewed clock can at worst misorder a few near-concurrent events and does not obscure the divergence OpGuard is designed to identify.

Trace Visualization. OpGuard exports its aligned traces to Perfetto [63], the timeline viewer used by `torch.profiler`, so engineers can inspect divergences without learning a new UI. Each GPU rank is shown as a separate lane with tracks for Python operators, kernel launches, and callstacks. Because OpGuard reconstructs a *logical* timeline, all slices are rendered with uniform width, focusing the view on ordering rather than noisy kernel durations. Aligned operators are color-coded and flow links connect corresponding slices across the two executions. This makes the first divergent boundary immediately visible and allows engineers to examine its neighborhood, jump to the source, and check whether later operations re-converge. By embedding alignment metadata and tensor signatures into Perfetto, OpGuard turns distributed tensor drift into a familiar profile-style visualization (Figure 5).

6 Evaluation

Our evaluation answers: (1) how effectively does OpGuard diagnose production failures in LLM training? (2) how accurately does it localize the first divergent operator under weakened configurations? (3) while designed for software debugging, does OpGuard help with hardware-induced SDC? (4) how robust is alignment when two executions differ in trace shape? (5) what are the coverage and runtime overheads of OpGuard across workloads and scales?

6.1 Deployment Status and Scale

OpGuard is deployed in ByteDance's production training environment and is actively used by more than **15** engineering teams across pre-training, post-training, vision–language training, heterogeneous hardware, platform, and compiler

groups. It is exercised on end-to-end model training jobs as well as compiler and kernel pipelines that introduce new fused operators and hardware-specific optimizations.

Debugging Workflow. When a run shows loss drift, nondeterminism, routing instability, or shape errors, engineers first try lightweight triage such as toggling flags, switching kernels, or bisecting the model. Cases unresolved by these approaches are escalated to OpGuard: engineers pick a reference run or configuration, replay both executions from a shared checkpoint with instrumentation, and inspect the first divergent operator in the visualizer. In this workflow, OpGuard is the *second-line* and often *final* localization tool for difficult cases.

Rollout Timeline. OpGuard was piloted within pre-training groups from Aug.–Oct. 2025, during which it was validated on real production failures and integrated with job orchestration tools. It was rolled out the broader infrastructure organizations in Nov. 2025. Adoption has since expanded across training, compiler, runtime, and platform teams. OpGuard is now routinely invoked in production debugging.

Scale and Deployment Modes. OpGuard has been applied on production jobs of up to 512 XPUs, covering diverse training pipelines. It exposes three deployment modes. In *trusted mode*, OpGuard skips a small allowlist of high-confidence primitives and instruments the remaining operators. In *full mode*, OpGuard instruments every operator boundary. Engineers use trusted mode by default for reactive two-run debugging and switch to full mode when they need complete coverage. The same debugging workflow can run either as a smaller-scale replay using fewer machines than the original job or as a targeted rerun from a shared checkpoint. The third mode, *online SDC detection* (§6.4), runs continuously alongside long-running production jobs and checks only the communication boundaries needed to identify suspect machines.

6.2 Production Failure Diagnosis

Following deployment, OpGuard has been applied on **20 production failures** escalated by engineers. We evaluate *all* cases, without filtering by reproducibility, complexity, or expected outcome. Across all cases, OpGuard quickly localized the culprit operators, reducing triage time from multi-day investigations to *minutes*. Engineers shared positive feedback after using OpGuard during incident response, *e.g.*,

> *"We had been chasing the wrong subsystem for almost a week. OpGuard showed the exact kernel in under fifteen minutes."*

> *"Without OpGuard, we would never have noticed that the drift originated in a single-row race. The loss precision is too low and gives us no clue where to start."*

Table 2 summarizes a representative subset of 11 failures with reliable engineering logs. "Manual triage" measures the time from when a ticket was opened to when engineers identified the root cause and proposed a fix. The fixes themselves are small (typically < 10 LOC), so this interval is dominated by diagnosis. The OpGuard times are coarse-grained estimates provided by engineers: the time to open OpGuard's UI, inspect the surfaced first-difference operator, and confirm its correspondence to the actual faulty region. The remaining cases are similar but lack precise timestamps. Table 3 lists the full set and the first diff OpGuard identifies.

Case Study: (Bug 1). The motivating example (Figure 1) illustrates the challenges of manual diagnosis. The underlying bug is a small race condition in a fused embedding-backward kernel that only corrupts a few floats, which were quickly diluted by gradient aggregation. We observe that the diagnosis was misled due to the lack of spatial and temporal localization. Logs offered little clue about which kernel, device, or communication path was at fault. When symptoms (gradient-norm spike) appeared, they surfaced in different training steps and downstream layers across reruns. Engineers focused debugging efforts on the forward step where the symptom showed up, while the race occurred in the previous backward step.

OpGuard pinpoints the earliest divergent operator. Across all evaluated failures, this operator lied inside the faulty kernel or its first consumer, which is precise enough for engineers to finish localization with a few quick checks such as selective gradient overrides or microbenchmarks.

In this case, when the same bug reappeared in a later run around Step 1535 instead of Step 3081, engineers did not need to identify that step manually. OpGuard surfaced the earliest boundary divergence, independent of where the symptom manifested. An early version of OpGuard did not wrap autograd-launched fused kernels, so it reported the next forward read of the corrupted embedding weights. Even this one-hop signal was decisive: adding a one-line gradient hook restored determinism, confirming `embedding_backward` as the origin. Pinpointing the fused kernel required only one additional targeted test. In current deployments, where OpGuard wraps backward kernels, it would directly report the `embedding_backward` kernel. This PyTorch kernel introduced the bug seven years ago and is in active use [74].

Case Study: (Bug 12). This case illustrates a different challenge: the first-difference boundary is precise, but the causal mechanism is non-obvious. OpGuard isolated the earliest divergence to a single `torch.scatter_` inside the expert-group repacking logic, where a one-bit SDC misrouted a token to the wrong expert group. Yet the externally visible symptom (a row-level shape mismatch in the *backward* pass) appeared unrelated to a forward-pass dispatch error, making it difficult for engineers to mentally connect the two.

What made the case tractable is that OpGuard wraps more than the first diff. After OpGuard reported the divergent scatter, engineers simply walked the trace downstream and found a shape mismatch in the expert-aggregation op roughly 30 operators later. This hop-by-hop propagation made the causal chain explicit and ruled out alternative hypotheses such

Case	Symptom	Root Cause	Manual	OpGuard
Bug 1	Loss diverges after ~3080; clean grad-norm	Racy torch.embedding backward kernel	5 days	15 min
Bug 4	Stream race in FP32 RMSNorm	CUDA stream race	5 days	5 min
Bug 9	Undeterministic backward kernel	Deterministic flag unset	3 days	5 min
Bug 10	Reduce-scatter mismatch by different nccl topology	Topology-dependent FP associativity	3 days	10 min
Bug 12	Shape mismatch on XPU pool A	Boolean scatter SDC	14 days	30 min
Bug 14	Routing drift in MoE	Histogram bin mismatch	4 hours	5 min
Bug 16	Fused embedding backward drift	Kernel race condition	8 days	5 min
Bug 17	Loss mismatch under activation offload	CUDA stream misuse	2 days	20 min
Bug 18	Backward attention drift	Triton kernel missing barrier	4 days	10 min
Bug 19	Incorrect QKV projections	Implicit contiguity assumption	5 days	5 min
Bug 20	Divergence after resume	Optimizer step var overwrite	3 days	5 min

Table 2. Subset of evaluated production bugs (full set in Table 3). OpGuard numbers are estimated debugging time provided by engineers.

as scheduling races or misconfigured parallelism. Most of the 30 min debugging time was therefore spent stress-testing the operator to confirm SDC and validating the propagation path.

False Positives. Across all 20 failures, OpGuard surfaced no false positives after initial adaptation. When first applied to a new model or backend, engineers typically encounter 2–10 benign differences arising from predictable patterns: unused padded regions [2], pinned-memory `copy_` operations that cannot be wrapped as normal kernels [72] (*e.g.*, host-to-device copies from dataloader buffers), internal helper buffers, GPU-side performance counters, or scratch workspaces with undefined contents. None affects model outputs.

Distinguishing these from real corruptions is quick: engineers confirm an FP in 2–3 minutes using OpGuard's visualizer. Each FP corresponds to a one-line filter rule; once added, the pattern never reappears for future runs on the same workflow. Because these rules accumulate over time, the FP rate quickly converges to zero.

Research Baselines. Besides the debugging tools engineers used in manual debugging, we evaluate four research solutions: DeepLocalize [89], DeepDiagnosis [88], DeepFD [9], and TTrace [34]. The first three systems are state-of-the-art for single-device architectural or hyperparameter bugs [32, 48], but they detect only 2 of 20 cases (Bug 3 and Bug 15). These are the only incidents whose root causes manifest as deterministic, single-layer faults in a standard computational graph (the failure model these tools are designed for).

TTrace is the closest prior system performing differential *numerical* comparison. It targets distributed training but relies on (1) a trusted single-device reference, (2) threshold-based numerical comparison, and (3) deterministic operator replays. Only 4 of our 20 cases have a native single-GPU path; for the others, we supply a multi-device reference via our deterministic replay to give TTrace the most faithful possible environment.

Under this adapted setup, TTrace successfully flags 11 cases. Its blame windows, however, remain coarse (on average 6.91 modules and 45.64 kernels), and it fails on all cases involving extremely small corruptions, nondeterministic kernels, or intermittent multi-stream races. These limitations stem from TTrace's perturbation-based calibration: numerical deviations smaller than the learned perturbation envelope are treated as benign, causing small drifts from bugs to be missed or attributed far downstream. In cases such as Bug 9 and Bug 16, only a few floating-point entries in a gradient shard were corrupted before being attenuated by reductions-well below TTrace's detection threshold. Moreover, TTrace's heavy tensor-dump instrumentation perturbs execution enough that some bug races become harder to reproduce.

6.3 Open-source Bug Diagnosis

We further evaluate OpGuard on 10 real open-source issues drawn from Megatron-LM, DeepSpeed, GPT-Neox, and HuggingFace Transformers. [4, 21, 79, 90] These cases span kernel nondeterminism, stream-ordering races, MoE dispatcher inconsistencies, and cache-management faults, etc. For each issue, we build the comparison from the smallest reproducer available in the public report: the reference is either a self-replay, a known-good configuration, a single-GPU/TP-simulator run, a stable library version, or an equivalent API or framework path. Both executions use the same inputs, seeds, and checkpoint when applicable, and OpGuard establishes alignment by retaining only model-level boundaries observed in both traces. OpGuard successfully produces a precise first-difference operator for 8 of 10 cases, including four long-standing unresolved issues where prior discussions had converged on incorrect or incomplete explanations. The surfaced operators, as summarized in Table 4, directly identify the corrupted tensor or boundary and map cleanly to the underlying faulty kernel, cache rule, or collective implementation. The remaining cases, where OpGuard does not yet apply cleanly, are discussed in §7.

6.4 Silent Data Corruption (SDC) Detection

OpGuard initially targets software-level correctness faults. Once deployed at scale, we observed a useful side effect: the same tensor-consistency checks that localize software bugs also surface silent data corruptions in hardware. When a single device begins producing inconsistent tensors, OpGuard flags

that divergence just like any other bug, and the first-difference report naturally attributes the fault to a specific computation or communication operator on that device. This operator-level attribution is valuable for subsequent vendor diagnostics, which typically only report that a card is "unhealthy" without identifying which workload or kernel exposes the fault.

We evaluate this emergent capability of OpGuard in its online and offline SDC-detection modes. In *online* mode, it runs alongside long-running production jobs and isolates suspect machines as soon as inconsistencies are observed. In *offline* mode, it replays training traces and pinpoints the exact operation where divergence first occurs. Throughout our evaluation, we compare OpGuard against the existing production baseline of vendor-provided device health checks (*e.g.*, NVIDIA's EUD [53], AMD's ROCm Validation Suite (RVS) [1], and analogous pre-flight diagnostics on other accelerators). These checks are executed *before* a training job is officially launched, and a machine is removed from service only if one of these diagnostics reports an error. Machines that pass these vendor diagnostics are considered healthy and are eligible to run large-scale training workloads.

To date, OpGuard has detected *21 distinct SDC machines* that all successfully passed these pre-flight health checks. In other words, these 21 machines were invisible to the baseline but were flagged by OpGuard during actual training. Each detection was subsequently validated through targeted stress testing and on-device EDC (error detection/correction) verification [100], and the confirmed faulty hardware was reported to engineers for further diagnosis and remediation.

6.5 Ablation Study

We evaluate how OpGuard components affect localization. For each production case, we compare the full configuration's localization index i_{full} with an ablated variant i_{abl}, reporting $\Delta\text{ops} = i_{\text{abl}} - i_{\text{full}}$. Thus $\Delta\text{ops} = 0$ means identical localization, while positive or negative values indicate later or earlier detections. Operators are globally ordered using machine and GPU timestamps.

We study five settings: (1) reducing instrumentation to 40 manual probes; (2–3) removing determinism controls and applying numerical tolerances of 10^{-5} and 10^{-3}; (4) replacing the XOR signature with a scalar `sum`; and (5) using a synchronous tracer that inserts global device synchronizations.

Figure 6 summarizes the results. Each column shows the twenty bugs under a different ablation, with markers indicating Δops clipped to $[-20, 20]$. The value above each column reports how many bugs remain perfectly localized ($\Delta\text{ops} = 0$).

We make three findings. First, reducing instrumentation severely degrades localization: only 2/20 bugs remain pinpointed, and many detections drift by tens of operators. Second, removing determinism controls substantially increases drift, especially at tolerance 10^{-3}, which yields only 7/20 exact localizations and several large outliers. Third, sum-based checking appears to work on easier cases but misses

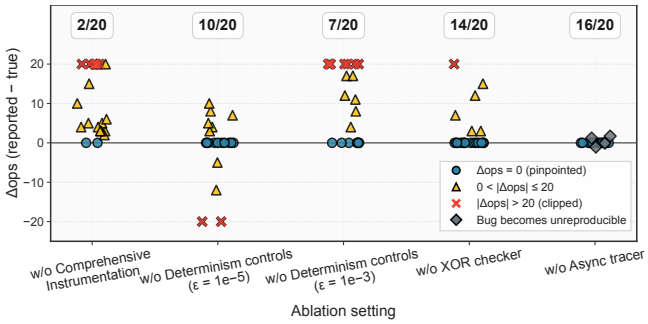

Figure 6. Localization regression under ablations.

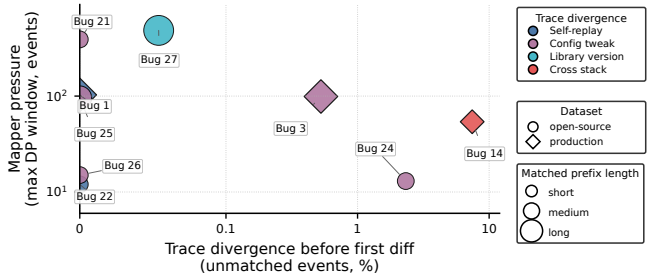

Figure 7. Alignment remains robust under real trace divergence.

subtle one-token or one-bit corruptions, leading to delayed detections; only 14/20 bugs remain precisely localized. The synchronous tracer preserves 16/20 cases but causes four bugs to become unreproducible due to perturbing concurrency.

6.6 Alignment Robustness to Trace Divergence

The mapper (§4.5) targets aligning executions that are comparable but typically do not produce identical traces due to fused kernels, helper operations, or local schedules. We evaluate whether the mapper can tolerate these differences and still identify the expected first-difference operator.

We sample nine paired traces: three production replays and six open-source replays. The sample covers self-replay, configuration tweaks, library-version changes, and cross-stack comparisons. For each pair, we evaluate alignment only over the comparable prefix preceding the expected first difference. This excludes subsequent divergence caused by the bug itself.

We measure alignment difficulty in three ways: (1) *trace-length ratio* captures the difference in event counts between the two comparable prefixes; (2) *unmatched-event fraction* measures the fraction of boundary events that the mapper classifies as insertions or deletions; (3) mapper pressure, measured as *maximum DP window*, the largest region that the mapper must align after partitioning the traces with anchors. A large window indicates that anchors are sparse or ambiguous, forcing the mapper to solve a harder local alignment problem.

Figure 7 relates the unmatched-event fraction to the maximum DP window. Marker shape distinguishes production and open-source traces, color denotes the source of trace divergence, and marker size denotes matched-prefix length.

The mapper reaches the expected first-difference operator in *all nine trace pairs*. Figure 7 shows that real trace divergence

is present but remains alignable. The median trace-length ratio is 1.005×, and the largest is 1.048×. The median unmatched-event fraction is 0; seven of nine cases are below 2.4%. Bug 14 has the largest fraction, 7.43%, but the mapper still identifies the expected first difference.

Anchor construction keeps the alignment problem local. The median anchor density is 15.1% (minimum 9.5%), and the median maximum DP window is 96 events. Two open-source pairs require larger windows (390 and 484 events), but these remain small relative to traces containing thousands of events.

The traces show two trends. First, production traces require smaller DP windows than open-source traces (54–103 events versus wider outliers). This matches our experience: their custom kernels and fused model-level operators often serve as distinctive anchors, whereas open-source framework traces contain longer sequences of generic operations such as `view`, `copy_`, `linear`, and helper bookkeeping calls. Second, unmatched events tend to increase as the two executions' implementations differ more: self-replay has little, configuration and library changes add localized gaps, and the cross-stack case has the largest unmatched fraction.

6.7 Aligned Coverage

A runtime tracer is only useful if it *sees* the kernels where failures occur. If a CUDA kernel is missing from the trace, any bug inside that kernel may be incorrectly attributed to its neighbors, sending engineers to debug the wrong part of the program. We therefore evaluate *aligned kernel coverage*: the fraction of profiler-recorded CUDA kernels that OpGuard associates with a model-level operator.

To measure this, we run each workload with OpGuard under `torch.profiler`, which provides the full set of kernels launched during the step; OpGuard's trace contains kernel slices grouped by high-level ops. Coverage is the fraction of baseline kernels that appear inside a OpGuard operator boundary. We evaluate eight training pipelines spanning LLM pretraining (with and without `torch.compile` [5]), VLM pretraining [75], RL actor/critic/rollout training [36], and two open-source systems (Megatron [79] and VERL [78]). These capture both eager and graph-based execution modes.

Across all workloads (Figure 8), OpGuard achieves at least 95% aligned kernel coverage, with many workloads reaching 98%–100%. The remaining small gaps mainly occur when a single Python source line launches multiple CUDA ops; OpGuard attaches one probe per line, so only the first launch is tagged. These launches occur contiguously in practice and do not affect localization: the divergence boundary still lands on the correct kernel or its immediate consumer.

6.8 Practicality and Overhead

Figure 9 reports the runtime overhead of OpGuard across pretraining and RL workloads from 8 to 512 XPUs. Online SDC detection adds effectively no cost (≈ 1.00×–1.01×); trusted mode incurs ≈ 1.25×–1.45× overhead; and full mode costs

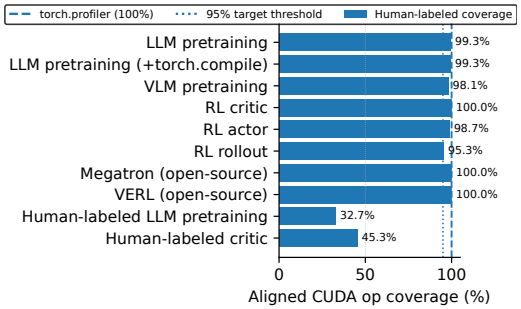

Figure 8. Aligned kernel coverage of OpGuard across workloads.

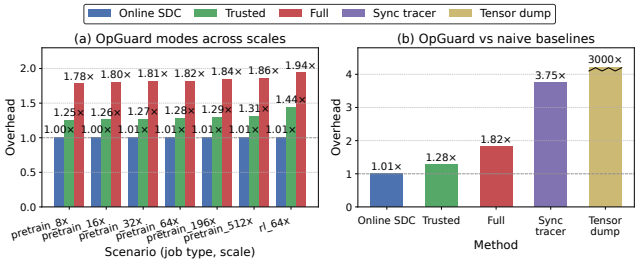

Figure 9. Runtime overhead under different deployment modes.

≈ 1.8×–1.95×. RL workloads show slightly higher slowdowns because they contain more inference- and control-heavy paths where checker kernels amortize less, but overhead is essentially flat with scale. Figure 9(b) further shows that even OpGuard's full mode is far cheaper than conventional debugging: a global-sync tracer slows training by ≈ 3.75×, and full tensor dumping would impose an infeasible ∼ 3000× cost.

The overhead gap follows from the amount of instrumentation each mode enables. Online SDC detection checks sparse communication boundaries, so its added XOR kernels are tiny compared with the data already in flight. Trusted mode avoids many checker launches on high-confidence primitives such as GEMMs and basic elementwise ops, which would otherwise dominate runtime; this balance makes it our standard configuration for production debugging. Full mode pays more for exhaustive operator coverage and is mainly used for stubborn or deeply latent bugs.

7 Discussions

Engineers consistently emphasized that precise, operator-level evidence is what accelerates debugging. Ambiguous signals rarely justify deep investigation. OpGuard's concrete divergence boundary provides such evidence. While fully automated debugging is ideal, engineers also noted that the first-diff localization is typically sufficient: once OpGuard surfaces the earliest corrupted tensor or kernel, they can reason about the root cause using their own domain expertise.

OpGuard relies on the two executions sharing a comparable model prefix: they must reach the same model-level boundaries with the same logical inputs, RNG choices, numerical policies, and distributed reduction rules. If a bug occurs before this prefix, or a version change intentionally changes one of these contracts, OpGuard can only report the earliest

downstream operator both executions reach in a comparable way. In Bug 29, for example, an early preprocessing regression changed model inputs, so the first alignable model operator was already affected. Such cases arise mainly from implementation differences in high-level preprocessing rather than faults in the model or runtime layers OpGuard targets.

Downscaled replay also changes the execution environment. Reducing a job from thousands of machines to hundreds may remove the faulty device that exposed an SDC, and smaller runs often create different memory pressure, allocator behavior, and scheduling. We observed this in one SDC incident: the failure appeared in a 1024-machine production run but did not reproduce in a 512-machine replay because the replay excluded the faulty machine. Thus, downscaled replay is best viewed as a debugging accelerator when the bug still reproduces, not a proof that a bug is absent. If the replay no longer reaches a comparable divergent execution, OpGuard cannot localize or explain that particular fault.

8 Related Work

Bug Detection and Monitoring for ML Training. Empirical studies have shown the prevalence of bugs and reliability issues in ML training [26, 31, 37, 93, 94, 97], which motivate work to detect bugs. Differential-testing tools [41, 62, 64, 92] expose inconsistencies in models, libraries, and compilers. Specialized analyzers such as PyTea [33], RANUM [37], and CUDASanitizer [54] aim to catch shape, numerical, or concurrency defects. TrainCheck [35] learns invariants to monitor training and detect silent errors at runtime. These solutions focus on detection and not diagnosis.

Fault Localization in ML Programs. Other work aims to diagnose faults by identifying specific model components or code regions responsible for erroneous behavior. DeepLocalize [89] correlates runtime metrics with suspicious layers. DeepDiagnosis [88] infers fault types and localizes them to model components or configuration issues. DeepFD [9] learns classifiers over rich runtime features to predict fault types and link them to faulty source statements. UMLAUT [76], Theia [45], and NeuraLint [49] combine structural analyses with behavioral signals to detect architectural defects or hyperparameter issues, while neuron/operator ranking methods [25] inspect trained models for internal inconsistencies. These approaches operate primarily at the framework or Python-operator level and assume single-node training environments.

Equivalence Checking. TrainVerify [43] uses symbolic reasoning to verify a parallel execution plan is mathematically equivalent to its single-device logical definition. It targets statically eliminating parallelization related bugs, and does not concern implementation or runtime behavior. TTrace [34] records full intermediate tensors and compares them numerically against a trusted single-device reference implementation. Such recording incurs high overhead and the tolerances its comparisons rely on are brittle. OpGuard targets debugging large-scale LLM training. It uses two production executions rather than requiring a single-device reference, which is often unavailable for large models. OpGuard introduces bitwise alignment and controls nondeterminism, while designing techniques to make the alignment robust across production-grade optimizations such as fusion, asynchrony, and graph capture.

Comparative Debugging. OpGuard builds on a long tradition of comparative debugging. Delta debugging [95] and related techniques isolate the root cause to a failure-inducing input or change, a cause-effect chain [96], a statistically suspicious predicate [38], or instruction sequence [99]. OpGuard shares the same high-level principle. Its contribution is to make this strategy precise for LLM training, where executions are expensive, tensor states are enormous, benign nondeterminism is pervasive, and implementation traces differ significantly. It introduces bitwise alignment with stable model-level boundaries, exact tensor equality, and certified-prefix localization.

Deterministic Replay. Deterministic multithreading [6, 7, 14–16, 42, 46, 47] and replay [3, 23, 30, 58, 61, 85] make conventional software executions reproducible by controlling thread schedules, synchronization, system-call results, and external inputs. These systems inspired OpGuard's use of controlled nondeterminism, but their goals differ. They seek to constrain whole executions by imposing strict scheduling discipline. In production LLM training, full-stack deterministic scheduling is rarely practical: it can impose high overhead and is fragile across heterogeneous hardware, libraries, drivers, compilers, *etc.* OpGuard instead controls only the sources of variation that would make bitwise alignment ill-posed while leaving residual schedule-sensitive behavior visible as a bug signal.

9 Conclusion

Debugging correctness issues in LLM training is notoriously difficult. We propose bitwise alignment as a precise correctness oracle and debugging primitive for addressing this challenge. We realize the ideas in OpGuard, which controls avoidable non-determinism, discovers semantic-stable boundaries, fingerprints them, and uses schedule-tolerant alignment with prefix certification to surface the divergence. OpGuard has been deployed across production pre-training and post-training pipelines, and helped engineers debug various difficult failures, reducing debugging time from days to minutes.

A Implementation Details

A.1 Preflight Operator Capturing

This appendix describes the mechanisms used by OpGuard to capture both semantic operator intent and concrete device execution.

Python-Level Monkeypatching. At the semantic layer, OpGuard instruments high-level tensor operations by wrapping relevant Python callsites through dynamic monkeypatching. This unified mechanism subsumes multiple pathways, including `__torch_dispatch__` and Triton's `JITFunction.run`, ensuring that all user-visible tensor operators—including custom Triton kernels—are intercepted before reaching the runtime.

Each intercepted call records the operator name, tensor metadata, argument summaries, and the Python callstack. This provides lightweight, framework-agnostic attribution to user code while introducing negligible overhead.

CUPTI: Comprehensive Device-Level Visibility. CUPTI (CUDA Profiling Tools Interface) supplies a stream of GPU activity records, including kernel launches, memory transfers, and synchronization events. These callbacks reveal exactly which kernels execute on the device, independent of Python semantics, fusion decisions, or scheduling.

However, CUPTI callbacks run asynchronously inside CUDA driver threads, which makes Python callstack collection unreliable—the interpreter may have already advanced beyond the callsite that triggered the kernel. Moreover, CUPTI callbacks can occasionally interact poorly with internal driver threads, creating rare reentrancy or deadlock hazards.

Despite these limitations, CUPTI is the default backend in OpGuard because it provides nearly exhaustive device-level visibility with minimal runtime interference.

CUDA API Interception: Safe Fallback Path. When CUPTI is unsafe or unavailable, OpGuard falls back to intercepting CUDA runtime and driver APIs such as `cudaLaunchKernel`, `cuLaunchKernel`, and `cublasLtMatmul`. This mechanism captures every kernel launch along with its stream and device association, and is highly robust even in applications that create custom CUDA contexts or employ heavy multithreading.

The tradeoff is wrapper completeness: new kernels introduced by vendor or third-party libraries must be added to the wrapper registry to maintain coverage.

Portability. For NPUs and other emerging XPU architectures, we are implementing analogous backends that expose kernel-launch activity streams comparable to the CUDA mechanisms above. All backends conform to the same operator–execution attribution model, keeping the upper layers of OpGuard hardware-agnostic.

A.2 Instrumentation Recognition

Extraction of Instrumentation Entries. For each operator recorded during preflight tracing, OpGuard re-parses the corresponding source file using both the abstract syntax tree (AST) and the concrete syntax tree (CST). The recognizer identifies the smallest AST node representing the operator and emits an `InstrumentationEntry` containing:

- operator form (call, assignment, augmented assignment, subscript write);
- symbol and attribute names;
- structural tags (receiver, argument shapes, keyword structure);
- metadata propagated from runtime traces (kernel symbols, stream IDs).

Entries represent all potential instrumentation sites surfaced during preflight, including user-defined operators, Triton kernels, and implicit tensor writes.

Signature-Based Matching. To locate instrumentation sites robustly across minor code edits, OpGuard performs tag-based signature matching. Rather than relying on fixed line numbers or function names, the recognizer compares extracted syntax tags against a library of operator templates using weighted-overlap scores. Tags include operator category, argument structure, receiver patterns, and indicator variables associated with device-kernel launches. The highest-scoring template determines which operator is being instrumented.

This matching model tolerates refactorings such as helper-function extraction, expression rewrites, and reordering of arguments, while still identifying the semantically correct operator.

Specialized Structural Patterns. Some operator forms require dedicated handling. Here are the two main cases:

- Triton kernels: The recognizer identifies Triton-style launches of the form `kernel[grid](...)` using structural cues such as grid blocks, pointer-style arguments, Triton-specific meta-arguments, and runtime correlation with kernel symbols.
- Indexed writes: Assignments such as `x[i] = v` are treated as in-place updates (e.g., `index_put`). The recognizer rewrites these sites into small shims that route through controlled OpGuard instrumentation while preserving evaluation semantics.

A.3 Window Alignment Algorithm

Algorithm 1 gives the dynamic program used inside each anchor-bounded alignment window. Anchor construction and the rescue pass are described in Section 4.5; the algorithm below focuses on the local monotone matching step.

Algorithm 1: AlignWindowDP($F_1[i_0..i_1], F_2[j_0..j_1]$)

Input: Two sequences of boundary events $F_1[i_0..i_1]$ and $F_2[j_0..j_1]$.
Output: Matches, a monotone, non-crossing set of pairs.
Initialize DP table $D[u, v]$ for $u \in [i_0..i_1], v \in [j_0..j_1]$.
Constrain the band: only fill entries with $|(u - i_0) - (v - j_0)| \le b$.
for $u \leftarrow i_0$ ***to*** i_1 **do**
  for $v \leftarrow j_0$ ***to*** j_1 **do**
    if $|(u - i_0) - (v - j_0)| > b$ **then**
      continue
    `// Skip, match, or gap`
    $s_{\text{match}} \leftarrow D[u{-}1, v{-}1] + \text{score}(F_1[u], F_2[v])$
    $s_{\text{gap1}} \leftarrow D[u{-}1, v] + \text{gap}$
    $s_{\text{gap2}} \leftarrow D[u, v{-}1] + \text{gap}$
    $D[u, v] \leftarrow \max\{s_{\text{match}}, s_{\text{gap1}}, s_{\text{gap2}}\}$
Backtrack from (i_1, j_1) to (i_0, j_0), collecting pairs (u, v) where the transition chose score$(F_1[u], F_2[v])$.
return Matches

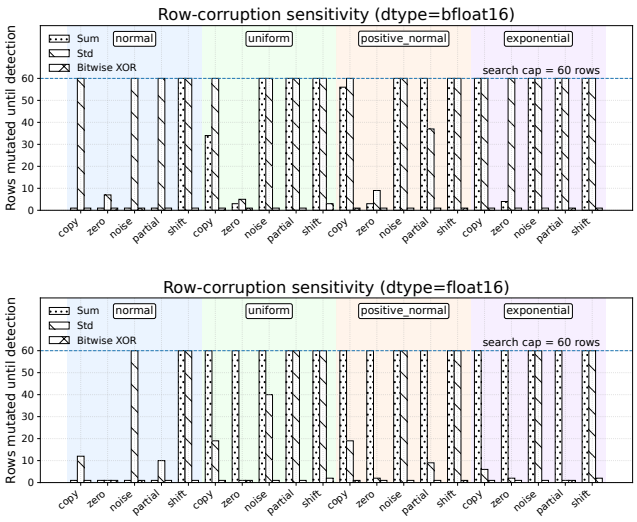

Figure 10. Sensitivity of the XOR fingerprint under row-level corruptions in `bfloat16` and `float16`.

A.4 XOR Fingerprints

To determine whether two tensors are bitwise identical, OpGuard employs a constant-size *XOR fingerprint*: a deterministic reduction over the raw byte stream of the tensor. Given a contiguous byte array $\{b_1, \ldots, b_N\}$, the fingerprint is

$$\text{XOR}(b_1, \ldots, b_N) \;=\; b_1 \oplus b_2 \oplus \cdots \oplus b_N.$$

Kernel implementation. At each instrumented Python or CUDA op, OpGuard launches a custom CUDA reduction on the same stream as the operator. The kernel processes the tensor in coalesced 4-byte lanes, reducing to a 32-bit signature in a single pass. If the total byte count is not a multiple of four, the remaining 1–3 bytes are padded with zeros to form the final word, ensuring identical semantics to the CUDA kernel. XOR is order-insensitive, precision-agnostic, and flips on *any* bit change. Runtime is on par with native `torch.sum/mean` and typically below `torch.std`, imposing negligible overhead. The CPU fallback follows the same rule by packing the byte stream into 4-byte words (zero-padding any leftover bytes) and XOR-reducing them.

Sensitivity. Across all tested tensor precisions (FP32, BF16, FP16), value distributions (normal, uniform, positive-normal, exponential), and corruption modes (full-row overwrite, partial overwrite, small-noise injection, circular shifts), fingerprints diverge after only *1–2 corrupted rows* (Figure 10). A single-bit flip always flips the fingerprint. In contrast, numeric summaries (e.g., sum, mean, variance) frequently require tens to hundreds of corrupted rows to manifest detectable changes, particularly under low-precision formats where numeric cancellation is common.

Known blind spots. XOR is intentionally a lightweight fingerprint rather than a cryptographic hash, and it inherits XOR's algebraic blind spots. In particular, it is insensitive to byte order: a pure permutation of tensor contents, such as swapping two rows, preserves the fingerprint. More generally, structured changes can cancel when the byte-level differences XOR to zero, for example two identical corruptions introduced an even number of times. We consider this acceptable for OpGuard's operating point for three reasons. First, the production failures we target are silent value corruptions, stale reads, missed writes, precision/path regressions, and communication inconsistencies, all of which typically introduce non-canceling byte changes at the first faulty boundary. Second, OpGuard records shape, dtype, device, rank, stream, and boundary identity alongside the fingerprint, so XOR is not used to validate semantic reordering or layout changes in isolation. Third, the constant-size XOR kernel is cheap enough to run continuously at many boundaries; replacing it with a stronger order-sensitive hash would reduce coverage or increase perturbation. When a bug hypothesis is specifically permutation-sensitive, OpGuard can rerun that small region with full tensor dumps or a stronger checker, but this has not been needed for the cases in our study.

Collision probability. As a linear map $\{0,1\}^{8N} \to \{0,1\}^{32}$, XOR admits collisions in principle, but only when the two tensors differ by a byte vector whose XOR reduces exactly to zero. For random corruptions, the probability is 2^{-32} (2^{-64} for a 64-bit variant), negligible relative to typical sources of training noise. No collision was observed in millions of trials.

False positives and negatives. False positives cannot occur because the fingerprint is deterministic and purely byte-based. False negatives require two distinct tensors to reduce to the same XOR value, which for random corruptions occurs with the same 2^{-32} probability noted above. A more subtle structural false negative may arise only when a tensor contains a permutation or *deliberate, perfectly duplicated byte sequences*

that appear an even number of times, allowing their contributions to cancel. We observed the latter once while diagnosing Bug 29, where the model carried two identical embedding tables for interface uniformity. Such duplication does not arise in optimized production or open-source training pipelines.

Precision-independence and practicality. Because the fingerprint operates directly on raw bytes, its sensitivity is invariant to the tensor's numeric precision and underlying distribution. The overhead consists of two small reduction kernels per operator boundary ($\approx 0.8\times$–$\approx 1.1\times$ the cost of `torch.sum`), making the method suitable for continuous use over multi-day runs.

A.5 Practical Determinism Controls

The main paper summarizes the control surfaces that make bitwise alignment well-defined. This section records the concrete knobs we use in practice. These controls are lightweight and do not alter model semantics or disable core optimizations.

Controlled randomness and initialization. We set consistent seeds for CPU and CUDA RNGs [71], dropout streams, and dataloader workers [67], and use deterministic distributed initialization so that all ranks construct identical parameters and mini-batch sequences [66].

Deterministic kernel and library behavior. Reproducible kernel selection is achieved with `torch.use_deterministic_algorithms`, deterministic cuDNN modes, disabled autotuning, and TF32 disabled (`torch.backends.cuda.matmul.allow_tf32 = False`) [70]. For cuBLAS, setting a fixed workspace configuration (e.g., `CUBLAS_WORKSPACE_CONFIG=:16:8`) prevents stream-dependent workspace choices and keeps accumulation order stable. cuBLAS reproducibility also assumes the same toolkit version, GPU architecture, and SM count across runs; multi-stream use requires either a user-provided workspace or `CUBLAS_WORKSPACE_CONFIG` [51].

Deterministic attention and MoE operations. Certain fused attention and MoE kernels vary in reduction order or token grouping. We select deterministic variants using internal control flags that enforce stable indexing and stable accumulation patterns, preventing kernels that compute the same math but use unstable internal scheduling or reduction orders from causing bitwise drift.

Deterministic collectives. Floating-point collectives must follow the same reduction tree. We therefore pin the collective algorithm, protocol, and topology so that partial sums are accumulated in an identical order across runs. [56] Residual divergence under fixed topology indicates a true correctness fault or silent data corruption (SDC) (Bug 10 and Bug 12).

Checkpoint-resume determinism. To resume bitwise-identically, all parallel ranks restore their RNG states, optimizer state, dataloader position, and scheduler counters. With complete restoration, a resumed run continues bitwise from saved prefix.

Bitwise Comparability Across Parallelism. We also achieve bitwise comparability across different parallelism degrees, including internal and open-source Megatron-style tensor parallelism (TP). Because standard TP changes arithmetic order via tensor sharding and parallel reductions, we introduce a *TP-simulator mode*:

- The logical TP size remains > 1, but each rank executes the full, unsharded computation: embeddings, attention projections, activations, and logits are replicated locally.
- Standard TP modules (vocab-parallel embedding, column-/row-parallel linear layers, dot-product attention, and parallel cross-entropy) are replaced with virtual TP layers that avoid scattering, reconstruct full inputs on each rank, and use collectives only as numerical no-ops.
- Parameter shapes, padded vocabulary sizes, and RNG streams are overridden to match the TP$= 1$ configuration.
- Optimizer-side reductions (e.g., gradient-norm all-reduce and distributed parameter synchronization) are routed through degenerate single-rank paths.

Under this mode, all ranks observe identical inputs, parameters, gradients, and updates, yielding training trajectories that are bitwise identical between TP$= 1$ and virtual TP. This enables OpGuard to compare executions across different parallelism settings without conflating arithmetic reordering with faults (Bug 23).

B Diagnosed Cases

B.1 Production Cases

Detailed diagnoses for the 20 production failures are summarized in Table 3, highlighting symptoms, root causes, and the precise operator boundary where OpGuard first detects divergence.

B.2 Open-source Cases

Detailed diagnoses for the 10 open-source issues are summarized in Table 4, showing how OpGuard isolates the earliest semantic boundary that diverges across implementations.

ID	Category	Symptom	Root cause	First diff	Reference run	Scale	Step at 1st diff
Bug 1	Kernel race	Loss jump after ~3080; clean grad-norm	Racy fused embedding-bwd kernel	Embedding-bwd grad	Self	Full	3080
Bug 2	Kernel nondet	NaNs; fwd/recompute mismatch	Nondet varlen Flash-Attn kernel	Attn fwd/recompute	Self	Full	1
Bug 3	Recompute bug	Mismatch on long sequences	Missing transpose in recompute path	Post-recompute act.	Config tweak (`recompute=False`)	Down	1
Bug 4	Stream ordering	Run-to-run expert drift	Input format conversion races default stream	Expert input	Self	Full	35
Bug 5	RoPE impl mismatch	Early attention drift	Mixed PyTorch/CUDA RoPE impls	RoPE output	Config tweak (`rope_backend=pytorch`)	Down	1
Bug 6	Dtype drift	Small reproducible loss drift	Different bf16 cast points in MTP norm	MTP norm	X-stack (>10k LOC)	Down	1
Bug 7	Optimizer impl	Loss drift across stacks	PyTorch vs. fused AdamW accumulate differently	Post-optimizer weights	X-stack (>10k LOC)	Down	1
Bug 8	State overwrite	Loss drift after EMA validation	Validation overwrites tensors reused by training	Next-step params	Config tweak (`ema_validation=False`)	Down	1
Bug 9	Kernel nondet	Inconsistent attn gradients	Deterministic flag disabled in bwd kernel	Attn bwd output	Self	Down	1
Bug 10	Collective topology	Node-type-specific loss drift	Different NCCL tree leads to different FP reduction order	Reduce-scatter	Self (same Python stack, NCCL/top differs)	Full	1
Bug 11	Recompute bug	Recompute ≠ forward (bitwise)	Wrong microbatch index + mismatched cast order	Early recompute act.	Config tweak (`recompute=False`)	Down	2
Bug 12	Hardware SDC	Rare MoE shape crash (pool A only)	Boolean scatter flips 1 bit on some XPUs	Router mask	Self	Full	4232
Bug 13	Hardware SDC	Same MoE crash on pool B	Same scatter op shows low-freq SDC	Router mask	Self	Full	4955
Bug 14	Config mismatch	Divergence from MoE layer 2	Histogram bin count inconsistent across stacks	Histogram output	X-stack (>10k LOC)	Down	1
Bug 15	Init bug	Immediate drift	Pad-token embedding not zeroed	Padded-token embedding	X-stack (>10k LOC)	Down	1
Bug 16	Kernel race	Deterministic drift at fixed step	Shared-mem read before sync in custom kernel	Embedding-bwd grad	Self	Down	220
Bug 17	Offload misuse	Small persistent drift	GPU upload races default stream	Reloaded activation	Stable (310 LOC)	Down	1
Bug 18	Kernel race	Occasional bwd NaNs / drift	Triton bwd uses shared mem before barrier	Attn bwd output	Self	Full	95
Bug 19	Layout assumption	Attention drift after minor schedule change	Fused QKV kernel assumes contiguous input	QKV projection	Stable (260 LOC)	Down	1
Bug 20	Checkpoint bug	Resume diverges instantly	Name collision zeroes optimizer step tensor	Optimizer step tensor	Config tweak (`checkpoint=False`)	Full	1

Table 3. Summary of 20 production failures diagnosed using OpGuard. The table reports the first divergent tensor, the reference run used for comparison, replay scale, and the training step where the first mismatch appeared. Reference runs are grouped as self-replay (Self), last stable commit (Stable), configuration tweak, or cross-stack comparison (X-stack); parenthesized LOC counts are approximate code differences.

ID	Category	Symptom	Root cause	Reference run	OpGuard first diff
Bug 21	Stream race	Inconsistent loss when overlap-comm is set to true	Race between default stream and reduction stream	Config tweak (`overlap_comm=False`)	Modified tensor on the reduction stream
Bug 22	Kernel bug	Non-deterministic model outputs with context length 1	Kernel implicitly use the cached states	Self-replay (same input)	Wrong kernel output
Bug 23	TP consistency	Tensor parallelism produces divergent loss	Diff padded vocab size in diff TP size	Single-GPU TP simulator	Padded vocab
Bug 24	Collective op impl	Precision issue caused by different token dispatchers in MoE training	Diff calculation impl between alltoall and allgather	Config tweak (AllGather dispatcher)	Backward output grad
Bug 25	Stream race	Deepspeed overlap-comm data race	Race between default stream and reduction stream	Config tweak (`overlap_comm=False`)	Corrupted tensors caused by race
Bug 26	Kernel bug	Non-deterministic inference with customized injected kernel	Incorrect offset when slicing the workspace	Config tweak (kernel inject off)	Diff tensor directly after the wrong kernel
Bug 27	Impl mismatch	Different vision embedding outputs across different library versions	Numerical implementation lead to diff rounding order	Stable library version (>5K LOC)	Patch coordinate grid
Bug 28	Cache bug	Qwen-2-VL generates inconsistent logits between generate and call	Cached RoPE deltas not reset when the cache is None	API path (`mode=generate`)	Get-rope-index output
Bug 29	Init bug	Accuracy regression across diff versions	Position id prepared wrong	Stable library version (>5K LOC)	Vision patch emd output
Bug 30	Init bug	Inconsistent loss between DeepSpeed and DDP on single GPU	Perform an extra step when init optimzier	Cross-stack DDP	Diff loss

Table 4. Summary of 10 open-source issues evaluated using OpGuard. The reference column reports the run or configuration used for alignment; the first eight cases produced precise first-difference operators, while the last two expose current alignment limits.

RobustRL: Role-based Fault Tolerance System for RL Post-Training

Abstract

RL post-training for LLMs has been widely scaled to enhance reasoning and tool-using capabilities. However, RL post-training interleaves training and inference workloads, exposing the system to faults from both sides. Existing fault tolerance frameworks for LLMs target either training or inference, leaving the optimization potential in the asynchronous execution unexplored for RL. Our key insight is role-based fault isolation so the failure in one machine does not affect the others. We treat trainer, rollout, and other management roles in RL training as distinct distributed sub-tasks. Instead of restarting the entire task in pretrain robust system ByteRobust, we recover only the failed role and reconnect it to living ones, thereby eliminating the full-restart overhead including rollout replay and initialization delay.

We present RobustRL, the first comprehensive robust system to handle GPU machine errors for RL post-training ETTR (Effective Training Time Ratio) improvement via a *Detect-Restart-Reconnect* paradigm. (1) *Detect*. We implement role-aware monitoring to distinguish actual failures from role-specific behaviors to avoid the false positive and delayed detection. (2) *Restart*. For trainers, we implement a non-disruptive recovery where rollouts persist state and continue trajectory generation, while the trainer is rapidly restored via rollout warm standbys. For rollout, we perform isolated machine replacement without interrupting the RL task. (3) *Reconnect*. We replace static collective communication with dynamic, UCX-based (Unified Communication X) point-to-point communication, enabling immediate weight synchronization between recovered roles. In an RL training task on a 256-GPU cluster with Qwen3-8B-Math workload under 10% failure injection frequency, RobustRL can achieve an ETTR of over 80% compared with the 60% in ByteRobust and achieves 8.4%-17.4% faster in end-to-end training time.

1 Introduction

Reinforcement Learning (RL) has emerged as a transformative paradigm for post-training LLMs (Large Language Models) [2, 6, 32], where the week-level [24] and 200K GPUs large-scale [80] RL training has been deployed to enhance their reasoning and tool-using capabilities through iterative policy optimization [57,59,85]. State-of-the-art models [7,24,52,63,64,80] all leverage RL post-training to achieve superior performance in complex tasks [91], such as mathematics [50], code generation [30,42], and search [31] *et al.*.

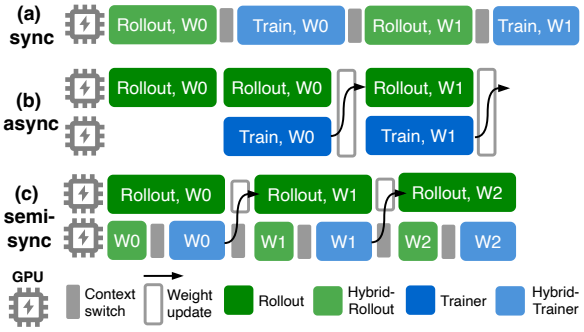

Figure 1: Different RL training architectures. The GPU role includes trainer, rollout and hybrid (colocate the both).

Unlike traditional LLM pre-training [19, 29, 73] or serving [34,62,75,81] workloads, RL post-training comprises two phases: rollout (generation and tool interaction) and training, where they contribute close to 100% and 70% post-training time in reasoning tasks and tool learning tasks [60]. To mitigate the long-tail latency inherent in the rollout phase, RL training frameworks have evolved from synchronous architectures that co-locate rollout and trainers [26, 43, 61, 84, 90] in Figure 1(a) to asynchronous designs [16, 25, 60, 77, 89, 93] in Figure 1(b) and (c). These include async mode with dedicated standalone rollouts and trainers, as well as semi-sync mode [7, 65] that combine co-located workers with additional standalone rollouts.

The efficiency of large-scale RL training is therefore critically dependent on the reliability of both the trainer and rollout because they consume the majority of training time [60]. When scaling to thousands of GPUs, machine failures become the dominant source of task interruption [11, 38, 73].

†Corresponding author.

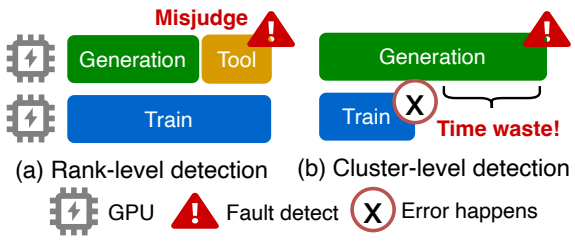

Figure 2: Fault detection of pre-train applied in RL. (a) Rank-level leads to false positive. (b) Cluster-level leads to delay.

However, because rollout and training are tightly interleaved in a single RL task, fault detection and recovery must handle failures stemming from both phases. A naive solution is applying different fault tolerance strategies to the specific roles of the failed components. Unfortunately, they lack the fine-grained mechanisms required for the unique demands of RL. Existing fault tolerance solutions are tailored to pure pre-training [4, 13, 17, 27, 36, 70, 71, 73] or pure inference workloads [39, 46, 54]. In current RL systems, the failure of a single critical worker would trigger a RL task restart, discarding training progress and wasting computation resources. Ideally, a fault in a machine hosting one distributed RL role should not disrupt the others. Only the ***detected*** failed role should ***restart*** and subsequently ***reconnect*** with others while the remaining roles continue to run. However, achieving this ideal state presents three significant challenges.

Challenge #1: Accurate and efficient fault detection. The rank-level detection for training in ByteRobust does not work for RL. It flags a process as suspect when its behavior deviates from peers or it exhibits zero GPU or network activity [11, 29, 38, 73] because each process runs identical forward-backward passes. As shown in Figure 2(a), however, rollouts can idle their GPUs while awaiting external tool responses, causing false positives. Conversely, cluster-level detects the error when all ranks have no GPU activity. It masks these idle periods and introduces significant detection delays as shown in Figure 2. For instance, a trainer network failure might remain undetected for hours until the long-tail rollout phase completes, wasting valuable cluster resources.

Challenge #2: Fine-grained and efficient restart. We need to guarantee both machine failures in trainer and rollout would not lose the trajectory due to the task restart. Furthermore, for the trainer, we need rollout to continue the generation during the recovery of the trainer. Besides, the gang-scheduling leads to the long blocking time until the new machine initializes, while the extra warm standby machine leads to the resource waste. An efficient and resource-friendly system is needed for efficient trainer restart. For rollout, we want the recovered rollout to soon get the latest weight for trajectories generation.

Challenge #3: Dynamic and efficient weight synchronization. The restart trainer or rollout needs to build reconnection for subsequent weight update as shown in Figure 1(b) and (c). Collective communication based on NCCL [1] needs to build the fixed communication group before transfer, so it cannot connect with the recovered role in the new machine and does not support fault tolerance. Point-to-point communication like UCX is available for dynamic reconnection, but needs asynchronous and parallel optimization to be efficient.

To address these challenges, we designed RobustRL, the first comprehensive role-based fault tolerance system for RL post-training in the three RL modes of Figure 1. It mitigates the impact of the machine failures for the rollout and trainer. Our contributions are as follows.

1. Role-phase-aware fault detection. It decides which roles should restart. We introduce a phase-aware and extensible detection strategy for trainer and rollout. Faults in corresponding roles are handled using appropriate robust strategies. (§4).

2. Role-based and resource-efficient restart. It decides how the roles restart. We propose a decoupled recovery strategy to avoid the RL task restart and preserve the rollout progress. In semi-sync and async mode, for trainer failures, we implement an efficient recovery that dynamically takes rollout as warm standbys, bypassing gang-scheduling delays without requiring extra idle resources. For rollout failures, the recovered rollout would pull the latest weight from other rollouts for trajectory generation immediately. (§5.1)

3. Efficient and reliable reconnection. It decides how the roles reconnect. We implement UCX-based (Unified Communication X) dynamic communication to replace NCCL for weight synchronization. It can achieve efficient weight update through asynchronous point-to-point communication and relay server design. In addition, it can handle the different failure cases during the recovery. (§5.2)

4. End-to-end benefits. In the scenario with frequent failures where a trainer fault is injected every 10% steps, RobustRL still maintains an 80% ETTR on the Qwen3-8B-Math training task with 20% higher than ByteRobust. The RL training time is 8.4%-17.4% faster than ByteRobust. (§7)

2 Background & Motivation

2.1 RL System for LLM Post-Training

Post-training using Reinforcement Learning (RL), which evolved from initial human feedback (RLHF) techniques [5, 55], is now critical for enhancing the reasoning [24, 59, 85] and tool-using capabilities [14, 30] of LLMs. This process consists of two phases, rollout and training.

Rollout. The rollout model generates trajectories based on prompts and the results of environment interaction, a process typically completed by an inference engine [35, 88]. For example, mathematical reasoning problems [50] can be solved using chain-of-thought (CoT) [76]. The rollout model can further achieve tool learning through multi-turn tool invocations. In software engineering [30] scenarios, trajectories include multi-turn interactions with a code sandbox to fix a bug or implement a specific function. In search scenarios [31, 33, 83],

trajectories involve multi-turn interactions with a search engine to retrieve target answers.

Training. The actor updates its policy by trajectory rewards evaluated in the training engine [49, 87]. The score can be obtained via various reward sources such as rule-based functions [24, 85] or learned reward models [5, 53]. Subsequently, the reference and critic models convert per-trajectory scores and advantages into training experience. Finally, the actor model consumes this experience through a specific policy update strategy [3, 57, 59, 85] to complete this iteration.

RL training system. RL frameworks like verl [22] adopt a synchronous mode. After the rollout phase is completed, they switch the inference engine to a training engine by resharding the model weights. However, the multi-turn interactions and decode latency in rollout leads to a significant long-tail latency. Therefore, existing async RL frameworks [16, 25, 60, 89, 93] allow the trainer to train within a certain range of offline steps without waiting for all rollout trajectories to complete. It greatly improves training efficiency while maintaining an acceptable loss in precision. Compared to the hybrid deployment of the sync mode, the async paradigm independently deploys the trainer and standalone rollouts, with weight synchronization through network pulling. The semi-sync [58, 65] mode replaces the async trainer with a hybrid one, thereby avoiding idle waiting caused by an improper ratio of trainer to standalone rollouts as shown in Figure 1.

2.2 LLM Fault Tolerance System

Like pre-training, the RL post-training of large models can last for several weeks or even months [80]. During this period, machine failures inevitably occur, leading to a loss of training progress. In RL, a GPU machine where a failure occurs could be executing either a training or an inference task. Prior works, ByteRobust [73] and EaaS [39], have respectively discussed machine failure scenarios during training and inference. In the pre-training process, at the scale of a 100K GPU cluster, machine-induced failures (e.g., GPU, network, CPU, memory, disk) cause over 3,000 interruptions per week on average (30/k-machine/week). For inference services, at the scale of a 4K GPU cluster, 8.8 failures also occur weekly (2.2/k-machines/week), with the main faults manifesting as GPU disconnection and ECC (Error-Correcting Code) errors.

On top of training and inference workload, RL introduces additional stages such as weight synchronization, Ray [48] management, and tool calls. It further increases the possibility of machine failures. Furthermore, by analyzing issues from open-source RL frameworks with keyword matching, we have found the similar problems caused by the machine error as shown in Table 1. Unfortunately, there is no specific robust system for the RL system as we know and the ByteRobust is applied since RL post-training is a kind of training task. Restarting the task when an error happens in ByteRobust is not the best optimization in RL.

Project	verl [61]	Roll [21]	OpenRLHF [20]	Slime [93]
Total issues	1830	127	719	162
CUDA error	189	7	74	14
Timeout	152	6	60	9
OOM	117	7	66	12
Job Hang	65	2	20	4

Table 1: Issues of machine error and job hang in open source RL training framework.

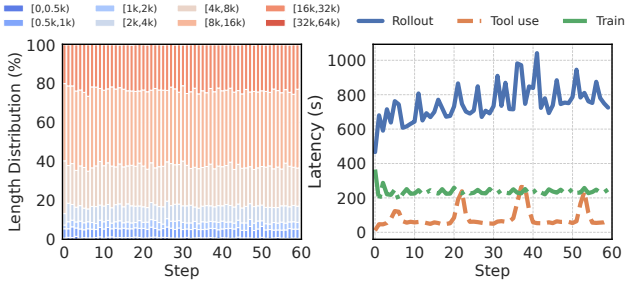

Figure 3: Trajectory length distribution (a) and time cost of each step (b) of Search R1 [31] training in HotPotQA dataset [83] with Qwen2.5-7B [67].

For instance, the pre-train robust system ByteRobust [73] achieves warm standby machines to enable fast recovery from a task restart. But it restarts the whole task whatever the error happens, leading to the large progress loss especially in RL training. A better solution is fine-gained restart by role and rollout can be the warm standby for the trainer. We can apply ByteRobust only when the role-based robust strategy in RL cannot handle the case like human-made code or configuration error. For the inference system, they mainly focus on keeping the service running [39,46] or avoid re-prefilling [18,54] when one inference machine fails. Current RL robust systems follow the inference design [60, 79] to achieve the robust rollout because it only needs to extra consider how to reconnect with the trainer in async mode. However, the trainer process has much higher failure frequency compared with inference. The robust trainer is important and the robust rollout should take the trainer failure into consideration.

2.3 Opportunity and Challenge

RL robust benefits. Role-based fault tolerance in RL has two benefits. First, it ensures the failure isolation of different roles. The task can continue to run, which guarantees that the current rollout and agent environment states are maintained. This is important under the long-tail phenomenon, where the rollout phase constitutes the main overhead. In Figure 3 of search agent training, rollout phase plays the major overhead in one step. Because the response length is long and the tool calling time contributes to the extra overhead. Second, it reduces the recovery time. We only need to restart the trainer instead of the RL task. In the case of async training, the failure of a rollout

does not affect the training task, as requests are forwarded to other rollouts. A trainer failure does not affect the rollouts from generating trajectories. To achieve so, we need to handle the following issues.

Per-step checkpoint. If weights are not saved each step, a weight inconsistency between the recovered trainer and the rollouts will occur when a failure happens. This leads to trajectory deviations and affects the training results. In this situation, it is necessary to roll back to the last checkpoint saved step to retrain and re-rollout. Per-step checkpoint can avoid the re-execution of the time consuming rollout phase.

We believe that a per-step checkpoint is available in the RL scenario based on the following insights. First, in pre-training scenarios, checkpoints are typically saved every ten or hundred steps because a single training step takes only seconds. In contrast, an RL step can last for minutes or even hours [91], which makes the checkpoint overhead ratio small. Second, in async RL training, the checkpoint process only blocks the trainer for a short time, while rollouts can continue inference during this period. Third, to further reduce the overhead brought by a per-step checkpoint, we apply the ByteCheckpoint [72]. The blocking time for saving weights is mainly the GPU to memory time within 5 seconds.

Efficient point-to-point communication. In asynchronous RL training, when trainer or rollout has faults, it needs to re-establish connections after recovery for later weight synchronization shown in Figure 1(b) and (c). The existing collective communication protocol NCCL only supports the static communication member so it cannot support robust cases. For example, the trainer would send its weight by layer to the rank-0 of the rollout machine by NCCL. Then the rollout machine boards the weight to other ranks through NVLink. When the number of communication members increases, the transfer overhead would increase linearly.

We solve this by the UCX-based point-to-point communication. It supports dynamic connection and asynchronous rank-level transmission from the trainer GPU to rollout GPU directly. It solves the traffic bottleneck of single NICs (Network Interface Cards) in NCCL. In addition, the rollout which finishes the weight update can be the relay server for the outdated or recovered rollout pulling. Finally, We further support the fault tolerance case during weight synchronization.

3 System Overview

The design goal of RobustRL is to ensure reliable RL training by using a role-based fault detection mechanism and applying different fault recovery strategies to trainer and rollout. RobustRL consists of two core components: control plane and data plane. The architecture overview is shown in Figure 4.

Control Plane. It mainly consists of the phase aware analyzer and the runtime controller. The analyzer is responsible for interacting with the RL robust runtime. It tailors fault-detection strategies to each RL role and training stage. The controller,

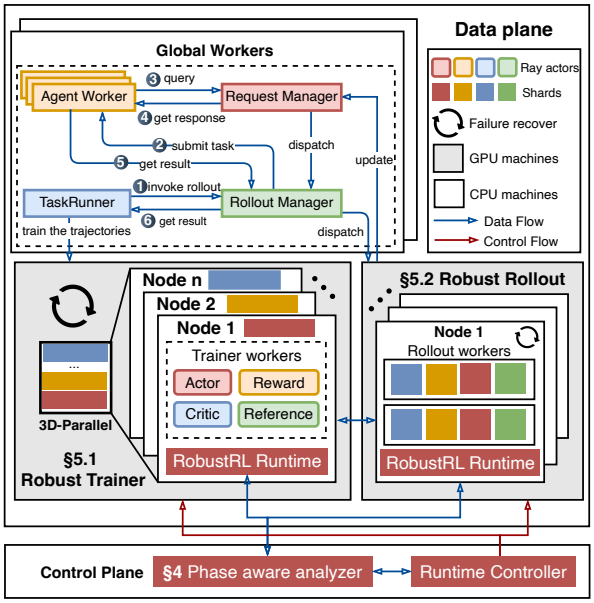

Figure 4: System overview of RobustRL.

responsible for machine scheduling, receives analysis results from the analyzer and adopts the appropriate fault tolerance and recovery strategy (§4).

Data Plane. The GPU machines are the primary failure sources and they all have fault tolerance capabilities (§5) for machine errors with RobustRL. All trainers would restart whenever any trainer machine fails, while rollouts would only restart or replace the corresponding faulty machine.

The CPU machine includes management roles, such as the `AgentWorker` for tool interaction, the `RolloutManager`, and the `RequestManager` for managing inference instances and requests. They are placed on CPU machines, and the number of machines is determined by the workload. There can be multiple `AgentWorkers`, while the other roles default to one instance each. The `TaskRunner` invokes the `RolloutManager` to get the trajectories (①). Then `RolloutManager` invokes the `AgentWorker` (②) to call the inference engine and tools to store the result in the `RequestManager` (③). This process can be a multi-turn conversation and the `AgentWorker` get the trajectories (④ and ⑤) to the trainer (⑥).

A failure in these roles triggers a RL task restart [73]. We use affinity scheduling to ensure that management roles are not scheduled on trainer or rollout machines. This eliminates RL task restarts that would otherwise be triggered by the termination of a management role when a trainer or rollout machine is replaced after a failure.

4 Role-based Fault Detection

We illustrate the semi-sync RL workflow in Figure 5 since both sync and async training are special cases of it. Our goal

is to detect which trainer or rollout machine has failed fast and apply the corresponding robust mechanism in §5.

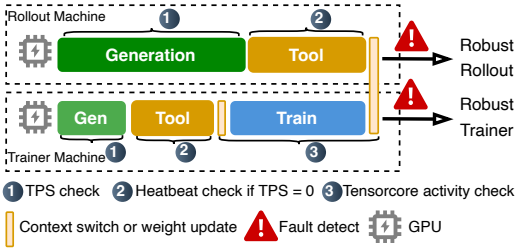

Figure 5: Role-phase-aware fault detection in semi-sync RL training. Row 2 is the hybrid. TPS: Throughput Per Second.

Trainer fault detection. As introduced in §2.1, the training phase is divided into the forward-only computation of the reference/critic/reward models and the forward-backward computation of the actor/critic policy update. The detection strategy during this process is consistent with that of pre-training. Failures manifest as zero GPU TensorCore activity for a five-minute window in RobustRL. When this occurs, we switch to the robust trainer workflow (§5.1.2).

Trainer detection is only applied during the training phase on the trainer machines (Figure 5 ③). Although phases such as context switching, weight updates, or advantage computation exhibit no GPU activity, their duration is short enough relative to the training phase. Thus, monitoring TensorCore activity is sufficient to detect failures without false positives from short GPU-idle phases. Users can also extend their own detection strategy for this case. For example in large scale RL training, the advantage computation can be over 5 minutes and we can set a large GPU idle threshold. The trainer fault detection method is orthogonal to both pre-training [10,11] and machine diagnostic methods [73].

Rollout fault detection. Rollout workloads comprise inference, weight synchronization, and awaiting requests or tool returns. TensorCore activity occurs solely during inference. In the other two stages, the worker exhibits no GPU activity yet remains healthy. We first periodically collect the throughput of each rollout from the `RolloutManager` (①). If the rollout exhibits zero throughput for a specified time interval (60 seconds in our system), we mark it as suspect and trigger heartbeat detection to further verify its status (②). No response within the timeout confirms a rollout machine failure and we will handle it with a robust rollout strategy (§5.2). The Rollout detection adopts throughput detection prior to heartbeat, avoiding misjudgment caused by unprocessed heartbeat requests and excessively long TTFT (time-to-first-token) in high-load Rollout scenarios. For the hybrid-rollout of sync and semi-sync mode, this detection method can also be applied. Since the error happens at the trainer machine, we switch to the robust trainer workflow (§5.1.2).

Extensibility to complex faults. It is worth noting that the role separation architecture proposed in RobustRL naturally facilitates the integration of advanced fault detection methods. By decoupling the execution contexts, our system becomes inherently compatible with specialized detection strategies designed for complex issues like silent data corruption (SDC) [28,40,41] and stragglers [38,78] to further harden the system.

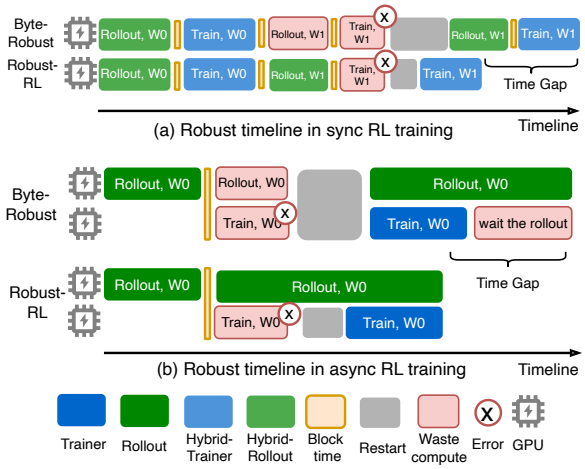

Figure 6: Timeline comparison between ByteRobust and RobustRL in (a) sync and (b) async mode when the trainer machine error happens.

5 Role-based Fault Tolerance

5.1 Robust Trainer

This section illustrates the benefit of robust trainers in different RL architectures (§5.1.1), appropriate restart strategy (§5.1.2) and reduction of restart overhead by rollout warm standbys (§5.1.3).

5.1.1 Robust Trainer Timeline

Figure 6 illustrates the difference between the ByteRobust and the RobustRL in both sync and async training mode. The semi-sync mode is the special case of sync and async mode because it contains both hybrid and standalone rollout. The yellow part denotes the time that blocks the RL training, which includes weight synchronization, per-step checkpoint and weight reshard between training and inference engine.

Robust trainer benefit. In sync training mode of Figure 6(a), ByteRobust restarts the entire task, with the rollout progress of the current iteration lost. RobustRL only restarts the affected hybrid role and preserves the rollout progress. After recovery, it simply resumes rollout and thus completes the iteration sooner than ByteRobust. In async training mode of Figure 6(b), the extra benefit is that rollout can continue running during the trainer recovery. Under the same failure case, the rollout in RobustRL ends earlier, it avoids the trainer to wait for the rollout to end in ByteRobust. In addition, compared

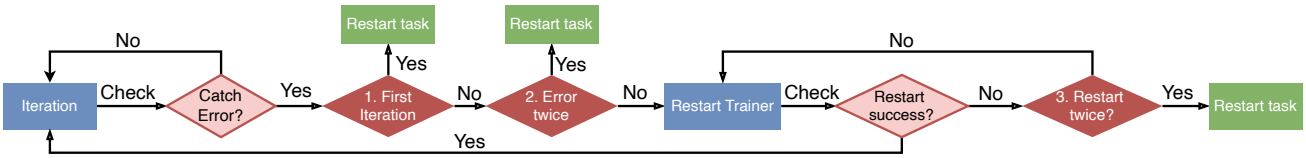

Figure 7: Robust trainer workflow. The blue part is the operation in RL training. The red part is the judge for the robust case. The green part is the policy to handle the robust case.

with restarting the RL task, we eliminate the overhead for container initialization, ray cluster initialization *et al.*.

Low blocking overhead. Due to the long-tail phenomenon of rollout, one step in RL is long shown in Figure 3(b), making the blocking time relatively short. The efficiency of rollout weight update has been solved in §5.2.1. In addition, we introduce ByteCheckpoint [72] to improve the checkpoint saving efficiency. The blocking time is only the GPU-to-memory, while the transfer from memory to disk or other persistent storage is executed asynchronously.

5.1.2 Robust Trainer Workflow

Robust trainer targets restarts from machine failures and we must avoid an infinite loop of trainer restarts by the human-induced fault. When a human-induced fault occurs, we restart the task and check the code or roll back the code version instead of trainer role restart as soon as possible. This operation "Restart task" is similar to ByteRobust's machine diagnostics and code rollback procedures. We present the robust trainer workflow in Figure 7.

Iteration. One iteration includes the step ① to ⑥ in Figure 4. The RL training is completed through the iteration of multiple steps. Robust trainer wraps the training step function with a `try-catch` block to capture exceptions during training. The sources of exceptions include both explicit and implicit failures, which are detected by the method in §4. When the exception happens it turns to the robust phase.

Trainer restart. First, `TaskRunner` terminates all trainer-related processes. Then, it re-executes the trainer's initialization phase and finally reloads the weights from the last saved model checkpoint. Since the model weights are saved each step, the reloaded weights are consistent with the rollout. Information that binds rollouts to the trainer, such as communication addresses for pulling weights, is updated concurrently with the trainer loading the weights.

When we restart to iterate, we skip to rollout a new batch. Instead, when the current batch finishes rollout, `TaskRunner` fetches the trajectories from the `RequestManager` to the trainer. Otherwise, if we use the sync or semi-sync mode for RL training, we switch the context to the inference engine to rollout the trajectories.

In the following situations, we restart the RL task instead of only the trainers shown in Figure 7.

1. First-iteration exception detected. If the model fails on the first step of training or on the first step after resuming training, this indicates an explicit machine or code error. [2]

2. Repeated exception detected. If it is the second time the fault has been detected in the current step, we indicate a reproducible fault exists in this step. This situation is also similar to a code error and we restart the task. For example, developers introduce a code error in the validation process, which is executed each 5 steps.

3. Repeated restart failure detected. The restart process itself may fail. For example, if resources are not fully released during the trainer restart or if connection establishment fails due to the restart. In such cases, one restart failure is permitted. If restart failure persists, we also consider it to be a reproducible machine or code error.

5.1.3 Trainer Warmup by Rollout

The trainer schedule follows the gang scheduling, meaning the trainer's initialization cannot begin until a new machine is scheduled and the environment is initialized, which is time-consuming as shown in Figure 8(a). ByteRobust prepares the extra warm standby machines to replace faulty ones, thereby saving scheduling and container initialization time. However, using redundant machines leads to potential resource waste, making this strategy limited to large-scale training.

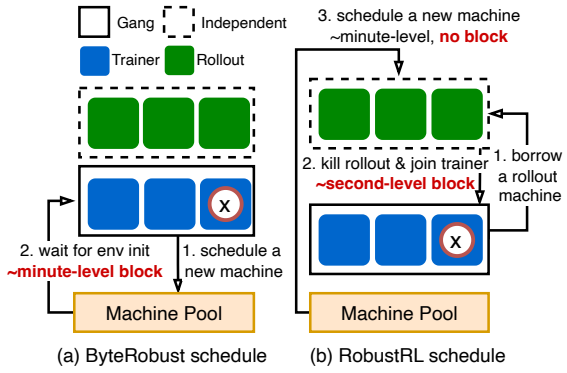

Figure 8: Schedule without extra warmup machines when trainer fails. (a) ByteRobust scheduled a new one from the machine pool. (b) RobustRL borrows a machine from rollout and rollout schedules a new one from the pool.

This design does not work for sync-mode training. In semi-

[2]Code errors in rollout trigger this process as well.

sync and async mode, we can use rollouts as warm standbys for the trainer as shown in Figure 8(b). When a failure occurs, one rollout is killed, and it will join the trainer's initialization. Since rollouts use independent scheduling, requests being processed by the rollout on the replaced machine are handled through the robust rollout strategy (§5.2).

The prerequisite for warmup rollout is that rollouts and trainers are in the same data center and rollout and trainer machines are homogeneous. In deployment, similar to ByteRobust, one can reserve a quantity of max(DP, TP, PP, EP, CP) rollouts as homogeneous machines in the same data center, enabling hot-swapping when a failure or suspected fault occurs in any parallel group. Since warmup rollouts have the same environment as the trainer, they can be quickly substituted when a trainer machine fails.

Our scheme is compatible with existing Trainer-Rollout heterogeneous deployment [89]. For example, we can add an H800 warm Rollout in cluster A for heterogeneous training with cluster A (10×H800 Trainer) and cluster B (10×H20 Rollout)). In addition, Rollout warmup requires no weight resharding because one Rollout machine is corresponding to one DP Group, which means recrimination only reduces inference concurrency. Trainer parallelism remains unchanged after borrowing a machine.

5.2 Robust Rollout

The design goals for robust rollout are to ensure that after a rollout fails, the recovered rollout can **1)** re-establish a connection with the trainer. **2)** Achieve high pulling efficiency for weight from the trainer or other relay rollouts. **3)** Update weights and resume inference as quickly as possible after recovery. To achieve these goals, we have introduced UCX-based weight synchronization (§5.2.1) and discuss the situation of the failure handling during rollout recovery (§5.2.2).

5.2.1 UCX-based Weight Update

The naive-UCX baseline transfers weights from GPU memory on machine 1 to host memory via PCIe, then across machines through a single network interface to machine 2's host memory, and finally from machine 2's memory to individual ranks via PCIe. The path is: PCIe -> NIC -> PCIe.The NCCL baseline uses RDMA GPU zero-copy (IB/RoCE v2) across nodes and intra-node NVLink for rank-to-rank communication. The path is: NIC -> NVLink. Compared to naive UCX, NCCL has a shorter data path and benefits from higher NVLink bandwidth than PCIe. Therefore, we need to shorten the communication path and improve the concurrency of UCX so as to combine the advantages both on the efficiency and elasticity. Previous work like Owl [15] discusses the data relay transfer mechanism to achieve the data-ready object sending to another object. But in RL weight synchronization, we need to further support GPU-to-GPU zero-copy transmission

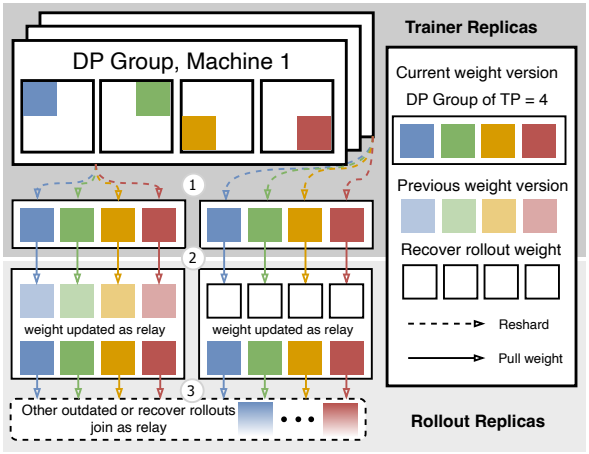

Figure 9: UCX-based weight update.

and weight shard management, and handle fault scenarios throughout the RL training lifecycle. The weight synchronization includes three parts.

① **Reshard.** As shown in Figure 9 step ①, we reshard the model to align with the sharding of the rollout. The implementation is based on verl [22], and this process takes under ten seconds.

② **UCX weight synchronization.** To ensure efficient weight synchronization, we implement point-to-point communication from the trainer's multiple data-parallel (DP) groups to the rollout replicas based on their corresponding ranks shown in Figure 9 ②. Each transfer initiates by placing the model layer by layer into a buffer for transmission. We ensure the buffer size is large enough to saturate the RDMA bandwidth. Besides, we also prevent OOM error on the GPU by preserving a buffer for transfer. The object pulling weights include both outdated and recovered rollouts awaiting weight updates. We ensure that at any given time, each weight is pulled by only one rollout to prevent network bandwidth contention.

Compared with current point-to-point communication design [60], the entire weight synchronization process is executed on the GPU. However, since torch tensors do not directly support UCX transfer, we convert them to cupy arrays [51], as cupy supports byte-level transfers. We use DLPack [12] to support a unified tensor memory layout, achieving zero-copy overhead for the conversion from torch tensors to cupy arrays.

③ **Relay transfer.** A weight updated rollout will act as a relay server, allowing other outdated and recovered rollouts to pull weights from it. Once weight pulling is complete, they join the relay-server set. The pulling process in this stage is the same as the one described in Figure 9 step ③. If a rollout recovers outside of a weight update stage, it directly pulls weights from a relay server, as shown in step ③.

The transfer efficiency between trainers and rollouts from different DP groups can vary due to network fluctuations. We make the entire weight synchronization asynchronous. It

allows the outdated and recovered rollouts to immediately pull from any rollout having the latest weights. A more extreme asynchronous strategy would be to allow asynchronous transfers at the tensor parallelism (TP) granularity, taking into account that stragglers can exist among different NICs [60]. However, the async DP transfer for a 235B model on 4×200Gbps NICs is under 10s. This overhead is sufficiently small compared to a single RL step in minutes or even hours level. Therefore, to maintain the simplicity of the weight synchronization design, we did not pursue further optimization.

In semi-sync RL training, the rollout phase does not begin until all rollouts have finished updating. In this case, the hybrid-rollout in the trainer machine also acts as a relay. In async RL training, the trainer resumes its shard once the first batch of relay rollouts finish their weight update, minimizing training stalls.

5.2.2 Rollout Failure Cases

Preserve the trajectories. We save the trajectories of the prompt of each tool iteration in the `RequestManager` to avoid the rollout progress lost when the rollout machine fails. After each tool iteration, the `RolloutManager` checks the liveness status of the corresponding rollouts. When a failure occurs on a rollout, the previous results are reassigned to other living rollouts. If it is a rollout machine failure, such as an ECC error, the machine is replaced with a new one. Since the `AgentWorker` and the sandbox reside outside the rollout machine, the rollout progress can be preserved.

Relay server failure during pulling. When resuming the weight pull, the rollout will first update its set of target addresses to the living rollouts. If a weight pull fails, it will find another relay server to pull from. The outdated or recovered rollout records their successful pulling progress and pulls the remaining one from other living relay servers.

Trainer failure during pulling. Failure may happen when the trainer prepares to be pulled or being pulled by rollout. In the first case, rollouts close their established connections with the trainer and wait for its recovery before re-establishing connections. In the case where a pull is in progress, the process is interrupted, and the partially updated weights are cleared. Finally, rollouts wait for the trainer to recover before re-initiating the weight pull.

6 Implementation

The implementation of the RL fault tolerance system at the framework level is 8k LoCs of Python for the semi-sync support, fault detection, and robust roles. RobustRL is built on verl [22] and its asynchronous RL extension [44]. We extend this foundation with a semi-sync training mode, which retains the trainer's resharding operation to the inference engine. The implementation of the training scheduler that supports the training architectures in Figure 1.

```
1.  class ElasticRayWorkerGroup
2.      # init function
3.      def __init__(self, cls, args):
4.      # support scale up/down for worker group
5.      def create_worker(...): # and destroy worker
6.      # create RayClass with init_args
7.      def scale_up(num_worker): # and scale down
8.      # invoke the create_worker
9.      def liveness_probe(...):
10.     # detect the liveness of worker groups
11. class ElasticPolicy:
12.     # define when to scale up/down
13.     def should_scale_up(...): # and scale down
14.     # define the scale up condition (recover phase)
15.     def _scaling_loop(...):
16.     # scale up if reinit, scale down if error
17.
18. rollout_cls = RayClassWithInitArgs(RolloutClass, args)
19. - rollout = RayWorkerGroup(rollout_cls, ...)
19. + elastic_rollout = ElasticRayWorkerGroup(rollout_cls, ...)
20. + rollout_policy = ElasticPolicy(elastic_rollout, ...)
```

Figure 10: The replicated ray worker group and scaling policy for the robust and elastic ray worker in RobustRL.

Robust API. In verl, the initialization of workers for the trainer or rollout roles uses the `RayWorkerGroup` (RWG) in line 19 of Figure 10. We further encapsulate this abstraction to handle fault tolerance and recovery scenarios (line 19-20). The `ElasticRayWorkerGroup` (ERWG) supports expansion and destruction, while a `ElasticPolicy` determines the timing for these actions. The ERWG supports monitoring the liveness status of the RWG and defines the initialization and destruction functions, `create_worker` and `destroy_worker`, along with their corresponding pre- and post-processing hooks. The `scale_up` is used to determine the number of workers to expand. For example, multiple rollouts fail or are taken to warm up the trainer (§5.1.3) or scales [79]. The policy defines the conditions for elastic scaling with a polling thread to check the liveness of the RWG. For instance, when the platform detects a machine failure during training, it is captured by this policy and scales up the failure worker. This abstraction avoids the need to repeatedly implement creation and destruction logic for different RWGs.

7 Evaluation

Our evaluation tries to answer the following questions.

Q1. What is the end-to-end training time and ETTR of RobustRL in scenarios with training failures? (§7.2)

Q2. What are the enhancements in RobustRL's fault recovery in terms of restart efficiency and state preservation? (§7.3)

Q3. What is the extra overhead introduced by RobustRL to implement role-specific fault tolerance? (§7.4)

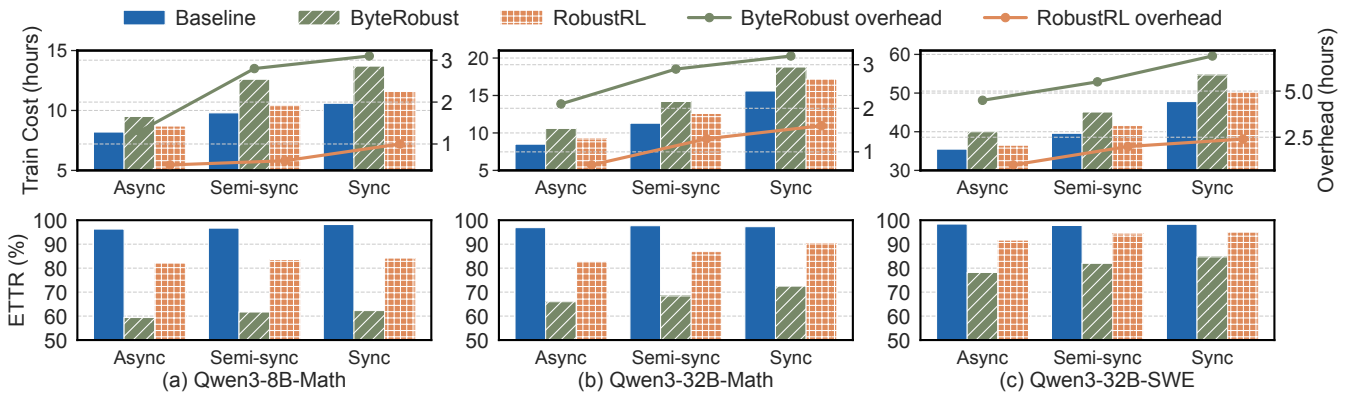

Figure 11: End to end evaluation for RL post-training of Qwen3 models in math [85] and SWE-bench [30]. The first row is the job completion time and the second row is the ETTR. The overhead of the first row is the time gap with Baseline.

7.1 Setup

Testbed. We deploy RobustRL on 32 GPU machines with 256 GPUs. Each machine is equipped with eight NVIDIA H20 96GB GPUs. The intra-machine and inter-machine bandwidths are configured with 900 GB/s NVLink and 4×200Gbps NICs, respectively. Each machine has 2TB of memory. Our software versions are CUDA 12.4, PyTorch 2.4.1, and NCCL 2.21.5. We build our system on verl 0.5.x [22], using Pytorch FSDP2 [87] and vLLM [35] as the training and inference backend. Our checkpointing uses ByteCheckpoint [72] with HDFS as the storage backend. We selected Qwen3-8B, 32B, and 235B-A22B [82] to evaluate the performance because they are the popular models for RL post-training research in academia and industry. We use the 8B and 32B models to test training performance and provide results from the 235B model to test weight saving and weight synchronization costs. The TP size of rollout is 8 to guarantee each rollout occupies a machine.

Baselines. The methods we compare are ByteRobust and our RobustRL. The baseline system is RL training without any injected faults. In ByteRobust and RobustRL, we inject a fault for the trainer at a random time within every 10% interval steps. Since the trainer follows the gang-scheduling, it would trigger the `TaskRunner` to automatically restart all the trainers. This failure frequency setting is higher than in practical production environments if the machine error rate is *i.i.d.* For example, the 100K GPU training in Meta [56] the error frequency is 18min, corresponding to 117 hours in a 256 GPU cluster. Our experiments are designed as stress tests to quantify the benefits of our fault-tolerant design under the extreme, large-scale training scenarios that will emerge in future workloads.

For ByteRobust, we retain only the in-place restart part of a failure, without machine rescheduling. The RL training includes the three architectures in Figure 1. Semi-sync switches from rollout mode to train mode when 50% of the prompts in a batch are completed and the sync mode is 100%. Async is 0% with a one-step warmup. For semi-sync and async mode, the number of GPUs for the trainer and rollouts is equal. We do not compare with the current robust rollout RL system [37, 60] because existing RL systems do not support trainer fault tolerance. Under trainer failures, their behavior is equivalent to ByteRobust. For rollout fault tolerance, the failure or recovery of rollout would not lead to the training bottleneck with further evaluation. For the weight synchronization efficiency, we directly compare with the time of ideal network bandwidth.

Dataset. For reasoning tasks on math with "DAPO-Math-17K" [85], we use a rule-based reward function to score the trajectories. For the multi-turn tool-learning task, we generate the trajectories by obtaining answers through multi-turn interactions with a sandbox in SWE-bench [30]. We use GRPO [59] for both tasks. RbustRL is independent of the specific RL algorithm and the effectiveness of RobustRL can generalize to the others. Our global batch size is set to 512, with 64 prompts per batch, and 8 responses generated for each prompt following the previous research [60]. We set the maximum text length to 65536 and the maximum number of tool interaction turns to 50. We train for 100 steps by default.

Metrics. Our primary evaluation metrics for fault tolerance are the end-to-end training time and the ETTR. We further evaluate the restart time overhead, additional fault tolerance overhead, and the time saved due to fault tolerance for different methods.

7.2 End to End Evaluation

We compare the end-to-end training time and ETTR for different training architectures under various GPU workloads on math and SWE post-training tasks on 128 GPUs.

End-to-End Training Time. As shown in the first row of Figure 11, the Qwen3-8B-Math takes the shortest time because the model is small and the post-training task is relatively simple. The SWE task takes the longest time because the introduction of tool interaction significantly lengthens the rollout time. Taking the Qwen3-8B-Math task as an example, the training time varies for different training architectures,

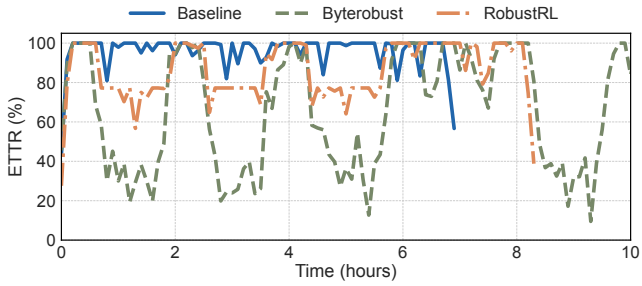

Figure 12: Sliding ETTR of the training process Qwen3-8B-Math. The sampling interval is 5 minutes.

where the async mode is faster than the sync one by mitigating long-tail overhead. Therefore, the end-to-end training time continuously increases from the async to the sync mode.

Since we inject a fault every 10 training steps, the end-to-end training times for ByteRobust and RobustRL are longer than the baseline. The overhead introduced by a fault restart is mainly caused by the restart initialization and the loss of training progress, especially the loss of rollout progress (§5.1.1). In contrast, RobustRL can restart only the trainers, allowing the rollouts to continue executing inference and environment interaction processes. Therefore, the overhead of RobustRL is smaller than that of ByteRobust. As we shift from async to sync training mode, the impact of the long-tail phenomenon becomes progressively more severe, thus the overhead of ByteRobust gradually increases. In sync mode, the rollout and training phases are executed sequentially as shown in Figure 1. By leveraging the role-based fault tolerance strategy, RobustRL explicitly preserves the rollout results. Consequently, if a failure occurs during the training phase, the system can resume directly from the training step, skipping the redundant rollout phase as shown in Figure 6(a). This stands in contrast to approaches like ByteRobust, which necessitate restarting the entire RL step. Lastly, the fault tolerance benefits of using RobustRL on complex tasks like SWE are greater than on math reasoning, because the rollout phase is more time-consuming. The benefit of preserving the rollout progress is more obvious.

In summary, under the extreme condition of a 10% failure rate, RobustRL can save 0.8-2.1h, 1.4-1.6h, and 3.5-4.5h in end-to-end training time compared to ByteRobust on the 8B-Math, 32B-Math and 32B-SWE tasks respectively. The restart overhead of RobustRL for fault tolerance accounts for less than 5% of the total time, while the ByteRobust introduces 20% overhead.

ETTR. As shown in the second row of Figure 11, computation stages such as actor policy updates and rollout are all counted towards the effective training time in RL post-training. In RobustRL, there is a phase where the trainer restarts for fault tolerance while the rollouts continue running. During this process, the recovery ETTR is calculated with the ratio $ETTR_{ratio} = \frac{\#Rollout}{\#Rollout+\#Trainer}$. Since RobustRL significantly reduces restart overhead compared to ByteRobust, its ETTR is better than ByteRobust's, and the advantage is more pronounced in simpler tasks like Qwen3-8B-Math. The reason is that the longer training time is, the more negligible the restart time. In addition, although ByteRobust would lose the progress during the restart, the re-execution of rollout is also counted towards ETTR. So the gap of average ETTR between ByteRobust and RobustRL is not large.

We further show the sliding ETTR for Qwen3-8B-Math in Figure 12 with semi-sync training mode. We sample the training process every 5 minutes. We take the process of 0.8-2h as an example. Since ByteRobust restarts both the trainer and rollouts when a fault occurs, its ETTR is significantly lower at 20%. During the same period, RobustRL's rollouts continue to execute, so the influence of failure is less. Compared to ByteRobust, RobustRL improves ETTR by 18-24% on the Qwen3-8B-Math task.

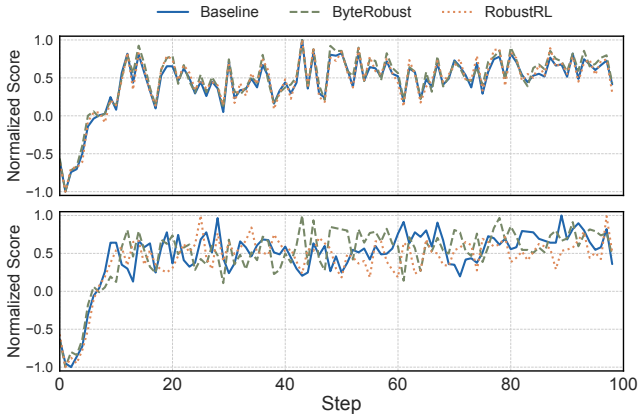

Figure 13: Training consistency in sync (row 1) and semi-sync (row 2) mode. The reward of the answer is normalized.

Training trend. We use the training trend of Qwen3-8B-Math with sync and semi-sync to verify the correctness of training in the presence of failures. We execute 100 training steps and obtain curves with similar training trends and the result is shown in Figure 13. In sync training, the three methods has the similar score tendency because we can make sure the training order of the prompt by batch mode instead of the streaming pipeline mode [89][3]. When the error happens, we can get the prompt and response from `RequestManager` to continue the training in RobustRL. However, the result in sync does not get fully alignment because we do not enable the deterministic inference [69] with FlashAttention [9] and CUDA atomic operations in our evaluation. In semi-sync situation, the results are still not deterministic and the trend difference is larger because the async schedule mode must use the streaming schedule, which cannot guarantee the order of the prompt. But generally, the three methods in semi-sync training shows the similar tendency.

[3]Batch mode is waiting for all the prompts in this batch to finish. Streaming mode is adding a new prompt to rollout if one prompt in this batch finishes.

Comparison under different error injection frequency. We further evaluate the performance of RobustRL and ByteRobust under diverse fault frequencies shown in Figure 14. All experiments are conducted on a 64-GPU in semi-sync mode with the same number of trainers and rollout for Qwen3-8B-Math workload and each experiment runs for 50 training steps. Notably, ByteRobust adopts a fixed checkpoint interval of one snapshot per 5 steps, and faults are uniformly injected throughout the entire training timeline.

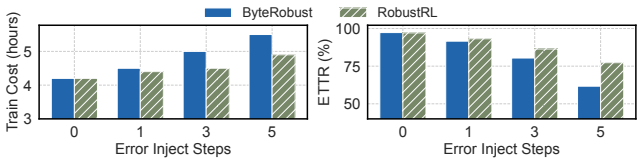

Figure 14: End-to-end training time and ETTR comparison of ByteRobust under different error injection frequency.

In the fault-free scenario, RobustRL and ByteRobust achieve comparable end-to-end training time and ETTR. Although RobustRL adopts a one-step checkpoint, the overall time for a small proportion of the full RL training §7.4. We provide an in-depth breakdown of checkpoint overhead in the following overhead analysis section. As the injected fault frequency increases from 1 to 5 (2%-10% in 50 steps), RobustRL outperforms ByteRobust by 2.2%–12.2% in end-to-end completion time reduction and 2.7%–15.7% in ETTR improvement because the time gain of RobustRL compared to ByteRobust is highly depends on the fault frequency. Considering that the performance advantage of RobustRL approaches saturation at a 2% fault rate, we omit additional evaluations for even lower fault frequencies.

7.3 Robust Benefits Analysis

Trainer restart benefit. Figure 15 shows a comparison of restart time breakdown between ByteRobust and RobustRL for different model sizes and numbers of GPUs. We use the semi-sync case as an example because its startup time is the longest, as the trainer machines need both the training and inference engines, in addition to the rollout roles. The main bottlenecks in starting an RL training task consist of four stages: instance restart, rollout initialization, checkpoint loading, and worker initialization. The "restart instance" stage includes container startup, installation of third-party libraries after startup, Kubernetes scheduling *et al.*. The "worker init" stage is primarily the initialization of the training engine. The "rollout init" stage is the initialization process for the standalone rollout inference engine, not including weight synchronization. The "load checkpoint" is the stage to load from memory to the GPU. When we detect a model anomaly, we asynchronously load the corresponding shards from HDFS to the local memory. The overhead from "rollout init" and "restart instance" phases does not exist in RobustRL, making it faster than ByteRobust. Benefited by the warmup by rollout

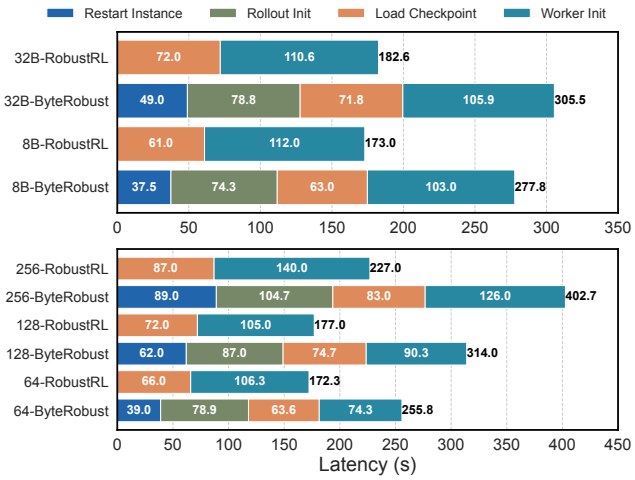

Figure 15: Restart cost comparison of ByteRobust and RobustRL. Row 1 is the result with different model size and row 2 is the result of 8B with different number of GPUs.

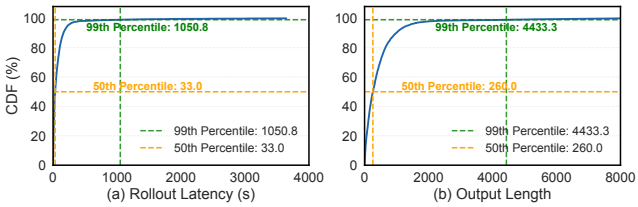

Figure 16: Benefit from preserving the rollout progress (a) Rollout cost CDF and (b) Rollout length CDF of all prompts in Qwen3-32B-SWE.

mechanism in §5.1.3, we avoid the trainer's gang scheduling process when the trainer has machine error because we can schedule the rollout machines to replace.

The second row of Figure 15 shows the results of restart latency of ByteRobust and RobustRL as the number of GPUs increases, where the duration of all initialization stages increases accordingly. The "worker init" overhead in RobustRL is larger than in ByteRobust. Compared to ByteRobust's startup, the trainer's restart includes a destruction phase, which introduces additional overhead for destroying network connections. Overall, RobustRL improves restart efficiency by a factor of 1.5-1.7× compared to ByteRobust.

Preserving rollout progress benefit. In addition to the restart benefit, RobustRL can preserve rollout progress compared to ByteRobust. We recorded the output time distribution and output length distribution for 50k prompts (batch size × steps = 512 × 100) on the Qwen3-32B-SWE task shown in Figure 16. The tail latency reaches 1050s, with an output length of over 4k tokens. RobustRL can avoid the overhead of re-executing this inference. When we extend to larger RL training scenarios involving more conversation turns and more complex tool invocation logic, the benefit can be more significant.

Rollout fault tolerance benefit. A machine failure on a rollout or a machine being borrowed by the trainer does not

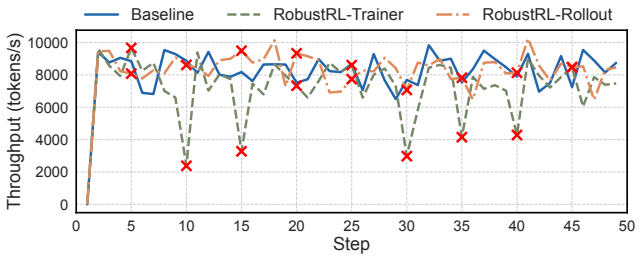

Figure 17: Rollout token throughput of Qwen3-8B-Math with 50 steps. We inject the error each five steps.

influence the RL task. There are multiple rollout instances, and in semi-sync mode, the trainer can also provide rollout capabilities. Compared to the over 300s required for a RL task restart shown in Figure 15, the impact of a rollout restart would not influence the throughput of token decode as shown in Figure 17. In the event of a rollout machine failure in 32B model, the time for a single rollout to start up and begin providing service includes machine scheduling (30s), container startup (under 30s), inference engine startup (49s), and weight synchronization (10s), for a total of 119s.

Throughput under the trainer and rollout failure. We visualize the rollout throughput of semi-sync training in Figure 17. The failure in trainer machines can lead to the throughput decrease because the error can happen when rollout phase finishes. In this phase, the trajectories wait for the consumption by the trainer and continue the next step rollout. The token throughput of rollout failure is not affected because we have multiple rollout replicas.

Detection benefit. ByteRobust [73] applies the 30 seconds interval for network-related fault detection and 10 seconds for the GPU ones (setup in its Table 1). As discussed in §1, it would lead to endless restart of the task since the RL task can have idle time waiting for the response from the tools. The RobustRL can continue the running process. Compared with the cluster-level detection in Figure 2(b), it can save at most about 1000 seconds as shown in Figure 16(a) since we set the hang detection interval for rollout as 60 seconds.

7.4 Robust Overhead Analysis

7.4.1 Weight Synchronization of Trainer and Rollout

Weight synchronization efficiency. Figure 18 shows the weight synchronization efficiency for an equal number of trainers and rollouts. The 235B model requires more than 64 GPUs for the trainer to start as shown in Figure 18(b). The NCCL communication method first gathers all weight to rank 0 and then broadcasts the weight to all the rollouts. The UCX uses point-to-point communication to the corresponding ranks in rollouts. Since UCX can fully utilize all the bandwidth of the NICs, it can have close performance to the NCCL. In addition, UCX allows for dynamic connections, providing fault tolerance capabilities. For a 235B model with FP16 precision, the model size is 470GB. With the 4×200Gbps NICs, the theoretical transfer cost is $\frac{235\times2}{4\times200/8} = 4.7$s. Our UCX-based weight synchronization cost is about 6s. The extra overhead can be introduced by the network bandwidth fluctuations and the async bubbles between NICs in one machine.

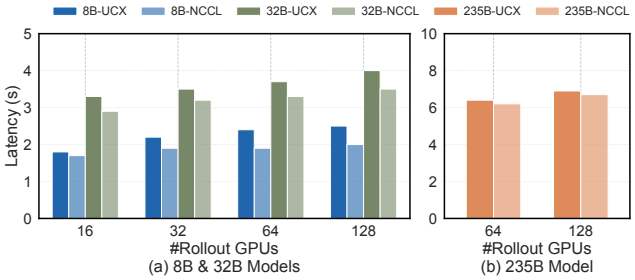

Figure 18: Weight synchronization latency with different number of GPUs and model size. The number of GPUs of trainer and rollout is equal. (a) 8B and 32B and (b) 235B.

We further evaluate the pulling efficiency of our weight synchronization strategy in Figure 19. Our UCX-based transfer can achieve a linear increase in cost even when the number of rollouts grows exponentially. Benefit by the joining as relay design (§5.2.1), the outdated or recovered rollout can pull the weight from the relay server. On the contrary NCCL-based weight synchronization strategy does not support dynamic connection with relay server and all the rollout must pull the weight from the trainer. When the number of rollouts is larger than the trainer, its efficiency decreases.

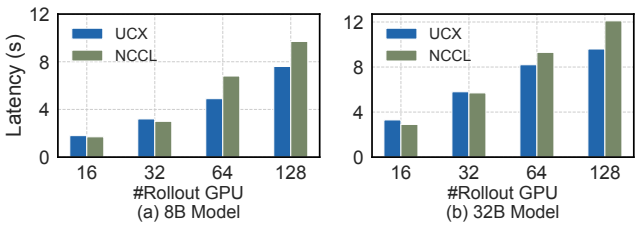

Figure 19: Weight synchronization latency with 16 trainer GPUs and different number of rollout GPUs. (a) 8B and (b) 32B models.

7.4.2 Per-step Checkpoint

Checkpoint efficiency. We evaluate the checkpoint overhead of both FSDP2 and Megatron in Figure 20. It shows the GPU to memory and memory to disk latency with different model size and number of GPUs for checkpoint. The GPU to memory and memory to disk are independent of the model size and the number of GPUs because the saving process only needs to save the shard corresponding to each rank. The 3s blocking time is 1% of the minutes or hours required for one step in the RL task. It guarantees that a per-step GPU-to-memory checkpoint would not lead to the OOM during the process of checkpoint from GPU to memory because each step takes

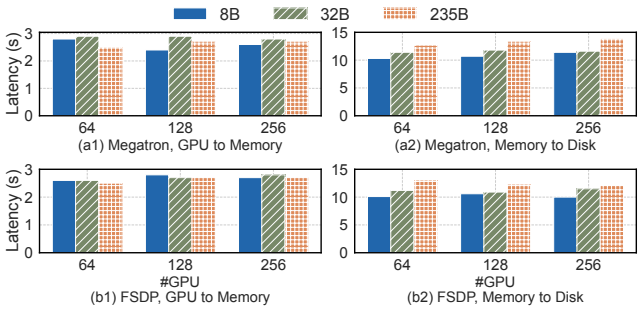

Figure 20: Checkpoint latency of ByteCheckpoint. (a) GPU to memory and (b) memory to disk with different model size and number of GPUs.

over minutes. We have enough time to offload the checkpoint from memory to the disk for about 10s. The disk writing stage is non-blocking, which further minimizes the overhead of checkpoint for the RL training.

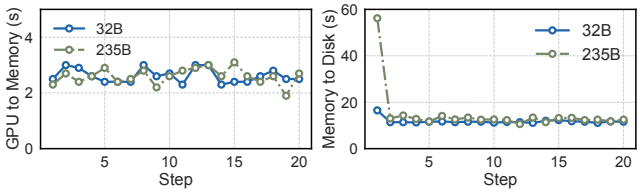

Figure 21: Checkpoint overhead of each step in GPU to memory (left) and memory to HDFS (right).

Continuous checkpoint. In Figure 21, we analyze the latency of GPU-to-memory and memory-to-disk across the first 20 training steps for the 32B model. For the 235B model, checkpoint saving is executed at a consistent 10-minute interval. Consistent with the observations, the GPU-to-memory latency is independent of model scale and training steps. This is because the GPU-to-memory address mapping in ByteCheckpoint [72] is pinned during the initialization phase.

In contrast, for the memory-to-disk persistence phase in Bytecheckpoint, the first weight saving needs extra full traversal of all model tensors, global shard metadata generation, distributed execution planning. Larger models introduce more tensors, larger metadata footprints, and greater volumes of data to be written, leading to a strong correlation between persistence overhead and model scale. Starting from the second checkpoint, however, distributed planning and metadata are fully cached. Redundant operations including tensor traversal, metadata parsing, cross-node communication, and structural construction are eliminated, leaving only raw data copying and disk I/O. This process is no longer affected by model size, but bounded by storage bandwidth for each shard.

Checkpoint frequency > 1. We further evaluate the reward trends under different checkpoint frequencies with a failure injected every 10 steps shown in Figure 22. All experiments are conducted in semi-synchronous mode on the math task using

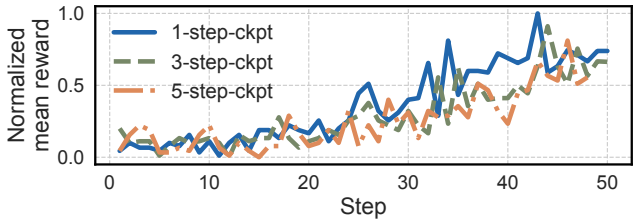

Figure 22: Reward under different checkpoint frequency with 10-step-frequency failures.

the Qwen3-8B-Base model. For a 3-step checkpoint interval, if a failure occurs at the 10th step, the rollback checkpoint is restored from the 9th step, resulting in 1 offline step. Similarly, a 5-step checkpoint interval introduces 5 offline steps when a failure happens at step 10. The experimental results demonstrate that the number of offline steps directly affects the upward trend of reward growth. Such degradation can be more severe for large-scale, highly complex reinforcement learning training workloads like search [31] and coding [30]. Given that the overhead of per-step checkpoint is negligible, we prioritize preserving algorithmic fidelity and training effectiveness in our design.

8 Discussion and Limitation

Limitation of Test Scaling. Frequent failures only emerge in large-scale training scenarios. Under small-scale settings with infrequent failures like 2%, RobustRL exhibits no substantial performance gains over ByteRobust because the benefit is highly dependent on the failure frequency and end-to-end training time. Even so, our experiments simulate large-scale frequent failure conditions via small-scale cluster testbeds, which adequately demonstrates the inherent advantages of RobustRL for future large-scale workloads.

Limitations of Diagnosis Tools. Current fault diagnosis tools are primarily designed for training [11, 38, 66, 73, 74], lacking specific capabilities for RL post-training scenarios. In RL, the presence of multiple roles and complex data and control dependencies makes root cause localization challenging. For instance, an OOM error in one role might be caused by a memory leak in another co-located role in the same machine. Similarly, a role hang event could be due to abnormal metrics from other roles. More precise RL training system diagnostic tools would help developers pinpoint root causes faster during failures, thereby further improving RL training efficiency.

Role-based Hot Updates. Adjusting parameters during training is a common requirement. For example, increasing the batch size when GPU memory utilization is found to be low. ByteRobust [73] proposes a hot update mechanism that allows instances to restart and update in-place, avoiding machine rescheduling. Building upon role-based fault tolerance for hot updates, it helps developers achieve faster role-specific parameter updates. RobustRL reduces restart overhead and

prevents the loss of rollout.

Elastic RL Training. Existing work supports elasticity for the rollout [79, 89]. Since the rollout performs inference tasks and uses independent scheduling, elastic scaling does not affect task execution. With the support of RobustRL, the trainer's elasticity in the data-parallel dimension can adopt a similar approach to previous work [8, 23, 36, 86], requiring only a trainer restart, thus reducing the overhead of elastic scaling.

9 Related Work

Fault tolerance systems for LLM training. For training systems, their main goal is to locate system failures and recover as soon as possible through fault detection [10, 11, 29, 38, 73, 78], checkpoint [47, 72], and elastic recovery [8, 36] to ensure the correctness of model training and reduce task restart overhead. Some works have further extended to elastic training scenarios, focusing on reducing the overhead of scaling due to resource changes. Examples include pipeline redundancy [27] and parallelism adjustment prediction [70] or in spot instance [4]. However, the fault detection strategies for pre-train are not incompatible in RL. For the trainer robust work like Torch-FT [45, 56], it is orthogonal to us since it can accelerate the trainer restart efficiency. But it does not consider the recovery of the trainer from partial failures in conjunction with rollouts, nor the design opportunities presented by the asynchronous execution of rollout.

Fault tolerance systems for LLM inference Existing inference fault tolerance systems primarily operate at the token, and rank levels. The token level refers to utilizing the KV Cache [18, 34, 54] to avoid re-prefilling requests. The rank level refers to scenarios with AF (attention-FFN) disaggregation [39, 68, 92], where the failure of a sub-ranks is prevented from causing a full service crash. For example, EaaS considers fault tolerance and recovery after an expert machine fails. However, async RL training scenarios also need to consider the interaction between rollouts and the trainer. Additionally, as an offline training task, we just need to guarantee the prompt can be generated.

RL Systems and Fault Tolerance. RL involves both training and inference stages. Considering the long-tail phenomenon of rollout, RL training paradigms have shifted from sync [43, 61, 90] to async mode [16, 60, 89, 93] to improve training efficiency. Some RL training works have considered the fault tolerance and elasticity of rollouts [60, 79]. However, the probability of failure in the rollout phase is much lower than in the training ones because the communication management of training is more complex. RobustRL further considers the case of trainer fault tolerance, utilizing rollouts as warm standbys and allowing them to continue inference during a trainer failure.

10 Conclusion

We have implemented RobustRL, the first fault tolerance system for RL training that supports all GPU roles against machine failures. Through techniques in *detect-restart-reconnect*, RobustRL can detect the fault by roles quickly, isolate the failure and minimize the restart overhead with rollout progress preserving. RobustRL can achieve 80% ETTR on the 8B-Math training task with 20% higher than ByteRobust on the Qwen3-8B-Math task in an extremely robust case.

[+]University of Illinois Urbana-Champaign [*]KAIST

Abstract

Fast storage hardware and computational SSDs have outpaced the traditional kernel-centric or kernel-bypass file system designs, fragmenting modern storage stacks across library file systems, kernel subsystems, and in-device file systems. Each architecture offers only a subset of desired properties: user-level designs deliver low latency but lose kernel services and isolation, kernel file systems retain rich functionality but become CPU-bound and slow, and device-resident logic reduces host load but suffers from PCIe latency and wimpy processors.

This paper presents Oxbow, a coordinated storage architecture that composes kernel, user-space, and device components to achieve all four goals simultaneously: high performance, strong kernel interoperability, low CPU consumption, and fast development velocity. Oxbow combines a kernel-based read path with a kernel-bypassing write path, shared-ownership metadata, and Split Journaling, a host–device journaling mechanism that decouples `fsync` from background commits using staging areas and DMA-based snapshots. We demonstrate that Oxbow delivers kernel-level protection and sharing semantics while matching or exceeding the performance of state-of-the-art user-level file systems and substantially reducing host CPU use through offload to computational SSDs.

1 Introduction

The storage landscape is undergoing a fundamental transformation. Storage devices have raced past 14 GB/s [23], turning the traditional kernel-centric architecture—once the bedrock of stability—into a performance bottleneck. To bypass this bottleneck, the industry has diverged into two competing directions. On one side, user-level file systems [36, 39] implement lightweight I/O data paths and eliminate system-call overhead to maximize host throughput. On the other, computational storage devices (CSDs) [15, 22] embed ARM cores to offload tasks entirely from the host, saving host CPU cycles [35, 42]. Yet, despite these advances, modern systems face an uncomfortable truth: no single architecture delivers high performance, efficient resource utilization, and robust kernel integration simultaneously.

The root cause is fragmentation. Storage functionality is now fractured across application libraries, user-space servers, kernel components, and in-device logic. This fragmentation forces systems into rigid trade-offs: User-level file systems achieve low latency but lose the kernel's rich functionality—page cache, readahead, access control, and zero-copy primitives such as `sendfile()`. Device-resident file systems [33, 56, 57] reduce host CPU load but are constrained by PCIe latency and weak device-side processors, making them unsuitable for latency-sensitive or metadata-heavy operations. Each architecture adopts a different subset of functionality, but none can satisfy all system goals at once. The prevailing wisdom dictates a choice: user space for performance, the kernel for integration, or the device for resource efficiency. However, this either-or framing ignores a deeper opportunity.

We present Oxbow, a file system embodying a *coordinated architecture* that harmonizes these fragmented pieces. Oxbow distributes operations across four components: a user-level library (oxLib) that exposes fast, application-aware interfaces, a trusted user-level file server (H-Server) that executes core file-system logic, a thin kernel shim (illuFS) that integrates with VFS, page cache, and kernel-managed file abstractions, and a device-side server (D-Server) that offloads crash-consistency work such as background journaling and checkpointing. The central idea behind Oxbow is to partition responsibilities strategically and minimize shared mutable state, allowing each component to excel at the tasks it is naturally suited for. This coordination enables Oxbow to combine high user-level performance, rich kernel interoperability, and efficient device offloading—without introducing excessive synchronization or communication overhead.

Realizing this architecture raises three coordination problems. *First*, the kernel must be engaged selectively: bypassing it forfeits the page cache, readahead, and zero-copy paths such as `sendfile()`, while routing all I/O through it reintroduces system-call and data-movement overhead. Oxbow applies *semi-kernel-bypassing I/O*, exploiting the kernel's asymmetric value for reads versus writes—reads traverse the kernel page-fault path to reuse the page cache and readahead, whereas writes bypass the kernel and stream from the application through H-Server to the device at user-level speed. *Second*, components must share metadata without the component-crossing synchronization that becomes a bottleneck under contention. Oxbow uses *shared-ownership metadata*, partitioning inode attributes by the component that updates them so that each attribute has a single writer (e.g., oxLib owns `size` and `mtime`, the kernel owns `uid` and `gid`), removing synchronization from the common path. *Third*, crash-consistency work—

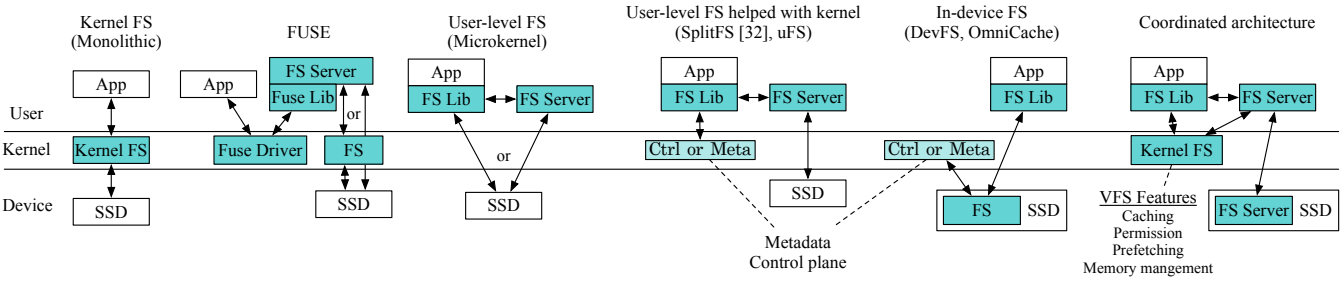

Figure 1: **Comparison of file system architectures.** Shaded boxes denote file-system components.

CPU-intensive I/O that runs in the background, making it a strong offloading candidate—should move to the device without stalling foreground `fsync` on slow device-side commits. Oxbow introduces *split journaling*, which stages `fsync` data on a fast host path while the CSD journals on a separate background path, letting `fsync` complete at host speed while reducing host CPU consumption.

We implement Oxbow with four components totaling 53K lines of code, emulating a CSD using a BlueField-2 DPU [22] and an SR-IOV-capable SSD [13] to enable concurrent host-device access. We evaluate Oxbow against Ext4, µFS [39], and OmniCache [57] using microbenchmarks and real-world workloads. Across microbenchmarks, Oxbow delivers up to 4.8× the write throughput of Ext4 and up to 86% higher throughput than µFS, while reducing host CPU consumption by up to 55% relative to µFS and improving throughput-per-CPU efficiency by up to 3.9× over µFS (4.7× over Ext4). In a LevelDB YCSB benchmark, Oxbow achieves the best throughput across read- and range-heavy workloads, improving throughput by up to 89% over µFS and 41% over Ext4. By retaining the kernel's VFS layer, Oxbow can transparently leverage `sendfile`, achieving 3.3× higher Nginx throughput than the same configuration without it.

We have made Oxbow publicly available at `https://github.com/xlab-uiuc/oxbow`.

2 Trends in Modern Storage Systems

2.1 The Fragmented Landscape

Modern file systems span a widening spectrum of architectures, each making fundamentally different design tradeoffs as illustrated in Figure 1. Monolithic kernel file systems [1, 25, 43] integrate tightly with VFS, page cache, and memory management, offering robust protection and strong sharing semantics. However, their reliance on the complex kernel I/O stack incurs kernel-crossing costs and software overheads. FUSE-based systems preserve kernel services while enabling user-space development, but frequent boundary crossings and data copies constrain them to non–performance-critical workloads. User-level file systems bypass the kernel entirely—either as application-linked libraries (e.g., Exokernel [29]) or user-space servers in microkernel designs [38], achieving impressive throughput by eschewing kernel mediation. Yet this performance comes at the cost of protection, global coordination, and transparent sharing. Even modern hybrids such as µFS [39] must combine user-level and kernel mechanisms in ad hoc ways that complicate correctness and maintenance. Finally, in-device file systems [33, 47, 56, 57] execute directly on CSDs, reducing host CPU usage and benefiting from near-data processing. Their shortcomings lie elsewhere: limited device compute, PCIe round trips, and difficulty integrating with host-side abstractions.

The result is a fragmented landscape: each architecture excels along one axis but none strikes a balanced design.

2.2 The Promise and Cost of User-level I/O

Fast storage hardware [2, 10, 11] has amplified the relative cost of kernel I/O paths and mode switches. To remove these bottlenecks, many modern systems adopt user-level drivers such as DPDK [3] and SPDK [7], which bypass kernel mediation entirely [36, 39, 42, 46, 52].

2.2.1 Promise

User-level I/O offers three advantages: (1) a fast, predictable data path, (2) scalable resource allocation by simply adjusting user-level thread counts [39], and (3) rapid development with rich user-space tooling. These benefits allow developers to quickly adapt file systems to emerging hardware such as CSDs, Compute Express Link (CXL) SSDs [49], Zoned Namespace (ZNS) SSDs [14], and Flexible Data Placement (FDP) SSDs [16].

2.2.2 Cost of Abandoning the Kernel

Bypassing the kernel, however, forfeits its mature, well-engineered services and system-wide management, forcing user-level designs to re-engineer kernel functionality in user space or forgo it entirely.

Isolation. Without kernel scheduling or memory reclamation, user-level file systems often require dedicated resources or entire machines to avoid interference. Many file systems partially delegate resource control back to the kernel [4, 33, 39, 47], complicating the architecture.

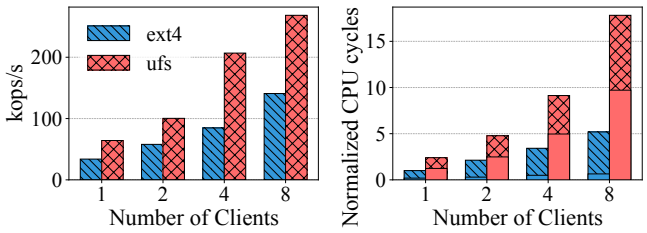

Figure 2: **Filebench (Varmail) throughput and CPU cycles.** CPU cycles are normalized to `Ext4` with one client; solid portions denote cycles in the file system layer. Both systems perform metadata journaling on the testbed (§6.1).

Performance. The kernel page cache, inode and dentry caches, prefetching, and memory management integration accelerate the I/O path. User-level systems that bypass the VFS cannot exploit these services and must build their own in user space—duplicating decades of kernel engineering effort and adding significant development overhead. Some user-level systems even lack essential features such as prefetching [39].

File Sharing. User-level implementations cannot leverage kernel page tables or VFS permission checks, so they must reimplement sharing and serialization in user space to enforce correctness. To emulate kernel-level sharing, systems such as Strata [36], µFS [39], and OmniCache [57] rely on leases [31]. However, lease revocation and renewal incur significant overhead under concurrent access [39, 41], and maintaining consistency in user space raises development costs.

Kernel Interoperability. Kernel interoperability enables file systems to support kernel-managed services transparently. For example, zero-copy system calls such as `splice` and `sendfile` move data directly between kernel buffers and are critical for high-performance web servers and file servers. If a file descriptor belongs to a user-level file system that does not interoperate with the kernel, data must traverse user space, incurring extra copies and mode switches.

2.3 The CPU Bottleneck and Device Offload

As storage speeds increase (e.g., 63 GB/s with PCIe 5.0 [12]), the bottleneck shifts from I/O to host CPU. Two trends exacerbate this: (1) Polling-based I/O—SPDK busy-waits for low latency, consuming 100% of a CPU core. (2) Massive parallelism—systems like µFS [39] and optimized Ext4 [26, 34] scale throughput but linearly increase CPU usage. Figure 2, with a mail server workload, shows the trade-off: µFS achieves 2.4× Ext4 throughput but consumes 3.4× CPU cycles, with over 50% spent in the file system layer. CPU-heavy operations such as journaling, checksums, and encryption steal cycles from applications.

Device Offloading. CSDs [15, 19, 22] now include ARM cores, DRAM, and accelerators. While prior work uses CSDs for I/O scheduling [33, 47] or near-data processing [54, 56, 57], we argue that they suit *background tasks* more than latency-critical data paths. CSD processors are weaker than host CPUs (e.g., 2.0 GHz ARM vs. 4.0 GHz x86), and PCIe crossings add latency; on the other hand, they excel at asynchronous, parallel processing. Offloading journaling, garbage collection, or compression to the device reduces host CPU load without penalizing foreground operations.

2.4 Requirements vs. Current Designs

These observations expose major tensions in modern file systems in the following dimensions:

- **High performance:** scalable, low-overhead I/O paths.
- **Kernel interoperability:** leveraging mature VFS services and interfaces.
- **Low CPU consumption:** minimizing interference with co-located workloads by device offloading.
- **Fast development velocity:** enabling rapid evolution in user space.

Existing architectures typically center on one primary placement: user-level designs place functionality in user space for performance and agility, kernel file systems keep it in the kernel for integration, and device-resident designs move it to the device to reduce host CPU load. Each choice satisfies a different subset of requirements, leaving open how to compose their strengths without inheriting their coordination costs.

3 Coordinated Architecture

Our key insight is that user-space, kernel, and device components are not adversaries to be chosen between, but complementary resources that can be orchestrated. We therefore propose a *coordinated architecture* that deliberately distributes file system responsibilities across components, assigning each task to the component best suited to perform it.

At a high level, the kernel remains responsible for caching, protection, and sharing; user space hosts flexible file-system logic and fast I/O; and the device handles CPU-intensive background tasks that would otherwise interfere with application performance. Crucially, unlike prior device-centric systems (e.g., DevFS [33], CrossFS [47], and OmniCache [57]) that migrate substantial foreground logic into the device, the coordinated architecture retains foreground file-system operations on the host to avoid PCIe round trips and preserve low latency.

Placement across User Space and Kernel. A key principle of the coordinated architecture is to place *dynamic, fast-evolving* features in user space, while reusing *stable, heavily optimized* functionality in the kernel. Kernel services such as the page cache, readahead, write-back, protection, and permission checking have decades of engineering investment and evolve slowly relative to hardware trends. Reusing these services avoids reimplementation, reduces complexity, and ensures transparent interoperability with other applications.

User space, in contrast, offers rapid iteration and flexible mapping to fast I/O paths, enabling adaptation to emerging device interfaces and application demands.

Composing multiple components into a coherent file system introduces several fundamental challenges beyond the limitations of any single component:

- **Balancing kernel involvement.** Fully bypassing the kernel forfeits its services, while routing all I/O through it reintroduces kernel-crossing overheads. The architecture must decide which operations genuinely benefit from kernel involvement.
- **Metadata synchronization.** If multiple components update file system metadata, every access risks cross-component synchronization. For example, both the kernel (through the VFS and memory subsystem) and the user-level file server may need to access or mutate inode state. Naively granting either component full ownership forces costly synchronization—e.g., fetching the latest version from the other component, invalidating cached state, or acquiring shared locks or leases that quickly become contended and add complexity.
- **Cross-component data movement.** Distributing functionality across user space, the kernel, and the device can amplify communication overheads. Data or metadata may traverse multiple boundaries: IPC between the application and user server, kernel crossings, PCIe round trips to a device, and memory copies within the host. Without careful structuring, these costs can overshadow the benefits of specialized components.
- **Crash-consistency dependencies.** Offloading journaling to a CSD is appealing because background journaling consumes substantial host CPU cycles in user-level I/O stacks, but traditional journaling schemes couple foreground `fsync` operations with background commit work. In-place data updates and POSIX ordering constraints can force the fast host CPU to wait for slower device-side commits, while the system still must preserve ordering and recovery semantics across host and device state.

To address these challenges, the coordinated architecture adopts three techniques that selectively place operations on the kernel path, minimize synchronization, reduce data movement, and restrict device offload to background work:

- **Semi-kernel-bypassing I/O.** The coordinated architecture exploits the asymmetric benefits of kernel involvement. Operations that depend on kernel services or state (e.g., page faults, eviction decisions, access-control checks) traverse the kernel, while others bypass the kernel to achieve user-level latency and throughput. In particular, reads benefit from kernel caching and readahead, whereas writes benefit from bypassing the kernel on the persistence path.
- **Shared-ownership metadata.** Instead of assigning an inode or metadata structure exclusively to a single component, the coordinated architecture partitions metadata fields and assigns each partition to the component best suited to maintain it. This single-writer structure avoids coarse-grained invalidation or locking while still allowing multiple components to read shared metadata.
- **File-semantics-agnostic device offloading.** The coordinated architecture decouples crash consistency from POSIX file semantics, allowing journaling and other maintenance tasks to run entirely on the device without host–device coordination on the foreground path. Because device CPUs are slower and PCIe adds latency, offloaded work is restricted to background operations (e.g., journaling, garbage collection, and compression) that tolerate latency but benefit from parallel, near-data execution.

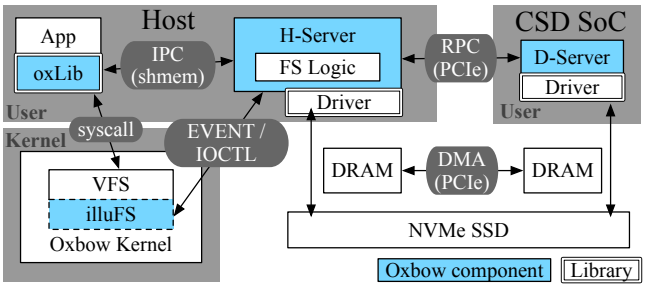

Figure 3: **Oxbow components and their communication.**

4 Oxbow File System

Oxbow instantiates the coordinated architecture of §3 with four components (Figure 3): a per-application user-level library (oxLib) and a trusted user-level file server (H-Server) on the fast user-space I/O path, a thin in-kernel shim (illuFS) that reuses kernel VFS services, and a device-resident file server (D-Server) that runs background work on a CSD.

The three techniques of §3 map onto these components as follows. *Semi-kernel-bypassing I/O* is realized by the oxLib/illuFS/H-Server split and its read/write paths (§4.1, §4.3, and §4.6); *shared-ownership metadata* partitions inode fields across oxLib, Oxbow Kernel, and H-Server (§4.2); and *file-semantics-agnostic device offloading* is embodied by Split Journaling, which keeps `fsync` on the host while D-Server performs background journaling (§4.4 and §4.5).

4.1 Components and Overall Architecture

Figure 3 shows the four Oxbow components and communication channels that realize semi-kernel-bypassing I/O and device-side journaling.

oxLib. oxLib is a user-space library linked into each application. It exposes the POSIX API, intercepts file system calls, and replaces read and write system calls with `mmap`-based loads and stores. For operations that require durable persistence or coordination, such as `fsync` and namespace operations (e.g., file and directory creation), oxLib forwards

requests to H-Server. oxLib also maintains per-file dirty-page and page-lock bitmaps in shared memory (§4.2), which allow H-Server to identify dirty pages and enforce page-granularity atomicity without involving the kernel in block management.

Oxbow Kernel and illuFS. To leverage the kernel's VFS services, Oxbow adds a lightweight in-kernel file system, illuFS. From the VFS's perspective, illuFS behaves like a normal kernel file system: it participates in mount/unmount, cooperates with the page cache, and integrates with readahead and eviction. Instead of implementing its own file system layer, however, illuFS forwards I/O and metadata requests to H-Server via an event-driven interface. Oxbow therefore reuses the kernel's page cache, permission checks, and sharing semantics without modifying kernel subsystems or routing data through the kernel block layer.

H-Server. H-Server is a trusted user-level file server that owns the storage device. It implements the core file system logic, including on-disk layout, block and inode allocation, indexing, and cooperation with journaling. Conceptually, H-Server plays the role of a generic "VFS for user-space file systems": it offers a pluggable interface for file-system-specific logic (such as Ext4-style layouts) while providing generic mechanisms for staging, journaling, and communication with oxLib and illuFS. All device I/O from the host passes through H-Server and is issued via a user-level driver, providing a fast data path and enabling kernel bypass for writes. H-Server also prepares transactions for Split Journaling, stages `fsync` data, and coordinates background journaling with D-Server (§4.4).

D-Server. D-Server runs on the CSD and executes background journaling and checkpointing. It receives prepared transactions from H-Server, pulls their contents into device DRAM via DMA, and persists them to an on-disk journal area. By running on the CSD, D-Server offloads the CPU and I/O work of background journaling from the host while exploiting device-level parallelism. D-Server implements data journaling and checkpointing, but it does not understand file semantics; instead, it operates purely on block addresses and extents provided by H-Server (§4.4).

Communication Paths. Oxbow adds explicit communication channels between components beyond system calls. The kernel communicates with H-Server using an event-driven mechanism based on `epoll`: illuFS enqueues I/O and metadata requests for H-Server, and H-Server responds via `ioctl` once operations complete. oxLib and H-Server share metadata and control information through shared memory and lightweight IPC, avoiding copies and unnecessary mode switches. H-Server and D-Server communicate over PCIe using an RPC mechanism for control (e.g., "transaction ready") and DMA for bulk data transfer. When H-Server prepares a transaction, it copies metadata and dirty pages into a contiguous DMA buffer and notifies D-Server. D-Server then pulls this DMA buffer into device memory using DMA, which does not consume host CPU cycles. These channels make coordination explicit while keeping latency-sensitive communication on the host and restricting PCIe traffic to background paths.

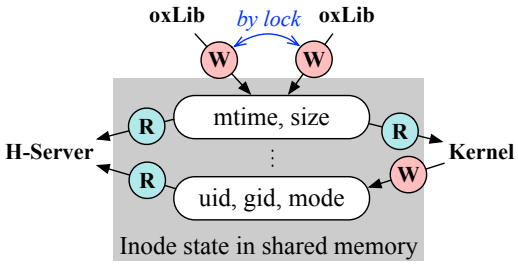

Figure 4: **Shared-ownership of states.** R: read, W: update.

4.2 State Ownership and Sharing

Oxbow adopts a shared-nothing design for most metadata, and shared-ownership only where components must cooperate. On disk, H-Server hosts arbitrary file system logic, using the underlying layout (e.g., Ext4 superblock, inode table, and allocation bitmaps); Oxbow adds its own structures for a dedicated journal area and a staging area (§4.3), each with a superblock. This design decouples crash consistency from base file system semantics and allows Split Journaling to operate independently.

In memory, each metadata object has a primary owner: H-Server manages global file system state such as free block and inode bitmaps and the inode cache as part of its core logic, while D-Server exclusively owns crash-consistency metadata.

Shared-ownership of Metadata. For metadata accessed by multiple host components, Oxbow uses *shared-ownership*. Inode state is split into small attribute groups with a single writer per group (Figure 4): permission fields such as `uid/gid` are updated only by the kernel, while file size and timestamps are updated exclusively by oxLib. H-Server reads these fields when updating on-disk metadata but does not modify them after initial load. All shared attributes are stored in shared memory so the kernel, oxLib, and H-Server can access them without copying. This single-writer, multi-reader pattern avoids global locks for synchronization in the I/O path, with locks needed only when multiple oxLib instances concurrently update the same inode.

Ownership is enforced rather than advisory: Oxbow treats the kernel and H-Server as trusted and oxLib as untrusted, and H-Server exposes each attribute group as a separate POSIX shared-memory region whose permissions derive from the file and are enforced by the kernel. Attributes that oxLib does not own (e.g., `uid/gid`) are mapped read-only, so a compromised oxLib can modify only the fields it owns (e.g., size and `mtime`), and only for files it may already write; it cannot read or corrupt metadata of files it is not authorized to access. H-Server also re-validates owned fields on use, so fabricated values stay contained—an inflated size, for instance, fails at block resolution instead of exposing unallocated blocks.

Dirty and Page-lock Bitmaps. File data is shared by all

host components. Applications write to `mmap`-ed pages via oxLib, the kernel manages those pages in the page cache, and H-Server writes them back to disk. Oxbow avoids data copies by sharing page-cache memory across components. Per-file dirty-page and page-lock bitmaps, maintained by oxLib in shared memory, let H-Server identify dirty data precisely without exposing page-to-block mappings to the kernel. These bitmaps are accessed only by oxLib and H-Server, not by the kernel: Oxbow delegates dirty-page tracking and page locking—tasks traditionally handled by the kernel as part of page-cache management—to user-level components, avoiding the mode switches and communication overhead that kernel-managed bookkeeping would otherwise incur.

When an application modifies a page, oxLib sets the corresponding dirty bit. H-Server consumes these bits when preparing `fsync` staging or background journaling, and clears each bit only after the page's contents have been copied into the DMA buffer. Page-lock bits provide page-granularity synchronization by guaranteeing exclusive access to a page-cache page, so different pages of the same file can be updated concurrently. A lock is held in two cases: when oxLib writes to a page-cache page, and when H-Server copies a page from the page cache into the DMA buffer. Because both writers acquire the same lock, an application write and H-Server's copy never race on the same page, preserving the kernel's page-lock semantics in user space.

In-memory Caches. H-Server maintains the authoritative in-memory inode cache and on-disk allocation structures, in a form compatible with `struct inode`. Selected attributes are shared with the kernel and oxLib via the shared-ownership mechanism, while the kernel's VFS layer continues to serve reads via the page cache. H-Server caches directory entries so namespace operations can avoid kernel involvement. Oxbow does not rely on the kernel's native VFS inode cache for on-disk updates. On the device, D-Server keeps journal metadata, including its superblock and commit/checkpointing state. Journal transactions store only block addresses, extents, and staging descriptors, keeping D-Server file-system-agnostic and reinforcing the separation between crash consistency and file system logic.

4.3 End-to-End Operation Flow

Open Path. On `open`, oxLib calls into the kernel to obtain a file descriptor. illuFS forwards the lookup to H-Server, which performs path resolution, allocates an inode number, and initializes per-file structures in both H-Server and shared memory. The kernel returns to oxLib once the inode number is known, while H-Server continues initialization in parallel. oxLib then maps the file for direct load/store access via `mmap` and the shared-memory region.

Read Path—Through the Kernel Page Cache. As shown in Figure 5, oxLib translates a `read` into loads from the `mmap`-ed region. A first access causes a page fault; the kernel allocates a

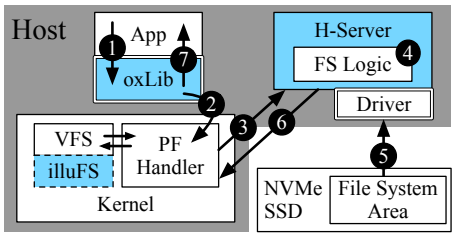

Figure 5: **The read path.** Numbers denote the order of steps.

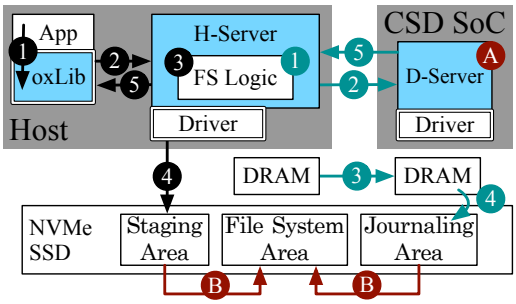

Figure 6: **The writeback path.** (X: `fsync`, X: background commit, X: checkpointing)

page and invokes illuFS, which issues a user-level read request to H-Server. H-Server computes block numbers using its file-system logic, submits I/O through its user-level driver, and fills the page cache upon completion. The kernel then resolves the page fault and resumes the application. Subsequent reads hit in the page cache. Because Oxbow uses the VFS layer, it also benefits from kernel readahead: asynchronous read-ahead requests are issued by the kernel and served by H-Server the same way, reducing read latency for sequential workloads.

Write Path and `fsync`—Bypassing the Kernel. Applications write by storing into `mmap`-ed pages (Figure 6, ❶). If the page is present, the store updates it directly; otherwise, a page fault loads it as in the read path. oxLib marks the page dirty and sets its page-lock bit while the page is being modified.

On `fsync`, oxLib forwards the request to H-Server (❷), which persists the file durably on the host using Split Journaling (§4.4). H-Server snapshots the file's metadata, resolves its dirty pages to block addresses (allocating blocks if needed) (❸), and writes the file's data and inode into a dedicated *staging area*, a persistent on-disk region (❹). `fsync` returns as soon as this staging write is durable (❺); it does *not* wait for the device-side background journaling. Background journaling then proceeds asynchronously on D-Server, batching many files into the journal area without blocking the application. §4.4 details how Split Journaling decouples these two paths so that `fsync` need not wait.

4.4 Split Journaling: Host–Device Journaling

Conventional journaling, as in Ext4 and other journaling file systems, persists updates in two phases: applications' data and metadata modifications are grouped into transactions and

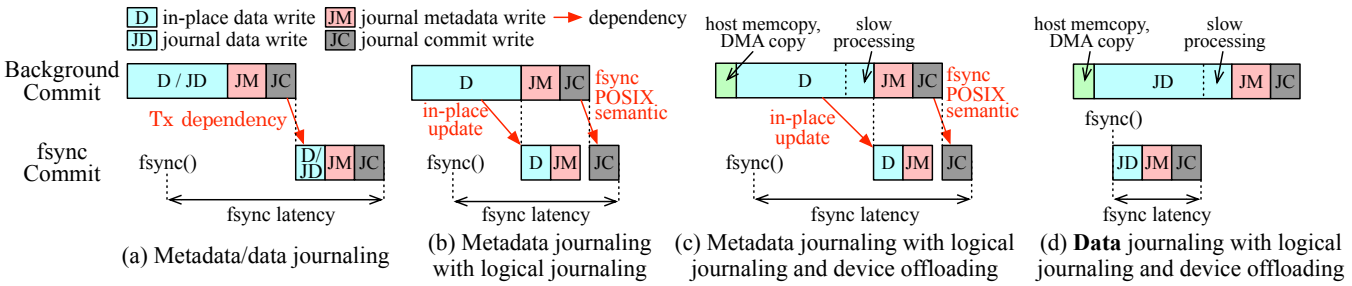

Figure 7: **Dependencies in different journaling schemes.** Host memcopy indicates copying dirty pages to a DMA buffer within the host. DMA copy represents data copy from the host DMA buffer to a device memory. The only dependency in (d) is host memcopy—`fsync` must wait for memcopy from the page cache to the DMA buffer.

written to a journal area, where a commit record marks each transaction durable; a later checkpointing phase applies those changes to the main file system area and frees journal space. Metadata journaling writes only metadata to the journal and updates data in place, reducing write amplification but weakening data consistency, while data journaling logs both data and metadata, providing strong crash consistency at the cost of more I/O. By utilizing a CSD, Oxbow offloads data journaling costs to D-Server.

Split Journaling keeps `fsync` latency on the host while offloading background commits to the device. Achieving this requires removing the dependencies that tie foreground `fsync` to background journaling in traditional designs. In conventional metadata journaling, foreground `fsync` and background commits share a single journal and are committed in order, so `fsync` is serialized behind outstanding background commits (Figure 7a). Logical journaling techniques [45, 48] break this coupling by separating `fsync`-induced transactions from background commits. Doing so, however, leaves two finer dependencies behind, each of which still introduces a delay (Figure 7b). First, `fsync`'s in-place write must wait for the completion of any in-progress background in-place update to the same file (*in-place update dependency*). Second, `fsync` must wait for all prior transactions modifying the file to be committed (*POSIX ordering dependency*).

Device offload exacerbates these residual dependencies: checking them requires frequent host–device coordination, and any slowdown in background commits directly impacts `fsync` (Figure 7c). Split Journaling eliminates both dependencies by using data journaling for its two paths and introducing a staging area that decouples `fsync` from background commits (Figure 7d).

Decoupling Staging from Background Commits. Split Journaling provides two data-journaling paths that target two on-disk areas: a fast *staging path* driven by the host for `fsync`, and a slower *background path* driven by D-Server. The background path runs as periodic *background commits*—triggered automatically by the file system—that batch updates for many files into a single journal transaction. On `fsync`, H-Server writes the file's data and inode metadata directly into the staging area through the DMA buffer of its user-level driver, forming a *staging transaction* that is independent of background commit progress. For background commits, H-Server instead fills a separate host-memory DMA buffer (Figure 6, ❶) and signals D-Server (❷), which pulls the data into device memory (❸) and writes it out to the journal area (❹). Because staged data is logged rather than updated in place, the in-place update dependency disappears.

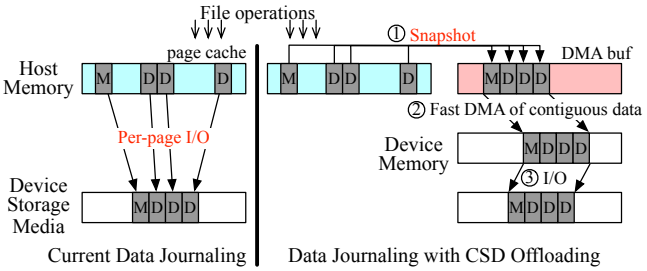

Figure 8: **DMA buffer for shadow copy.** A write to a page is blocked while it is being persisted (left) vs. only while it is copied into the DMA buffer (right). D: data, M: metadata.

To eliminate POSIX ordering dependencies, staging transactions are self-contained. If a file is part of any in-flight journal transaction, H-Server re-logs the data and metadata relevant to that file into the staging area along with new `fsync` data. Each staging transaction also records the ID of the latest committed journal transaction for recovery (§4.5). As a result, `fsync` no longer waits for background commits, and host and device can operate in parallel (Figure 7d).

DMA Snapshots as Shadow Copies. Offloading to CSD requires transferring data over PCIe, and issuing per-page DMA operations is too costly. Split Journaling copies all pages of a transaction into a contiguous DMA buffer and performs a single DMA transfer. This extra copy is repurposed into a snapshot: the DMA buffer becomes a shadow copy of the page cache (Figure 8).

The snapshot copying brings two benefits. First, it removes interference between page updates and background commits. H-Server briefly locks pages, copies them into the DMA buffer, and immediately unlocks them, allowing subsequent

writes to proceed while the device processes the snapshot. Existing journaling (e.g., JBD2 of Ext4) also relies on shadow copies (frozen buffers) for this, but creates them only lazily: once a page's journal I/O is in flight, a conflicting write must block until that I/O completes [50]. Second, it raises the granularity at which the global lock is acquired from pages to files when adding metadata to a transaction. In traditional journaling, each page inserted into the running transaction—whether data or metadata—must acquire a single global lock. Since data journaling journals data as well, it performs far more insertions and contends for this lock heavily [50]. In Oxbow, snapshots reduce the blocking time to the duration of the memory copy, making metadata insertion with file-granularity locks practical at lower contention. Note that data pages remain synchronized using per-page locks (§4.2).

Parallel and Aggressive Journaling. Background commits exploit both pipeline and thread-level parallelism. The commit pipeline consists of: (1) copying metadata and dirty data into the DMA buffer in H-Server, (2) DMA transfer to D-Server, and (3) device-side journal writes. Once the DMA buffer is handed off, H-Server begins preparing the next transaction.

Oxbow also triggers background commits more aggressively than kernel journaling. Shorter intervals reduce the amount of data written during `fsync`, lowering foreground latency. Because background commits run on CSD CPUs and rely on DMA for transfer, this aggressiveness reduces host CPU consumption and improves perceived `fsync` cost. D-Server further parallelizes journal I/O across its cores, maximizing device bandwidth.

Checkpointing. D-Server reclaims journal and staging space by checkpointing committed transactions (Figure 6, Ⓐ) into the main file-system area when either the journal or the staging area runs low on free space (Ⓑ). Because a journal transaction commits after the staging transactions it records, D-Server checkpoints those staging transactions first and the journal transaction last, preserving commit order.

4.5 Crash Consistency

Oxbow's crash consistency reduces to a single invariant: every `fsync`-ed file is recoverable from its self-contained staging transaction together with the journal prefix whose ID the transaction records. The transaction contents below maintain this invariant, which recovery relies on directly.

Background Journaling. Journal transactions contain snapshots of file-system state (superblock fields, allocation bitmaps), per-file metadata, and data. They are indexed purely by block addresses and extents so that D-Server can process commits without interpreting file semantics. Each journal transaction also records, for every staging transaction committed since the previous journal commit, the address of its *staging descriptor* (the staging transaction's on-disk header). This enables D-Server to reconcile staging and journal state during checkpointing and recovery.

Staging for `fsync`. A staging transaction contains only the inode and data for the `fsync`-ed file, plus the ID of the most recently committed journal transaction. To guarantee recoverability, Oxbow re-logs all uncommitted data for that file into the staging transaction, even if a background commit is in progress. As a result, each staging transaction is self-contained: after a crash, the file can be reconstructed solely from its staging transaction and the journal prefix up to the recorded ID.

Recovery. On initialization, D-Server checks whether the journal is clean. If not, it replays all committed but uncheckpointed journal transactions in order, applying any staging transactions referenced by them. It then scans for "dangling" staging transactions whose associated journal commit was lost or never issued. Because a staging transaction captures all modifications since the last committed journal transaction, D-Server can safely apply these remaining staging transactions on top of the replayed journal state, ensuring durability for all `fsync`-ed files. Since H-Server allocates blocks and inodes after snapshotting the free bitmaps, snapshots lag behind actual allocations. During recovery, D-Server scans all transactions and reconstructs free block and inode bitmaps and superblock counters based on the extents stored in transactions, avoiding reliance on stale bitmap images.

Partial Failures. Oxbow assumes fail-stop components. Durability is established at `fsync` via a self-contained staging transaction persisted to the on-disk staging area, so a host-side failure (oxLib, illuFS, or H-Server) loses only data not yet `fsync`-ed, exactly as under POSIX, while `fsync`-ed files remain durable in the staging area. Such failures need no recovery: since H-Server is a client of D-Server and the device retains this durable state, H-Server can simply be relaunched and reconnect without restarting D-Server. A D-Server failure, by contrast, invalidates H-Server's session, so both are relaunched and D-Server runs the recovery procedure on restart. If the CSD's compute capability is lost (e.g., due to a hardware failure) while its storage remains reachable as a block device, D-Server can run on the host without losing availability.

4.6 File Sharing and Protection

Oxbow preserves the kernel's protection and sharing model by relying on the page cache and permission checks in the VFS layer. When a file is opened, the kernel enforces discretionary access control (DAC) and refuses to `open` or `mmap` the file for unauthorized processes. Once a page is in the page cache, the kernel maps it into the address spaces of all processes that have opened the file, enabling efficient sharing without additional mechanisms in user space. This avoids the lease-based file sharing and custom coherence protocols that user-level file systems must implement [24, 36, 39, 57].

The only additional mechanism Oxbow requires for safe sharing is the arbitration of concurrent writes. The page-lock bitmap maintained by oxLib substitutes for the kernel's in-

ternal page locks: oxLib and H-Server consult the bitmap to avoid concurrent updates to the same page. Because the bitmap lives in shared memory, all oxLib instances share a consistent view of page ownership.

Device access is restricted to H-Server and D-Server. No other process can issue I/O to the storage device directly, which prevents malicious applications from bypassing Oxbow 's protection mechanisms. Shared-memory regions such as dirty and page-lock bitmaps inherit the file's permissions, so an application that modifies oxLib code can corrupt only files that it already has permission to write.

5 Implementation

We use lwext4 [5] as H-Server's file system logic with minor modifications for integration. lwext4 originally targets embedded systems, providing the essential Ext4 logic and on-disk structures such as extents and block groups. We add multi-threading support and disable its built-in journaling because Oxbow provides crash consistency through Split Journaling. Oxbow is implemented in C/C++ totaling 53K lines of code excluding lwext4.

We emulate a CSD using a SmartNIC and an SSD supporting SR-IOV and NVMe Namespace Sharing [18]. Emulation requires (1) an in-device SoC and (2) the ability for the device and host to access the same storage media concurrently. For (1), we use an NVIDIA BlueField-2 DPU [17] which provides 8 ARM cores and 16 GB DRAM within the PCIe power budget, making it a realistic proxy for a CSD processor. For (2), the SmartNIC must access the host SSD. Because BlueField-2 communicates with the host only via RDMA, we expose the SSD to the SmartNIC using NVMe-oF. RDMA transfers place data directly into host DRAM and flush it to the SSD without host CPU involvement, closely matching the host-CPU savings of true CSD offload.

SR-IOV and Namespace Sharing allow both host and SmartNIC to operate on the same SSD namespace. The SSD exposes multiple NVMe controllers—e.g., a Physical Function (PF) for the SmartNIC (D-Server) and a Virtual Function (VF) for the host (H-Server)—each appearing as an independent PCIe device. Oxbow's coordination prevents H-Server and D-Server from accessing the same block concurrently.

6 Evaluation

We evaluate Oxbow in terms of performance, host CPU consumption, and interoperability with the kernel's subsystems. We compare Oxbow with µFS [39], OmniCache [57], and Ext4 [43]. µFS is the state-of-the-art user-level file system designed for high scalability on SSDs. We evaluate the coordinated architecture by comparing Oxbow with OmniCache. Unlike Oxbow, OmniCache operates a whole file system on CSD and selectively caches data between host and device memory (Figure 1). Ext4 is the most widely used journaling file system in the Linux kernel.

Our evaluation proceeds as follows. We first use latency and throughput microbenchmarks to characterize basic file system operations under append, sequential, and random patterns, sweeping the I/O size (§6.2.1) and the number of concurrent clients (§6.2.2). We then run an ablation study to isolate each design choice (§6.3), followed by real-world workloads—LevelDB under YCSB, RAG retrieval, LLM checkpointing, and Nginx with `sendfile`—to assess end-to-end benefits (§6.4). We additionally evaluate Oxbow with metadata-intensive workloads in the appendix (Appendix B).

6.1 Experimental Setup

Testbed. We run all the experiments on a dual-socket server equipped with two Intel(R) Xeon(R) Gold 5218 CPUs @ 2.30GHz, 128GB of DRAM, and a 3.2 TB Samsung PM1735 NVMe SSD [6] that supports SR-IOV and NVMe Namespace Sharing. We emulate a CSD with this device as described in §5. For the emulation, we use an NVIDIA BlueField-2 DPU [17] which is equipped with eight 2.0 GHz ARMv8 A72 cores and 16 GB of DRAM, and 64 GB eMMC for the storage. It supports 100 Gbps Ethernet; hence, PCIe bandwidth is not a bottleneck.

System Configuration. As we implement illuFS in the kernel version 6.2, we use the Ext4 data journaling mode in the same kernel. We disable the lazy initializations of Ext4 to get consistent and stable performance after mounting. We configure a sufficiently large journal (39 GB) and adjust the checkpointing threshold to avoid Ext4 performance degradation caused by journal space exhaustion.

µFS performs user-level I/O using SPDK and guarantees crash consistency with its own metadata journaling. µFS has two modes: a POSIX mode that is transparent to applications and a mode with a custom memory allocator that avoids memory copies between applications and the user-level file server. We use the latter mode to represent the best performance of µFS. We set the number of µFS server threads equal to the number of clients, since we observed having fewer server threads degrades performance [39]. We scale the number of clients up to 10, which is the maximum number µFS supports.

The OmniCache artifact runs only with persistent memory instead of SSDs and emulates CSD using a kernel module. We extend it to operate with a real CSD. The custom NVMe commands are replaced with RPC calls as in Oxbow. We run Ext4 on CSD as OmniCache's NearStorageFS as described in its paper [57]. Here, Ext4 runs in metadata journaling mode to enable direct I/O because OmniCache bypasses the kernel page cache and manages its own user-level cache.

In H-Server, we pin each I/O worker thread to an SSD I/O queue. Unless otherwise stated, H-Server is configured with eight I/O worker threads. Similar to Ext4, we provision Oxbow with sufficient journal space to avoid journal-space exhaustion during the experiments.

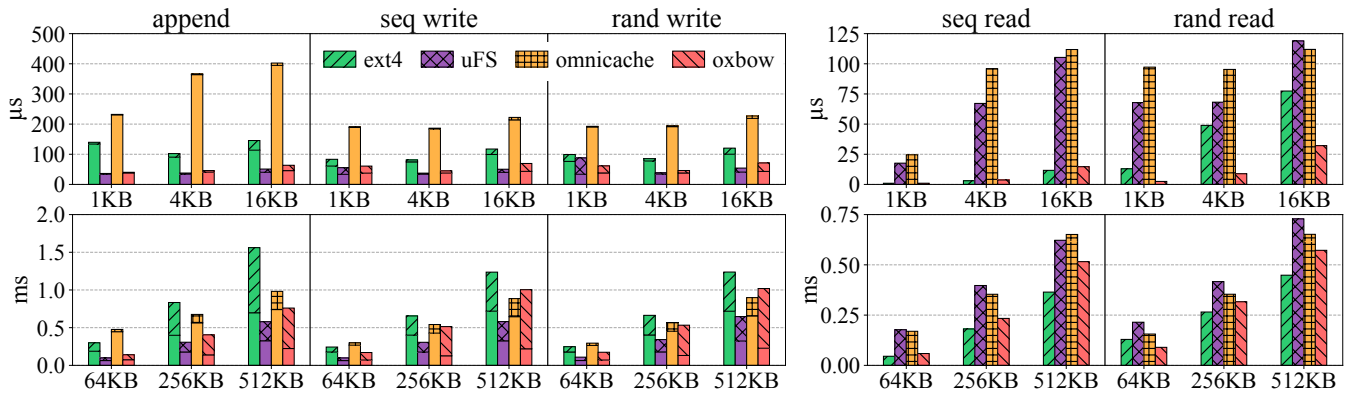

Figure 9: **Latency microbenchmark.** Average per-operation latency of five workload patterns across I/O sizes. The top row shows small I/Os and the bottom row shows large I/Os. The solid portion of each bar denotes the `fsync` latency. Lower is better.

6.2 Microbenchmarks

To evaluate basic file system operations of Oxbow we use the microbenchmark from the µFS paper [39].

6.2.1 Latency

We evaluate the performance of foreground I/O operations using the latency benchmark. A total of 1 GB of data is written to or read from a file with different I/O sizes, and the latency of individual file operations is measured. In particular, in write benchmarks, each `write` call is followed by a `fsync`, and the total latency is measured. The bars in Figure 9 represent the average total latency, and the solid portion of each bar represents the average `fsync` latency.

Write Latency. The two user-level file systems, µFS and Oxbow, achieve lower latency than Ext4 because they have fast foreground paths. Ext4's latency suffers due to its heavier kernel software stack and transaction commit mechanism. Compared with Ext4, Oxbow achieves 2.1–3.5×, 1.2–1.8×, and 1.2–1.9× lower latency for append, sequential, and random writes, respectively. However, µFS achieves up to 43% lower latency than Oxbow because Oxbow performs two additional memory copies: from the application buffer to the kernel page cache during a `write`, and from the page cache to an SPDK buffer during `fsync`. In contrast, µFS exposes SPDK buffers to applications to achieve zero-copy I/O, sacrificing application transparency. This overhead is the cost of leveraging the kernel's VFS.

OmniCache suffers from PCIe-crossing overhead inherent to its architecture. On `fsync`, data always traverses the device-side file system logic over PCIe, requiring copies from the user buffer to a DMA buffer and then to device memory. In contrast, we place the file system logic in H-Server, which enables host-side I/O without interacting with the device. Additionally, running a complex file system on the CSD's slow cores increases the latency further.

Read Latency. The sequential read latency of Oxbow is 18.2× lower than µFS for the 4KB I/O size, which is attributed to the kernel's readahead mechanism. While Ext4 achieves the lowest latency based on the kernel's readahead, it is 3–29% lower than Oxbow because of Oxbow's longer read path that involves two context switches between the kernel and H-Server and one additional memory copy (i.e., SPDK buffer to page cache). For 4KB random read, Oxbow delivers 5.5× and 7.7× lower latency than Ext4 and µFS, respectively. This is due to a faster I/O than Ext4 through a user-level driver and a prefetching effect within the 1 GB file relative to µFS. As the I/O size increases, this benchmark increasingly represents sequential reads, where Oxbow achieves lower throughput than Ext4 (§6.2.2). Compared to µFS, Oxbow's additional memory copies worsen the latency with larger I/O sizes. OmniCache shows high latency for the same reasons as in the write latency cases.

6.2.2 Throughput and Scalability

In the throughput microbenchmark (Figure 10), each thread writes 2 GB of data to its private file with 4KB I/O size and calls `fsync` after every 512 MB is written, i.e., many writes to a file followed by a single `fsync`. We increase the number of application processes from 1 to 32 (64 for reads) to measure the scalability of file systems. For this benchmark, we configure H-Server with 16 I/O worker threads. Because each client keeps at most one `fsync` (writes) or readahead (reads) request outstanding, the number of active I/O worker threads is bounded by the number of clients.

Write Throughput. For write workloads, Oxbow outperforms µFS by up to 86%. Fundamentally, Oxbow bypasses the kernel as µFS does, which enables faster I/O than Ext4. In addition, the background commit by D-Server reduces the amount of data written during `fsync`. This offsets the overheads from two more memory copies than µFS, resulting in higher throughput. OmniCache also achieves comparable throughput to Oxbow and µFS for the append and sequential write workloads. Different from the latency benchmark, the data is batched in 512 MB chunks and sent to the device. It en-

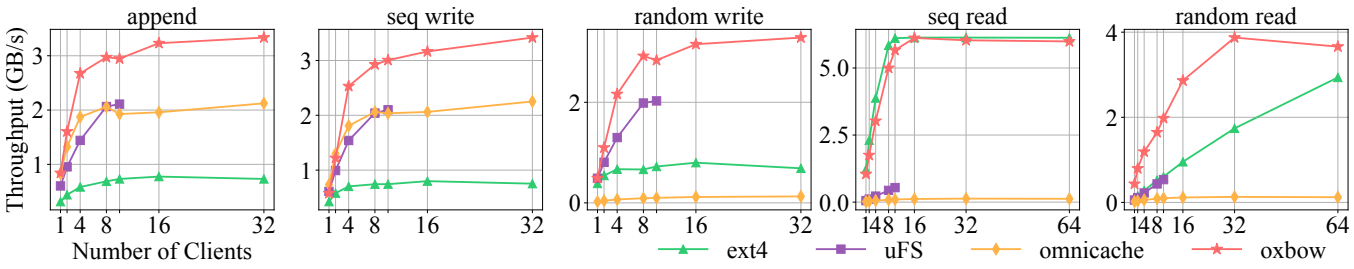

Figure 10: **Throughput microbenchmark.** The maximum SSD read and write bandwidths are 6.1 and 3.6 GB/s, respectively.

Clients	Workload	Ext4	µFS	OmniCache	Oxbow no-bg-jnl	Oxbow
1	Append	0.602 (34.21×)	0.339 (19.23×)	0.454 (25.76×)	0.155 (8.79×)	0.018 (1.00×)
	Seq write	0.628 (31.59×)	0.333 (16.77×)	0.527 (26.52×)	0.156 (7.86×)	0.020 (1.00×)
	Rand write	0.723 (28.73×)	0.442 (17.59×)	20.825 (828.12×)	0.176 (6.98×)	0.025 (1.00×)
10	Append	5.196 (4.55×)	2.866 (2.51×)	2.395 (2.10×)	1.205 (1.06×)	1.141 (1.00×)
	Seq write	5.329 (5.12×)	2.518 (2.42×)	2.255 (2.17×)	0.962 (0.92×)	1.041 (1.00×)
	Rand write	5.455 (5.57×)	1.957 (2.00×)	49.686 (50.74×)	1.030 (1.05×)	0.979 (1.00×)

Table 1: **Throughput microbenchmark `fsync` time (sec).** Numbers in parentheses are relative to Oxbow.

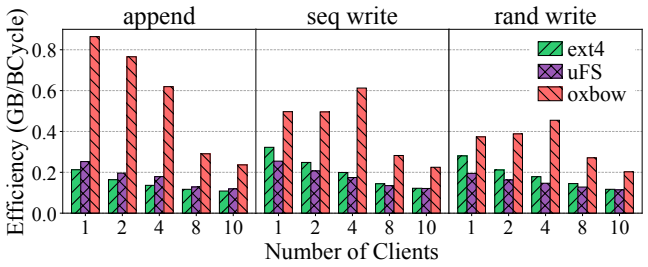
ables OmniCache to fully utilize PCIe lanes and available I/O bandwidth, hiding its high latency. On the other hand, random writes issue a large number of I/O requests for fragmented block chunks, creating a bottleneck in CSD's CPU resources. It prevents OmniCache from scaling beyond four processes. Ext4 suffers from contention in the block-based transaction composition of JBD2, resulting in inefficient use of I/O bandwidth and low throughput. In contrast, Oxbow composes a transaction at file granularity, which significantly reduces contention. As a result, Oxbow achieves 2.7–4.6×, 1.4–4.5×, and 1.3–4.8× the throughput of Ext4 for the append, sequential write, and random write workloads, respectively.

Fsync Time Reduction. We evaluate how effectively Oxbow reduces the foreground `fsync` time. Oxbow's `fsync` times are the lowest among all the other file systems (Table 1). With a single client, its `fsync` times are 16.8–19.2× lower than the second-best system, since D-Server commits most data in the background and leaves little to persist on `fsync`. With 10 clients, the gap narrows to 2.0–2.2× as I/O bandwidth saturation leaves less headroom for background commits to run ahead of `fsync`. This demonstrates Oxbow effectively reduces the foreground `fsync` latency by aggressively committing data with D-Server.

Read Throughput. For sequential read, Oxbow's throughput is 10.5–18.5× that of µFS thanks to the kernel's readahead prefetching, but 0.2–24% lower than Ext4 due to its longer read path. The kernel triggers the next readahead batch (e.g., 32 pages) when the application reaches a marked page in the current window; in Oxbow this cycle is longer because of kernel–H-Server context switches and an extra memory copy, which lowers the block-layer request rate and bandwidth utilization. Enlarging the readahead window compensates—e.g., raising it from 32 to 128 pages via a mount option lets Oxbow outperform Ext4 in all cases. Like µFS, OmniCache lacks a prefetching mechanism and achieves low sequential-read throughput; implementing custom prefetching would raise their performance but also their development cost. OmniCache further suffers from CSD CPU bottlenecks when 4 KB requests are issued one by one, as in random writes.

For random read, Oxbow achieves the highest throughput. Oxbow and Ext4 issue identical kernel readahead requests, so the difference comes from the lower layers: Oxbow uses a faster user-level driver and a lighter block layer (avoiding the kernel's I/O scheduler and interrupt-based stack), batches requests to reduce block-layer crossings, and pipelines across I/O worker threads. Even for random reads, kernel readahead prefetches some pages, disadvantaging µFS; still, its fast user-level I/O keeps it on par with Ext4, while OmniCache again suffers from CSD resource deficiency.

CPU Utilization. To demonstrate how effectively Oxbow reduces the host CPU resource consumption of user-level file systems by offloading journaling to CSD, we measure the CPU utilization of a whole system while running the throughput microbenchmark. For a fair comparison, we exclude the CPU cycles that µFS spends busy-waiting for client-server communication—but not those for I/O completion polling—when reporting its CPU usage; this is generous to µFS, since it would lose performance if such busy-waiting were removed. We introduce a metric, *efficiency*, to represent how much throughput a file system achieves given a certain amount of CPU resource, i.e., the number of bytes processed per CPU cycle. Figure 11a compares efficiency of Oxbow, µFS, and Ext4. For write operations, Oxbow achieves 1.8–3.9× the efficiency of µFS. This gain comes from D-Server's background commits, which reduce the amount of data written by the host and, in turn, lower the host CPU time spent polling for I/O completion. The efficiency of Oxbow decreases as the number of clients increases, because bursts of `fsync` calls reduce the opportunity for I/O offloading. Ext4 consumes less host CPU



(a) Efficiency (throughput / host CPU usage). Higher is better.

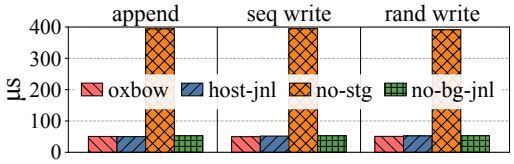

Figure 13: **Latency microbenchmark ablation study** with 4 KB I/O size. Lower is better.

resources than Oxbow, due to its interrupt-driven I/O. However, its performance is much lower than Oxbow, resulting in Oxbow achieving 1.3–4.7× the efficiency of Ext4.

Figure 11b breaks the absolute host CPU usage—reported in cores, i.e., consumed cycles/s normalized to one 2.3 GHz core—down into the benchmark application, the kernel, journaling, and the user-level file server. µFS demands the most CPU (e.g., 7.6 cores at 10 clients): it runs one busy-waiting file server thread per client to poll for I/O completion, so its file server dominates (around 80%) and grows with the client count, while its small kernel time mainly reflects memory-management overhead from its user-space processes. Ext4 instead spends most of its cycles in the kernel—where its entire storage stack, including JBD2 journaling, resides—but its interrupt-driven I/O yields the lowest overall consumption of the three (e.g., 2.9 cores at 10 clients). For Oxbow, the file server (H-Server) dominates as clients increase, since more worker threads busy-wait for user-level I/O completion once I/O becomes the bottleneck (e.g., H-Server uses 2.7 of 5.4 cores at 10 clients for append). In contrast, the background journaling thread uses only 0.1 core because it offloads journaling I/O to the CSD, and the kernel portion here covers both illuFS and the VFS.

6.3 Ablation Study

We perform ablation studies to evaluate the contribution of each major design choice of Oxbow. We compare the default Oxbow against three variants: *host journaling* (`host-jnl`), *no staging* (`no-stg`), and *no background journaling* (`no-bg-jnl`). Figure 12 reports the throughput and host CPU usage of the throughput microbenchmark (§6.2.2), and Figure 13 reports the results of the latency microbenchmark with 4 KB I/O size (§6.2.1).

Host Journaling. In this configuration, D-Server runs on the host, so Oxbow has no device component. Instead of using DMA, D-Server communicates with H-Server through shared memory, which eliminates one data copy compared to the default Oxbow. Under less contention, i.e., with fewer clients, the throughput degradation of host journaling is marginal. As the number of clients increases, host-journaling throughput becomes up to 21% lower than that of Oxbow due to host resource contention. For example, the host memory bandwidth is shared between H-Server and D-Server, and D-Server runs on the remote NUMA node because the local NUMA node lacks sufficient cores. Figure 12b shows that host journaling consumes up to 44% more host CPU resources than the default Oxbow even though it achieves lower throughput. The performance gap decreases as the number of clients grows, because of I/O bandwidth saturation.

No Staging. Staging is disabled, so `fsync` persistence requests are handled by the background-journaling path. With this configuration, all I/O operations are performed by the device, resulting in a drastic reduction of host CPU consumption (Figure 12b). However, its latency is about 7.8× that of

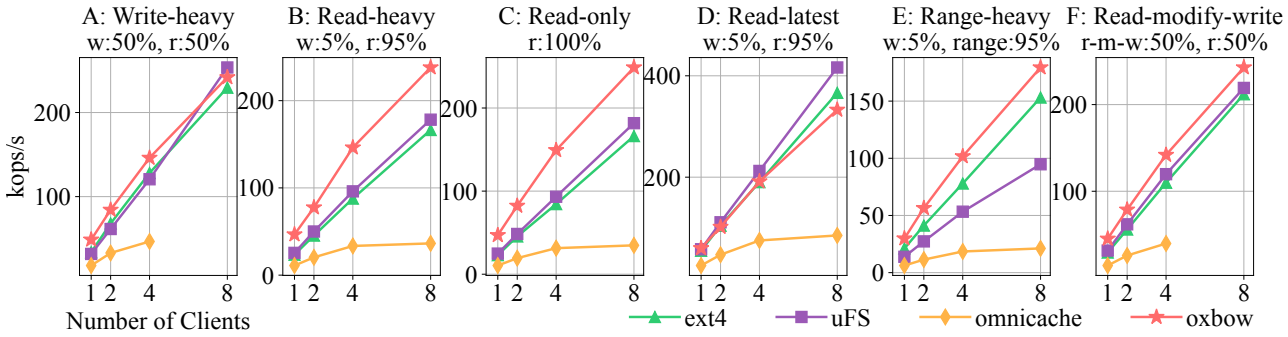

Figure 14: **LevelDB throughput with YCSB workloads A–F.** Subplot titles show the operation mix of each workload (w: write, r: read, range: short-range scan, r-m-w: read-modify-write). Higher is better.

the default Oxbow (Figure 13), because this path incurs two overheads for every `fsync`: waiting for the ongoing background commit to complete and crossing PCIe. The other configurations show similar latency to the default Oxbow.

No Background Journaling. Background journaling is disabled, so there is no periodic journaling and data is persisted only by `fsync`. In the throughput microbenchmark, this configuration shows up to 33% lower throughput because it does not utilize CSD resources, whereas the other configurations benefit from them. In particular, its `fsync` time is up to 8.8× that of the default Oxbow (Table 1), because it does not persist data ahead of `fsync` calls. Note that, even without device offloading, this configuration still outperforms Ext4, demonstrating that Oxbow's kernel-bypass write path is effective.

Type	File system	Avg	P50	P90	P99	P99.9
End-to-end (ms)	Oxbow	40	33	71	97	240
	Ext4	40	33	71	95	260
Per-probe I/O (μs)	Oxbow	61	41	150	290	530
	Ext4	122	110	210	330	960

Table 2: **RAG retrieval latency.** A probe is a single vector read from the on-disk store during a retrieval request.

File system	Throughput (MB/s)	Avg. latency (s)	Max. latency (s)
Ext4	200.47	23.87	39.72
Oxbow	316.72	12.93	13.00
OmniCache	309.42	13.24	14.34

Table 3: **LLM checkpointing throughput and latency.**

6.4 Real-World Benchmarks

LevelDB. We run LevelDB [28] with the YCSB [9] workloads to evaluate the end-to-end performance of Oxbow. We configure it to have 10M entries of 16B keys and 80B values for each client and run 100K operations [39]. Each run starts cold, so the reported run-phase throughput reflects on-device I/O rather than pure in-memory cache hits. Because the working set is spread across the 10M-key space and exceeds LevelDB's in-memory block cache, the read-dominated workloads, except for workload D, issue many reads that reach the device. Oxbow's high random-read performance makes it the best for the random-read-dominated workloads, B and C (Figure 14). It outperforms µFS, the second best, by 83% and 89% with 1 process and 34% and 37% with 8 processes for workloads B and C, respectively. Oxbow achieves the best throughput for workload E as well. In workload E, both sequential and random reads matter, as each short-range scan performs a random seek across LSM levels followed by a short sequential read. Oxbow and Ext4 outperform µFS with the kernel's readahead, while Oxbow's higher random-read performance keeps it ahead of Ext4. Oxbow has 41% and 17% higher throughput than the second best, Ext4, with 1 and 8 processes, respectively. For workload D with eight processes, where most reads are cache hits, Oxbow performs 20% worse than µFS. The gap is attributed to µFS's zero-copy between the user and file-system buffers. Workloads A and F mix reads with updates that rarely trigger `fsync` under LevelDB's default settings, so Oxbow's read-path advantage and µFS's zero-copy writes partly offset each other, narrowing Oxbow's lead as concurrency grows. Meanwhile, OmniCache's high latency limits its performance on the latency-sensitive LevelDB.

RAG Retrieval. We evaluate how Oxbow performs in the trendy AI domain. We develop a RAG (Retrieval-Augmented Generation) Retrieval benchmark. It models an SSD-backed vector search service that generates many small random reads to file systems. We construct a 20GB on-disk vector store from synthetic embeddings with a vector size of 768 (3072B) and a 1024B payload. We generate 400-client loads using a Locust [21]-based HTTP client. Table 2 shows the end-to-end and I/O latencies of Oxbow and Ext4. Although the end-to-end latency is not dominated by I/O, Oxbow has 50% lower I/O latency than Ext4 thanks to its high random read performance. Similarly, it reduces tail I/O latency by up to 45% relative to Ext4.

LLM Checkpointing. Next, we benchmark the disk I/O patterns during the checkpointing phase of large LLM (Large Language Model) training. We assume a single process that checkpoints a large tensor iteratively. In each iteration, the process writes a whole tensor to SSD and calls `fsync` at the

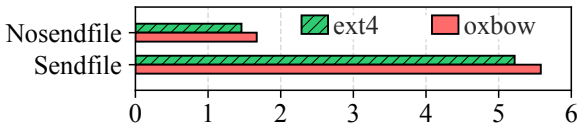

Figure 15: **Nginx web server throughput (GB/s)** with the `sendfile` enabled vs. disabled. Higher is better.

end. We configure the tensor size to 4 GB, run 5 iterations of checkpointing, and measure the average throughput and latency (Table 3). Oxbow achieves 58% higher throughput and 46% lower latency than Ext4. It is mainly due to the higher sequential write performance of Oxbow over Ext4. Ext4's high maximum latency is attributed to its heavier transaction composition, compared to Oxbow's Split Journaling and OmniCache's device-side metadata journaling. OmniCache achieves throughput comparable to Oxbow. This single-threaded workload writes a large tensor sequentially, so each checkpoint is transferred with only a few large DMA operations, incurring little PCIe-crossing overhead and no CSD CPU contention. Oxbow retains only a slight edge over OmniCache, as its background journaling persists a small amount of data ahead of `fsync`.

6.5 Kernel Interoperability

We run Nginx web server version 1.26.2 on Ext4 and Oxbow to demonstrate the benefit of leveraging the kernel's VFS layer. `sendfile` is a system call that accelerates data transfer from one file descriptor to another. It eliminates data copying between user and kernel buffers by directly copying the data between two kernel buffers within the kernel context. As Oxbow interoperates with the kernel's VFS layer, it can leverage the `sendfile` feature at no development cost.

We configure the server to run with 8 threads and compare the throughput with the `sendfile` option enabled and disabled. On clients' request, the server reads the file and sends it to them. When `sendfile` is enabled, the server copies data directly from the file descriptor to the network socket descriptor. When disabled, it reads the file into user space and writes back to the socket, incurring additional copy and context switch overheads. We use `wrk` [8] version 4.2.0 as a client load generator. It launches 10 clients, each of which sends requests to fetch a file from the server for a fixed duration.

Figure 15 shows that Oxbow exploits the kernel's `sendfile` interface as effectively as Ext4. With `sendfile` enabled, Oxbow's throughput is 3.3× higher than with it disabled, similar to Ext4's 3.6×. Note that after reading the file once, the data is copied from the page cache, which decreases the throughput difference between Oxbow and Ext4.

7 Related Work

User-level File Systems. FUSE [4, 27] forwards requests to user-space daemons via kernel modules, but this design incurs multiple user-kernel switches per operation [51]. Several studies [32, 36, 37, 39, 53] intercept system calls to avoid these overheads and achieve high performance with user-level file systems. Prior work [32, 39] considers a hybrid architecture by delegating privileged operations to the kernel. TriCache [30] moves caching out of the kernel to maximize out-of-core data-path performance, but trades away features such as cross-process data sharing, global memory management, and in-kernel optimizations. No prior work considers a cooperative user-kernel design that jointly optimizes both data and metadata paths.

File System Operation Offloading to SoC-based CSD. Various offloading techniques in the file system context have been explored [33, 47, 54, 56, 57]. Prior work [33, 47] proposes a firmware-level file system running on the CSD. Another work [57] proposes a selective data-caching scheme in addition to offloading compound operations. Other studies [54, 56] offload small tasks to the CSD and implement near-data processing. These studies focus on enabling near-data processing by using CSD resources, whereas we instead focus on orchestrating CSD offloading with other file system components.

Logical Journaling. Recent work [39, 45, 48] proposes logical journaling techniques to improve `fsync` latency in metadata journaling. We are inspired by these ideas and retrofit them to data journaling to enable offloading journaling operations to the CSD. Furthermore, we propose a new scheme that eliminates the remaining dependencies between transactions.

Development Cost Reduction. Existing work [20, 40, 42, 44, 55] highlights the importance of development cost for in-kernel file systems and proposes techniques such as microkernel architectures, layered abstractions, and safety guarantees to reduce development complexity. We also reduce file-system development cost through an architectural design that is distinct from prior work.

8 Conclusion

Fast storage and computational SSDs have fragmented the storage stack, forcing file systems to trade performance, kernel interoperability, and CPU efficiency against one another. We argue that this tension is an artifact of granularity: committing an entire file system to user space, the kernel, or the device inherits that tier's weaknesses along with its strengths. Oxbow instead places each operation where its properties are best served, with reads in the kernel page cache, writes on a user-level bypass path, and background crash-consistency work on the device. The challenge then becomes coordination cost, which Oxbow keeps low through single-writer state and by severing foreground operations from background ones. Oxbow suggests that the path beyond today's fragmented storage stack lies not in choosing one architecture, but in coordinating user space, the kernel, and the device.

A Artifact Appendix

A.1 Abstract

Oxbow is a coordinated file system that distributes file-system operations across a user-level library (oxLib), a trusted user-level server (H-Server), a thin kernel shim (illuFS), and a device-side server (D-Server) on a computational SSD. This artifact provides the complete source code of Oxbow—including the custom kernel—together with build and run scripts, the benchmarks used in the paper, and documentation.

A.2 Scope

The artifact lets reviewers validate the experiments in the main paper by reproducing the reported results and analyzing the system's performance. Beyond reproduction, it can serve as a foundation for file-system researchers and developers who wish to build their own user-level file-system logic on top of the services Oxbow provides—namely the kernel's VFS functionality and file-system-agnostic journaling.

A.3 Content

The artifact contains the following:

- Source code of Oxbow, including oxLib, H-Server, and D-Server, along with the custom kernel that hosts illuFS.
- Scripts to build and run the system.
- Benchmarks for reproducing the performance results reported in the paper.
- Documentation listing the hardware and software requirements and a step-by-step guide to building and running the system.
- License files for the source code.

A.4 Hosting

We host the artifact on GitHub at `https://github.com/xlab-uiuc/oxbow`, on the `osdi26-ae` branch and tagged `artifact`.

A.5 Requirements

The detailed software and hardware requirements are listed in the top-level `README.md` of the artifact repository. The development and test platform matches the testbed described in the main paper; in particular, reproducing the device-offload results requires a BlueField-2 DPU and an SR-IOV-capable NVMe SSD.

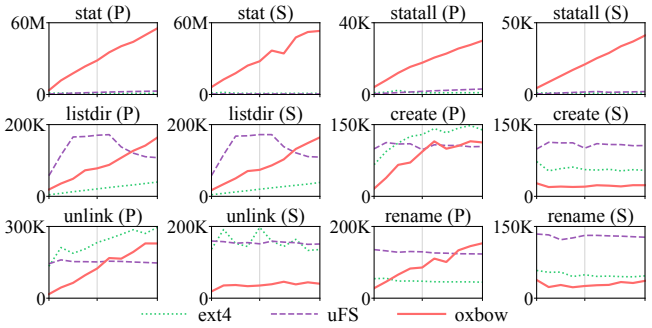

Figure 16: **Metadata microbenchmark throughput** in ops/s across 1–10 clients. P and S denote private and shared metadata operations, respectively; all operations run in memory.

Operation	Description
`stat`	`stat` a single file.
`statall`	`stat` all files in a directory.
`listdir`	`opendir`, `readdir` all entries, then `closedir`.
`create`	`mkdir`.
`unlink`	`unlink`.
`rename`	`rename`.

Table 4: **Metadata microbenchmark operations.**

B Metadata Benchmarks

We run the metadata operations from µFS's microbenchmark suite [39], comparing Oxbow against µFS and Ext4 (Figure 16). It exercises six operations (Table 4), each in a *private* variant (every client uses a separate file or directory) and a *shared* variant (all clients contend on a common one). All operations run in memory, so the measured differences stem from the file systems' software architectures.

Oxbow scales linearly on `stat` and `statall` because oxLib reads inode state directly from shared memory (§4.2) under a read lock (no contention), without kernel or H-Server crossing, whereas µFS and Ext4 pay a context switch per operation. At 10 clients, Oxbow reaches up to 19× and 10× the throughput of µFS and 57× and 30× that of Ext4. `listdir` scales likewise because oxLib reads the directory-entry cache directly from shared memory. µFS leads at low client counts by prefetching entries on `opendir`—an optimization that Oxbow could also adopt—but flattens because a single file server thread serves all directory operations by design. Consequently, Oxbow overtakes µFS at higher client counts, ending at 1.5× µFS and 4.1× Ext4. Because these lookups are read-only, Oxbow scales in the shared case as well.

The `create` and `unlink` operations go through both H-Server and the kernel; hence, Oxbow's single-client throughput is the lowest of the three systems despite an asynchronous design. User-level parallelism nonetheless lets it scale with clients, surpassing µFS by 10 clients (up to 1.6× on `unlink`) but still trailing Ext4. `rename` also enters the kernel, but Oxbow bypasses the kernel's coarse-grained VFS rename mutex, which is typically a scalability bottleneck as clients increase, and instead handles synchronization with fine-grained locks in H-Server. As a result, despite the component-crossing overhead, Oxbow scales 5.5× from 1 to 10 clients and leads in the private case. This is an example of the performance optimizations made possible by Oxbow's flexible multi-component design. In shared configurations, parent-directory lock contention prevents all three file systems from scaling across `create`, `unlink`, and `rename`.

Abstract

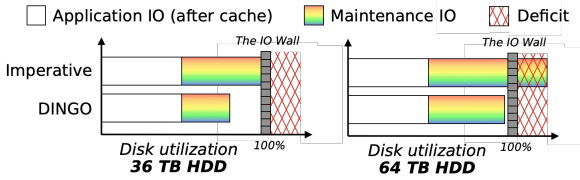
HDD capacities will greatly increase over the next ten years, lowering cost-per-TB in large-scale storage systems. Unfortunately, device bandwidth will not grow proportionally to device capacity. Hence, storage systems will face an *IO wall* where the demand for HDD IO will outstrip supply.

We find that, surprisingly, between 45% and 70% of after-cache HDD IO demand for 6 hyperscalers comes from crucial maintenance tasks that ensure data reliability and efficiency (e.g. scrubbing, garbage collection). Unfortunately, caching maintenance tasks is ineffective — individual tasks have little reuse and inter-task reuse is too far apart in time. Fortunately, maintenance tasks are flexible in the timing, ordering of data accesses, and even which data they access. However, the current imperative storage interface (e.g., read/write) hides maintenance tasks' flexible nature. We propose *Declarative IO*, a new interface for distributed storage systems that allows developers to expose tasks' flexibility to the storage system. This interface allows tasks to send a *declaration* to our distributed storage system, DINGO, specifying sets of data and their associated deadlines, such as "process all blocks of this device within 7 days". In processing declarations, DINGO coordinates IO across different tasks to create timely data reuse. DINGO achieves a 26–51% IO savings for maintenance task mixes corresponding to real hyperscalers, enabling the deployment of 1.7× larger HDDs than in imperative systems.

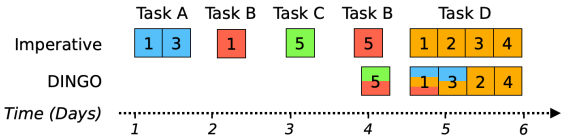
1 Introduction

Large distributed storage systems store exabytes of data over hundreds of thousands of disks [22, 33, 55, 61, 70]. Mechanical disks (HDDs) remain more cost-effective for most high-capacity workloads than flash (SSDs) due to new technologies that increase HDD density, such as heat-assisted magnetic recording (HAMR) [6, 59]. Thus, HDDs continue to be an integral piece of datacenter storage systems. Most vendors expect 40TB drives in the near-term and 100TB drives as soon as 2030, with the cost-per-TB decreasing 6× [60]. These high-capacity HDDs will allow hyperscalers to accommodate data growth while minimizing the power usage and physical footprint of their storage systems.

Storage IO wall. Unfortunately, HDD accesses are not scaling proportionally to their capacities. In particular, the IO supply — i.e., IOPS and bandwidth per device — has remained roughly constant as capacity has sharply increased over time (Sec. 2.2). Put differently, the IO supply per TB of HDD storage is trending precipitously downward. Hence, as HDDs grow denser, we are approaching a point where the total IO demand of datacenter workloads on HDDs exceeds IO supply — a phenomenon we refer to as the *IO wall*. Beyond this wall, storage systems will be unable to use higher-capacity HDDs, forgoing their power, footprint, and cost advantages.



(a) The IO wall limits HDD density in imperative storage systems.



(b) DINGO finds data reuse between different maintenance tasks, reducing disk IO.

Fig. 1: (a) Storage clusters are running into an IO wall. If maintenance tasks cumulatively use 50% of disk IO (commonly observed in hyperscalers), imperative IO uses all of a 36 TB disks' time (or has 100% IO utilization). Since DINGO reduces maintenance IO by 40%, it enables the deployment of 64 TB disks under the same IO requirements. (b) DINGO leverages Declarative IO and each maintenance task's flexibility to enable IO reuse between tasks that imperative storage systems would schedule independently over time.

To deploy higher-capacity HDDs, storage systems need to reduce IO demand. Systems have thus far adapted to decreasing IO supply by deploying flash caches that absorb application requests before they reach HDDs [16, 26, 30, 38, 49, 71]. While these caches absorb a large fraction of IO, the remaining disk IO is increasingly hard to cache. Hence, there are diminishing marginal returns to adding caching capacity.

Maintenance tasks dominate IO demand. Analysis of storage cluster workloads across six hyperscalers[1] surprisingly indicates that, on average across a cluster, 45–70% of HDD IO comes from various *data maintenance tasks* (Sec. 3).

[*]These authors contributed equally.

[1]We use the term hyperscaler to refer to companies that run large-scale, distributed datacenters, delivering extremely scalable compute and storage for many applications including cloud, AI, batch analytics, and web.

Maintenance tasks pervade datacenters, from integrity checking [39,53,58], to reliability maintenance [25,34], to capacity compaction [2,3], to adaptive efficiency enhancement [40–42]. Maintenance tasks are crucial to the durability and availability of stored data, but — importantly — *are not* latency-sensitive. They also generally access large amounts of data with little reuse, rendering caches ineffective and demanding HDD IO.

Opportunity: Maintenance IO is flexible. While maintenance tasks are individually hard to cache, we observe that *there is significant data overlap between different maintenance tasks*. For instance, while scrubbing exhibits no reuse as it scans over all blocks in the cluster, these scans will overlap with every other maintenance task. However, because maintenance tasks are not generally synchronized, most inter-task reuse is also too far apart in time to result in cache hits. Fortunately, *maintenance tasks are generally flexible in access order, access time, and even which data they access*. A single maintenance task (e.g., "scrub a given disk to check data integrity") is composed of several lower-level *requests* (e.g. "scrub a given block"). A maintenance task must complete all of its requests within a certain timeframe, but the timing of individual requests is flexible. Our goal is to leverage maintenance task flexibility to cause overlapping requests from different maintenance tasks to execute at similar times. For instance, we can change the order and timing for scrubbing accesses to mirror those from a capacity-balancing task.

Unfortunately, the current *imperative* distributed storage interfaces (e.g., `GET`/`PUT`, `read`/`write`) do not expose flexibility — each request is for a *specific* data unit to be accessed *now*. While it is possible in principle to coordinate imperative IO, in practice maintenance tasks are generated by disparate teams working on different applications or different layers of the system (e.g., block-level scrubbing vs. garbage collection from a database application). Explicit coordination of imperative IO across teams, software layers, and even organizational boundaries is impractical.

Our solution: Declarative IO. We introduce *Declarative IO*, a new distributed storage interface that allows tasks to *declare* upcoming IO reads along with a deadline for those requests. Our system, DINGO[2], processes declarations to find overlapping IO across maintenance tasks, leveraging data reuse to reduce aggregate IO demand (Fig. 1b).

DINGO uses its *IO Planner* to track IO declarations, plan which IO to schedule, and then dispatch callbacks to maintenance tasks so that they know to access their data. The IO Planner enables DINGO to reduce disk IO *without changes to maintenance tasks' requested work*. The IO Planner respects task deadlines, and is feasible to deploy for large, single-datacenter storage clusters. We accomplish this by developing a rate-based scheduler for the IO Planner (Sec. 5.1) and an efficient dispatcher (Sec. 5.2) that quickly finds and exploits overlap between outstanding maintenance tasks.

In small-scale experiments on a HDD cluster, we find that Declarative IO decreases disk reads by 26%. To evaluate DINGO at scale on a broader set of maintenance tasks, we simulate 100 PB clusters. While imperative IO is limited to 36 TB HDDs, DINGO enables the deployment of 1.7× higher capacity devices, or 64 TB, on maintenance task mixes based on real hyperscalers. Finally, we show that adding additional work to DINGO comes with only a small IO penalty. This lowers the barrier to increasing maintenance activities and improving the performance of storage clusters (e.g. more garbage collection to reduce fragmentation and save capacity).

Contributions. This paper contributes the following:

- We characterize the IO wall for HDDs and demonstrate why caching alone will not avoid this wall (Sec. 2.2).
- We identify that data maintenance tasks account for 45-70% of HDD time in storage clusters at six hyperscalers and present per-task IO breakdowns for three of these hyperscalers (Sec. 3).
- We introduce the Declarative IO storage interface, allowing tasks to declare their order, time, and data flexibility to the storage system (Sec. 4).
- We present DINGO, a storage system implementing Declarative IO. DINGO's IO Planner finds IO overlap while meeting declarations' deadlines, scales to large clusters and minimizes caching overheads (Sec. 5).
- We show that DINGO achieves 26–51% maintenance IO savings, enabling deployment of 1.7x larger HDDs (Sec. 6).

2 The impending IO wall

Distributed storage systems are the backbone of modern datacenters, containing exabytes of data across 100Ks of disks and supporting applications from ML training [21] to the internet [33]. This section describes how data flows in these storage systems (Sec. 2.1) and how HDDs' increasing capacity is leading to the IO wall (Sec. 2.2).

2.1 IO in distributed storage systems

Datacenters store and process data through a complex, interconnected collection of data storage, caching, management, and serving systems. Fig. 2 illustrates this architecture.

Datacenter architecture. The *bulk storage tier* combines 100Ks of HDDs into a single distributed storage system [22, 32, 44, 55, 62, 70]. The *caching tier* absorbs IO on DRAM or SSDs to reduce latency and handle IO that would otherwise burden HDDs [16, 26, 49, 50]. The *data management tier* consists of services such as object stores or databases that organize, index and process content in the lower storage tiers. The *application tier* consists of applications on compute clusters that read/write data from the storage tier directly or via the data management tier.

IO at the caching or bulk storage tier is requested via *im-*

[2]A dingo is Australian canine. DINGO is the Declarative INterface for Global storage Optimization. Both rely on packs: packs of dingoes to hunt kangaroos and packs of maintenance tasks in DINGO to find IO reuse.

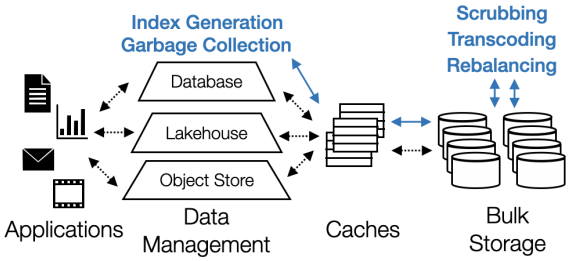


Fig. 2: Datacenter architecture has four tiers: application, data management, caching, and bulk storage. IO requests come from both applications and maintenance tasks, but maintenance tasks' IO is less cache-friendly so more of results in disk IO. In some hyperscalers, the caching tier and bulk storage tier may be combined into one distributed storage system.

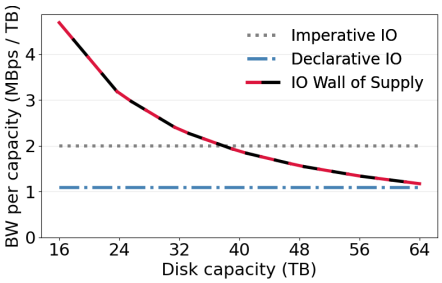

Fig. 3: As disks become larger, their IO supply decreases. Therefore, storage clusters are running into an IO wall where they will no longer have enough IO supply to fulfill their IO demand. Assuming maintenance tasks are allowed to use only 50% of disk bandwidth, imperative IO can only use 36 TB disks.

perative interfaces, interfaces that only allow read/write or get/put requests for data now. These interfaces are typical for everything from key-value stores [3] to caches [16] to distributed file systems and their distributed block-level interfaces [22, 33, 55].

Quantifying disk IO. Each tier ultimately fetches all non-cached data from disk. We measure disk IO with two metrics: (1) bandwidth and (2) *disk-head time* [15, 26, 57], the sum of the disk's seek latency and transfer time for the requested data. Since disk-head time measures active time of the disk, we can divide it by wall-clock time to get disk utilization[3].

2.2 HDDs are IO bound

While HDDs have seen significant increases in capacity, their seek latencies and transfer rates have not improved proportionately [28, 59]. Thus, the disk-head time of a given request has remained roughly constant as HDD capacities have grown. For a given unit of time, a smaller percentage of the disk's data is accessible as its capacity increases. This trend will accelerate over the next ten years as HAMR devices, which have recently come to market, lead to continued increases in HDD capacity [1, 4, 5, 42].

We describe both the IO supplied by the storage system and the IO demanded by maintenance reads in terms of *Bandwidth-per-TB*. Fig. 3 shows the projected IO supply (in MB/s-per-TB) for maintenance reads (Sec. 3) as HDD capacity increases. Given a constant IO demand, storage systems will not have enough IO to deploy HDDs larger than 36 TB.

We term this IO-induced capacity limit the *IO wall*. Unless system designers find a way to decrease IO demand, *distributed storage systems will hit an IO wall, where IO demand will significantly outstrip IO supply*, and prevent larger HDDs' cost, power, and footprint advantages.

Caches cannot climb the IO wall. The main tool to address decreasing IO supply on HDDs has been caching. In particular, datacenters deploy increasingly large SSD caching tiers to absorb an outsized fraction of IO demand [16, 19, 26, 71] for reasonable cost. So far, scaling the caching tier to offset decreases in HDD IO supply has been feasible.

Unfortunately, we are now reaching the end of this scaling regime. The caching tier already absorbs the easily cacheable parts of the IO workload. The IO that currently passes through the caching tier to the bulk storage tier tends to be composed of scanning access patterns with little data reuse (Sec. 3). Hence, adding additional capacity to the caching tier will not significantly reduce this HDD IO demand, closing the gap between the decreasing IO supply and static IO demand.

Key insight. Latency-sensitive application IO dominates the pre-cache IO workload, and is largely absorbed by the caching tier. On the contrary, flexible maintenance IO tasks access large amounts of data *with little reuse* and are hard to cache. After years of scaling the caching tier to absorb more application IO, maintenance IO now accounts for a significant portion of disk IO. As adding additional cache capacity does little to absorb maintenance IO, storage systems need a new approach to scale the IO wall.

3 Maintenance tasks

To overcome the IO wall, we need to reduce maintenance IO. This section discusses why maintenance tasks are necessary (Sec. 3.1), analyzes the IO demand of maintenance tasks (Sec. 3.2), describes the challenges in reducing maintenance IO (Sec. 3.3), and discusses how flexibility provides an opportunity to reduce maintenance IO (Sec. 3.4).

3.1 Maintenance tasks are essential

Distributed storage systems need to ensure data durability and efficient accesses. Thus, storage systems are designed to provide fault tolerance and reliability while minimizing request latency, maximizing throughput, and limiting the total cost of the system. To meet these goals, storage systems run essential maintenance tasks, such as integrity checking (reads data and metadata to check fidelity, e.g., scrubbing [39, 53, 58], fsck [29, 47, 51]), reconstruction (rebuilds data from erasure coding after detecting data loss), and rebalancing (copies data to enable fault tolerance, load balancing, capacity distribution, etc.). Some maintenance tasks may be even more obscure, like moving data for "short stroking" (places hotter data on the

[3] See Sec. A.1 for details on calculating disk-head time.

outer HDD tracks for faster transfer times and moves colder data to inner tracks).

While the distributed storage system generates some maintenance tasks itself, much originates from other tiers (Fig. 2). Shingled disks internally garbage collect to reclaim overwritten tracks [28]. Log-structured stores and LSM-tree-based databases perform garbage collection or compaction to minimize space overhead and reduce read amplification [2, 3, 23, 45, 54]. Data lakehouses transcode data as it ages to save space while storing newer data in narrower encodings to lower tail latency [42] and geo-replicate data to ensure redundancy to datacenter-scale failures [67, 69]. Databases create indexes [14, 43, 48], materialized views [18, 35], and summary statistics [20] for better performance[4].

3.2 Maintenance tasks use most HDD IO

Although data maintenance activities play a critical role throughout the datacenter, prior literature does not address their cumulative impact on HDD utilization. Based on communication with six hyperscalers and analysis of their storage workloads, we find that maintenance tasks account for *at least 45-70%* of disk IO. This number is a lower bound for each hyperscaler — the remaining IO is from both applications and unaccounted maintenance (e.g., database-tier maintenance tasks running on top of cloud storage). For simplicity, we refer to the remaining IO as application IO.

Breakdown of maintenance IO. To understand the breakdown of maintenance IO between tasks, we examine data from three hyperscalers: Meta, Microsoft, and Google (listed here in a random order for anonymity). For these hyperscalers, we present each maintenance tasks' disk IO normalized to that hyperscaler's total known maintenance disk IO.

Hyperscaler A. We present measured bandwidth, IOPS, and estimated disk-head time from a storage cluster over 3 months in 2025. These results highlight why we favor disk-head time as a metric for IO: IOPS understates the impact of large requests and bandwidth understates the impact of per-request overheads.

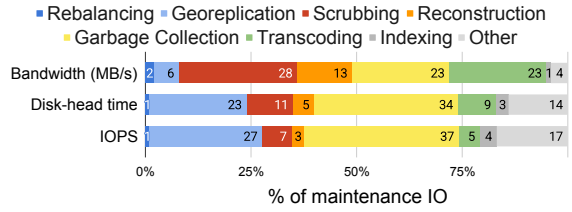

Fig. 4: The average IO from different maintenance tasks over 3 months at hyperscaler A, broken down by bandwidth, estimated disk-head time, and IOPS.

Hyperscaler B. We present data on disk-head time for reads from maintenance tasks over 2024 from three general-purpose clusters at hyperscaler B (Fig. 5). Rebalancing comes from 3 independent maintenance tasks since 3 different tiers in the distributed architecture control different data placement decisions. Other tasks include metadata operations, fsck, and short stroking. We note that measuring maintenance IO throughout the datacenter architecture is important. For example, maintenance IO generated by the bulk storage tier comprises only 43.9% of the total maintenance IO of Cluster 1.

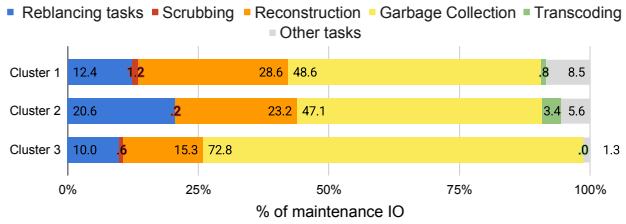

Fig. 5: For hyperscaler B, we show the maintenance task split of 2024 disk-head read time from three different clusters.

Hyperscaler C. We finally present data on disk-head time from the perspective of hyperscaler C's an object store over the course of a week in 2024. Migration reads data to move it to a separate cold storage system. Other includes object-level scrubbing and other tasks. Hyperscaler C's final task is a programmatically-combined compaction and transcoding task. This combination is possible because both tasks are generated by the same system, but trying to replicate this coordination across different tiers is prohibitively complicated. This IO breakdown also does not include the copious amounts of maintenance IO generated by the bulk storage system itself upon which the object store depends, highlighting the importance of considering maintenance IO across tiers.

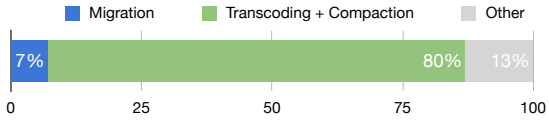

Fig. 6: Disk-head time spent for each maintenance task in hyperscaler C's object store. Hyperscaler C combines transcoding and compaction into one operation to reduce IO.

Observations: Based on this data, we make three main observations that will shape how we reduce maintenance IO. (1) Maintenance tasks account for the majority of after-cache disk IO across many hyperscalers and their different storage architectures. (2) Both hyperscaler A and hyperscaler B's maintenance IO comes from many different tasks. (3) Maintenance tasks occur across layers of the datacenter stack — such as rebalancing in hyperscaler B occurring at 3 separate tiers and object-level scrubbing in hyperscaler C's object store. Sec. 3.3 discusses how these observations complicate reducing maintenance IO.

3.3 Challenges in reducing maintenance IO

We identify two crucial challenges to reducing maintenance IO: (1) maintenance tasks are hard to synchronize at scale and (2) maintenance tasks' IO requirements scale with capacity.

[4] More details on maintenance tasks in Sec. A.2.

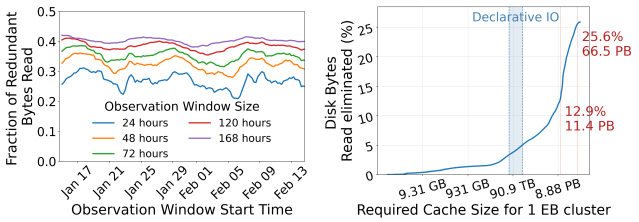

Fig. 7: Fraction of redundant reads in a cluster at Google over varying windows of time flexibility over a month in 2024 (left), and cache size required to eliminate redundant reads in 1 EB cluster with imperative IO in one 24 hour window (right).

Reuse between maintenance tasks is hard to cache. Even though maintenance tasks are not cache friendly (Sec. 2.2), there is data overlap *between* maintenance tasks. For instance, scrubbing touches all data, overlapping with every maintenance task. Hyperscaler B has 3 different rebalancing tasks that independently choose data to prevent adding unnecessary complexity, but should have overlap in which data to move.

More concretely, our analysis of publicly released Google I/O traces from 2025 [56] reveal substantial data reuse across applications, but with reuse distances too long to be effectively captured by conventional caches. Fig. 7 shows the fraction of redundant disk reads in a Google cluster over one week in different periods of observational windows. We find that approximately 24% of after-cache disk read traffic is redundant when requests may be delayed or reordered within a 24-hour window. This redundancy increases to approximately 42% when reads are observed over 7 days [5].

Using a Miss Ratio Curve (MRC) computed from the LRU stack distance of 4 KB blocks, we find that for capturing all of the reuse over a 24-hour window using caching alone would require increasing the cache tier by at least 6% of cluster capacity (66.5 PB in a 1 EB cluster). This is an order-of-magnitude more caching than hyperscalers typically have [26, 55]. Thus, we need to find a different way to capture reuse other than just caching. With Declarative IO, we show that we eliminate significant redundancy in bytes read with two orders-of-magnitude less cache space (Sec. 5.2).

Maintenance tasks are hard to synchronize at scale. If only a few maintenance tasks dominated maintenance IO, hyperscalers could effectively reduce IO demand by manually synchronizing overlapping maintenance tasks. However, across both hyperscalers, we observed a large number of maintenance tasks account for the aggregate maintenance IO (Sec. 3.2). Hence, many possible groups of tasks could be synchronized, with no single maintenance task representing a clear target for optimization. Additionally, the manual synchronization approach does not scale well to combining a large number of tasks. This development effort is made even more difficult by the need to combine tasks from different tiers of the datacenter architecture that different teams or even different organizations manage. To reduce maintenance IO, we need a solution that allows us to use maintenance task overlap at scale, and across many tasks.

[5] Although the provenance of IO in the trace is anonymized, and some requests may correspond to inflexible or latency-sensitive application I/O, we expect such requests to constitute only a small fraction of the workload because our analysis focuses on *after-cache* disk traffic, which is typically dominated by maintenance workloads.

Many maintenance tasks grow with capacity. One might hope that, as the overall capacity of the storage system grows, data would become on average colder and the disk IO-per-TB demand would decrease. Then, the reduced IO demand would allow device capacity to grow despite its lower IO supply.

Unfortunately, we find that this is not the case because maintenance tasks' IO grows with capacity. For example, assuming a constant disk failure rate, the total IO of reconstruction over time scales with the cluster's capacity. Our analysis of hyperscaler B's data suggests that maintenance tasks will use an additional 0.9% of a disk's time for each additional TB of HDD capacity. Hence, counterintuitively, we cannot amortize the impact of data maintenance across larger storage capacities and we need to address maintenance tasks' IO.

3.4 Opportunity: Maintenance IO is flexible

While data reuse across maintenance tasks typically occurs too far apart in time to be captured by traditional caches, maintenance tasks exhibit significant flexibility. Maintenance tasks often have *order-* and *time-flexibility*: target data must be read by a *deadline*, but these reads can occur in any order and at any time within said deadline. For instance, scrubbing aims to validate every data block within a specified period, but it does not care about the order of blocks read. We could leverage this flexibility to schedule different tasks' overlapping accesses close together, increasing cache hits and decreasing disk IO. Some maintenance tasks also exhibit *data-flexibility*: they are flexible about *which* exact data they need. For instance, rebalancing typically has many data blocks to choose from when moving data. We could carefully select blocks that other maintenance tasks were already planning to read, reducing IO through rebalancing's data flexibility.

Imperative IO impedes flexibility. Unfortunately, there is no way to express flexibility in today's imperative storage interface (e.g., read/write). The imperative interface only allows a task to specify that it needs a *specific* piece of data *now*, imposing order, time, and data constraints. Thus, data reuse can only be found through explicitly combining task implementations and manually aligning IO patterns.

Distributed storage needs a new interface. To exploit maintenance task time-, order-, and data-flexibility in a scalable manner, we need a new interface for distributed storage systems. We propose *Declarative IO*, a *declarative* interface that allows maintenance tasks to specify sets of data blocks that must be read before a deadline. With this information, the storage system can delay or reorder IO to increase temporal locality. While declarative interfaces are found across many

areas of computing [9, 24, 52, 72], we believe we are the first to introduce the concept to distributed storage's IO interface. The Declarative IO interface gives us a tool to confront the IO wall by reducing maintenance tasks' growing share of IO.

4 Declarative IO

In this section, we define the Declarative IO interface (Sec. 4.1, Sec. 4.2), discuss how maintenance tasks can adopt a declarative paradigm (Sec. 4.3), and explore the correctness guarantees that Declarative IO provides (Sec. 4.4).

4.1 Interface Overview

The Declarative IO interface centers on a `declare` function, which sends a *declaration* to the storage system describing a set of flexible read requests. The caller (e.g., maintenance task) passes a description of the data it wants to read, a deadline by which the data is needed, and a callback to notify when parts of the declared data should be read. Upon callback invocation, the caller reads the specified data through the standard imperative interface. The storage system will invoke the callback, potentially multiple times, such that all declared data can be read before the deadline.

Unlike imperative IO, Declarative IO does not guarantee when or in what order data is read, only that the appropriate callbacks will be called before the deadline. This requires: (1) targeting append-only storage systems where sealed blocks are immutable, (2) tasks handling the possibility that declared blocks may be deleted before callback, and (3) tasks using the block IDs specified in each callback to issue imperative reads for the data they need.

Declarative IO allows tasks to express flexibility. Expressing a declaration's maximum flexibility is vital to reducing IO. `declare` allows tasks to express order-, time-, and data-flexibility. A single call to `declare` specifies groups of data that the task wants to read. These groups can be read in any order (order-flexibility) as long as they are completed by the deadline (time-flexibility). While the system's default behavior is to make *all* declared data available, the caller can specify that only a subset of data is necessary (data-flexibility).

Asynchronous callbacks in `declare` provide a mechanism for the storage system to shift, reorder, and select declarations' data based on this flexibility. By shifting and reordering these callbacks, the system turns data reuse that originally spanned weeks (ineffective to cache) into overlapping reads that occur within minutes (easy to cache). Furthermore, data-flexibility creates reuse that is difficult to express imperatively by giving the storage system choice over data selection.

By changing the storage system interface, we can aggregate flexible declarations from throughout the system architecture. Any task that calls `declare` exposes its flexibility to the storage system. This allows us to find, create, and exploit data reuse between tasks ranging from a node-local scrubbing task to a file-system transcoding task to an object-store garbage-collection task (Sec. 6).

```
1 class BlockSet { set<BlockId> block_ids };
2 void declare(list<BlockSet> read_sets,
3   size_t sets_needed, time_t deadline,
4   void callback(list<BlockSet> sets_selected,
      bool overloaded));
```

Fig. 8: Maintenance tasks use the `declare` *call to explicitly communicate their flexibility to the storage system. Maintenance tasks specify three main components: what data they need (via* `BlockSet`*s and* `sets_needed`*, when they need that data by (via the deadline), and how to notify the task to read the data (via the callback).*

4.2 Interface Details

We formalize the interface for `declare` in Fig. 8. A declaration must identify the data to be read, how much of that data must be read, a deadline, and a callback.

Declaring data. Maintenance tasks need to specify which data they want to read. Importantly, many tasks need to read data in specific groups (e.g. stripes, files, objects), but have order and flexibility between these groups. Therefore, `declare` takes the `read_sets` argument, which represents a list of `BlockSets`, the group of data that a maintenance task needs at the same time. Specifically, each `BlockSet` in `read_sets` is a set of `BlockIds`, each representing a unique block of data in the distributed storage system[6].

To support data-flexibility, `declare` optionally takes a `sets_needed` argument, allowing maintenance tasks to specify how many `BlockSets` must be read from the declaration. If `sets_needed` is specified, the system will schedule some subset of *exactly* `sets_needed` elements of `read_sets`. Otherwise, all elements of `read_sets` will be scheduled.

Deadline. Although maintenance tasks are not latency-critical, they still have performance requirements. Maintenance tasks use the `deadline` argument to specify the time by which a declaration must be completed. In practice, deadlines can range from hours (e.g., for high-priority reconstruction) to multiple weeks (e.g., for scrubbing). Specifying the longest feasible deadlines improves time flexibility and thus enables more IO savings. If deadlines cannot be met due to overload, the callback is invoked with `overloaded=true` and tasks may fall back to imperative reads.

Callback. Maintenance tasks need to know when to read data that they declared. Therefore, they pass in the `callback` argument to `declare`. When a maintenance task should read one or more of its declared `BlockSets`, the storage system will invoke the callback and pass back a list of `BlockSets` to read. The storage system can invoke the callback multiple times depending on how the storage system schedules IO for the declaration. Thus, the callback's list of `BlockSets` may be a subset of `sets_needed`.

The callback does not include `BlockSet`'s data. Rather, the

[6]These blocks are *not* the same as LBAs in a local file system. They are the unit of data tracked in the distributed file system and are typically both much larger (>8 MB) [42] and stored as a file in a bulk storage node's local file system. They are also immutable (Sec. 4.4).

callback serves as a prompt from the storage system to a task that reading the specified data *now* will result in IO savings. Leaving the task in charge of reading the data simplifies consistency, failure handling, and access control by leveraging existing storage system consistency mechanisms (e.g., leases) when reading (Sec. 4.4). Additionally, Declarative IO may perform *callback elision* and not callback maintenance tasks about `BlockSets` that are completely deleted.

Extending `declare` to files. Some maintenance tasks may express their data needs in higher-level abstractions such as objects, database tables, or files. To support these tasks, we extend Declarative IO to file declarations. Specifically, maintenance tasks can declare sets of file segments (tuples of file path, offset, and length)[7]. These calls are translated into `declare` calls at declaration time using the metadata service. This means that declarations are snapshots at declaration time; new blocks appended to files after declaration are not included (Sec. 4.4). A similar translation strategy would allow tasks to declare other data abstractions.

4.3 Converting tasks to Declarative IO

While many developers are well-versed in writing IO-efficient code using an imperative interface, there are different design considerations when using Declarative IO. Declarations should remain simple, while exposing as much flexibility as possible. We show two examples of building effective declarations that (1) express all time- and order-flexibility and (2) hunt for data-flexibility[8].

Express all time- and order-flexibility. Consider scrubbing, a task that periodically checks that each block in the system is still valid over a long time horizon (e.g., monthly). Imperative scrubbing iterates over all blocks at a fixed rate and in a fixed order. A naïve declarative scrubbing might instead generate declarations when imperative scrubbing would have issued a read, with a deadline before the next declaration. This naïve approach exposes limited time-flexibility (Fig. 9) and no order-flexibility. A better approach would use a single declaration to read all blocks with a one-month deadline, giving the storage system freedom to decide the order and timing of scrubbing's reads and creating massive overlap with other tasks. While scrubbing is a simple example, it illustrates how a small change in declaration pattern can drastically change the flexibility afforded to the storage system.

Hunt for data-flexibility. Now, consider capacity balancing, which moves data to ensure that all disks have about the same amount of data. Capacity balancing needs to move *some* amount of data, not any *specific* data, making it well-suited to using Declarative IO to express data-flexibility. Even though it suffices to move a small set of blocks, capacity balancing should declare all blocks that *could* be moved (potentially all

[7]The exact interface is in Sec. A.3.

[8]An example of applying these concepts to a more complex task is in Sec. A.4.

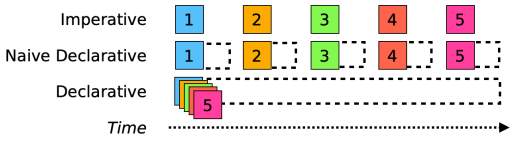

Fig. 9: Comparison of how scrubbing changes with Declarative IO. Declarative scrubbing expresses both order- and time-flexibility by declaring all blocks at once with a long deadline.

blocks on a disk) and specify how many *need* to be moved (Fig. 10). The storage system can then create data reuse by selecting blocks also needed by other declarations. Notably, larger HDDs tend to have more candidate blocks for capacity balancing, resulting in more data-flexibility.

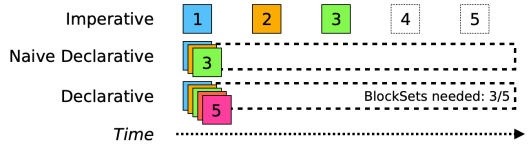

Fig. 10: Comparison of how capacity balancing requests blocks over time. Leveraging the balancing task's data-flexibility maximizes the chance for overlap with other maintenance tasks.

4.4 Consistency with Declarative IO

Declarative IO changes what data a task reads when. The following section describes our assumptions about distributed storage system behavior, how Declarative IO provides consistency based on these assumptions, and what happens if a declarative storage system cannot meet deadlines.

Storage system assumptions. We target append-only distributed storage systems. Append-only storage is the standard approach in hyperscalers [31, 33, 36, 44, 55, 70] due to its relative simplicity enabled from its block-level immutability guarantees. Append-only file systems enforce block-level immutability by sealing fully-written blocks. The only way to change a sealed block is to delete it.

Declarative IO only operates on sealed blocks. Given that these blocks are immutable, we only need to reason about the correctness properties of certain file operations: deletions, creations, appends, and metadata operations.

Deletions. A declaration can refer to a block that will be deleted before the declaration's deadline (e.g. *Block 4* in Fig. 11). We have to assume that Declarative IO callbacks may include deleted blocks, since blocks can be deleted during callback invocation. Fortunately, maintenance tasks' use imperative reads and thus inherit their guarantees. Existing distributed storage systems already handle similar problems (e.g. cached block metadata can become stale by the time of the actual request). Thus, Declarative IO relies on the pre-existing storage system's consistency to ensure it operates correctly when declared blocks are deleted.

Declarative IO may also perform *callback elision* for `BlockSets` composed entirely of deleted blocks. That is, to prevent the storage system from processing repeated requests

for deleted blocks, the system may forgo callbacks for any deleted `BlockSets`. Since these reads would have failed, callback elision does not change the data a maintenance task sees, but may require updating some error-handling in the task.

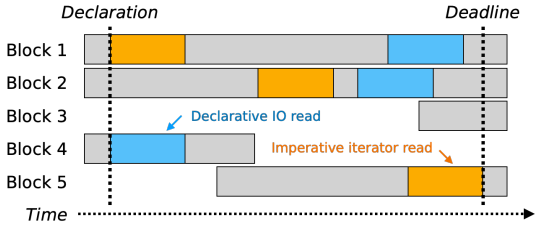

Fig. 11: An imperative vs a declarative rebalancing implementation read different blocks even if rebalacing is implemented in a naive manner (Sec. 4.2). Declarative rebalancing would not read blocks 3 or 5 because they were written after the declaration.

Metadata and data consistency. Declarative IO guarantees that file declarations will be a snapshot of blocks that exist at declaration time. It does not know about subsequent file appends, creations, or metadata changes (e.g., renaming, changes to access permissions). For instance, after a maintenance task makes a file declaration, new data can be appended to the file that would have been in the declared segment. The resulting new blocks will not be part of that declaration. Thus, tasks must create additional declarations if they need to read these newly appended blocks or any newly created files. This is not a new problem — most maintenance tasks already have to handle new files and blocks in their imperative iterators.

Any metadata changes, like access permissions changes, must be handled by the maintenance tasks themselves. After receiving a callback, a task will reobtain metadata needed for its imperative reads, both to check read permissions and file mappings. Hence, while metadata changes can reduce IO savings, they do not affect correctness.

Corner cases with Declarative IO vs imperative interfaces. When introducing a new interface to distributed storage systems like Declarative IO, it can introduce risk of failures. We find that many of these issues in Declarative IO are simply new instances of typical failures in imperative distributed storage or they are easily remedied with a slight reduction in IO reuse. To show this, we discuss three scenarios: coordinated disk failures causing large amount of reconstruction, compute unavailability, and IO load spikes.

Correlated disk failures. When many disks fail at once, reconstruction becomes urgent for all stripes that have lost multiple blocks due to a low mean-time-to-data-loss (MTTDL). Since this reconstruction is high priority due to the risk of data loss, it should use imperative requests instead of declarations. In most systems that can lose multiple blocks without data loss, this is both a rare event (thus not expected to significantly affect Declarative IO's overall IO reduction) and a potentially catastrophic event (thus already requiring extra attention to avoid data loss). Thus, these disk failures do not introduce new challenges in declarative vs imperative systems.

Compute unavailability. While imperative requests come from a scheduled compute job, Declarative IO may send its callback to tasks that do not have enough compute resources at the time of the callback, a new type of failure. While maintenance tasks generally require little compute and we expect compute to usually be available, compute unavailability, at worst, means the task cannot use the data upon callback[9], resulting in additional IO when the task is able to respond to the callback. This is still correct behavior, even if it will decrease IO reuse if its a frequent occurrence.

IO load spikes. Both of the other failures hint at a different type of failure, a spiking IO load that overwhelms the disks' ability to respond to IO. This is not a new problem and can be caused by higher than average user loads, cache failures, or unsustainable maintenance loads. In many of these cases, Declarative IO gives system owners new tools to reduce (Sec. 6.2) and handle IO spikes due to centralizing maintenance IO. Declarative IO allows owners to monitor whether maintenance IO will likely complete before the deadlines appear and to lower the maintenance IO rate in the event of too much IO from other sources (Sec. 5.1).

However, if Declarative IO ends up in a state where it is failing to meet most deadlines resulting in imperative IO from maintenance tasks and the system's IO is provisioned expecting a certain level IO reuse, the system can enter a metastable failure [37] analogous to caching. While this is an important edge case to be aware of in a declarative system, we do not believe Declarative IO adds additional risk when compared to the main alternative — *much* larger caches with their own metastable failure patterns.

5 DINGO Design

We introduce DINGO, a distributed storage system that implements Declarative IO. DINGO consists of an append-only file system with a metadata service and storage nodes (Fig. 12). Like other distributed storage systems, DINGO supports an imperative interface for both maintenance tasks and foreground applications. DINGO's main contribution is its *IO Planner*, which enables the Declarative IO interface. We first give an overview of how imperative requests, metadata requests, and declarations work in DINGO, and then discuss the design and optimizations in the IO Planner.

Imperative and metadata requests. Imperative and metadata requests (read, write, file creation, etc.) operate the same as in other distributed storage systems. Imperative requests first go to the metadata service to translate file requests into node-specific block requests and to get a lease on the requested data. The imperative task then queries this data from the appropriate data nodes, traversing the cache.

[9] Due to caching, a declarative system can handle a reasonable amount of latency in accessing IO as discussed in Sec. 5.2)

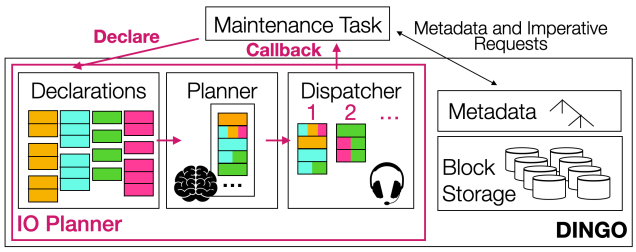

Fig. 12: DINGO *is a storage system that implements Declarative IO in addition to an imperative interface. Declarations go to the IO Planner, which keeps track of outstanding declarations, schedules them each quantum, and then dispatches them based on reuse.*

Declarations. Unlike imperative requests, declarations go to and are stored by the IO Planner. Each scheduling quantum, the IO Planner decides which `BlockSets` (a set of blocks needed by a declaration, Sec. 4.1) to fulfill, aiming to meet all declaration deadlines while adhering to a per-quantum IO limit. For each scheduled `BlockSet`, the IO Planner dispatches callbacks, prompting the maintenance tasks to read the associated data. A good scheduling algorithm aims to maximize overlap in `BlockIds` between scheduled `BlockSets` as this translates to data reuse over a short time horizon, making the maintenance workload more cacheable. DINGO uses a rate-based scheduler to optimize IO while making progress towards deadlines (Sec. 5.1). We also optimize DINGO with a dispatcher that reduces the required cache space, minimize memory overheads in the IO Planner, and explicitly manage the cache for DINGO to ensure reuse is captured (Sec. 5.2).

5.1 Scheduling in DINGO's IO Planner

The IO Planner seeks to minimize disk IO needed to fulfill all declarations by their deadlines. For each scheduling quantum, it must decide which of the outstanding `BlockSets` to schedule given that it can only schedule a limited amount of total disk IO. To minimize disk IO, an optimal schedule will maximize block reuse, but finding the optimal schedule is NP-hard[10] and we need a scheduling solution that can run periodically as tasks create new declarations. Thus, we develop a rate-based scheduling heuristic.

Rate-based scheduling. For DINGO's scheduling heuristic, we prioritize meeting deadlines over finding data reuse because (1) scheduling for reuse is NP-hard, (2) we find that this approach still produces significant data overlap in practice, and (3) missing deadlines leads to more imperative reads. To bias the scheduler towards meeting deadlines, we implement a rate-based scheduling heuristic.

For each declaration, the IO Planner calculates the IO rate needed to complete the request by its deadline. Until the quantum's total disk IO limit is reached, the IO Planner schedules declarations from highest to lowest IO rate. Any blocks already scheduled are considered "saved" and do not count towards the total disk IO limit (i.e., `BlockSet` 1 in Fig. 13 only causes one disk IO, leading to 2 saved reads). Declarations that consist of entirely saved blocks will also be scheduled. Within each declaration, we choose `BlockSets` that have the most free blocks in the quantum. Thus, the IO Planner finds more free blocks for declarations with more data-flexibility.

[10]The problem even without deadlines reduces to VM packing [63] as described in Sec. A.5.

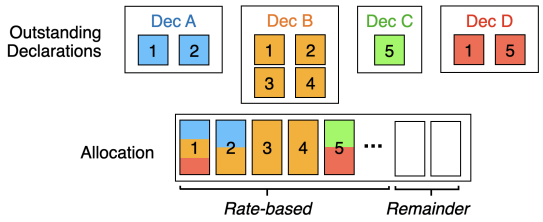

Fig. 13: DINGO*'s IO Planner must decide which blocks to schedule each quantum within its disk IO allocation. It uses a rate-based scheduler which biases toward completing all declarations. When multiple declarations access the same block (e.g., declarations A, B, and D read block 1), only one disk read is needed for that block because these reads are now close together in time.*

Dispatching decouples cache space and scheduling quanta. While the rate-based scheduling heuristic accomplishes its goal of prioritizing deadlines while finding reuse, we cannot naïvely deploy it in the IO Planner. To maintain the assumption that each unique block in a scheduling quantum only incurs one disk IO, the cache needs enough space for all saved blocks in that period. Therefore, to reduce cache resources, the ideal scheduling quantum is short. However, this is not practical as the scheduler's runtime is O(`BlockSets`).

Instead, the IO Planner uses dispatching logic to divide scheduled IO into smaller *dispatching groups* of overlapping `BlockSets`. By invoking each group's callbacks at even intervals during the quantum, we break the dependency between cache overhead and scheduling period: the cache now only needs enough space for saved blocks in a single dispatching group. Furthermore, since dispatching only considers scheduled `BlockSets` rather than all declared `BlockSets`, it can be optimized for frequent execution (Sec. 5.2).

Handling leftover IO allocation. The IO Planner may meet all the declarations' rates and still have remaining disk IO (white boxes in Fig. 13). One option is to schedule more `BlockSets` and fully use the allocation. However, this is not always ideal as it can lower future overlap. The default policy in DINGO is to leave this remaining IO unscheduled and available for other higher-priority IO. We find that in practice we do not violate deadlines due to this policy even when the per-quantum disk IO limit changes over time (Sec. 6.4).

5.2 Optimizing the IO Planner

We now discuss optimizations in DINGO's IO Planner: (1) a dispatcher leverage erasure coding for efficient overlap identification and (2) how DINGO uses explicit cache management to ensure IO savings.

EC-group based dispatcher to minimize runtime Optimally finding dispatching groups has a naive runtime com-

plexity of $O(|\text{scheduled } \texttt{BlockSet}|^2)$. In a cluster processing millions of outstanding declarations, executing this search within a scheduling quantum becomes intractable — defeating the goal of dispatching to minimize cache space. To make dispatching tractable, we introduce an erasure-coding (EC) group based dispatcher which bounds the search space to a handful of `BlockSets` accessing a given set of EC groups. For every EC group in the system, we maintain a list of outstanding `BlockSets` accessing any subset of its blocks. In order to find the dispatching group for a scheduled `BlockSet`, DINGO identifies its EC-groups and searches for overlapping `BlockSets` exclusively within this metadata, lowering the complexity to $O(|\text{scheduled } \texttt{BlockSet}|)$.

Explicit cache management to ensure overlap. DINGO saves disk IO by assuming the cache will absorb multiple reads for the same block. However, we found that in practice this approach results in less saved IO than the IO Planner predicts since blocks can be evicted between reads or not placed in the cache at all. Additionally, DINGO causes multiple reads to the same data in a short period of time, potentially causing the cache to think the blocks are popular and useful to store.

To help ensure that scheduled free IO is actually saved and to avoid cache pollution, the IO Planner issues cache directives for scheduled blocks each dispatching round. We dedicate a small amount of cache space for DINGO. The cache places blocks contained in the cache directive in this reserved space upon a read of the block. To account for delays in maintenance task read requests, blocks are kept in this dedicated cache space for the entire dispatch round. In the rare event that the cache runs out of dedicated space, the cache applies its eviction policy to the reserved space.

We find that the cache space required by DINGO is minimal. The required capacity is primarily a function of (i) the effective IO rate after eliminating redundant reads and (ii) the time window over which blocks must remain pinned until application IO requests are actually issued following dispatch. For a maintenance IO rate of 2 MB/s per TB, even in the extreme scenario where no overlap is found, and conservatively assuming it takes one minute for applications to issue the corresponding IO after dispatch, the required cache allocation would be only 120 MB per TB of disk. If data blocks need to remain pinned to the cache for two minutes, we would still only need 240 MB of cache per TB of disk. This translates to a pessimistic upper bound of 240 TB of cache spread across many servers for a 1 EB storage cluster (Fig. 7).

6 Evaluation

We evaluate Declarative IO through both a small-scale prototype and a simulation of a datacenter-scale storage system. We find that for a standard set of HDFS maintenance tasks, DINGO reduces disk reads by 26%. With datacenter-scale workloads, these savings increase: DINGO decreases disk reads by 28-51%, enabling devices that are 1.7× larger. This section discusses experimental setup (Sec. 6.1), DINGO's IO savings (Sec. 6.2), an attribution of these IO savings (Sec. 6.3), and DINGO's sensitivity to both workload characteristics and IO availability (Sec. 6.4).

Task	Frequency	Deadline	Logical Bytes Read
Rebalancing	On node addition	14hr	750GB
Reconstruction	On node failure	3hr	4.9TB
Scrubbing	Every 4 days	81hr	18TB
Transcoding	Every 40 mins	3hr	160GB

Table 1: Maintenance task parameters for HDFS experiments. We run a 3/24 scaled down version in both time and capacity.

6.1 Experimental Setup

DINGO Prototype. We build a DINGO prototype on top of HDFS [61] due to HDFS being an open-source append-only distributed storage system like most deployed systems (Sec. 4.4). The IO Planner supports both block-level and file-level declarations. We evaluate DINGO against a version of HDFS with no modifications other than the addition of transcoding support (baseline). Both storage systems run on 10 SuperMicro 4042G-6RF nodes, each with 64 cores, 128 GB RAM and a 3TB HDD connected with 40 GbE InfiniBand. We limit both systems to 10 GB of memory per disk to better emulate the ratio of cache to disk in larger capacity systems with large SSD caches. We would limit the memory usage further to replicate smaller caches, but the HDFS Datanode process requires sufficient memory. Thus, our prototype uses 2 GB per TB of disk. The cluster starts with ∼80% capacity used (18TB of data with 25% in 3-way replication and 75% in RS-3-2-1024k). We measure disk IO with `iostat` [7].

The maintenance workload follows the distribution from hyperscaler A (Sec. 3.2), but isolated to four maintenance tasks pertinent to HDFS: rebalancing, reconstruction, scrubbing, and transcoding. We scale down both capacity and time by an eighth to reflect our cluster's 3TB HDDs compared to a 24TB datacenter HDD and to run for the full length of our longest declaration. The parameters of the scaled maintenance tasks are described in Table 1. We configure DINGO with a scheduling quota of 120 MB/s and run the experiment for 81 hours (i.e., a month at our experiment scale).

Datacenter Simulator. To evaluate IO savings at scale, we build a time-driven cluster storage simulator. It models IO activity from real-world datacenter maintenance workloads in discrete 3-hour steps over a 30-day period on a 100 PB cluster. The simulated cluster stores data in 7.5 GB files, distributed in 256 MB blocks [22, 61] and maintains 80% storage capacity utilization. Blocks are either 3-way replicated or part of 6-of-9 or 30-of-33 erasure-coded stripes [41, 42]. We assume an IO demand of 2.0 MBps/TB for maintenance reads and show how results vary with different demands in Sec. 6.4.

We simulate two cluster workloads, one based on each of the two hyperscalers described in Sec. 3.2 (exact workload breakdowns are in Fig. 17). We simulate eight workloads: reconstruction, scrubbing, garbage collection, transcoding,

Maintenance task	Event frequency	Deadline
Reconstruction	On disk failure	36 hours
Scrubbing	Once in 30 days	30 days
Garbage Collection	Once in 6 hours	5 days
File transcoding	Once in 12 hours	5 days
Rebalancing	Once in a day	5 days
Georeplication	Once in 30 days	30 days
File Scrubbing	Once in 30 days	30 days
FSCK	Once in 15 days	7 days

Table 2: Maintenance task parameters for simulator experiments.

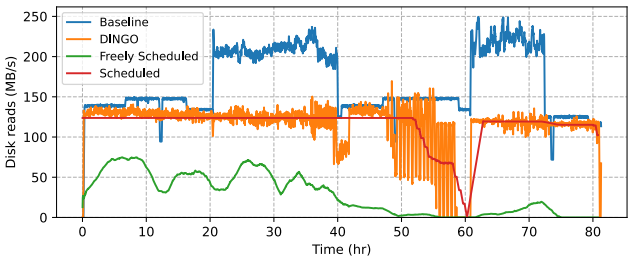

Fig. 14: Maintenance task disk reads for DINGO *(orange) and unmodified HDFS (blue). The red and green lines represent the logical IO scheduled by the IO Planner for* DINGO*, with the red line being IO that counts toward the disk IO limit and the green line being IO that is free due to overlap. For the baseline, periods of increased IO occur around hours 20 and 60 due to reconstruction events.*

FSCK, georeplication, and rebalancing.[11] Maintenance task frequency and deadlines are listed in Table 2. We validated our simulator, finding that its IO savings are within 5% of those measured in the analogous HDFS experiment.

We open-source both the HDFS prototype and the simulator at `www.github.com/Thesys-lab/declarativeIO-osdi26-artifact`.

6.2 DINGO enables higher capacity HDDs

We first explore DINGO's IO savings in our prototype and in our datacenter simulator.

Takeaway 1: *Our prototype shows* DINGO *works in a storage cluster, reducing bytes read by 26% for the four maintenance tasks.*

We evaluate the IO reduction benefits of DINGO in our storage cluster. Fig. 14 compares the maintenance disk reads in DINGO to that of unmodified HDFS (baseline). The baseline has to read a byte from disk per every logical byte needed by each maintenance task. By comparison, DINGO completes the maintenance workload while only reading 0.74 bytes from disk per logical byte, a 26% reduction in total bytes read.

Additionally, DINGO enables a steadier maximum rate of maintenance IO. While DINGO sometimes has more IO than scheduled due to cache misses, metadata operations, and other noise (scheduled IO savings are 28% compared to DINGO's observed 26%), DINGO is aware of all outstanding maintenance tasks and schedules their combined IO rate. In fact, DINGO's largest deviations from a constant rate only occur

[11] We describe how the workloads were simulated in detail in Suppl. A.2.

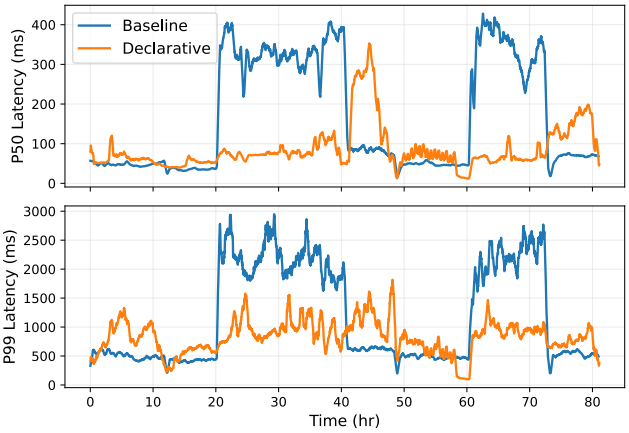

Fig. 15: Max of clients' P50 and P99 read latencies per minute over time. Ongoing maintenance IO impacts latency. For instance, reconstruction events around hours 20 and 60 increase latency in the baseline due to lack of a central rate limiter for maintenance read IO, and dense scheduling of transcoding events around hour 40 in DINGO *increases P50 latency due to elevated write IO.*

when it finishes most of its outstanding work ahead of schedule, such as around hour 50. At such points, disk reads oscillate based on when new declarations arrive.

With the imperative paradigm, even when each maintenance task rate limits itself independently, the combined IO shifts significantly depending on which tasks are running. For example, the baseline in Fig. 14 has periods of higher disk IO starting around hours 20 and 60 due to reconstruction.

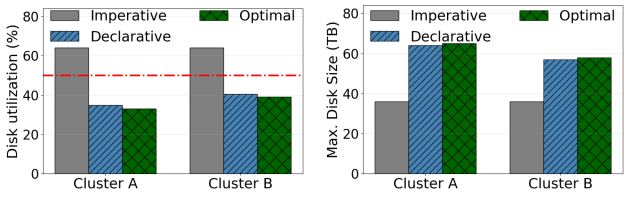
Takeaway 2: DINGO *has similar or better client P50 and P99 read latencies than the baseline.*

To determine whether DINGO affects client performance, we repeat the experiment with a read workload based on analysis of Alibaba block storage traces [73]. We configure this foreground workload to contribute around 30% of total disk read IO (Sec. 3.2). The average client throughput is 6.36 MB/s for the baseline and 6.82 MB/s for DINGO. As seen in Fig. 15, we find that the median client read latencies are better than the baseline both on average (86 vs 167 ms) and at worst (423 vs 587 ms). The 99th percentile has an even larger difference, 832 vs 1181 ms on average and 4969 vs 6877 ms at worst, due to its more stable read IO from maintenance tasks.

However, as seen in Fig. 15, for certain time intervals, the client latency differs significantly (up to about 6× lower or higher) due to increases in maintenance IO. The baseline's latency spikes when it is reconstructing data. Similarly, although DINGO respects the read bandwidth limit, bursts of write activity from clustered transcoding can cause temporary P50 read latency increases. Future work can improve robustness by integrating other metrics into scheduling (e.g. write IO, CPU and network utilization, etc.).

Takeaway 3: DINGO *enables 1.7× larger drive adoption on petabyte-scale clusters in our* DINGO *simulator.*

For a representative maintenance read demand of 2 MBp-



(a) Disk-head utilization. *(b) Max. Drive Sizes supported*

Fig. 16: (a) DINGO's IO savings in terms of disk-head utilization across two clusters with a cumulative maintenance IO demand of 2 MBps/TB and 48 TB drives. The red line represents the maximum disk utilization maintenance tasks can use and still allow deployment of 48 TB drives in a cluster where half of disk IO is from applications. (b) Maximum drive sizes that can be supported in the two clusters for a total demand of 4 MBps/TB, half of which is maintenance.

s/TB, Fig. 16a shows the percentage of disk head utilization required in a cluster with 48 TB drives. With this IO demand, the imperative approach consumes 64% of disk time to fulfill all reads for the maintenance workload. Declarative IO allows DINGO to identify up to 45% of bytes read as redundant and reduce disk utilization to as low as 34.8% in Cluster A.

DINGO's significant reductions to disk head utilization allow the adoption of higher capacity drives in storage clusters. Fig. 16b shows how Declarative IO enables 64TB drives in Cluster A (assuming maintenance reads can only use 50% of disk bandwidth), a 1.7× increase in the maximum supported drive size compared to an imperative system. Cluster B sees similar benefits with a 1.5× drive capacity increase to 58TB.

Takeaway 4: DINGO *achieves near-optimal IO reduction.*

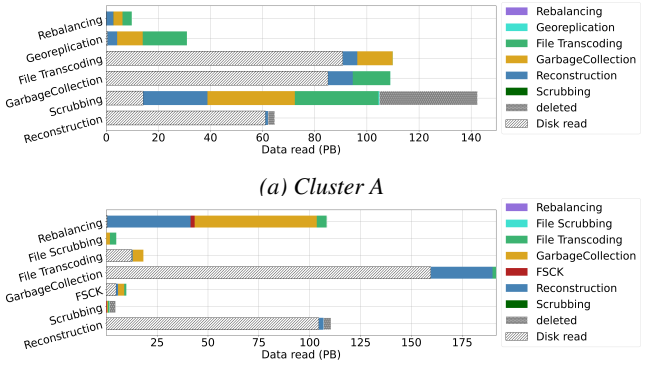
We also compare DINGO's savings against `Optimal`, an infeasible theoretical lower bound. `Optimal` knows all future declarations, does not consider per-quanta disk IO limitations, and does not consider deadlines. `Optimal` reads a block only when it is not in any future declarations to avoid missing IO reuse. Even under many more constraints, DINGO only incurs slightly more IO than `Optimal`. DINGO stays within 5% of this lower bound for both Cluster A and Cluster B.

Takeaway 5: *Even for exabyte storage clusters, the IO Planner can run on a single server.*

We assess the scalability of DINGO by measuring the time and memory overheads of the IO Planner in our simulator on a Dell PowerEdge R640 server with 240 GB of RAM. For a 1 EB storage cluster performing 2 MBps/TB of maintenance reads, our IO Planner was able to find all dispatching groups for a one-hour scheduling quanta in under 15 minutes with a peak memory usage of 205 GB. With more powerful and memory-rich compute nodes typically available in hyperscale environments, DINGO can be directly adopted for multi-exabyte storage clusters.

6.3 Where are DINGO's IO savings from?

Fig. 17 shows the breakdown of IO savings for the two simulated clusters. For each workload in each cluster, we report the amount of data read directly from disk, and the



(a) Cluster A

(b) Cluster B

Fig. 17: Volume of data read by different workloads across two clusters. White hatched bars represent data that had to be read directly from disk. The solid colored bars represent data that was read for free due to cache hits. The colors represent the workload with which these free bytes overlapped. The dotted gray bars represent data that was deleted (so the IO was avoided altogether).

amount of IO saved, either because of cache hits (the data was recently read by another task) or because the corresponding data was deleted, eliminating the need for IO. When tasks are scheduled with overlapping IO, we attribute disk reads to the tasks with the nearest deadlines as those are the first to decide which data to read in our scheduling heuristic (Sec. 5.1).

Takeaway 6: DINGO *allows more flexible tasks to piggyback on IO from more urgent and less-flexible tasks.*

Since reconstruction tasks have the shortest deadlines, reconstruction often drives the IO Planner to choose data in a scheduling quantum, though this changes when other declarations are close to their deadlines. Other tasks are then able to exploit these reads when overlapped by the IO Planner.

Another interesting example is rebalancing, which becomes completely free. While rebalancing has equal or worse time-flexibility than file transcoding, garbage collection, or index checking, it has much better data-flexibility. Rebalancing declares more blocks than it needs and only requires a single block at a time. This pattern greatly increases the odds of finding overlap with other tasks and shows why finding data-flexibility is important to saving IO in a declarative paradigm.

Takeaway 7: *Imperative storage systems often do unnecessary maintenance IO.*

In a traditional storage system with no additional information about the remaining lifetime of data blocks, scrubbing indiscriminately reads and verifies all data in the system. But DINGO's results reveal that a large portion of this work is unnecessary. Maintenance tasks such as garbage collection and file transcoding write new file contents and then delete the original file. By simply allowing a flexible time window to accomplish scrubbing, we find that ∼26% of reads declared for scrubbing were unnecessary because the data was subsequently deleted.

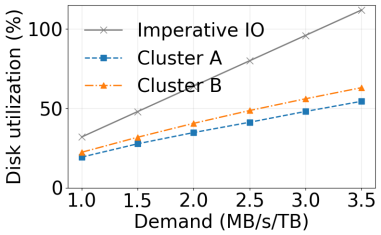


Fig. 18: Disk utilization by maintenance tasks with different demands. Utilization with imperative IO increases proportionally with demand. DINGO *is able to reduce the utilization by effectively scheduling tasks requesting common bytes together.*

6.4 Sensitivity studies

We now explore how DINGO responds to a variety of different situations — particularly when IO demand, task deadlines, and IO supply change.

Takeaway 8: DINGO *is effective across different maintenance IO demands.*

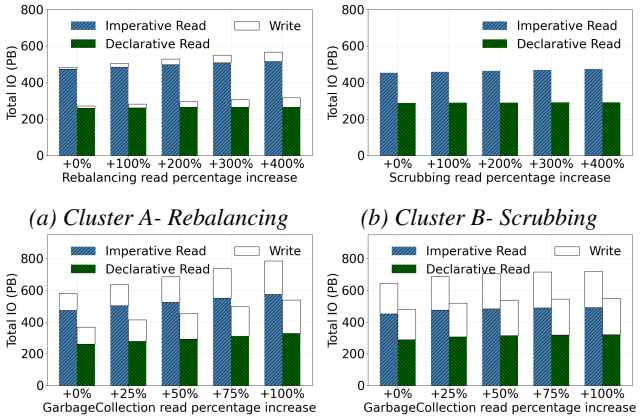
Depending on the nature of data stored and the users being serviced, the IO demand for maintenance reads can vary across clusters, even within a hyperscaler. Fig. 18 shows savings with a demand of maintenance reads ranging from 1 MBps/TB to 3.5 MBps/TB for two cluster workloads using 48 TB drives. To scale the IO demand, we increase the frequency of each maintenance task. For scrubbing, we also shorten the deadline since otherwise it would overlap with itself. Disk utilization grows proportionally with the requested rate of maintenance reads as expected.

Disks spend 22% of their time on maintenance reads at 1 MBps/TB, but exceed 90% utilization at 3 MBps/TB with imperative IO (we set imperative's IO demand to be the same for both clusters). If the demand exceeds 3 MBps/TB, it would be physically impossible for the disk to service even just the maintenance reads, leaving no room for foreground IO. Declarative IO reduces the disk-head time from disk by 39-51% in Cluster A and 28-46% in Cluster B, saving more at higher IO demands.

Takeaway 9: DINGO *enables each maintenance task to perform more work with less additional IO than imperative IO.*

Due to the lack of IO supply, different hyperscalers prioritize some maintenance workloads and throttle others based on their trade-offs. For example, many clusters dynamically adjust the rate of garbage collection based on when available capacity or IO is needed more. Fig. 19 illustrates the IO overheads incurred when the rate or the IO demand of maintenance tasks increases.

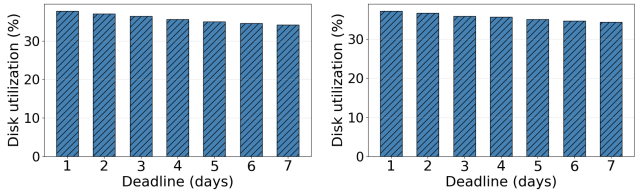
By leveraging data reuse, DINGO can perform additional maintenance work for substantially less IO than an imperative system. For example, Cluster B is able to scrub 4× more data with virtually no extra IO, whereas an imperative-only cluster performs proportionately more reads. DINGO can also perform more garbage collection and rebalancing by consuming less read bandwidth. Note that DINGO only reduces the bandwidth needed for *reading* data; maintenance tasks still need to write their data to disk. Despite this, in Cluster A, DINGO can perform 4× more rebalancing and still consume 45% less IO than the imperative baseline. Similarly, for both clusters, DINGO is able to perform 2× more garbage collection for the same IO as the imperative IO baseline. That is, if these clusters adopted declarative IO today, they could garbage collect twice as aggressively without any additional disk IO.



(a) Cluster A- Rebalancing *(b) Cluster B- Scrubbing*

(c) Cluster A- GC *(d) Cluster B- GC*

Fig. 19: Declarative IO allows for increasing maintenance tasks' work while incurring the same, or less, disk IO than the imperative baseline, reducing the need to throttle maintenance tasks. Total IO is from all maintenance IO in the cluster, not just that of the task being adjusted.



(a) Garbage Collection *(b) File transcoding*

Fig. 20: In cluster A, DINGO*'s disk utilization decreases as garbage collection and file transcoding increase their time-flexibility through extending their deadlines.*

Takeaway 10: *Exposing more time-flexibility with longer deadlines saves IO.*

We investigate how the time-flexibility of a workload, as defined by its completion deadline, impacts achievable savings with the IO Planner. Fig. 20a and Fig. 20b show IO savings in Cluster A as deadlines vary from 1 to 7 days for garbage collection and file transcoding. Longer deadlines allow DINGO to find more overlap for the declared tasks. For instance, moving from a 1-day deadline to a 7-day deadline for file transcoding resulted in ∼7% lower disk utilization in the cluster. Note that a realistic deadline will depend on the SLOs that the workload is required to meet. Depending on IO traffic, garbage collection tasks may mandate shorter deadlines to limit the accumulation of garbage, reduce storage overheads and improve IO performance.

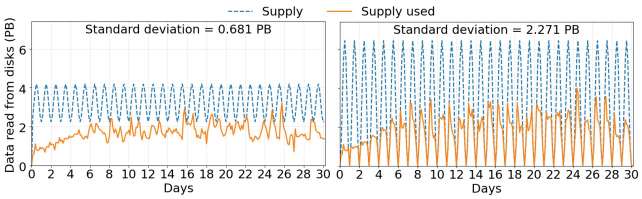


Fig. 21: Bytes read over a month by maintenance tasks with declarative IO following a diurnal IO supply. DINGO *rate-limits the IO schedule based on the quota allocated during both low and high supply variance.*

Takeaway 11: DINGO *adapts to changes in IO supply, such as those driven by foreground workload variations.*

Maintenance tasks are often throttled in order to prioritize user-facing application IO. One approach to throttling is to allocate a dynamic IO quota to each maintenance task. This IO supply typically follows a diurnal pattern, reflecting user demand throughout a day. DINGO is able to dynamically rate-limit the amount of scheduled maintenance work in order to stay within the allocated IO quota. Fig. 21 shows that the IO used by declarative IO is always below the allocated threshold, even with a high variance in IO supply.

7 Related Work

This section discusses additional related work with similar techniques and goals to Declarative IO.

Duet and Quartet. Duet [10] uses page events to inform local maintenance tasks about new in-cache data. Quartet [27] builds on Duet to schedule subtasks of map-reduce jobs with overlapping IO requests close in time to each other. DINGO instead introduces an interface that allows a large variety of different maintenance tasks to declare multiple types of IO flexibility across large distributed storage systems.

Disk optimizations. Disk-level optimizations can re-order IO. For instance, freeblock scheduling [46] re-orders low-priority IO to exploit disk-head time spent rotating to the right disk location. This can be extended to local maintenance reads [68]. These optimizations are orthogonal to Declarative IO since the maintenance reads will still go through these disk-level optimizations.

Semantically-smart disks [11, 64, 65] intuit the structure of the file system or database to make better data placement decisions or secure deletion of data, increasing disk functionality without changing the disk interface. Declarative IO both addresses a different problem — the impending IO-wall in distributed storage system on HDDs — and also takes a different approach — embracing interface change as necessary.

Database optimizations. The database community has tried to combine data requests, such as through shared scans [8, 12, 66]. These optimizations rely on having database queries — a higher-level abstract than many maintenance tasks operate at. Declarative IO instead targets the file and block level since all maintenance tasks that perform disk IO must eventually go through the bulk storage tier. Thus, we need an interface specifically at that tier and we find that we do not need one as verbose for databases.

Reducing IO from individual maintenance tasks. There has been work trying to reduce IO from individual maintenance tasks such as transcoding [13, 42]. This work is orthogonal. Any improvements in reducing this IO will just contribute to the end goal of overcoming the IO wall and deploying higher-capacity hard-disk drives.

8 Conclusion and Discussion

We show that HDDs are running into an IO wall. Because application IO is cacheable and maintenance IO is not, we find that maintenance IO now dominates disk IO demand. We introduce Declarative IO to allow maintenance tasks to express their IO flexibility to the storage system. DINGO uses this flexibility to find reuse between maintenance tasks, enabling deployment of 1.7x larger HDDs.

Declarative IO has broader implications than just reducing disk IO to save cost, emissions, and footprint from using larger-capacity devices. Datacenters subject to bursty application workloads or dynamic power constraints (e.g., power grid limits) [17] now have a powerful tool to throttle cluster-wide maintenance IO. Using less IO supply for maintenance tasks also allows more low-priority opportunistic workloads to run, since there is more likely a surplus in available IO even with larger-capacity devices. Finally, while we target maintenance tasks, there are many higher-level applications, such as batch analytics or machine learning training, where Declarative IO could help further reduce disk IO.

Abstract

Our production experience in large-scale data-processing pipelines shows that, despite its attractive programming model, memory-mapped I/O (*mmap-IO*) on distributed file systems (DFS) exhibits severe operational pathologies—livelocks during write-heavy phases, chronically low multi-threaded throughput, and high memory footprints that may trigger out-of-memory kills in containerized environments. Our measurements further show that mmap-IO on DFS is 3×–10× slower than on local file systems (LFS) for matrix random-access workloads, primarily because page-granularity network I/O underutilizes high-speed networks and deferred write-back behavior incurs expensive distributed flushes and metadata operations. We present *umap*, a DFS-agnostic runtime that delivers near-in-memory matrix-access performance on DFS via network-efficient communication, a concurrency-aware cache protocol with linear scalability, and lazy-expansion cache management. Deployed in production for over 18 months, *umap* has eliminated livelocks and out-of-memory-induced job failures while improving throughput by up to 6.7× across diverse matrix-access workloads. Our experience shows that rethinking mmap-IO's interaction with DFS is essential for robust, predictable performance in modern large-scale clusters.

1 Introduction

Matrix access underlies many modern data center workloads, including machine learning (ML) [27,66], quantitative finance pipelines such as large-scale backtesting [31,47], LLM inference [40,71], and scientific computing [15,18]. For example, in quantitative finance, matrices encode per-asset state over long historical windows and are intensively accessed in offline backtesting and factor-research pipelines; In serverless LLM inference, matrices hold model parameters that must be repeatedly loaded into CPU memory (e.g., via *mmap*) and transferred to GPUs [29,65]. As these workloads grow, matrix access increasingly dominates overall cost and can even exceed the FLOP cost itself [51,72].

To balance performance and scalability, practitioners commonly adopt *file-backed matrices* (FBM), implemented via *mmap-IO*[1]. FBM offers a compelling abstraction: data appears memory-resident, while the kernel transparently fetches pages on demand. This abstraction is commonly used to enable out-of-core access without loading entire datasets into memory, which is essential when working with matrices that exceed physical memory capacity. This model is widely adopted in practice and is supported by widely used systems. For example, NumPy provides `memmap` for out-of-core array access [13], PyTorch data pipelines commonly use disk-backed and memory-mapped loading mechanisms to stream large training datasets [17], and systems such as vLLM use mmap to load multi-GB model weights into CPU memory during initialization [20]. Across these systems, FBM is often the primary mechanism for accessing datasets and model parameters that exceed memory capacity, rather than an optional optimization.

Yet our large-scale deployment reveals that this long-standing abstraction *breaks down* under today's disaggregated storage architectures. Modern clusters increasingly adopt high-performance DFS [9, 22, 38, 45] to separate compute from storage, enabling independent scaling and higher aggregate bandwidth. This shift fundamentally disrupts assumptions baked into the virtual memory (VM) subsystem.

Abstraction mismatch under disaggregated storage. *mmap-IO* was designed for local, low-latency storage and page-granularity VM, whereas DFSes export block-oriented semantics with distributed metadata, locking, and cache coherence. This structural mismatch causes each page fault to incur fragmented remote I/O, heavy metadata traffic, and cross-node synchronization. In our production cluster that supports large-scale financial backtesting, scientific computing, and

[1] We use *mmap-IO* to denote the full Linux memory-mapped I/O subsystem, including the `mmap` syscall, page cache, page fault path, and filesystem integration.

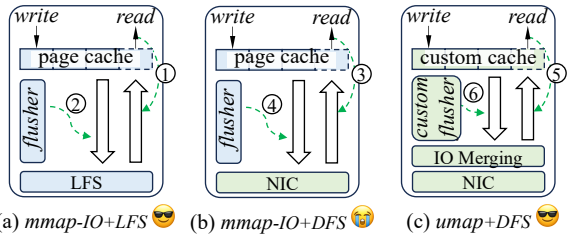
AI workloads, we observed substantial FBM slowdown after migrating from direct-attached storage to a disaggregated architecture (i.e., replacing LFS with DFS). Despite the DFS providing over *25 GB/s* of per-node remote bandwidth—an order of magnitude higher than a local SSD—FBM workloads still suffer *3×–10× lower throughput*, poor bandwidth utilization, and extreme tail latency. Increasing page granularity via hugepages further exacerbates amplification for irregular access patterns [50]. These findings highlight a deeper issue: the traditional VM loading model no longer aligns with the disaggregated storage substrate.

Implicit VM "magic" undermines predictability and operations. A more serious operational issue arises from *mmap-IO*'s *implicit* I/O behavior. On LFS, deferred write-back and on-demand paging are fast and predictable. On DFS, these mechanisms become opaque and failure-prone: asynchronous write-back competes for distributed locks, triggering prolonged stalls; page faults inflate into multi-millisecond network operations; blocked threads accumulate in `iowait`, and under pressure they may be misclassified as deadlocked. In our production cluster, such misbehavior caused tasks to remain idle for tens of minutes, cascade into *livelock*, and even trigger system-level miskill events—directly affecting SLAs and service availability. The core problem is not merely low performance, but the absence of observability and control: performance anomalies disappear into the kernel's page-fault machinery, hidden from operators, turning performance debugging into a black-box guessing game.

Greedy caching harms multi-tenant stability. Finally, the kernel's default caching policy—designed for single-node, single-tenant environments—does not translate to multi-tenant clusters. Linux aggressively expands the page cache to retain remote data, with little regard for reuse or isolation. For FBM workloads on DFS, this leads to memory pressure, noisy-neighbor interference, and occasional out-of-memory (OOM) kills, even when applications exhibit modest working sets. In contrast, our measurements show that an application-aware, lazy-expansion strategy can achieve higher throughput while using *less than 10%* of the memory consumed by vanilla *mmap-IO*. This highlights a growing need for user-level control over caching behavior in shared clusters.

Recent work aims to accelerate *mmap-IO* on fast local storage through prefetching [30, 41, 44, 52], per-core caches [54], and access pattern-specific optimizations [46, 56, 57]. In the era of disaggregated storage, where bandwidth is plentiful but metadata and consistency dominate, these assumptions collapse: their optimizations amplify page-granular I/O, stalls, and livelock. FBM workloads therefore need a new abstraction that preserves memory-style access while exposing coarse-grained, explicit control for predictable high performance on DFS.

This paper presents *umap*, a high-performance, drop-in compatible runtime for FBM on DFS. *umap* addresses the abstraction mismatch and operational challenges above without requiring changes to applications or DFSes. It introduces: (1) a network-friendly communication manager that merges page-level requests into DFS-native transfers; (2) a concurrency-aware, lock-minimizing cache protocol that adapts to parallel random access; and (3) a lazy-expansion cache manager that enforces predictable memory usage in multi-tenant settings.



(a) *mmap-IO+LFS* (b) *mmap-IO+DFS* (c) *umap+DFS*

Figure 1: Comparison of mmap and umap runtimes on LFS and DFS. Page-granularity network I/O and deferred write-back significantly degrade "mmap-IO+DFS" performance.

Deployed for 18 months in production, *umap* eliminates livelock and writeback-induced stalls observed with *mmap-IO*, stabilizes tail latency, and improves availability. Experiments show that *umap* achieves up to 2.8× faster reads and 8.3× faster writes than state-of-the-art (SOTA) NVMe-backed *mmap-IO*, and accelerates real-world training, inference, scientific, and quantitative workloads by up to 6.7×.

2 Motivation, Challenges and Solutions

2.1 Background

***mmap-IO* enabled file-backed matrix (FBM).** A FBM stores data on the file system while providing transparent in-memory access via *mmap()* [10]. The example below maps a file into the process's address space, exposes it as a memory buffer, and accesses it as a $ROWs \times COLs$ matrix.

```
1 float* mat = mmap(... /*fd=*/open("~/mat.dat"));
2 for (size_t i = 0; i < ROWs; ++i)
3   for (size_t j = 0; j < COLs; ++j)
4     mat[i * COLS + j] = i + j;
```

Figure 1(a) illustrates how *mmap-IO* constructs the FBM *mat* on LFS. It maps the file from LFS into the process's virtual memory, allowing applications to access file as if it were in RAM. Upon a page fault (①), the OS loads the data into the *page cache* [16] via IO bus, potentially evicting existing pages (dirty pages are flushed to the LFS by a *deferred, asynchronous* flusher thread (②)) if memory is limited.

Unlike memory-backed matrices that consume physical RAM and risk OOM errors, FBMs utilize the file system and *mmap-IO* to access datasets beyond physical memory efficiently and scalably. Compared to direct I/O, which bypasses the page cache and requires manual management, *mmap-IO* benefits from OS-level caching and demand paging, reducing redundant I/O and improving performance.

FBM behavior changes in LFS-to-DFS transition. In traditional direct-attached storage architecture, storage is physically tied to compute nodes (e.g., LFS in Figure 1(a)), whereas disaggregated storage architectures consolidate storage into DFS, accessible via dedicated storage networks (Figure 1(b)). Unlike LFS, which relies on local storage devices (e.g., SSDs), DFS distributes data across multiple *storage nodes* to support concurrent access by many clients. Despite data distribution across nodes, DFS retains the same API as LFS, enabling compute nodes to access files as local. As a result, migrating from LFS to DFS does not change *mmap-IO*'s behavior; the primary difference is that *mmap-IO* now issues network I/O via NIC to access DFS (Figure 1(b)).

2.2 Performance Issues of *mmap-IO* on DFS

Key characteristics of FBM-based workloads. FBM-based workloads present unique challenges that influence both application performance and deployment stability:

C1: Random access patterns. Depending on the algorithm, threads may access matrix elements sequentially or randomly. Random access reduces spatial locality and can significantly increase I/O overhead, especially on DFS, directly impacting user-perceived performance.

C2: High concurrency. FBM applications often use multiple threads, each accessing different rows or columns. While enabling parallelism, such concurrency can strain file systems when threads generate overlapping I/O.

C3: Large scale. FBMs often exceed physical memory, making *mmap-IO* essential to scale workloads beyond RAM limits. However, this can lead to frequent page faults and high memory pressure, potentially threatening deployment stability—especially in containerized environments where excessive memory use may trigger out-of-memory kills.

These characteristics reveal that *mmap-IO* is not an ideal intermediary between applications and DFS, due to a fundamental mismatch in access patterns, which is further amplified by optimizations designed for LFS. We next validate these observations through experiments.

1) Storage underutilization in random small I/O. To better understand the limitations of *mmap-IO* as an intermediary for FBM workloads, we first measure single-threaded random access performance of *mmap-IO*-based FBM on a LFS (ext4 [19] over an Optane NVMe SSD [7]) and on two DFSes (GPFS [5] and IBM NFSv4 [12]). Using `fio` [4], we benchmark FBM by varying request size to observe its effect, and also measure random *direct I/O* performance—where reads and writes bypass the page cache—for reference.

Figure 2 presents the results (lines without the "*mmap-IO*" prefix indicate direct I/O). On LFS, *mmap-IO* and direct I/O achieve similar throughput, while on DFS, *mmap-IO* performs significantly worse, with the gap widening as request size increases: for example, DFS throughput triples from 4KB to 64KB I/Os under direct I/O, whereas *mmap-IO* remains flat.

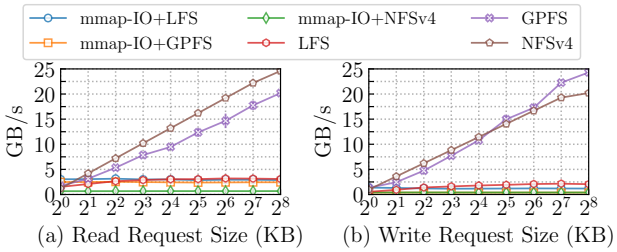


Figure 2: Single-threaded performance of direct I/O versus memory-mapped I/O (setup in §6.1).

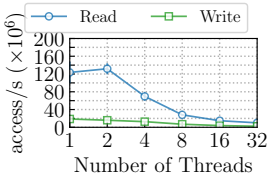

Figure 3: Concurrent random access to a *single* FBM stored on a **DFS** (GPFS).

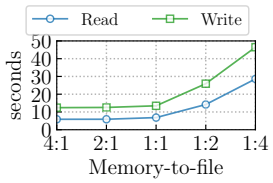

Figure 4: Concurrent random access to *multiple* FBMs stored on an **LFS**.

The reasons for *mmap-IO*'s poor performance are twofold. On LFS (Figure 1(a)), reads and writes go directly over the I/O bus to the LFS, allowing efficient access with minimal overhead. On DFS (Figure 1(b)), each *mmap-IO* operation is fragmented into 4KB network I/Os and incurs additional latency from RPCs, metadata lookups, and locks—orders of magnitude higher than LFS access. *Write* throughput suffers even more, as the Linux *flusher* thread performs deferred, asynchronous write-backs (④), limiting effective throughput.

2) Non-scalable I/O throughput in multi-threaded scenarios. Figure 3 extends the workload from Figure 2 by scaling from single-threaded to multi-threaded execution. The results on GPFS and NFSv4 are similar; for simplicity, we only present those on GPFS. As shown, increasing thread count leads to worse performance. Kernel profiling attributes this to growing time in *iowait*—mainly queued for distributed locks—and in spin locks within the system call *native_queue_spin_lock_slowpath* in Linux. Moreover, as the thread count grows, time spent in both *lock* and *iowait* increases. At 32 threads, the task spends 88.9% of its time in *iowait*, and 76.1% of the remaining time waiting on locks.

The scalability of *mmap-IO* does not align with the I/O performance gains offered by DFS. Two primary factors limit *mmap-IO*'s scalability on DFS: (i) One is that the spin lock (e.g., *tree_lock* in Linux) is used to enforce the atomic page replacement. Consequently, concurrent access to the memory-mapped region incurs three primary overheads, ranked in descending order: file I/O (>4000 clock cycles in LFS [7]), lock overhead (750∼2500 clock cycles [11]), and memory access

(144∼192 clock cycles [6, 8]). These overheads can overlap, so the actual performance is determined by the slowest among them. After migrating to DFS, using the RDMA-enabled network reduces file I/O overhead to levels close to memory access. However, this improvement shifts the bottleneck to lock overhead, which becomes dominant in data access performance. (ii) Another is that an increase in concurrent threads leads *mmap-IO* to generate numerous parallel I/O requests to DFS, escalating contention for distributed locks and exacerbating performance degradation.

3) Performance impact of excessive caching in *mmap-IO*. *mmap-IO* employs a *greedy-expansion* strategy, aggressively caching file data into memory to minimize access latency. While effective for moderate workloads, this approach becomes counterproductive in data-intensive FBM workloads—particularly with many FBMs—where the total mapped size exceeds available memory. The resulting memory pressure leads to performance degradation.

To validate this, we run experiments on a node with memory restricted to 64GB using *cgroup*, with other configurations as described in §6.1. Each test consists of multiple concurrent tasks, where each task uses *fio* [4] to perform 4 million single-threaded random accesses to a 16GB FBM (*float32*). We vary the number of concurrent tasks from 1 to 16, resulting in total mapped sizes from 16GB to 256GB—corresponding to memory-to-file size ratios of 4:1 to 1:4. As shown in Figure 4, where the y-axis denotes the completion time of each test, performance remains stable while the data fits in memory but degrades sharply once it exceeds capacity, highlighting the cost of excessive caching under memory pressure.

2.3 Challenges and Solutions

The slowdown arises not from flaws in *mmap-IO* or DFS individually, but from a fundamental semantic mismatch between them. *mmap-IO* assumes a local, page-granular backing store and issues demand-driven 4 KB page faults. DFS, however, provides remote, block-granular storage, where each access traverses network stacks and metadata services. Consequently, page faults fragment even large sequential accesses into thousands of tiny remote I/Os, amplifying metadata contention and serialization, which explains the severe bandwidth underutilization and long-tail stalls observed under concurrency.

To address these limitations, the core is to design DFS-friendly cache and write-back mechanisms. Figure 1(c) illustrates the key idea behind *umap*: reshaping implicit page-level access into explicit, network-efficient operations to restore system predictability and observability, while preserving the *mmap-IO* abstraction and high-performance. Achieving this requires overcoming the following challenges.

Challenge 1: Small-I/O amplification prevents DFS from reaching full bandwidth. *mmap-IO* generates bursty streams of 4 KB requests, which are inefficient for DFS. Larger I/Os (e.g., through hugepages) reduce metadata pressure but introduce I/O amplification [50], wasting network bandwidth.

Solution 1: *umap* preserves the 4 KB page size but introduces *network-friendly communication management* that merges page requests using a rank-based, time-aware policy and fairly schedules them across I/O channels. This reduces request volume and mitigates network burstiness and overhead. (§4.1)

Challenge 2: Lock contention limits scalability in multi-threaded workloads. *mmap-IO* relies on locks to ensure atomic cache replacement [10, 54]. In data-intensive multicore workloads, frequent replacements trigger high lock costs—e.g., acquiring a lock costs ∼2500 cycles vs. 144–192 cycles to load a page [11]. While negligible on LFS due to slow disk access [7], these costs dominate with fast DFS networks (200 Gbps [38]), capping throughput.

Solution 2: *umap* employs a *concurrency-aware cache protocol* that detects runtime access parallelism and uses a state-machine–based mechanism to perform lock-free cache lookups and replacements. This enables near-linear scalability and efficient random access. (§4.2)

Challenge 3: Unbounded cache growth inflates memory usage in multi-job environments. Existing memory-mapping systems [10, 54] rely on *greedy expansion*, where page caches grow opportunistically until memory pressure forces eviction. This reduces memory available for applications and exacerbates interference across concurrent jobs. However, limiting cache size risks increased cache misses and costly DFS I/O.

Solution 3: *umap* introduces *lazy-expansion cache management*, which dynamically adjusts cache size based on observed access patterns. It prioritizes replacement over expansion, estimates runtime memory demand for FBM workloads, and reclaims memory when pressure rises—achieving near-peak performance with substantially lower memory usage. (§4.3)

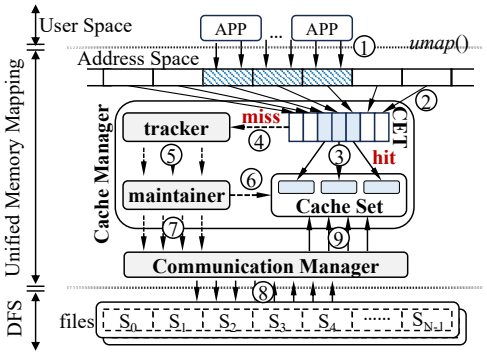

Figure 5: *umap* architecture. Files are divided into cache-block–sized segments and mapped on demand.

3 Overview of *umap*

umap is a memory mapping runtime that constructs a full-stack I/O path over DFS. By replacing implicit OS paging with user-space orchestration, it bridges application-level memory access and low-level data movement while ensur-

ing predictable performance and fault observability. From the user's perspective, *umap* provides a drop-in replacement interface, *umap()*, which is compatible with *mmap()* and returns a memory buffer that supports direct read/write operations. As a result, applications written using the *mmap* APIs can be easily migrated to the *umap* APIs with minimal modifications.

Architecture. As illustrated in Figure 5, *umap* comprises two main components: the *Cache Manager (CaM)* and the *Communication Manager (CoM)*. The CaM manages two core data structures. The *Cache Set* is a global pool of fixed-size cache blocks (CB) that temporarily store file segments fetched from the DFS. The *Cache Entry Table (CET)* is a collection of index arrays, each corresponding to a mapped file. CaM also includes two submodules: the *tracker*, which makes decisions about cache allocation and replacement based on reuse policies, and the *maintainer*, a background thread that enacts the *tracker's* decisions by allocating new CBs or selecting existing ones to load data. Mapping a new file with *umap()* just adds a new index array to the CET. This array holds α pointers, where α equals the file size divided by the CB size. Each entry represents a file segment and indicates whether it has been loaded. In our configuration (4 bytes per pointer and a 4 KB CB size), the memory overhead is approximately 1/1024 of the file size. The CoM merges I/O requests, manages concurrency, and performs asynchronous data transfers between the DFS and the local cache set.

Execution flow. Once initialized, *umap* intercepts memory accesses from applications (① in Figure 5). Given a virtual address within a mapped file, it computes the corresponding segment index and accesses the associated entry in CET's index array. If the entry points to a valid CB, it indicates a *cache hit*, and the data is returned directly from the cache set (②, ③). Otherwise, a *cache miss* occurs (④): the *tracker* selects a CB (⑤) —potentially evicting an existing one—and the *maintainer* prepares it for reuse (⑥ ⑦). The CoM then asynchronously fetches the required segment from the DFS (⑧ ⑨). Once the data is loaded, the CET entry is updated to reference the new CB, allowing execution to resume.

umap prioritizes throughput over per-access latency. By batching and merging requests, it may increase individual access latency, but significantly improves overall system throughput under concurrent workloads. This tradeoff is aligned with the characteristics of the target workloads.

Consistency model. *umap* follows a mmap-style weak consistency model with explicit synchronization. Each node maintains a local cache and does not enforce implicit cross-node coherence. This design targets data-parallel workloads where cross-node concurrent writes are rare, and avoids the excessive coordination overhead that arises from enforcing strong consistency at page granularity in distributed file systems.

4 Design

4.1 Network-friendly I/O Management

The communication manager (CoM) transforms fine-grained page faults into coarse-grained I/O requests. It achieves this by merging adjacent requests and batching them through a queueing mechanism, thereby improving network efficiency and reducing I/O amplification.

I/O Merging and Prioritization. A natural way to improve network throughput is to merge consecutive requests that are contiguous on DFS. While random matrix accesses exhibit spatial locality, naïve merging only captures strictly adjacent requests, leaving much of the locality unused. Caching requests can create additional merging opportunities, but delays may underutilize the network.

To this end, we design a *Push-In Admission-Out (PIAO)* queue to facilitate I/O request merging. Elements in the PIAO queue are ordered by a unique *rank*. When an element with rank r is inserted, it is placed at position i such that r is greater than the rank of the $(i-1)_{th}$ element and less than that of the $(i+1)_{th}$ element. Adjacent elements with consecutive ranks are then merged into a single, larger network I/O request.

Merging via PIAO may starve higher-rank, earlier-arriving requests. To prevent this, each request is also enqueued into a *FIFO* queue. When a merge occurs in PIAO, the corresponding request in FIFO is updated rather than enqueued again. Dequeueing always begins with the FIFO queue; the CoM retrieves the request from FIFO and removes the corresponding elements from PIAO.

umap associates a pair of PIAO and FIFO queues with each mapped file. At runtime, each request is tagged with a tuple $(timestamp, rank)$ (index of the file segment is used as *rank*) and sent to the CoM. Figure 6 gives an example. The CoM receives two requests with ranks r_8 and r_4 at times t_5 and t_6, respectively. The request (t_5, r_8) is inserted at the tail of both the PIAO queue and the FIFO queue because r_8 is greater than the ranks of all existing requests, and t_5 is later than all existing timestamps. In contrast, the request (t_6, r_4) can be merged with (t_1, r_5) and (t_4, r_6), so it is inserted at the third position in the PIAO queue. Meanwhile, the CoM updates the merged I/O request in the FIFO queue. During dequeueing, the request $(t_1, r_4 - r_6)$ will first be removed from the FIFO queue. Meanwhile, the corresponding requests (t_6, r_4), (t_1, r_5), and (t_4, r_6) will also be removed from the PIAO queue.

Communication Scheduling. Even with I/O merging, single-threaded communication may underutilize DFS bandwidth [34]. To address this, CoM leverages modern multi-queue NICs [35], which handle packets in parallel to sustain line-rate throughput. By establishing multiple I/O channels and distributing FIFO requests across them, CoM improves network utilization.

To ensure fair scheduling of each FIFO queue, the CoM utilizes a *least-first* mechanism to select a queue. At runtime,

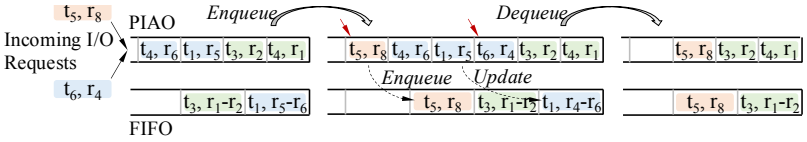

Figure 6: Example of I/O merging and prioritization.

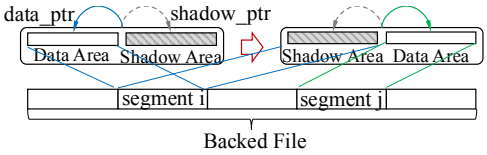

Figure 7: The shadow-copy mechanism.

it maintains a *min-heap* to manage all FIFO queues, and employs T_r to track the transmitted data amount of the heap's root node, while each FIFO queue uses T_q to record its own transmitted data amount. The heap starts empty with $T_r = 0$. When a queue is added to the heap, its T_q is initialized to T_r. All I/O channels proactively fetch requests from this heap. Upon fetching the root node, if the corresponding queue is not empty, the CoM dequeues a request from the queue, updates T_q ($T_q \leftarrow T_q +$ request_size) and T_r accordingly ($T_r \leftarrow T_q$). Otherwise, the queue will be removed from the heap.

Data Synchronization. Accessing a DFS involves distributed locking and coordination across multiple computing nodes [24, 60, 67], introducing significantly higher overhead than LFS. To address this, CoM introduces a *shadow-copy* mechanism [34] that overlap communication with computation. Each CB in CoM maintains two equal-sized buffers (Figure 7): one serving as the *data* buffer for application access and the other as the *shadow* buffer for background synchronization. At runtime, CoM alternates the roles of the two buffers, enabling continuous access while synchronization proceeds in parallel.

(1) Data fetching: Whenever a CB is recycled for caching another segment, CoM fetches data from the corresponding file segment to the CB's data area. Usually, only one data fetching operation occurs for each CB. Before a write-back, regardless of whether other threads are mapped to this CB, data fetching will not be triggered again.

(2) Write back: Figure 7 outlines *umap*'s write-back process. When a CB's data area changes association with the underlying file segment, *umap* initiates several steps. First, it removes the mapping between the CB and index array entry. Then, it atomically swaps the pointers *data_ptr* and *shadow_ptr*, respectively pointing to the data area and shadow area. Subsequently, an I/O request is generated to flush the shadow area back to the file (i_{th} segment). CoM uses atomic state transitions to ensure exclusive access during write-back, preventing *Write-after-Read (WAR)* hazards. Concurrently, it repopulates the CB's data area from the j_{th} segment.

4.2 Concurrency-Aware Cache Protocol

The concurrency-aware cache protocol determines the system's concurrency in real-time and sets CBs to different states based on thread access behavior. By leveraging the system's thread scheduling characteristics, it partitions the CBs into different sets, achieving lockless cache replacement and lockless data access, thus scaling the performance linearly.

4.2.1 Thread Tracking for Concurrency Awareness

Using locks to enforce data consistency when multiple threads access the same CB would hinder scalable throughput in memory-mapped I/O. Instead, CaM detects the concurrency degree at runtime and distinguishes threads accessing the same data, preventing one thread from preempting resources used by another. This ensures correctness and performance without locking, avoiding the following WAR hazards.

Consider a *false eviction* scenario with threads t_1 and t_2 accessing a mapped file concurrently. Thread t_1 accesses a loaded CB at the 10th entry E[10], while t_2 accesses an unloaded CB via E[100], initially pointing to a *sentinel CB* (a special marker with a NULL data area). Before t_1 returns, a cache replacement updates E[100] to the CB previously at E[10] and sets E[10] to the sentinel CB. Consequently, t_1 would encounter a segmentation fault when accessing a NULL data area.

A naive approach to prevent WAR hazard is to use a lock (e.g., *tree_lock* in *mmap-IO*) to protect cache replacement process on each access. With this method, in the aforementioned example, t_1 will update the status of CaM before the function returns, preventing thread t_2 from mistakenly setting E[10] to the sentinel CB during cache eviction. However, this approach is inefficient: even a single Compare-and-Swap (CAS) costs 15–30 cycles without contention and up to 2500 cycles under contention. Accessing an element with locks can thus cost hundreds of cycles. In contrast, *umap* requires only ∼12 cycles per access (§6.3).

The challenge arises because CaM aims to enhance throughput with limited cache capacity (§4.3). Unlike *mmap-IO*, which aggressively allocates new pages on cache misses and may pause threads during page faults, CaM reuses existing CBs to avoid thread suspension and reduce overhead.

In the concurrency-aware method, CaM attaches a unique identifier (*tid*) to each running thread to identify the current concurrency degree. This is accomplished by allocating a thread-local storage variable using the C keyword *__thread*. The *tid* is initialized when a thread triggers a cache replacement in *umap* for the first time, which is typically the first time it accesses data. Additionally, as shown in Figure 8(a), each CB has a reference map *rmap* to record which threads are referring to it. For a file, the *rmap* of CBs is non-overlapping. This means when a thread triggers a cache replacement, the *tid* should be removed from the *rmap* of the thread's previous CB and added to the *rmap* of its newly assigned CB. A CB with a non-empty *rmap* will never be evicted, thus avoiding

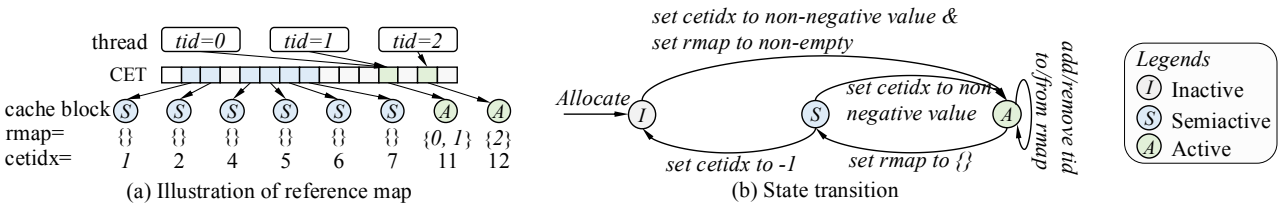

Figure 8: Overview of the concurrency-aware mechanism and its state machine.

false eviction. The reference counting [36] is not applicable here because a CB's lifetime may exceed that of a thread. A corner case is that when a thread terminates, it cannot modify the state of the last CB it accessed, which would result in some CBs never being released; *umap* solves this issue by checking the status of *rmap*'s associated threads to determine whether a CB can be released.

4.2.2 FSA-Based Cache Management Protocol

With only the *concurrency-aware* mechanism, multi-threaded random access causes *cache thrashing* [42,61,69,70], degrading performance. Assuming zero lock overhead, let t_a be the cost to access a CB element and t_r the cost of a replacement ($t_a \ll t_r$). For a task with x accesses and y replacements, the total overhead is $xt_a + yt_r$, dominated by y since x is fixed. If a CB is replaced once every k accesses on average, $y = x/k$, so higher randomness (smaller k) makes yt_r the dominant cost. Frequent loading and eviction of CBs also increase network overhead, reducing throughput and causing unpredictable performance.

The CaM maintainer employs a finite-state machine (FSA) to implement the concurrency-aware cache protocol to manage CBs. This protocol enables CBs of a file to transition between specific states without requiring data synchronization and triggering cache replacement, thereby eliminating the cache thrashing problem. Combined with *rmap* in the concurrency-aware mechanism, each normal CB has three states (Figure 8(b)):

(1) *Active*: referred to by threads and pointed to by a CET index array. CaM will return data directly upon accessing the corresponding entries. This allows CaM to bypass the cache replacement phase, enhancing performance by reducing unnecessary cache operations.

(2) *Semiactive*: not referred to by any thread but still pointed to by some index array entries. When accessing the corresponding entries, CaM returns data directly. These CBs are ready to be evicted to the inactive list but can also be re-activated.

(3) *Inactive*: not referred to by any thread and not pointed to by any index array entry. When a cache miss occurs, CaM picks one from the inactive list, sets it to active, binds it to a entry, and returns it. Additionally, newly allocated CBs are also added to the inactive list. This approach ensures efficient reuse of CBs, reducing the overhead of frequent allocations and evictions while maintaining performance.

Figure 8(b) illustrates the workflow of the FSA-based protocol. We elaborate on the state transition as follows:

Case 1 (Ⓘ → Ⓐ): An uninitialized CET index array entry is accessed, and then *umap* initializes an inactive CB, loads data and updates CB's metadata.

Case 2 (Ⓢ → Ⓐ): An initialized but not referred CB is accessed, and then *umap* just updates metadata.

Case 3 (Ⓐ → Ⓐ): If a referred CB is accessed by a new thread, or if a thread associated with the CB is detected to be dead or is accessing another entry, and then *umap* just updates the metadata.

Case 4 (Ⓐ → Ⓢ): All threads associated with this CB have either been detected dead or are accessing other CBs.

Case 5 (Ⓢ → Ⓘ): When inactive CBs are insufficient, *umap* flushes data to the backed file, sets the associated CET entry uninitialized, and converts a semiactive CB into inactive.

In CaM, inactive CB is used for cache replacement, and other states are used for data access. Since no data synchronization is involved when the semiactive and active states transition and CB has been initialized, the entire process is lockless. And the number of cache replacements y can be significantly reduced. Moreover, since the CB that can be used for cache replacement has been placed in the inactive state, there is no need to worry that cache replacement will evict the CB being used. Thus, we can use lockless techniques (e.g., concurrency queue [49]) to retrieve a CB from the inactive CB list and associate it with the target index array entry in the cache replacement process.

Except for case 5 (Ⓢ → Ⓘ), other state transition conditions are clear. CaM minimizes the number of inactive CBs to ensure that as many CBs as possible are used for caching data while ensuring that a CB being set to inactive is not accessed by other threads before the status modification is completed. Since the cost of state switching is less than that of associating a CB to an index array entry, and the number of threads scheduled for execution does not exceed the number of CPU logical cores (denoted as N_{core}), the number of simultaneous accesses in the inactive list is less than N_{core}. Therefore, CaM only needs to trigger Ⓢ → Ⓘ once when the number of CBs in the inactive list is less than N_{core}.

CaM's cache protocol can use cache efficiently. For **sequential access**, semi-active CBs are reused along the path of Ⓢ → Ⓘ → Ⓐ → Ⓢ → ⋯ without need to allocate new CBs. For workloads with repeated random access [53], semi-active CBs are reactivated to reduce data synchronization overhead.

Algorithm 1: Lazy-expansion cache management

```
1  Interface: CB* get_CB(idx)
2  Stateful Variables: counter, lru_list, lru_map,
     last_appearance
3  if last_appearance == NULL then
4      last_appearance ← (int*) malloc(4 × ⌈S_f / S_c⌉)
5      Initialize all elements in last_appearance to -1
6  N_c' ← 1
7  if last_appearance[idx] ≠ -1 then
8      N_c' ← counter - last_appearance[idx]
9  if lru_map.find(idx) ≠ lru_map.end() then
10     CB* cb ← get_CB_pointer(lru_map.find(idx))
11     lru_list.erase(lru_map.find(idx))
12     lru_list.push_front((cb))
13 else
14     if N_c' ≥ N_c then
15         Allocate N_new CBs and add them to inactive_list
16         N_c ← N_c + N_new
17     if inactive_list.size() > 0 then
18         lru_list.push_front(get_CB_pointer(inactive_list.front()))
19         inactive_list.pop_front()
20     else
21         CB* cb ← get_CB_pointer(lru_list.back())
22         lru_list.pop_back()
23         lru_list.push_front(cb)
24 last_appearance[idx] ← counter++
25 lru_map[idx] ← lru_list.front()
26 return get_CB_pointer(lru_list.front())
```

4.3 Lazy-Expansion Cache Management

The *Lazy-expansion Cache Management* module (tracker in Figure 5) decides whether to allocate a new CB or reuse an existing one on a cache miss. Allocating more CBs can improve performance, but mapping too many files increases pressure on the kernel's memory subsystem [53], potentially causing burst I/O [26] and degraded performance in multi-tenant environments (§2.2). To mitigate this, the tracker minimizes the number of CBs N_c of a mapped file while maximizing the cache hit ratio.

Obviously, N_c depends on the user's access pattern and must be determined dynamically. Accesses may be sequential or random, but due to spatial locality, data accessed within a short period is usually nearby in storage. Given an access sequence $X = \{\cdots, x_i, \cdots\}$, we define the degree of randomness at the i-th element as $R_i = n - i$, where $n > i$, *and* $x_i = x_n$ and $\forall j \in (i,n), x_j \neq x_i$. We then have the following result.

Theorem 1 $N_c = \max(R_i)$, $i \in \mathbb{N}$, is the optimal number of CBs for minimizing the cache capacity in an Least Recently Used (LRU) cache.

Proof. From the definition, $R_i \leq N_c$ for the i-th element e, meaning the distance to its next occurrence cannot exceed N_c. In an LRU cache with a capacity of N_c, when an element is added to the cache, it is placed at the head of the LRU list. In the worst case, subsequent evictions will push it one position back in the LRU list until it is removed. Thus, the element will remain in the cache for at least $N_c - 1$ evictions. Given that $R_i \leq N_c$, the element e will be accessed again and moved back to the head of the LRU cache before it is evicted, specifically during the R_i-th cache replacement. This process repeats indefinitely. Consequently, each data segment is loaded into the cache only once during its first access. Subsequent accesses to the same data will not result in a cache miss. □

Lazy-expansion: umap develops a variant of LRU cache to achieve the lazy-expansion of the capacity at runtime. Algorithm 1 shows the process to find optimal N_c. Based on Theorem 1, N_c should be set to be $max(R_i)$, $i \in [1, I]$ when processing I_{th} element. When processing the next element, there are three cases

- cache hit: then update the state of LRU cache and return (line 9-12).
- cache miss: If the element has never appeared, perform a regular LRU replacement (line 21-23).
- (*expansion*) cache miss: Otherwise, let i denote the index of the last appearance, expand the LRU cache to $N_c' = I + 1 - i$, and allocate $N_c' - N_c$ new CBs. Then update N_c and associate the element with a new CB (line 7-8 & line 14-19).

Note that in line 15-16 of Algorithm 1, when new CBs need to be allocated, *umap* will allocate N_{new} CBs instead of $N_c' - N_c$. This ensures the robustness of the algorithm by preventing elements with low frequency but large R_i from causing excessive CB allocations. With this algorithm, for file scanning workloads [46] where each element is accessed only once, such as in training [59], only one CB is needed regardless of the dataset size. For random-access workloads [53] that may repeatedly access the same elements, the memory required for the cache is minimized to achieve optimal performance.

Dynamic Cache Reclamation: The cache tracker maintains a virtual capacity N_v for each file, allowing the cache to shrink dynamically. Whenever N_c is updated, N_v is set to $N_c/2$, and Algorithm 1 is executed to update N_v without triggering actual allocation or replacement. Under memory pressure signaled by the Linux *kswapd* thread, the tracker instructs the cache maintainer to free $N_c - N_v$ CBs. Dynamic cache reclamation is needed because N_c is optimal only for the previous access sequence and may be too large for future accesses. If a smaller capacity can be sustained without cache misses, memory can be safely released.

5 Implementation

Seamless Integration. *umap* is implemented as a drop-in replacement for legacy `mmap`. We supply a lightweight shim library supporting two integration modes. (1) Source-

compatible mode: Applications can redirect `mmap` to *umap* through a small wrapper or macro-level substitution, requiring minimal code changes (see Appendix B of the supplementary material). (2) Binary-compatible mode: For closed-source or large distributed frameworks, *umap* can be injected via standard LD_PRELOAD–based interposition, intercepting libc `mmap` to transparently accelerate file-backed mappings on DFS paths. This design enables existing workloads to adopt disaggregated storage with low friction while preserving their original architecture.

Consistency model and operational semantics. Rather than enforcing cross-node coherence through distributed locking, *umap* adopts the conventional mmap-style consistency model where updates are cached locally and synchronized only when explicitly requested. We intentionally avoid implicit strong coherence across nodes for overlapping writes, which can cause false-sharing storms in distributed settings. This design follows common practice in distributed shared-memory systems and favors predictable performance for data-parallel workloads, where cross-writer conflicts are rare.

umap further improves robustness and performance through the following enhancements.

(1) DFS-agnostic implementation. *umap* abstracts away the differences between specific DFS implementations by focusing only on their common characteristics—such as relying on network I/O. As a result, it adopts a DFS-agnostic design that interacts with the file system through POSIX APIs, capturing the generic behavior of DFS. This approach ensures that *umap* remains compatible with any POSIX-compliant DFS without requiring system-specific adaptations.

(2) Optimize the branch hit rate for the fast path. There is a special *Sentry* CB, a globally unique single CB node whose status is always inactive. In practice, *umap* uses this node as the default pointer for the CET entry. Setting this node reduces the number of operations when the cache hits in the fast path. With this node, in the case of cache hits, *umap* needs only two steps: (i) check whether the CB's state is non-inactive and (ii) return the result. Without this node, *umap* would need an additional step to verify whether the CET entry is NULL before performing the two steps.

6 Performance Evaluation

Our evaluation tries to answer the following questions: (1) How much speedup does *umap* achieve in real-world workloads (§6.2)? (2) How does *umap* perform under various settings (§6.3)? (3) In *umap*, how much benefit does each key technique bring (§6.4)? (4) What is the cost of *umap* 's performance gains in terms of system overhead (§6.5)?

6.1 Methodology

Testbed. We evaluate *umap* on a cluster where each node has two 200 Gbps ConnectX-6 NICs (one for storage traffic and one for compute), 1.82 TB DRAM, dual Intel® Xeon® 8260 CPUs (128 logical cores), a 3.84 TB Optane NVMe SSD [7], and eight NVIDIA A100 GPUs. We compare two configurations that are identical except for the DFS backend: one uses GPFS [5] and the other uses NFSv4 [12]. Both DFS deployments run as shared services across the cluster.

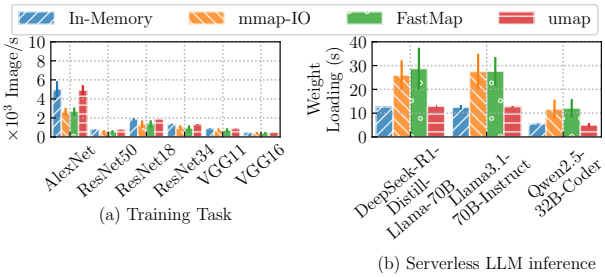

Figure 9: Impact of the FBM backend on AI workload performance.

Baselines. We use *mmap-IO* and FastMap [2, 54] over the SSD-backed LFS as baselines. *mmap-IO* is the de facto memory-mapped I/O mechanism in production systems, and FastMap is the leading academic design. Both are evaluated using their default configurations. We omit *mmap-IO*/FastMap on DFS because their performance is orders of magnitude lower, making them impractical for comparison.

Workloads. We evaluate four classes of FBM-based workloads, each with distinct access patterns and runtime behaviors. Unless otherwise stated, all real workloads run on GPFS; both GPFS and NFSv4 are used to evaluate *umap*'s DFS-agnostic design.

(i) AI workloads, where *PyTorch* and vLLM [40] use *umap*, *mmap-IO*, FastMap, or in-memory variants to load large FBMs—either as training datasets or LLM model weights. These workloads stress large-granularity, partially sequential accesses.

(ii) Cache-intensive scientific computing, represented by *OpenBLAS* [15], where we run all six FBM-backed matrix kernels using their default parallel configuration. These kernels repeatedly access small, high-locality regions of FBMs, placing pressure primarily on the cache manager rather than the DFS.

(iii) I/O-intensive financial analytics, represented by *backtrader* [1], where we run offline backtesting on 2020–2025 historical stock data across multiple markets. This workload scans multi-GB FBMs with low spatial locality, placing pressure primarily on sustained read/write throughput.

(iv) Microbenchmarks. We map 1–128 GB FBMs and use fio [4] with 1–32 threads to generate controlled random, sequential, and strided accesses.

Metrics. FBM workloads are mostly offline; we measure throughput and Job Completion Time (JCT) to capture large-matrix processing efficiency rather than per-request latency.

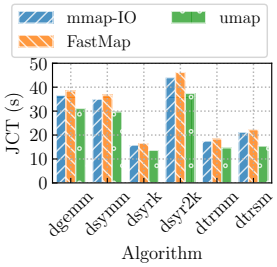

Figure 10: JCT comparison across different memory-mapped I/O runtimes.

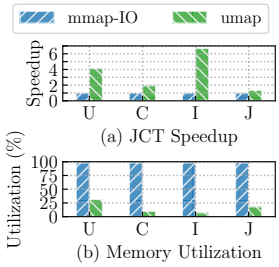

Figure 11: Improved JCT and lower memory usage achieved by *umap*.

6.2 Performance on Real-world Workloads

Performance in AI workloads. We evaluate the impact of different PyTorch [23] *Dataset* loaders on training performance: an in-memory loader, *mmap-IO*/FastMap loaders on LFS-backed FBMs, and a *umap* loader on DFS. To isolate FBM access, we preprocess ImageNet into a matrix-based format, allowing samples to be fetched without decompression overhead. We train AlexNet [39], ResNet [33], and VGG [63] using up to eight GPUs on a single node (Figure 9(a)). Although computation dominates end-to-end time, *umap* still provides 1.2–1.9× speedups. FastMap performs similarly to *mmap-IO* because ImageNet samples are relatively large (200–300 KB) and accessed single-threadedly, limiting the benefit of its lock-free parallel I/O optimizations.

In serverless LLM inference, model initialization time directly impacts request latency. Figure 9(b) shows the weight-loading time when vLLM [40] loads various LLMs via different backends, each implemented as a dedicated *model loader*. *umap* achieves near–in-memory performance and outperforms *mmap-IO* by 2.3×. LLM weight loading issues much larger I/O requests (often several megabytes per read) and uses only 1–8 threads, producing an access pattern that favors *umap* 's DFS-aware caching while reducing the benefit of FastMap's multi-threaded optimizations.

Performance in scientific computing. We further evaluate *umap* on cache-intensive workloads characterized by frequent reuse of cached FBM data. Specifically, we benchmark OpenBLAS [15] on six preset matrix routines using synthetic matrices of size $2^{15} \times 2^{15}$ (float64), filled with random values. On LFS, FBMs are accessed via *mmap-IO* and FastMap; on DFS, they are served by *umap*.

Across all benchmarks, *umap* outperforms *mmap-IO* and FastMap by 13%–28% (Figure 10). This is expected for cache-intensive workloads: OpenBLAS matrix operations are $O(n^3)$ and dominated by computation with frequent cache reuse, leaving little room for I/O optimizations. Even though OpenBLAS fully utilizes all CPU cores (up to 128 threads), FastMap shows no advantage over *mmap-IO*, consistent with prior observations [46] that its lockless optimizations mainly benefit small-file workloads (e.g., < 1 GB).

Performance in financial workloads. Financial backtesting is I/O-intensive, involving frequent random reads and writes on large historical market data files that cannot fit in memory, making I/O efficiency and cache management critical. To evaluate such workloads in practice, we run *backtrader* [1] on five years of historical stock data from four countries (U/I/C/J), using FBMs for market data. FastMap is omitted in this experiment due to deployment restrictions on the production market data servers; however, comparison with *mmap-IO* alone is sufficient to highlight the benefits of *umap*.

Figure 11(a) shows normalized JCT, with *mmap-IO* normalized to 1 for cross-dataset comparability. *umap* delivers up to 6.7× speedup by mitigating DFS I/O bottlenecks and enabling high-throughput FBM access on high-bandwidth storage. Due to the large size of market data, full in-memory loading is infeasible and also imposes significant overhead on the Linux memory subsystem. Figure 11(b) shows that *mmap-IO* leads to nearly 100% memory utilization, whereas *umap* maintains higher performance while keeping memory usage between 8% and 31%, thanks to efficient cache management.

Operational Resilience. In large-scale DFS environments, frequent *livelocks* arise from *mmap-IO* 's deferred-write mechanism. While this mechanism is effective on LFS, it interacts poorly with DFS consistency, which is typically enforced at coarse block sizes (hundreds of KBs to several MBs, e.g., 256 KB–16 MB in GPFS and Lustre). As a result, even when data resides in the local page cache, reads may trigger forced write-back and remote coherence checks, causing compute nodes to queue for distributed locks. In PB-scale systems, flushing 1 TB could take up to 3 hours, and in our production cluster, financial jobs experienced ≥10 livelock incidents per day, during which threads spent up to 90% of execution time in iowait without progress. These stalls were often misclassified as deadlocks by the batch scheduler, leading to forced termination and ≥100 core-hours lost per incident. After deploying *umap*, which bypasses *mmap-IO* 's asynchronous writeback via explicit POSIX writes and synchronous DFS metadata updates, livelocks were eliminated, with zero job terminations observed over 18 months of operation (§6.4).

6.3 Micro-benchmarks

In this section, we take a closer look at how *umap*'s performance varies across different configurations.

Throughput gains of *umap*. Figures 12(a) and 12(b) show the random parallel *read* and *write* performance of *umap* versus baselines on both LFS and DFS. The results are consistent across FBM sizes; here we focus on the 128GB FBM.

In single-threaded mode, *umap* on DFS shows a modest 20% drop in *read* performance compared to *mmap-IO* and FastMap on LFS (worst-case small random I/O; AI workloads use large I/O and thus see positive improvements). This is due to the lack of internal prefetching and lock-free optimizations for single-threaded access. Nevertheless, *umap* narrows the

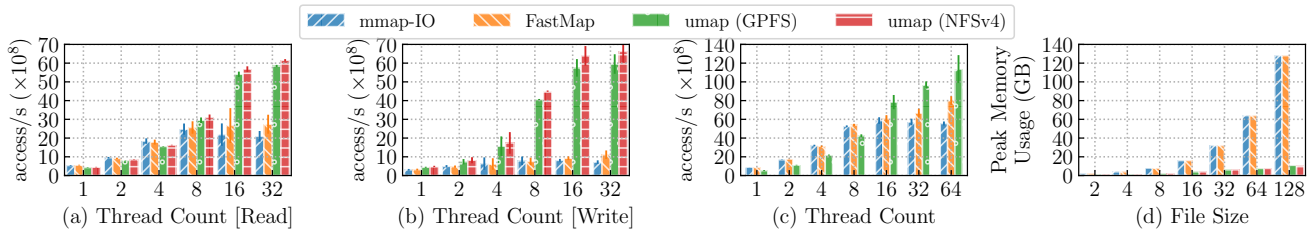

Figure 12: End-to-end performance comparison. In (c), only one bar is shown for *umap*, since it is not backed by a file system.

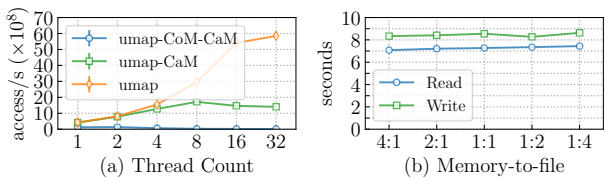

Figure 13: Ablation study results for *umap*.

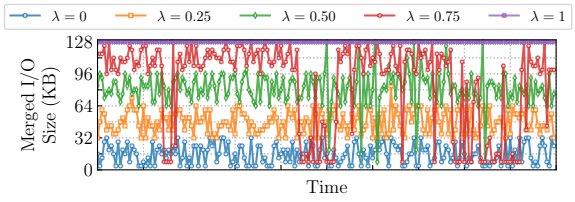

Figure 14: Impact of spatial locality on merged I/O sizes. A larger λ indicates stronger spatial locality.

performance gap between DFS and LFS used with *mmap-IO* (see Figure 2).

For single-threaded *write* operations, *umap* outperforms the baselines. Its network-friendly communication management and lazy-expansion cache strategy minimize overhead by reusing existing cache blocks and performing parallel write-back of the shadow copy. In contrast, baselines incur page faults and allocate new pages, incurring extra overhead.

Throughput scalability with *umap*. Figures 12(a) and 12(b) show that *umap* scales consistently and outperforms baselines. At 32 threads, *umap*+GPFS achieves 2.8× higher *read* throughput and 8.3× higher *write* throughput than *mmap-IO*+LFS. In contrast, *mmap-IO* performance degrades beyond 8–16 threads due to contention on the global *tree_lock*, which limits atomic page replacement during page faults. *umap*'s gains are more pronounced in *write* tasks because *mmap-IO* and FastMap benefit from prefetching on reads. Disk I/O is asymmetric; for example, the Optane SSD [7] has 5 μs read latency and 6 μs write latency. In contrast, *umap* 's performance over DFS shows near-parity between *read* and *write*, as both are limited by NIC bandwidth.

Beyond 32 threads, *umap*+DFS throughput plateaus around 190 Gbps, approaching the 200 Gbps NIC ceiling. To explore further scalability, we simulate a bandwidth-unconstrained environment where *umap* bypasses data synchronization and *mmap-IO* uses anonymous mappings. Figure 12(c) shows

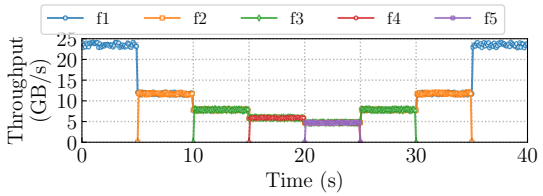

Figure 15: Inter-process fairness under *umap*.

that *umap* scales to 64 threads, while *mmap-IO* stalls at 16 threads, demonstrating the superior scalability of *umap* 's concurrency-aware caching protocol.

FastMap scales better than *mmap-IO*, but its overall performance gain is limited due to memory-stealing overhead: it divides system memory into 32 free-page lists, making it suitable only for small files. *umap* exhibits similar performance on GPFS and NFSv4; throughput is slightly higher on NFSv4, because NFSv4's weaker consistency model reduces the complexity of coherence management.

Memory efficiency of *umap* with sustained performance. Figure 12(d) shows the peak memory consumption of the *write* benchmark under varying file sizes with 32 threads. We observe that *mmap-IO* and FastMap consumes nearly as much memory as the file size itself, whereas *umap* uses less than 10.4% of the memory required by *mmap-IO* under the same conditions. This indicates that *umap* achieves higher performance with significantly lower memory usage, validating the effectiveness of its cache management strategy.

6.4 Effects of Individual Techniques

Communication management and cache protocol. We demonstrate that *umap*'s performance improvement is attributed to network-friendly communication management within the CoM and the concurrency-aware cache protocol within the CaM. In Figure 13(a), we compare the *read* performance of *umap* with and without CoM and CaM. Disabling both CoM and CaM (line *umap*-CoM-CaM) shows that *umap* performs poorly without these components. With only CoM enabled (bar *umap*-CaM), *umap*'s performance improves by 3.5× in single-threaded mode but does not scale beyond 8 threads. The inclusion of CoM and CaM (line *umap*), however, scales the performance linearly.

To analyze the effectiveness of CoM, we evaluate its I/O merging mechanism PIAO under varying access locality.

Table 1: Breakdown of execution progress for *mmap-IO* and *umap* over GPFS.

Test Type	context-switches	CPU-migrations	CPU cycles	page-faults	branches	branch-misses	$\frac{lockcost}{JCT-iowait}$	$\frac{iowait}{JCT}$
mmap-IO+LFS	7.6×10^3	7.1×10^1	2.5×10^{11}	2.0×10^6	1.2×10^{10}	3.6×10^7	68.0%	1.7%
mmap-IO+DFS	1.1×10^8	8.6×10^5	3.4×10^{12}	4.0×10^6	2.7×10^{11}	1.5×10^9	76.1%	88.9%
umap+DFS	2.1×10^3	3.1×10^1	6.3×10^{10}	6.3×10^5	1.4×10^{10}	3.1×10^7	1.2%	15.0%

We use a synthetic model, inspired by stochastic locality studies [48] and fio [4], that interpolates between random and sequential access via a parameter $\lambda \in [0,1]$. Each file has N blocks, and requests evolve as $x_t = (x_{t-1} + \Delta_t) \bmod N$, $\Delta_t \sim \text{Uniform}(0, R(\lambda))$, where $R(\lambda) = \lceil \texttt{iodepth} \cdot \lambda \rceil + jitter$ bounds the run length and `iodepth` is the number of concurrent outstanding I/O requests. Thus, $\lambda = 0$ yields fully random access, $\lambda = 1$ fully sequential access, and intermediate values partial locality. As shown in Figure 14, the average merged size grows from 17.2 KB ($\lambda = 0$) to 127.9 KB ($\lambda = 1.0$), confirming that PIAO effectively exploits locality and achieves DFS-friendly communication.

Cache Management. Figure 13(b) replicates the experiment from Figure 4 to evaluate *umap* 's lazy-expansion cache strategy under multi-task workloads. We run tests on one node, but restrict the available memory to 64 GB using *cgroup* limits, launching up to 16 concurrent tasks. Each task uses *umap*-backed *fio* [4] to issue 4 million single-threaded random accesses to a 16 GB FBM stored on DFS. This yields total mapped sizes from 16 GB to 256 GB, with memory-to-file ratios from 4:1 to 1:4. As shown, task performance remains stable across all ratios—even when the total mapped size far exceeds physical memory. By contrast, *mmap-IO* suffers severe slowdowns once memory falls short (Figure 4). These results highlight *umap* 's ability to sustain performance under memory pressure via its efficient cache management.

Fairness. We evaluate the fairness of *umap* 's CoM across concurrent processes, focusing on network bandwidth utilization. Fairness here refers specifically to network bandwidth sharing rather than memory usage, which we do not enforce, following the semantics of *mmap-IO*and FastMap; memory isolation can still be achieved via *cgroup* limits if needed. We launch multiple sequential *read* processes with staggered start/end times to ensure continuous bandwidth demand. As shown in Figure 15, a single process nearly saturates the available bandwidth (>95%), while N concurrent processes share it roughly equally. When a process finishes, its bandwidth is immediately redistributed to the remaining processes. These results demonstrate that *umap* 's CoM layer enforces fair bandwidth sharing while maintaining high efficiency in multi-tenant DFS deployments.

Resolving Livelock. We further profile kernel-level behavior to explain the poor performance of *mmap-IO*+DFS. Table 1 shows the execution breakdown of each *write* task under 32 threads. Several insights emerge. First, *mmap-IO*+DFS suffers from severe *iowait*, where CPUs stall on flushing dirty pages to DFS, causing a form of *livelock* [21] in which threads remain active but make no progress. Second, *umap* significantly improves CPU efficiency, cutting CPU usage by 98.2% and CPU migrations by 56.3% by eliminating the lock contention and wasted cycles that dominate *mmap-IO*. Third, lock contention accounts for most non-iowait time in *mmap-IO* (68.0% on LFS, 76.1% on DFS), largely due to spin locks (*native_queued_spin_lock_slowpath* in Linux). *umap* reduces this overhead to 1.2%. Although it shows a higher proportion of iowait than *mmap-IO*+LFS, the absolute time is lower because of its shorter JCT.

6.5 Latency Trade-offs

One concern is that *umap* introduces higher per-access latency due to its request-merging and scheduling logic (Figure 16). Although *mmap-IO* shows lower latency for individual 4KB reads, this benefit is largely irrelevant for FBM workloads, whose performance is governed by aggregate throughput rather than single-access latency. Even for online serverless services such as vLLM, the key metric is model loading time (cold-start latency), not single-byte access time. As shown in Figure 9, *umap* speeds up bulk loading by 2.3×, directly improving service availability and elasticity. For latency-critical sub-4KB random I/Os, *mmap-IO over local NVMe SSD remains ideal*; however, in the throughput-bound regimes typical of disaggregated data processing, the added latency by *umap* is a necessary trade-off to fully utilize the network.

7 Related Work

Page cache management. Many studies have examined techniques for high-performance page cache management for emerging fast storage devices like NVMe [14] SSDs. These approaches include designing concurrency-friendly page cache indexes [53, 54, 58], isolating memory mapping performance across applications [55, 62], and reducing cache allocation overhead through batch allocation or dedicated cache management units [43, 54, 64, 68]. *umap* is the first memory mapping runtime specifically tailored for DFS, fully accounting for the network behavior inherent in DFS—a factor that has been overlooked in previous studies.

Prefetching. Beyond the Linux kernel's built-in prefetching, many techniques have been proposed to enhance storage performance. OS-level approaches such as Lynx [41], ATS [37], HoPP [44], FastMap [54], and MMap [52] improve memory mapping via learning-based strategies or optimized disk layouts. Other studies [25, 32] target workload-specific prefetching at the application layer, while cross-layer designs [30] al-

low applications to influence system-level prefetching. These techniques are orthogonal to *umap*, which does not implement prefetching. Integrating them could further boost *umap*'s performance in read-heavy scenarios.

Workload-specific cache management. Some studies [46, 56, 57] optimize memory mapping for specific workloads such as key-value stores, databases, and distributed training by tailoring caching strategies. In contrast, *umap* targets random matrix access on network-attached DFS and remains agnostic to any particular workload. Prior work on user-space caching (e.g., Tricache [28]) focuses on improving local cache efficiency, while *umap* targets coordination and I/O amplification issues specific to DFS. User-space file systems based on FUSE [3] have gained popularity in recent AI systems. However, since they rely on the OS page cache, they inherit the limitations of mmap-IO in distributed settings. In contrast, *umap* redesigns the mmap path to be aware of distributed file system characteristics.

8 Discussion

In our 18-month deployment, *umap* eliminated previously observed livelock scenarios and significantly reduced instability such as OOM-induced failures, leading to more stable large-scale job execution. Our large-scale deployment of *umap* reveals broader implications for memory and storage system designs in disaggregated architectures. We summarize two *conceptual observations* and three *practical lessons* from our deployment.

Observation #1: Rethinking VM for Disaggregated Storage. Compute–storage decoupling exposes a structural mismatch between page-granularity VM and the block-oriented semantics of DFSes. Page-fault-driven I/O fragments remote accesses, amplifies metadata coordination, and prevents effective bandwidth utilization. As workloads increasingly operate over remote datasets (exceeding 95% in our cluster), future systems must move beyond traditional VM-based loading models toward coarser-grained, storage-aware abstractions.

Observation #2: Workload Semantics Favor Coarse-Grained Access. Across data analytics, model training, and financial computing, we observe that matrix- and tensor-dominated workloads rarely benefit from fine-grained paging or generic read-ahead heuristics. Their access patterns are coarse, structured, and explicitly known by the application. Exposing these semantics to the memory system enables much better performance than page-level mechanisms designed for general-purpose locality.

These observations motivate deeper cross-layer co-design between runtimes and DFSes. DFSes increasingly require semantic hints to schedule I/O efficiently, while applications require predictable interaction with remote memory. *umap*'s chunk-oriented abstraction suggests a path toward unified compute–storage interfaces that preserve memory-like convenience while embracing DFS-native granularity.

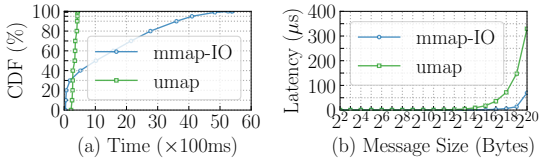

Figure 16: Message synchronization latency.

Lessons Learned. Operating *umap* in production reveals additional operational insights that go beyond the abstraction mismatch.

Lesson #1: Implicit page-based I/O undermines observability. On remote storage, *mmap-IO* turns network delays, DFS contention, and metadata bottlenecks into opaque page stalls, obscuring both performance anomalies and root causes. Coarse-grained, explicit I/O operations expose system behavior and produce far more predictable failure modes.

Lesson #2: Kernel-level greedy caching is harmful in multi-tenant clusters. Linux's page cache aggressively retains remote data with limited reuse, amplifying noisy-neighbor effects and triggering avoidable OOM events. Effective caching must shift to the application or runtime layer, where reuse semantics are known and can be explicitly controlled.

Lesson #3: Predictability outweighs micro-optimizations at scale. Eliminating livelock paths, bounding long-tail behavior, and simplifying retry logic improved job completion rates far more than median-performance tuning. In large clusters, robustness and isolation—not marginal throughput gains—dominate overall efficiency.

Applicability. The issues addressed by *umap* arise primarily in network file systems that involve distributed metadata management and locking (e.g., NFSv4 and GPFS). In contrast, block storage systems (e.g., EBS) or locally mounted file systems do not exhibit the same *mmap-IO* pathologies, as page faults do not trigger distributed coordination. *umap* is therefore designed for the former setting.

9 Conclusion

The rise of resource-disaggregated architectures presents both challenges and opportunities for optimizing memory mapping on DFS in FBM workloads. We present *umap*, a memory mapping runtime tailored for random matrix access in FBM workloads on DFS. By integrating network-aware I/O scheduling with dynamic cache management, *umap* improves data access efficiency while reducing memory overhead. Evaluation across synthetic benchmarks and production environments demonstrates consistent advantages over existing approaches.

CoPilotIO: CPU as a Co-pilot for GPU I/O to Free GPU Compute

Guanyi Chen[†] Qi Chen[†] Shu Yin[‡] Jian Zhang[†]

[‡]*ShanghaiTech University* [†]*The Hong Kong University of Science and Technology (Guangzhou)*

Abstract

Limited GPU memory increasingly forces modern AI and data analytics workloads to access terabyte-scale datasets and model states from storage, making efficient GPU I/O critical. Existing GPU I/O engines are either CPU-centric or GPU-centric. CPU-centric approaches avoid consuming GPU resources but often fail to provide high-throughput, on-demand GPU access due to kernel overheads and limited parallelism. GPU-centric approaches enable fine-grained on-demand I/O but require intensive I/O polling that consumes valuable GPU resources and introduces intra-warp, inter-warp, and inter-SM I/O stalls. We present CoPilotIO[1], a novel GPU I/O engine that delivers high-throughput, on-demand storage access without sacrificing GPU compute resources. CoPilotIO adopts an asynchronous GPU I/O architecture in which GPUs initiate I/O while CPU cores act as I/O co-pilots responsible for completion polling. To enable efficient coordination, CoPilotIO introduces a split SQ/CQ architecture, hardware barrier-based synchronization, a lock-free barrier-table, and adaptive CPU–GPU co-polling. Across microbenchmarks and real applications, including GoFS, LLM Mixture-of-Experts (MoE) inference, and Deep Learning Recommendation Models (DLRM), CoPilotIO reduces I/O-induced stalls by up to 55.5%, requires 50% fewer SMs to saturate the GPU PCIe bandwidth, accelerates GoFS by up to 17.4%, and improves application performance by up to 85%.

1 Introduction

Graphics Processing Units (GPUs) have become the primary compute device powering today's most demanding applications, including large-scale graph analytics [20, 36], scientific simulations [4, 13], high-performance computing (HPC) [8, 16], and the rapid emergence of generative AI, such as large language models (LLMs) [6, 9, 32]. These workloads routinely operate on multi-terabyte datasets, trillion-token corpora, and model checkpoints exceeding hundreds of gigabytes [6, 34, 38]. However, despite substantial advances in compute capability, GPU memory capacity remains fundamentally restricted: modern high-bandwidth memory (HBM) typically offers only 40–192 GB [1, 2, 24] per accelerator. This mismatch between massive data footprints and limited on-device memory means GPUs must continuously fetch data at extremely high throughput to keep their compute units fully utilized. As a result, the design of an efficient, scalable GPU I/O stack becomes critical.

Existing GPU I/O engines *exhibit a fundamental tradeoff among I/O performance, support for on-demand access, and GPU compute efficiency*. Broadly, prior designs fall into two categories: CPU-centric I/O and GPU-centric I/O.

CPU-centric I/O engines, exemplified by NVIDIA GPUDirect Storage (GDS) [23], enable peer-to-peer (P2P) data transfer between storage and GPU memory, but the entire control path remains on the CPU and relies heavily on the mature kernel I/O stack. This design offers high GPU compute efficiency because no GPU cores are consumed in the I/O path. However, limited CPU parallelism and substantial kernel storage stack overhead prevent GDS from saturating the available GPU PCIe bandwidth (e.g., PCIe 4.0 ×16 at ~25 GB/s) [28, 39]. Moreover, GDS lacks true on-demand access for GPU kernels: GPU threads cannot directly initiate I/O, so applications typically rely on CPU-side preloading, which introduces significant data amplification and unnecessary data movement [28].

To overcome these limitations, recent work [28] introduces GPU-centric I/O engines that empower the GPU to directly initiate I/O and manage the entire I/O path, including NVMe command submission, completion-queue polling, and request processing. This design achieves high throughput and allows GPU kernels to fetch data just-in-time, providing true on-demand access. However, shifting the full I/O stack onto the GPU introduces a critical drawback: *valuable GPU compute resources are consumed by the I/O stack, particularly by intensive I/O polling on NVMe completion queues.* This polling interferes with normal GPU execution and leads to substantial I/O-induced stalls, preventing compute kernels from making forward progress and ultimately degrading overall application

[1] Artifact available at https://github.com/HKUST-GZ-SYSTEM/OSDI26-CoPilotIO

performance. Our analysis (Section 3) shows that three types of stalls manifest at multiple levels, including intra-warp, inter-warp, and inter-SM stalls. For example, an intra-warp stall occurs when a GPU warp issues an on-demand I/O request to prefetch data; subsequent independent computation stalls because the warp must continuously poll the completion queue to detect I/O completion. This busy-waiting prevents the warp from making forward progress and reduces available GPU compute throughput by up to 87%. In effect, GPU-centric I/O can inadvertently convert highly parallel GPU SMs into inefficient I/O controllers.

Therefore, existing designs face a fundamental limitation: CPU-centric approaches offer high GPU compute efficiency but suffer from low I/O performance and inefficient CPU-mediated I/O control or data movement [19, 23, 30], whereas GPU-centric approaches provide high I/O performance and on-demand capability but consume substantial GPU compute cycles [18, 27, 28, 39]. This tension raises a central design question: **Can we achieve high-performance, on-demand GPU I/O without sacrificing valuable GPU compute resources?**

In this paper, we answer this question affirmatively. We argue that GPU compute resources are extremely valuable and should be prioritized for application computation rather than I/O servicing. Therefore, we advocate for a new GPU I/O architectural direction in which the CPU and GPU cooperate as peers rather than one replacing the other, delivering high-throughput I/O while preserving GPU compute availability.

We present CoPilotIO, a GPU I/O engine that treats the CPU as an I/O co-pilot for GPU applications. CoPilotIO introduces a new asynchronous I/O architecture across CPU and GPU in which the GPU initiates fine-grained on-demand I/O, while the CPU handles I/O queue polling. By offloading polling to the CPU, CoPilotIO fully eliminates GPU-side I/O stalls while preserving true on-demand access for GPU kernels. Designing such an architecture raises several key challenges. First, how can we achieve both high I/O throughput and low latency when the I/O stack resides across two devices (CPU and GPU), especially given that traditional CPU-side I/O stacks suffer from substantial OS kernel overheads? Second, how do we design an efficient synchronization and notification mechanism when the I/O submission and completion paths span both the CPU and GPU? Third, given the limited parallelism available on CPUs, how can we saturate the high PCIe bandwidth of modern GPUs while avoiding I/O-induced GPU stalls?

CoPilotIO addresses the above challenges with the following contributions: (1) A split SQ/CQ architecture across CPU–GPU memory, combined with a user-level SPDK-like I/O library on the CPU side [15], enabling fast GPU-initiated I/O submission and efficient CPU polling without OS kernel software overheads. (2) A hardware barrier–based synchronization mechanism [22] and a lock-free barrier-table, providing efficient, contention-free coordination and notification between the CPU and GPU. (3) A CQ-based adaptive CPU–GPU co-polling mechanism that dynamically migrates the polling role between CPU and GPU based on runtime I/O load, ensuring high throughput under high I/O load, while still avoiding GPU-side polling stalls.

We implement CoPilotIO in approximately 5K lines of code. We evaluate CoPilotIO using a comprehensive suite of microbenchmarks that measure reductions in I/O-induced stalls, pure I/O performance, the effectiveness of CQ-based adaptive polling, and the scalability and GPU compute efficiency of CoPilotIO. Our results show that CoPilotIO reduces I/O stalls by up to 55.5% compared to the state-of-the-art GPU-centric I/O engine, BaM. Enabled by CQ-based adaptive polling, CoPilotIO consistently sustains high I/O throughput even under dynamically changing I/O loads. In addition, CoPilotIO requires 50% fewer SMs to saturate four SSDs (i.e., the GPU's PCIe bandwidth) than BaM. We further demonstrate the practicality of CoPilotIO by integrating it into the state-of-the-art GPU filesystem GoFS [18], where CoPilotIO delivers up to 17.4% performance improvement. Finally, we evaluate CoPilotIO on real-world applications, including LLM Mixture-of-Experts (MoE) inference [12, 29] and Deep Learning Recommendation Models (DLRM) [21], both of which show up to 85% performance gains.

2 Background

2.1 GPU Architecture

Modern GPUs consist of many streaming multiprocessors (SMs), each acting as an independent parallel compute unit equipped with hundreds of CUDA cores. When a CUDA kernel launches, its threads are grouped into thread blocks, which are assigned to SMs. Within each SM, threads are further partitioned into warps of 32 threads, which execute instructions in lock-step. All SMs share a global L2 cache and the off-chip DRAM memory. A warp is the fundamental execution and scheduling unit in the SIMT model: all active threads in a warp issue the same instruction but operate on different data. Each SM has four warp schedulers, allowing up to four warps to issue instructions (active) simultaneously. Each scheduler selects the next ready warp to issue to the CUDA cores whenever the currently executing warp goes to sleep or completes, ensuring high concurrency. If a warp continuously occupies the cores without making progress, it limits scheduling opportunities and reduces overall GPU parallelism. For instance, an NVIDIA A100 GPU [22] contains 108 SMs with a total of 40-80 GB of memory, and each SM can track up to 64 resident warps (2,048 threads). Across the whole device, the A100 can therefore have over 200,000 in-flight threads, providing massive hardware-managed multi-threading.

In addition, GPUs also support directly reading from and writing to CPU memory over PCIe using zero-copy access [25]. In this mode, GPU threads can access host memory without an explicit DMA transfer, allowing the GPU to

operate on data resident in CPU memory with low latency. Conversely, GDRCopy [10] enables CPU threads to directly read and write GPU VRAM by creating user-space mappings of GPU memory through GPUDirect RDMA, providing a low-latency path for CPU-initiated accesses to GPU-resident data structures.

2.2 GPU I/O Engines

We categorize the state-of-the-art GPU I/O engines into two approaches: CPU-centric I/O and GPU-centric I/O.

CPU-centric I/O: GPUs rely on the host CPU to initiate I/O. As discussed above, CPU-centric approaches offer high GPU compute efficiency but suffer from low I/O performance and lack true on-demand GPU access. The standard solution is NVIDIA GPUDirect Storage (GDS) [23], which enables peer-to-peer PCIe DMA transfers between NVMe SSDs and GPU memory, allowing data to be written directly into GPU buffers without staging through host memory. However, its control plane remains CPU-orchestrated, which prevents true GPU on-demand access [28]. Data must be pre-loaded from storage into memory before GPU computation can proceed, leading to unnecessary data movement and read amplification. In addition, GDS suffers from limited I/O performance because its control plane resides in the OS kernel, incurring substantial kernel software overheads [28] that make it difficult to fully saturate the GPU's PCIe bandwidth (e.g., ~25 GB/s). Although GDS enables direct SSD-to-GPU DMA transfers, each I/O request still requires CPU-side I/O submission, completion handling, and synchronization through the kernel I/O stack, introducing significant control-path overheads such as system calls, kernel traps, buffer registration, DMA mapping, and NVMe queue management [23]. While asynchronous I/O interfaces (e.g., `cuFileReadAsync`) can overlap the data-transfer latency of individual requests, they cannot eliminate the per-request control-path overhead that CPU cores must process. As a result, the aggregate control-path overhead can exceed what the available CPU cores can sustain, even when using asynchronous I/O.

Additionally, several CPU-centric GPU I/O designs have been proposed to provide on-demand access for GPU applications. GPUfs [33] introduces a wrapper library that exposes familiar filesystem APIs directly to GPU code. However, all I/O operations are ultimately executed by the CPU through the host kernel's filesystem stack, resulting in limited I/O performance due to kernel overheads and CPU mediation. Moreover, GPUfs incurs substantial GPU compute overhead: the GPU issues I/O requests via an RPC mechanism to the CPU, causing excessive GPU-side communication and synchronization costs during I/O operations. ActivePointers [30] introduces a memory-mapped file abstraction for GPUs by moving the control path of page-fault handling onto the GPU. However, the data movement path remains entirely CPU-centric: for every major page fault, the OS still reads the page from the SSD into CPU memory and then copies it to the GPU. As a result, substantial GPU compute resources are wasted on complex page-fault handling logic, leading to significant overhead during I/O-intensive workloads.

GPU-centric I/O: To provide GPU on-demand I/O, BaM [28] allocates submission/completion queues and I/O buffers directly in GPU memory, maps NVMe doorbells into the GPU address space, and allows GPU threads to prepare commands, ring doorbells, and poll completions without invoking CPU-side I/O stacks. BaM provides high I/O performance and on-demand capability, but wastes substantial GPU compute cycles as the entire control and data paths of each I/O operation are initiated and completed on the GPU. This design forces GPU threads to actively poll for I/O completion, introducing substantial I/O-induced stalls into GPU applications, as detailed in Section 3. AGILE [39] builds on top of BaM to provide asynchronous I/O by dedicating additional SMs for polling, but its control and data planes remain entirely GPU-driven, which cannot avoid inter-warp and inter-SM stalls mentioned in Section 3. CAM [35] offloads SSD management to the CPU, but adopts a two-level submission path where GPU threads write request metadata into CPU memory and CPU-side threads issue the actual NVMe commands, adding a CPU-mediated indirection on the submission path.

Additionally, several GPU-centric filesystems have been proposed [18, 27], all of which build on BaM as their underlying GPU I/O engine. GeminiFS [27] adopts a companion filesystem design that embeds essential metadata into files, retrieves this metadata into GPU memory, and, together with a GPU-friendly page cache and NVMe queues, exposes simplified file-based direct storage access to the GPU. GoFS [18] further pushes the entire filesystem into the GPU to fully bypass the CPU. However, offloading the full filesystem and I/O management to the GPU introduces substantial interference and I/O stalls for regular GPU compute workloads. All filesystem tasks, including metadata lookup, caching, traversal, and I/O queue management, now compete with AI kernels for SM cycles. In modern AI workloads where GPU compute resources are extremely precious and increasingly scarce, dedicating GPU threads to non-compute tasks directly undermines utilization. Every GPU cycle spent on the filesystem I/O stack is a cycle not spent on model training or inference, leading to degraded performance, reduced parallelism, and poor cost efficiency at cluster scale.

3 Motivation

Tradeoff between I/O performance and GPU compute efficiency: For CPU-centric I/O systems such as GDS, GPU compute resources are not consumed for I/O operations. However, GDS suffers from limited I/O throughput due to substantial OS kernel software overheads and restricted CPU parallelism. As shown in Figure 3a, with 16 CPU threads, GDS fails to saturate a single SSD's bandwidth across a range of I/O sizes. Achieving full GPU PCIe link bandwidth (approximately 25

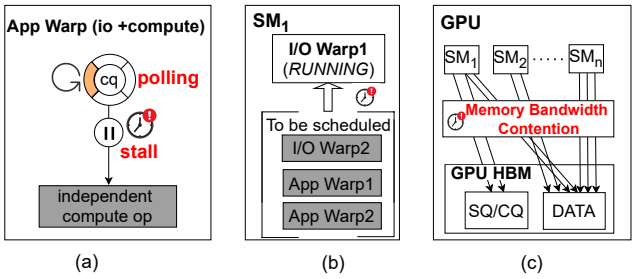

Figure 1: (a) Intra-warp stall: independent compute operation is stalled by I/O polling; (b) Inter-warp stall: compute warp is delayed from being scheduled as I/O polling warps keep occupying the GPU cores; (c) Inter-SM stall: I/O polling warps and regular application memory accesses contend for the global GPU memory.

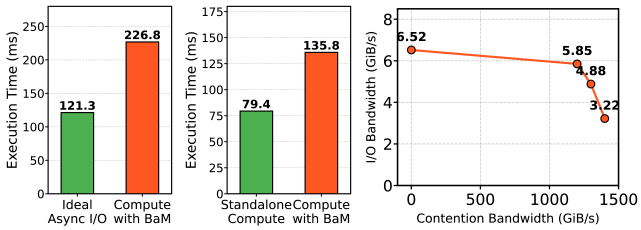


(a) Intra-warp **(b)** Inter-warp **(c)** Inter-SM

Figure 2: I/O Stall Analysis of the GPU-Centric Design.

GB/s for PCIe 4.0 ×16) requires saturating four SSDs concurrently, which is difficult for GDS because its kernel-level overhead and limited core parallelism prevent it from issuing and completing I/Os at a sufficiently high rate. On the other hand, BaM can saturate the bandwidth of four SSDs because it moves the entire I/O path onto the GPU, eliminating CPU-side software overheads and exploiting the GPU's massive parallelism. However, achieving this level of throughput requires more than 80 SMs (Figure 10a) on an NVIDIA A100 for I/O, which results in extremely poor compute efficiency. Moreover, when I/O and compute tasks are co-located on the GPU, they introduce multiple levels of stalls, including intra-warp, inter-warp, and inter-SM stalls as discussed next.

Lesson 1: Modern GPU I/O designs face a fundamental trade-off: *CPU-centric approaches preserve GPU compute capacity but deliver low I/O throughput, while GPU-centric approaches achieve high throughput but severely degrade GPU compute efficiency.*

Co-locating I/O and compute tasks on the GPU causes severe I/O stalls: Although GPU-centric I/O provides high throughput and supports on-demand access while fully bypassing the CPU, we observe that designs such as BaM incur substantial I/O polling stalls when I/O tasks are co-located with compute tasks on the GPU. Because BaM must continuously poll the NVMe completion queue to detect I/O completions, polling warps interfere with compute warps, leading to significant stalls and reduced overall GPU efficiency. As shown in Figure 1, we identify three polling-induced stalls.

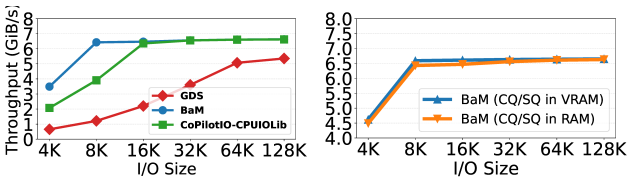
(1) Intra-warp stall: A stall inside a warp. When an application warp polls for data (e.g., waiting for the completion queue), it cannot execute subsequent instructions until that data arrives. Even if later instructions are independent of the polling data, the GPU's in-order warp execution model prevents them from being issued, causing the entire warp to stall.

(2) Inter-warp stall: A stall between warps but within an SM. When an I/O warp aggressively polls the completion queue, the GPU hardware warp scheduler is unaware that this warp makes no forward progress, as it remains marked as "ready". Consequently, it reduces the opportunities for other ready compute warps to execute and wastes valuable SM execution cycles while the requested data has not yet arrived. Since each SM can issue only one warp instruction per cycle, these unproductive polling instructions suppress useful compute work, reducing parallelism and overall SM efficiency.

(3) Inter-SM stall: A stall across SMs. In GPU-centric I/O designs, both application data and the NVMe SQ/CQ structures reside in global GPU memory. Unlike the previous two types of stalls, here the I/O performance itself is directly affected by application memory traffic (Figure 2c). Because application kernels concurrently access global memory, they introduce contention on memory channels and bandwidth, which interferes with BaM's frequent CQ polling. This contention delays CQ detection, slows down I/O completion handling, and ultimately degrades overall I/O performance.

Recent work, AGILE [39], proposes an asynchronous GPU-centric I/O model by dedicating specific SMs to poll the completion queue and overlap I/O with computation. However, this design requires allocating additional SMs exclusively for polling, consuming GPU execution resources that would otherwise be available for computation. For example, to saturate the bandwidth of 4 SSDs (limited by GPU PCIe bandwidth), AGILE must reserve 32 SMs purely for polling on an A100, which has only 108 SMs in total. Furthermore, AGILE continues to suffer from the inter-warp and inter-SM stalls discussed above. The application warp (i.e., the warp that initiates the I/O) must repeatedly poll a software lock flag to detect completion, which directly contributes to inter-warp stalls. In addition, the dedicated SMs used for CQ polling generate substantial memory traffic, further exacerbating inter-SM contention.

Analysis: We conduct a set of experiments to analyze the three types of stalls in detail. For intra-warp stalls, we launch multiple application warps, with each warp running computation alongside I/O operations that the computation does not depend on. We compare BaM against our CoPilotIO I/O engine. As shown in Figure 2a, using BaM increases intra-warp stall time by up to 1.87× due to synchronous polling. For inter-warp stalls, we co-run multiple compute warps with I/O warps. As illustrated in Figure 2b, compared to running the compute warp alone, co-running with BaM's polling warp increases the total execution time by up to 1.71×, showing that a spinning I/O warp competes aggressively with ready compute warps for SM scheduling slots. Finally, for inter-SM memory contention, we evaluate how regular GPU memory



(a) User-space I/O Polling **(b)** SQ/CQ on CPU vs GPU

Figure 3: (a) User-space CPU I/O polling performance comparing GDS and BaM; (b) Impact of placing Completion Queue (CQ) and Submission Queue (SQ) in CPU DRAM versus GPU VRAM.

traffic interferes with GPU-driven I/O. As shown in Figure 2c, increasing the memory bandwidth consumed by the application significantly degrades BaM's I/O bandwidth, demonstrating that GPU-side queue polling contends with application memory accesses across SMs.

Lesson 2: There is a fundamental flaw in current GPU-centric I/O: as long as the GPU is responsible for polling NVMe queues, the architecture inevitably imposes intra-warp, inter-warp, and inter-SM stalls. This motivates the adoption of a *fundamentally new asynchronous I/O engine that removes GPU-side polling and decouples I/O progress from GPU execution, eliminating the root cause of all three stall types.*

CPU can be used as a copilot for GPU I/O: Prior works [7, 18, 27, 28] often assume that CPU-centric I/O (e.g., GDS) suffers prohibitive OS kernel overhead, leading to the conclusion that its performance is substantially slower than GPU-centric designs such as BaM. This assumption motivates a series of GPU filesystems [18, 27] that rely on BaM to fully bypass the CPU. However, such bypassing overlooks CPU-side capabilities and may leave significant performance opportunities unexploited.

First, user-level CPU I/O polling can achieve performance comparable to GPU-centric I/O by removing the kernel software overheads. We implement a user-level SPDK-like system (CoPilot-CPUIOLib) by moving the NVMe queue pair into user space and using the CPU to handle SQ/CQ polling and directly moving data from storage to the GPU. As shown in Figure 3a, CoPilot-CPUIOLib can saturate SSD bandwidth with 16 CPU threads once the I/O size exceeds 16 KB.

However, **naive user-level CPU I/O polling alone cannot meet our goals.** First, it cannot provide fine-grained on-demand I/O initiation from the GPU, as all requests must originate on the CPU side. Second, the limited CPU parallelism is insufficient to sustain the high polling rate required for small I/O sizes (e.g., <16 KB), causing throughput to fall short of device capabilities. Moreover, saturating a GPU PCIe link would require more than 64 CPU cores dedicated solely to I/O polling, which is an unrealistic requirement in real server environments where CPU resources are shared with other applications. Therefore, an efficient adaptive polling design is required between CPU and GPU (Section 4.5).

In addition, **placing the SQ/CQ in CPU memory achieves I/O throughput comparable to GPU-resident queues.** This is because GPU accesses to pinned CPU memory through PCIe provide sufficiently high bandwidth for the small, cacheline-sized SQ/CQ entry performed during I/O. The GPU's polling only reads or writes a few bytes (4B) per command (e.g., command ID, status fields), so the control-path traffic is negligible relative to the large datapath DMA transfers. As a result, the overhead of using the GPU to poll the CQ in CPU memory is minimal and does not limit end-to-end NVMe throughput. As shown in Figure 3b, our evaluation of both configurations, SQ/CQ placed in CPU memory versus GPU memory and both using the GPU for polling, reveals that GPU-polling of CPU-resident queues can sustain throughput close to the optimal GPU-VRAM polling case while offering significantly lower interference with GPU compute workloads.

Properties	CPU Centric	GPU Centric

Saturate GPU PCIe bandwidth	✗	✓	✓	✓
High GPU compute efficiency	✓	✗	✗	✓
Avoid intra-warp stall	✓	✗	✓	✓
Avoid inter-warp stall	✓	✗	✗	✓
Avoid inter-SM stall	✓	✗	✗	✓

Table 1: Capabilities and limitations of state-of-the-art GPU I/O approaches. The last column shows our proposed CoPilotIO.

Lesson 3: *CPU cores and CPU memory are essential co-pilots for GPU I/O.* However, naive user-level CPU polling cannot sustain high throughput under limited CPU parallelism. Meanwhile, GPU polling of SQ/CQ placed in CPU memory still delivers sufficiently high bandwidth. These observations motivate the need for an efficient adaptive polling design that dynamically coordinates between CPU and GPU.

4 CoPilotIO Design

4.1 Design Goals and Principles

Goal 1: Eliminate I/O-induced stalls. CoPilotIO introduces a split SQ/CQ design across CPU-GPU memory and utilizes an asynchronous I/O architecture that leverages CPU cores as I/O co-pilots for CQ polling and uses GPU hardware barriers (*cuda::barrier*) to coordinate cross-device data synchronization. This design avoids GPU-side I/O polling stalls, including intra-warp, inter-warp, and inter-SM stalls.

Goal 2: Support high-performance on-demand I/O access from the GPU side. First, CoPilotIO provides a scalable, lock-free barrier table that allows the GPU to efficiently communicate with the CPU. Second, CoPilotIO implements a user-level SPDK-like design (CoPilot-CPUIOLib) that enables high-performance I/O polling on the CPU side.

Goal 3: Sustain high I/O bandwidth when CPU cores are insufficient under high I/O loads. CoPilotIO introduces the CQ-based adaptive polling. At runtime, CoPilotIO dynamically selects the most suitable polling agent based on I/O load. This adaptive design maintains high I/O bandwidth while simultaneously avoiding GPU I/O polling stalls.

Goal 4: Free more GPU cores for computation rather

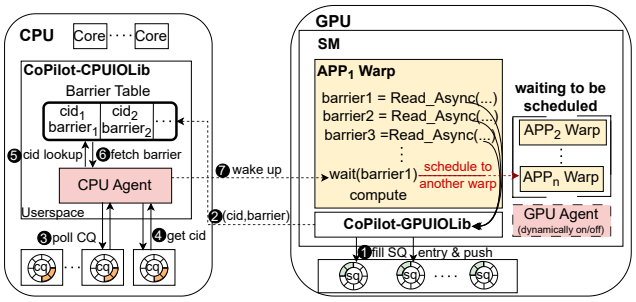

Figure 4: Design Overview of CoPilotIO. Application warps initiate I/O through CoPilot-GPUIOLib, after creating `cuda::barrier` and `cid`, ❶ CoPilot-CPUIOLib submits the I/O requests to SQs and immediately returns control to the application. ❷ CoPilot-GPUIOLib writes the `cid` and the `cuda::barrier` to barrier-table that resides on the CPU memory. ❸ and ❹ CPUAgent polls the CQ until it receives a CQ entry and extracts the `cid`. ❺ and ❻ CoPilot-CPUIOLib looks up the `cuda::barrier` using the `cid`. At the end, CoPilot-CPUIOLib uses ❼ to notify the application warp on the GPU.

than I/O. CoPilotIO enables CPU–GPU co-polling, allowing the system to saturate the full GPU PCIe bandwidth while using significantly fewer GPU cores for I/O.

4.2 CoPilotIO Design Overview

CoPilotIO is a new asynchronous GPU I/O engine that leverages the CPU as a co-pilot to deliver high on-demand I/O throughput while minimizing I/O-induced stalls and maximizing GPU compute efficiency. CoPilotIO consists of two libraries. On the GPU side, CoPilot-GPUIOLib enables GPU applications to initiate I/O requests and handles I/O submission operations. On the CPU side, CoPilot-CPUIOLib provides a high-performance, SPDK-like user-level library responsible for polling I/O completions. Both CPU and GPU have their own polling agents. CPUAgent is enabled by default, as one of the design goals is to free GPU cores for computation. GPUAgent is disabled initially but can be dynamically activated when needed. Its activation is governed by our CQ-based adaptive polling mechanism, which determines when GPU-side polling is necessary to sustain high I/O throughput under increasing load.

4.3 Split SQ/CQ Across CPU–GPU Memory

Traditional GPU-centric I/O designs co-locate both the NVMe submission queue (SQ) and completion queue (CQ) in GPU memory. While this enables GPU-initiated commands, it also introduces I/O polling stalls when co-located with GPU compute applications. To overcome this limitation, CoPilotIO adopts a split-queue architecture that places the SQ in GPU memory and the CQ in CPU memory. This split design preserves the key benefit of GPU-centric I/O that the GPU can directly fill the SQ with low latency, while shifting I/O completion detection (polling) to a CPU memory region that can be efficiently polled by both the CPU and GPU (Figure 3b).

First, placing the CQ in CPU memory naturally eliminates inter-SM polling stalls. In our design, the GPU accesses CPU memory directly over PCIe using zero-copy loads/stores without invoking explicit `cudaMemcpy()`. This approach ensures that I/O polling bypasses GPU memory, preventing interference with other compute kernel memory accesses and preserving SM parallelism.

However, naively splitting the SQ/CQ across CPU and GPU memory is not sufficient. Although this design removes inter-SM stalls and improves I/O performance, it cannot eliminate intra-warp and inter-warp stalls. Regardless of where the SQ resides, a GPU warp must still continuously poll the CQ to determine whether an I/O request has completed. As a result, any independent computation within the same warp is forced to wait for the I/O to finish. Similarly, other ready warps on the same SM cannot make forward progress because the polling warp remains "ready" and repeatedly preempts the scheduler, preventing efficient warp-level parallelism. Fortunately, placing the CQ in CPU memory enables the CPU to take over CQ polling. This observation motivates us to design a novel asynchronous I/O architecture built upon the split SQ/CQ design, which we discuss in the next section.

4.4 CoPilotIO Asynchronous I/O Architecture

At the core of CoPilotIO is a fully asynchronous I/O architecture that spans both the CPU and GPU. The key idea is to offload I/O polling to the CPU while using NVIDIA's hardware barrier to notify the GPU when data becomes ready. By eliminating GPU-side polling entirely, CoPilotIO effectively removes both intra-warp and inter-warp stalls. Next, we first describe the end-to-end asynchronous I/O flow by going through the main components of CoPilotIO.

Issuing I/O from the GPU: As mentioned, CoPilotIO provides a lightweight GPU-side library, *CoPilot-GPUIOLib*, which enables GPU applications to initiate I/O requests on demand. Applications interact with CoPilot-GPUIOLib through familiar POSIX-like interfaces (e.g. `async_read` and `async_write`) as mentioned above. For each I/O request, CoPilotIO creates a corresponding `cuda::barrier` instance, implemented using NVIDIA's hardware barrier support in the CUDA runtime. Once the application receives a `cuda::barrier` handle, it can simply place the barrier before dependent compute operations to ensure data availability. Crucially, unlike conventional polling, a `cuda::barrier` allows the GPU to suspend the waiting warp and let the hardware scheduler issue other ready warps, effectively eliminating inter-warp stalls during I/O wait periods while maintaining correctness. Before returning the `cuda::barrier` to the user, CoPilot-GPUIOLib allocates an NVMe Command ID (`cid`) [37] for the I/O request and saves the `cid` to `cuda::barrier` mapping in a *barrier-table* (described shortly). Each `cid` is uniquely associated with a `cuda::barrier`. After that, CoPilot-GPUIOLib immediately submits the I/O request to the SQ and returns control to the application.

I/O completion detection on the CPU: On the CPU side, *CoPilot-CPUIOLib* is the CPU-side user-level I/O engine of CoPilotIO and plays the role of an I/O "co-pilot" for the GPU. CoPilot-CPUIOLib uses an SPDK-like architecture, which moves NVMe queue management into user space and dedicates CPU cores to handle SQ/CQ submission, completion polling, and DMA coordination without kernel involvement. This design enables CoPilotIO to deliver high I/O throughput while serving as the control plane that drives GPU-initiated I/O. CoPilot-CPUIOLib continuously polls the CQ using dedicated CPU cores. Once the SSD updates a CQ entry to indicate completion, the CPU detects it, looks up the corresponding `cuda::barrier` in the shared barrier-table using the I/O request identifier (`cid`), and signals the GPU by triggering the associated `cuda::barrier`. When the barrier is signaled, the waiting GPU warp wakes up and the dependent computation resumes. On platforms that do not support the hardware barrier, the CPU can alternatively use GDRCopy [10] to write a completion flag directly into GPU memory.

Synchronization between CPU and GPU: To enable efficient CPU–GPU coordination, CoPilot-CPUIOLib preallocates *a lock-free barrier-table* in CPU memory, which is directly accessible by both processors. The table maintains a one-to-one mapping between each NVMe command ID (`cid`) and its corresponding `cuda::barrier`. First, on the GPU side, upon receiving an I/O request, CoPilot-GPUIOLib performs a GPU zero-copy write to insert the (`cid`, `cuda::barrier`) pair into the barrier-table. Each barrier-table is assigned to a private warp instance, eliminating lock contention between warps. During insertion, CoPilot-GPUIOLib uses the `cid` as the index. Since each entry is only 8 bytes, the GPU-to-CPU-memory write latency remains low. On the CPU side, once CoPilot-CPUIOLib observes a completion queue (CQ) entry, it retrieves the associated `cid` and directly indexes into the same barrier-table to fetch the stored `cuda::barrier`. The CPU then signals this `cuda::barrier` to notify the GPU that the requested data has arrived. In this way, the barrier-table provides a lightweight, lock-free communication channel that efficiently connects CQ polling on the CPU with barrier-based synchronization on the GPU.

CID reclamation: When the CPU observes a CQ completion entry, it extracts the `cid`, signals the corresponding `cuda::barrier`, and immediately marks the `cid` as available for reuse. Because each `cid` is uniquely bound to a single in-flight I/O request and the barrier-table is indexed by `cid`, reclamation is a simple index reset with no synchronization required. If an NVMe-level I/O error occurs (indicated by the status field in the CQ entry), the CPU still reclaims the `cid` and signals the `cuda::barrier`, but sets an error flag in the barrier table. Upon waking up, the GPU warp checks this flag and handles the failure (e.g., retries or propagates the error to the application). This design ensures that `cid` resources are never leaked, even under I/O failures.

Memory overhead of barrier-table: In the NVMe protocol, the `cid` is a 16-bit field, allowing up to 65,536 outstanding commands per SQ/CQ pair. Each table entry (`cid` + `cuda::barrier` object) is 8B. To saturate a modern NVMe SSD typically requires 128 SQ/CQ pairs, each configured with a queue depth of 1024. To fully utilize the GPU's PCIe bandwidth, four SSDs are enough to saturate it. Thus, the total memory footprint is 8 B × 1024 × 128 CQs × 4 SSDs = 4 MB. As a result, the barrier-table imposes negligible memory overhead while supporting the full bandwidth required to saturate the GPU PCIe link.

This asynchronous handshake between CPU, GPU, and NVMe SSD eliminates GPU-side I/O stalls and saves more GPU compute for application execution. First, there is no GPU I/O polling, thereby eliminating intra-warp stalls. Once an I/O request is issued, the application kernel can continue executing independent work without waiting for data. Second, even with dependent operations, `cuda::barrier` suspends the waiting warps, allowing the scheduler to issue other ready warps, effectively avoiding inter-warp stalls. In addition, by separating the SQ and CQ across devices, CoPilotIO eliminates contention on GPU memory accesses during I/O polling, thereby further reducing inter-SM stalls.

Challenges: GPU I/O polling can only be fully avoided when the system has sufficient CPU cores to sustain high CQ polling throughput. As shown in Figure 3a, our evaluation uses 16 CPU cores for I/O polling; however, in a real server environment where other applications compete for CPU resources, fewer cores may be available, making it difficult for CPU-side polling to saturate the full GPU PCIe bandwidth (25 GB/s). Moreover, for small I/O sizes, even 16 polling cores are insufficient: small requests require high I/O depth and many active SQ/CQ pairs to reach the device's peak bandwidth, but limited CPU parallelism cannot provide enough polling throughput. In contrast, the GPU offers thousands of hardware threads capable of providing ample parallelism to saturate storage bandwidth. Yet shifting polling back to the GPU would reintroduce the very GPU-side stalls we aim to eliminate. Thus, **the central challenge is achieving high I/O bandwidth when CPU cores are insufficient, while simultaneously avoiding GPU I/O polling stalls.** Therefore, we propose CQ-based adaptive CPU-GPU co-polling.

4.5 CQ-based Adaptive CPU-GPU Co-Polling

We propose CQ-based Adaptive CPU-GPU Co-Polling, which addresses two questions: (1) When should GPUAgent be turned on or off? (2) How to minimize I/O stalls when I/O polling is on the GPU?

As shown in Figure 5, GPUAgent is disabled by default. Initially, only CPUAgent is responsible for polling. We decide when to turn on the GPUAgent based on the number of pending entries in the CQ. The number of outstanding CQ entries reflects the CPU's ability to keep up with I/O processing: if many entries remain unconsumed, it indicates that the CPU

Algorithm 1: CQ-based adaptive polling algorithm

Input: For each queue CQ_i: current number of pending entries p_i;
Upper migration threshold T_i^{high} and lower migration threshold T_i^{low} ($T_i^{\text{low}} < T_i^{\text{high}}$);
Decision batch size R_i (trigger a migration decision every R_i I/O requests);
Current polling mode $mode_i \in \{\text{CPU}, \text{GPU}\}$;
Current I/O submission binding $bind_i \in \{\text{CPU_CQ}, \text{GPU_CQ}\}$
State: For each CQ_i, a request counter req_i since the last decision, initialized to 0
Output: For each CQ_i, an adaptive choice of polling location and I/O binding

```
1  Function OnIORequest(CQ_i)
2      req_i ← req_i + 1;
3      if req_i ≥ R_i then
4          req_i ← 0;
5          DecideMigration(CQ_i);
6      end
7  end
8  Function DecideMigration(CQ_i)
9      p_i ← ReadPendingCount(CQ_i);
10     if mode_i = CPU and p_i > T_i^high then
11         mode_i ← GPU;
12         WakePollingWarpOnSameSM(CQ_i);
13         bind_i ← GPU_CQ;
14         UpdateQueueBindingToGPU(CQ_i);
15     else if mode_i = GPU and p_i < T_i^low then
16         mode_i ← CPU;
17         bind_i ← CPU_CQ;
18         UpdateQueueBindingToCPU(CQ_i);
19         OptionallySleepPollingWarp(CQ_i);
20     end
21     else
22         Keep current mode unchanged; return;
23     end
24 end
```

does not have enough cores to poll and process CQ entries in time.

In our design, each CQ is associated with a threshold. As Algorithm 1 shows, when CoPilot-CPUIOLib observes that the number of pending CQ entries exceeds this threshold, CoPilotIO stops inserting new CQ entries into the CPU-polled queue and immediately activates the GPUAgent. Newly generated CQ entries are then redirected to the queue polled by the GPU. Conversely, when the pending count falls below the threshold, CoPilotIO stops inserting new CQ entries into the GPU-polled queue, and the GPUAgent is disabled after draining all remaining pending CQ entries. At that point, polling

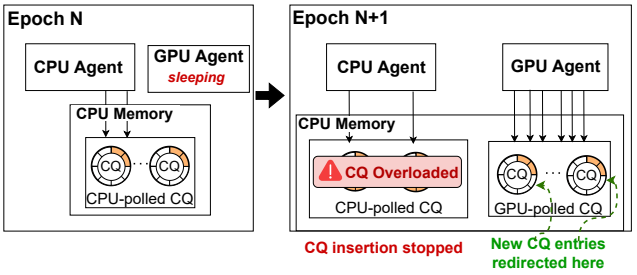

Figure 5: CQ-based Adaptive Polling. At epoch N, CPUAgent is enabled by default to poll the CQ, while GPUAgent remains disabled. At epoch N + 1, CoPilotIO detects that the CQ is becoming overloaded and the CPU can no longer sustain high throughput, GPUAgent is activated to assist with polling.

responsibility shifts back to the CPU as new CQ entries are inserted into the CPU-polled queue.

Importantly, first, the CQ itself always resides in CPU memory to avoid inter-SM stalls. When the GPUAgent is active, the GPU directly polls the CPU-resident CQ using zero-copy reads. As shown in Figure 3b, GPU polling achieves similar throughput regardless of where the CQ is placed, making CPU-resident CQs preferable for reducing GPU-side contention. Second, CoPilotIO does not migrate polling threads between CPU and GPU; instead, it simply controls which CQ receives newly inserted entries, thereby steering the polling load to the appropriate device. This design avoids costly thread migration or context switching while enabling fast, lightweight transitions between CPU-side and GPU-side polling. Third, the CPUAgent is not disabled when the GPUAgent is enabled. Instead, CoPilotIO allows true CPU–GPU co-polling, where each agent polls its own dedicated CQ without interfering with the other. Because the CPU and GPU poll separate queues, there is no contention or shared-state synchronization overhead between them, enabling smooth load balancing and higher sustained I/O throughput under bursty or high-concurrency workloads.

Moreover, when I/O polling is moved back to the GPU, we need to minimize the I/O stalls reintroduced by GPU-side polling. BaM requires each warp that issues I/O to poll for completion itself, leading to severe inter-warp stalls as multiple polling warps contend for the warp scheduler. AGILE improves upon this by assigning one agent warp to each NVMe queue and consolidating all agent warps onto a few dedicated SMs that do not run any application computation. However, this design has two drawbacks: first, it wastes GPU compute resources since those dedicated SMs cannot be used for application workloads; second, because multiple polling warps are consolidated onto the same SM, inter-warp interference among them still exists. Furthermore, AGILE's polling warps cannot be disabled once launched and continue to occupy GPU resources even when the I/O load is low.

In contrast, GPUAgent takes a different approach. For each SM, GPUAgent is initialized at kernel launch time and activates a single dedicated warp to perform I/O polling only

when polling responsibility is transferred from the CPU to the GPU. Unlike BaM, GPUAgent uses only one warp per SM for polling rather than having each I/O warp poll individually, thereby significantly reducing inter-warp stalls. Unlike AGILE, GPUAgent runs alongside the application kernel on the same SM rather than consolidating polling warps onto dedicated SMs, thus avoiding inter-warp interference among multiple polling warps. Since only a single warp serves as the GPUAgent per SM, the impact on application performance is minimal. Moreover, GPU application kernels can seamlessly switch to having GPUAgent handle polling without any code changes. Furthermore, the polling warp of GPUAgent can enter a sleep state when not polling and be woken up on demand, and can be completely disabled when all I/O polling is moved back to the CPU, allowing all warps on each SM to be fully available for computation.

GPUAgent operates similarly to CoPilot-CPUIOLib: it shares the barrier-table located in shared memory with the application kernel, polls the CPU-resident CQ via zero-copy reads, and upon detecting a completed CQ entry, uses the corresponding `cid` to locate the associated `cuda::barrier` in the table and signals it to wake up the waiting application warp.

5 Evaluation

We evaluate CoPilotIO to answer the following questions:

- How effective is the asynchronous I/O of CoPilotIO in avoiding I/O-induced stalls when I/O and compute tasks are co-located on the GPU?
- What I/O throughput and latency does CoPilotIO achieve when running I/O tasks alone?
- How effective is the CQ-based adaptive CPU-GPU co-polling mechanism?
- Can CoPilotIO saturate the GPU's PCIe bandwidth?
- What is the overall impact of CoPilotIO on real-world applications?

5.1 Experimental Setup and Methodology

Testbed: Our testbed consists of a dual-socket Intel Xeon Gold 6530 system, with 32 cores per socket, 256 GB of DDR5 DRAM (4 × 64 GB), and we evaluate on both an NVIDIA A100 GPU with 40 GB of memory and an NVIDIA H800 GPU with 80 GB of memory. The system runs Ubuntu 22.04.4 with Linux kernel 5.15.0, CUDA 12.4, and NVIDIA driver version 550.54.14. We use four 1 TB Samsung 990 Pro NVMe SSDs (PCIe 4.0 x4) for storage.

Methodology: We compare CoPilotIO against state-of-the-art GPU-centric I/O systems, including BaM (synchronous I/O) and AGILE (asynchronous I/O). We evaluate GDS in Figure 8, but exclude it from the other experiments as it does not support on-demand GPU-initiated I/O, and prior work has already demonstrated its limited I/O performance (Section 3).

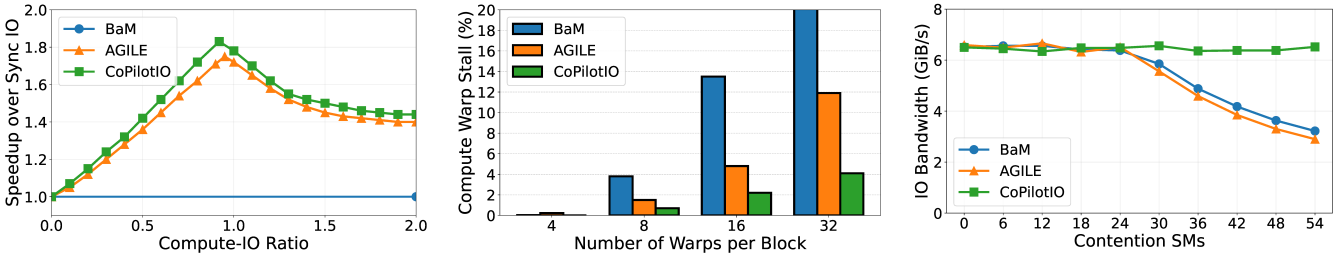
5.2 Microbenchmarks

5.2.1 Reduction of I/O Stalls

First, in Figure 6, we design three microbenchmarks by co-locating I/O and compute tasks on the GPU to evaluate the effectiveness of CoPilotIO in reducing I/O-induced stalls.

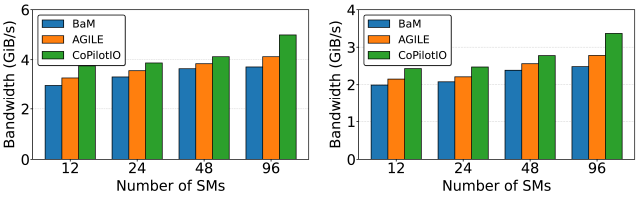
Intra-warp stalls: We launch 32 warps, where each warp performs computation (Fused Multiply-Add) interleaved with random read operations. The computation is independent of the data returned by the reads. For the x-axis, we vary the compute-to-I/O ratio by fixing the number of I/O operations while progressively increasing the amount of computation. For the y-axis, we report the speedup relative to synchronous I/O (BaM), which cannot overlap I/O with computation. As shown in Figure 6a, before the compute-to-I/O ratio reaches 1.0, both AGILE and CoPilotIO continue to improve performance. In this region, the workload is I/O-dominated, so avoiding intra-warp stalls directly increases throughput. Once the ratio exceeds 1.0, the amount of computation becomes larger than the amount of I/O, causing the workload to become compute-dominated, and the relative speedup naturally decreases. Overall, both AGILE and CoPilotIO effectively reduce intra-warp stalls, but CoPilotIO achieves better performance. The key reason is that AGILE dedicates an entire SM to I/O polling, yet the application's I/O warp must still repeatedly poll a software lock flag to detect I/O completion, leaving residual intra-warp stall overhead. In contrast, CoPilotIO completely eliminates intra-warp stalls by offloading all I/O polling to the CPU and leveraging a hardware barrier to provide fully asynchronous I/O–compute overlap.

Inter-warp stalls: We co-run I/O warps that issue purely random reads alongside compute warps that perform pure computation (Fused Multiply-Add). We fix four compute warps and progressively increase the number of I/O warps. The x-axis represents the total number of active warps. The y-axis reports the compute warp's stall ratio. As shown in Figure 6b, as the number of I/O warps increases, the compute warp under using BaM experiences stall rates of up to 20%. This is because BaM performs I/O polling on the GPU, causing I/O warps to repeatedly occupy GPU execution resources and delay compute warps. As mentioned, AGILE still relies on polling a software lock flag to detect I/O completion, which introduces substantial overhead. This overhead is particularly severe for inter-warp stalls because the application's I/O warp cannot sleep and therefore continues occupying the GPU cores, preventing compute warps from being scheduled to run. Moreover, the dedicated SM wastes GPU compute capacity. In contrast, CoPilotIO offloads I/O polling entirely to the CPU and relies on hardware barriers to notify the GPU. This allows I/O warps to sleep and enables the hardware GPU scheduler to issue ready compute warps without interference. Consequently, compared with BaM, CoPilotIO reduces inter-warp stalls by up to 18.6%.



(a) Intra-warp stalls **(b)** Inter-warp stalls **(c)** Inter-SM contention

Figure 6: Stall-elimination microbenchmarks across three dimensions.



(a) Random read **(b)** Random write

Figure 7: Pure-I/O performance.

Inter-SM stalls: We co-run I/O warps with compute warps, where the compute warps frequently access global GPU memory, generating substantial memory traffic. For the x-axis, we vary the number of contending SMs (i.e., SMs running compute warps), and for the y-axis, we report the achieved I/O bandwidth. As shown in Figure 6c, for both BaM and AGILE, I/O bandwidth begins to drop once memory contention exceeds 24 SMs and continues to decline as additional SMs generate memory traffic. Under heavy contention, the I/O bandwidth can drop by up to 50.6%. This degradation occurs because both designs use the GPU to poll the CQ located in GPU memory, which exacerbates on-chip memory contention. For AGILE, the need to poll additional software lock flags further increases memory contention, resulting in even worse performance than BaM. In contrast, CoPilotIO maintains high I/O bandwidth regardless of the number of contending SMs. This is due to its split SQ/CQ design, which places the CQ in CPU memory and therefore naturally avoids inter-SM stalls caused by GPU global-memory contention.

System	Read Latency (us)	Write Latency (us)
BaM	47.72	43.11
AGILE	38.77	34.28
CoPilotIO	37.75	33.14

Table 2: Average latency comparison with 96 SMs, each utilizing 32 warps for 4 KB I/O operations.

5.2.2 Pure-I/O Performance

Next, we evaluate CoPilotIO with pure-I/O workloads. We run random reads and random writes with a 4 KB I/O size and vary the number of SMs. Figure 7 reports the I/O throughput, and Table 2 shows the corresponding latency. CoPilotIO outperforms both BaM and AGILE across workloads in terms of both throughput and latency. First, these results demonstrate that the split SQ/CQ design does not compromise I/O performance: GPU-resident SQs enable fast submission, while CPU-resident CQs maintain high throughput through efficient user-level CPU polling. Second, compared to BaM and AGILE, the performance gains of CoPilotIO arise because inter-warp stalls and inter-SM stalls also occur even in pure-I/O workloads. For instance, under inter-warp interference, a pending I/O warp cannot be scheduled if a previously issued I/O warp continues polling, leading to reduced parallelism.

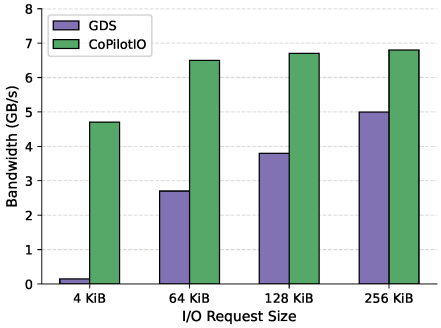


Figure 8: Random read bandwidth: GDS vs. CoPilotIO.

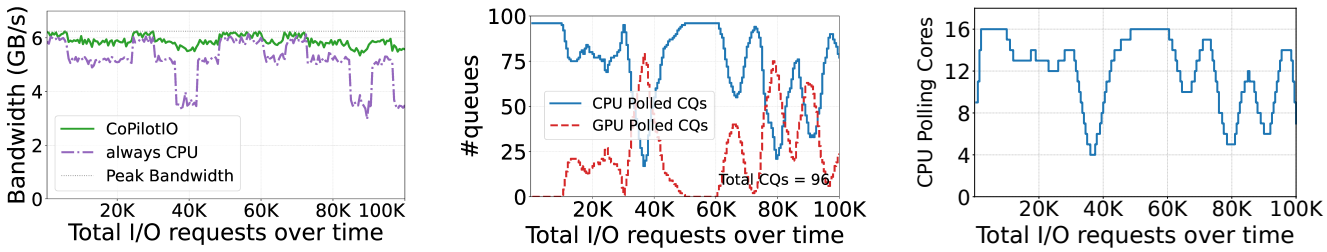
5.2.3 Comparison with GDS

We compare CoPilotIO against NVIDIA GDS with 16 CPU threads, performing random reads on an SSD. Figure 8 shows the achieved bandwidth across different I/O request sizes.

CoPilotIO consistently outperforms GDS across all I/O sizes. The performance advantage comes from avoiding the high kernel software overheads in GDS, including system calls, buffer registration, and DMA address mapping in the kernel I/O path. As the I/O size increases, these overheads become less dominant because the data transfer time increasingly amortizes the per-request kernel software cost. In contrast, with the benefit of CoPilot-CPUIOLib, CoPilotIO bypasses the kernel entirely: the GPU submits NVMe commands directly through user-space queues, while the CPU performs only lightweight CQ polling without kernel involvement. This design enables CoPilotIO to sustain near-peak I/O bandwidth even for small 4 KB I/O requests.

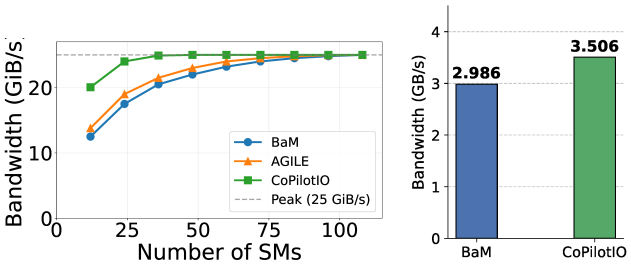
5.3 Effectiveness of Adaptive Polling

Next, we validate the effectiveness of GPUAgent-based adaptive CPU-GPU co-polling. We design a microbenchmark that emulates an AI application whose IOPS fluctuate over time.



(a) Bandwidth **(b)** CQ Distribution **(c)** CPU Resource Analysis

Figure 9: Analysis of CPU and GPU polling: (a) Bandwidth curves, (b) CQ polling distribution, and (c) CPU resource analysis.



(a) **(b)**

Figure 10: (a) The scalability of CoPilotIO; (b) GoFS random read performance over different I/O engines: BaM vs. CoPilotIO.

We use CoPilotIO-cpu-only to denote a configuration where CoPilotIO always uses the CPU for polling, and CoPilotIO-adaptive-polling to denote CoPilotIO with our CQ-driven adaptive polling mechanism enabled.

Figure 9a shows how I/O throughput evolves over time. CoPilotIO-adaptive-polling consistently sustains high throughput, while CoPilotIO-cpu-only exhibits significant variation as the IOPS load changes. This occurs because, under very high IOPS, CPU-only polling cannot keep up due to limited CPU-side parallelism, causing delays in processing CQ entries. In contrast, with adaptive polling, CoPilotIO detects CQ overload and gradually activates GPUAgent to offload polling to the GPU, allowing the system to maintain stable high throughput. Figure 9b shows the corresponding breakdown of CQ entries processed by the CPU and GPU over time. Initially, most CQs are handled by the CPU, but as the IOPS increase, the number of CQs processed by the CPU gradually decreases while the number handled by the GPU increases. This trend directly validates the behavior of our adaptive polling algorithm, demonstrating that CoPilotIO automatically shifts polling responsibility to the GPU when CPU-side polling becomes a bottleneck.

CPU Resource Analysis: Figure 9c shows the number of active CPU polling cores over time under adaptive polling. When I/O load is low and the GPU is not polling, CoPilotIO uses up to 16 CPU cores for CQ processing. As I/O pressure increases and the adaptive mechanism activates GPU co-polling, the CPU polling load decreases, and the number of active CPU cores drops to as few as 3 or 4 cores. This demonstrates that the adaptive mechanism dynamically reduces CPU core usage when GPU co-polling is engaged, freeing CPU resources for other system tasks. In steady state with moderate I/O load, CoPilotIO typically requires only 4 to 8 dedicated CPU cores.

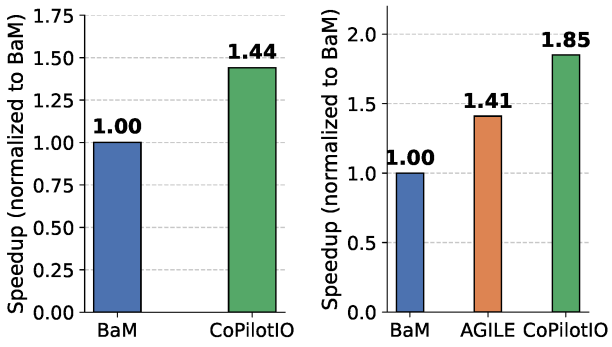
5.4 The Scalability of CoPilotIO

Next, we evaluate the scalability of CoPilotIO with multiple SSDs. Figure 10a shows the aggregate bandwidth achieved by BaM, AGILE, and CoPilotIO when performing 8 KB random reads across four SSDs. Each SM runs 16 warps, and we configure 108 NVMe queue pairs with a queue depth of 1024.

The results demonstrate two key advantages of CoPilotIO. First, CoPilotIO exhibits excellent scalability as the number of SMs increases, with bandwidth growing smoothly until saturating the PCIe 4.0 x16 limit of 25 GB/s. Second, and more importantly, CoPilotIO saturates the PCIe bandwidth with only 24 SMs, whereas BaM and AGILE require more than 72 SMs to achieve the same throughput. This 3× reduction in SM usage stems from CoPilotIO CPU-GPU co-polling design: by offloading CQ polling to the CPU, CoPilotIO eliminates GPU-side polling overhead and allows each SM to sustain higher effective I/O throughput. Furthermore, when the I/O load is high, the CPU and GPU can poll CQs simultaneously, further improving completion queue processing capacity. In contrast, BaM and AGILE rely solely on the GPU for polling and must dedicate significant GPU resources to this task, requiring substantially more SMs to reach peak bandwidth. This efficiency gain is particularly valuable for mixed compute–I/O workloads, where the saved SMs can be allocated to application computation rather than I/O management.

5.5 Performance with GPU Filesystem

We further evaluate CoPilotIO using the state-of-the-art GPU filesystem GoFS [18], which is built on the BaM GPU-centric I/O engine and fully offloads filesystem management to the GPU, bypassing the CPU entirely. GoFS is a mixed compute–I/O workload: its filesystem operations involve multiple compute tasks such as data indexing, block management, and metadata manipulation. We integrated CoPilotIO into GoFS with fewer than 20 lines of code changes. Although AGILE does not natively support GoFS, we attempted to extend AGILE for this experiment, but it encountered unknown runtime errors; therefore, AGILE is excluded from this evaluation. Figure 10b presents the random-read (4 KB I/O size)



(a) MoE SSD offloading. **(b)** DLRM inference.

Figure 11: Real-world application performance.

performance of GoFS when using BaM versus CoPilotIO. CoPilotIO achieves up to 17.4% performance improvement over BaM due to our efficient asynchronous I/O architecture, which removes all I/O stalls.

5.6 Performance on Real-world Applications

LLM Mixture-of-Experts (MoE) inference: We retrofitted the FlashMoE [3] megakernel MoE operator to support SSD offloading of expert weights, enabling an evaluation of CoPilotIO in MoE inference scenarios. FlashMoE was originally a fully GPU-resident distributed MoE operator that fuses gate computation, expert FFNs, and token dispatch/combine communication into a single persistent GPU kernel. It uses an actor model (Processor, Scheduler, Subscriber) to implement tile-level pipelined scheduling, eliminating multi-kernel launch overhead and hiding communication latency. We preserved this in-kernel scheduling framework while moving expert-weight storage from GPU memory to NVMe SSDs: when a Processor needs to execute a given expert's GEMM, it first issues an NVMe read request directly from the GPU to load the corresponding up-projection and down-projection weight matrices from the SSD into the GPU page cache, then executes the fused GEMM-activation-GEMM computation.

Experiments use a synthetic workload with 2,048 experts, hidden and intermediate dimensions of 2,048, Top-2 routing, sequence length 8,192, and capacity factor 1.0. Each expert's weights occupy 32 MB (16 MB each for up- and down-projections, TFloat32 format), totaling 64 GB for all experts. All experts are stored contiguously on the SSD. At the I/O layer, we configure 108 NVMe queue pairs, queue depth 128, and a 64 KB page size. Every expert corresponds to 512 pages, which are read cooperatively by 32 threads within a warp. After 32 warm-up iterations, we measure the average latency of 32 forward passes, comparing end-to-end inference performance between CoPilotIO and BaM. Similar to the GoFS case, AGILE does not natively support MoE workloads with unknown runtime access patterns.

Figure 11a shows the performance speedup of CoPilotIO over BaM. CoPilotIO achieves up to a 1.44× speedup. The improvement arises because MoE inference is a mixed compute–I/O workload: while some warps execute expert GEMMs, others must fetch the next expert's weights from the SSD. Under BaM's synchronous model, I/O warps stall and occupy GPU resources during NVMe polling, delaying compute warps and reducing overall SM utilization. CoPilotIO eliminates these stalls by offloading CQ polling to the CPU, enabling I/O warps to yield immediately after issuing requests. This allows the GPU scheduler to overlap expert computation with weight prefetching, thereby reducing end-to-end latency.

DLRM: We evaluate CoPilotIO on DLRM inference using the Criteo 1TB Click Logs dataset [11], following the experimental setup used in AGILE [39]. We construct the categorical feature vocabulary from the first three days of data and use cuBLAS for all dense matrix multiplications. Embedding vectors are fetched from the SSD through CoPilotIO, BaM, or AGILE, and integrated into the same CUDA stream pipeline as in AGILE for fair comparison. We adopt the standard DLRM architecture from [21], where the bottom MLP consists of three fully connected layers of size 512, while the top MLP consists of three fully connected layers of size 1,024 (referred to as Config-1 in AGILE). We use a batch size of 2,048 and measure the end-to-end inference time over 10,000 iterations. Unless otherwise specified, we use a 2 GB software cache with the clock replacement policy, 128 NVMe queue pairs, and a queue depth of 256 per queue, consistent with AGILE's configuration.

Figure 11b reports the end-to-end inference speedup normalized to BaM. CoPilotIO achieves a 1.85× speedup over BaM, outperforming AGILE's 1.41× speedup. The performance gain of CoPilotIO over AGILE stems from two factors. First, AGILE dedicates 4 SMs exclusively to I/O polling, which wastes GPU compute resources that could otherwise be used for MLP computation. Second, AGILE's I/O warps must still poll software lock flags to detect completion, introducing residual intra-warp stalls during embedding lookups. In contrast, CoPilotIO offloads all polling to the CPU and uses hardware barriers for completion notification, allowing I/O warps to fully overlap with cuBLAS kernels without occupying GPU execution resources.

6 Discussion

This section discusses the workload regimes where CoPilotIO provides the greatest benefit, as well as scenarios where its advantages are limited.

6.1 Beneficial Regimes

Compute-to-I/O ratio: The speedup from CoPilotIO scales with the fraction of execution time spent on GPU-side polling. In MoE, GEMM computation and GPU polling overhead account for approximately 32% of the total execution time. The remaining time is spent on storage I/O. CoPilotIO achieves a 1.44× speedup by eliminating the polling overhead. In contrast, DLRM exhibits a more balanced compute-to-I/O ratio:

embedding lookups are interleaved with MLP computation of comparable duration, allowing CoPilotIO to pipeline I/O with useful GPU computation. The freed GPU cycles are immediately consumed by MLP layers that would otherwise wait behind polling warps, yielding a higher 1.85× speedup.

GPU Resource Contention: GPU applications operate under high SM occupancy and massive warp concurrency, leading to intense contention for shared GPU resources, including warp slots, registers, shared memory, and memory bandwidth. In BaM, polling warps remain active on the SM while waiting for I/O completions, continuously occupying these shared resources and reducing the resources available for application kernels. For example, the additional GPU memory traffic generated by polling further contends with application memory accesses. In contrast, CoPilotIO significantly reduces GPU-side polling overhead due to our async I/O and split SQ/CQ design, leaving more SM resources and memory bandwidth available for concurrent application computation.

I/O concurrency and SSD utilization: CoPilotIO asynchronous completion model allows GPU warps to have multiple I/O requests in flight simultaneously, since warps do not block on CQ polling between submissions. This increases the effective NVMe queue depth seen by the SSD, enabling its internal NAND dies to operate in parallel. The benefit is most pronounced for workloads issuing many fine-grained requests (4 to 64 KB): in our microbenchmarks (Figure 7a), CoPilotIO sustains higher IOPS than BaM precisely because it maintains deeper queues without dedicating GPU threads to polling.

Application Domains: Beyond the applications evaluated in this paper, the architecture of CoPilotIO benefits a range of emerging GPU applications that combine I/O with computation. GPU-accelerated database engines (e.g., HeavyDB [14] and BlazingSQL [5]) perform table scans from SSD while executing filter, join, and aggregation operators on the GPU, a pattern where I/O and compute naturally overlap. Graph analytics frameworks (e.g., Emogi [20] and GIDS [26]) traverse out-of-core graphs by fetching neighbor lists from storage while processing vertices on the GPU. Retrieval-augmented generation (RAG) [17] systems fetch embedding vectors from SSD-resident indices during LLM inference, interleaving I/O with attention computation. KV cache offloading frameworks (e.g., FlexGen [31]) swap KV cache tensors between GPU memory and SSDs to serve long-context or large-batch LLM inference under limited GPU memory, generating bursty fine-grained I/O that competes with ongoing attention computation on the GPU. In each case, the application workload exhibits the characteristics identified above: mixed I/O and compute, high SM pressure from I/O management, and fine-grained access patterns requiring high queue depth.

6.2 Limited-Benefit Regimes

In contrast, CoPilotIO provides limited benefit in the following scenarios. First, purely compute-bound workloads spend little time waiting for storage operations. Since GPU resources are already dominated by application kernels rather than polling threads, removing polling contributes little to end-to-end performance. Second, workloads dominated by large sequential transfers typically require only modest queue depths to saturate SSD bandwidth. In these cases, storage efficiency is already high, and GPU polling overhead constitutes only a small fraction of execution time. As a result, the advantages of CoPilotIO asynchronous completion model and split SQ/CQ design are less pronounced. Finally, CoPilotIO relies on CPU threads for completion polling. When CPU resources are scarce or heavily utilized by other applications, CPU-side polling may become a bottleneck under high IOPS workloads. While adaptive co-polling can partially mitigate this issue by shifting polling work to the GPU, the resulting behavior increasingly resembles GPU-centric polling, thereby reducing the relative advantage of CoPilotIO.

7 Conclusion

In conclusion, CoPilotIO demonstrates that high-performance, on-demand GPU I/O does not require sacrificing GPU compute resources. By treating the CPU as an I/O co-pilot and introducing a fully asynchronous cross-device architecture, CoPilotIO eliminates GPU-side polling stalls while sustaining high throughput. Our evaluation shows that CoPilotIO significantly improves GPU compute efficiency, storage utilization, and end-to-end application performance.

Acknowledgments

We thank the OSDI '26 shepherd and reviewers for their insightful feedback, which helped improve the quality of this paper. We also thank the members of the HKUST(GZ) Systems Lab for their valuable comments and discussions. This research was supported by HKUST(GZ) startup funding. Jian Zhang is the corresponding author.

Abstract

Remote Direct Memory Access (RDMA) has become the de facto standard for high-performance data center networking. However, current deployments rely heavily on fixed-function, commercial NICs. These "black box" commercial hardware implementations prevent researchers and system architects from modifying the transport layer for specialized tasks. In parallel, research on NICs often lacks offloaded networking stacks or uses simplified protocol implementations, limiting insight into novel networking solutions in realistic settings. In this paper, we bridge this gap by introducing BALBOA, an open-source, 100 Gbps RDMA offload engine designed for research on networking and fully compatible with commercial RNICs. Unlike prior stack implementations which lack scalability and bandwidth, or struggle with data center interoperability and miss strict protocol compliance, BALBOA supports hundreds of Queue Pairs in switched network environments and allows for line-rate offloads, making it a viable platform for realistic data center research. We describe the system architecture, detailing how BALBOA overcomes FPGA memory and timing bottlenecks through a decoupled state architecture and streaming control-data separation. We evaluate BALBOA on a hardware cluster with FPGAs, RNICs, and switches, showing that it matches the performance of commercial ASICs while offering full customization. Finally, we showcase BALBOA's potential through novel case studies: protocol enhancements for infrastructure purposes (encryption, deep packet inspection) and an offloaded preprocessing pipeline for deep learning recommender systems, which applies streaming transformations to the incoming data before feeding it directly to a GPU for model serving.

1 Introduction

With the ever-increasing scale of modern applications, such as large language models (LLMs) and big data analytics, computer systems have become increasingly constrained by network performance. This network bottleneck [101] has driven the widespread adoption of Remote Direct Memory Access (RDMA), which accounts for up to 70% of cloud network traffic [17]. By offloading the network stack to the NIC and bypassing the host operating system (OS), RDMA achieves low latency, high throughput, and reduced CPU utilization. These properties facilitate the implementation of novel platforms for memory disaggregation [5–7], distributed key-value stores [52], and data analysis [47]. However, such deployments often rely on commercial, fixed-function NICs, limiting customization for researchers. For example, having been adopted from trusted HPC domains, RDMA lacks access control and cryptographic policies [78, 85]. Furthermore, research has proposed a wide range of customized congestion control schemes for RDMA [19, 57, 71, 108], but commercial NICs typically only include one or two standard solutions. More generally, modifying the transport protocol or the packet-processing pipeline to address these security and architectural limitations or adapt it to a given application is nearly impossible on commercial NICs, limiting the options for experimental evaluation and prototyping.

To further address the network bottleneck and improve NIC programmability, recent work has shifted focus to SmartNICs and data processing units (DPUs), moving computation closer to the network. Commercial platforms such as AWS Nitro [82], NVIDIA BlueField [22], and Meta FBNIC [16] achieve high performance and improve programmability by enabling application offloads using NIC-hosted CPUs and on-datapath accelerators. However, such offloads often fall short of peak performance and require careful tuning [24]. Additionally, like traditional NICs, SmartNICs and DPUs implement the packet processing pipeline in hardware, remaining "black boxes" at the transport layer, thus limiting possibilities for customization.

FPGA-based platforms, both academic [33, 37, 62, 63, 65] and commercial [23, 32, 70], improve programmability and customizability. However, they suffer from low performance, limited scalability, and a lack of data center interoperability. For example, FPGA-based SmartNICs often lack an offloaded network stack [33, 98], relying on the host OS for the

packet processing pipeline, leading to increased latency and CPU utilization. Similarly, they also often fail to achieve high throughput (less than 100G) [68, 99] and compatibility with the specification [67, 84, 99], due to missing components that are complex to implement and affect performance such as the cyclic redundancy check (CRC) or retransmission logic.

In this paper, we bridge this gap with BALBOA, an open-source[1], 100G, RoCEv2-compatible RDMA stack designed for research flexibility without compromising performance or interoperability. As such, BALBOA enables the exploration of novel RDMA extensions and in-network computation, while additionally being usable as a plug-and-play component for SmartNICs. The paper makes the following contributions:

1. **High-performance architecture:** We propose RoCE BALBOA, an open-source, 100G, switched network-tested, and RoCE-v2 compatible RDMA stack for FPGAs that offers direct memory access to server-grade CPUs and GPUs [92]. It matches commercial NICs in both throughput and latency while offering flexibility for extensions and modifications on the hardware level. This demonstrates that the properties prior work treats as fundamentally in tension — 100G line rate, strict protocol compliance, and datapath extensibility — can be reconciled at the architecture level through decoupled state management and deep pipelining.
2. **Protocol evolution:** We demonstrate BALBOA's extensibility by implementing two line-rate protocol enhancements impossible on fixed-function NICs: inline Advanced Encryption Standard (AES) Counter Mode (CTR) encryption and ML-based deep packet inspection (DPI) for NIC-level access control. BALBOA thus enables the implementation of RDMA protocol modifications at line-rate, on a switch-compatible platform.
3. **Application acceleration:** We illustrate the performance benefits of on-datapath acceleration by deploying a commercial ML preprocessing pipeline for recommender models [109]. By utilizing BALBOA to preprocess and stream model data directly to the GPU, bypassing the host CPU, we achieve significant latency reductions and throughput improvements compared to the baseline.

2 Background and Motivation

This section reviews the RDMA protocol and motivates the need for an extensible stack with support for protocol enhancements and application acceleration at line rate.

2.1 The Rigidity of Commercial RDMA

RDMA achieves high throughput and low latency by offloading the transport layer to the NIC and utilizing OS-bypassing DMA [53]. Flows between remote nodes are managed via Queue Pairs (QP) as a connection abstraction and used for remote read and write accesses through either one- (`RDMA WRITE` and `RDMA READ`) or two-sided (`RDMA SEND` and `RDMA RECEIVE`) transactions [15, 66]. The central problem of commercial RDMA NICs (RNICs) is that the key logic is hardwired. Modifying the protocol pipeline to, for example, add a flow-tracking state machine, collect telemetry, or encrypt data to address some of the well-known security flaws of RDMA [78, 85, 89], requires modifying the transport logic. Because commercial silicon cannot be modified, these modifications have to be implemented either in software, thus reducing the performance benefits of RDMA and increasing CPU utilization, or on slow, off-datapath coprocessors [24] that add considerable latency.

2.2 The Case for Application Logic Offload

With ever-increasing amounts of data and improved accelerator performance, the gap between compute performance and network bandwidth is becoming more acute. At the same time, network virtualization is becoming increasingly expensive, consuming significant CPU cycles [32]. These shifts have motivated the offload of both network functions and application-specific logic [80] onto specialized accelerators. Recent examples range from data analytics [73] to ML preprocessing tasks [55], which can be implemented on both FPGA-based platforms [50, 63] as well as commodity SmartNICs and DPUs. The combination of SmartNICs and GPUs for ML-related use cases, such as offloaded object storage clients [51] or shared memory implementations [39], is currently of particular interest. However, as explained in Section 3, most of these examples suffer from critical shortcomings:

- SoC-based SmartNICs rely on embedded ARM cores for programmability in the off-datapath compute model. While flexible, they suffer from the "look-aside" bottleneck: processing a packet requires moving it to the core's memory hierarchy, incurring significant latency penalties, making line-rate processing at 100Gbps infeasible for complex applications [24].

- Existing FPGA prototypes for stream-oriented in-network compute either lack an offloaded network stack and rely on the host CPU, sacrificing performance and CPU utilization, or build on simplified network stacks that are not compatible with common data center NICs and accelerators.

In this paper, we demonstrate how BALBOA bridges this gap through an open and extensible architecture, allowing it to serve as a critical piece of research infrastructure and a building block for future SmartNICs and DPUs.

3 Related Work

RDMA is extensively used in HPC and data centers to implement systems such as distributed key-value stores [52], disaggregated memory [110], data analytics platforms [47], among others. These platforms are orthogonal to our efforts and can benefit from the stack offloading we propose. The same is true for FPGA-based SmartNICs [61, 62] which focus on offload management rather than the stack itself. We thus focus only on RDMA implementations and efforts that overlap with the use cases we explore in the paper.

On the commercial side, several products support RDMA. The Mellanox ConnectX-5 [91] is a standard 100G-capable RDMA NIC. A SmartNIC version of the system is NVIDIA's BlueField 3 [2], combining the network functionality with both flexible and hardened compute cores for on- and off-datapath offloads. Such commercial systems are useful, but limiting: the programmable on-datapath offloads are limited by access to cache and memory [24], while the hardened decompression core fails to meet line-rate throughput while entirely lacking support for compression [60]. Being a closed system, there is no way to either extend the system or address its limitations. This makes it difficult to explore logic suitable for offload and how to best implement it since the bottlenecks are inherent to the platform and cannot be addressed.

Table 1 summarizes RDMA implementations on FPGAs from academia and industry, highlighting their network capabilities, open-source availability, support for on-datapath acceleration, and communication with GPUs. One of the earliest approaches of RDMA on FPGAs [99] adopts the general principles of RDMA data transport with NIC-offloaded networking and DMA, but neither follows the actual protocol nor achieves 100G throughput. There are also solutions developed for very concrete use cases (e.g., high-energy physics or telescope data readouts) that demonstrate throughput performances of 100G [67] and 10G [29, 68] respectively, but do not implement `RDMA READ` and focus on embedded devices rather than the cloud and data center. For that purpose, several other solutions have been developed [26, 81, 84]. StRoM [84] is open-source, supports 100G, and has been used extensively for RoCE-enabled FPGA projects [27, 35, 42, 56, 77, 87], but misses key features. Due to its lack of high-performance checksum logic, it does not provide interoperability with commercial RNICs. Since its implementation of retransmission and handling of packet loss lack robustness, StRoM also does not support communication via switches. These two shortcomings eliminate StRoM as a platform for realistic data center network prototyping. Similarly, the lack of support for GPU-direct RDMA diminishes its applicability for modern AI-driven networks. Furthermore, the stack presented in [26, 81] provides a protocol-adherent RDMA implementation only for `RDMA WRITE` between FPGAs. Being closed-source and thus not extensible, the system makes it impossible to add missing functionality for `RDMA READ`, access to host memory, and RoCEv2 compliance. As such, the platform can enable data exchange between FPGAs but has limited applicability for network research in realistic data centers. Both StRoM [84] and the stack presented in [26, 81] explore offloading of application logic to the FPGA as we do here, but are limited due to the missing GPU-DMA-compatibility and the lack of demonstrated enhancements in the packet processing pipeline itself. Commercially, AMD's original implementation of RDMA [97] targeted mobile applications. The current version, ERNIC [11], is better suited for data center applications with 100G throughput. In [107], it was used to implement on-datapath offloads. However, the stack is oriented towards FPGA-to-FPGA communication and is closed-source, not allowing changes to the packet processing.

RoCE BALBOA aims to provide a comprehensive coverage of RDMA functionality and compatibility with commercial data center switches and NICs. Furthermore, it enables researchers to extend the protocol and add application offloads with direct access to GPU memory. Adding the missing functionality, while achieving high performance and enabling arbitrary offloads involves non-trivial design decisions that we discuss in this paper. A survey of existing network studies using FPGAs and custom SmartNICs reveals the gap that BALBOA tries to fill: many prominent FPGA-based NIC platforms, such

Table 2: Overview of the implemented features of BALBOA

Networking Speed	100G (200G theoretically possible)
RDMA Mode	Reliable Connection (RC)
Supported RDMA-verbs	RDMA WRITE and READ
Flow Control	ACK-clocked sliding window of static size
Retransmission Logic	Go-back-N, backed by on-device HBM
Multi-QP support	500 QPs by default, build-configurable

as Corundum [33], PANIC [61] and OpenNIC [98] do not include an offloaded networking stack, thus relying on the host CPU, while others, such as DUA [83], SuperNIC [62] and ACCL+ [42], implement parts of the packet processing pipeline or simplified protocols while focusing on function offloads. BALBOA is orthogonal to these works, aiming to offer a plug-and-play data center-compatible RDMA stack that provides connectivity and interoperability to these existing frameworks. Similarly, BALBOA could be used for the exploration of alternative transport stack principles as frequently discussed in research [46, 76, 96] through the customizability of its packet processing logic. The same is true for recent work focused on adding programmability and configurability to transport stacks [14, 21] and specifically RDMA [102]. Finally, BALBOA could be integrated with higher-level network management tools [59] due to its interoperability with commercial NICs.

4 RoCE BALBOA Architecture

4.1 Design Requirements and Challenges

Given the task to develop a widely usable RDMA stack for network research in data centers, we identify four key requirements that guide our design:

(R1) 100G Throughput: The stack should be able to satisfy the 100G networking throughput on current FPGA boards and offer the potential to be upgraded to 200G for the next generation of boards.

(R2) Protocol Adherence: To support integration into data center networks with commodity NICs and switches, the stack must adhere to the RoCEv2 standard and be interoperable with other networking cards. This adds significant complexity to the design, requiring, e.g., robust and fast retransmission, and the computationally complex CRC, which are both often ignored in existing systems.

(R3) Resource Efficiency: To provide space for application offloads and protocol enhancements, the resource and power consumption of the stack itself should be minimal.

(R4) Openness and Extensibility: Integrating offloads and protocol enhancements into the packet-processing pipeline calls for a degree of openness that fundamentally complicates the NIC design. To support such offloads, the stack must adopt a modular structure and expose well-defined, standardized interfaces between its components.

The design of a research-grade RDMA stack faces a fundamental trade-off: it must provide the transparency and modularity required for experimentation **(R4)** while still achieving high performance **(R1)** and protocol compliance **(R2)** available in commercial NICs. Standard open-source stacks often sacrifice **(R1)** and **(R2)** for **(R4)**. The core research contribution of BALBOA lies in demonstrating how openness and protocol-adherent performance can be satisfied at the same time through architectural design choices.

To achieve protocol compliance **(R2)** while maintaining a manageable development workload, we decided to limit BALBOA to a relevant subset of RoCEv2 features, deemed sufficient for data center deployment and research (Table 2). We implement the Reliable Connection (RC) mode with focus on one-sided RDMA verbs (`RDMA WRITE` and `RDMA READ`). As shown by prior works [8, 49, 93, 100, 111], the RC mode, together with one-sided verbs, is the most commonly used configuration in RDMA networks, enabling on-datapath offloads with minimal CPU involvement. Furthermore, RC mode demands the most complex hardware support among RoCEv2 transport types, encompassing retransmission, timeout handling, and in-order delivery guarantees. Supporting UC mode would follow as a straightforward extension, gating the reliability logic on QP type and extending the opcode decode tables to cover the UC opcode range — demonstrating that the design cleanly separates the reliability layer from the core datapath.

4.2 Architecture Overview

The core architecture of BALBOA (Figure 1) consists of several distinct building blocks for: ④ header (UDP, TCP, IB) processing, ③ checksum calculation, ② retransmission buffering, ① flow control, and ⑤ arbitration. These blocks communicate through well-defined, industry-standard AXI4-Stream interfaces for both data and control. From a development perspective, the modular design simplifies testing of the complex network stack by enabling stand-alone simulation and verification of individual components. At the same time, it improves accessibility, as components can be modified or extended independently, making the design suitable for future research **(R4)**. And from a performance point of view, the modular design lends itself to deep pipelining between components, helping to achieve timing closure with limited routing complexity **(R3)**.

Internally, BALBOA uses 512-bit–wide AXI data streams that operate at a system-wide clock frequency of 250 MHz. This configuration is sufficient to sustain an end-to-end throughput of 100 Gbps (250 MHz × 512 bit = 128 Gbps), satisfying the performance requirement **(R1)**. The chosen bus width and clock frequency create a balance between routing complexity and resource overhead compared to designs that would rely on wider datapaths or higher frequencies, addressing **(R3)**. The design also provides headroom for future

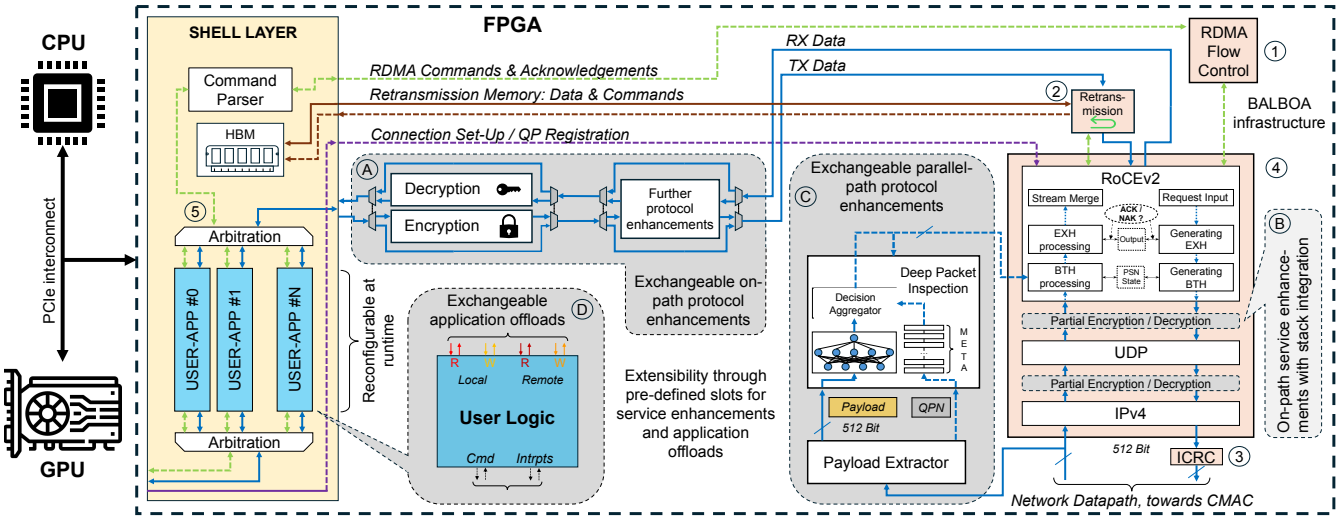

Figure 1: Overview of RoCE BALBOA, consisting of the customizable 100G RoCE packet processing pipelines ④ with surrounding infrastructure ①-③ and stack-adjacent slots for exchangeable on-datapath (Example: Ⓐ - AES CTR) and parallel-path service enhancements (Example: Ⓒ - ML-DPI). The open BALBOA-architecture also enables on-path enhancements within the packet processing pipeline (Ⓑ). Allows for DMA to both CPUs and GPUs with data routed through reconfigurable logic slots Ⓓ in the FPGA shell.

networking standards. The complete stack successfully synthesizes and meets timing at clock frequencies of up to 400 MHz, enabling a clear upgrade path towards 200 Gbps as suitable FPGA platforms become available.

By exposing industry-standard AXI4-Stream interfaces, RoCE BALBOA enables plug-and-play integration of custom offloads **(R4)** and allows it to be deployed in different FPGA platforms (shells). While this paper evaluates the stack in the open-source Coyote v2 shell [77] with the XDMA-core [12] for direct memory access to the host and the 100G CMAC-core [13] for network access, a port to the AMD RecoNIC/ONIC platform [107] has been realized in the past [69], demonstrating BALBOA's portability across platforms.

4.3 Packet Processing Pipeline

The core packet processing pipeline is implemented in AMD Vitis HLS using a vertically (per protocol-header) and horizontally (for RX / TX) partitioned architecture (Figure 1 - ④). To achieve 100Gbps throughput **(R1)** while ensuring maintainability and extensibility **(R4)**, we map the RoCEv2 header stack (IP, UDP, IB) to individual, pipelined HLS functions. This design pattern ensures sufficient readability and maintainability of the entire stack with the option of easily adding input parameters and processing logic in high-level description (as exemplified in subsubsection 5.2.2) to fulfill the goal of an open and extensible networking stack **(R4)**. In comparison, an RTL-based (e.g., Verilog, VHDL) design would make the effort for development, testing, and subsequent offload integration too demanding, especially for non-hardware engineers. Lastly, this separated design pattern enforces an a-priori pipeline architecture and allows the use of HLS auto-pipelining, helping with both the timing constraints for a 100G throughput design **(R1)** and the optimization of resource consumption **(R3)**.

A critical challenge in bidirectional 100G RDMA is maintaining QP-state consistency without stalling the pipeline. BALBOA solves this through a decoupled state architecture with physical state tables (Connection, PSN, MSN) implemented in dual-port BRAM and initialized during QP-setup. This design allows simultaneous access by both RX and TX pipelines **(R1)**, enabling independent line rate processing of incoming and outgoing network packets. By default, these tables support up to 500 QPs, but can be scaled depending on resource restrictions and use case (Table 3). A shared transport timer also measures packet timeouts to trigger retransmissions and potentially generate round-trip-time (RTT) based congestion signals for future extensions of the flow control.

Throughout the packet processing pipeline, BALBOA implements a versatile, three-fold interface with data, control, and completion streams: built around the notion of function offloads **(R4)**, split data and control streams allow placing processing pipelines directly on the datapath while manipulating and synchronizing the control commands in parallel, as opposed to a unified transmission where the command-manipulation, i.e. for size-expanding data operations, would be much more complicated. Building on this set of interfaces, the RX- and TX-path process traffic independently as follows:

- RX Path: Incoming headers are stripped and processed by dedicated finite state machines (FSMs) which

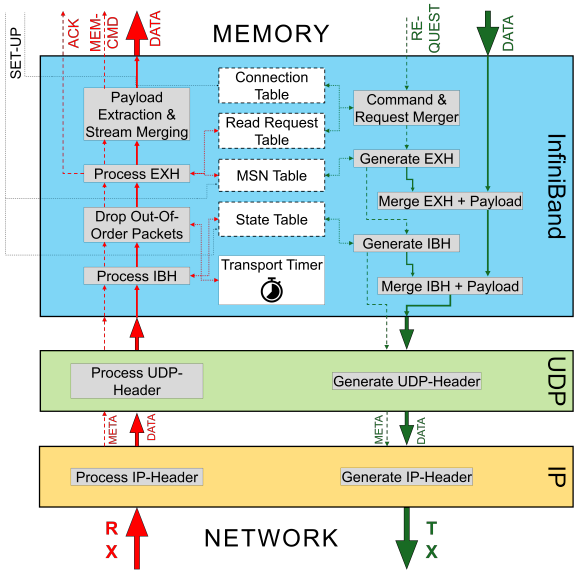

Figure 2: Packet processing pipeline for the sequence of IP, UDP, and InfiniBand headers of RoCE-v2 packets.

generate lightweight meta-commands for state retrieval and checks on parallel control buses. This isolates the main payload stream from the transport logic for improved timing and resource consumption (**R1, R3**). Crucially, BTH and RETH processing stages generate completion events on a dedicated bus, allowing the flow control logic to operate as a stand-alone, replaceable module (subsection 4.5).

- TX Path: The transmission pipeline accepts independent data and command streams from the host. This decoupling allows the architecture to absorb arbitration latency or retransmission fetches (Section 4.4) without stalling header generation. The command flow retrieves QPN/PSN state to generate headers (RETH/BTH), which are stepwise interleaved with the payload stream in the pipeline before the finished packet is forwarded to the checksum calculation (ICRC) and CMAC-unit for transmission.

4.4 Retransmission Buffers and Stream Multiplexer

The retransmission and stream multiplexer module (Figure 3 - ②) manages data delivery to the stack and buffers packets for potential retransmissions. A core challenge in RDMA stack implementations is the inherently opposing nature of local `RDMA WRITE` and remote `RDMA READ` operations. Delivering data for both over a single stream can cause stalls, preventing full throughput saturation. By separating data delivery for `RDMA WRITE`s and `RDMA READ`s onto distinct AXI streams, BALBOA manages to achieve bidirectional 100G throughput **(R1)** while also improving extensibility **(R4)**. More specifically, different offloads for `READ` and `WRITE` can be deployed on separate streams, enabling advanced enhancements and experimentation with the stack design.

Within the retransmission module, the two incoming buses for `READ RESPONSE`s and `WRITE`s are demultiplexed into a single stream via arbitration, while all incoming payloads are buffered in a dedicated, directly exposed HBM channel. Payloads, whether incoming from host or reloaded from HBM, are picked up and released by incoming commands from the packet processing pipeline.

If retransmissions are required due to packet timeouts or PSN sequence errors, the required payload cannot be refetched from the host, since an additional PCIe transfer would lead to unacceptable latency overheads. At the same time, on-chip SRAM is insufficient for buffering the bandwidth-delay product of a 100G link. Instead, all transmitted payloads need to be buffered in directly accessible fast card memory (HBM) until the remote side acknowledges receipt. This design principle is also backed up by the initial idea of adhering to the RoCE v2 standard **(R2)**: BALBOA implements Go-Back-N retransmission as defined in the protocol for RC-mode, and is compatible with off-the-shelf NICs, which means that up to N outstanding packets at any point in time need to be buffered for potential retransmission.

To explore the efficiency of the design, we analyze the resource implications for the Alveo U55C platform used for the evaluation: To saturate the bandwidth-delay-product, the flow control allows up to $N = 16$ outstanding packets per flow, which amounts to a retransmission buffer footprint of 64kB given the standard 4k MTU of RoCE. The FPGA provides 32 GB of fast off-chip HBM, offering a theoretical capacity for up to 500,000 QPs and thus preventing buffer overflows even for very large-scale deployments. In fact, this buffer capacity provides an advantage for an FPGA-based evaluation platform compared to commercial RNICs, which are typically limited to a few MB of on-chip SRAM [96, 106]. The practicability of this HBM-based approach to retransmission is further demonstrated under packet loss: The design only requires 1.732 μs to fully retrieve a buffered MTU-sized payload from memory, with an overall latency of 1.86 μs from the first indication of required retransmission to transmitting the fully formed packet towards the Ethernet-block of the design. This timespan is only a fraction of the round-trip time for packets of this size.

4.5 Flow Control Logic

BALBOA uses an ACK-based flow control over a fixed-size sliding window of outstanding packets, which are identified by their PSNs. This design enables timeout- and PSN-triggered Go-back-N retransmission while remaining compatible with commodity NICs. The flow control logic resides in the con-

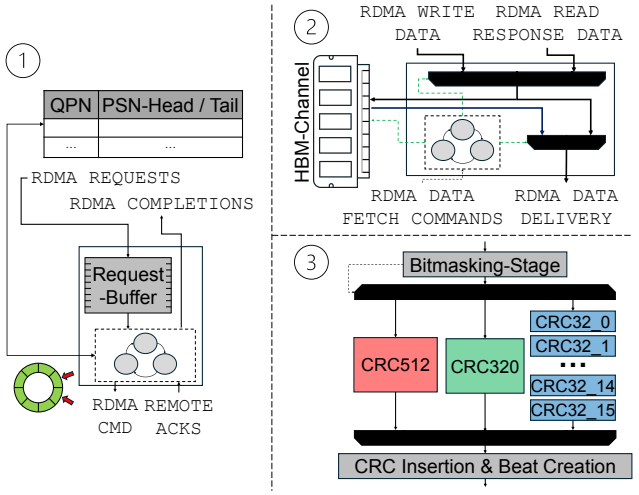

Figure 3: Building blocks of BALBOA: ① - ACK-clocked flow control, ② - Retransmission logic, ③ - ICRC pipeline

trol path (Figure 3 - ①), where incoming RDMA requests are either forwarded to the packet-processing pipeline or queued to limit the number of outstanding packets. The remaining packet budget per QP is stored in BRAM and updated; decreased when new requests are sent and increased upon receipt of RDMA ACKs.

By implementing flow control as a standalone block separate from the packet-processing pipeline (Figure 1 - ④) with standardized interfaces, BALBOA makes it easy to integrate alternative congestion control algorithms **(R4)**. Algorithms like DCQCN [108] or TIMELY [71] can simply replace the current implementation and throttle the command flow to the stack. Another reason for the modular design is to leverage partial reconfiguration on FPGAs, which, in the future, would enable programmable congestion control by dynamically exchanging the flow control module during runtime.

In addition to BALBOA's flow control, the underlying CMAC core on the target platforms natively supports Priority Flow Control (PFC) as specified by the RoCE standard [13], providing compatibility with this aspect of the protocol definition **(R2)**.

4.6 ICRC Pipeline

As described in [81], efficient calculation of the ICRC checksum is performance-critical for achieving high throughput **(R1)** and a well-known challenge for any RoCE implementation on FPGAs due to its combinatorial complexity. Since off-chip memory access to pre-calculated values would incur a significant latency penalty, impacting end-to-end throughput, RoCE BALBOA reimplements the concepts presented in [81]. More specifically, we calculate and concatenate the partial checksum of every incoming AXI beat within a packet. As a further trade-off between processing speed and resource consumption, we follow the referenced work in implementing separate, parallel pipelines for the full 512-bit and the partial 320-bit AXI beats, which are the most common fill-levels in RoCE packets on a 512-bit bus. A third, multi-stage pipeline for chunks of 32 bits length allows one to calculate the required checksum for any possible AXI beat, given the guaranteed 4-byte alignment of all RoCE messages.

4.7 Traffic Sniffer as a Debugging Utility

Developing a full FPGA network stack is challenging, especially when debugging faults that appear only during long-running jobs. To address this and maintain sustainable development, we built a performance-preserving traffic sniffer for bidirectional 100G RX/TX paths. It captures all packets and outputs standard PCAP files suitable for analysis with tools such as Wireshark. A header-based filter at the CMAC-level allows users to capture only specific protocols (e.g., RoCEv2) or omit payloads to reduce memory usage, which is crucial for tracing lengthy flows. This tool proved invaluable during development and supports our goal of comparability with off-the-shelf NICs and deployment in realistic networks **(R2)**, where traffic capture is essential for tuning and debugging.

5 Compute Offloads in BALBOA

The open design of BALBOA enables two types of offloads: protocol enhancements and application-specific offloads in configurable logic slots on the datapath.

5.1 Design Methodology for Offloads

For both types of offloads, developers can choose from a diverse toolbox of development strategies with specific trade-offs. Thus, we now discuss the design methodologies available in the framework and their implications for design effort, latency, and resource footprint. BALBOA's implementation-agnostic stream interfaces open a wide design space around the tradeoffs between development effort versus control. At the lowest level, RTL (VHDL / (System)Verilog) as showcased in Section 5.2.1 gives maximum control over timing and resources but requires hardware expertise and typically weeks of development per module. HLS (e.g., Vitis HLS) allows the direct synthesis of C/C++ expressions, reducing the development effort to days and enabling non-hardware engineers to leverage BALBOA's capabilities. The usefulness of this approach is demonstrated in Section 8. Finally, tools like hls4ml [30], showcased in Section 5.2.2, or P4-to-hardware compilers (e.g., Vitis Networking P4 [3]) take a cross-disciplinary approach and eliminate the manual creation of hardware by compiling pretrained ML-models or P4-scripts directly into FPGA-images, reducing the development time.

Regardless of the implementation methodology, coordination with the packet processing pipeline for on-datapath

offloads reduces to a backpressure signal on the AXI4-stream signal as a consequence of the realized design goal **(R4)**. As laid out in Section 5.3, RX-path offloads must be non-stalling, while TX-path offloads benefit from the decoupled command/data architecture. Parallel-path enhancements need to interact with the processing pipeline through HLS-hooks, requiring more attention to potential pipeline stalls.

5.2 Protocol Enhancements as a Service

The RDMA protocol enhancements are located close to the stack and interact directly with both data- and control flow. Compared to application-specific offloads, protocol enhancements implement network-specific tasks applicable to the entire BALBOA-stack. Function offloads as user-defined applications for selected QPs (e.g., data preprocessing) can select to utilize these protocol enhancements as a service of the network stack, just like the general RDMA transport mechanism. In our example, we focus on the aforementioned security flaws of RoCE and demonstrate the unique capability of BALBOA to deploy enhancements that close important security gaps of the protocol. In general, two forms of protocol enhancements are possible:

On-datapath protocol enhancements are located right before or after the packet processing pipeline and consume the incoming AXI data streams, without interfering with the actual protocol logic of the packet processing pipeline (Figure 1 - Ⓐ). While we only show host-facing offloads located after the BALBOA-stack, future work could also place additional logic on the network streams leading to the packet processing pipeline, such as a network impairment model for congestion control testing.

Contrary to this, *parallel-path protocol enhancements* (Figure 1 - Ⓒ) are placed in parallel to the core packet processing pipeline. These enhancements operate on a multiplexed copy of the incoming or outgoing packets and can directly interact with the packet processing logic via interfaces to the pipeline. The latency of these protocol enhancement services is hidden by the partial latency of the parallel packet processing pipeline. Parallel-path protocol enhancements are unique to an open stack design as demonstrated with BALBOA **(R4)**, since they require direct integration into the protocol logic.

5.2.1 AES Encryption

To demonstrate secure, line-rate stream processing, we integrated an open-source AES-CTR engine[2] (Figure 1 - Ⓐ). The module operates as a 'bump-in-the-wire' on the AXI datapath, adding a deterministic latency of only 11 cycles (44ns) while sustaining full 100Gbps throughput.

BALBOA's architecture provides a critical advantage for cryptographic correctness: unlike fixed-function NICs where internal state is hidden, our stack exposes the transport state machine to the encryption logic. This gives us the opportunity to construct a cryptographically unique counter (IV) for AES-CTR by combining the Queue Pair Number (QPN) with per-packet counters. This state-aware synchronization ensures semantic security without requiring software intervention or side-channel signaling.

Furthermore, BALBOA's modular AXI-based design allows for flexible placement of encryption blocks. Beyond standard payload encryption, the engine can be repositioned within the packet processing pipeline (Figure 1 - Ⓑ) to obfuscate transport headers (e.g., BTH, UDP) for stealth communication within trusted subnets, or extended to protect specific metadata fields. Similar concepts have been discussed in research before [90] and are currently seeing deployment in production environments (e.g., NVIDIA / Google PSP [36, 75, 86]).

5.2.2 ML-based Deep Packet Inspection

As an example of parallel-path protocol enhancements (Figure 1 - Ⓒ), RoCE BALBOA deploys an open-source machine learning-based deep packet inspection module [44]. It leverages low latency inference of ML on FPGAs to offload packet checking to the NIC and identify, at line-rate, potentially malicious executables embedded in RDMA flows, countering the well-known shortcomings of the protocol in terms of access control. This maintains host bypassing while marking and rejecting potentially malicious packets before they ever reach host memory and possibly inflict damage. The ML model was trained to distinguish between common payloads, such as CSVs, PNGs, and TXTs, and compiled malware executables. The trained and quantized model was converted to a hardware module suitable for FPGA inference through the hls4ml compiler [30]. The end-to-end inference latency for DPI decisions is only 44ns per AXI beat. This is shorter than the latency of the packet processing pipeline and, therefore, DPI does not lead to performance degradation. Utilizing the open stack design, the aggregated DPI decision is communicated as an input value to the BTH-processing function of the packet processing pipeline and included as a flag in the resulting command to the host. This allows the stack to raise an interrupt, upon which the host OS could decide to run additional checks. In more conservative setups, packets can also be immediately dropped by the NIC, before reaching the host.

The integration of the DPI model into the packet processing logic is a prime example of a protocol enhancement only possible with a customizable and open-source design like BALBOA **(R4)**. Following this design principle, other modules can be installed in a similar position for, e.g., data analytics on incoming packets to control the further processing in the stack.

5.3 On-datapath Application-specific Offload

Thanks to its generic AXI stream interfaces, RoCE BALBOA allows users to deploy arbitrary logic on the RX- and TX-datapath to manipulate payloads. Multiple design criteria must be met for such offloads:

- For both directions, special care is required for any data expansion operation on the payloads. Backpressure is exerted if an offload exceeds the available bandwidth.
- Similarly, all operations placed on the RX datapath for incoming packets must not stall at any point to avoid causing backpressure to the network stack as it would lead to packet drops. For offloads below line rate, this requires an end-to-end approach with adapted data sending rate from the remote node.

At the same time, the user finds powerful design tools for customized data processing in the application-specific on-datapath offloads:

- The user has access to both the data and control flow for incoming packets. This allows manipulating the local data forwarding, e.g., scatter-gather operations to multiple host memory locations for arriving data. On top of that, payloads can also be forwarded to local NIC-attached memory for buffering.
- Finally, also stateful offload operators can be configured by the user: By using memory-mapped control registers, the user is able to provide context or state for processing to such hardware modules.

To facilitate development against these design constraints, we provide a comprehensive logic simulation framework that tests any on-datapath user-application against the realistic network behavior of RoCE BALBOA and helps to easily spot throughput bottlenecks, data dependencies, and race conditions while hiding the actual complexity of the implementation. In fact, the workflow for deployment and simulations only differs by a single compile flag and does not require any framework or code adaptation. This makes it possible to design and test advanced on-datapath compute offloads. As a consequence, BALBOA has been proven useful and easy to handle for developers in many collaborative projects with both industry and academia in the past, where it was deployed in research and production systems.

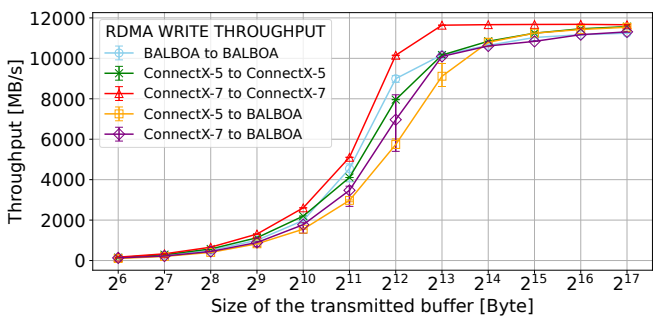
6 Experimental Evaluation

We evaluate RoCE BALBOA along multiple dimensions in a public research cluster [72] that resembles a typical data center network. The 100G subnet connects servers with Mellanox ConnectX-5 (MCX515A-CCAT) and NVIDIA ConnectX-7 (integrated in a BlueField-3 B3220-DPU), as commodity NICs, and BALBOA deployed on AMD Alveo U55C FPGA accelerators as PCIe cards over CISCO Nexus 9000 Series switches, tuned to 4K maximum transmission units (MTU). We evaluate the performance between RoCE BALBOA on the Alveo FPGAs and the commercial NICs through a single layer of switches, but also verify the same results in a 2-tier fat-tree network topology more common for HPC-oriented cloud setups. Additionally, we have successfully deployed and tested BALBOA on other AMD Alveo accelerators with CMAC blocks (U250, U280).

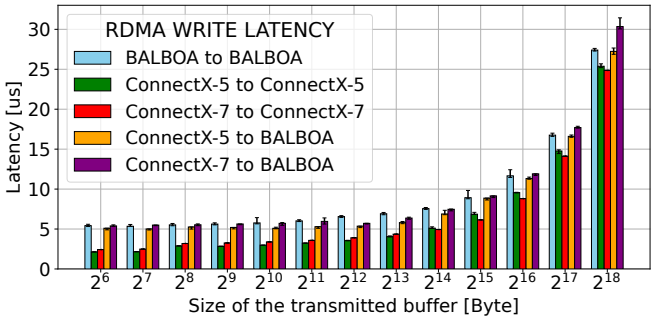
6.1 Basic Performance & Cross-compatibility

RoCE BALBOA is evaluated in the described setup for latency and throughput at various buffer sizes, both in FPGA-to-FPGA flows as well as heterogeneous FPGA-to-Mellanox connections (Figure 4). Additionally, Mellanox-to-Mellanox results are plotted for comparison. Following the general practice of network performance testing, latency values are obtained through repeated single buffer transmissions and completion-polling, while throughput performance is measured with repeated batched transmissions.

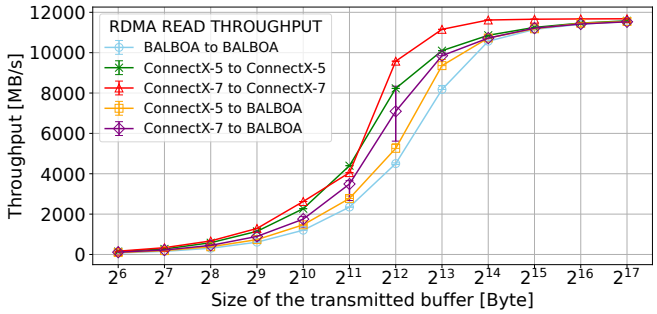
When first comparing only the BALBOA-to-BALBOA performance with the NIC-to-NIC performance, it becomes evident that both BALBOA and the commodity NICs perform similarly, especially for `RDMA WRITE` operations. As shown in Figure 4a, all three devices reach the 100G saturation point for 32kB buffers at the latest, with a marginal advantage for the newer generation ConnectX-7. In terms of latency (Figure 4b), the higher internal clock frequency of the ASIC-based NIC results in a latency advantage, especially for small buffers, with diminishing differences for larger messages. All three devices have a steady latency performance with a negligible tail latency as shown by the 95th-percentile lines. The same general observations hold true for the `RDMA READ` behavior. A more pronounced throughput difference for medium-sized buffers becomes visible for `RDMA READ` (Figure 4c). Unlike `RDMA WRITE` operations which utilize posted PCIe transactions (fire-and-forget), `RDMA READ` relies on non-posted memory read requests. This requires the NIC to manage the round-trip latency of fetching data from the host root complex. To saturate the link, the NIC must maintain a high volume of outstanding split-transactions (PCIe tags) to mask this latency. The commercial ASIC, utilizing a custom controller clocked at $\approx$1GHz, can issue and track these requests at a higher rate than the FPGA. In BALBOA, the lower logic frequency (250 MHz) and the interface overhead of the generic PCIe hard-block introduce slight serialization delays in the request-issue loop, preventing full saturation for medium-sized transfers where the per-transaction overhead is most pronounced. Heterogeneous connections between BALBOA and an ASIC-based NIC exhibit characteristics of both devices as described before. The measurements demonstrate that RoCE BALBOA is capable of saturating a 100G link for both `RDMA READ` and



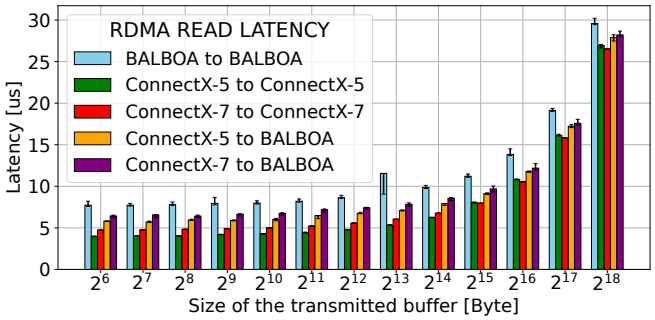
(a) Throughput evaluation for `RDMA WRITE`.



(b) Latency evaluation for `RDMA WRITE`.



(c) Throughput evaluation for `RDMA READ`.



(d) Latency evaluation for `RDMA READ`.

Figure 4: Performance evaluation of RoCE BALBOA in a switched 100G data center network, 100 repetitions per measurement.

`WRITE` in connections to both another FPGA and a commodity NIC. The adaptability across different generations of ASIC-based RNICs appears even more crucial, as such connections are known to be troublesome even in commercial deployments [59]. The experiment validates the design choices for achieving the network bandwidth **(R1)** and compatibility of the stack with commodity hardware **(R2)**.

6.2 Multi-QP Performance Scaling

RoCE BALBOA can serve up to hundreds of independent QPs in parallel from independent threads. By intertwining batched transmissions of multiple QPs, we demonstrate that the arbiters used in RoCE BALBOA are capable of evenly distributing the available bandwidth between the competing flows (Figure 5), while maintaining full aggregated throughput saturation. Results obtained with a Mellanox card show similar behavior to BALBOA.

6.3 Protocol Enhancements: Encryption and DPI in BALBOA and Other Platforms

We showcase the performance of encryption and DPI and, if applicable, compare them to software-based implementations of the same functionalities on the host CPU (AMD EPYC 7302P, 16 cores, 64GB RAM) coupled to a Mellanox ConnectX-5. While the processing steps in RoCE BALBOA

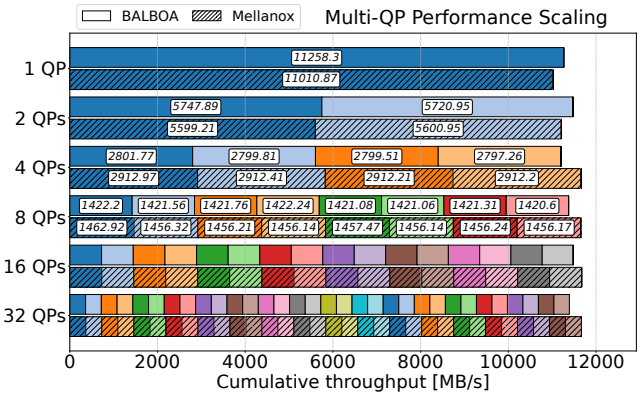


Figure 5: Bandwidth distribution and aggregation across multiple QPs for interleaved `RDMA READ`s of 32k size.

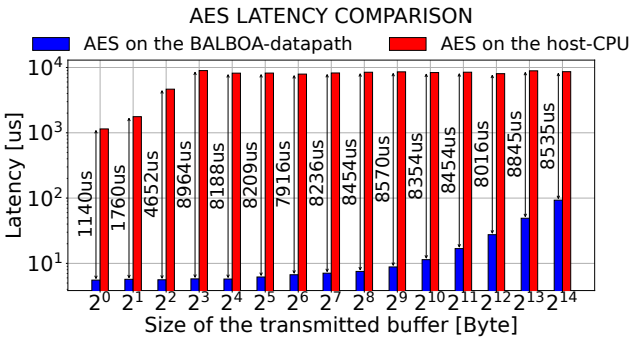
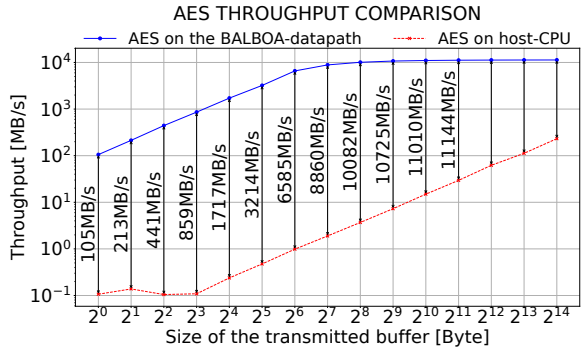
reside on the datapath and are therefore executed automatically, the execution on the CPU is triggered via a remotely written doorbell register with host-polling.

6.3.1 AES-CTR Encryption on RDMA Traffic

The direct comparison of latency and throughput for both the on-datapath BALBOA implementation and the realization of AES CTR on the host CPUs demonstrates a stark performance difference (Figure 6). Even with all 16 cores of the server-grade CPU (AMD EPYC 7302P) and with



(a) Latency comparison for AES-CTR on the BALBOA datapath vs. on the host CPU with a Mellanox NIC for RDMA WRITEs.



(b) Throughput comparison for AES-CTR on the BALBOA datapath vs. on the host CPU with a Mellanox NIC for RDMA WRITEs.

Figure 6: Comparison of AES implementations residing on either the BALBOA-datapath or the host CPU.

hardware support for AES via the standard OpenSSL library, the software-based implementation is only able to saturate a small fraction of the 100G network bandwidth (Figure 6b). Conversely, the hardware-based implementation in BALBOA achieves full throughput and only adds negligible additional latency - the AES pipeline has an end-to-end latency of 11 clock cycles/44 ns (Figure 6a). This performance difference is further backed up by existing research on accelerator-based encryption, where these solutions consistently outperform CPUs [25], while also reducing the "data center tax" of continuously thrashing CPU cores for repetitive tasks.

For completeness, we also tried to compare to the performance achievable with the hardware encryption accelerators in NVIDIA BlueField-3 DPUs, but ran into difficulties: The officially documented path for hardware-accelerated IPsec on BlueField-3 relies on a VXLAN+IPsec tunnel architecture via a patched strongSwan, which is not directly comparable to BALBOA's per-flow RDMA payload encryption. We were unable to build the patched strongSwan instance due to its sparse documentation and dependency as well as timestamp issues. There is no evidence that another per-flow RDMA encryption is supported in any documented configuration. Requests for assistance on the NVIDIA developer forum went

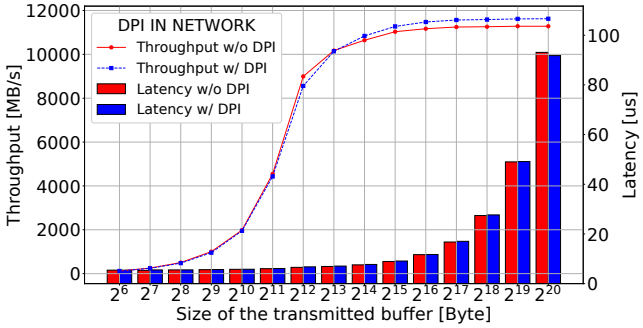


Figure 7: Throughput and latency with and without deployed ML model for deep packet inspection.

unanswered beyond a referral to enterprise support, and independent community reports confirm the same unresolved issues as recently as late 2025.

6.3.2 Deep Packet Inspection

Analyzing the performance of the DPI enhancement, we first observe that the deployed fully-connected ternary neural network provides an excellent detection rate of executables with 97.83% for full payloads and 89.35% for partially embedded executables. Compared to the low false positive rate of flagging acceptable payloads of the model, a highly effective and fine-grained differentiation policy is possible based on the ML-decisions. More details on the accuracy and performance of this model can be found in [44].

At the same time, Figure 7 shows that the deployment of the ML model alongside the BALBOA stack does not have a negative impact on either end-to-end latency or throughput, since the inference latency of DPI is completely hidden by the parallel packet processing pipeline.

7 Hardware Resource Evaluation

We analyze the FPGA resource utilization and power consumption with post-routing hardware and power estimation results for an AMD Alveo U55C FPGA (Table 3). The design aims to minimize the "transport tax" - the resources consumed by the network stack - to maximize the area available for offloads and enhancements:

- **Resource Efficiency (R3):** The base BALBOA stack utilizes only 3.4% of the Look-Up-Tables (LUTs) and 5.1% of Block RAM (BRAM). Notably, the complex transport logic fits entirely within on-chip memory, ensuring deterministic access times without consuming external HBM bandwidth for state management. Even with the AES-Encryption and ML-DPI offloads enabled, the total LUT utilization remains below 12.15%. This confirms the successful combination of resource-efficient and still extensible stack architecture achieved with BALBOA.

Table 3: Resource and power estimation breakdown for RoCE BALBOA, and for the AES and DPI service offloads.

	LUTs	BRAM	FFs	Power
BALBOA	43732 [3.4%]	101 [5.1%]	102988 [4%]	1.745 W
ICRC	12462 [0.96%]	0 [0%]	23942 [0.9%]	0.233 W
Retrans-Logic	587 [0.05%]	34 [1.7%]	1157 [0.04%]	0.073 W
Flow Control	787 [0.06%]	1 [0.05%]	2836 [0.1%]	0.022 W
Packet Process.	29897 [2.3%]	66 [3.4%]	75053 [2.9%]	1.416 W
- Conn Table	64 [0.01%]	4 [0.2%]	230 [0.01%]	0.014 W
- State Table	202 [0.02%]	6 [0.3%]	265 [0.01%]	0.014 W
- Trans. Timer	209 [0.02%]	2 [0.1%]	248 [0.01%]	0.022 W
- MSN Table	92 [0.01%]	5 [0.25%]	373 [0.01%]	0.016 W
AES Crypto	65662 [5%]	0 [0%]	11669 [0.5%]	0.356 W
ML DPI	54404 [3.75%]	0 [0%]	40508 [1.6%]	3.231 W
Payload Ext.	6252 [0.09%]	0 [0%]	1135 [0.04%]	0.072 W
ML Model	48152 [3.66%]	0 [0%]	39373 [1.5%]	3.159 W

- **Power Consumption:** The estimated power draw for the full 100Gbps design is $1.745W$, validating that FPGA-based transport is power-efficient enough for dense data center deployment.

- **Scalability:** Given the low LUT utilization, the design would theoretically allow for multiple parallel BALBOA instances of a single data center FPGA. This would enable multi-port 200G or 400G deployments in future work, limited only by the available PCIe-bandwidth for host communication.

To contextualize these numbers, a direct comparison with an established open-source TCP stack is instructive: Limago [41, 79] implements simplified 100G TCP and has been widely used in the community for network research [43] and distributed applications [9, 40, 48, 54, 94, 95]. Despite implementing full transport-layer reliability — including Go-Back-N retransmission and flow control as required by RoCEv2 — BALBOA consumes 18% fewer LUTs than the Limago 100G TCP stack under equivalent conditions (capacity for 500 flows, targeting AMD Alveo U55C), the primary scarce resource for co-located applications as evidenced by the AES and DPI offloads in Table 3. BALBOA uses more FFs (102,988 vs. 72,974) and BRAM (101 vs. ∼78 BRAM36-equivalent), though both remain comfortably within the available budget of the U55C and do not constrain placement of additional logic.

8 Use Case Example: ML Preprocessing Pipelines for RDMA-to-GPU

Deep learning recommendation models (DLRM) comprise a large fraction of all ML workloads in data centers [38]. To maintain accuracy of the recommendations during data drift and evolution, frequent online re-trainings are necessary [20, 31]. While the multi-modal input data consists of images, audio, or text, the training process itself operates on vector embeddings [105], so a preprocessing step for conversion is required. Traditionally, such training systems utilize a hybrid hardware configuration with CPUs and GPUs [104], as the GPU utilization should not be bloated with frequent kernel launches for preprocessing. When transferring data from disaggregated storage to the GPUs for DLRM-training, preprocessing becomes a critical bottleneck, as more and more CPU cores are required to saturate the increasing bandwidth of GPUs, leading to more than 60% share of total power consumption for just this initial data preparation step [18, 104]. This motivates an accelerated approach which combines network and compute using the capabilities of BALBOA. We demonstrate how to significantly increase the efficiency and the processing speed of DLRM preprocessing by offloading it onto the BALBOA datapath in deep pipelines operating at line-rate and combining it with the direct-to-GPU capability. Thus, the CPU as a potential bottleneck is completely bypassed.

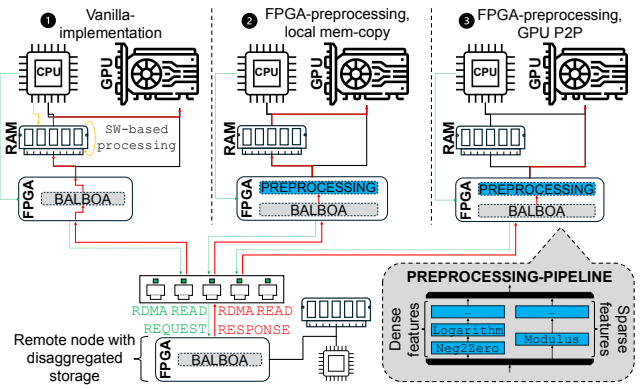

Figure 8: Comparison of three setups: ① - CPU-based preprocessing, ② - preprocessing on the FPGA, mem-copy to GPU, ③ - preprocessing on the FPGA and DMA to the GPU

8.1 Functional and Design Overview

For a realistic evaluation, we deploy operators from Meta's training toolkit [1, 74] implemented in deep pipelines for non-stalling line-rate execution in hardware [109]. We select the following three stateless operators and concatenate them to a preprocessing pipeline, as they are deemed relevant for optimization in hardware [58] and software [103]: `Neg2Zero` and `Logarithm` operate on dense input features by clipping negative values to zero and compressing very large values. `Modulus` restricts the range of sparse feature values. With an initiation interval of one clock cycle each, pipelines composed of these operators are able to maintain network speed and do not bottleneck the BALBOA datapath.

8.2 Performance Benchmarking

To explore the performance of the preprocessing offload and the direct memory access to the GPU, we conduct three experiments (Figure 8). In all three cases, the local node reads

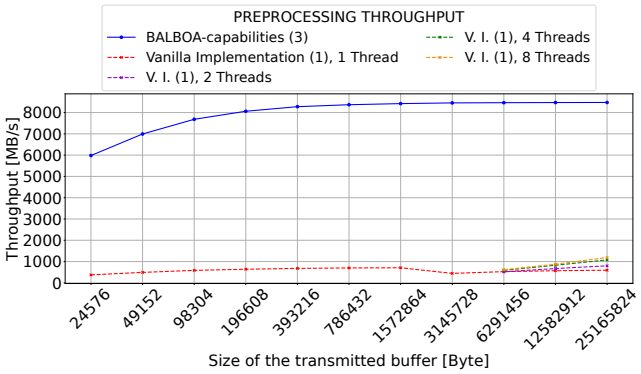

Figure 9: Throughput of preprocessing in BALBOA with direct-to-GPU vs. CPU preprocessing and copy to GPU for different levels of multithreading.

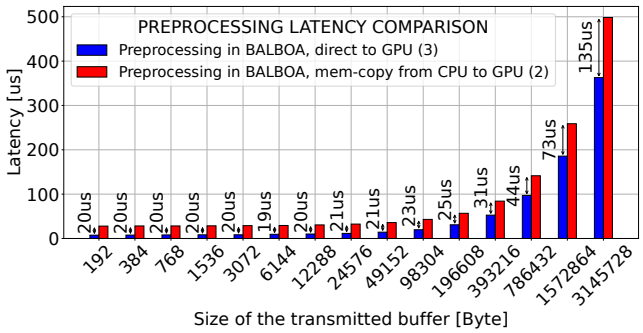

Figure 10: Latency of ML preprocessing in BALBOA with direct-to-GPU vs. an additional step through CPU memory.

the input data from remote memory via `RDMA READs`. In the vanilla setup, without offloaded processing or the direct-to-GPU feature, the received data is written to local host memory, preprocessed in software on the CPU and then locally copied to GPU memory. In a more optimized setup, the preprocessing is implemented in BALBOA's datapath, while still relying on intermediate buffer copies from host to GPU memory. The final setup utilizes both on-datapath preprocessing and direct memory access to the GPU. Again, all experiments are conducted in the same public research cluster with Alveo U55C FPGAs, AMD MI210 GPU accelerators and AMD EPYC 7V13 CPUs. However, a PCIe-switch on the GPU-FPGA path limits the maximum throughput between FPGA and GPU to 70 Gbps (8500 MB/s).

Comparing the vanilla implementation to the BALBOA-optimized design reveals the throughput and utilization benefit of on-datapath pipelines. Even when using multithreading on the CPU and using up to 8 cores for preprocessing tasks, the achievable throughput is limited to 1190 MB/s compared to the FPGA throughput of 8500 MB/s (Figure 9). At the same time, the latency comparison between the GPU-direct utilization of BALBOA compared to the additional copy through host memory shows latency savings of around $20-135\ \mu s$ (Figure 10). Additionally, the direct transfer to GPU remains compliant with RDMA principles of bypassing the CPU.

In summary, the combination of DMA-to-GPU mechanisms with on-datapath preprocessing in the NIC is a promising way to fully use the bandwidth of modern GPUs, avoiding running into CPU bottlenecks and blocking valuable cores.

9 Future Work

In future work, we plan to further leverage the openness and extensibility **(R4)** of BALBOA for research in network infrastructure and application acceleration, similar to the previously demonstrated ML-preprocessing in Section 8: On the application level, the on-datapath enhancements provide an exploration space for operator push-down in distributed database systems [28] to eliminate CPU-passes in query execution, content-aware packet steering as a natural extension of the demonstrated DPI-example or hardware-offloaded gradient compression at line rate [4].

Another potential line of research focuses on network-level transport characteristics: A major problem in RoCE-dependent AI-networks is congestion control [34], which is hard to investigate with commercial NICs due to hardwired congestion controllers. BALBOA maintains an open interface for congestion algorithms deployed in hardware, thus forming an ideal platform to investigate and prototype programmable congestion control, ML-driven congestion control or test other algorithms in hardware instead of simulation. Similar to this, an extensible and open stack allows modifying key RoCE behavior and testing alternative approaches to retransmission [45], packet reordering for per-packet load balancing [64] or custom verbs for interaction with remote memory [10]. Finally, the open nature of BALBOA allows us to further improve its performance in the future, e.g., scaling the throughput to 200G on newer FPGA platforms.

10 Conclusions

In this paper, we present RoCE BALBOA, an open-source, RoCE v2 capable and data center network-ready RDMA stack for exploring and developing in-network accelerators and SmartNICs that allows for far-reaching customization with protocol-enhancing services and on-datapath acceleration of function offloads. We demonstrate the protocol enhancements with AES encryption and ML-based deep packet inspection while also showcasing a realistic use-case scenario of on-datapath function offloads for realistic ML-preprocessing pipelines for recommendation models.

11 Acknowledgements

The authors thank AMD for the donation of the Heterogeneous Accelerated Compute Cluster (HACC), which was used for the development and testing of this project, and Geert Roks for the support and help with the cluster set-up. Also, thanks to the AMD Research team in Dublin for useful feedback and discussions on the design of RoCE BALBOA. We thank Heejae Kim from Seoul National University for his support with Limago.

Abstract

Remote in-memory key–value (KV) stores are fundamental to a wide range of applications, many of which depend on efficient range operations. However, existing designs fall short of simultaneously providing high performance, low complexity, and full range-query support. Host-based systems like REDIS and MEMCACHED are constrained by the kernel network stack and NIC–host interactions. Implementations of hash-based structures that bypass the OS kernel or serve directly from SmartNICs demonstrate upper performance limits but cannot support range queries. Distributed RDMA systems offer high throughput and range functionality when using stateful clients, but these clients increase the risk of faults and complicate scaling. Finally, SmartNICs traversing host-memory trees suffer from high numbers of DMA round-trips.

This paper presents *DPA-Store*, which uses the on-path *Data Path Accelerators* (DPAs) of the BlueField-3 SmartNIC to circumvent OS overheads while supporting stateless clients and range queries. The DPAs fetch incoming requests directly from the NIC buffers and traverse a lock-free learned index tree within the DPA memory. Values are fetched from a host-side replica of the tree when reaching the leaf level. Writes are buffered in DPA memory and transferred in batches to the host. Compute-heavy structural operations are executed on the host and transactionally *stitched* back to the SmartNIC. Complemented with a read cache directly on the NIC, DPA-Store sustains 33 million operations per second (MOPS) for lookups and 13 MOPS for range queries. Our evaluation shows that DPA-Store is already faster than or competitive with state-of-the-art solutions, and we demonstrate how small changes to the BlueField-3 hardware could additionally increase performance.

1 Introduction

Many modern workloads rely on remote key-value (KV) stores that support lookups, inserts, and range queries. However, remote performance is often limited by transport bottlenecks. Traditional remote KV stores such as REDIS [38] and MEMCACHED [33] are accessed over TCP/IP sockets, commonly over Ethernet. Their reliance on the operating system (OS) kernel network stack, together with PCIe bottlenecks between the network interface card (NIC) and the host, limits throughput and increases latencies.

To mitigate OS overhead, some approaches use the Data Plane Development Kit (DPDK) [12] to bypass the network stack via direct user-space access. MICA reaches nearly 100 million operations per second (MOPS) on a single server node [28]. Other works like KV-DIRECT achieve even higher throughput by removing host involvement and serving requests directly from an FPGA SmartNIC [23]. This reduces latencies because the KV store is closer to the network. However, to achieve these results, KV-DIRECT is constrained in the complexity and capacity of the underlying data structures. Both MICA and KV-DIRECT use hash-based point lookups and lack range queries. Recent works apply similar offload designs to newer SmartNIC generations and are affected by the same shortcomings [15, 37]. Approaches like HONEYCOMB [29] traverse data structures in host memory and support range queries. However, their performance falls behind because they issue frequent DMA round-trips.

Clients of KV stores that use remote direct memory access (RDMA) can access host memory directly [25, 26, 39, 47–49, 57]. These approaches introduce architectural challenges because every client eventually needs to know the remote addresses of the data on the server to access it. SHERMAN minimizes round-trips for writes but requires client caches for tree traversals [25]. Similarly, ROLEX [26] maintains metadata indexes on the clients and optimizes accesses using learned indexes. These systems can deliver high performance but their dependence on client-side logic and resources raises scaling complexities, introduces consistency concerns, and requires additional failure handling.

In this paper, we present *DPA-Store*, an ordered in-memory KV store that uses the BlueField-3 SmartNIC [36] and its *Data Path Accelerators* (DPAs) [35] to bypass OS overheads and to allow stateless clients. DPAs are highly parallel, programmable compute units embedded in the network data path.

DPAs have direct access to NIC buffers and NIC-side DRAM, and can perform DMA operations to access host memory, enabling low-latency and flexible request processing [7].

DPA-Store is built around the high level of concurrency of the DPA subsystem, which consists of 16 cores, each with 16 threads, for a total of 256 threads. When receiving requests, these threads traverse a learned index tree [20], stored in NIC memory, without involving the host. To circumvent memory capacity restrictions of the NIC, values are stored in a replica of the tree on the host. As a result, point and range lookups, at most, need to issue DMA operations at the leaf level. This keeps the number of DMA operations, and thus PCIe crossings, to a minimum.

When an insert request is received, the responsible DPA thread appends the entry to an insert buffer at the leaf level on the NIC side. These entries are immediately visible to subsequent lookups. The insert buffers are transferred in batches to the host when they are full. The host, with its greater compute capabilities, performs expensive structural updates to its tree replica using concurrent *patcher* threads that apply the inserts to the host-side tree, retrain affected subtrees, and prepare new nodes. *Stitcher* threads then copy the new nodes into the NIC-side tree and make them available via pointer swaps. This guarantees consistency while keeping the NIC-side traversal path lock-free.

We employ a NIC-side read cache for hot entries to reduce the number of tree traversals and DMA operations. Requests are routed to DPA threads based on a hash of their key, so that small Bloom filters that guard cache accesses fit within each thread's unused cache-line space. These cache-lines are rarely evicted from the L1 caches of the DPA threads, allowing efficient caching of hot key-value pairs.

Our learned index allows fine-grained optimizations for the DPA subsystem's memory characteristics, scheduling, and concurrency. We design the traversal logic around optimal cache-line accesses and employ fixed-point calculations to compensate for the lack of floating-point units on the DPAs. Our contributions are as follows:

- We show that it is possible to build a KV store supporting lookups, inserts, and range queries on a BlueField-3 SmartNIC that is already competitive, for most operations, with state-of-the-art RDMA-based KV stores *without* relying on stateful clients. DPA-Store achieves 33 MOPS for `GET` and 13 MOPS for `RANGE` operations.
- Our extensive experiments to evaluate DPA-Store reveal in-depth performance characteristics of the BlueField-3, going beyond what prior works have reported. These insights also explain DPA-Store's low `INSERT` performance of only 1.7 MOPS.
- We demonstrate how modest modifications to the BlueField-3 hardware, without changing the overall programming model, could unlock substantial performance gains, which would easily surpass the performance of today's fastest RDMA-based KV stores.

The paper is structured as follows. Section 2 provides background and surveys related work. Section 3 details the DPA-Store architecture and implementation. Section 4 evaluates DPA-Store with a sensitivity analysis and comparison benchmarks. Finally, Section 5 concludes the paper.

2 Background & Related Work

In this section, we summarize the background on learned indexes and the BlueField-3 DPU, and position DPA-Store relative to kernel-bypass, NIC-assisted, and RDMA-based remote KV systems.

2.1 Classical & Learned Index Structures

Key-value (KV) stores expose a compact interface, providing `GET`, `INSERT`, `UPDATE`, `DELETE`, and optionally `RANGE` operations. Typically, KV stores rely on either hash tables or, if range operations are required, ordered tree structures. Modern, non-remote in-memory KV stores serve node-local processes using optimized variants of traditional data structures such as B$^+$-trees, tries, or hash maps, with highly optimized traversals and concurrency control [3, 21, 22, 30, 52]. However, traditional data structures often suffer from suboptimal memory access patterns [20].

To address this issue, *learned indexes* [9, 11, 13, 19, 20, 24, 27, 32, 51, 54] capture the key distribution using lightweight models. This allows lookup operations to jump directly to the relevant region inside a node, followed by a short scan, and requires only a few cache-line accesses per tree level (see Figure 1). A common choice for approximating the key distribution is a piecewise linear approximation (PLA). Short linear segments are fitted to the cumulative key distribution, enabling a linear prediction $p = a \cdot k + b$ of the target position of key k using parameters a and b with an error of at most ε.

Thus, instead of $O(\log n)$ memory accesses per node of size n, with potentially many independent cache-line accesses (e.g., in a B$^+$-tree), lookup operations in a learned index are aggregated in a small contiguous window $[p-\varepsilon, p+\varepsilon]$, trading relatively slow memory accesses for fast CPU cycles.

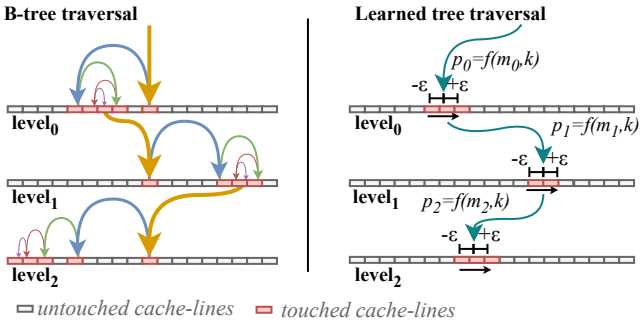

Figure 1: Access patterns in B$^+$-trees vs. learned index trees.

The error bound ε balances capacity efficiency against scan effort. Smaller bounds reduce the scan range but increase the number of models, whereas larger bounds keep more data in continuous segments, requiring larger regions to be scanned. Therefore, choosing a suitable parameter ε is important when mapping learned indexes to accelerators like SmartNICs with their limited memory access performance.

Insert and model rebuild strategies further impact runtime behavior. ALEX [9], for example, stores keys in gapped arrays with small buffers and does not require relearning until gaps are full. HYPER [54] combines bottom-up and top-down strategies and uses overflow buffers to limit memory overheads, while XINDEX [43] targets highly concurrent workloads. In all cases, buffer layout, size, and update policies govern retraining cost and concurrency characteristics.

2.2 Remote KV Stores

Remote KV stores introduce additional complexity by allowing access over network protocols. Widely deployed Ethernet-based KV stores [10, 17, 33, 38] serve general-purpose workloads. However, their request throughput is limited by the host networking stack and related OS components, such as network sockets and context switches, as well as the NIC-host PCIe boundary [4, 34, 40].

To address these issues, RDMA-based KV stores bypass the OS and networking stack [6, 14, 57]. They are based on either traditional tree architectures [25, 47, 48] or learned indexes [26, 49] and offer the full set of KV operations, including range queries.

SHERMAN [25] is a write-optimized distributed B$^+$-tree over disaggregated memory that employs hierarchical NIC on-chip locking, client-side index caching, and lock-free reads to increase write throughput. SMART [39] optimizes this approach by addressing RDMA-NIC scale-up bottlenecks. XSTORE [49] couples a server-side B$^+$-tree with a learned cache on the client, which the client uses to predict the location of the KV pair on the server, saving RDMA round-trips. This allows range queries to complete with as few as two RDMA operations. The server retrains models in the background. ROLEX [26] addresses dynamic workloads by strictly controlling data movement within a learned tree, allowing asynchronous retraining of models. A leaf-atomic shift scheme keeps leaves sorted and minimizes interference.

These systems demonstrate that low-latency serving of ordered range queries can achieve high throughput. However, they either rely on stateful client logic or on multiple RDMA round-trips per request.

The discussed bottlenecks can also be overcome by minimizing the impact of the operating system or by using SmartNICs. MICA combines DPDK user-space networking with parallel data partitioning to bypass kernel overheads, allowing a single server to sustain nearly 100 MOPS [12, 28]. KV-DIRECT offloads the KV store to FPGA-programmable NICs by extending RDMA primitives [23]. It serves NIC-resident point lookups that scale with multiple NICs per server and reach microsecond tail latencies even at high throughput, albeit with constrained capacity. Both MICA and KV-DIRECT use hash-based data structures that achieve very high throughput but do not support range queries.

Some recent works [15, 37, 50, 55] also lack support for range operations but contribute detailed insights into the capabilities of current SmartNICs, which can offload increasingly complex KV-store mechanisms [16, 18, 41, 42, 45].

HONEYCOMB [29] implements a B-tree traversal within an FPGA on a SmartNIC that accesses a tree in host memory via DMA. It provides a KV-store interface, including ranges, but requires multiple expensive DMAs for uncached KV pairs. HIDPU [56] performs address translation for disaggregated storage and uses the Huawei Hi1823 SmartNIC's DPAs to map partially continuous address areas. HIDPU stores those mappings in specialized segments, accessed through learned models within the 4 MB NIC-side memory. This work is orthogonal to a general-purpose KV store in terms of features and requirements, relies on hashed segments, and does not support range queries across multiple mappings. Nevertheless, its performance benefits motivate offloading KV stores to SmartNICs. DALDEX, on the other hand, uses SmartNICs to offload the training of a learned index for persistent memory to save host overheads, rather than for network serving [46].

2.3 BlueField-3 and DPA Subsystem

The BlueField-3 SmartNIC is a ConnectX-based network adapter. In addition to high-speed network functions, it offers an off-path ARM CPU and an on-path DPA cluster, as well as 16 GB DDR5 memory (see Figure 2). The ARM CPU allows the BlueField-3 to run a dedicated operating system, e.g., for control plane management, and to access accelerator engines on the SmartNIC (e.g., de/encryption engines).

The DPA subsystem consists of 16 physical RISC-V cores, each running at 1.8 GHz and featuring 16 threads. Currently, only 189 of the 256 available threads can be used by application code [7]. DPA threads are hardware-scheduled at fine granularity, enabling high concurrency and packet-processing

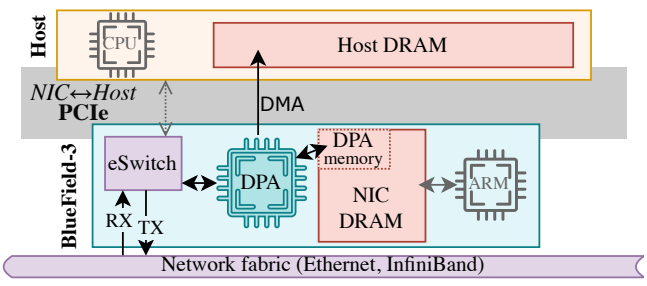

Figure 2: NVIDIA BlueField-3 architecture configured in NIC mode, allowing DMA access to host memory.

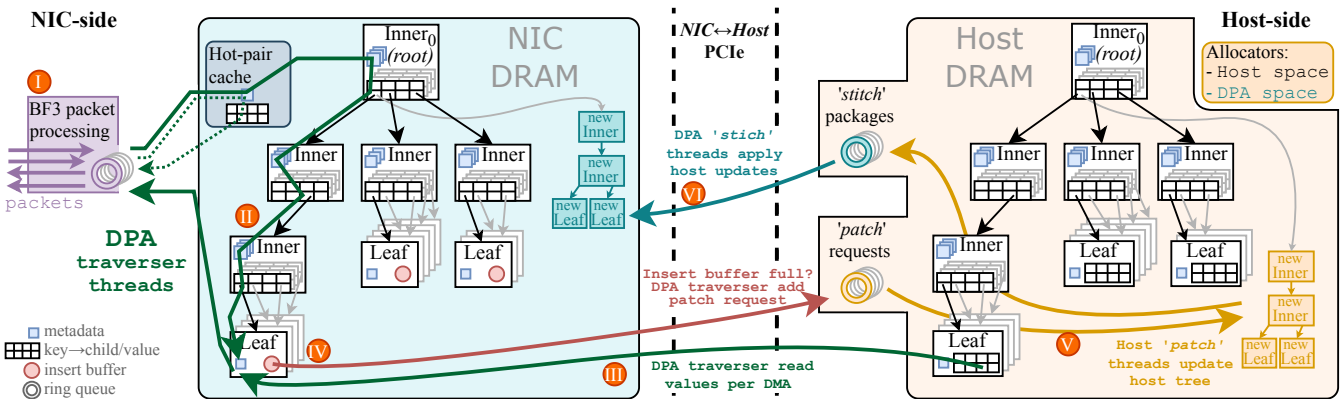

Figure 3: DPA-Store architecture: (I) Request packets are assigned on-path to a DPA traverser thread, which (II) walks a NIC-side learned index. (III) Values are fetched per DMA using leaf-level models, and (IV) inserts are placed in leaf-level insert buffers. (V) The host performs structural updates that are (VI) transactionally *stitched* back to the NIC without interrupting traversers.

pipelining.

Each DPA thread has a private L1 cache and shares 1.5 MiB L2 and 3 MiB L3 caches. The cache hierarchy is backed by a dedicated 1 GiB region of the BlueField-3 DDR5 memory, termed *DPA memory*. Additionally, the DPAs can access either the remainder of the BlueField-3 memory or the host memory, depending on the configuration. If the BlueField-3 is configured for DPA DMA access to the host, the ARM CPU is disabled [7].

DPA thread invocation can be controlled by applications on the host or on the ARM, or by defining a Transport Interface Receive (TIR) target for incoming network packets. For the latter, packet matching rules on hardware-defined fields (e.g., source or destination addresses, ports, or VLAN tags) can be used to filter relevant packets at line rate. Matched packets are placed directly into the L2 cache of the DPAs, allowing low-latency access to packet data. Unmatched packets are transparently placed on the default network path.

The BlueField-3 aims for a broad range of applications by featuring on-path and off-path compute, specialized accelerator engines, and dedicated memory. However, developing high-performance applications requires an in-depth understanding of the limitations of the architecture. For example, memory accesses to DPA memory induce a latency of nearly 500 ns and are significantly slower than DRAM accesses of a standard CPU [7]. In the context of this work, it is therefore important to minimize the number of memory accesses to the tree-based data structure, motivating the use of learned indexes with their limited number of memory accesses per tree level.

3 DPA-Store: Architecture & Implementation

In this section, we present DPA-Store, our remote KV store that supports range queries and allows stateless clients. DPA-Store uses the DPA subsystem of the BlueField-3 DPU to process incoming requests, avoiding all OS overheads and leveraging the high degree of parallelism of the DPAs.

We selected a learned index tree to reduce the number of accesses to the latency-constrained DPA memory. A DPA-memory access averages 465 ns [7], which is about five times the latency of a host DRAM access from a standard CPU. Therefore, the number of cache-line accesses per level dominates compute time and impacts performance as much as tree depth. A B$^+$-tree with the same fan-out as a learned-index tree uses binary search inside each node and accesses $O(\log n)$ cache-lines per level (see Figure 1). In contrast, a piecewise-linear learned index with error bound ε searches only a contiguous window $[p-\varepsilon, p+\varepsilon]$, which we bound to at most two DPA-memory cache-lines in inner nodes and at most three DMA-accessed cache-lines at the leaf level. We quantify this trade-off relative to a B$^+$-tree baseline in Section 4.2.5 and with a closed-form memory model in Section 4.2.6.

Given the restricted 1 GiB capacity of DPA memory, DPA-Store uses the high-capacity host memory to store values in a tree replica. Each lookup retrieves a value with a minimum number of DMA operations between NIC and host. Furthermore, the host is used for compute-heavy or blocking tree operations, such as model retraining and node splits. The host propagates tree updates to the NIC side via read-copy-update (RCU) semantics, enabling the DPAs to traverse the index tree without locks and maintaining consistency at all times.

DPA-Store employs thread-local caches for hot KV pairs. Insert and update operations are batched in a leaf-level insert buffer, reducing the number of tree updates propagated to the host. Figure 3 shows the overall architecture, which is discussed in detail in this section. We start with the NIC-side request path (Sec. 3.1), including the learned index and caching details, and then continue with the update cycle involving the host (Sec. 3.2).

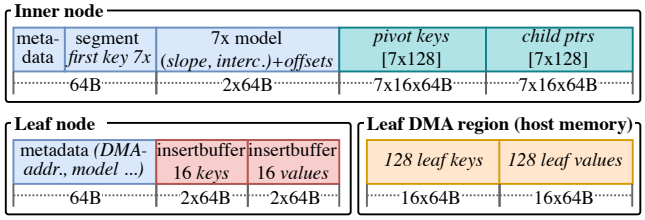

Figure 4: Layout of NIC-side nodes and leaf DMA regions.

3.1 Request Processing in the DPA Subsystem

DPA-Store uses the User Datagram Protocol (UDP) over Ethernet for transporting requests, with each request consisting of a single UDP packet. All requests are terminated on the DPA threads of the BlueField-3. We have defined packet matching rules to map each of the listening UDP ports to a designated DPA thread, effectively utilizing hardware steering rules to distribute requests over available DPAs. While every request can be served from every DPA thread, the port selection can be used by clients to facilitate load balancing or to improve cache utilization. By default, clients use a shared key hashing function so that the load is distributed uniformly across all DPA threads.

Incoming requests are consumed by the responsible *traverser* threads (176 in total), which descend the learned index tree until reaching the appropriate leaf node. Inner nodes contain seven learned models, where each model consists of a PLA over its interval, pivot keys, and pointers to the respective children (see Figure 4). We limit the number of pivot keys and child pointers to 128 per segment, chosen to match our selected ε values.

Partitioning inner nodes into seven segments allows us to fit the segments' first keys and node metadata into a single cache-line. While the traverser thread performs a binary search, comparing the operation key with the segment keys, the segment models are prefetched, overlapping compute with memory access. Having found the target segment for a key, the traverser thread evaluates the segment's model to obtain the predicted position. Again, during the computation, we prefetch the cache-lines containing the pivot keys of the current segment. The prediction is used to scan the pivot array to find the index and the pointer to the designated child node before the traverser thread moves to the next level. We store pivots and child pointers separately to compare more pivots per cache-line before incurring a single access to the child.

Once a traverser thread reaches a leaf node, it performs the requested operation. Leaf nodes contain a single learned model and an insert buffer with space for 16 key-value pairs. `INSERT`, `UPDATE`, and `DELETE` requests operate only on the insert buffer. The key-value pair (or key-delete marker for deletes) is appended using two atomic counters: one atomic increment takes place before and the other after the data write, allowing concurrent writers. We ensure that concurrent lookups read values before the corresponding key to guarantee correct mappings.

When a traverser writes into the last slot of the insert buffer, it sends a *patch* request to the host via DMA. The host can then perform the required tree operations and propagate the tree updates via *stitcher* threads back to the NIC-side tree (see Section 3.2). During this period, the NIC-side still has read-only access to the corresponding insert buffer. If a traverser cannot append to an insert buffer because it is full, the traverser re-enqueues the request for later processing.

`GET` requests must first scan the insert buffer, since it holds the most recent version of any updated or inserted KV pair. Each leaf node has a separate insert buffer, which is unlikely to be cached by the DPA thread. We prefetch it in parallel with the model computation, so a predicted position is ready for the DMA fallback in case of a miss. If the insert buffer contains the requested KV pair, the traverser exits early. Otherwise, the traverser scans the leaf keys array in host memory around the predicted position. To further reduce DMA latency, we also prefetch the keys before final scan range clamping. Once the key position in the array is found, the value is read from host memory via DMA.

`RANGE` requests reach the leaf node with the target key $k_{\min}$ in the same way as `GET` requests. Then, the insert buffer is scanned, and all values within the requested range are added to a temporary buffer, which later becomes the response. The traverser then scans the leaf keys array in host memory. When the scan reaches the end of a leaf, the traverser resumes at the next leaf by re-descending for the smallest key strictly larger than the last key returned.

Once the DPA thread finishes the request, it sends a response packet to the client. Response packets mirror the request layout but extend the type field with a status code and populate the value or range fields. For range responses, each packet carries at most 64 KV pairs to stay within a 1500-byte maximum transmission unit (MTU).

Tree traversal by DPAs is always lock-free because the tree structure is only changed on the host side, with changes being *stitched* back to the NIC via RCU semantics (see Section 3.2). Therefore, DPA threads do not stall during tree traversal, and the tree maintains consistency at all times.

3.1.1 Learned Index Parameters

We employ PLAs with slope a, intercept b, and prediction $p(k) = a \cdot k + b$. For inner nodes, each segment's model predicts the index of the child node at the next level. For leaf nodes, the model predicts the location of the value. After prediction, the linear search visits at most 2ε keys in $[p-\varepsilon, p+\varepsilon]$. We enforce an error bound of $\varepsilon_{\text{inner}} = 4$ for inner nodes (resulting in at most two cache-line accesses) and $\varepsilon_{\text{leaf}} = 8$ for leaf nodes (resulting in at most three DMA-accessed cache-lines).

We use the greedy algorithms provided by PGM [11] to compute model parameters from sorted keys. The selected

ε values are fixed and enforced during training. To optimize for node allocation overheads during updates, we restrict the size of inner node segments and leaf nodes equally to hold at most 128 pivot keys and child pointers.

BlueField-3 DPAs do not offer floating-point operations [35]. Hence, all arithmetic operations use fixed-point numbers for slopes and intercepts. To maintain precision over the full 64-bit key space, we temporarily expand operands to 128-bit during the calculations (see also [56]).

3.1.2 Hot Entry Caching on the NIC

Accesses to KV stores often follow a skewed distribution [1,5,8,53], so caching hot entries can save tree traversals and DMA fetches. Therefore, each DPA traverser thread maintains a cache (see Figure 5) consisting of (i) a three-way Bloom filter and (ii) a hash table composed of an array of buckets containing four KV pairs each. Each bucket is cache-line sized for better memory utilization. In this section, we detail the cache implementation.

Key-based per-thread caching. To ensure that the same keys are always processed by the same DPA thread, clients send packets to a designated DPA thread by selecting its UDP port via shared key hashing. Each key, therefore, has a single *home* traverser that owns its cache slot, so no cross-thread invalidation traffic is required when a key is mutated. The client also adds data needed for cache lookups, such as the Bloom hash index and the hash bucket index, to reduce the effort required for DPA computations. Each Bloom filter contains 256 bits, which is the maximum size that fits into the remaining cache-line of the traverser's thread context. The same cache-line also contains important metadata for controlling RX/TX queues and is therefore unlikely to be evicted from the thread's L1 cache. Thus, the Bloom filter incurs no additional memory access cost.

We set the cache capacity to 96 entries per traverser thread, leading to an average false-positive rate of 31%. A false positive only triggers one additional cache-line probe in the per-thread hash table and can never return an incorrect value because both keys and values are stored in the cache. With 176 traverser threads, a total of 16,896 entries can be cached. Assuming a dataset of 200M entries and an access pattern following a Zipfian distribution for $\alpha = 1$, these cached entries make up more than 50% of all requests.

Mutations and working-set shifts. `UPDATE` and `DELETE` requests on a cached key invalidate the corresponding cache slot before the response is sent. We deliberately do not update the Bloom filter on invalidation as removing a key would require either re-hashing all remaining keys in the affected bits or maintaining a counting Bloom filter. Both techniques would undermine our performance goals. We tolerate the resulting residual false-positive rate because its cost is bounded by a

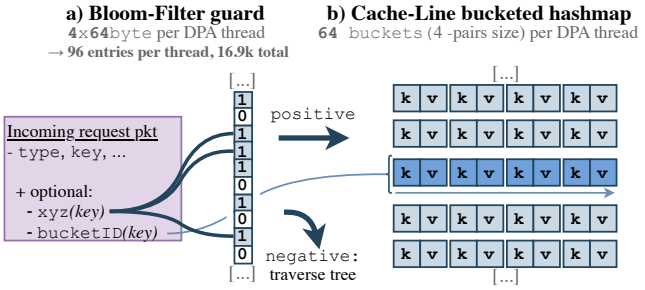

Figure 5: DPA-side hot-entry cache.

single extra hash-table probe. `INSERT`s of new keys are not actively admitted to the cache. A new key enters the cache only after a `GET` operation. This approach keeps `INSERT`s from polluting the cache with cold data. Since admission and replacement are local to the home traverser, working-set shifts are handled opportunistically, since new `GET` misses may replace old entries. Furthermore, a reset of a single traverser's cache and Bloom filter is safe and requires no cross-thread coordination.

In the case of rerouting overloaded keys to a non-home traverser (see Section 3.1.3), `GET` requests bypass the cache, whereas `UPDATE` and `DELETE` requests, as an exception, perform the required cross-thread invalidations.

Cache admission strategy. On receiving a `GET` request, the DPA thread randomly decides to admit the requested key, yielding an overall hit ratio of 25% on the workload with $\alpha = 1$. The chance of selection can be adjusted based on the workload characteristics to adjust adoption speed for new values. We treat this as a deliberate lightweight design choice under DPA constraints, leaving more sophisticated admission strategies for future work. We note that the Bloom filter and bucket array are highly optimized for cache-line access and any non-trivial admission policy must pay the cost of additional DPA-memory accesses on the hot path. To emphasize this, we evaluated a lightweight variant of the Space-Saving heavy-hitter algorithm [44] per traverser to drive cache admission. We scaled it to achieve hit ratios of up to 50% under a test workload with $\alpha = 1.1$. Due to the additional read and write per request, the overall `GET` throughput could not exceed that of the random admission strategy. With wider per-thread caches in future BlueField generations, the ability to use the full range of the 256 DPA threads, or a shared DPA-cluster admission service, we expect more sophisticated admission strategies and hotness tracking to become attractive.

3.1.3 Maximizing Delivery Rate

DPA-Store receives requests and sends responses as distinct UDP packets via Ethernet. We do not implement a connection-oriented transport such as TCP on the DPA. DPA threads are

invoked on packet arrival and run with a tight per-invocation compute budget. Additionally, they have only a few cache-lines of effective per-thread context (see Section 3.1.2). A full TCP proxy implementation would require per-flow session windows, retransmission buffers, sequence tracking, and time-driven retransmissions, all of which fit poorly into the event-driven execution model. It would also multiply per-thread state well beyond the L1 cache capacity of the DPAs. We consider the implementation of such a flow and congestion control framework overall unfit for DPA-Store and out of the scope of this work. We note that network-intercepting designs such as KV-DIRECT and MICA [23, 28] utilize UDP for similar reasons.

Retries and Idempotence. We assume that NIC-based KV stores are ill-suited to ensure reliable request transport. For example, DPA-Store has no knowledge about requests that were lost in transit due to the UDP-based transport. Therefore, DPA-Store expects a client to resend a request if it does not receive a response within a configurable time frame.

DPA-Store does not keep information about duplicate requests since doing so would require extensive metadata at every traverser and would work against the stateless-client design. We argue that the resulting transport semantics therefore permit duplicates. `GET` and `RANGE` requests are always safe to retry. Repeated `DELETE`s, `UPDATE`s, or `INSERT`s with identical arguments are handled by the host-side patcher, which ignores them in the insert buffers when recreating the respective leaf (Section 3.2). However, DPA-Store does not provide exactly-once semantics for write requests: if a write is delayed and interleaves with a conflicting write to the same key, the duplicate may be ordered after the conflicting write. If the application requires a specific ordering, including between `UPDATE`s or `INSERT`s on different keys, the client must serialize them.

A write is acknowledged to the client as soon as it has been appended to the leaf-level insert buffer, which is its linearization point in the delivered-request history. The written KV pair is then immediately visible to all subsequent `GET` and `RANGE` requests, irrespective of whether the updated subtree has already been stitched into the NIC-side index. Because every read consults the insert buffer prior to traversing the tree, and because stitches are atomic, the design of DPA-Store leaves no observable consistency gap for delivered requests.

Per-thread queues and overload. Each traverser has a 256-packet DPA receive queue, giving the DPA an aggregate capacity of 45,056 queued requests across 176 traverser threads. Whether queues fill up is a function of offered load relative to per-thread service time, not of the absolute number of clients: a single client that issues more in-flight requests than a thread can drain produces the same effect as many clients that collectively over-subscribe the same thread. In practice, we observe two regimes in which the queues fill up: (i) extreme key skew, where a single hot key is routed to its home traverser and a single thread becomes the bottleneck, and (ii) aggregate bursts that briefly exceed the average per-thread service rate of $\sim$187,500 `GET`s/s (33 MOPS / 176 threads).

To reduce loss in these regimes, clients can monitor their own response-to-request ratio as a local overload heuristic. For `GET` requests whose responses time out, a client may retry with an alternative hash that maps the affected key to a non-home traverser. The client may then throttle the rate of its outgoing requests. Each key has a single *home* thread that owns its cache slot (Section 3.1.2), so requests served by a non-home thread deliberately bypass the hot-entry cache. We understand this as a lightweight mitigation and leave the implementation of full congestion control for future research.

3.2 Update Cycle

This subsection explains how buffered writes become structural updates without blocking traverser threads. We introduce concurrent *patcher* threads on the host and *stitcher* threads in the DPA subsystem. DPA-Store guarantees that the NIC-side tree is consistent at all times by employing RCU semantics, so nodes are never modified in-place but exchanged via atomic pointer swaps. More complex tree updates are executed bottom-up until the procedure reaches the last node to be modified. Its address is updated in its parent via a pointer swap. This stitching procedure is transparent to all traverser threads.

The cache consistency protocols of the DPA subsystem guarantee that a node's address is always consistent over all DPA threads [35]. However, a traverser may descend an outdated subtree. To maintain overall consistency, epoch-based garbage collection reclaims outdated nodes and host-side DMA locations only after every traverser has moved on to its next request.

3.2.1 Host-Side Patching

The DPA traverser threads append insert, delete, and update operations to the per-leaf insert buffers. When an insert buffer becomes full, the corresponding traverser enqueues a patch request to its dedicated host-memory queue via DMA. Only the traverser that fills an insert buffer is allowed to emit a patch request, ensuring at most one patch request per buffer. On the host, a small number of *patcher* threads (four by default) process the patch requests and update the host-side tree. Patcher threads are not pinned to specific host CPU cores. Under sustained update load, they poll their queues to minimize patch-to-stitch latency. Under low update activity, the patcher threads `sleep` and are therefore subject to the OS scheduler. For read-only workloads, no patch requests are emitted, and host CPU involvement is therefore negligible.

If the patch request contains only `UPDATE` operations, the patcher modifies the values accordingly. In this case, the

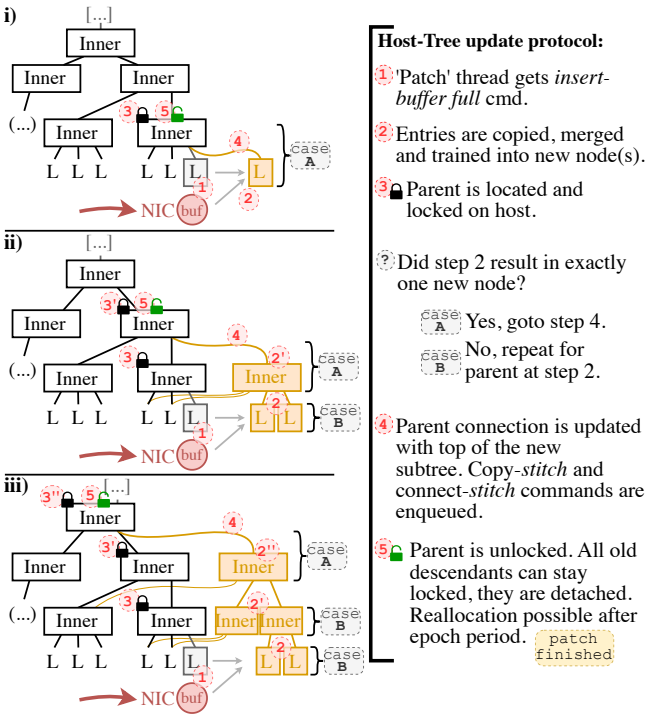

Figure 6: Host-side *patching* protocol.

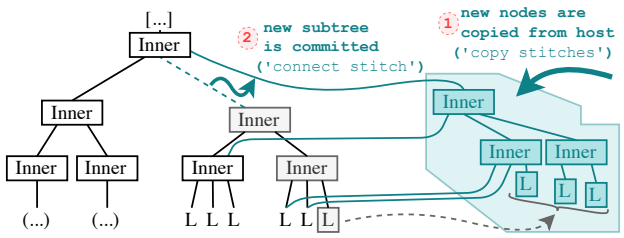

Figure 7: The NIC-tree stays valid while *stitches* are applied.

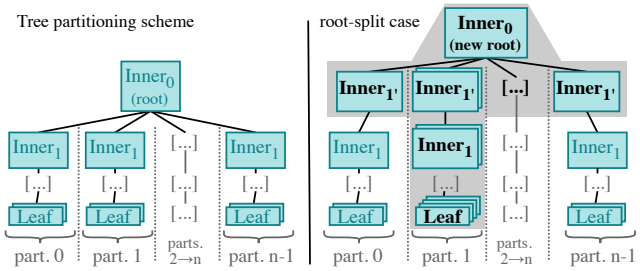

Figure 8: Tree partitioning to allow concurrent *stitches*.

patcher thread notifies the DPA-side stitcher threads to clear the insert buffer and perform no further action. If the patch contains `INSERT` or `DELETE` operations, the patcher first merges the key-value pairs with the existing leaf contents into a temporary, sorted array. The resulting array is then partitioned using PLA segmentation with error bound $\varepsilon_{\text{leaf}}$, where each segment becomes a new leaf node. This results in either a single segment that fits within the leaf capacity or multiple segments. When splitting becomes necessary, we limit segment sizes by a *retrain bound* (0.25×capacity). The resulting leaf nodes are sparsely populated, and future patch requests may be absorbed without another split, reducing the overall number of split operations.

After the leaf nodes are updated on the host, the patcher thread locates the parent of the original leaf by descending from the root. It then locks the parent for exclusive access, so that concurrent updates from sibling nodes must wait for the current one to finish. We avoid explicit parent pointers because maintaining bidirectional references under concurrency requires complex synchronization schemes.

If the retraining produced exactly one leaf, a single pointer swap in the parent is sufficient. Otherwise, the parent must also be rebuilt. We merge the new child pivots with the parent entries and apply PLA segmentation with $\varepsilon_{\text{inner}}$. PLA ranges in this step represent the inner-node segments. If the segmentation yields more ranges than the maximum allowed per node, multiple inner nodes are created, each containing a balanced number of segments. Similarly to splitting leaf nodes, we limit the number of segments within inner nodes using the *retrain bound*. Overall, this process is iterated bottom-up for every level of the tree, stopping only when the parent node does not need to be split or the root node has been reached.

Once the host tree contains the new nodes, we propagate the changes to the NIC-side tree using our stitcher threads. We enqueue the individual node updates to the stitcher queues as `COPY` stitches. Afterward, a single `CONNECT` stitch command is issued that translates to a single pointer swap, making previous `COPY` stitches effective (see Figure 6).

3.2.2 NIC-Side Stitching

The NIC-side DPA stitcher threads apply stitch commands submitted through stitcher thread queues. Stitcher threads process incoming `COPY` and `CONNECT` stitches in order, redoing the host-tree changes on the NIC side (Figure 7). The host has pre-calculated every destination address in the DPA memory space, and the stitcher threads do not have to allocate any memory. Instead, they execute the provided commands on the pointers passed from the host. To enable concurrent stitching, we partition the tree beneath the first level of inner nodes (Figure 8, left). Each parallel stitcher thread (four by default) works on a dedicated partition of the tree. The host is aware of the mapping of stitcher threads to partitions and assigns stitch commands accordingly.

Ordering of stitches and single-thread ownership eliminate most race conditions. However, root-level updates can produce conflicting stitches: (i) a `CONNECT` could reference a node that has not yet been installed by a corresponding `COPY` stitch, or (ii) newly copied and connected nodes could refer-

ence child nodes that are not yet available on the NIC-side tree. Therefore, we have implemented two safeguards. First, we delay the execution of stitches targeting nodes originating directly from a root split until their destination is available. We do this by using unique identifiers (UIDs) to probe whether the target node of a `CONNECT` stitch is already in place. Second, the stitch that installs an updated root node is blocked by a queue fence until earlier updates have completed. To preserve the partitioning scheme, the host ensures that root splits maintain balanced partitions and distribute new top-level nodes across all partitions (Figure 8, right-hand side).

3.2.3 Memory Reclamation

NIC-side subtrees become obsolete after a new version is installed using `COPY` and `CONNECT` stitches, in which case the leaf memory must eventually be freed. However, traverser threads may still descend into subtrees containing the affected nodes. Therefore, we perform epoch-based reclamation of obsolete nodes, using all DPA threads' incoming and outgoing packet counters to compute a global epoch value.

3.2.4 Bulk Loading

Bulk loading partitions a set of sorted KV pairs into PLA segments for the configured leaf error bound $\varepsilon_{\text{leaf}}$ on the host. Each PLA segment becomes a leaf node. Once all leaf nodes are available, their first keys form the scaffolding for building upper levels. We then apply the same PLA construction bottom-up. The first keys of child nodes serve as input for constructing the nodes at the next-higher level, with an error bound of $\varepsilon_{\text{inner}}$ to regulate tree fan-out. This recursive process continues until a single inner node remains, which becomes the root node.

Throughout bulk loading, the host enqueues `COPY` and `CONNECT` stitch commands to the stitcher queues. The stitcher threads assemble the initial tree following the enqueued host commands, ending with a final root-pointer stitch that makes the structure visible to traverser threads. As the host implicitly determines the tree partitions by selecting a stitcher queue for every tree update, no further actions on the NIC side are necessary.

4 Evaluation

In this section, we first provide an overview of the experimental setup before presenting an in-depth analysis of DPA-Store. Finally, we compare DPA-Store with ROLEX [26], a state-of-the-art RDMA-based KV store.

4.1 Experimental Setup

Unless stated otherwise, our test environment consists of one server and six client machines connected through a 100 Gb/s Dell PowerSwitch S5232F. The switch is Ethernet-based and supports RDMA over Converged Ethernet (RoCE). The clients use dual-socket AMD EPYC 7301 CPUs (32 cores) with Mellanox ConnectX-5 NICs. Clients use DPDK [12] for request transmission, bypassing OS bottlenecks. The server uses a BlueField-3 B3140L on a system with a 32-core AMD EPYC 9354P and 128 GB of DDR5 memory. In all experiments, including DPA-Store, the BlueField-3 operates in NIC mode, i.e., with DPA DMA access to the host and disabled ARM cores. When the DPA subsystem is not in use, the BlueField-3 behaves like a ConnectX-7 NIC. This allows us to evaluate related work on a conventional host/NIC setup. At the same time, DPA-Store executes on the same hardware and software stack, ensuring a fair comparison.

Many learned indexes are sensitive to key distributions. We ensure rigorous testing of our learned index by using the common SOSD datasets [2, 31]. They consist of the synthetic *sparse* and *dense* datasets, as well as real-world datasets derived from Facebook (*face*), Amazon (*amzn*), Wikipedia (*wiki*), and OpenStreetMap (*osmc*) workloads. The *sparse* dataset randomly selects keys from the full 64-bit range, while our *dense4x* selects 50M keys from a consecutive range keys four times that large. Unless stated otherwise, we bulk load 25M entries before each experiment and use a value of $\alpha = 0.99$ for skewed key popularities according to Zipf's Law. Similar to most related work, we use 64-bit keys and 64-bit values.

We averaged throughput values over four runs for long-running benchmarks (e.g., `GET`) and eight runs for short-running ones (e.g., inserts of new keys). Latency measurements were gathered from all clients and combined. Client start times were synchronized via MPI. Measurements showed a standard deviation of less than 5% for throughput and less than 9% for latencies.

4.2 DPA-Store Evaluation

In this section, we first investigate the memory consumption of DPA-Store. We then analyze the effects of the learned-index parameters, client parameters, and DPA/host thread counts on throughput and latency. Using our findings, we deduce default values for DPA-Store. Furthermore, we analyze whether different BlueField-3 models or changes to the BlueField-3 hardware influence performance.

4.2.1 Memory Consumption

We evaluated the overheads of the index structure compared to the raw KV data on the host side for 50M inserted KV pairs (Table 1). Since *face* and *osmc* show the highest memory consumption and overheads for values of $\varepsilon_{\text{inner}} = 4$ and $\varepsilon_{\text{leaf}} = 8$, we demonstrate that their memory impact can be significantly reduced with $\varepsilon = 16$ for both, inner and leaf nodes. In the following benchmarks, we select the larger values for ε for

Table 1: Relative overhead and NIC-side memory consumption for 64-bit key distributions and 50M entries.

Dataset (50M)	Rel. overhead of index	Overall DPA memory req.
sparse	32%	207 MB
dense4x	26%	169 MB
wiki	23%	147 MB
amzn	54%	346 MB
osmc	74%	472 MB
face	104%	672 MB
osmc ($\varepsilon_{in} = \varepsilon_{lf} = 16$)	35%	228 MB
face ($\varepsilon_{in} = \varepsilon_{lf} = 16$)	52%	332 MB

those datasets.

Compared to other learned indexes, DPA-Store chooses small ε values to minimize the cost of searching for the key around the predicted position in latency-constrained DPA memory. For example, ROLEX uses $\varepsilon \in \{128, 256\}$, allowing it to maintain much larger nodes and thus reducing per-node memory overheads. ROLEX reports a metadata overhead of 6.5% for cache data on a 500 M dataset, assuming 16 B KV pairs [26]. However, it requires all clients to hold a separate cache, increasing memory overhead proportionally to the number of clients in addition to the number of keys.

4.2.2 DPA and Host Thread Counts

In this subsection, we evaluate the impact of a varying number of traverser, patcher, and stitcher threads on the performance of DPA-Store. Figure 9 (left) shows the throughput and latencies of a `GET`-only workload with uniform key popularity on the sparse dataset. We observe that the throughput scales proportionally to the number of traverser threads. Latencies exhibit higher variance with few traverser threads but stabilize with a larger number of threads. This is because these few threads are overwhelmed by the number of incoming packets, causing them to fail to process requests in a timely manner. For values larger than 16, multiple DPA hardware cores are used, resulting in lower latencies.

Throughput increases slightly beyond 176 threads, which fully occupy eleven hardware DPA cores. The remaining usable 13 DPA threads reside on the next, partially-used physical core. We found that using the last available hardware core for both traverser and stitcher threads leads to worse throughput for `INSERT` operations. This is a result of the hardware scheduler that prioritizes NIC doorbell events. These events invoke traverser threads and therefore stall the execution of stitchers. We observed a 14% degradation in throughput for `INSERT` when mixing both types of DPA threads on one core. For both `INSERT` and `UPDATE` workloads, throughput flattens beyond four patcher threads and four stitcher threads. We note that the throughput of host-side patcher threads is limited by the NIC-side stitcher threads (see Section 4.2.8 for details).

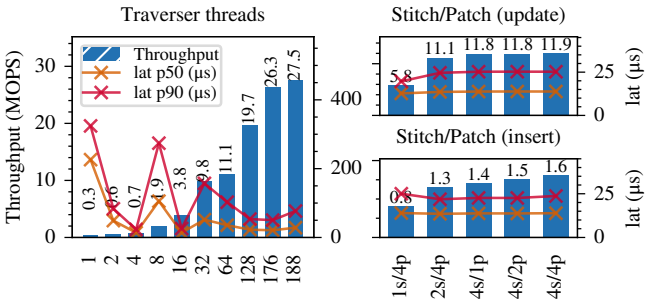

Figure 9: DPA-store throughput and latencies for different numbers of traverser, patcher, and stitcher threads. The left plot shows the number of traverser threads for `GET` requests. The right plot varies patcher/stitcher thread count for `INSERT`- and `UPDATE`-only workloads with 176 traversers.

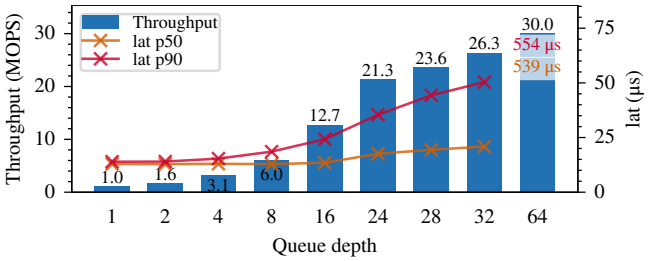

Figure 10: DPA-Store `GET` throughput and latency using different client-side queue depths.

Lessons learned: Prioritizing NIC doorbell events by the BlueField-3 requires partitioning the 189 available DPA threads into 176 traverser threads on 11 physical cores and four stitcher threads on a dedicated core, leaving nine threads unused. Furthermore, we configure DPA-Store to run four host-side patcher threads.

4.2.3 Client-Side Queue Depth

In the following, we investigate the impact of the client-side queue depth and the resulting total number of in-flight requests on throughput and latencies. Each of the six client nodes is running 31 threads. Threads issue between 1 and 64 concurrent requests. NIC-side hash tables ensure that outgoing and corresponding incoming packets are handled by the same thread and that requests lacking an acknowledgment are resent after a timeout. Figure 10 shows how client-side queue depth affects `GET` performance under a uniform key distribution.

Throughput increases significantly up to a client queue depth of 32 with a maximum of 5,952 in-flight requests. After this point, throughput continues to rise; however, latency increases beyond acceptable levels because the processing rate of DPA-Store cannot keep pace with the request submission rate. Accordingly, a queue depth of 32 is used for `GET`

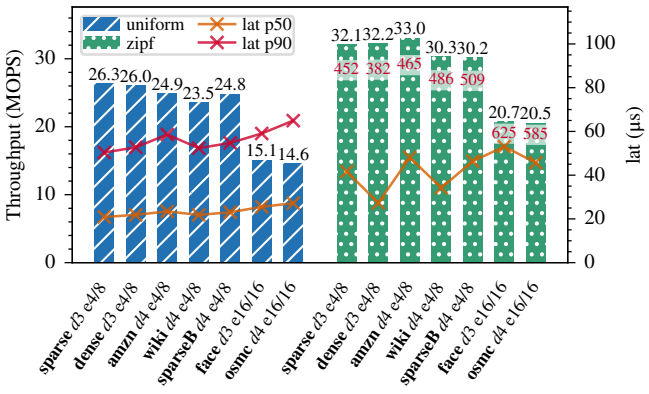

Figure 11: Results of DPA-Store using `GET`-only workloads.

requests throughout all subsequent experiments. We similarly set a queue depth of 18 for `INSERT` and `RANGE` workloads. Integrating adaptive flow control is left as future work.

4.2.4 Effect of Tree Depth and Index Error Bound

We evaluate the effect of tree depth and the error bound ε on the throughput and latency of DPA-Store. To demonstrate the effect of the tree depth, we include the *sparseBig* dataset in this section. Bulk loading *sparseBig* (consisting of 50M KV pairs) results in a tree depth of four, whereas *sparse* has a depth of three. Figure 11 shows `GET` performance for different datasets under uniform and skewed key popularity. Under uniform access, we observe a slight reduction in throughput for deeper trees because of the extra accesses to an additional inner node. For the datasets *face* and *osmc*, choosing a larger ε value causes a more significant performance degradation. This illustrates the impact of additional cache-line accesses required when verifying the model predictions (see also the DPA-Store performance model in Section 4.2.6).

With skewed key popularity, the hot-entry cache increases throughput by up to 30%, which meets our expectations in Section 3.1.2. However, tail latencies increase because some traverser threads receive a disproportionate share of requests, leading to longer wait times in the DPA queues.

4.2.5 B$^+$-tree Comparison

We chose a learned index as the fundamental data structure behind DPA-Store. To motivate this decision, we compare the `GET` throughput and latencies of the learned index tree against a B$^+$-tree baseline, measured directly after bulk-loading the data. For the B$^+$-tree we set $\varepsilon = \infty$ during construction, leading to fully packed 2 KiB nodes with 128 entries each. For lookups inside nodes, the B$^+$-tree uses standard binary search starting from the middle of the node; it does not extrapolate the start position from split keys in the parent. We deliberately keep the baseline at this canonical form because adding parent-key interpolation would itself constitute a partial learned index

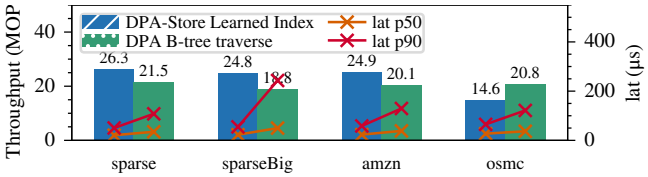

Figure 12: Comparing B$^+$-tree and learned DPA traversals.

and blur the comparison. We use 176 traverser threads for both variants, matching the DPA-Store configuration. The corresponding B$^+$-tree metadata overhead is about 145%.

Figure 12 shows that latencies are mostly higher for the B$^+$-tree than for the learned index. With the default ε, the learned index achieves higher throughput on the *sparse*, *sparseBig*, and *amzn* datasets, even though the more densely populated nodes in the B$^+$-tree yield lower tree depths. The *osmc* dataset is, in our default configuration, trained with $\varepsilon = 16$ to keep the metadata footprint manageable (see Table 1). At this setting the B$^+$-tree wins on raw throughput because the cost of scanning a 32-key learned window approaches that of binary search over a packed node, although median latency remains slightly worse due to a suboptimal balance between compute and memory accesses. Using $\varepsilon_{\text{inner}} = 4$ and $\varepsilon_{\text{leaf}} = 8$ here increases NIC-side metadata substantially. The trade-off is therefore governed by ε and the resulting in-node scan length. Small ε exploits the contiguous-window property of the learned index, while larger ε reduces the effect, making a compact B$^+$-tree competitive.

4.2.6 Analysis of `GET` Operations and Memory Accesses

The previous two subsections have shown that DPA-Store depends heavily on the performance of the memory subsystem, particularly the access latency of the DPA-addressable DDR5 memory. Prior work [7] reports average memory access times of 465 ns for DPA memory, compared with 910 ns for DMA accesses to host memory. In the following, we model the minimal duration of a full tree traversal, assuming our default parameters of $\varepsilon_{\text{inner}} = 4$ and $\varepsilon_{\text{leaf}} = 8$.

The first cache-line accessed in every inner node includes the node's metadata and the segments' first keys. The second cache-line contains each segment's model. The next one or two cache-lines (depending on the node fullness) contain the pivots, and the fifth cache-line contains the child pointer. Assuming nodes are 50% full on average, this results in an average of 4.5 cache-lines per inner node. Similarly, leaf nodes require one cache-line for metadata, up to three DMA operations to fetch the key, and one DMA operation to fetch the value. Note that we assume insert buffers to be empty in this analysis, requiring no additional memory accesses.

For a tree of depth 3, we access two inner nodes and one leaf node, resulting in overall memory access times of

$$2 \cdot \delta_{\text{inner}} + \delta_{\text{leaf}} = 2 \cdot 4.5 \cdot 0.465\,\mu\text{s} + 0.465\,\mu\text{s} + 2 \cdot 0.91\,\mu\text{s} = 6.47\,\mu\text{s}$$

Note that the cache-lines for the leaf key are sequential on the host and collapse into a single DMA. Assuming DPA scheduling overlaps one thread's computation with another thread's memory accesses, the maximum throughput is $176/(6.47\,\mu\text{s}) = 27.2$ MOPS, provided none of the relevant cache-lines are cached.

If we further assume the root node's first cache-lines (node metadata, segment keys, and models) are cached for all DPA threads, and the two memory accesses are replaced by L3 access times of 64 ns each, we compute $\delta_{\text{root}} = 1.2905\,\mu\text{s}$ and obtain a maximum throughput of 31.05 MOPS. While this model is an approximation, our evaluation of DPA-Store achieves similar results (e.g., Figure 9).

As detailed in Section 3.1, we optimized the traverser path to prefetch cache-lines optimistically, overlapping memory access with compute. Due to the relatively weak per-thread compute capabilities, we measured an improvement of 19% for this optimization.

Lessons learned: `GET` performance is limited by the access latencies to DPA memory and could increase significantly if memory access latencies were comparable with latencies of standard CPUs. For memory latencies of 100 ns, `GET` latencies could decrease to less than 2.82 μs and throughput could increase to more than 62 MOPS. Decreased memory latencies would also allow increasing ε values and becoming more memory efficient.

4.2.7 Bulk Load Performance

We evaluated the bulk load throughput using a 50M *sparse* dataset and four stitcher threads. Traverser threads are disabled during bulk loading. The full bulk load is finished on the host after an average runtime of 1,643 ms. The copying and processing of stitch requests accumulates to 1,605 ms. The bulk load copies 192 MB of tree data into DPA memory, resulting in a host-to-DPA memory bandwidth of only 120 MByte/s. This low bandwidth arises because fine-grained writes targeting scattered addresses cannot be issued efficiently from the host directly to DPA memory. Instead, the stitcher threads have to poll for incoming stitches via DMA and then first load the data into the stitcher thread's local context before writing it into DPA memory.

Lessons learned: Bulk load performance and, as shown in the following section, insert performance could be greatly increased if the BlueField-3 supported efficient transfers from host memory to DPA memory.

4.2.8 `INSERT`/`UPDATE` Performance

We evaluate throughput and latency for `INSERT` and `UPDATE` operations, mixed varying proportions of `GET` operations, using the *sparse*, *amzn*, and *osmc* datasets (see Figure 13).

Stitch requests for `UPDATE`-only patches require no data to be copied to DPA memory. Instead, only the host-side values are updated, and a stitch command resets the original DPA leaf's insert buffer. Here we reach up to 12.1 MOPS. We observe particularly low throughput for `INSERT` operations across all three datasets, with at most 1.7 MOPS. As soon as nodes are retrained on the host side from the leaf upward, `COPY` stitches are transferred. For leaves, only model parameters and DMA addresses are transferred, while inner nodes copy their complete pivots and child pointers. As we already saw for the bulk load performance, which uses the same stitching method as runtime updates, we are heavily constrained by the BlueField-3's inability to efficiently write data from host to device. The stitching bandwidth during runtime in an `INSERT`-heavy scenario cannot exceed the low rate measured for bulk loading. Although the polling stitchers perform below our expectations, future SmartNIC generations with a stronger host-to-DPA write path could address this limitation.

To rule out that the host-to-DPA bandwidth limit is an artifact of our DPA-pull stitching design, we also investigated a host-initiated copy-stitching path implemented with NVIDIA's FlexIO APIs [35, 36]. In this variant, the host directly pushes stitch payloads into DPA memory rather than enqueueing pointers that DPA stitcher threads pull via DMA. This removes the polling stitcher and one DPA-side memory hop from the critical path. The host-pushed path delivered comparable, but not better, host-to-DPA throughput, and `INSERT` performance did not improve. This suggests that the limiting factor is the underlying host-to-DPA write path on BlueField-3 rather than the direction of the copy, so we retain the simpler DPA-pulled stitching protocol.

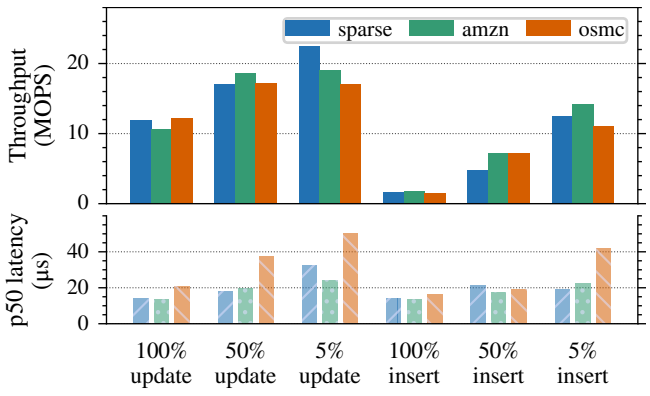

Figure 13: DPA-Store performance of `UPDATE`s and `INSERT`s.

4.2.9 BlueField-3 Model Comparison

We ran tests on an additional setup to evaluate the B3220 model of the BlueField-3 family. Unlike the B3140L with single-channel memory and one network port, the B3220 features dual-channel DPA memory and two network ports. The number and type of DPA cores, however, remain the same. Unfortunately, comparable client nodes were unavailable, and we had to generate requests with another BlueField-3 B3220 NIC via DPA programs. This allowed us to saturate the throughput of DPA-Store, but the client card lacked the compute performance to evaluate response latencies. We also disabled the restriction on the number of in-flight requests for the B3140L. Therefore, the throughput of DPA-Store was saturated for both models, enabling a fair comparison.

Figure 14 shows `GET`-only workloads on different datasets with uniform and skewed key popularities, for both NICs. We observe that throughput for the *sparse* dataset with a uniform key distribution is nearly identical for both NICs. This shows that `GET` throughput is dominated by DPA memory latencies and that moving from single- to dual-channel memory has no direct effect on DPA-Store. DPA-Store's `INSERT`, `UPDATE`, and `RANGE` throughputs also do not differ significantly.

However, with a skewed key distribution for `GET`-only workloads, The B3220 shows higher throughput than the B3140L, reaching 48.5 MOPS compared to the B3140L's 39.9 MOPS. Additionally, we ran ping tests in which the receiving DPA thread returns packets without any memory access. For ping, the B3140L model reached 44.9 MOPS, whereas the B3220 delivered 69% higher throughput. Since cached requests trigger only a single memory access and uniform accesses remain unchanged, these results demonstrate that the dual-port B3220 features stronger packet-matching hardware and therefore can process small requests faster.

4.3 Comparison with ROLEX

We compared DPA-Store against ROLEX [26], the fastest RDMA KV store that runs on modern hardware and is available for comparison, to highlight the effects of different architectural choices. We evaluated ROLEX in the same configuration as DPA-Store. This led to better throughput results for ROLEX compared to its own published results but also increased its latencies. We evaluated both solutions using YCSB workloads [8] consisting of six scenarios: A (50% reads, 50% updates), B (95% reads, 5% updates), C (100% reads), D (95% reads, 5% inserts), E (95% range, 5% inserts), and F (50% reads, 50% read-modify-update). Additionally, we include experiments for 100% inserts and 100% range queries covering 10 adjacent keys. The experiments were executed using *sparse*, *amzn*, and *osmc* datasets, which resulted in different tree depths and error-bound configurations for DPA-Store (see Figure 11). We measured with a uniform key distribution to reduce the effect of the hot-entry cache.

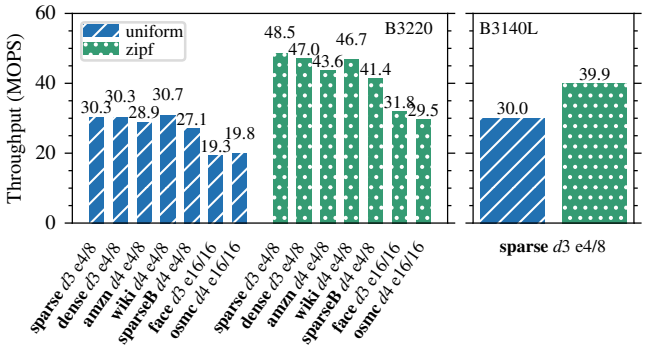

Figure 14: `GET` throughput for different BlueField-3 models.

Figure 15 shows that DPA-Store exceeds the throughput of ROLEX for the *amzn* and *osmc* datasets for YCSB-A and for all `RANGE`-only workloads. For `GET`-only workloads, DPA-Store achieves higher throughput and lower latencies compared to ROLEX on *sparse* and *amzn*. However, ROLEX achieves better results on *osmc*, where its larger values of ε are more suitable.

ROLEX shows higher throughput for `INSERT` workloads. Its clients can issue `INSERT` requests via one-sided RDMA writes directly into large server memory buffers and lazily decouple model retraining, so the structural update cost is spread over the client side instead of being concentrated in a host-to-DPA copy path. This is an effective design for insert-heavy workloads, but it relies on stateful clients that maintain learned-cache metadata and issue one-sided RDMA operations. The client-side cache also scales with the number of clients. DPA-Store makes the opposite trade-off. Clients only select a DPA traverser by hashing the key and sending a request packet, while the SmartNIC and host maintain the index. As a result, DPA-Store's `INSERT` throughput is limited by copying new node contents from the host back into DPA memory (see Section 4.2.8). The `INSERT`-only workload is therefore a worst-case comparison.

In workloads where inserts of new keys are infrequent compared to `GET` or `RANGE` requests, such as YCSB-D and YCSB-E, DPA-Store nearly reaches ROLEX's performance. Updating existing keys is less restricted by the host-to-DPA bottleneck because raw updates do not change inner nodes, and no additional copy stitches are sent. Consequently, even for high update ratios, as in YCSB-A, DPA-Store can surpass ROLEX for *amzn* and *osmc*.

Figure 15 shows lower latencies for DPA-Store compared to ROLEX in all experiments. While DPA-Store may cross the relatively slow PCIe bus to the host for DMA access during `GET` operations, the hot cache and insert buffer reduce the number of DMA operations on the lookup path. ROLEX requires RDMA operations for every request and, in uncached or mispredicted cases, additional round-trips. This difference is particularly visible for higher numbers of in-flight requests, where the extra RDMA traffic causes contention delays.

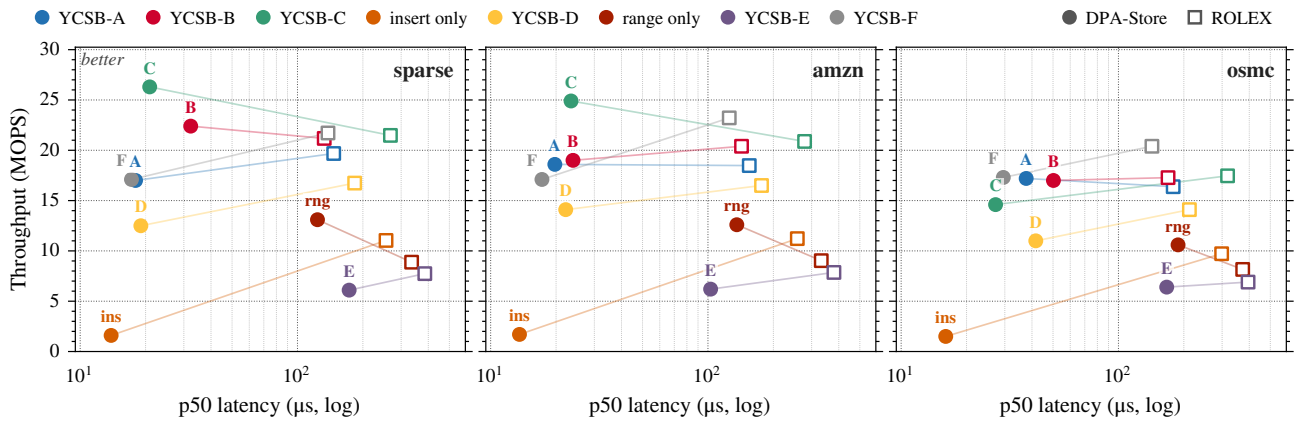

Figure 15: YCSB workloads on *sparse*, *amzn*, and *osmc* datasets. Each of the three subplots shows the throughput and latency for all workloads as 2D scatter. Connected points represent DPA-Store's and ROLEX's performance for the same workload.

Lessons learned: DPA-Store is, at the cost of more complex NIC-side hardware, faster for most workloads than the state-of-the-art ROLEX KV store while keeping clients stateless. Its main weakness is lower `INSERT` throughput, which is bounded by the BlueField-3 host-to-DPA write path. A future BlueField generation with a better DPA memory interface and efficient host-to-DPA transfers could remove this bottleneck without changing DPA-Store's client model.

5 Conclusion

We have proposed DPA-Store, a KV store residing on a SmartNIC that removes OS latencies from all operations while keeping clients stateless. By carefully analyzing the internal hardware of the BlueField-3, we have designed DPA-Store to maximize operation throughput. We have offloaded computation-heavy learned-index maintenance to the host while keeping tree traversal lock-free and highly concurrent. We have shown that DPA-Store is competitive with ROLEX and that a better DPA memory interface and host-to-DPA transfer path could significantly improve these results.

FARLock: Asymmetric RDMA Locking Made Fair

Yuehao Hu Jiatang Zhou Tianzheng Wang Keval Vora

Simon Fraser University
British Columbia, Canada

Abstract

Distributed locking is essential for coordinating access to shared resources in modern RDMA-based distributed systems. While state-of-the-art RDMA locks can deliver high-performance by introducing asymmetry (*i.e.*, treating requests that are local and remote to the lock differently), they often trade off fairness as they fail to grant locks in the expected first-come first-serve manner. This can lead to long delays for critical tasks, missing service level objectives.

We present FARLock, a fast and fair RDMA lock to solve this problem. Drawing inspiration from ticket and MCS locks, FARLock employs tickets and MCS-style handover to ensure that locks are granted strictly by arrival order. Through careful coordination between request queues and the ticket, FARLock provides strong fairness semantics with high performance. Our evaluation on a range of workloads shows that FARLock guarantees fairness and achieves lower latencies compared to prior state-of-the-art. Incorporating FARLock in a recent RDMA-based distributed indexing solution improves its query tail latencies.

1 Introduction

Distributed locks are a fundamental building block of distributed systems to coordinate accesses to shared memory across server boundaries. Importantly, they must be carefully designed to deliver both strong performance (i.e., low-latency lock acquire/release operations) *and* fairness among requesters (*i.e.*, locks are granted in a first-come-first-serve manner [15]). While both are critical and desirable, offering strong fairness is particularly important for a broad range of systems—such as database systems [8, 11, 24, 33, 35, 38], key-value stores/indexes [3, 20, 22, 23, 32, 34, 42], and distributed file systems [6, 25, 36]—to reach their service level objectives. For example, it would be unacceptable if a mission-critical database query is delayed due to unfair granting of locks that govern shared buffer accesses in a multi-tenanted database system [27]. As emerging applications [5, 19, 21, 29, 31, 39] continue to pose stringent deadline and real-time requirements, the need for fair distributed locking has become crucial to prevent biases and delays.

RDMA for Efficiency. Modern distributed systems are increasingly built around remote direct memory access (RDMA) that enables ultra-low latency and high throughput. For example, RDMA over InfiniBand HDR can deliver 200Gb/s of bandwidth and μs-level latency [2]. With kernel bypassing and zero-copy data transfer, RDMA allows machines to communicate directly with each other's memory without involving their CPUs. RDMA also provides one-sided atomics such as RDMA compare-and-swap (CAS) that offer similar interfaces to their CPU-based counterparts. These make RDMA atomics an attractive choice for designing distributed locks which can be hosted on a server and accessed via one-sided RDMA by a remote server without involving the host's CPU.

Problem: Efficiency at the Cost of Fairness. RDMA atomics guarantee atomicity only when concurrent atomic operations execute on the same RDMA-enabled NIC (RNIC) [30] as they bypass the CPU. As a result, atomicity is not guaranteed when RDMA atomics contend with local CPU memory accesses. To preserve RDMA atomicity, even local accesses must be routed through the host's RNIC [41], but this indirection is expensive than a direct local access. For RDMA-based locks, using loopback for local lock acquisitions introduces unnecessary latency and becomes a poor choice for performance-critical coordination.

Recent work [4] mitigates this issue by introducing asymmetric RDMA locking where lock requests targeting a lock that is local to the requesting thread are handled separately from those that target a lock stored on another server. This way, local requests can perform local CPU-based atomics without involving expensive RDMA operations, which are only required by remote requests. Given the large latency gap between local and RDMA memory accesses ($\sim$100ns vs. μs-level), this can greatly improve overall lock operation performance. As we elaborate in Section 2.3, however, it sac-

rifices fairness as the lock requests get reordered, leading to biased access patterns that no longer reflect true arrival order.

Our Solution. In this paper, we present FARLock, an efficient and fair RDMA lock. FARLock is the first RDMA lock that ensures lock requests are granted in the expected first-come first-served order while eliminating loopback for local requests. FARLock's design is inspired by two classic designs and combines the advantages of both: (1) ticket-based acquisition found in classic ticket locks [15] and (2) the queue-based handover strategy of the MCS lock [26]. Similar to prior work [4], local and remote requests are handled differently in FARLock, allowing them to be separately optimized and using RDMA operations only for remote requests. However, each request additionally draws a ticket from a global counter, and locks are granted in ticket order. By globally ordering all requests (local and remote) based on their arrival time, FARLock ensures fairness.

However, designing FARLock correctly with queue-based handover between requesters and global ticket ordering is challenging. Naïvely merging the two strategies could lead to inconsistency issues where the ordering of requests in queues is different from their ticket ordering. This is problematic as granting locks in ticket order would require searching the right requester in queue and handling the resulting queue manipulation properly.

To overcome this challenge, we identify the *ordering consistency* property that dictates a correlation between the ticket ordering of requests and their respective queue ordering. The property provides flexibility between local and remote requests, allowing each type to be managed in a customized manner. FARLock ensures the property is maintained throughout execution. This is achieved by reversing the order of ticket acquisition and enqueuing, and coordinating ticket assignment based on each request's position in the queues. The benefit of this approach is that it requires no additional atomicity or coordination to maintain ordering consistency.

The next challenge is coordinating local and remote requests as they safely acquire their tickets, which is non-trivial because they access the ticket differently (the local requester does not use RDMA). With ordering consistency, this challenge reduces to mutual exclusion between just two requesters, *i.e.*, the head of the local and remote queues. This allows us to leverage the Peterson's lock [28] which requires no atomics and can be implemented entirely with simple reads and writes, making it an ideal fit.

FARLock is scalable, offering low-latency in less contention scenarios thanks to RDMA, and maintaining low-latency under high contention by avoiding ordering biases. In addition, we propose a *fairness-preserving grouping* mechanism to reduce the overhead of accessing the Peterson's lock during high-contention workloads. Our mechanism groups same-type requests by sharing the Peterson's lock, allowing multiple requests to acquire their tickets together. FARLock then ensures ordering consistency by granting locks in ticket order, similar to the usual case.

On top of the mutual exclusion support provided by FARLock, we further present an optimistic reader lock extension that only requires minor changes.

We evaluated FARLock's performance on a cluster of 10 RDMA-enabled machines using various microbenchmarks and RDMA locking strategies. Our results show that FARLock achieves lower tail latencies than all other RDMA locks. This comes from its efficient handling of local requests compared to designs that rely on the expensive loopback mechanism, and from avoiding the reordering delays seen in unfair locks that eliminate loopback but sacrifice fairness.

To understand FARLock's effectiveness in practice, we further incorporated FARLock in Sherman [32], a recent high-performance RDMA-based distributed B+-tree. Our deployment showed that Sherman benefits from FARLock's unbiased lock granting especially during write-heavy scenarios as the tail latencies improve by up to 14×.

2 Background and Motivation

In this section, we give the necessary background and motivate our work. To set the stage, we first introduce shared-memory locking and RDMA which today's distributed locks are built upon. We then expand on the implications of RDMA on locking to motivate our work.

2.1 Shared-Memory Locking

Locking mechanisms for shared-memory multicore systems have motivated the design of scalable distributed locks. The simplest is the (test-and)test-and-set (TTS) [15] locks, which rely on hardware-supported primitives such as compare-and-swap (CAS) [16] to provide mutual exclusion across multiple threads. However, TTS locks do not scale with core count as contending threads need to repeatedly poll the lock word at central memory location, generating heavy inter-thread communication and interconnect traffic. TTS locks also do not provide any ordering guarantees and is known to be vulnerable to starvation. Ticket locks [15] provide strong fairness guarantees by introducing a global ticket counter. Each requester atomically obtains a unique ticket via a single fetch-and-add (FAA) or CAS operation, and the lock is granted in ticket order. However, threads still have to spin on a central location (*i.e.*, the ticket counter) while waiting for their turn, leading to performance bottlenecks. The MCS lock [26] addresses both issues (centralized contention and ordering) by organizing requesters in a FIFO queue and allowing each requester thread to spin locally in its queue node. The lock itself always points to the tail of the queue and is only modified by an atomic swap (exchange) operation. The lock is then handed over directly from each holder to its successor in the queue. This eliminates global contention and naturally

preserves fairness, since the lock handover follows the order of the queue.

2.2 Remote Direct Memory Access

Remote Memory Direct Access (RDMA) allows one machine to directly access the main memory of another machine without involving the remote CPU. On top of a recent high-bandwidth, low-latency interconnect, such as InfiniBand [1], RDMA can enable competitive latency profiles at the μs level, making it possible now to build distributed and disaggregated in-memory applications that span multiple nodes. Different from traditional TCP/IP, RDMA exhibits a verbs interface that operates around queue pairs. Applications can perform two-sided operations (send/receive) or one-sided operations (read/write) by posting an RDMA request to a queue pair. The main difference between one- and two-sided operations is that the former does not require the remote end to coordinate, thus freeing up CPU cycles. Distributed locks also mostly rely on one-sided RDMA operations. The RDMA protocol also supports atomics such as RDMA CAS and RDMA FAA, which are also one-sided and operate on single 8-byte memory words, like their x86 counterparts.

Notably, RDMA atomics provide atomicity when they are executed on the same RDMA-enabled network interface card (RNIC) [30]. At the hardware level, atomic operations and other memory accesses are performed by RNIC via the PCIe on the remote machine [41]. Since the RNIC operations are independent of those from the remote CPU, the atomicity of RDMA atomics is *not* guaranteed when they are performed concurrently with local memory accesses by the remote CPU. This leads to asymmetric performance between local and remote accesses [4] that ideally should be leveraged by RDMA locks, which is one of the motivations of our work as we elaborate next.

2.3 Fairness and Latency of RDMA Locks

Several RDMA-based lock designs achieve high efficiency by reducing network round trips through one-sided RDMA [12, 13, 37, 40, 41]. In these designs, the lock is exposed via the RNIC. This allows lock operations to bypass the CPU of the server hosting the lock and enables low-latency lock operations. Beyond adaptations of the aforementioned centralized TTS or ticket locks, the MCS lock has also been adapted to support distributed locking using RDMA. Distributed requesters directly manipulate the remote tail pointer to enqueue themselves using one-sided RDMA, and the lock is handed over along the queue whose nodes are also accessed using one-sided RDMA. This approach preserves MCS lock's fairness properties by maintaining FIFO handover ordering based on the arrival order of distributed requesters.

Due to the aforementioned consistency issue in Section 2.2 between remote accesses from an RNIC and from the local

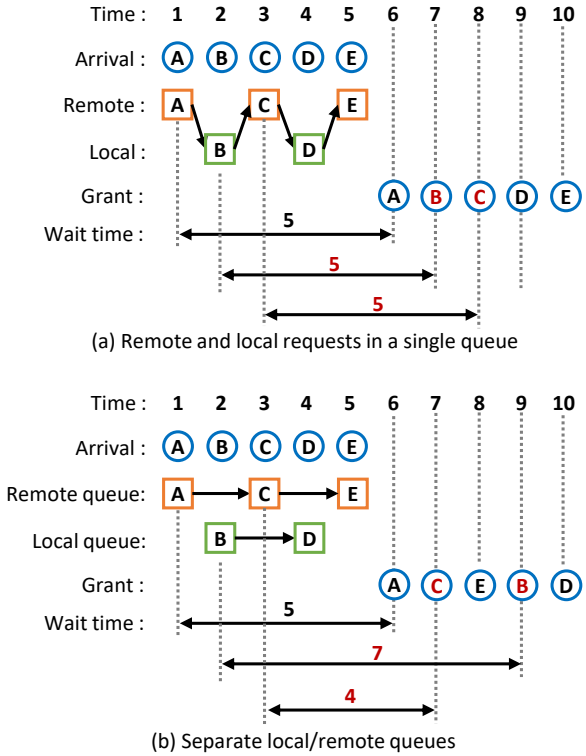

Figure 1: Performance vs. fairness guarantees in prior work. (a) Using a single queue (e.g., MCS) ensures fairness across all requests but sacrifices performance without considering asymmetry. (b) Existing asymmetry-aware locks can grant locks without considering arrival order, leading to long wait times for certain requests (e.g., B and D).

CPU, however, it is important that regardless of where the requesters are located relative to the lock (*i.e.*, whether on the same or different servers), the requester always needs to use RDMA operations to operate on the lock. This leads to high latency especially for local requesters (*i.e.*, threads on the server hosting the lock). Because RDMA does not guarantee atomicity between local and remote accesses, local requesters must interact with the lock through a loopback mechanism [4, 41], meaning their accesses are routed through the local RNIC which is unnecessarily expensive. A potential way to eliminate the expensive loopback is to treat local and remote requesters differently while enforcing correct coordination between them. However, doing so while preserving fair lock acquisition order is challenging. Maintaining fairness in terms of lock acquisition order is important because it directly impacts task latency, as discussed next.

Lock Acquisition Order. Lock acquisition order is the order in which waiting requesters acquire the lock. The common notion of fairness in lock acquisition requires that *requesters obtain locks in the order of their arrival* [15]. Such fairness is important because it prevents the additional delays that arise when requests are served out of order.

Figure 1 shows an example where 5 lock requests arrive one after the other from different tasks. For simplicity, we assume each task takes 1 unit of time to execute its critical section and release the lock. When the lock becomes available at time $t = 6$, the first scenario (a) maintains a single queue which preserves arrival order, so each request's latency directly reflects its position in the queue. This is how an RDMA-adapted MCS lock would work. In the second scenario (b), however, local and remote requests are maintained in separate queues (*e.g.*, in ALock [4]) and the lock is granted out of order as lock granting alternates between two queues. This reduces the wait times for some requests that arrive later (*e.g.*, C) but increases wait times for the earlier ones (*e.g.*, B). When considering end-to-end task latencies, such reordering can inadvertently increase latency for some requesters relative to others. Under highly contended workloads, these effects become especially pronounced, manifesting as high tail latencies.

We verified this by measuring tail latencies of RDMA-based lock implementations. We ran the RDMA implementation of the MCS lock, which guarantees fairness but incurs high overhead due to its loopback mechanism, and a recent RDMA-based lock, ALock [4], which removes this overhead by treating local and remote requesters differently but at the cost of not enforcing fairness between them. We used a cluster of 10 machines over an RDMA network (detailed setup in Section 5), with one of the machines hosting 10 locks and all machines running 12 threads that randomly (uniformly) access those locks. As shown in Figure 2, the MCS lock yields similar tail latencies for both local and remote requests. In contrast, ALock shows a gap between its local and remote latencies, which stems from its asymmetric treatment of local versus remote requests. ALock effectively prioritizes local requests and disregards arrival order across the two classes, which causes its remote tail latencies to become significantly higher than those of MCS lock.

To confirm this impact on ALock latencies, we conducted an experiment where we controlled the order of lock requests. In this experiment, we used two machines and a single lock on one of the machines. We orchestrated the lock acquisition requests such that 12 local threads issued requests before the 12 remote threads. With this setup, we captured the lock acquisition order as well as the waiting time for each request to acquire the lock. Since ALock reshuffles the requests to alternate between local and remote, as shown in Figure 3(a), the wait times to acquire the lock are not correlated to the arrival order. Moreover, the constant bouncing over the network increases the wait times even more; when considering tail latencies in this example, the last local request (arrival index 11) contributes to the highest tail latency.

The issue with shuffled processing becomes more pronounced at scale. We sampled lock requests for ALock over a longer run and captured the difference between the arrival order and the processing order. Figure 3(b) shows the standard deviation of this difference as number of threads increase.

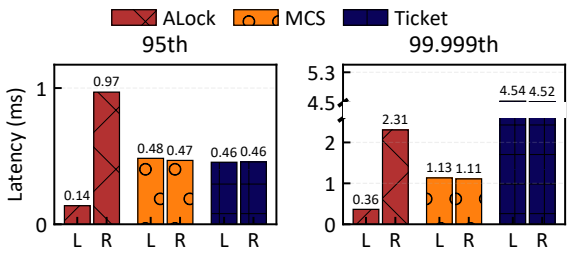

Figure 2: Tail latencies for local (L) and remote (R) requests for ALock, MCS and ticket locks.

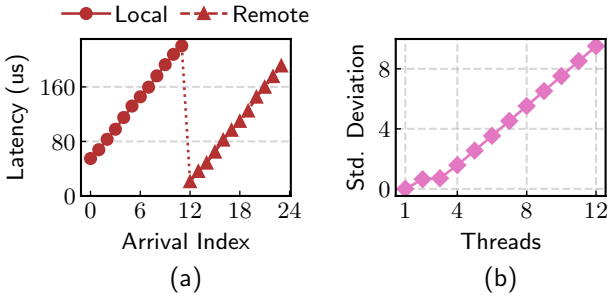

Figure 3: (a) Lock acquisition wait times versus arrival index under controlled arrival order for ALock. (b) Standard deviation of acquisition order relative to arrival order in ALock.

Effectively, with more threads, lock contention increases and more requests remain queued up waiting. This causes more requests to be shuffled which would result in longer delays and higher tail latencies.

Maintaining fairness is important to avoid arbitrary delays that increase tail latencies under high contention. Both the MCS and ticket locks provide fairness, with MCS outperforming ticket locks as expected (shown in Figure 2) because of its handover mechanism. This raises a crucial question: *how to design an RDMA lock that preserves fairness while also eliminating the costly loopback mechanism for local requesters?*

3 FARLock: Fair Asymmetric RDMA Locks

We present FARLock, an efficient RDMA lock that guarantees fairness and considers asymmetry for high performance. FARLock maintains fair lock acquisition order and does not slow down the local requests for coordination. This not only reduces lock latencies but also eliminates reordering delays that impact tail latencies.

FARLock's design is inspired from the queue-based handover strategy of the MCS lock [26] and strict lock grant ordering in ticket locks [15]. FARLock combines the benefits of both while also treating the local requests and remote requests differently. To avoid having local requests perform RDMA operations during lock acquisition, we place local and remote requests in separate queues, as shown in Figure 4.

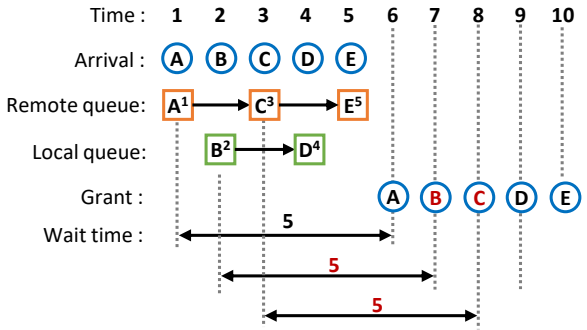

Figure 4: FARLock employs separate remote and local queues to accommodate asymmetry, and assigns requests a ticket following their arrival order to guarantee fairness.

Local requests can then enqueue using purely local operations without contending with remote requests. As requests arrive, each request obtains a ticket from a global ticket counter, and when the lock is released, the request with the next ticket in sequence acquires it. This ensures all the waiting requests, regardless whether local or remote, are globally ordered based on their arrival time and thus treated fairly. Compared to existing designs in Figure 1(b), in Figure 4, FARLock attaches a ticket to each requester according to arrival order using the global ticket counter. The lock is acquired in order shown by the ticket numbers, giving a fair wait time (5) for all requests in this example.

While the idea is straightforward, achieving it is challenging given the lock needs to maintain several separate structures—two queues and a ticket counter—that cannot be atomically updated. (1) The ordering in each queue needs to be consistent with the ordering of ticket values. (2) Accessing the ticket counter itself must be atomic. Additionally, (3) the ticketing mechanism adds more roundtrips which FARLock should try to reduce. Our solutions as summarized below constitute the major building blocks of FARLock.

Consistent Ordering. Consistency between queue ordering and ticket values entails the following invariant to hold: *any two local (remote) requests A and B with ticket of A smaller than ticket of B must be enqueued in the local (remote) queue such that A is enqueued before B.* This invariant does not enforce any requirement on requests of different types as they end up in different queues. FARLock maintains this invariant by having the requests enqueued in the queue before acquiring the ticket. By doing so, requests acquire the ticket one after the other based on their order in the queue. This is achieved similarly to the handover mechanism in the MCS lock, except that consecutive requests hand over the chance to acquire the ticket value. This way, global contention on the ticket counter is eliminated as each requester waits for its turn based on its position in the queue.

Atomic Global Ordering. Consistent local ordering orchestrates requests of same type, reducing the atomicity problem down to a single local and global request (*i.e.*, the heads of each queue). We then employ the Peterson's lock [28] which ensures mutual exclusion between two processes, similar to prior work [4]. The Peterson's lock uses only local or RDMA-based reads and writes without relying on any atomics. This allows local requesters to safely perform ticket-related lock operations locally on remotely-visible memory, while remote requesters use RDMA reads and writes. Moreover, local requests update the ticket counter directly while remote requesters use RDMA, allowing local requests to complete lock acquisition entirely without accessing RNIC.

Fairness-Preserving Grouping. Each request needs to acquire and release the Peterson's lock to obtain a ticket, adding additional roundtrips. However, we observe that this is not always necessary, especially under high contention when many concurrent requests arrive at the same time on each queue. Requests always queue up first, allowing later concurrent requests in the queue to piggyback on their predecessors to obtain the ticket (*i.e.*, passing the ticket along the queue). Since the queue already maintains ordering among same-type requests, concurrent requests could then share the same ticket. Subsequently, only the first requester in a group would need to access the Peterson's lock to allocate a new ticket, greatly reducing the lock and unlock operations on the Peterson's lock and speeding up the ticket acquisition process. Moreover, a useful side-effect of our grouping strategy is that it reduces the bouncing of lock over the RDMA network. Our grouping strategy preserves the fairness as requests of the same type are still granted the lock in the order of their queue position. We elaborate the detailed design of FARLock next.

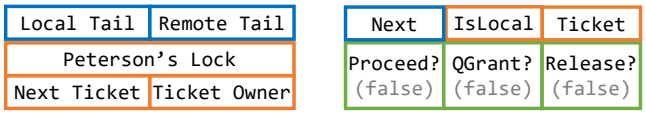
4 FARLock Design

Now we describe FARLock's design in detail, including its data structures, lock acquire/release protocols, optimizations and extensions for supporting readers.

4.1 FARLock Structures

Similar to prior work [4], FARLock employs two queues—one for local requests and another for remote requests—to optimize for asymmetric accesses. The lock itself, as Figure 5(a) shows, then includes two pointers to respectively the tail of the queues of local (`local_tail`) and remote (`remote_tail`) requesters. FARLock's lock structure also carries the necessary fields for ticketing (`next_ticket` and `ticket_owner`) protected by a Peterson's lock. As we elaborate later, this allows FARLock to enforce both consistent local ordering and atomic global ordering for fairness among lock requesters based on arrival time.

Each requester is represented by a queue node whose reference is passed in as a parameter of the lock acquire/release protocols (details later). As Figure 5(b) shows, a queue node includes fields that are similar to those typically found in an



(a) Lock structure (b) Queue node

Figure 5: FARLock structures. (a) The lock uses two queues whose tails are identified by two separate RDMA-aware pointers, a Peterson's lock and ticket (orange) related fields for ordering guarantees. (b) Each lock requester is represented by a queue node which carries a ticket and boolean fields (green, with default values) for ticket and lock handover.

MCS lock's queue node such as a `next` pointer to the immediate successor of the same type (either remote or local) and a `qgrant` field that indicates whether the requester has been "queue-granted." That is, whether the requester can be granted the lock if the lock's `ticket_owner` matches the requester's own ticket. Each queue node also carries additional fields that will be used to support the ticketing mechanism and lock handover between local and remote requesters in the locking protocols, which we describe next.

4.2 Basic FARLock

With the data structures described above, now we discuss how FARLock supports lock acquire and release operations. Here we start with the basic protocols for mutual exclusion; we discuss further optimizations including ways to reduce ordering overhead and supporting (optimistic) readers later.

Acquire. The lock acquisition protocol resembles that of the MCS lock [26], but with additional operations to accommodate for asymmetric accesses and ordering across remote and local requests. From a high level, a requester needs to (1) join the local or remote queue, (2) obtain a ticket and (3) wait for its turn to acquire the lock. Algorithm 1 shows the details. To acquire the lock, the requester first initializes its queue node with the `next` pointer set to null and `ticket` set to a sentinel `Invalid` value. Using an RDMA-aware exchange operation (`XCHG`),[1] the requester first lines up at the corresponding local/remote queue (line 3) identified by the `get_tail_ptr` function which based on the addresses of `qnode` and `lock` to return the pointer (address) of the target queue. The RDMA-aware `XCHG`'s API follows its single-node counterpart [16] to return the previous value that was stored on the target memory word. If the return value is not null, i.e., a predecessor of the same type exists, the requester then links itself with the predecessor (lines 6–7) and then needs to ensure that it will not acquire a ticket that is smaller than the predecessor's. This is done in a two-step, *consume-release* handshake protocol that is respectively executed by the requesting successor and releasing predecessor. The first step is for the requester to

[1]Could be implemented as an RDMA CAS loop or masked CAS [30]. The latter is no longer available in the latest RDMA drivers, so our implementation uses the former, following prior work [4].

Algorithm 1 FARLock's lock acquire protocol.

```
1  def acquire(lock, qnode):
2    # Install queue node to the target queue
3    pred = XCHG(get_tail_ptr(lock, qnode), qnode)
4
5    # Ensure predecessor has acquired a ticket
6    if pred != null:
7      pred.next = qnode
8      t = pred.ticket
9      pred.release = true
10     if t == INVALID:
11       spin_until qnode.proceed == true
12
13   ... acquire Peterson's lock ...
14   my_ticket = lock.ticket++ # Obtain ticket
15   ... release Peterson's lock ...
16
17   qnode.ticket = my_ticket
18
19   # Unblock my potential successor
20   if qnode.next != null:
21     qnode.next.proceed = true
22
23   if pred != null:
24     spin_until qnode.qgrant == true
25
26   # Wait for my turn
27   spin_until my_ticket == lock.ticket_owner
```

"consume" the ticket at line 8. Note that it is important to ensure that the successor (current requester) reads a stable copy of the predecessor's ticket value (i.e., the queue node memory should not be recycled until the current requester has finished using it). We therefore introduce a `release` boolean to facilitate this: the predecessor can only finish its release protocol (line 14 of Algorithm 2, more details later) after its `release` is set to true. After consuming the predecessor's ticket t, if t turns out to be invalid, the requester spin-waits for the predecessor to obtain a valid ticket (lines 10–11) before proceeding to obtain its own ticket.

After ensuring the predecessor-successor ticket ordering, now the requester moves on to acquire its own ticket at lines 13–15 which is protected by the Peterson's lock. Note that it is important for the requester to avoid assigning the ticket to its `ticket` field until the Peterson's lock is released at line 17: assigning it earlier (e.g., at line 14), however, would make it possible for a third requester to start competing for the Peterson's lock which only supports two requesters (as a result of executing lines 8–10), leading to undefined behavior. The requester then waits for the predecessor (if any) to finish its release handshake protocol by toggling the `qgrant` field (lines 23–24) and waits for its turn (line 27) to eventually be granted the lock.

Release. The release protocol starts by atomically incrementing the lock's ticket owner (line 3 of Algorithm 2) which

Algorithm 2 FARLock's lock release protocol.

```
1  def release(lock, qnode):
2    # Announce the next ticket (lock) owner
3    lock.ticket_owner = qnode.ticket + 1
4
5    # Make sure there is no successor
6    if qnode.next == null:
7      if CAS(get_tail_ptr(lock, qnode), qnode, null):
8        return
9
10   # Wait for the successor to gather my ticket
11   spin_until qnode.release == true
12
13   # Grant successor (pending ticket ordering)
14   qnode.next.qgrant = true
```

would unblock the requester spinning on line 27 of Algorithm 1, passing the lock to the next requester (if any). Algorithm 2 then follows the same approach as MCS lock's to make sure whether there is a successor using an RDMA-aware CAS and return if the CAS succeeded (i.e., there is indeed no successor, lines 6–8). The remaining steps facilitate the aforementioned consume-release handshake by (1) waiting for the `release` field to be toggled to true (by another requester at line 9 of Algorithm 1), and (2) setting the successor's `qgrant` field to true. The first step in essence waits for the acknowledgment of a successor's consumption of the releasing requester's ticket, while the second step allows the lock to be passed along the queue of the same type.

4.3 Fairness-Preserving Grouping

The use of tickets allowed the basic FARLock protocols to provide fairness, enabling requesters be granted the lock at arrival order. But this at the cost of additional roundtrips. We observe that FARLock's queue-based design can help remove most of such additional roundtrips. (1) Concurrently arriving requests could be combined to share a single ticket. (2) The queue nodes provide additional storage space for passing along information on ordering. Importantly, as we will elaborate soon, neither breaks fairness guarantees.

Based on these observations, we introduce fairness-preserving grouping to solve this problem. Akin to the classic lock cohorting idea [10], fairness-preserving grouping allows concurrently arriving requests to form a group (of a predefined maximum size) which will share the same ticket. Instead of for each requester to obtain a different ticket (hence contending on the ticket and subsequently spinning on it), only the head of a group will contend for the Peterson's lock to obtain a ticket, which is then passed along the queue. Requesters that inherited a ticket from a predecessor will then only need to rely on the queue-local grant, without spinning on the central `ticket_owner` field of the lock, effectively mitigating contention. Fairness is also preserved because grouping only

Algorithm 3 Fairness-preserving grouping. Starting line number aligned with Algorithm 1, with overlapping code shaded.

```
-1 def acquire_fpg(lock, qnode):
 0   joined_group = false
 1
 2   # Install queue node to the target queue
 3   pred = XCHG(get_tail_ptr(lock, qnode), qnode)
 4
 5   # Ensure predecessor has acquired a ticket
 6   if pred != null:
 7     pred.next = qnode
 8     t = pred.ticket
 9     pred.release = true
10     if t == INVALID:
11       spin_until qnode.budget != 0
12       if qnode.budget != get_group_size():
13         my_ticket = qnode.group_ticket
14         joined_group = true
15         goto skip
16
17   ... acquire Peterson's lock ...
18   my_ticket = lock.ticket++ # Obtain ticket
19   qnode.budget = get_group_size()
20
21 skip:
22   succ = qnode.next
23   # Pass ticket to successor if budget allows
24   if succ && qnode.budget != 1:
25     succ.group_ticket = my_ticket
26     succ.budget = qnode.budget - 1
27   else: # End of this batch
28     ... release Peterson's lock ...
29     qnode.ticket = my_ticket
30     succ = qnode.next # Refresh the successor
31     if succ: # Tell successor it is in a new batch
32       succ.budget = get_group_size()
33
34   if pred != null:
35     spin_until qnode.qgrant == true
36
37   if joined_group:
38     return # Joined group, rely on qgrant only
39   spin_until my_ticket == lock.ticket_owner
40
41 def release_fpg(lock, qnode):
42   if qnode.ticket != INVALID:
43     lock.ticket_owner = qnode.ticket + 1
44   ... Same as lines 6-14 of Algorithm 2 ...
```

reorders the concurrently-arriving requesters on the same queue. In other words, these requesters would have received consecutively increasing tickets without grouping anyway.

Realizing this idea requires slight changes to the queue node design shown in Figure 5(b) to include in each queue node two additional fields (`batch_ticket` and `budget`) to allow passing along necessary ticket information on the queue. The lock is also augmented with two more parameters to re-

spectively indicate the maximum group size of the remote and local queues; we experimentally evaluate their effect later in Section 5. With these changes on lock structure, Algorithm 3 describes the idea in detail.

Acquire. Compared to Algorithm 1, the requester attempts to join an existing group after lining up after a predecessor (lines 11–15 of Algorithm 3). The requester starts this process by waiting for its `budget` field to be filled out by its predecessor (more later). The `get_group_size()` function returns the predefined maximum group size, which is then stored in the queue node's `budget` field. As more requesters join the group, the `budget` field of each requester tracks the remaining number of allowed members in the group. The `group_ticket` field in each queue node then denotes the ticket of the current group, which will be passed along the queue until the running budget is depleted. Here, at line 12, if the requester's budget is not the initial maximum (i.e., a predecessor has started a group), it will inherit the ticket from its predecessor and skip the process of acquiring the Peterson's lock (lines 17–19). Otherwise, it proceeds to acquire the Peterson's lock to obtain a ticket as the head of the group. The algorithm then continues to inspect its successor state to pass on the ticket (lines 21–32). Note that at line 21, the group head is still holding the Peterson's lock, which will only be released by the last member of the group.

Figure 6 shows an example where a group is formed at the remote and local queue, respectively. On either side, the group head acquires the Peterson's lock and the last member in the group releases it. The "last member" can be a successor (or the head itself if group size is one) when budget is depleted or when there is no successor (lines 28–29). In the latter case, it is necessary to re-read the `next` field of the queue node to ensure the (non)existence of a successor, in case a successor has finished executing line 10 before the predecessor finishes line 29. Finally, if a requester inherited a ticket as a group member (non-head), it only needs to rely on its queue-local grant signal at lines 34–35 and directly return at line 38 to finish acquiring the lock. Otherwise, the group head will still need to wait for its turn (line 39), same as in the basic protocol.

Release. In the above lock acquire protocol, the inherited ticket is stored in `group_ticket` and the `ticket` field in each queue node is only filled when the requester is the last to acquire the lock (i.e., it is the last member) at line 29 after releasing the Peterson's lock. Therefore, the field will remain `INVALID` for all but the last member, which should increment `ticket_owner` of the lock upon release (lines 42–43). Subsequent logic for the release protocol remains the same as the basic protocol's.

4.4 Supporting (Optimistic) Readers

Beyond mutual exclusion which we have focused on so far, modern distributed applications (e.g., data analytics) also desire shared reader support to enable more concurrency by allowing multiple read-only requests to enter the critical section when no writer is present. This is often done in pessimistic approaches that explicitly enforce (shared) reader or (exclusive) writer accesses using additional fields in the lock word and/or queue nodes to track the active reader count to support this coordination [13, 37]. Such designs are generally more challenging to implement and introduce additional roundtrips through the RDMA NIC, ultimately increasing latency, especially for local requests.

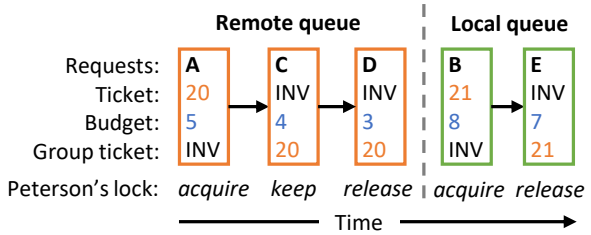


Figure 6: Fairness-preserving grouping example with five requests forming two groups on the remote ($A \rightarrow C \rightarrow D$) and local ($B \rightarrow E$) queues. The group heads (A and B) acquire the Peterson's lock, which is kept by intermediate members (e.g., C) and released by the last members (D and E). Upon releasing the FARLock, the remote group's last member D increments the ticket number from 20 to 21, which is picked up by the subsequent head request B and passed along to E.

FARLock instead advocates a simpler, optimistic approach that can be easily added on top of the protocol described in earlier sections. Classic optimistic locks [7, 14, 18] where (1) the lock carries a version number that records the number of times a writer has executed the critical section and (2) readers proceed to read without taking the lock but only need to verify that the lock is free and the version number remained the same before and after their accesses. FARLock's optimistic readers follow similar ideas, but offloads all the conflict checking that was done jointly by checking the lock state and version number (step 2) to a dedicated 0-initialized `version` field in the lock. With the dedicated version field, writers proceed by incrementing it both upon acquiring the lock (i.e., immediately after line 27 of Algorithm 1 or line 37/39 of Algorithm 3), and releasing the lock (e.g., at line 2 of Algorithm 2). Correspondingly, readers start by taking a snapshot of the version number. It then checks whether `version` is odd, and if so, that means a writer is in progress and retries until `version` is even. The reader then can start its work and will verify upon release that the version number did not change.

Such optimistic designs are inherently unfair between readers and writers, by favoring writers. However, we believe this is a reasonable tradeoff given the benefits: throughout the entire read process, optimistic readers perform no (RDMA or local) writes. Using a dedicated version field (instead of co-locating it with the lock word itself as in prior work) also frees us from handling complex interactions between readers and writers, and leads to a composable design; if optimistic readers are not needed, their support can be easily turned off.

Table 1: Locks under comparison.

Lock	Asymmetric	Fair	# Remote Spinners
TS	No	No	Unbounded
Ticket	No	Yes	Unbounded
MCS	No	Yes	0
ALock	Yes	No	1
FARLock	Yes	Yes	2

The write path incurs additional roundtrips, but can be merged with other steps (e.g., spinning or incrementing the ticket) to effectively hide the overhead, which we leave as future work.

5 Evaluation

We empirically evaluate FARLock through microbenchmarks to show the following:

- How much does tail latency improve with FARLock? (Section 5.2)
- Does FARLock deliver high throughput? (Section 5.3)
- How much does FARLock's fairness-preserving grouping strategy benefit performance? (Section 5.4)

5.1 Experiment Setup

Testbed. We perform experiments on a 10-node cluster from CloudLab's Apt Cluster.[2] Each node is equipped with two 2.6Ghz Xeon E5-2650v2 CPUs (16 cores in total), 64GB DRAM and a Mellanox FDR CX3 RNIC (similar as ALock [4]). The nodes are interconnected via a InfiniBand FDR switch, giving 56Gbps of bandwidth between nodes.

Compared Locks. Since FARLock mainly targets mutual exclusion, for fair comparuison we limit our comparison to classic and recent mutual exclusion locks. We evaluate FARLock against baselines shown in Table 1. Among them, TS, MCS and Ticket are the corresponding shared-memory locks but adapted to use RDMA atomics to work in distributed scenarios. ALock [4] is the asymmetric lock that misses fairness, maintaining two queues to serve local and remote requests separately. ALock also supports batching to reduce frequently bouncing over the network. We evaluate against the default ALock and its batched version; for this, we tested various batching parameters and found that ALock performs best when using batch sizes 20 and 5 for its local and remote queues. We use `ALock (20, 5)` to indicate this configuration of ALock with batching. Finally, FARLock denotes FARLock without grouping, and FARLock-G represents FARLock with grouping. Unless otherwise noted, we set group size to 5 and explore the impact of different group sizes later.

Benchmark Settings. All locks are hosted on a single node, and the rest of the nodes act as remote requesters. Each node runs 12 threads to issue lock requests concurrently. This defines the 12 threads from the hosting node as local requesters, and the 12 threads from each remaining node as remote requesters. We vary the number of locks on the hosting node between 1 (high lock contention) and 240 (low lock contention) to test different contention levels. Inside the critical section, each thread performs a busy-wait loop for a specified number of cycles to simulate work. Accesses to the CPU's last-level cache (LLC) typically complete within a few tens of nanoseconds [9], and RDMA routinely exhibits μs-level latency [11,17]. This presents a speed gap of 10–100$\times$ between CPU cache and RDMA accesses. We account for this gap by assigning different critical section sizes for local and remote requests to model realistic workloads where local operations are typically faster than remote operations. We set the remote critical section size to 15,000 cycles ($\sim$5μs) and the local critical section size to 300 cycles ($\sim$100ns).

Metrics. Each experiment runs for 20 seconds, and use the middle 10 seconds to collect results to rule out impacts of different thread progresses and stragglers. We measure the throughput and latency of jobs where each job includes a lock acquire operation, its critical section and the unlock operation. We present tail latencies to showcase delays experienced from (un)fairness by the slowest requests, measured as the 95th, 99th, 99.9th, and 99.999th percentile of a latency distribution. Each experiment is repeated for three times, and standard deviations across multiple experiments were 0.97-14.88% on average, with highest being 14.88% for 99.999th percentile latency measurements. We therefore report the averages of three runs for each experiment.

5.2 Latency

Figure 7 shows tail latencies when using 1 and 10 locks (representing high contention scenario) and Figure 8 shows tail latencies when using more than 10 locks. Across different percentiles, as we include more locks, contention becomes lower, leading to better performanc (lower latency) for all locks. FARLock exhibits the lowest local tail latencies compared to all other locks, and competitive remote latencies across all scenarios. By grouping (five) requests, FARLock-G gives very similar tail latencies as FARLock.

High Contention (1 – 10 locks / Figure 7). We observe up to 62$\times$ lower local tail latencies compared to other fair locks (MCS and Ticket), while 8$\times$ lower than ALock and 55-5898$\times$ lower than TS. In these scenarios, no delays are introduced for FARLock (benefit of fairness) and requests are processed in their arrival order. The other two fair locks, Ticket and MCS, exhibit much higher local tail latencies as their local requests are routed through RNIC (loopback) which is expensive. FARLock's latencies are lower than those of ALock because ALock ends up reordering requests, resulting in more delays and network bounces as locks get handed over between

[2] https://docs.cloudlab.us/hardware.html

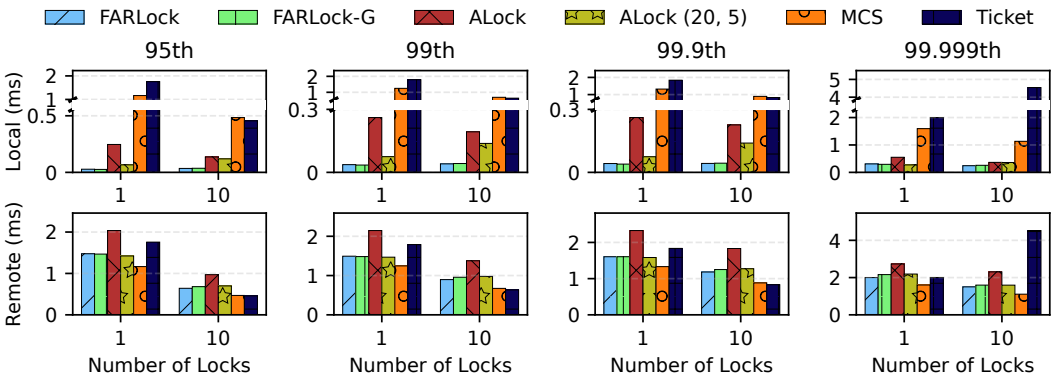

Figure 7: Tail latency for local (top) and remote (bottom) requests under high contention with 1 and 10 locks. Latencies for TS are not shown here since they are very high (2-171× higher than the next highest data point).

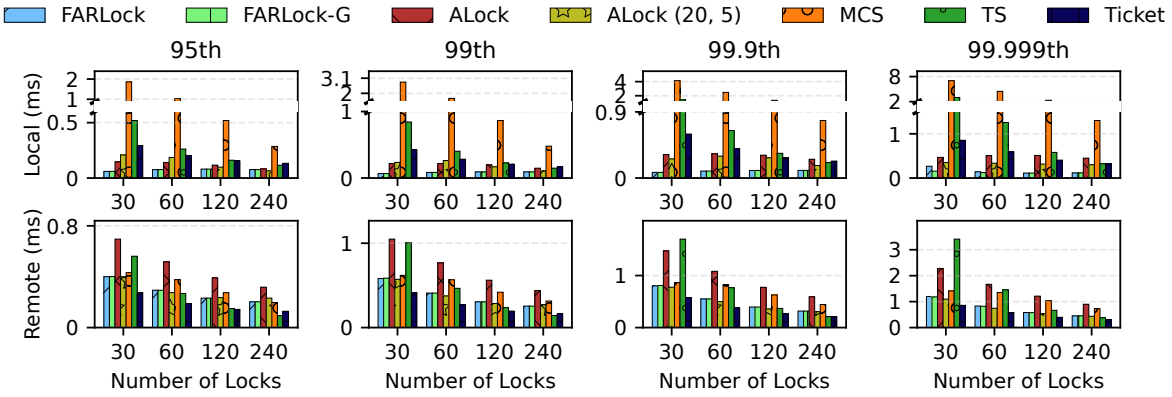

Figure 8: Tail latency for local (top) and remote (bottom) requests under decreasing contention.

different requests. ALock(20, 5) reduces the effect of such bouncing via batching (similar observation as the original paper [4]), but still suffers from reordering of requests which causes arbitrary delays and results in higher tail latencies compared to FARLock. MCS consistently provides competitive remote latencies with under high contention (i.e., low number of locks). This is because the MCS lock requires fewer instructions than FARLock to process a lock request. FARLock provides competitive remote latencies, often lower than the unfair ALock. Finally, TS shows the highest tail latencies due to its well-known starvation issue (resulting from unfairness).

Decreasing Contention (beyond 10 locks / Figure 8). FARLock still has lower tail latencies because of its advantages over MCS and Ticket (no loopback for local requests), and over TS and ALock (no reordering due to fairness). The impact of using more RDMA oprations in FARLock compared to Ticket is observed in their tail latencies as the number of locks increase beyond 30.

Comparing ALock with and without batching shows that its batching is effective in reducing remote tail latencies as batching processes more remote requests before bouncing over the network for handover. However, this benefit is marginal when compared to FARLock.

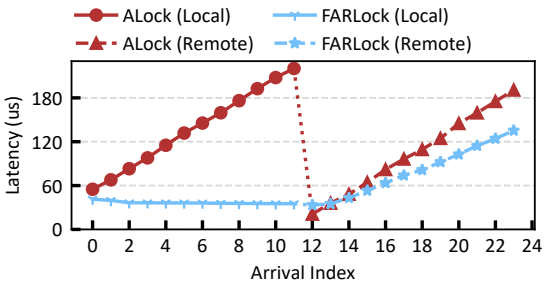

Figure 9: Latency for controlled arrival order.

Fairness Study. We perform the same experiment from Figure 3(a) where we controlled request arrival order. Along with measuring the acquisition latencies for ALock, this time we also measure for FARLock. We use two machines, and 12 local requests are submitted followed by 12 remote requests. As shown in Figure 9, latencies for FARLock are lower than that for ALock because FARLock processes requests in order, and hence, all local requests get processed followed by all remote requests. This eliminates the continuous bouncing

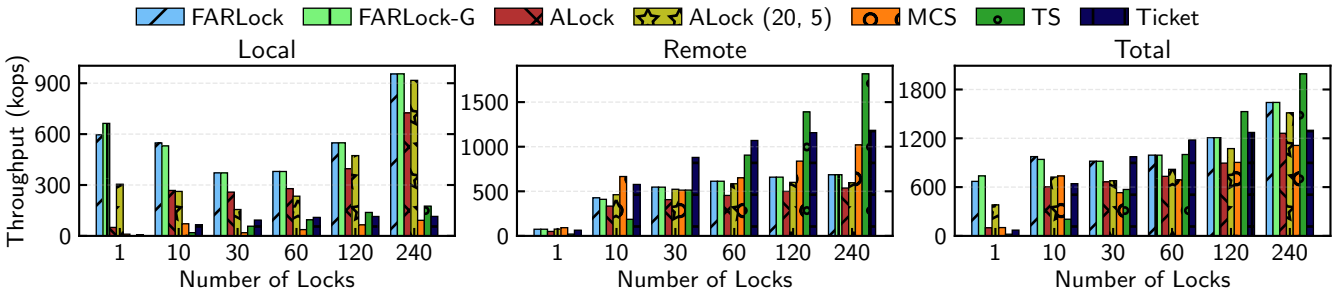

Figure 10: Throughput under different contention.

delays that ALock's ordering introduces, and results in lower latencies overall; the highest latency for the last remote request is 135.30μs which is much lower than highest latency with ALock (incurred by the last local request).

5.3 Throughput

While fairness benefits tail latency, we also assess FARLock's ability to deliver high throughput. Figure 10 compares the local, remote and total throughput of FARLock and other locks. FARLock's benefits for local requests are visible as it delivers the highest local throughput across the board with up to 891× higher than MCS, TS, and Ticket. MCS and Ticket show similar remote throughputs as FARLock under 1 lock, with both providing higher remote throughput as the number of locks increases; this is due to fewer instructions involved in remote paths of those two locks. While TS also enjoys high remote throughput under low contention for similar reasons, the expensive remote retries during high contention (with 1 and 10 locks) significantly limit its throughput compared to FARLock.

Compared to ALock, FARLock achieves 11.9× and 2× higher local throughput with 1 and 10 locks respectively, and this gap closes gradually with more locks. This is because ALock's reordering mechanism forces the lock to be handed over across nodes more often, which is less favorable when more requests line up on fewer locks. FARLock, on the other hand, is able to handle more lock requests on the same node depending on the arrival order which results in less bouncing. For instance, in the highest contention scenario (1 lock), we observed that FARLock frequently performs up to 12 consecutive local lock handovers before serving a remote request. In contrast, remote requests tend to hand over the lock on the same node far less often. Batching in ALock(20, 5) reduces its bouncing issue, with ALock(20, 5) providing much higher local throughput. However, it still consistently forces handover across nodes, albeit less often, which limits its throughput.

Finally, we observe a dip in FARLock's local throughput going from 1 lock to 30 locks which gets balanced by a sharp increase in remote throughputs. This is likely due to a side effect of fairness combined with efficiency in local requests. For the single lock scenario, local requests queue up faster than remote requests as the latter must go through RDMA with higher latency. As the number of locks increase, remote requests have more chance to queue up across different locks since local requests get spread out, resulting in remote requests being served more often (fair ordering in FARLock) compared with just a single lock.

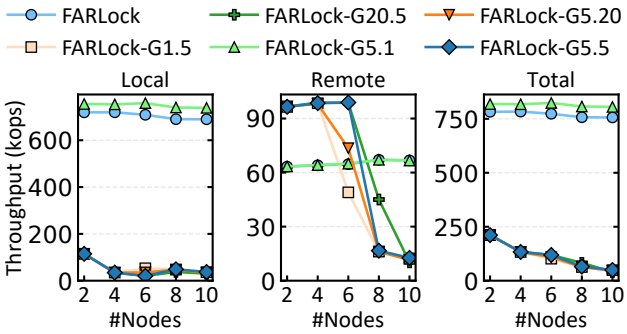

Figure 11: Throughput for FARLock with grouping. FARLock-GX.Y means at most X local and Y remote consecutive requests are grouped together while preserving fairness.

5.4 Fairness-Preserving Grouping

Grouping in FARLock is achieved by sharing the Peterson's lock across consecutive waiting requests. We evaluate its by measuring improvements in throughput. Since each group would contain requests of the same type, grouping in FARLock can be configured differently for local and remote requests. Figure 11 compares the throughput achieved by grouping 5 and 20 requests of each type, with a single lock and varying number of nodes to capture increasing remote requests.

Since FARLock optimizes local requests, grouping them improves local throughput. However, we observe that grouping remote requests leads to decreasing throughput as contention increases with more nodes. We hypothesize this is due to the remote queue getting emptied more quickly, causing more frequent bounces, which additionally cancels out the benefits brought by local grouping. The total throughput without remote grouping remains high, and we observe grouping 5 local requests gives higher total throughput. As observed in previous experiments, this grouping gives very similar tail latencies to when grouping is disabled, while there is a visible increase in throughput for high contention single lock scenarios (Figure 10).

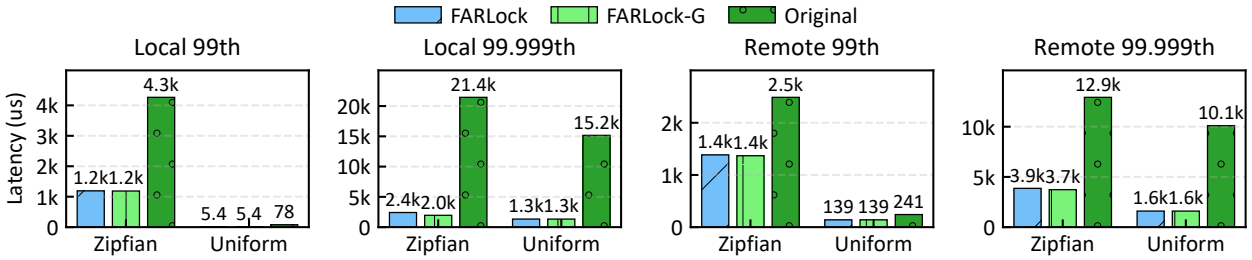

Figure 12: Tail latency of Sherman queries when using FARLock instead of its original lock.

6 FARLock in Practice

We demonstrate how FARLock can improve practical systems using a database indexing scenario. Sherman [32] is a recent RDMA-based distributed B+-tree that uses locks to coordinate access to leaf nodes. Its original lock implementation is a local ticket lock with a global spin lock for hashed memory locations. Sherman uses RDMA atomic operations to acquire locks on remote memory locations (*i.e.*, it does not use asymmetric RDMA locking), and passes the lock ownership locally with the local ticket lock in each node until a predetermined local budget. This is an unfair RDMA locking strategy as it reshuffles requests. We replaced this lock with FARLock while keeping Sherman's use of RDMA operation combination to hide remote access latencies.

We deployed Sherman on the same 10-node cluster used in Section 5. One of the nodes emulates as a memory server (MS) as well as compute server (CS), while the remaining 9 nodes act as compute servers. The MS hosts 40GB shared memory, and each CS maintains 500MB cache. The system is warmed up with 800 million key-value pairs (8-byte keys and 8-byte values). To stress test locks, we focus on update operations over random keys, emphasizing tail latencies that can impact service-level objectives under high contention. We vary the key distribution between uniform and Zipfian (θ = 0.99, skewed) to test different contention levels. Figure 12 shows improvements in tail latency when using FARLock. We observe 11-14$\times$ and 3.6-11$\times$ lower local tail latencies with uniform and Zipfian distributions respectively, and 1.7-6$\times$ and 1.8-3.5$\times$ lower remote tail latencies respectively. This is due to FARLock's efficient local request handling combined with its fair ordered processing which eliminates delays caused by reshuffling. We also observed similar throughput with and without FARLock, indicating that Sherman's high throughput is retained.

7 Related Work

Our work is most related to recent work on RDMA based locks and lock managers. Ziegler et al. [41] gives guidelines for correct and scalable synchronization using one-side RDMA which we also follow in this work. ShiftLock [13] is a reader-writer lock that also adopts the MCS-style handover mechanism, where the lock holder explicitly transfers ownership to the next requester before exiting the critical section. Similar to MCS and FARLock, ShiftLock strictly enforces FIFO ordering for writes, ensuring fair serialization among exclusive lockers. However, ShiftLock does not leverage asymmetry, so both local and remote requesters must use RDMA operations. ShiftLock further implements mechanisms to handle node failures; considering node failures is interesting future work for FARLock.

DSLR [37] is a decentralized distributed lock manager for reader-writer locks using one-sided RDMA. It adapts the principles of ticket locks and assigns monotonically increasing tickets to requesters. Although DSLR has a short lock acquire path and ensures fairness, DSLR also does not distinguish between local requester and remote requester. Local requesters still need to use RDMA to acquire locks. Citron [12] proposes a distributed range lock manager with one-sided RDMA. It leverages a segment tree to map dynamic range requests to tree nodes, allowing clients to secure specific data ranges without global serialization. However, their underlying locking mechanism is orthogonal to Citron's architecture. Beyond RDMA, FISSLOCK [40] reduces CPU overhead using programmable switches by implementing a high-performance, centralized in-network lock manager. By mediating all acquisition and release traffic, the switch maintains global visibility over the system's lock states. Programmable switches have limited memory and compute power and it remains to be seen how this approach can be combined with RDMA-based locks such as FARLock to overcome these limitations.

8 Conclusion

We presented FARLock, an efficient and fair RDMA lock. FARLock ensures lock requests are granted in the expected first-come first-served order while eliminating expensive loopback for local requests. FARLock enables efficient lock handover across different queues while adhering to a global ticket ordering. We developed a fairness-preserving grouping mechanism in FARLock to reduce operation overheads, and proposed optimistic reader lock extensions. Our evaluation shows that FARLock achieves lower tail latencies than other RDMA locks as it enables efficient local requests while avoiding reordering delays (effect of fairness). We also evaluated FARLock's practical effectiveness and observed that it significantly boosts query latencies in a state-of-the-art RDMA-based database indexing strategy.

When DDIO Meets Page Coloring: Revisiting DDIO Performance with Sepia

Abstract

In modern host network stacks, Direct Cache Access (DCA) technology, such as Intel's Data Direct I/O (DDIO), plays a crucial role in packet processing by allowing received packet data to be accessed directly from the last-level cache (LLC) instead of host memory. However, DDIO performance is often constrained by the leaky DMA problem, where the packet data is evicted from the LLC before processing completes due to the limited capacity of the DDIO-reserved portion.

In this study, we revisit this issue and reveal that conflict misses, rather than capacity limitations alone, are the primary co-contributor to LLC misses in DDIO. Our in-depth analysis indicates that introducing *page coloring* to DDIO can increase the effective LLC capacity by 77.8–94.4% over Linux. Motivated by this insight, we present Sepia, a color-aware page allocator that reduces LLC misses during packet processing (including copy-to-user) by leveraging a deeper understanding of LLC behavior. Under configurations that jointly avoid capacity and conflict misses, our Linux kernel prototype saturates a 200Gbps link using only 3.5 CPU cores, 2.5 fewer than the default Linux stack, while maintaining low LLC miss rates (∼0.4%). This improves total throughput per unit of core utilization by ∼1.51× across diverse setups and real-world applications.

1 Introduction

Prior studies on Intel's Direct Cache Access (DCA) implementation, Data Direct I/O (DDIO) [33], have highlighted both its strengths and limitations [9, 14, 22, 24, 41, 58, 60]. On the positive side, for example, DDIO can improve network throughput by ∼1.4×, on top of well-established TCP optimizations such as TCP Segmentation Offload (TSO), Generic Receive Offload (GRO) and Jumbo Frames, by reducing CPU cycles required for data copy between the kernel and user space [14]. Tail latencies can also be improved by ∼21.5% with extended operations during DDIO [25]. On the other hand, the DDIO-reserved portion of the LLC is highly constrained, which limits DDIO's effectiveness, as packet-related cache lines are often evicted before processing completes. For example, Intel's default configuration reserves only two LLC ways for DDIO, corresponding to 3–8MB in Intel Ice Lake microarchitectures [35]. Our experiments show that CPU efficiency (i.e., total throughput per unit of CPU utilization) drops by ∼46% as the number of concurrent TCP connections contending the same LLC increases from 1 to 6 on a 200Gbps link, with ∼60.4% LLC miss rates (§3). This phenomenon, commonly known as the *leaky DMA* problem, has also been reported in prior studies [14, 24, 40, 51, 52, 58, 60, 64]. While conventional wisdom suggests that it stems from the limited DDIO-reserved capacity, we find this explanation to be incomplete. Our key findings are:

What "capacity" means depends on traffic load. Memory pages are loaded into the LLC via DDIO writes or CPU reads. On a DDIO write hit, DDIO updates the corresponding cache line; on a DDIO write miss, it allocates a new line into one of the DDIO-reserved ways. In contrast, CPU reads bring data into the LLC only on read misses, and newly allocated lines may be placed in arbitrary ways according to the cache's replacement policy. Therefore, when the LLC can hold the active page working set (i.e., the memory pages used for NIC DMA and network processing), DDIO tends to hit and update existing lines, even if they reside outside the DDIO-reserved ways. Thus, capacity misses occur when the working set exceeds the *full LLC capacity*. Under high load, however, when the LLC cannot hold the increased working set, DDIO write misses become more frequent, allocating new lines into the reserved ways. As a result, capacity misses occur when incoming traffic exceeds the *DDIO-reserved capacity* (§3.2).

Cache conflicts reduce the effective capacity. Our analysis further reveals that even when load stays within capacity, LLC miss rates can still increase. This is because the page working set constructed by the default Linux memory allocator is not evenly distributed across the LLC sets, leading to significant cache conflict misses (§3.3). Moreover, today's sliced LLC architecture (de facto standard in modern CPUs; Figure 2) can make this skewed distribution even worse. Our experiments with real page-address traces on our sliced LLC indicate that cache conflicts can occur even when the page working set

size is only 46.2% of the full LLC capacity! (§4.2)

Based on these observations, we adopt the page coloring technique to reduce conflict misses and increase the effective LLC capacity. While integrating page coloring into real systems has been viewed as challenging [12, 59], we find that applying it to DDIO scenarios presents new opportunities in the following aspects. First, prior studies [13, 42, 63, 66, 67] often rely on complex coloring as applications may have irregular memory access patterns, which significantly increases its logic complexity. In contrast, network stacks show highly deterministic behavior; for example, in the kernel, page sequences for DMA are dictated by device drivers, and payload pages are typically accessed during copy-to-user operations and then recycled (userspace stacks exhibit similar behavior). This predictability simplifies the coloring logic and enables a simple, uniform policy for all page working sets across cores. Second, coloring in virtual address space may suffer from poor efficiency as physical pages are scattered across memory. However, pages for NIC DMA can be pre-allocated over a large contiguous region in advance, enabling effective page coloring. In combination, these properties make DDIO-oriented, color-aware page allocations more effective. Building on these insights, we design *Sepia*, a color-aware page allocator that realizes practical page coloring for CPU-efficient network I/O processing. Sepia consists of two simple design components (§4.3):

Sepia Manager: The manager pre-allocates a large contiguous memory chunk and models it as a two-dimensional page array based on the cache structure, such that pages in the same row share the same color (i.e., the same cache sets). The manager then constructs per-core colored page pools[1] in a way that ensures page colors are evenly distributed and conflicts are avoided. This design also allows each core to operate independently without tracking other cores' status, minimizing management overhead while keeping colors balanced across cores on average. It also tracks page availability within each pool, as page-recycle timing naturally varies.

Sepia Allocator: Given that contiguous pages have different colors in our page pools, the Sepia Allocator adopts a simple *stride-1* allocation pattern, selecting colors sequentially (§4.1). Even when Sepia encounters unavailable pages (not yet recycled into the pool), it preserves sequential ordering to balance utilization across colors, selecting the next available page with the same color. This strategy enables low-conflict allocations from the pools. When wrapping around in the color sequence, it prefers the earliest available pages in each color, helping reduce the active working set size at low load.

We implement our Sepia prototype in the Linux kernel 6.6 (§5) and evaluate its performance across diverse experimental setups and real-world applications, including SPDK, Nginx, and Memcached (§6). Our implementation is available at https://github.com/skku-syslab/sepia. We outline several key benefits of Sepia as follows:

- Sepia increases the effective LLC capacity theoretically by 77.8% over Linux, utilizing 82.1% of the total LLC even under an imbalanced slice-hashing configuration.
- Sepia saturates a 200Gbps link using 3.5 cores while keeping near-zero LLC miss rates in the best-case scenario; the default Linux network stack requires 6 cores.
- Sepia is fully compatible with existing network applications, requiring no modifications. Our experiments demonstrate that Sepia improves CPU efficiency (throughput per core) by $\sim$1.51$\times$ compared to the default Linux network stack.

While Sepia is effective for applications that benefit from DDIO, our study comes with two caveats. First, building Sepia's page pools relies on LLC architectural details, such as the width of the set-index field (Figure 2). Although we provide a detailed methodology for color-aware page allocations through §4, we tested it on a limited set of recent Intel processors, including Intel Xeon Gold 6354 (Ice Lake) and Xeon 6526Y (Emerald Rapids). Thus future CPU models may require updates to this methodology. Nonetheless, our study focuses more on a comprehensive, end-to-end understanding of network processing, spanning NIC drivers, the LLC, the network stack, and applications, under DDIO. Second, Sepia's performance gains may depend on system configurations; for instance, the benefits diminish when excessive traffic from multiple cores contends for a small LLC capacity, as capacity misses are not the focus of our design. Instead, Sepia fills a missing piece by complementing prior work on capacity-miss issues—e.g., LLC architectural redesigns [24, 64], working-set reduction [51, 52], and traffic shaping [58]. Therefore, our goal is to show how Sepia, along with these solutions, enables further CPU-efficiency gains.

2 Background

This section provides a brief review of the page lifecycle in Rx packet processing, the modern LLC architecture, and DDIO operations. We focus on the ConnectX-series NIC driver, though most modern NICs follow a similar design.

Lifecycle of pages in Rx packet processing. Modern datacenter NICs expose multiple Rx queues, typically one per CPU core, so each queue is mapped to a particular core. Packet processing is therefore distributed across cores by steering packets to the corresponding queues using policies such as Receive Side Scaling (RSS) and accelerated Receive Flow Steering (aRFS). The Linux kernel maintains per-queue Rx ring buffers and page pools (see Figure 1), enabling lock-free per-core processing for multi-queue NICs. At initialization, ring-buffer entries (descriptors) are associated with pages and posted/synchronized with the NIC, allowing the device to locate available descriptors and the corresponding

[1] Throughout the paper, we assume a typical multi-queue NIC configuration in which NIC Rx queues, their corresponding Rx rings, and CPU cores have a one-to-one mapping. Thus, each core has a dedicated page pool for its Rx ring. Otherwise, page pools can be constructed per Rx queue.

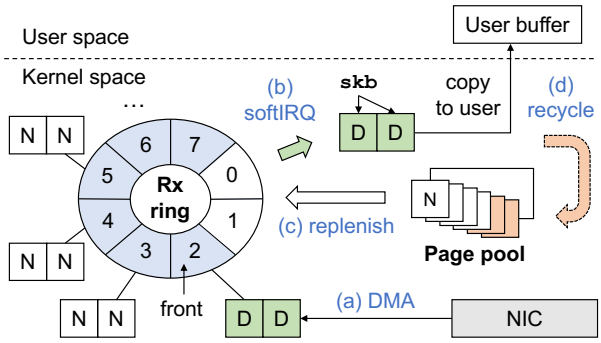

Figure 1: **Page lifecycle with Rx ring and page pool** (N=new pages, D=DMAed pages): **(a)** the NIC DMAs incoming packets into the corresponding ring-buffer pages; **(b)** the softIRQ handler allocates skbs, detaches the DMAed pages from the Rx ring, and hands them off to the skbs; **(c)** consumed ring entries are replenished with new pages from the page pool; **(d)** after network processing (including data copy), the pages are returned to the page pool for reuse. See §2 for more details.

page addresses for DMA writes when packets arrive. In ConnectX, Rx descriptors are implemented via multi-packet work queue elements (MPWQEs) [1], where each element consists of 64 pages to efficiently serve multiple packets arriving at high line rates. Network operators can tune the number of WQEs by adjusting the ring-buffer size and MTU using Ethtool [4]. Internally, drivers convert these two parameters into the WQE count proportionally. For example, in a default Linux setup with 1024 Rx ring entries and jumbo frames (9000-byte MTU), the driver initializes 64 WQEs per ring, corresponding to 16MB of pages per core.

After packets are DMAed into the descriptor pages, the softIRQ handler allocates socket buffers (skbs, the Linux packet representation) and maps the DMAed pages into those skbs for subsequent packet processing. Meanwhile, the driver refills the Rx ring by drawing new pages from the per-core page pool[2]. Once processing completes—including data copy to userspace—the pages are returned to the page pool.

Modern LLC architecture. With DDIO support [33], incoming Rx packets are steered to the LLC rather than to DRAM. Thus, a solid understanding of modern LLC architecture is essential for explaining DDIO behavior. Unlike the monolithic private caches (L1/L2), modern CPUs adopt a sliced LLC architecture [47, 61]. Each LLC slice is shared across multiple cores and connected via a high-speed interconnect, enabling parallel access and improving overall memory bandwidth. Figure 2 illustrates a high-level view of the typical LLC architecture and its physical address mapping mechanism. For each memory reference, a slice-hash function takes both the tag and set bits as input to select a target slice; once the slice is determined, the set index is derived from the set bits (as in a monolithic cache), and the remaining tag bits are used to identify the matching cache line. Note that LLC microarchitectural details (e.g., the slice-hash function, the width of the set bits, the set mapping policy) are undocumented and vary across CPU platforms, necessitating in-depth analysis and reverse engineering with carefully designed microbenchmarks. Following well-known methodologies [47], our experiments reveal that, for our Intel Ice Lake system, the LLC comprises 2048 sets (11-bit index), 12-way associativity, and 26 slices. We further confirm that the slice-hash function uses the entire tag and set bits, and that the set index is derived directly from the set bits without any additional hashing.

[2]In practice, pages are recycled from the memory-pool/page-pool and fall back to the default Linux page allocator when the page pool is empty; we omit these details in Figure 1 for the sake of simplicity.

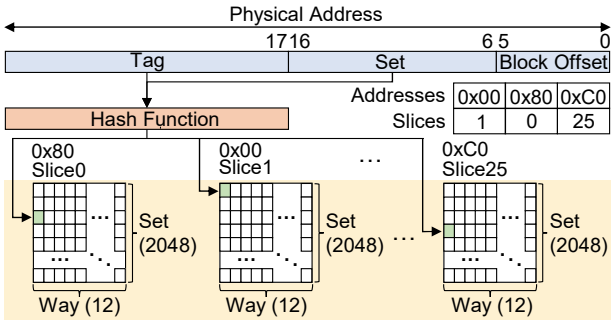

Figure 2: **LLC architecture and physical address mapping for Intel Ice Lake.** When address 0xC0 is accessed, the slice hash (from the full set of *tag* and *set* bits) maps the address to a slice (e.g., slice 25). Given a set index of 3, the access targets the cache line in set 3 of slice 25. See §2 for more details.

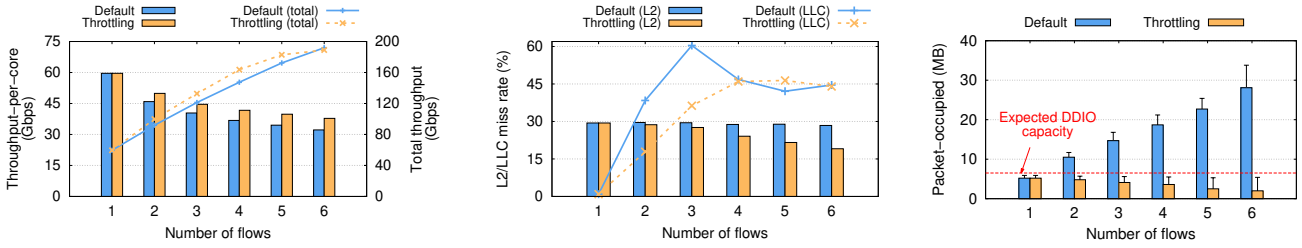
DDIO write hits and misses. DDIO uses way partitioning, reserving a subset of cache ways for DDIO writes (i.e., device-initiated writes to the LLC), typically two ways per set, with behavior similar to CPU store instructions: when the cache lines for the descriptor-page addresses are already present in the corresponding LLC slices (in any way, not only the DDIO-reserved ones), they are updated in place (**DDIO write hit**); otherwise, DDIO allocates new lines within the DDIO-reserved ways (**DDIO write miss**) [24, 33, 48, 60]. In either case, subsequent CPU reads (data copy) can hit in the LLC and avoid cold misses unless those lines have been evicted.

3 Revisiting Leaky DMA Problem

This section analyzes DDIO performance trends in modern Linux kernel stacks and identifies the underlying cause of the leaky DMA problem, focusing on Rx-side processing where CPU bottlenecks arise. We first describe our measurement setup (§3.1) and revisit the leaky DMA behavior with DDIO. We then present key observations and insights (§3.2), which lead to our motivation (§3.3).

3.1 Measurement Setup

Following the measurement methodology of prior studies [14, 15], we use a testbed consisting of two physical machines directly connected via a 200Gbps link to focus on CPU-bottleneck scenarios. Each machine has a 2-socket Intel Xeon Gold 6354 3.0GHz processor (18 cores per socket),



(a) Throughput-per-core (Gbps). (b) L2/LLC miss rate (%). (c) Total packet-occupied (MB).

Figure 3: **Leaky DMA performance with DDIO.** (Default setting) Traditionally, the leaky DMA problem has been attributed to cases where the volume of incoming packets exceeds the DDIO capacity, causing packets stored in DDIO-reserved cache ways to be evicted before processing completes. This results in reduced throughput-per-core and increased LLC miss rates. (Throttling setting) However, throttling incoming traffic to stay within the DDIO capacity is insufficient to fully resolve the issue. See §3.2 for more details.

1.25MB per-core L2, 12-way 39MB LLC, 256GB DRAM, and an NVIDIA ConnectX-6 (200Gbps) NIC. Both machines run Ubuntu 20.04 with the Linux kernel 6.6. We enable TCP Segmentation Offload (TSO), Generic Receive Offload (GRO), Jumbo frames (9000B), Dynamically-Tuned Interrupt Moderation (DIM), and aRFS to maximize receiver-side CPU efficiency during network processing. We disable hyper-threading, IOMMU, and `irqbalance`, since these settings maximizes performance in our measurements. Unless stated otherwise, we use default values for all system parameters.

We use iperf [21] to generate long-lived TCP flows and measure total throughput, overall CPU utilization, L2 and LLC miss rates. Throughput-per-core is calculated as total throughput divided by total CPU utilization, representing the throughput achievable by one fully utilized core. This metric serves as an indicator of CPU efficiency in network processing. In addition, we measure the packet-occupied memory, the total memory consumed by incoming packets that have not yet completed processing (i.e., in-flight bytes); this metric allows us to estimate whether total in-flight bytes exceed the expected DDIO-reserved LLC capacity (hereafter, DDIO capacity). In our testbed, the DDIO capacity is approximately 6.5MB (39MB$\times$2/12). We instrument the Linux kernel to measure packet-occupied memory in both the Rx socket buffer and the backlog queue, which holds packets when the corresponding socket is temporarily locked by user-level system calls [14]. To minimize overhead, we sample every 100 softIRQ events and record both the mean and the maximum with error bars (Figure 3(c)).

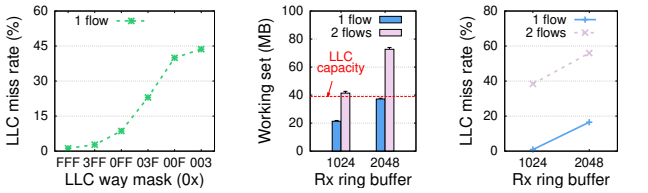
3.2 Understanding DDIO Miss Behaviors

We begin by reproducing the leaky DMA phenomenon observed with DDIO. Specifically, we measure throughput as the number of TCP flows increases, with each flow running on a separate core that shares the same LLC. Figure 3(a) shows that the Linux network stack (labeled "Default") benefits from the LLC with a single flow but experiences a ~46% drop in throughput-per-core as the number of flows increases from 1 to 6, primarily due to high LLC contention; correspondingly, the LLC miss rate rises to ~60.4%, as shown in Figure 3(b).

(1) Single-flow case: Near-zero miss rates due to a small working set (DDIO write-hit regime). In the single flow case (one core), the NIC driver holds 16MB of pages by default (§2). We further observe that ~6MB of additional pages are needed to replenish *page-consumed* Rx descriptors after the DMAed pages are handed to `skb`s (matching the maximum TCP Rx buffer memory size), so a single-flow replenishment cycle spans approximately 22MB in total. The key LLC behavior is that, even if DMAed pages are evicted from the DDIO-reserved ways (e.g., when more than two lines contend for the same set and slice), they are eventually reloaded into the LLC (likely into non-DDIO ways) by the CPU during the copy-to-user operation. Therefore, if the LLC can accommodate the entire page working set (~22MB), subsequent DDIO writes tend to hit in the LLC, as DDIO can leverage all LLC ways rather than only the two DDIO-reserved ways. This explains why the single-flow case sees near-zero miss rate (0.9%) in Figure 3(b). To support this observation, we rerun the single-flow experiment while reducing the number of LLC ways available to that core from 12 (LLC mask: 0xFFF) to 2 (LLC mask: 0x003), as shown in Figure 4(a). With fewer ways, the reloaded pages are more likely to be evicted from the LLC, resulting in more DDIO write misses.

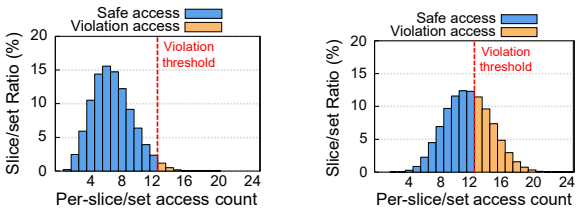
→Yet keeping the working set within the LLC capacity isn't enough. To clarify the impact of working set size, we increase the ring buffer to 2048 (32MB) in the single-flow experiment, making the total working set ~38MB, close to but below the LLC capacity (Figure 4(b)). Despite this, the LLC miss rate increases to 16.5% as shown in Figure 4(c) (while throughput drops by 11%). This indicates that simply keeping the page working set under the LLC capacity is insufficient to suppress LLC misses.

(2) Multi-flow case: High miss rates due to small DDIO capacity (DDIO write-miss regime). With two or more flows, the LLC cannot hold the entire page working set, so even CPU-reloaded pages are likely evicted before DDIO can reuse them on later writes. This shifts DMA traffic into a DDIO write-miss regime, where new lines are allocated in the DDIO-reserved ways. However, because the aggregate incoming traffic (i.e., packet-occupied memory in Figure 3(c)) far exceeds



(a) Limiting LLC ways. (b) Working set (MB). (c) LLC miss rate (%).

Figure 4: **DDIO write behavior.** (a) Limiting the number of available LLC ways increases DDIO write misses even in the single-flow case, indicating that DDIO write hits drive low LLC miss rates. (b–c) The write-hit regime can collapse even with working sets near the LLC capacity, raising LLC miss rates. See §3.2 for more details.



(a) Working set size: 22MB. (b) Working set size: 38MB.

Figure 5: **Violation ratio comparison (22MB vs. 38MB).** For given page footprints: (a) when per-slice/set access counts stay at or below the violation threshold (i.e., ≤associativity), accesses are safe (blue bars), so evictions are unlikely; (b) counts above this threshold are violations (orange bars), indicating potential conflict misses and LLC underutilization. See §3.3 for more details.

the DDIO capacity in multi-flow cases, those new lines are rapidly displaced by subsequent DDIO writes, which in turn increases the LLC miss rate during the CPU reads.

→**Yet throttling traffic below the DDIO capacity isn't enough.** Prior work suggests limiting in-flight bytes to fit within the DDIO capacity [58], so that CPU reads ideally hit in the LLC. Surprisingly, we find this is not sufficient by itself to keep LLC miss rates low. In Figure 3(c), we throttle the incoming rates of individual TCP connections (labeled "Throttling") by adjusting the TCP receive buffer size, ensuring that total packet-occupied memory remains within the DDIO capacity even with multiple flows. However, Figure 3(b) reveals that Throttling does not suppress LLC misses; instead, the miss rate rises to as high as 46.4%.

Despite similarly high LLC miss rates at 4–6 flows (Figure 3(b)), Throttling still offers a slight improvement compared to Default (Figure 3(a)); our measurements indicate that, beyond three flows, its L2 miss rate decreases while Default's remains unchanged, which is evidence of the improvement. This behavior is likely due to increased L2 hits on frequently recycled objects (e.g., `skb`) as the per-core throttled traffic (i.e., packet-occupied memory) approaches the L2 capacity. We also note that the average packet-occupied memory under Throttling decreases as the number of flows increases in Figure 3(c). This is because, given the same total incoming traffic, increasing the number of cores accelerates packet processing, which in turn reduces the average amount of packet-occupied memory before subsequent packets arrive.

3.3 Motivation: Conflict Misses Matter

To dive deeper into DDIO miss behavior, we analyze how the page working set is distributed across the LLC. Specifically, we compare the 1-flow and 2-flow cases under Throttling in Figure 3, configured so that both the Rx ring buffer and in-flight bytes fit within the LLC capacity (22MB vs. 38MB), yet the LLC miss rates differ (0.9% vs. 18%). Our methodology is as follows: First, by leveraging well-known reverse-engineering techniques [47], we identify the LLC details of our processor, including its slice hash function (§2). This allows us to compute the slice and set for any physical memory address. Second, we collect page-address traces while rerunning the two cases and examine the slice/set distribution over a working-set window. To quantify cache contention, we define a *violation* when the number of mappings to a particular slice/set exceeds the LLC associativity (i.e., 12 ways); the *violation ratio* is the fraction of such violations over all slice/set combinations.

Skewed page addresses lead to conflict misses and LLC underutilization. Figure 5(a) shows that, in the 22MB working-set case, mappings to any slice/set mostly stay below the associativity limit, yielding a violation ratio (orange bars) of only 1.97%. In contrast, the 38MB working-set case in Figure 5(b) jumps to 39.3% even though the working set still fits within the LLC. This indicates that parts of the LLC are underutilized because page addresses are skewed across slice/set mappings, which can lead to conflict misses. We note that a high violation ratio does not necessarily result in a high LLC miss rate; since tracing precise CPU access timing is prohibitively expensive, our analysis in Figure 5(b) does not reveal whether evictions occur before or after CPU reads. Nonetheless, a high violation ratio is necessary for high miss rates, whereas near-zero violation implies conflict misses are unlikely. In our measurements, we observe a clear correlation between violations and actual LLC misses.

Avoiding conflict misses is key. Revisiting the leaky DMA problem, we draw two key insights. First, expanding the DDIO allocation beyond two LLC ways [24, 64] is insufficient: in the DDIO write-hit regime, DDIO already exploits LLC ways outside the reserved portion. Although this provides DDIO with access to more LLC space, *conflict misses* still prevent full utilization of that space (Figure 5(b)). Second, throttling traffic to stay within the DDIO capacity [58] also falls short: our analysis reveals that capacity pressure is driven more by the page working-set size than by the amount of incoming traffic (Figure 3), while *conflict misses* further reduce the effective LLC capacity available to that working set (Figure 5(b)). These findings motivate a new design that actively reduces conflict misses to make DDIO effective, particularly for the applications that benefit from DDIO.

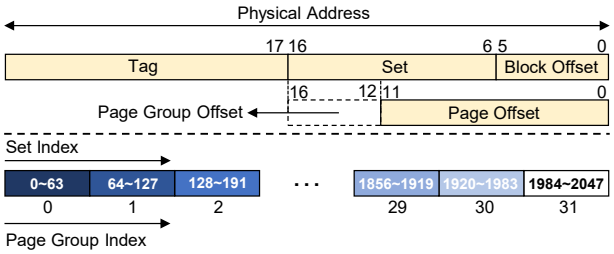


Figure 6: **Page group allocation.** The set index and block offset fields span 17 bits in total. Of these, 12 bits are used as the 4KB page offset. Thus, five upper set index bits remain available for page grouping, which we refer to as the page group offset. Accordingly, the 2048 LLC sets in the system can be partitioned into 32 page groups, each consisting of 64 sets. See §4.1 for more details.

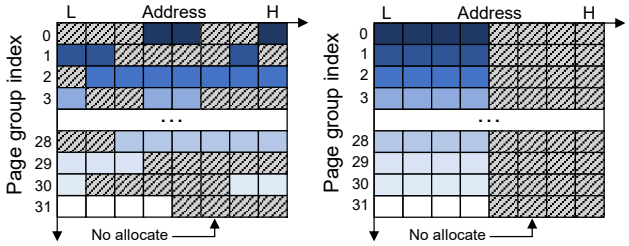

Figure 7: **Memory allocation behavior.** (a) The default Linux buddy allocator ignores set indexing, resulting in uneven page distribution across page groups and set-level imbalance. (b) Stride-1 enforces set balance by allocating an equal number of pages to each of the 32 page groups. See §4.1 for more details.

4 Sepia: DDIO Meets Page Coloring

To tackle conflict misses, we bring a classical yet effective technique—"page coloring"—into the DDIO context, adapting it to the packet I/O path. In this section, we introduce Sepia, a color-aware page allocator for DDIO. We first outline our page-coloring methodologies (§4.1). We then evaluate how coloring improves the effective capacity of modern sliced LLCs in both DDIO write-hit and write-miss regimes (§4.2). Finally, we present our Sepia design that makes page coloring practical in real DDIO-enabled systems (§4.3).

4.1 Page Coloring Methodology

As modern processors employ a sliced LLC architecture (recall §2), we must design our coloring mechanism by considering its structural characteristics. Figure 6 shows the bit-level structure of a physical address. Under page-granularity allocation, the lower set index bits overlap with the page offset, so we can use only the upper five bits (e.g., bits 12–16 in Figure 6) for page coloring. We use these specific bits to partition memory into 32 *page groups*, where each group consists of pages sharing the same upper set index (i.e., page group offset). Accordingly, we employ this page group as the basic unit of our page coloring technique.

Baseline: Stride-1. We first observe that the default Linux page allocator (i.e., buddy allocator) operates in both set- and slice-agnostic ways, leading to significant conflict misses in the LLC. As illustrated in Figure 7(a), the allocator does not consider the set-index mapping, resulting in imbalanced page-group usage: it allocates more pages on some page groups, increasing pressure on the corresponding sets and causing frequent conflict misses. Likewise, the allocator ignores the slice mapping, leading to imbalanced slice usage as well. Thus, the default allocator suffers from both set- and slice-level imbalance, directly degrading effective LLC capacity.

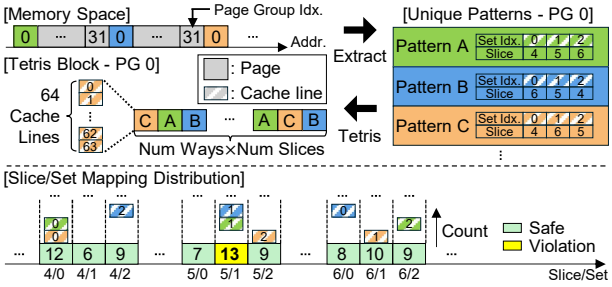

Figure 8: **Construction of a Tetris Block.** First, unique slice/set mapping patterns are extracted from the physical memory space for each page group (e.g., PG 0). Then, these patterns are assembled (i.e., *Tetris*) into a *Tetris block* to maximize the balance of the slice/set mapping. **However, due to the finite number of unique patterns, violations inevitably occur in the mapping distribution.**

To address this issue, we introduce Stride-1, a practical page-coloring technique that improves effective LLC capacity by balancing both set and slice usage (Figure 7(b)). Stride-1 first achieves set balance by allocating the same number of pages to each of the 32 page groups. Within each page group, it then allocates physical pages sequentially in ascending address order, leveraging an inherent behavior of modern LLC slice-hash functions (i.e., contiguous physical addresses tend to be distributed across slices), which is shown in prior work [46] and also confirmed by our own reverse engineering. By combining set-balanced allocation with this intrinsic slice-spreading behavior, Stride-1 successfully eliminates set conflicts and substantially reduces slice conflicts.

We observe that, while Stride-1 substantially reduces slice conflicts, it cannot fully eliminate slice-level imbalance due to an inherent hardware constraint. Modern processors often employ a non–power-of-two number of LLC slices (e.g., 26 in our system), which introduces modulo bias in the slice-hash function [47]. As a result, slice mappings are not uniformly distributed, creating hotspots on specific slices even when pages are allocated contiguously. This slice imbalance represents a fundamental limitation that prevents Stride-1 from achieving perfectly balanced slice usage.

Tetris: Slice-balanced Stride-1. To quantify how much performance potential remains beyond Stride-1, we further introduce *Tetris*, a theoretically optimal page-allocation sequence designed to minimize slice conflicts. Unlike Stride-1's sequential allocation, Tetris leverages reverse-engineered slice/set mappings to construct an allocation order that achieves near-perfect slice balance. As illustrated in Figure 8, Tetris first

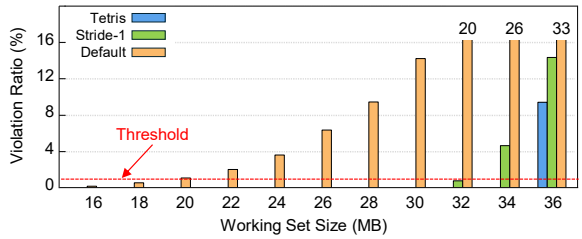

Figure 9: **Evaluation of effective LLC capacity.** Comparison of *violation ratio* across working set sizes. We define the effective LLC size as the working set size at which the violation ratio remains negligible ($< 1\%$) (Default: 18MB, Stride-1: 32MB, Tetris: 35MB (0.04%, not shown)). See §4.2 for more details.

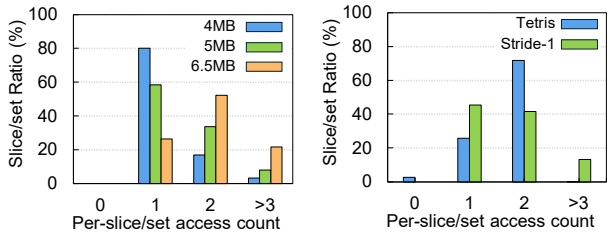


(a) Violation analysis of Stride-1. (b) Tetris vs Stride-1 (5.5MB).

Figure 10: **Comparison of slice/set distributions.** (a) The effective DDIO capacity of Stride-1 is limited to 3MB (not shown), where the violation ratio remains 0%. (b) Tetris extends the effective DDIO capacity up to 5.5MB while maintaining a 0% violation ratio through optimized slice/set mapping. See §4.2 for more details.

extracts all unique patterns (i.e., distinct per-page slice/set mappings). For each page group, it then assembles these patterns into a *Tetris block*, a carefully arranged sequence that balances slice usage within that group. We use this Tetris block as the allocation unit, allowing us to achieve an optimally balanced slice distribution under page-granularity constraints. Tetris therefore serves as an upper bound, revealing how much headroom remains if Stride-1 were to run under a perfectly slice-balanced distribution in a system with a non-power-of-two number of LLC slices. In the following section, we rigorously evaluate the effective LLC capacity of three allocation mechanisms: Default (slice/set-imbalanced), Stride-1 (set-balanced and partially slice-balanced), and Tetris (set-balanced and fully slice-balanced).

4.2 Validation of Coloring Effectiveness

This subsection quantifies the gain in effective LLC capacity achieved by coloring compared to Default.

Experimental setup. We evaluate the three schemes across a range of allocation sizes to examine their sensitivity under different working set sizes. We use the *violation ratio* (defined in §3.3) as our metric, as we observe that it strongly correlates with cache miss rates. To control page allocation patterns, we use a large physical memory chunk for all three schemes. To quantify their effectiveness, we employ the *effective LLC size*, defined as the maximum working set size where the violation ratio remains negligible ($< 1\%$).

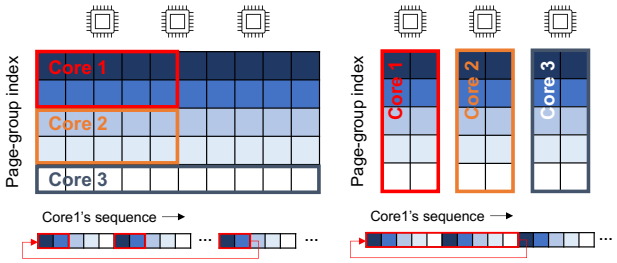
Analysis of effective LLC size (Write-hit regime). Figure 9 illustrates how the violation ratio changes as the working set size increases. First, we observe that Default fails to utilize the cache efficiently, limiting its effective LLC size to only 18MB (46.2% of capacity). In contrast, Stride-1 significantly shifts the point at which the violation threshold (1%) is reached, extending the effective LLC size to 32MB. This represents a 77.8% expansion in effective capacity compared to the baseline, allowing Stride-1 to utilize 82.1% of the total LLC. Tetris further pushes this limit to 35MB (89.7% of capacity). However, although Tetris represents the theoretical optimum, it does not reach 100%. As shown in Figure 8, this gap arises from the finite number of unique mapping patterns; since memory allocation operates at page granularity, the reuse of patterns inevitably causes set collisions on specific slices, thereby bounding the maximum achievable capacity.

We note that Tetris's violation ratio spikes from 0.04% to 9.43% beyond 35MB, exposing a critical dependency on a perfectly predefined allocation order. Given that this order is inevitably disrupted in real systems (detailed in §4.3), Tetris is practically infeasible.

Analysis of effective DDIO capacity (Write-miss regime). To verify whether the benefits of coloring observed in the full LLC carry over to the restricted DDIO region, we repeat the analysis with 2-way DDIO associativity. Figure 10 shows that coloring effectiveness is notably reduced compared to the full LLC results. While Stride-1 and Tetris utilized 82.1% and 89.7% of the total LLC, their efficiency in the 6.5MB DDIO region drops significantly to 46.2% (3MB) and 84.6% (5.5MB), respectively. This degradation highlights the impact of non-uniform mapping (i.e., modulo bias detailed in §4.1); the restricted 2-way associativity provides insufficient buffer to tolerate skewed load distributions among slices. Therefore, DDIO performance can be limited if we rely on coloring exclusively within such a restricted LLC region.

4.3 Sepia Design

We now present Sepia, which realizes the Stride-1 coloring over DDIO-enabled CPU cores; as discussed in §1, applying page coloring to DDIO scenarios creates new opportunities for CPU-efficient packet processing. However, two design challenges remain: inter-core and intra-core interference. First, since CPU cores share the LLC, colors must be balanced across cores to maximize effective LLC capacity while minimizing coordination overhead among per-core page pools. Second, although network processing behavior is deterministic, page recycling times can still vary within the same page pool, paced by application read calls. Thus, the allocator must choose the best color from the (recycled) pages currently available in the pool when replenishing the Rx ring. Once pages are submitted to the NIC, the corresponding ring entries are fixed and cannot be recolored until those entries are



(a) Shared pool. (b) Per-core pool.

Figure 11: **Sepia Manager** constructs per-core page pools, which is the right design that reduces working-set reconstruction overhead. See §4.3 for more details.

replenished. From these insights, our design goal is simple: *keep a per-core, color-aware page pool robust to cross-core conflicts and uneven page recycling speeds.* To this end, we introduce two design components: (1) Sepia Manager, which builds per-core colored page pools and tracks page availability; and (2) Sepia Allocator, which selects the best available page at allocation time.

Sepia Manager. The Sepia Manager organizes the Rx-ring working set as a two-dimensional page array (see Figure 7(b)), which enables the Stride-1 allocation strategy. This page array is modeled after the structure of the LLC: vertically, there are N page-groups, and horizontally, M pages per group; pages within the same group share the same color. The value of N is determined by the LLC specification (§4.1); M is then set by the total number of pages required by each Rx ring. For example, if we provision 16MB per ring with 32 page groups, then $M = 128$ pages per group ($32 \times 128 \times 4\text{KB} = 16\text{MB}$).

For scenarios where multiple cores contend for the LLC via DDIO writes, we consider two options for constructing the colored page pool: (1) assign a subset of page groups to each core while sharing a single pool (Figure 11(a)); or (2) provision a separate per-core pool that permits access to all page groups (Figure 11(b)). The first option reduces cross-core conflicts but raises management costs: we must track which cores are active to assign page groups preferentially to busy cores for better LLC utilization. Moreover, since pages already submitted to the NIC cannot be recolored, any working-set rebuild triggered by changes in active-core counts must wait for a full recycle turn, consuming the previously colored pages in the meantime. Finally, color distribution can become unfair depending on the number of active cores and the value of N. For example, in Figure 11(a), Core 3 is assigned a single page group while others receive two. Sepia avoids this overhead by building per-core colored page pools (Figure 11(b)), allowing each core to operate independently without tracking other cores' status. While the per-core pool design accepts some cross-core interference as a trade-off, each core can draw from the full set of page groups, which helps keep per-group page counts balanced across cores on average.

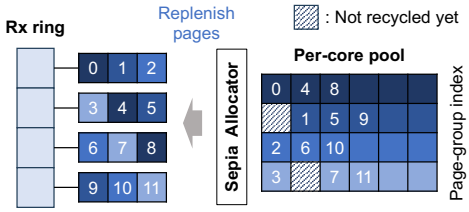


Figure 12: **Sepia Allocator** selects pages one by one from each page-group index, choosing the earliest page within the group. The numbers inside the pool illustrate an example allocation order. When previously unavailable pages are recycled, they become eligible for selection in subsequent rounds. See §4.3 for more details.

Sepia Allocator. The Sepia Allocator is responsible for providing pages from the per-core page pools. Ideally, allocation cycles through page groups sequentially in a wraparound manner—i.e., the Stride-1 pattern over a contiguous memory chunk, as illustrated in Figure 11(b) (see "Core 1's sequence"). This ideal ordering is attainable at initialization; however, as pages are recycled, the order in which they return for Rx-ring replenishment may diverge from the original allocation, creating gaps—or "page holes"—in the pool, as shown in Figure 12. Given that the recycle timing of individual pages is outside our control, Sepia prioritizes preserving sequential color ordering during Rx-ring replenishment. If the Sepia Allocator encounters a page hole during sequential allocation, it selects the next available page within the same group (and thus the same color). This ensures that Rx descriptor pages are filled in page-group order and preserves the low-conflict allocation pattern. A simplified example of this scenario is illustrated in Figure 12. Additionally, the allocator prefers the earliest available page per group, which helps minimize the active working set at light load. Lastly, if a particular page group reaches the right boundary (M) earlier than others due to page holes, the Sepia Allocator skips that group until pages become available. Once the pool is exhausted, it falls back to the standard Linux allocator. Although this may temporarily introduce non-colored pages into the pool, Sepia continues to manage and prioritize colored pages. As the load decreases and colored pages are recycled, Sepia can naturally restore the effectiveness of page coloring (§6.3).

5 Sepia Implementation

We implement the Sepia prototype in the Linux kernel 6.6. Although our current implementation is integrated with a specific network device driver (ConnectX), our goal is to provide a generic API for network drivers, thereby minimizing the effort required to port Sepia to other network drivers. This portability is enabled by the fact that Sepia's implementation is decoupled from any driver-specific logic.

Page working set management. Sepia requires a carefully constructed working set of well-aligned, consecutive pages to minimize cache conflicts. Since the default Linux memory allocator does not provide this level of control, we leverage the Contiguous Memory Allocator (CMA) [18] to obtain large,

physically contiguous memory regions suitable for coloring-aware allocation. Specifically, we pre-allocate 16MB of pages per core (4MB for the Rx ring and 12MB for descriptor replenishment). Given that our testbed has 18 DDIO-enabled cores, this results in a total allocation of 288MB of contiguous memory, comparable to the default Linux footprint for Rx rings (excluding packet-occupied memory). When additional pages are further needed, Sepia falls back to the standard Linux allocator as discussed in §4.3.

Sepia interfaces. To facilitate driver integration, we introduce Sepia interfaces, for example, `sepia_init()` to initialize per-core colored page pools. The function `sepia_alloc()` can be invoked by network drivers when new pages are needed for Rx descriptor replenishment. Initially, the network drivers populate Rx descriptors using the default Linux allocator. However, once Sepia detects that a core is actively consuming Rx descriptors and a colored page pool has been created, Sepia seamlessly switches the replenishment source to the Sepia Allocator. This implementation design allows Sepia to operate transparently alongside existing kernel infrastructure while optimizing memory placement and minimizing cache conflicts during high-throughput packet processing. Note that Sepia recognizes colored pages by verifying that their addresses lie within the CMA-allocated range, which ensures they are correctly returned to Sepia's pools during recycling.

Handling capacity misses in Sepia. While Sepia focuses on reducing conflict misses, CPU efficiency is typically maximized when both capacity and conflict misses are effectively avoided. In the write-hit regime, Sepia expands the effective working set by 77.8% over Linux (Figure 9); thus, if the aggregate working set is kept beneath this effective LLC budget, both types of misses can be avoided. Prior proposals shrink the working set by cross-core Rx-ring sharing [51, 52], but they operate in user space [2] or on the device. We instead tune the per-core Rx ring (we plan to integrate the prior approach [51] into Sepia as future work). Considering that, in our default setup, the NIC's DIM [3] is configured to coalesce up to 128 packets (∼1.1MB at 9000B MTU) before triggering softIRQ and ring sizes are powers of two, we set Sepia's default to 4MB per core (ring size 256) as our baseline configuration to constrain the working set. In our evaluation, this setup successfully replenishes the consumed ring entries before the next DMA arrivals; for comparison, we also evaluate the default ring in §6.2. In addition, reducing TCP Rx buffer further helps shrink the working set; for example, combining 4MB per-core rings with 4MB TCP Rx buffer (`tcp_rmem`) per core keeps Sepia's working set within the effective LLC capacity (32MB; Figure 9) up to 4 cores (∼8MB per core), saturating 200Gbps with ∼4 cores (§6.1). We use this configuration for Sepia in our microbenchmarks to evaluate the best-case regime.

In the write-miss regime (aggregate working set > LLC capacity), the key is to keep total in-flight bytes below the effective DDIO capacity. On our platform, two DDIO ways yield only ∼3MB effective capacity (Figure 10). Although system-wide TCP tuning (as in §3) could enforce this, throttling every connection under such a tight budget is impractical: per-flow traffic monitoring and rate regulation typically incur high overhead as flow loads vary over time [30][3]. Accordingly, we use the write-hit regime to represent the best case (we also evaluate excessive working-set scenarios).

6 Evaluation

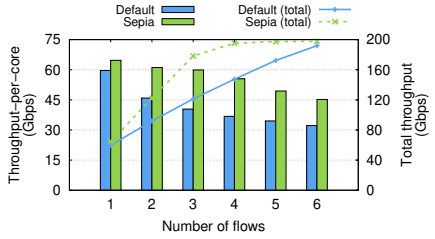
This section evaluates Sepia's effectiveness across diverse experimental setups and real-world applications. We first perform microbenchmarks, comparing it with default Linux (§6.1). Next, we provide a performance breakdown of Sepia in terms of throughput-per-core to understand the performance gains in the best-case regime (§6.2). Finally, we evaluate Sepia with real-world applications, including SPDK, Nginx, and Memcached (§6.4). We describe each setting in place. Unless stated otherwise, we use the same evaluation setup described in §3.1.

6.1 Microbenchmarks

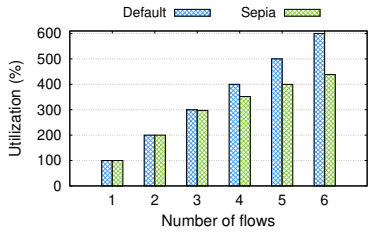
We use iperf [21] for our microbenchmarks, varying the number of flows with one flow per core as we did in §3. Specifically, we use two configurations of Sepia discussed in §5 to evaluate it under (1) the write-hit regime, where capacity and conflict misses are avoided (best case), and (2) the write-miss regime, where capacity misses occur (worst case).

Write-hit regime. Our goal is to understand how increasing the effective LLC capacity translates into improved CPU efficiency. In Figure 13(a), we first observe that Sepia improves throughput-per-core by ∼1.51× compared to Default, saturating the 200Gbps link with 3.5 cores, whereas Linux requires 6 cores to reach link saturation (Figure 13(b)). This is because DDIO's benefits are maximized with near-zero LLC miss rates (∼0.4%) up to 6 flows (cores) (Figure 13(c)). To further investigate how Sepia achieves this, we plot its working set size corresponding to Figure 13, as shown in Figure 14. As discussed earlier, each working set consists of per-core Rx descriptor pages and packet-occupied memory (i.e., in-flight bytes controlled by TCP). Consequently, the Rx descriptor portion of the working set increases linearly with the number of cores (i.e., 4MB per core), as shown in Figure 14. On top of this, the packet-occupied memory increases to ∼7.8MB up to 3 cores, and then decreases as the link becomes saturated (we discussed this phenomenon in §3.2). Since Sepia increases the effective LLC capacity from 18MB to 32MB via the color-aware allocations (Figure 14), it can avoid both capacity and conflict misses up to 6 cores (and also 7 cores;

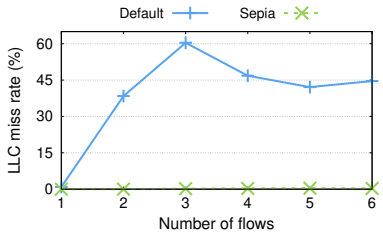
[3] One alternative is to increase the DDIO way budget, making DDIO write-missed pages more likely to remain in the LLC until CPU reads [64], so coarse TCP controls suffice. We thoroughly followed existing open methodologies [10, 16, 23, 34] to adjust the DDIO-allocated portion, which worked on earlier generations of Intel CPUs, but none succeeded on our recent Intel Ice Lake and Emerald Rapids machines. In any case, Sepia remains effective because its design is independent of the DDIO-associativity configuration.



(a) Throughput (Gbps).



(b) CPU utilization (%).



(c) LLC miss rate (%).

Figure 13: **DDIO write-hit regime: Sepia's benefits are maximized as both capacity and conflict misses are avoided.** (a) Sepia achieves up to 1.51× improvement in terms of throughput-per-core, compared to Default, reaching the link saturation (200Gbps) using (b) 2.5 fewer cores than Default, (c) while keeping near-zero LLC miss rates (∼0.4%). See §6.1 for more details.

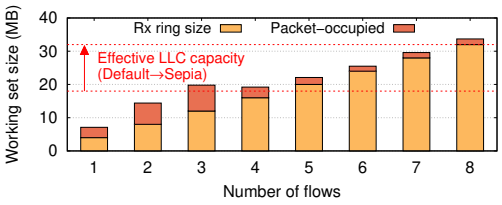


Figure 14: **Sepia's working set trend (write-hit regime).** Our color-aware allocation expands the effective LLC capacity from 18MB to 32MB, accommodating the page working sets of up to 7 cores.

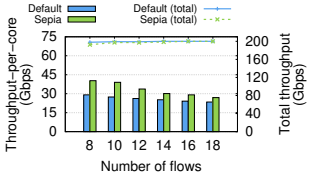
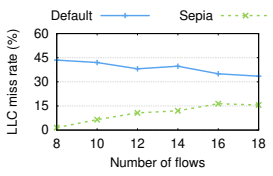


(a) Throughput (Gbps).



(b) LLC miss rate (%).

Figure 15: **DDIO write-miss regime: Sepia's benefits shrink as capacity misses become unavoidable.** (a) Even in this worst-case scenario, Sepia still improves throughput-per-core, and (b) reduces LLC miss rates compared to Default. See §6.1 for more details.

results not shown). These results also confirm that our analysis in §4.2 matches real-world experiments. Note that if our LLC were fully slice-balanced (so that the effective capacity would become 35MB in our system), LLC misses would be suppressed up to 8 cores.

Write-miss regime. In Figure 15, we further increase the number of flows from 8 to 18 using all available DDIO-enabled cores. Sepia's working set starts to exceed the effective LLC capacity at 8 flows (Figure 14), thus shifting to the write-miss regime and showing a 1.5% LLC miss rate (> 1%). As the number of flows grows to 18, Sepia's LLC miss rates increase up to 16.4% (Figure 15(b)). We find that after 8 flows, Sepia's packet-occupied memory fluctuates between 2.6–3.7MB; given that the effective DDIO capacity for Sepia is around 3MB (Figure 10), this can lead to high LLC miss rates. Nonetheless, Sepia still shows lower LLC miss rates than Default, achieving better CPU efficiency overall (Figure 15(a)) even in the worst-case scenarios, where capacity misses are unavoidable.

6.2 Understanding Performance Gains

To understand how Sepia improves CPU efficiency and to quantify the contribution of each technique, we perform an ablation study by enabling our mechanisms one at a time under the best-case scenario shown in Figure 13. Starting from the baseline Linux allocator (Default), we first replace Linux's page allocator with our Sepia Allocator (Stride-1). Next, we reduce the default Linux Rx ring size by *throttling* the number of ring entries to 256 while retaining the baseline Linux allocator (Ring Throttling). This setup evaluates the effect of working set reduction, following a similar approach to SHRing [51]. Lastly, We evaluate Sepia, which incorporates both Stride-1 and our working-set throttling techniques (i.e., limiting the number of ring entries and the TCP buffer size). Figure 16 shows the performance breakdown across different configurations, where the x-axis denotes the number of concurrent flows and the y-axis reports throughput-per-core.

Stride-1. Overall, Stride-1 improves per-core throughput by up to 11.4% (8.62% on average) by increasing the effective LLC capacity through reduced conflict misses compared to the default Linux memory allocator. With a single flow, the total working set size (21.2MB on average), including Rx ring and TCP buffers, exceeds the baseline's effective LLC capacity (18MB) but fits within that of Stride-1 (32MB). Here, Stride-1 reduces unnecessary LLC conflicts and lowers the LLC miss rate (from 0.9% to 0.1%), yielding a modest but measurable throughput improvement. As the number of flows increases, the working set exceeds the effective capacity of both Default and Stride-1, making both cases operate in the DDIO write miss scenario. In this case, efficient use of the DDIO-reserved ways becomes critical. Note the leaky DMA problem becomes even more severe with fewer available ways, making it difficult for the baseline to utilize the DDIO-reserved ways efficiently. On the other hand, Stride-1 can mitigate this problem, so DDIO write misses are more uniformly distributed across LLC slices and sets, improving overall efficiency even under high flow counts.

Ring Throttling. The results show that throttling the Rx ring also provides meaningful performance benefits. With a single flow, its performance is comparable to Default because the Default's working set size is already small and fits within

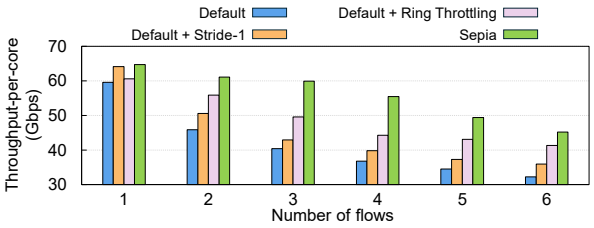


Figure 16: **Sepia performance breakdown.** This result indicates that Sepia's color-aware allocation (together with Ring Throttling) allows the network stack to utilize the LLC more efficiently during DDIO. See §6.2 for more details.

Table 1: **Memory bandwidth consumption** for the 4-flow case in Figure 16. This result indicates that Sepia is more cache-friendly, requiring less memory bandwidth than the other configurations.

Mechanism	Default	Default w/Stride-1	Default w/Ring-Thrtt.	Sepia
BW (GB/s)	31.29	30.01	16.59	0.96

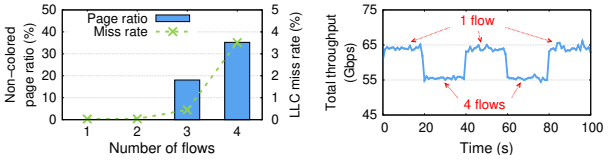
the effective LLC capacity. However, as the number of flows increases, Rx ring throttling provides substantial performance improvements over both Default and Stride-1. This is because its reduced working set improves the LLC efficiency, resulting in lower LLC miss rate. To quantify this effect, we additionally measure the memory bandwidth consumption for each configuration at 4 flows (Table 1). The results show that Ring Throttling reduces memory bandwidth usage by 47.0% and 44.7% compared to Default and Stride-1, respectively.

Sepia. On top of Stride-1, Sepia adopts working-set throttling techniques: limiting both the number of active ring entries and the TCP buffer size. For lower flow counts (1–4 flows), the working set can fit within the effective LLC capacity because Sepia reduces the working set size compared to the baseline. This allows additional flows to continue operating in the DDIO write hit scenario. Here, the combination of Stride-1 (larger effective capacity) and memory throttling (smaller working set) produces a clear synergistic effect, yielding substantial throughput improvements by up to 50.8%. For higher flow counts (5–6 flows), the working set again exceeds the LLC effective capacity, placing all cases in the DDIO write miss scenario. Here, Sepia shows consistent performance improvement over Default and Stride-1. This is because Sepia can improve L2 cache efficiency by constraining the number of active descriptor pages per core. This reduces the overall load-miss stall cycles, leading to higher throughput.

In summary, Sepia delivers significant performance improvement across all flow counts by reducing the working set size, amplifying the benefits of color-aware page allocation, and improving L2 efficiency.

6.3 Performance under Bursty Workloads

We now evaluate Sepia under an extreme scenario where its page pool is exhausted by bursty DMA requests, causing the default Linux allocator to introduce *non-colored* pages into the pool. To generate this bursty workload, we increase



(a) Page ratio and miss rate (%). (b) Total throughput (Gbps).

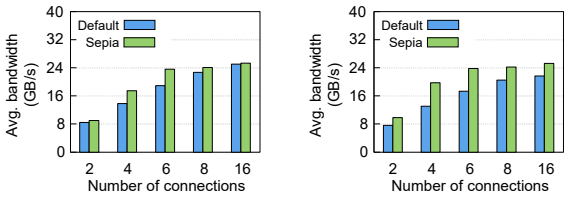
Figure 17: **Sepia performance under bursty workloads.** (a) Page-pool exhaustion can introduce non-colored pages from the default allocator, increasing LLC miss rates. (b) Sepia quickly recovers once enough colored pages become available. See §6.3 for more details.

the number of flows on a single core, each using a 6MB TCP Rx buffer, to consume Sepia's per-core page pool more aggressively. Figure 17(a) shows the non-colored page ratio (i.e., the fraction of non-colored pages in the pool), along with the corresponding average LLC miss rate for different numbers of flows. With 4 flows, non-colored pages account for 35% of the pool, increasing the LLC miss rate to 3.5% and reducing total throughput from 64Gbps to 55Gbps compared to the 1-flow case. Based on these static measurements, we then alternate between 1 and 4 flows every 20 seconds, as shown in Figure 17(b). The results demonstrate that Sepia effectively recovers from colored-page depletion as soon as enough colored pages become available.

6.4 Real-world Applications

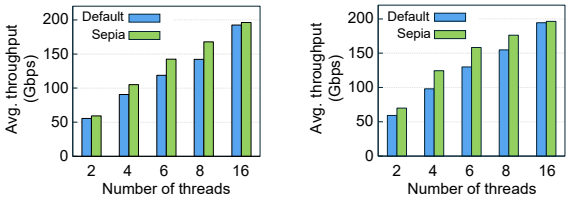
SPDK. We evaluate Sepia using SPDK, a high-performance userspace storage stack. Specifically, we use NVMe-over-TCP, which connects host and target machines through the Linux network stack [28, 29, 62]. The host NVMe initiator generates SPDK read requests with two block sizes (64KB, 128KB) and a queue depth of 16. For the NVMe remote target, we deploy 36 SPDK polling threads pinned to 36 cores, so that the initiator with Sepia becomes the bottleneck. We use a NULL block device [8] for a backend storage medium to eliminate the storage bottlenecks. We measure the average I/O bandwidth across different numbers of NVMe-over-TCP connections (five runs for each configuration), as shown in Figure 18. The results show that Sepia improves I/O bandwidth by up to 26.7% for 64KB blocks and 51.1% for 128KB blocks. Notably, Sepia shows huge performance improvement over the default Linux kernel when the working set is kept within the effective LLC capacity. The benefit becomes much larger with 128KB blocks, where each request spans more packets and enlarges the working set size. In this case, the default Linux quickly encounters conflict misses and LLC capacity pressure (due to higher portion of packet occupied), leading to significant performance degradation. On the other hand, Sepia achieves stable link-saturating throughput without any performance degradation at higher connection counts (>6). These results demonstrate that Sepia substantially improves real-world I/O performance.

Nginx. We evaluate Sepia using Nginx [7], a widely used web server, running all worker processes over DDIO-enabled cores.



(a) Block size: 64KB. (b) Block size: 128KB.

Figure 18: **Evaluation results with SPDK.** Sepia achieves up to 1.27× and 1.51× improvements in average bandwidth over the default Linux with 64KB and 128KB block sizes, respectively.

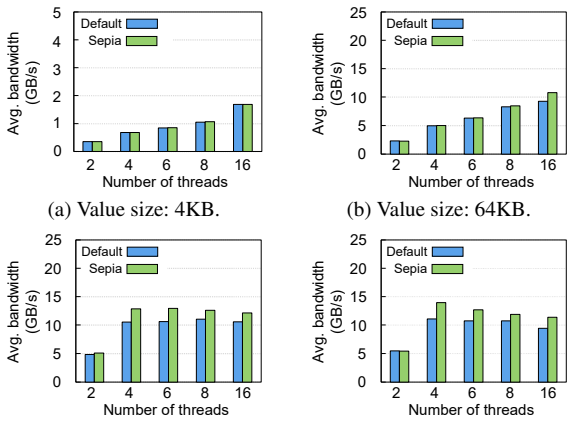


(a) Web page size: 2MB. (b) Web page size: 4MB.

Figure 19: **Evaluation results with Nginx.** Sepia achieves up to 1.2× and 1.27× improvements in average throughput over default Linux with 2MB and 4MB web page sizes, respectively.

For input traffic, we use the wrk benchmark [27] to generate HTTP POST requests, so that the Nginx server with Sepia becomes the bottleneck on the receiver side. We configure one TCP connection per wrk thread and increase the number of threads to scale the request concurrency. We compute upload bandwidth (requests/sec × payload size) and report the average upload bandwidth over five runs for each configuration (Figure 19). Following prior work that reports the average size of modern webpages to be around 2MB [32], we evaluate two payload (web page) sizes: 2MB (Figure 19(a)) and 4MB (Figure 19(b)). With 2MB payload, Sepia improves the upload bandwidth by up to 20% at six wrk threads. With 4MB payload, Sepia achieves up to 27.1% bandwidth improvement at four wrk threads. Larger payloads increase the number of packets per HTTP request and enlarge the descriptor working set, making the default Linux allocator more susceptible to LLC capacity pressure. In contrast, Sepia can keep their working set compact, allowing Nginx to sustain higher upload bandwidth over Default across all configurations.

Memcached. We evaluate Sepia using Memcached, one of the most widely used in-memory key-value applications [5]. We use four Memcached worker threads and pin them to four CPU cores to evaluate how efficiently each scheme can handle incoming requests under constrained resources. On the client side, we use Memtier benchmark [6] configured to issue 100% SET requests to ensure the Memcached server with Sepia becomes the bottleneck. Similar to Nginx evaluation, we create one TCP connection per client thread, and use a pipeline depth of four. We measure the average throughput by varying the number of client threads (Figure 20). Here, we use four different value sizes: 4KB, 64KB, 512KB, and 1MB. The 4KB value size represents a workload with limited



(a) Value size: 4KB. (b) Value size: 64KB.
(c) Value size: 512KB. (d) Value size: 1MB.

Figure 20: **Evaluation results with Memcached.** For workloads with limited DDIO benefit (e.g., 4KB values), Sepia matches the performance of default Linux. As the value size increases to 512KB and 1MB, where DDIO efficiency becomes more important, Sepia improves average bandwidth by up to 1.26× over default Linux.

DDIO benefits, because each request touches only a small amount of data. As shown in Figure 20(a), Sepia does not degrade performance compared to Default even for this workload, indicating that it can remain safely enabled when DDIO benefit is limited. Starting from 64KB, Sepia begins to show modest benefits (Figure 20(b)). For larger value sizes, where DDIO efficiency becomes more important, Sepia provides clearer improvements: up to 22% with 512KB values (Figure 20(c)) and up to 25.9% with 1MB values (Figure 20(d)). Note that Sepia sustains higher throughput once the server becomes core-saturated (more than four threads), indicating that Sepia processes requests more efficiently under resource-constrained environment. This throughput improvement is also aligned with latency results. With 512KB, Sepia reduces average latency from 0.74ms to 0.60ms. With 1MB, Sepia provides more latency reduction from 1.40ms to 1.12ms.

7 Discussion

This section further discusses how Sepia complements existing solutions and can be extended to future architectures.

Sepia's benefits with shared ring buffer schemes. Our work shows that conflict misses are another key contributor to high LLC miss rates in DDIO operations, making Sepia complementary to existing shared ring buffer schemes such as SHRing [51]. SHRing reduces cache capacity misses by sharing DMA buffers across flows, while Sepia reduces conflict misses by allocating colored pages. Two aspects of the cache footprint are particularly important. First, the TCP Rx buffer contributes to the total cache footprint in addition to Rx ring pages, so the total working set size can increase beyond the ring size, imposing higher cache capacity pressure. By increasing effective cache capacity, Sepia can also improve the effectiveness of SHRing. Second, under heavy incoming traffic, SHRing's single shared ring may need to allocate more

pages to accommodate concurrent DMA requests. In this case, SHRing can benefit from a larger effective ring size because Sepia reduces conflicts among DMA target pages.

Sepia's benefits with zero-copy receive. DDIO efficiency remains important even when zero-copy is enabled, because applications may still read or write network data after it has been received. Sepia can therefore benefit such applications by allowing them to access received data from the LLC instead of main memory. One possible extension is to expose an application-level allocation interface that returns pages from the Sepia Manager rather than from the standard memory allocation datapath. This would ensure that the NIC can directly DMA into page-colored application buffers.

Sepia's benefits with different and future architectures. While Stride-1 can utilize 82.1% of the total LLC capacity in our hardware configuration (§4.2), our additional simulations suggest that power-of-two slice counts (e.g., 16 slices [47]), would allow Stride-1 to utilize 100% of the LLC capacity by eliminating slice-hash imbalance. However, this architectural property alone is not sufficient: without color-aware allocations, cache utilization remains similar to Figure 5(b), even under power-of-two slice configurations. We also found that, for non-power-of-two slice counts, using only tag bits in the slice hash function can make Tetris more feasible, as all sets within the same page map to the same slice, making it easier to find alternative Tetris blocks for unrecycled pages. These observations provide useful insights for hardware vendors designing future architectures that better support cache-friendly network processing with Sepia, while applying Sepia to other CPU architectures, such as AMD, remains future work.

8 Related Work

Improving cache efficiency. Prior work has found that direct cache access (e.g., DDIO) becomes inefficient as network bandwidth increases across both user-space and kernel network stacks [14, 23, 58]. Intel Cache Allocation Technology (CAT) can isolate cache usage across applications; however, it cannot isolate I/O traffic, so I/O operations still contend for DDIO-reserved cache ways [58]. To reduce this contention, prior work either limits the buffer size to match the DDIO cache capacity [58] or ensures that the I/O working set fits within the LLC capacity [51, 52]. Nevertheless, we show that avoiding capacity misses alone is insufficient. NeBuLa reduces network queuing and improves RPC tail latency by pushing RPC payloads directly into the processor's L1 cache [57]. Finally, NanoPU [31] extends NeBuLa's scheme to transfer data directly from the NIC into CPU registers.

Page/cache coloring. Prior work has shown that page/cache coloring can improve cache performance by reducing cache contention and conflict misses [42, 59, 63, 66, 67], but these benefits have primarily been explored for application memory accesses. For example, Memstrata [67] treats Compute Express Link (CXL) memory as a second tier and local memory as a cache to extend memory capacity with Intel Flat Memory mode; to avoid inter-virtual machine (VM) interference in local memory, it uses page coloring to provide performance isolation across VMs. With DCA support, NIC-induced cache conflicts can also degrade performance, while Sepia mitigates them with page coloring to improve CPU efficiency (§6).

Improving CPU efficiency. Hardware-based solutions [17, 55] achieve zero-copy processing by allowing applications to provide their buffer addresses directly to the NIC, so the NIC can DMA data straight into application memory. Recently, Linux has added support for TCP zero-copy send and receive [19, 20], which may require hardware features such as header–data split. Cornflakes leverages the NIC's scatter-gather capability to aggregate small messages into a single packet, achieving zero-copy processing to reduce latency [54]. Beyond zero-copy, there are works aiming to reduce other packet processing overhead. For example, NetChannel reduces CPU load by recycling pages—after data copies—into Rx descriptor memory pools, thus avoiding expensive slow-path memory allocations [15]. Sepia is orthogonal to these approaches and can further boost CPU efficiency alongside them as discussed in §7.

Network stacks for scaling/scheduling resources. NetChannel [15] disaggregates network processing into multiple layers, enabling each layer to scale and schedule independently; this allows the Linux network stack to saturate terabit network links. Similarly, FlexToE [56] parallelizes the TCP processing pipeline into multiple processing units within smartNICs to scale the performance. And also, there has been a lot of recent work on userspace network stacks [11, 26, 36, 37, 38, 39, 43, 44, 45, 49, 50, 53, 65]. Integrating Sepia with these userspace stacks would be interesting future work.

9 Conclusion

In this paper, we revisit DDIO's leaky DMA problem and show that conflict misses are a missing piece in understanding high LLC miss rates in DDIO. By introducing page coloring into DDIO, we demonstrate that the effective LLC capacity can increase by up to 77.8–94.4% over Linux, substantially improving cache utilization. Building on this insight, we design Sepia, a color-aware page allocator that reduces LLC conflict misses during packet processing. Our Sepia prototype implemented in the Linux kernel saturates a 200Gbps link with 3.5 cores (2.5 fewer cores than Linux), while maintaining near-zero LLC miss rates in the best-case scenarios.

Disentangling Graph Dependencies for Efficient Billion-Scale GPU Vector Search

Haoru Zhao*, Jingkai He*, Jingyao Zeng, Mingkai Dong, Dong Du
Institute of Parallel and Distributed Systems, Shanghai Jiao Tong University

Abstract

Graph-based approximate nearest neighbor search (ANNS) drives high-performance vector search for AI systems. Nowadays, GPU becomes the emerging ANNS platform for its high performance and cost efficiency. However, GPU's limited memory capacity hinders graph ANNS systems from scaling to billion-level, due to graph's high memory consumption (239–334 GB). Existing efforts mitigate this by offloading graph to CPU memory; however, this incurs severe performance penalties due to data transfer overhead and GPU stalls.

We identify the root cause of this inefficiency: a strict *step-level dependency* in graph search, where each step relies on the traversal and computations of all nodes in the previous step. Our key insight is that *this monolithic step-level dependency can be disentangled into a more flexible, fine-grained node-level dependency*. Specifically, for each node, it is first accessed as a neighbor via an edge (i.e., *discovery*), and later selected as a parent to traverse its neighbors (i.e., *expansion*). These two stages are typically separated by many steps, exposing a sufficient discovery-expansion window. Leveraging this time window, the edge fetching to access some neighbors can be deferred and overlapped with computation. Based on this insight, we propose FlowANN, a graph-based ANNS system that efficiently supports billion-scale search on a single GPU. FlowANN employs a tiered graph structure, offloading the edges connected to neighbors that have sufficient time windows to the CPU. It effectively pipelines GPU computation with edge fetching via optimized asynchronous transfer and dynamic coordination. Evaluations show that FlowANN outperforms state-of-the-art systems by 4.08–45.7× on average (up to 172.6×), without compromising search accuracy.

1 Introduction

Approximate nearest neighbor search (ANNS) serves as a foundational component of modern AI systems, and is widely used in retrieval-augmented generation (RAG) [1, 2], recommendation systems [3, 4], image retrieval [5], and LLM serving [6, 7]. These systems embed data into high-dimensional vectors and employ ANNS to identify nearest vectors to the query vector, enabling efficient retrieval of relevant information. Among all ANNS indexes, graph-based approaches [8–18] are favored for their superior search efficiency.

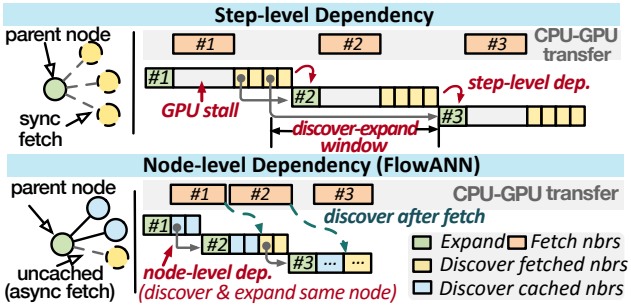

Figure 1: Step-level dependency vs. node-level dependency. *"nbr" is short for neighbor; "dep" is short for dependency.*

The rapid growth of data scales and the explosive computational demands of ANNS has driven the emerging adoption of GPUs for ANNS [19–23], leveraging their high computational efficiency and cost efficiency. GPU's parallel computing capabilities naturally align with ANNS' vector computation requirements, making a single mid-tier GPU achieve over 200× the throughput of a high-end CPU server[1] (Fig. 2). Thus, GPU ANNS has been widely adopted by the community [24, 25] and industry (Meta [26], NVIDIA [27], etc. [28–30]).

However, the limited memory capacity of GPUs poses significant challenges for deploying large-scale graph-based ANNS on GPUs. For instance, even after quantization [31, 32], billion-scale graph-based ANNS indexes [33–36] (datasets in Table 1) still require 258–350 GB memory, with the graph alone consuming 239–334 GB. This far exceeds the 80–96 GB memory capacity of mainstream GPUs.

Alternatively, offloading graph to host memory and fetching data on demand suffers from high data transfer overhead due to the strict dependencies in the search process. Specifically, graph ANNS employs a *best-first search* algorithm, which proceeds iteratively. In each step, it selects the node closest to the query from the *candidate pool* as the parent, fetches the parent's edges from the graph to retrieve its neighbors, computes all neighbors' distances to the query, and adds them into the candidate pool for subsequent steps. As the selection of the parent requires that all neighbors from the previous step

*Both authors contributed equally to this work and should be considered as co-first authors.

[1] GPU: NVIDIA H20, with 15% of computing capability (TFLOPS) of H100; CPU: 2x Intel Platinum 8457C. All experiments follow settings in §7.

complete the computations and are inserted into the candidate pool, this rigid step-level dependency results in significant GPU stalls to wait for edge fetching, as Fig. 1 shows.

However, this conventional view of step-level dependency is overly strict, and the associated waiting may be unnecessary. We disentangle the step-level dependency into a finer-grained *node-level dependency*. From a node's perspective, during the search process, it is first reached as a neighbor (i.e., *discovery*) and then used to find its neighbors (i.e., *expansion*). The best-first search algorithm ensures that, in each step, multiple nodes are *discovered* and only one node is *expanded*. Therefore, for most nodes, there exists a time window (i.e., several steps) between their *discovery* and *expansion* (**Insight #1**). For instance, ~95.6% of expanded nodes have an average window > 5 steps (§ 3).

Such discovery-expansion windows suggest an opportunity to offload some edges to CPU with (almost) zero overhead: when expanding a node, its offloaded edges can be asynchronously fetched to discover the neighbors. As long as these neighbors have sufficient discovery-expansion windows, their deferred discoveries will not disrupt the nodes' expansion order in search process (i.e., preserving best-first search's search path). Moreover, such deferred discovery effectively hides data transfer by overlapping it with computations.

However, though the discovery-expansion window presents an opportunity for zero-overhead offloading, identifying suitable edges for offloading remains challenging, since predicting the window is difficult. We find that the expanded nodes' nearby neighbors (i.e., connected via short edges) are expanded sooner, leaving insufficient windows for deferred discovery. This is because the node and its nearby neighbors are close in space, so once one is expanded (i.e., being near the query), the other is also likely to be close to the query and expanded soon. Therefore, generally, long edges are more suitable for offloading, while short edges should reside on the GPU to ensure timely discovery (**Insight #2**).

Based on these insights, we propose **FlowANN**, a GPU graph ANNS system that efficiently supports billion-scale search on a single GPU. As Fig. 1 shows, at each step, it discovers the parent's neighbors residing on the GPU and the nodes deferred from previous steps, while asynchronously fetching other neighbors from the CPU. We have mathematically proven that deferred discoveries do not compromise search accuracy, even if FlowANN might (sometimes) yield a different search path compared to synchronous edge fetching.

FlowANN further addresses the following challenges.

Challenge #1: Imbalanced graph tiering. While edge length provides a macroscopic criterion for graph tiering, selecting on-GPU edges based on a static edge length threshold leads to critical imbalances. Due to the uneven distribution of data points in high-dimensional space, edges in dense regions are typically short, while nodes in sparse regions have few short edges. Simply using a length threshold causes queries located in sparse regions to suffer from excessive uncached edges.

Challenge #2: Lagging edge fetching. FlowANN has to fetch edges to GPU asynchronously. However, despite many methods to copy data between CPU and GPU (e.g., `cudaMemcpy`, unified memory) [37], current GPU ecosystems lack support for GPU-initiated async transfers. Existing methods either require returning control to CPU to initiate async copies, or rely on GPU-initiated synchronous copies. Furthermore, existing CPU-GPU transfer methods typically rely on DMA. But DMA's high initialization overhead severely degrades the performance of edge fetching, whose size is relatively small.

Challenge #3: Uncoordinated pipelining. Although the discovery-expansion windows enable deferred discovery, excessive deferrals lead the search to suboptimal search paths, thereby sacrificing efficiency. Thus, FlowANN has to wait for some discoveries if their deferred steps exceed their discovery-expansion windows. However, estimating the window is challenging due to its dynamic evolution throughout the search. Furthermore, GPU computational resources (e.g., CUDA cores, shared memory) are statically allocated for the GPU kernel, but deferred discovery leads to dynamically varying workloads in each step, resulting in resource under-utilization.

To address the challenges, we propose the following designs. Firstly, we design the *grouping-based graph tiering*, which partitions the graph by grouping spatially proximate nodes and places edges between nodes within the same group on the GPU. Building on recent theoretical advances [38], we employ a multi-level label propagation scheme for grouping, which considers both edge lengths and node spatial distribution. Furthermore, we introduce a compact matrix layout to store the tiered graph, which reduces memory waste from padding and enables more edges to reside in GPU memory.

Secondly, we design *xCopier* to enable GPU-initiated asynchronous data transfers. xCopier coordinates GPU-side ring queues and CPU-side data-moving threads, and provides GPU-optimized programming primitives for GPU kernels. To facilitate edge fetching (i.e., small copies), xCopier employs MMIO-based data transfer, bypassing the overhead of conventional DMA-based approaches. xCopier makes edge fetching in FlowANN both trap-less and asynchronous, enabling effective overlap of data transfer and computation.

Finally, we design a coordinated pipeline for efficient execution. FlowANN employs the *adaptive synchronization* to prevent excessively deferred discoveries, which holistically considers global search convergence and local fluctuations. To efficiently utilize GPU resources, FlowANN introduces *cross-step balancing*, which adaptively balances workloads across steps to align computing demands with hardware resources.

We evaluate FlowANN on billion-scale datasets [39–41], and compare it with SOTA GPU ANNS systems from industry and academia. FlowANN outperforms cluster-based ANNS systems like cuVS [27], Faiss [24], Rummy [19], and FusionANNS [22] by 4.08–8.41× on average, while maintaining the same accuracy. It outperforms graph-based systems like BANG [20] and FlashANNS [42] by 45.7× and 14.3×

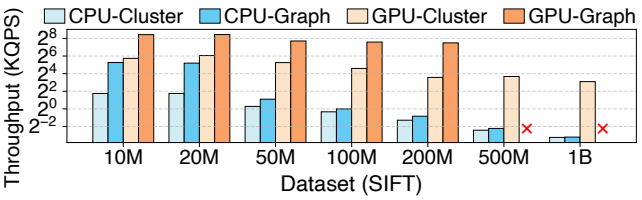

Figure 2: ANNS performance across indexes on GPU/CPU with different dataset sizes. *Recall@10 = 0.9. Recall@α means the proportion of true neighbors found within the top-α results. We use Faiss [24] (w/ HNSW [10]) and cuVS [27] for CPU/GPU ANNS. For CPU ANNS, all (160) cores are used. Detailed settings in §7.*

on average, and achieves comparable throughput (using one GPU) with multi-GPU graph system GGNN [43] using 8 GPUs. FlowANN consistently achieves improvements across different accuracies, GPUs, and algorithm configurations.

FlowANN is fully open-sourced at https://github.com/SJTU-IPADS/GPU-Graph-ANN.

2 GPU Graph ANNS: Fast yet Memory-bound

2.1 GPU Graph ANNS Primer

Vector search underpins modern AI systems, such as RAG [1, 2], recommendation systems [3, 4, 30], image retrieval [5], and LLM inference [6]. These systems embed data (e.g., text, images) into *vectors*, and use vector search to retrieve data relevant to the embedded query vector. The core operation of vector search is *k-nearest neighbor search*, which tries to find the k nearest vectors (*top-k*) to a query. As exact nearest neighbor search via brute-force is infeasible at large data scales (e.g., billion-level [33–35, 41]), modern vector search adopts *approximate nearest neighbor search (ANNS)*, which leverages pre-built indexes for efficient approximate retrieval.

Graph-based ANNS. Mainstream ANNS indexes generally fall into two broad categories: partition-based [44–49] and graph-based [8–12]. Partition-based indexes divide the dataset into multiple *partitions*, such as clusters of spatially proximate points or discrete buckets mapped via hashing.[2] Subsequently, the search process scans the vectors within the partitions that are close to the query via brute force. In contrast, graph-based methods construct a proximity graph to capture the relationships between vectors, and the search proceeds by traversing the graph.

Graph-based ANNS systems offer superior search efficiency over cluster-based ones. As shown in Fig. 2, they deliver 1.6–10.5× higher performance and superior scalability. This advantage stems from the graph structure, which allows the search to navigate directly toward nearest neighbors by graph traversal, significantly reducing distance computations compared to the brute-force scans of cluster-based methods.

[2]While partition-based indexes encompass various approaches (e.g., hash-based and cluster-based ones), our subsequent discussion mainly focuses on the cluster-based ones.

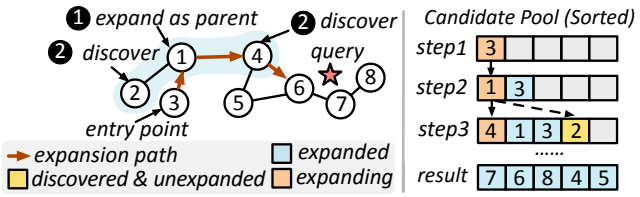

Figure 3: Best-first graph search procedure.

KNN graph and best-first search. The graph structure for ANNS is the *K-Nearest Neighbor (KNN)* graph, a graph where each node (vector) is connected to its approximately K nearest neighbors in the dataset, as determined by distance metrics like Euclidean distance. The graph is stored as a 2D matrix, where each row contains the K neighbor IDs for a node.

The graph search algorithm utilizes a *best-first search* strategy. As illustrated in Fig. 3, it maintains a candidate pool that contains a fixed number of the closest nodes found so far, sorted by their distance to the query. The algorithm begins from an entry point (e.g., node 3) and proceeds iteratively. At each iteration, it selects the nearest unexpanded node from the candidate pool as the *parent* and traverses its edges to obtain its neighbors (❶).[3] It then computes the distances between these neighbors and the query, and inserts them into the pool (❷). This process repeats until all nodes in the pool have been expanded, and the algorithm returns the top-k nearest vectors in the pool as the final result. During the search, each node undergoes two main stages: ❶ it is reached as a neighbor via an edge and is inserted into the candidate pool after distance computation (termed *discovery*); ❷ it is selected as the parent to further *discover* its neighbors (termed *expansion*).

GPU-based ANNS. Given the growing demand for large-scale vector processing (e.g., billions of vectors), GPU-based ANNS is increasingly favored for its parallel capabilities and cost-efficiency [22]. Currently, GPU-based ANNS is widely adopted by industry leaders such as Meta [26, 50], NVIDIA [27, 51], etc. [28–30]. With both data and indexes (e.g., graph) placed on the GPU, SOTA systems accelerate key ANNS operations (e.g., distance computation, sorting) through parallel execution [27, 51, 52], significantly boosting search speed and throughput. As Fig. 2 shows, GPU-based ANNS achieves a 9.0–222.0× speedup over CPU-based ones across various dataset sizes. Notably, graph-based GPU ANNS outperforms cluster-based ones by 5.2–15.1×, highlighting the superiority of graph-based ANNS on GPU.

2.2 Memory Strain in GPU Graph ANNS

Although exhibiting computational efficiency, the substantial memory footprint of the graph limits the applicability of GPU graph ANNS at billion-scale. For example, even after

[3]A common variant of best-first search selects multiple parents in each step (i.e., beam search). We also consider it in our evaluations (§7.4.2).

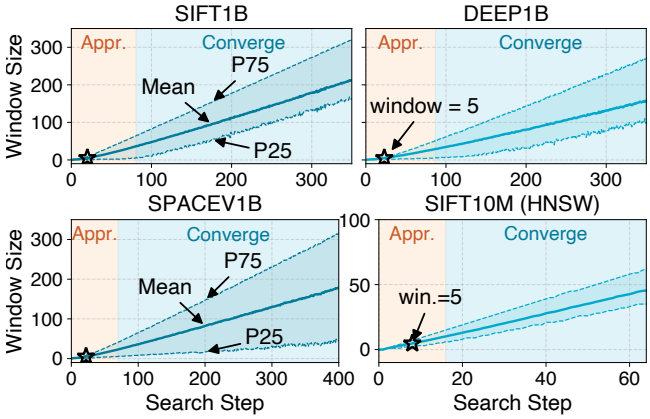

Figure 4: Discovery-expansion windows over steps. *For a node being expanded, its window size = current step − the step when it was discovered − 1. We also validate other KNN graph variant (i.e., HNSW) exhibits similar results. The HNSW index is from FAISS [24].*

quantization[4], which reduces the vector memory footprint to 12.5% of the original, graph ANNS on SIFT1B dataset [39] demands ~258 GB memory. This far exceeds the 80-96 GB capacity of mainstream GPUs, making it undeployable on a GPU (Fig. 2). Notably, the graph alone consumes ~93% of the total memory, constituting the key bottleneck. Such memory consumption is unavoidable to preserve adequate graph connectivity and ensure search quality. Thus, the core challenge in scaling GPU graph ANNS to billion-scale lies in *breaking the memory bottleneck while maintaining high performance.*

2.3 Existing Efforts and Possible Solutions

Multiple GPUs. Although employing multiple GPUs [23, 43] (e.g., through graph sharding) presents a theoretical solution, it faces non-trivial challenges. Firstly, efficient graph partitioning for ANNS remains challenging, as the search algorithm's step-by-step discovery-oriented nature makes the traversal path for a given query inherently unpredictable. Secondly, it introduces frequent inter-GPU communication, which consumes computational resources, increases search latency (several ms), and degrades throughput, as demonstrated in §7.1.

Unified memory (UM). UM extends memory capacity by creating a unified address space across CPU and GPU. However, it is ill-suited for graph traversal, which exhibits virtually *no locality*. Consequently, the traversal frequently triggers page faults and migrations (62 μs), which are exceedingly costly.

CPU-GPU tiering. Another approach is to store the graph primarily in CPU memory and transfer edges of parent nodes to GPU on demand (e.g., BANG [20]). However, the strict *step-level dependency* in best-first search severely limits computation-transfer overlap: each step's new parent selection depends on all the neighbors of the parent being fetched and *discovered* in the previous step. Consequently, it is nearly impossible to hide transfer latency by overlapping it with computation (< 10% overlapped). Additionally, this approach leads to severe GPU memory under-utilization (~50 GB idle on an 80 GB HBM GPU for the quantized SIFT1B dataset), as it treats GPU memory merely as a transient staging area.

[4]To enhance computational efficiency, SOTA systems search with lower-dimensional, quantized vectors, and return a candidate set with more than k items, which is *re-ranked* using the full-dimensional vectors to produce the final top-k results. Product Quantization (PQ) [32] is the most widely used.

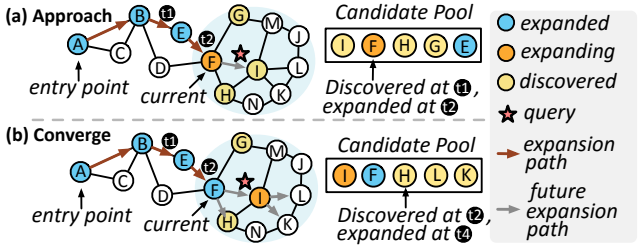

Figure 5: Two phases in the graph search process. *The upper figure shows approach phase, and the lower shows converge phase.*

3 Disentangling Dependency in Graph Search

Given the conventional strict step-level dependency, CPU-GPU tiering for graph ANNS seems infeasible due to high data transfer overhead. However, we find that *this step-level dependency is overly rigid and can be disentangled into* ***node-level dependency***. Specifically, at each step of a given best-first search path, only the node to be expanded needs to have been discovered. Based on this fine-grained dependency, we analyze the graph search traces for tens of thousands of queries on three billion-scale datasets (§7).[5] From the analysis, we identify opportunities to defer certain discoveries, thereby overlapping data transfer with computation without sacrificing accuracy.

Observation #1: Discovery-Expansion window. We discover that during the search process, *there exists a time window between a node's discovery and expansion* (**discovery-expansion window**). As Fig. 4 shows, for 95.6% of the search steps, the average discovery-expansion window exceeds 5 steps (6–14 μs per step, depending on the batch size). Moreover, the window size consistently grows throughout the search process.

Insight #1: Deferrable discovery. The discovery-expansion window presents an opportunity to defer the discovery of certain nodes without compromising accuracy. Specifically, since this window can typically overlap the edges' host-to-GPU transfer latency (~8 μs, Fig. 17b), we can offload the edges connecting to neighbors with sufficient windows to CPU memory, and defer the discovery of these neighbors until the edges are fetched to GPU. When fetching the edges, GPU can continue executing subsequent steps' computations without blocking.

Observation #2: Short edges indicate non-deferrable dis-

[5]We deploy CAGRA [51] (NVIDIA) using UM to capture node-level traces.

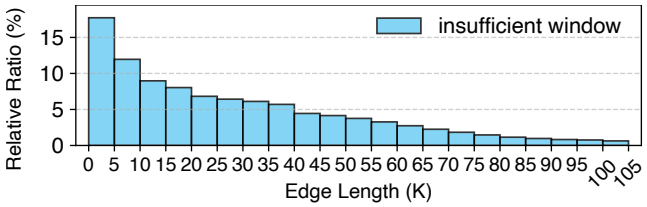

Figure 6: Proportion of edges with insufficient windows (≤ 5 steps) for each edge length bucket (SIFT1B). *E.g., in the shortest-edge bucket (0–5), 17.7% of the edges connect to neighbor nodes with insufficient windows. Other datasets exhibit similar results.*

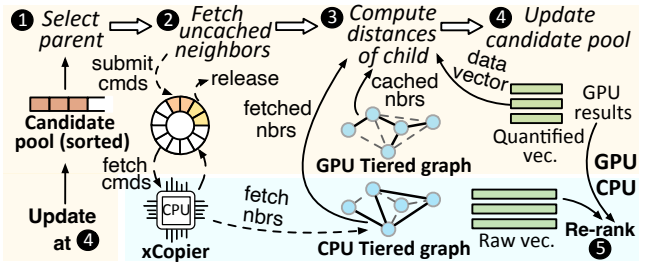

Figure 7: Overview of FlowANN workflow. *Currently, the tiered graph is constructed and placed offline. "nbr" stands for neighbor.*

coveries. While the discovery-expansion window presents a general opportunity for deferrable discovery, not all nodes are equally suitable for deferral. As Fig. 5 (a) shows, when expanding node F at t_2, its neighbor I is less suitable for deferral than G, as I will be expanded soon. To systematically identify non-deferrable discoveries, we analyze the correlation between edge length and window size. Specifically, for each expanded node, we collect the length of the edge used to discover it, and analyze edges whose corresponding discoveries have insufficient windows (conservatively ≤ 5 steps).

Results reveal that *discoveries through short edges are less likely to be deferrable.* As Fig.6 shows, shorter edges are more frequently associated with discoveries that have insufficient windows. The proportion of edges with insufficient windows in the shortest-edge bucket (17.7%) is much higher than that in the longest-edge bucket (0.63%). We also find that short edges have higher access frequency. Nevertheless, most discoveries (~90.6%) have sufficient windows (>5 steps) for deferral, demonstrating broad applicability of deferrable discovery.

Insight #2: Length-based graph tiering. In the graph, since discoveries via short edges are less deferrable and more frequently accessed, short edges should be retained in GPU memory. This effectively utilizes the remaining GPU memory after storing the quantized vectors. Conversely, long edges can be safely offloaded to host memory and fetched to GPU on demand, thus maximizing memory efficiency.

Root cause and generality. These observations are derived from the nature of best-first search, which aims to find the query's top-k closest nodes, specifically from its surrounding region (e.g., shaded area in Fig. 5). This process is naturally divided into two phases: *approach* and *converge* [11, 53].

During the approach phase, the search rapidly advances from the entry point toward the vicinity of the query (e.g., node A→F in Fig. 5 (a)). Each discovery tends to find nodes closer to the query, which are then quickly expanded, resulting in small windows. As Fig.4 shows, the first quartile of window size (*P25*) remains close to zero during the first ~22% steps.

However, upon entering the converge phase, the search has reached the nodes near the query (e.g., node F in Fig. 5 (b)). During this phase, the search generally follows a query-centric, outward-expanding trend [53] to collect the actual top-k nearest neighbors. As the search progresses, the likelihood of discovering a closer node diminishes (e.g., expansion of node I at t_3 cannot find a closer node than I). Consequently, the node selected for expansion (i.e., nearest unexpanded node) is typically the one that was discovered several steps earlier (e.g., node H at t_4), resulting in the presence of a window.

Meanwhile, since the nodes expanded during this phase are already close to the query, their nearby neighbors (connected by short edges) are also likely to be close to the query and thus expanded sooner, resulting in smaller windows. This pattern is reflected in the overall search behavior (Fig. 6) due to the dominance of the converge phase in the search process.

Correctness and accuracy. Some may concern that precisely predicting the discovery-expansion windows is difficult, potentially leading to over-deferral of some nodes' expansion, and thus compromising accuracy. We mathematically prove that, given the greedy nature of graph search, even in the worst case (i.e., all discoveries are over-deferred), FlowANN can achieve identical accuracy within a bounded and deterministic number of steps, which is proved in Appendix A. We further design the synchronization mechanism to proactively prevent excessive deferral of discoveries (§ 6.2).

4 FlowANN Overview

We design FlowANN, a graph-based ANNS system that efficiently handles billion-scale vector search on a single GPU.

Workflow. As Fig. 7 shows, FlowANN tiers the graph and offloads the edges with low access frequency and large discovery-expansion windows to the CPU. It fuses the entire GPU search process (multiple steps) into a single GPU kernel. Each step can be divided into four phases. ❶ First, it selects the closest unexpanded node to the query from the candidate pool as the parent. ❷ Subsequently, it asynchronously fetches the parent's offloaded edges (i.e., uncached neighbors) from the CPU-tiered graph to the GPU using xCopier. ❸ Meanwhile, for the parent's cached neighbors and those neighbors already fetched to the GPU, FlowANN calculates their distances to the query using their corresponding data vectors stored on the GPU. Like mainstream systems [24, 27], for better computational efficiency, the vectors stored on the GPU are quantized. ❹ Finally, the candidate pool is updated with these discovered neighbors and re-sorted. ❺ After the completion of the whole GPU search phase, the nodes in the

candidate pool (i.e., GPU results) are re-ranked on CPU using the original full-precision vectors to ensure final result accuracy. The CPU re-ranking and GPU search are also pipelined across batches. Algorithm 1 provides the precise pseudocode of the search procedure.

GPU-CPU graph tiering. FlowANN prioritizes storing short edges on the GPU. To avoid distributional imbalance of cached edges caused by a static length threshold, it utilizes grouping to select edges for GPU residency, considering both edge length and graph spatial distribution. Specifically, we employ *multi-level label propagation* (§5.1) to partition the graph into balanced groups while maximizing the retention of short edges within groups, and then place intra-group edges on the GPU. Moreover, on GPU, FlowANN replaces each node's global ID from a billion-scale namespace with a shorter local ID within each group, and designs a compact matrix graph layout (§5.2), allowing more edges to reside on GPU.

Trap-less async data transfer. We design *xCopier*, a system service that enables GPU-initiated asynchronous data transfer (§6.1). xCopier further enhances transfer performance by leveraging hardware capabilities: it employs Memory-Mapped I/O (MMIO) via BAR mapping to replace DMA-based `cudaMemcpy`, reducing transfer latency by 40× and ensuring the overlap of data movement and computation.

Coordinated pipeline. FlowANN pipelines GPU computation and CPU-GPU transfer. To preserve search efficiency, it prevents excessively deferred expansion through *adaptive synchronization*, which considers both global search convergence progress and local fluctuations. FlowANN employs *cross-step balancing* to align the dynamically varying per-step workload with hardware resources, and selects suitable entry points to shorten the approach phase (§6.2).

Discussions. We discuss FlowANN's scope and generality.

• **Generality for graph structures.** FlowANN is based on the widely-used CAGRA [51] (i.e., NN-Descent [54]) graph.

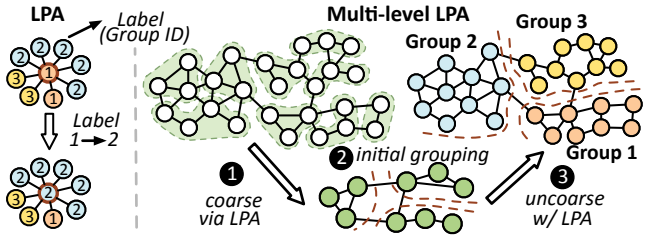

Figure 8: Multi-level LPA. *The node colors represent groups.*

Its motivations and designs are general and adaptable to various KNN graphs [9, 10].

• **Graph updates.** Like prior efforts [19, 20, 22, 55], FlowANN focuses on the search process. It can use existing online or offline graph update methods [56–59], and update the tiered graph with minimal effort, e.g., via a single round of label propagation (§5.1) to assign new nodes to groups.

• **Cluster serving and multi-GPU.** FlowANN aims to maximize single-GPU capability for billion-scale ANNS. It can be deployed with multiple replicas in clusters. It can be integrated into multi-GPU systems for prospective larger datasets.

• **Hardware generality.** While FlowANN is implemented on NVIDIA GPUs, which represent cutting-edge architectures, it can be adapted to other SIMT-based GPUs (e.g., AMD).

5 Deferrable Discovery with Graph Tiering

Guided by *Insight #2* (§3), graph tiering should prioritize placing short edges on GPU. However, applying a fixed length threshold to select on-GPU edges causes imbalance due to the non-uniform distribution of data points in high-dimensional space. Specifically, in dense regions, many edges are short and would be stored on GPU, while nodes in sparse regions have few edges cached. This leads to queries located in sparse regions benefiting little from tiering. Thus, graph tiering should consider both edge length and spatial node distribution.

We find that after grouping spatially proximate nodes into the same group (i.e., *grouping*), the intra-group edges are suitable for GPU placement: (1) Nodes connected by short edges are often close to each other and naturally cluster within the same group, which satisfies the goal of prioritizing short edges; (2) Grouping holistically considers the spatial distribution of all nodes, preventing nodes in sparse regions from being excluded by a single edge length threshold.

Challenges. However, designing a high-quality graph grouping and tiering scheme is still challenging due to two issues. First, partitioning a billion-scale graph to maximize the retention of short edges within groups is an NP-Complete problem [60, 61]. Simply applying common grouping methods (e.g., K-means) often causes poor grouping quality, as they only consider global node distribution while ignoring the graph's structural information (e.g., edge connections). For instance, when grouping via K-means, only ~60% of edges

Algorithm 2 Multi-level LPA Graph Grouping

end for
return the final group label for each node

that have insufficient windows are retained within groups (Fig. 17a). This necessitates a grouping scheme tailored to KNN graphs to maximize intra-group short edge retention, while keeping computational complexity tractable. Second, after grouping, the number of intra-group neighbors per node may vary. Continuing to store each node's neighbors in a 2D matrix results in non-trivial memory waste due to padding.

5.1 Spatial Locality-aware Graph Grouping

For high intra-group short edge retention, the graph grouping scheme in FlowANN should consider both edge connections and node distribution. To achieve this, we employ *Multi-level label propagation (multi-level LPA)* for graph grouping, which is inspired by a theoretical graph grouping scheme [38].

Procedure. Multi-level LPA is based on the *size-constrained weighted label propagation*, which proceeds as follows: First, each edge is assigned a weight, where shorter edges receive higher weights. Then, each node is initialized with a unique group label. In each subsequent iteration, every node calculates the sum of weights from its neighbors for each distinct label and updates its own label to the one with the highest total weight [62] (Fig. 8).[6] To ensure balanced group sizes, we introduce a size constraint to limit the maximum group size during propagation.[7] Notably, the edge weight efficiently incorporates edge length information, ensuring that shorter edges have a higher likelihood of being retained within groups.

As Fig. 8 shows, multi-level LPA involves a coarsen-uncoarsen process: The graph is recursively coarsened by grouping nodes into super-nodes through LPA until it is sufficiently small (❶); Then initial groups are generated on the coarsened graph via recursive bipartitioning [63] (❷); Finally, the groups are projected back to the original graph, with LPA applied during uncoarsening to refine group boundaries (❸). The full procedure is given in Algorithm 2.

[6] If all neighbor labels' summed weights are tied, one is randomly chosen.

[7] FlowANN chooses the maximum group size that retains the most intra-group short edges while staying within the current GPU memory budget.

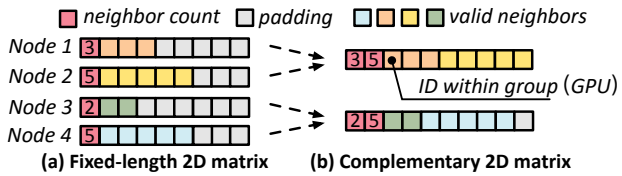

Figure 9: Graph layout with complement.

Benefits. Multi-level LPA can effectively preserve short edges within groups and obtain balanced, high-quality groups from a global perspective. This is mainly because: (1) *local structure awareness*: it captures local graph structure through label propagation based on edge connections and edge lengths, ensuring that nodes connected by short edges are grouped together; (2) *global distribution consideration*: by generating groups from a global view of the coarsened graph and refining them locally during uncoarsening, it holistically takes the nodes' distribution into account. Moreover, since LPA mainly relies on local label propagation, it achieves near-linear time complexity, making it well-suited for billion-scale graphs.

5.2 Compact Graph Layout with Complement

To ensure quick random access to each node's neighbors, existing graph ANNS systems store the graph on GPU using a 2D matrix with fixed-length rows, where each row corresponds to a node's neighbor list, as shown in Fig. 9 (a). However, after grouping, the number of intra-group neighbors for each node becomes variable. Continuing to use this 2D matrix would lead to significant memory waste due to padding (Fig. 9 (a)).

Through the analysis of intra-group neighbor count distributions, we identify a potential memory-saving opportunity: the distribution exhibits a quasi-symmetric shape, indicating that the space saved by the half of nodes with fewer neighbors effectively complements the extra space required by the half with more neighbors. Thus, as Fig. 9 (b) shows, we employ a new graph layout for the subgraphs on the GPU and CPU.

For the subgraph on the GPU, nodes are first sorted by their intra-group neighbor counts. They are then paired by iteratively matching the node with the most intra-group neighbors to the one with the fewest. Each pair is stored in a single row. The case for CPU is similar. This method not only reduces space waste from padding (§ 7.3) but also preserves efficient random access, as the graph is still stored in a 2D matrix with a fixed number of neighbor lists per row.

Moreover, leveraging the property that nodes in the GPU-tiered graph are only connected within the same group, we use shorter group-local IDs (e.g., 20–24 bits) rather than global graph-wide IDs (e.g., 32 bits) to represent each node. This

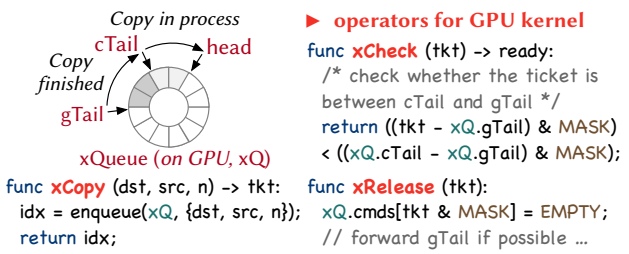

Figure 10: xQueue operators. *The atomic operations are simplified.*

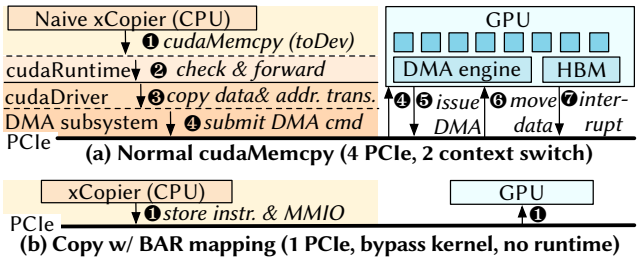

Figure 11: Copying process of xCopier and cudaMemcpy.

enables more edges to reside on the GPU (Fig. 17a), thereby allowing more computation to overlap with data transfer.

6 Execution with Coordinated Pipeline

The tiered graph enables deferred discovery. However, efficient transfer-computation pipelining remains challenging. We design xCopier to support efficient trap-less asynchronous transfer (§6.1), and further develop the coordinated pipeline that ensures search efficiency and hardware utilization (§6.2).

6.1 Streaming Data Movement with xCopier

During search, FlowANN employs an asynchronous data pipeline to fetch non-cached edges from the CPU to the GPU, overlapping transfer cost with on-GPU computation.

Challenges. This design, however, is impeded by two fundamental constraints in GPU architecture: (1) To minimize kernel launch overhead, FlowANN fuses all search steps into a monolithic kernel. However, no existing mechanism permits a GPU kernel to initiate asynchronous copies between device and host. (2) The performance of standard CUDA copy operations (e.g., *cudaMemcpy*) [37, 64] is poor for small data blocks (typically 64–256 bytes per node's edges), as they are bottlenecked by the inherent DMA engine launch overhead.

CPU-GPU data movement. We begin by recapturing existing data movement mechanisms between the CPU and GPU. On CPU side, transfers are initiated using *cudaMemcpy* [37], which can be asynchronous with GPU computation. On GPU side, data access to CPU memory is facilitated through two mechanisms: Unified Memory (UM) and Zero-copy (Pinned) Memory [37]. UM provides a unified address space, migrating pages (triggered by GPU page faults) upon access. Zero-copy Memory enables direct GPU access to CPU memory. Critically, both are synchronous and block GPU kernel execution.

For FlowANN, each transfer mechanism presents a critical limitation. CPU-initiated transfers require the search flow to return to the CPU after each step (i.e., trap) [20], thereby incurring substantial kernel termination and launch overhead. Conversely, Unified Memory and Zero-copy Memory forfeit the ability to construct an asynchronous copy pipeline.

Trap-less async copy with xCopier. We introduce xCopier, a system-level service for asynchronous data movement initiated directly from GPU threads, bridging the architectural gap in the GPU ecosystem. xCopier is built around a GPU-side ring queue (xQueue) and a CPU-side data-moving thread (xThread). The xQueue, featuring one head and two tails, exposes three primitives: xCopy, xCheck, and xRelease.

Specifically, as Fig. 10 shows, a GPU thread initiates an async transfer via xCopy, which enqueues a transfer command into xQueue and returns its queue index as the ticket. The xThread polls xQueue's head, detects new commands, executes the data transfers, and finally advances the cTail (cpu_tail). The GPU thread checks the status of an async transfer with xCheck, which compares the ticket against current cTail. Once the transfer is confirmed completed, the thread can reclaim the command slot using xRelease. The release is a two-step process, which allows out-of-order release: it first marks the command as invalid, then attempts to advance gTail (gpu_tail) if there are invalid commands at the tail.

These primitives are highly optimized for GPU parallelism. We employ batched invocation and warp-level aggregation, so that all xCopy/xRelease in a warp require just one atomic operation to update head/gTail. xCopier further mitigates atomic operation contention by supporting multiple xQueues. The xThread can be scaled to multiple threads under high load.

Efficient data transfer via BAR mapping. In FlowANN, every data transfer command involves copying the uncached edges of a parent node (64–256 bytes). Even when batched, the transfers remain relatively small. However, conventional DMA-based mechanisms (e.g., cudaMemcpy) perform poorly for such fine-grained transfers. As Fig. 11 (a) shows, this inefficiency stems from the DMA overhead, which involves four PCIe transactions, two context switches into/from GPU driver, and runtime overhead. A cudaMemcpy-based xCopier transfer for 64B–1KB data incurs a latency as high as 21–22 μs (Fig. 12), which cannot be overlapped with GPU computation.

To solve this challenge, we employ a novel hardware strategy: GPU's Base Address Register (BAR) mapping. Leveraging the open-source driver [65][8], xCopier maps the GPU memory regions directly into CPU's physical address space. Subsequent accesses to the regions are then performed via Memory-Mapped I/O (MMIO). With hardware write-combining, consecutive writes are transparently coalesced into fewer, larger MMIOs. As Fig. 11 (b) shows, this reduces CPU-to-GPU copy

[8] BAR mapping is also supported by other GPUs, e.g., AMD ROCm [66].

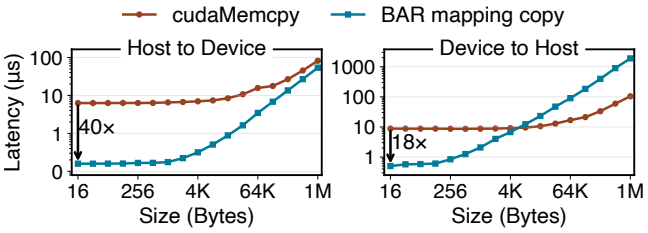

Figure 12: Copy latency of BAR mapping and cudaMemcpy. *Each (batched) xCopier transfer requires one D2H copy (xQueue head read) and two H2D copies (data write, xQueue cTail update).*

to a single PCIe transaction, which is executed by CPU SIMD instructions, eliminating context switches and runtime overhead, and accelerating small transfers by up to 40× (Fig. 12).

In FlowANN, each xQueue is associated with a pre-allocated (and BAR-mapped) GPU buffer pool for the fetched edges. As a general-purpose system service [67], xCopier is readily applicable to other GPU workloads [68–70].

6.2 Pipelining with Adaptive Coordination

Leveraging xCopier, FlowANN pipelines GPU computation with CPU-GPU edge fetching. At each step, the search kernel first selects the unexpanded node closest to the query from the candidate pool as the parent, then asynchronously fetches its uncached neighbors to GPU (xCopy). Subsequently, it checks the completion status of previously issued transfer commands (xCheck), and discovers both the parent's cached neighbors and the neighbors that have already been transferred.

Challenges. Efficient pipelining faces non-trivial challenges. ❶ Although discovery-expansion windows enable deferred discovery, excessive deferrals lead the search to suboptimal paths, sacrificing efficiency (§6.2.1). ❷ Due to deferred discoveries, the discovery workload per step varies dynamically, resulting in a mismatch with pre-determined hardware resources (§ 6.2.2). ❸ During the approach phase (§ 3), the windows are too small to hide edge transfers (§6.2.3).

6.2.1 Near-optimal Search with Adaptive Synchronization

Excessive deferral of discoveries leads the search to suboptimal paths, sacrificing efficiency. To avoid unnecessary computation and transfer, FlowANN synchronously waits for the completion of some discoveries if their deferred steps exceed their discovery-expansion windows. However, estimating the window is non-trivial, as it varies with the search process.

Estimating the window size. We find *the expanded node's position in the candidate pool* (P_e) can be an effective indicator to estimate the window size. Specifically, during the approach phase (§ 3), the search rapidly advances toward the query, and both the window size and P_e are usually zero. As the search converges, the window size increases (Fig. 4). Meanwhile, the expanded node's position shifts rightwards (i.e., P_e increases), as nodes near the query gradually accumulate at the head of the candidate pool and are successively expanded. Our analysis across tens of thousands of query traces confirms the strong correlation between P_e and the window sizes of the expanded node's neighbors, with a Pearson correlation[9] = 0.77.

FlowANN thus uses P_e to estimate the window size (W) of the expanded node's neighbors in each step, i.e., $W = \alpha * P_e$, where α is derived from offline profiling with linear regression. Relying on offline profiling is sufficient here because α depends primarily on the dataset's underlying data distribution. Furthermore, this formulation robustly adapts to dynamic variations in the approach phase's length. Specifically, since P_e typically remains zero during the approach phase, the estimated window W will also be zero, ensuring accurate synchronization without depending on offline statistics.

Beyond the normal cases, we observe that *fluctuations* during search convergence can lead to unexpectedly small windows, which manifest as a sharp drop in P_e. This happens when the search in the converge phase unexpectedly discovers a node much closer to the query (i.e., a sharp drop in P_e). Once such a node is found, its neighbors become the prime targets for subsequent expansion, thus their windows are small. FlowANN needs to handle such cases specially.

Adaptive synchronization based on window size. To handle the fluctuation cases, when FlowANN detects a sharp drop in P_e, it waits for all neighbors of the parent node to be fetched. While this incurs a performance cost, such fluctuations occur with very low probability (<3%). In our evaluation, FlowANN sets the threshold for a sharp drop in P_e to 10% of the candidate pool size. Meanwhile, in each step, if some neighbors from previous steps have been deferred for more than their estimated windows, FlowANN also waits for their discoveries to complete.

Stall-less synchronization. To avoid wasting computational resources, FlowANN yields the hardware threads to schedule other queries' computations during the wait. This scheduling is very lightweight, as it is handled by the hardware scheduler.

6.2.2 Regularizing Workload with Cross-Step Balancing

In previous synchronous execution, the number of nodes discovered per step (i.e., the parent node's neighbor count) is deterministic. However, as FlowANN defers some nodes' discoveries, this count becomes dynamic. This causes severe GPU under-utilization because computational resources (e.g., CUDA cores, shared memory) are statically predetermined.

FlowANN introduces a cross-step balancing mechanism to align the discovery workload with hardware resources. Specifically, when each step begins, FlowANN identifies three categories of nodes to discover: ❶ the parent's neighbors that reside on the GPU, ❷ deferred nodes that must be discovered

[9] Pearson correlation measures the linear relationship between two variables, with values > 0.7 indicating strong correlation [71, 72].

due to synchronization constraints, and ❸ deferred nodes that have already been transferred to the GPU but can be further deferred. If the total number of these nodes does not align with the hardware resources, FlowANN defers the discovery of some nodes from category ❸ to the next step. For example, if 32 thread teams (each team discovers the nodes collaboratively) are allocated for each query, FlowANN tries to align the number of nodes discovered per step to a multiple of 32. The extra nodes are passed to the next step via shared memory.

6.2.3 Shortening Approach Phase with Entry Points

In the approach phase (§ 3), the small discovery-expansion windows necessitate frequent synchronization, leading to non-negligible overhead. To reduce the proportion of this phase, FlowANN selects suitable entry points for each query, instead of starting from random nodes. Inspired by the principles of cluster-based ANNS, we select a set of representative nodes from the dataset (e.g., K-means centroids) as candidate entry points, and choose the ones closest to the query through parallel computation. This approach quickly identifies suitable entry points by leveraging the GPU's parallel capabilities. Thanks to the selected nodes' representativeness, only a very small number of candidates (one in a million) are required to reduce the approach phase to ~5% of total search steps.

7 Evaluation

Implementation. We build FlowANN with 14,700 lines of CUDA/C++ based on CAGRA [51] (i.e., graph-based ANNS in cuVS [27]), a SOTA system open-sourced by NVIDIA.

Hardware setup and datasets. All experiments run on a server with 2 Intel Xeon Platinum 8457C CPUs (2.60 GHz, 160 cores), 2 TB DRAM, and NVIDIA H20 GPUs. We also evaluate FlowANN on other GPUs (§ 7.4.2). We mainly use three widely-used billion-scale datasets [39–41]. The specifications of GPUs and datasets are summarized in Table 1.

Baselines. We compare with 8 GPU ANNS systems.

• **Quantized cluster-based ANNS.** SOTA cluster-based ANNS systems first search on GPU using quantized vectors (e.g., PQ [32]), then re-rank the results with full-precision vectors on CPU. We evaluate *cuVS-cluster* [27] (NVIDIA) and *faiss-cluster* [24] (Meta). We carefully implement in-memory *FusionANNS* [22] based on cuVS as it is not open-source.

• **Full-precision cluster-based ANNS.** *Rummy* [19] stores all full vectors on CPU and transfers them to GPU on demand, overlapping data transfer with computation via pipelining.

• **Graph-based ANNS.** *BANG* [20] supports in-memory billion-scale graph ANNS on a single GPU. It stores PQ-quantized vectors on GPU, while the graph and full vectors are stored in CPU memory and transferred to GPU on-demand.

• **Graph ANNS with related dependency.** The latest work, *FlashANNS* [42] relaxes step-level dependency for better pipelining. Its step *n* depends on step *(n - 2)*. We implement its in-memory version based on its available artifact.

	Dataset	Dimension	Type	#Vector	#Queries	PQ dim
Datasets	**SIFT1B**	128	uint8	1B	10,000	16
	DEEP1B	96	float32	1B	10,000	24
	SPACEV1B	100	int8	1.4B	29,316	13

	GPU & Arch.	Memory	GPU & Arch.	Memory
GPUs	**H20 (Hopper)**	96 GB HBM3	**A800 (Ampere)**	80 GB HBM2
	L20 (Ada)	48 GB GDDR6	**V100 (Volta)**	32 GB HBM2

Table 1: Datasets and GPUs used in evaluation.

• **Unified memory (UM).** UM unifies CPU and GPU memory. We extend CAGRA [51] with UM (*CAGRA-UM*).

• **Multi-GPU.** *GGNN* [43] is the only billion-scale multi-GPU graph ANNS system known to us.[10] It shards data across multiple GPUs, with each GPU performing searches on its corresponding subgraph, and then merges the results.

Configurations. Given the characteristics of the datasets and the constraints of CAGRA, we quantize the vectors to the dimensions in Table 1 (*PQ dim*) for GPU search, and apply the same quantization settings to cuVS-cluster and faiss-cluster. However, since BANG cannot achieve high accuracy with these quantization parameters, we use BANG's default quantization settings (PQ dim = 74) to ensure it attains comparable accuracy. For FlowANN and all graph-based baselines, we set the graph degree to 32, following CAGRA [51]'s official practice. We also measure FlowANN's performance under different quantization settings and degrees in § 7.2.

Metrics. We measure search accuracy using *recall@k* [32]: the fraction of true *k* nearest neighbors in the returned results. Without explicit mention, we measure the throughput (i.e., queries per second, QPS) and latency at 0.9 recall, a commonly used accuracy target in ANNS [11, 36, 73]. We also evaluate FlowANN under different accuracy targets in § 7.1.

7.1 Overall Performance

We evaluate FlowANN and the baseline systems under various batch sizes (from 16 to 2048) to reflect different application scenarios, such as online serving (small batch size) and offline processing (large batch size), similar to prior works [19].

Throughput. As Fig. 13 shows, FlowANN outperforms all baselines across batch sizes and datasets. Compared to cluster-based baselines, it achieves 8.67× and 8.15× higher average throughput for batches of 2048 and 16, respectively. The performance gain improves with larger batches, as the increased per-step computation time better hides data transfer. The cluster-based methods underperform FlowANN and scale poorly with batch size as their brute-force intra-cluster search

[10] A recently proposed system (PathWeaver [23]) cannot support billion-scale datasets on our testbed due to its high memory consumption.

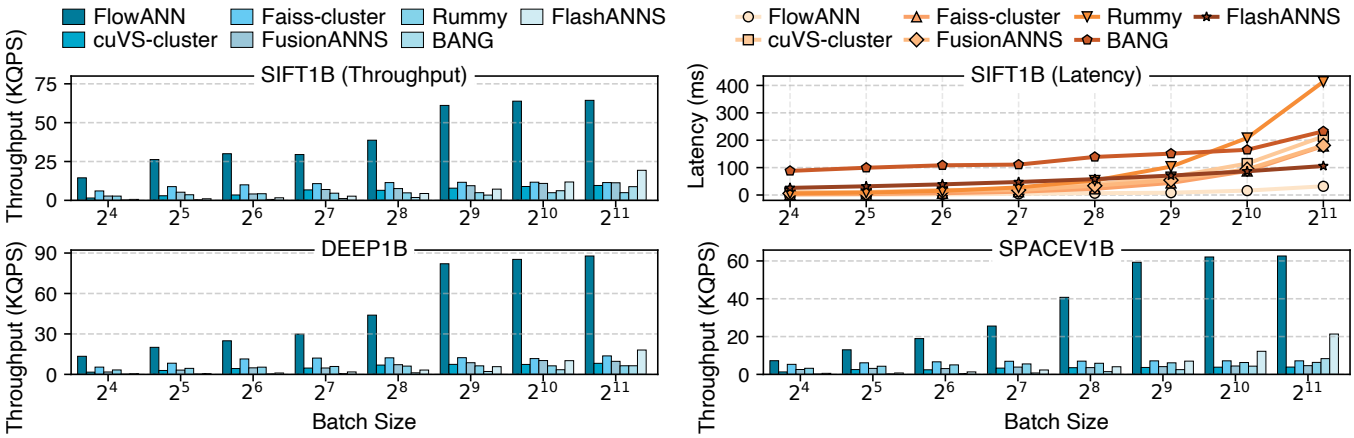

Figure 13: Throughput and average latency of FlowANN and baselines. *Recall@10 = 0.9. Due to space constraints, we only present the latency results on SIFT1B; trends on DEEP1B and SPACEV1B are similar. We omit CAGRA-UM in the figure for its low performance.*

saturates GPU resources earlier than graph traversal. FusionANNS outperforms cuVS-cluster because of its heuristic re-ranking.

FlowANN achieves 9.52× and 78.8× higher throughput than BANG on average for batch sizes 2048 and 16. This is because BANG only overlaps edge fetching with limited computation (i.e., pool updates) and relies on costly *cudaMemcpy*, causing GPU stalls. Smaller batch sizes further worsen BANG's overlapping efficiency. In contrast, FlowANN effectively hides data transfer by leveraging the discovery-expansion window and ensuring efficient data transfer via xCopier.

FlowANN outperforms FlashANNS by 3.71× and 21.8× on average for batch sizes 2048 and 16. FlashANNS' relaxation of step-level dependency is limited and inflexible. It fails to overlap I/O effectively for small batches. It leads to suboptimal search paths during the approach phase, and excessive waiting in the converge phase.

Compared to CAGRA-UM, FlowANN achieves 110.8–1888.8× higher throughput. Since UM is unaware of the graph traversal's random access patterns, frequent page faults and migrations are triggered, severely hampering performance.

Latency. FlowANN achieves lower latency than all baselines. It reduces latency by 83.8% and 81.6% on average compared to baselines for batch sizes of 2048 and 16. Notably, at batch size 16, it only takes 0.962 ms to process a query. This efficiency stems from its accurate graph traversal and efficient pipeline, which preserves high accuracy while effectively hiding transfer overhead. It reduces the P99 tail latency by 75.4% and 86.1% on average for batch sizes of 2048 and 16.

Cluster-based baselines exhibit higher latency than FlowANN, especially in larger batches. Among them, Rummy has the highest latency, as its full-precision GPU computation increases processing overhead. BANG and FlashANNS exhibit high latency at small batches as the non-overlapped data transfer becomes more pronounced with fewer queries.

Comparison with multi-GPU systems. We compare single-GPU FlowANN with GGNN [43]. As Fig.14 shows, even with 8 GPUs, single-GPU FlowANN outperforms GGNN by 2.22–15.3× at batch sizes of 8–1024. Only at batch size 2048 does FlowANN's throughput slightly lag behind 8-GPU GGNN (92.2%). GGNN requires 8 GPUs and a large batch to match FlowANN, because of its high communication overhead and GPU under-utilization at small batches.

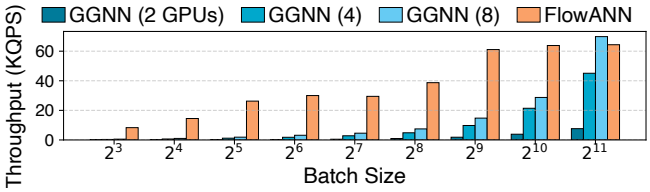

Figure 14: Throughput of FlowANN and GGNN on SIFT1B. *We use GGNN's default configurations. When running on 2 GPUs, GGNN offloads part of the graph and data to CPU memory.*

Different accuracy targets. As shown in Fig.15, we measure FlowANN's throughput across recall@10 from 0.8 to 0.995 under small (64) and large (2048) batch sizes. We choose cuVS-cluster as the representative of cluster-based methods, as it shares fundamental operations (e.g., distance computation) with FlowANN, enabling a more direct comparison. FlowANN outperforms baselines across all accuracy levels, and the performance gap widens at higher accuracy. At recall = 0.8, FlowANN outperforms cuVS-cluster and BANG by 5.4× and 28.9× on average; At recall = 0.995, these gains increase substantially to 29.1× and 111.8×, respectively.

Impact of deferred discovery on search steps. We compare search steps to reach the same accuracy with and without deferred discovery (via CAGRA-UM). Across three billion-scale datasets at accuracies from 0.8 to 0.995, FlowANN introduces no extra steps in most cases (~96%), with only a few showing a marginal increase of ~0.7–2.1% in steps. This shows that deferred discovery preserves search correctness and has a negligible impact on convergence speed in practice.

7.2 Sensitivity Analysis

We evaluate FlowANN under different configurations, i.e., various quantization settings and graph degrees.

Quantization configurations. We evaluate FlowANN under varying quantized vector lengths, using batch sizes of 64 and 2048 (Fig. 16 (a)). Across different quantization configurations, FlowANN achieves average throughput improvements of 8.47× (small batch) and 5.12× (large batch) over cuVS-cluster, demonstrating its adaptability to different quantization settings. Longer quantized vectors improve traversal accuracy, reducing search steps to reach target accuracy.

Graph degree. We evaluate FlowANN under varying graph degrees (i.e., neighbor counts). It outperforms BANG in all cases, achieving 136.37× (small batch) and 14.72× (large batch) higher throughput on average (Fig. 16 (b)). A higher graph degree discovers more edges, improving accuracy and reducing the number of steps, but raising transfer and computational overhead. This degrades FlowANN's throughput with small batches; whereas under large batches, the transfer is overlapped by computation, resulting in performance gains.

7.3 Breakdown Analysis

Graph tiering. To evaluate multi-level LPA, we measure the GPU edge cache ratio for each discovery-expansion window size of all queries (Fig. 17a). For edges with insufficient windows (i.e., window ≤ 5, § 3), it keeps ~87.9% of them on the GPU (89.1% for window = 0), a 29.6% improvement over K-means. Moreover, Fig. 17a reveals that FlowANN improves memory efficiency via group-local node IDs, storing 18.2% and 30.2% more edges on GPU than K-means and the original (no grouping) method. This is because multi-level LPA generates smaller, more balanced groups than K-means. The complement-based graph layout reduces space waste, leaving only ~0.506% padding for billion-scale datasets, reducing memory waste by ~98.5% compared to the original layout.

xCopier. We evaluate xCopier on different data sizes and concurrency. As Fig. 17b shows, compared to using cudaMemcpy, xCopier with BAR mapping reduces the end-to-end fetching latency by 78–80% for 32–8192 B data. xCopier achieves high scalability to serve 2048 concurrent thread blocks (1024 threads per block) with 64 xQueues during search, thanks to its lock-free design and thread block-level aggregation.

Adaptive synchronization. We compare the search accuracy with and without adaptive synchronization, using the same number of search steps. As Fig. 17c shows, adaptive synchronization improves accuracy by 21.7% and 6.2% on average at batch sizes of 64 and 2048, enabling high-accuracy search of recall@10 > 0.9. Smaller batches lead to shorter computation time per step, demanding more proper synchronizations.

7.4 Extensive Studies

7.4.1 Performance Upper Bound and Lower Bound

Gap to ideal upper bound. We compare FlowANN with CAGRA on small datasets. It caches only 50% of the edges, while CAGRA retains the entire graph on the GPU. As Fig. 18 shows, at batch sizes of 64 and 2048, FlowANN achieves average throughput equal to 67.9% and 85.4% of CAGRA. This confirms the efficiency of its tiered graph and edge fetching pipeline. Its performance nearly matches CAGRA's at large batches, which enhances GPU utilization and extends per-step execution time, providing a wider window for async transfers.

Performance without GPU edge cache. We measure FlowANN's throughput when all edges reside on the CPU (i.e., w/o tiering). As Fig. 19 shows, the throughput of FlowANN

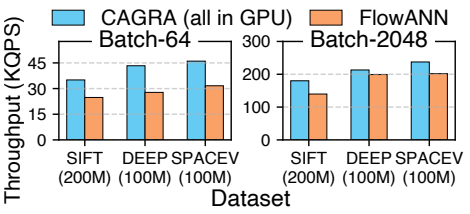

Figure 18: FlowANN's throughput on 100M and 200M datasets and the upper bound.

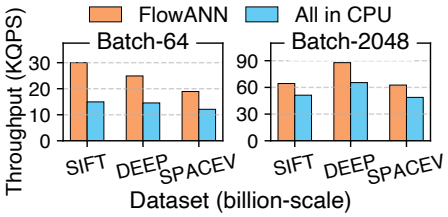

Figure 19: Throughput of FlowANN w/o GPU cache (representing lower bound).

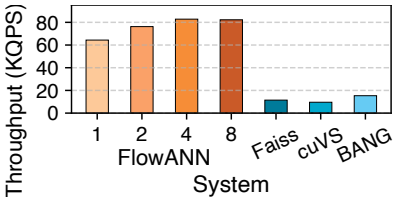

Figure 20: Throughput under different search widths (1-8). *SIFT1B dataset.*

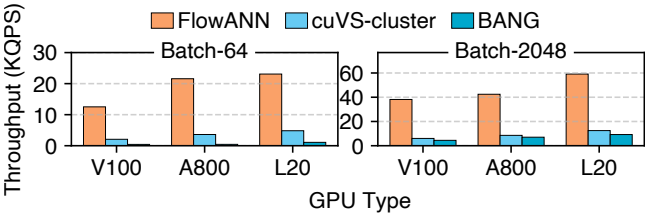

Figure 21: Throughput across GPUs.

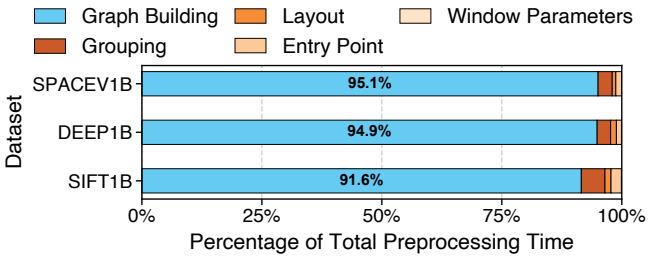

Figure 22: Preprocessing time breakdown of FlowANN.

w/o tiering reaches 58.4% (batch size 64) and 78.1% (batch size 2048) of standard FlowANN. Larger batches narrow this gap, as they better overlap transfer overhead. It still outperforms the baselines (Fig. 13) by 1.5–50.6× (batch 64) and 4.5–12.6× (batch 2048). This shows that even without GPU edge caching, FlowANN's optimizations (e.g., xCopier, adaptive synchronization) still yield non-trivial performance gains.

7.4.2 Generality for Algorithms and Hardware

Applicability to best-first search variants. A common variant of best-first search is to expand multiple nodes per step [8] (i.e., search width > 1) to improve efficiency. We evaluate FlowANN's throughput with different search widths (1–8). As Fig. 20 shows, FlowANN outperforms the baseline across all search widths. Larger search widths allow FlowANN to find high-quality neighbors faster, reducing total search steps and improving throughput up to a width of 4. Beyond that, throughput declines due to higher per-step computation cost and diminishing improvements in result quality.

Applicability to other GPU architectures. Besides NVIDIA H20, we also evaluate FlowANN on V100, A800, and L20, covering mainstream GPUs [74], as Table 1 details. As Fig. 21 shows, under different architectures and memory capabilities, FlowANN consistently outperforms the baselines (by 4.97–29.4×), demonstrating its generality. For small batches, its gains over baselines grow with larger memory. For large batches, the gains increase with GPU compute power, as longer per-step computation time already overlaps data transfer, amplifying the impact of computational capability.

7.4.3 Preprocessing Cost

FlowANN's additional preprocessing steps beyond graph building (offline) include graph tiering, entry point selection, and parameter acquisition for window estimation. Fig. 22 shows the proportion of each step in the total preprocessing time. The results indicate that the extra overhead introduced by these new steps is relatively small: only 4.9%, 5.1%, and 8.4% on the three datasets, respectively.

8 Discussion

Offloading strategy and future adaptability. FlowANN primarily offloads graph connectivity because it constitutes the main memory bottleneck in current billion-scale workloads (e.g., SIFT1B). This rationale aligns with mainstream tiered ANNS designs [8, 11]. To accommodate the massive high-dimensional vectors typical of emerging LLM workloads, FlowANN's tiering design can naturally support offloading both graph edges and data vectors. In such a case, the neighbor's data vector is fetched simultaneously during the asynchronous neighbor fetch phase.

Compatibility with dynamic updates. While FlowANN mainly focuses on optimizing the search process, its preprocessing mechanisms do not inherently hinder dynamic graph updates. FlowANN can readily integrate with existing online or offline graph update methods. When newly inserted points are added to the graph, the system does not require a complete, global re-grouping. For example, a newly inserted node can be grouped by simply calculating its neighbors' weights and joining the valid group with the highest total weight. Only when the number of groups exceeds a certain threshold, a global re-grouping is required.

Compatibility with variant graph structures. FlowANN is compatible with variant graph structures that support best-first search. The core optimization of FlowANN is disentangling

step-level dependencies to exploit the time windows between node discovery and expansion. This mechanism is rooted in the iterative nature of best-first search. Thus, FlowANN does not require an exact KNN graph structure and can seamlessly adapt to diverse proximity graphs.

Cost-effectiveness of GPU for ANNS. Due to the massive parallelism of GPUs, GPU-based ANNS can yield superior cost-efficiency (i.e., QPS/$) compared to CPU-based ones [19, 22]. This economic advantage has driven the adoption of GPU-based ANNS in industry [75], further amplified by hardware repurposing. While older or lower-tier GPUs (e.g., NVIDIA V100) are no longer suitable for demanding LLM workloads, they remain highly efficient for ANNS and can be repurposed for cost-effective deployment.

Scalability of xCopier with MMIO-based data transfer. xCopier utilizes MMIO-based data transfer (§ 6.1), which maintains its performance advantage over DMA even under high concurrency (i.e., large batch sizes). For instance, with batch size 10 k, the total data transferred in one step is merely ~1 MB, allowing MMIO to maintain its advantage (Fig. 12). As a result, xCopier does not encounter bandwidth bottlenecks even when all SMs are fully saturated. xCopier will fall back to DMA-based copying when MMIO is unavailable.

Necessity of deferred expansion. A seemingly straightforward alternative to deferred expansion is to rely purely on hardware yielding (i.e., swapping to other queries during data transfers). However, yielding alone is insufficient to hide latency due to GPU resource limits and batch size constraints. Because GPU computational resources (e.g., shared memory and registers) strictly bound the maximum number of queries simultaneously residing on SMs, yielding during data transfers quickly stalls all active queries, leaving the GPU idle. Furthermore, pure yielding requires massive batch sizes to successfully interleave queries, rendering it ineffective for latency-sensitive online serving. FlowANN's deferred expansion overcomes both limitations by overlapping transfer overhead within each individual query, ensuring high performance without requiring massive concurrency.

9 Related Work

SSD-based ANNS. Prior efforts [76–78] employ pipelining for fetching data from SSD. Although FlashANNS [42] a one-step relaxation in the search process, it still maintains the strict step-level dependency. PipeANN [11] relaxes compute-I/O order to better saturate SSD I/O bandwidth. However, it treats all nodes' expansions equally, which may cause sub-optimal search paths when some important expansions are delayed. Additionally, unlike the CPU-SSD setting, the compute-I/O gap for GPU-CPU is relatively narrow (similar latency), which limits the degree of I/O parallelism that can be exploited. FlowANN accounts for the variability in the discovery-expansion window across nodes, keeping a near-optimal search path with minimal computational overhead, improving both latency and throughput.

Moreover, we believe that SSD is unsuitable for GPU-based graph ANNS' second-tier storage: (1) SSD's latency (~100 μs [79]) far exceeds graph search's per-step execution time (6–14 μs), and is hard to be overlapped, leading to low GPU utilization; (2) GPU servers typically have TB-level memory [80–82], which is sufficient to hold billion-scale datasets and graphs.

Distributed ANNS. Distributed ANNS systems [43, 83, 84] focus on horizontal scaling to support ANNS on multiple nodes. They are complementary to FlowANN, as FlowANN primarily focuses on maximizing the search capability of a single GPU. Additionally, to support the multi-node scenario, FlowANN can be deployed as multiple replicas.

GPU ANNS' computational optimizations. Previous works explore parallelism [21, 51, 85, 86], quantization [22, 55], and multi-GPU collaboration [23, 43]. They can be (or already have been) integrated with FlowANN.

Graph-based ANNS on CPU. Many works optimize graph-based ANNS on the CPU, such as parallelism [87, 88], enhancing graph structures [9, 10, 57, 89–92], improving quantization methods [12, 31, 93, 94], and tuning parameters [46, 95–99]. These efforts are complementary to FlowANN.

10 Conclusion

We present FlowANN, a graph ANNS system enabling efficient billion-scale vector search on a single GPU. FlowANN is built on the key insight that the rigid step-level dependency in graph search can be disentangled into a fine-grained node-level dependency. Guided by this insight, FlowANN adopts a tiered graph structure that offloads the edges with sufficient discovery-expansion windows to the CPU. Leveraging these windows, FlowANN defers the discovery of some nodes and overlaps their edge fetching with GPU computation. Evaluations on billion-scale datasets show that FlowANN outperforms state-of-the-art systems by 4.08–45.7× on average (up to 172.6×) without compromising search accuracy.

A Proof of Correctness and Convergence

We provide a theoretical analysis regarding: (1) **Search correctness**, proving that the asynchronous fetching strategy does not compromise the termination and accuracy of the best-first search; (2) **Convergence speed lower bound**, proving that the worst-case search steps are strictly bounded, ensuring the system efficiently converges to the target; and (3) **Search budget bound**, proving that the required candidate pool size to guarantee accuracy remains within practical limits.

A.1 Search Correctness

The core concern is whether deferring the discovery of host-side neighbors prevents the algorithm from finding the true nearest neighbors. We model the search process as a traversal on a connected graph $G = (V, E)$.

Lemma 1 (Lossless Candidate Availability)**.** *In FlowANN, for any node u visited at step t, its full neighbor set $N(u)$ is eventually added to the candidate pool Q. Let $N(u) = N_{GPU}(u) \cup N_{Host}(u)$.*

- *$N_{GPU}(u)$ is added to Q at step t.*
- *$N_{Host}(u)$ is added to Q at step $t+\delta$, where δ represents the asynchronous fetch latency (in steps).*

Since δ is finite ($\delta < \infty$), no candidate is permanently discarded.

Theorem 1 (Top-k Convergence Consistency)**.** *Given a monotonic distance measure and a connected graph, for any query q, the deferred discovery mechanism ensures that the final candidate set $\mathcal{R}$ converges to the same set of top-k nearest neighbors as the synchronous baseline (i.e., the original best-first search), provided that the search budget is sufficient.*

Proof. Let $\mathcal{C}_t$ denote the candidate pool at step t, maintaining the best candidates found so far, sorted by distance to q. The capacity of $\mathcal{C}_t$ is bounded by the search budget L ($L \geq k$). Let $d_L(t)$ be the distance of the worst candidate in $\mathcal{C}_t$ (i.e., the L-th nearest). If $|\mathcal{C}_t| < L$, we define $d_L(t) = \infty$.

In the synchronous baseline, a node v is added to $\mathcal{C}$ if $\mathrm{Dist}(q, v) < d_L(t)$.

In FlowANN, consider a potential top-k neighbor v^* residing on the host side. Due to the fetch latency, v^* arrives at step $t+\delta$ instead of t.

- **Persistence of entry condition:** Since v^* is a true top-k neighbor (or a node on the path to one), its distance $\mathrm{Dist}(q, v^*)$ is inherently small.
- **Insertion logic:** When v^* becomes available at $t+\delta$, *provided that the search budget is sufficient* (i.e., L is large enough), the system compares v^* against the current state $\mathcal{C}_{t+\delta}$. Even if the pool has evolved during the delay δ, since v^* is optimal (one of the true top-k) and L is sufficient, it holds that:

$$\mathrm{Dist}(q, v^*) < d_L(t+\delta) \tag{1}$$

  This inequality holds because a sufficient budget L ensures that the queue is not filled with L candidates *strictly better* than a true top-k neighbor (by definition of top-k).

Therefore, v^* is successfully inserted into $\mathcal{C}_{t+\delta}$ and correctly sorted. The delay δ only shifts the moment of insertion but does not prevent the node from displacing a suboptimal candidate. Thus, under the sufficient budget assumption, the final set $\mathcal{R}$ retains the same top-k accuracy as the strict synchronous execution. □

A.2 Bound of Search Convergence Speed

While Theorem 1 establishes the convergence to top-k neighbors under the assumption of a sufficient search budget, it is imperative to ensure that this required budget remains within practical limits. If asynchronous fetch latency were to cause the search path to deviate indefinitely, the system would require an unrealistically large budget to avoid premature termination. Therefore, to validate the practicality of the sufficient budget assumption, we must prove that the additional search cost induced by asynchronous fetching is strictly bounded.

We assume the goal is to limit the "detour" caused by the asynchronous fetch latency, and we define the search efficiency by bounding the total traversal steps.

Definitions:

- Let $\mathcal{P}_{base}$ be the search path of the strict synchronous baseline (best-first search). Let $|\mathcal{P}_{base}| = T$.
- Let $\mathcal{P}_{sys}$ be the search path of FlowANN.
- Let τ be the constant fetch latency (in steps) for host-resident edges.
- Let $W(e)$ be the discovery-expansion window for an edge $e = (u, v)$ in the best-first search, defined as $W(e) = step_{expand}(v) - step_{discover}(u)$.

Theorem 2 (Bounded Step Deviation)**.** *The number of steps in FlowANN, denoted as $|\mathcal{P}_{sys}|$, is bounded by:*

$$|\mathcal{P}_{sys}| \leq T + \sum_{i=1}^{K} \max(0, \tau - W(e_i)) \tag{2}$$

where $\{e_1, \ldots, e_K\}$ denotes the set of K offloaded edges (i.e., neighbors) encountered along the critical path $\mathcal{P}_{base}$.

Proof. Consider a critical node v on the optimal path $\mathcal{P}_{base}$ reached via edge $e = (u, v)$. We analyze the impact of fetching latency in three cases:

Case 1: $e \in E_{GPU}$ **(Cached Edge).** The node v is available immediately at step t. No delay is introduced. The deviation $\Delta = 0$.

Case 2: $e \in E_{Host}$ **and** $W(e) \geq \tau$ **(Successful Prediction).** Node u is expanded at step t, and the fetch request for v is issued. Due to the window property, the baseline algorithm would not have popped (expanded) v from Q until step $t' = t + W(e)$. In FlowANN, v arrives at Q at step $t + \tau$. Since $\tau \leq W(e)$, it follows that $t + \tau \leq t'$. Thus, v arrives *before* or *exactly when* it is needed by the best-first search. The availability of v matches the baseline's requirement, so $\Delta = 0$.

Case 3: $e \in E_{Host}$ **and** $W(e) < \tau$ **(Prediction Miss).** This is the only scenario causing a detour. The algorithm needs v at step $t + W(e)$, but v arrives at $t + \tau$. The system is forced to discover suboptimal nodes for a duration of $\Delta_{step} = \tau - W(e)$. Once the τ steps pass, v enters Q and corrects the path.

Conclusion: The total extra cost is the sum of these "waiting gaps" ($\tau - W(e)$). Since the fetch latency τ is effectively overlapped with computation in most steps (Cases 1 and 2), and the candidate pool ensures automatic path correction, the search complexity of FlowANN remains linear $O(T)$, providing a guaranteed lower bound on convergence speed comparable to the synchronous baseline. □

Quantitative Worst-Case Analysis: We now instantiate the bound to demonstrate the limits of search expansion under extreme conditions. We assume a catastrophic scenario where two worst-case conditions occur simultaneously: (1) **Zero cache hit**, implying that every node on the search path resides on the host and requires a fetch operation (i.e., $K = T$); and (2) **Zero discovery-expansion window**, where window prediction fails completely for every step, meaning data is needed immediately (i.e., $W(e_i) \approx 0$ for all i).

Substituting these conditions ($K = T, W = 0$) into Equation (2), we obtain the general upper bound:

$$|\mathcal{P}_{sys}|_{worst} \leq T + \sum_{i=1}^{T} (\tau - 0) = T + T \cdot \tau = T(1 + \tau) \quad (3)$$

In practice, xCopier's asynchronous fetch latency is ~8 μs (Figure 19, Section 7.3), which does not exceed the duration of two search steps (6–14 μs per step, Section 3). Therefore, we set the latency penalty $\tau \approx 2$ steps. Substituting this into the general formula yields:

$$|\mathcal{P}_{sys}|_{worst} \leq T(1 + 2) = 3T \quad (4)$$

This derivation explicitly quantifies that even in the absolute worst-case scenario—where no caching or window optimization works—the search complexity remains strictly linear ($O(T)$), bounded by a small constant factor of the baseline steps.

A.3 Bound of Search Budget

While the step bound established in Equation (2) guarantees time efficiency, it is equally critical to verify the search budget constraints (i.e., candidate pool capacity). A potential risk introduced by deferred discovery is *candidate overflow*: the intermediate nodes visited during the waiting period might populate the candidate pool with numerous suboptimal candidates. To rule out this possibility, we explicitly derive the upper bound of the required candidate pool size.

Theorem 3 (Bounded Candidate Pool Size)**.** *Let U_{base} be the worst-case upper bound of the candidate pool size for the synchronous baseline. The worst-case candidate pool capacity U_{sys} required by FlowANN is bounded by:*

$$U_{sys} \leq U_{base} \cdot (1 + \tau) \quad (5)$$

where τ is the latency factor defined in Theorem 2.

Proof. The maximum number of candidates stored in the pool is determined by the number of expanded nodes and the maximum graph degree. For the synchronous baseline, which executes T steps (where $T = |\mathcal{P}_{base}|$), the worst-case pool size is bounded by the cumulative number of added neighbors:

$$U_{base} \approx T \cdot D_{max} \quad (6)$$

where D_{max} represents the maximum node degree in graph G.

For FlowANN, Theorem 2 proves that the search process expands at most $T(1 + \tau)$ nodes in the worst case to recover the optimal path. Since the node expansion logic remains identical (adding neighbors of visited nodes), the required pool capacity scales linearly with the maximum number of visited steps:

$$U_{sys} \leq [T \cdot (1 + \tau)] \cdot D_{max} \quad (7)$$

By rearranging the terms, we can express the bound of FlowANN in terms of the baseline's bound:

$$U_{sys} \leq (T \cdot D_{max}) \cdot (1 + \tau) = U_{base}(1 + \tau) \quad (8)$$

Conclusion: This result proves that the space complexity of FlowANN (i.e., required search budget) remains in the same order of magnitude as the baseline. Given that $\tau \approx 2$ in our system, a modest linear increase in the candidate pool capacity is sufficient to prevent valid candidates from being evicted, ensuring high recall without unbounded memory consumption. □

Abstract

Large-scale evolving graph analytics (EGA), which evaluates graph queries over sequences of snapshots, is facing growing demands for real-time insight extraction. While GPUs offer immense potential for accelerating graph workloads, they suffer from the memory capacity wall and poor hardware utilization when applied to EGA.

To bridge this gap, this work presents POEGA, a GPU-centric framework for efficient large-scale EGA. The core idea of POEGA is to leverage *proxy graphs* to minimize out-of-memory IO. It achieves this by first analyzing a compact in-memory graph abstraction to drive approximate results, thereby guiding the out-of-memory refinement. Although this approach incurs more computations, our key insight is that this cost can be amortized by exploiting the GPU's massive parallelism to process multiple snapshots concurrently. This concurrency is supported by a carefully designed fused kernel and a novel bound-based pruning technique. Furthermore, we address a commonly overlooked memory bottleneck caused by multi-version vertex states, which arises when scaling concurrent analysis to a large number of snapshots, by introducing an adaptive state compaction format. Evaluation shows that POEGA yields 3.7–23.5× speedups over the state-of-the-art EGA solutions across a range of real-world datasets.

1 Introduction

Graph processing serves as the backbone for unstructured data analysis across diverse domains. Since real-world graphs naturally expand and evolve, Evolving Graph Analytics (EGA), which extracts insights from a sequence of snapshots in a specific time window, has become a cornerstone of many modern decision-making systems. Crucially, these applications face an imperative demand for *real-time* responsiveness to the continuously changing real-world data. For instance, financial systems rely on evolving connectivity trends for instant fraud detection [31, 81]; network infrastructure requires evolving reachability analysis to pinpoint and recover from failures [29]; cybersecurity analysts track changing path properties to identify malicious DNS domains [69]; and epidemiological platforms leverage EGA for real-time influenza forecasting during COVID-19 pandemics [79].

A straightforward approach for EGA is to apply the query to snapshots individually, yet this yields significant overhead. A series of incremental graph analytics approaches, such as Tornado [66], Kickstarter [70], Graphbolt [46], CommonGraph [1], and others [16, 83], are proposed for resolving the urgent need for evaluating queries on graphs under dynamic environments. They have proven the superior efficiency of incremental computation over re-computing from scratch, given that evolving graphs typically exhibit high similarity (often exceeding 99% [12, 60]) between consecutive snapshots.

In recent decades, GPUs have been an attractive computing platform for graph applications [6, 24, 27, 35, 36, 49, 67, 71, 75]. State-of-the-art GPU-based incremental analysis systems, such as Grapin [74], have demonstrated over 10× speedups compared to CPU-based counterparts. However, applying these GPU-accelerated systems to large-scale graphs faces a fundamental challenge of limited GPU-resident memory, known as the GPU *memory oversubscription* problem [43, 56]. While general GPU data management techniques, ranging from explicit transfer [22, 62, 63] to implicit unified memory [58] or zero-copy [51], have been proposed, they often incur prohibitive data transfer overheads when applied to the incremental EGA (§2.3). Consequently, the I/O bottleneck fundamentally prevents existing GPU-based EGA systems from scaling to massive evolving graphs.

To bridge this gap, we introduce POEGA, an efficient evolving graph processing framework that tackles the memory wall problem. The main idea of POEGA is to leverage proxy graph, a concept that has recently been proven feasible for retaining the computation-critical structures of original graphs within a compact footprint [32]. By confining the initial analysis to a resident-memory proxy graph, POEGA derives approximate results to guide the subsequent exact refinement on the full graph, thereby significantly reducing the I/O traffic required. However, this two-phase paradigm (approximate-

then-refine) inherently introduces extra computations. They make previous proxy graphs yield marginal gains or even performance degradation because the extra compute overhead outweighs the I/O savings [32]. Our insight is that this computation overhead can be effectively *amortized* by exploiting the GPU's massive parallelism to process multiple snapshots in the evolving graph concurrently. We propose a snapshot-level concurrent execution model that fuses computations across snapshots into a single kernel to maximize instruction throughput and coalesce memory accesses. Furthermore, we mitigate redundant work across snapshots via a runtime bound-based pruning technique.

Finally, scaling this concurrent analysis introduces a new bottleneck: the memory pressure from maintaining vertex states across numerous snapshots, a challenge largely overlooked by existing concurrent models [10, 17]. To address this, we design an adaptive multi-version format that efficiently compacts vertex states, enabling POEGA to sustain high concurrency without exhausting GPU memory. To confirm the effectiveness of the proposed designs in POEGA, we conduct extensive experiments with real-world large-scale graphs and commonly used query benchmarks. The results show that POEGA outperforms the state-of-the-art EGA solutions, including EGraph [86], Grapin [74] and state-of-the-art incremental analysis methods, Kickstarter [70], and CommonGraph [1], combined with diverse GPU data management techniques [51, 58, 62] by 8.9× on average and up to 23.5×.

In summary, this paper makes the following contributions:

- Proposes POEGA, a framework for large-scale EGA that utilizes proxy graphs to shift the bottleneck from expensive I/O operations to GPU-friendly compute-intensive workflows;
- Presents a concurrent analysis method that fuses the execution and coalesces the data transfer, as well as a runtime pruning technique to reduce redundant computations across snapshots;
- Identifies the memory pressure of multi-version vertex states as a key impediment to scaling concurrency and proposes an adaptive multi-version format to address it;
- Provides an efficient implementation of POEGA and compares it with the state-of-the-art solutions through systematic evaluations. The results demonstrate its significant performance improvements. POEGA is open-sourced at https://github.com/YunMoZhang/POEGA.

2 Background and Motivation

2.1 Evolving Graphs Analytics

Analytics over dynamic graphs can be generally classified into three categories [18, 84], including: (1) *Streaming graph analytics* [14, 16, 46, 48, 70] which mainly explores the latest version of the graph as it continually changes; (2) *Temporal graph analytics* [8, 13, 28, 44, 47, 89], which exploits the timestamps of edges (and optionally vertices) to analyze fine-grained time-constrained behaviors, such as investigating general temporal path problems [52, 78, 89]; and (3) *Evolving graph analytics*, which is also called *snapshot sequence analytics* [1, 17, 23, 30, 37, 40]. Formally, EGA evaluates a query Q (such as single-source-shortest-path) on N snapshots of an evolving graph $[G_1, \cdots, G_N]$ (usually taken periodically) over a specified time period $[t_1, t_N]$, where $G_i = \{V, E_i\}$, and thus offers precise insights or information drawn from discrete historical data. Changes between consecutive snapshots[1] consist of a batch of edge additions Δ_i^+ and a batch of edge deletions Δ_i^-. This paper focuses on evolving graph analytics. An example is shown in Figure 1.

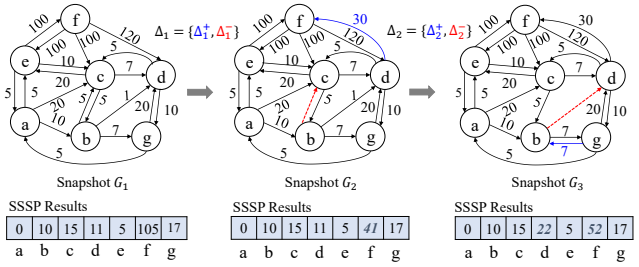

Figure 1: An EGA example which evaluates a query *SSSP(a)* on 3 snapshots.

Incremental EGA. The naive EGA approach evaluates the query independently on each snapshot from scratch, known as *re-evaluation*. To reduce redundant computations during re-evaluation, incremental algorithms have been proposed [14, 16, 46, 66, 70]. This paper focuses on the widely studied monotonic path-based graph algorithms [11, 70, 82]. Specifically, to process Δ_i^+, the incremental algorithm detects impacted vertices by propagating the value through the edges in Δ_i^+, and then adds updated vertices to the frontier. It reuses evaluation results on the previous snapshot and then propagates computation from affected vertices forward through the graph until re-convergence. For example, when the edge (d, f, 30) is inserted during $G_1 \rightarrow G_2$ in Figure 1, we apply the edge function from d to its out-neighbor f based on d's current value 11, and thus detect a new best value 41 for f.Then we put f to the frontier and resume the iterative evaluation until all values converge again. To process Δ_i^-, incremental algorithms usually maintain one-to-one dependencies that record which in-neighbor contributed to each vertex's computed value. When a deleted edge belongs to a dependency, incremental algorithms first perform *dependency tracing* to identify affected vertices. Tracing is also iterative, starting from directly impacted vertices and traversing along the cas-

[1]This work considers changes in the form of edge addition/deletion. Vertex or edge weight updates can be transformed to edge addition/deletion [83].

cading relationships till the end. All the affected vertices need to reset their values, pull the new one, and re-converge. As this kind of incremental algorithm [46, 70], such as representative Kickstarter [70], requires maintaining evaluation results in the previous snapshot, it is referred to as **streaming-based** incremental analysis.

As handling edge deletions in streaming-based approaches is generally more expensive (typically 2-3×) than processing the same number of additions [1], **batch-based** incremental analysis, such as pioneer work CommonGraph [1], has been proposed in recent years [1, 17, 88]. This approach first evaluates the query over a subgraph shared across all targeted snapshots. It then identifies per-snapshot Δ (only containing additions) relative to the common subgraph, and applies deletion-free incremental analyses to each snapshot independently. As it removes the dependency between snapshots, concurrent query evaluation is enabled in this approach.

2.2 GPU-based Large-scale Graph Processing

GPUs have become a popular platform for accelerating graph processing due to their high compute throughput and memory bandwidth [24, 27, 36, 49, 75]. However, GPU-based graph processing frameworks remain constrained by limited device memory, facing challenges when processing today's ever-growing graph datasets. This constraint becomes even more pronounced in EGA, where queries must be evaluated over multiple snapshots, further increasing memory demand.

Handling GPU memory oversubscription. To enable graph processing when the graph size exceeds the GPU memory capacity (i.e., oversubscription), existing efforts can be mainly classified into two categories: (1) ***Explicit management***. A coarse-grained approach [40, 86, 93] partitions the oversized graph into subgraphs that can fit into GPU memory, and then transfers partitions containing active edges in each iteration. However, this often incurs unnecessary data movement, as an entire partition may be transferred even when only a few edges are active. To address this inefficiency, finer-grained design [62, 91], including state-of-the-art Subway [62], adopts a dynamic partitioning strategy that generates subgraphs on demand per iteration. It first applies data compaction after knowing the active frontier, and then transfers compacted subgraphs. While minimizing transfer volume, it requires additional computation overhead. (2) ***Implicit management***. To ease the engineering efforts of explicit data movement, recent studies explore leveraging Unified Virtual Memory (UVM) [3, 4, 19, 34], which maps host and GPU memory into the same address space and triggers on-demand page migration (typically 4KB pages) during graph processing. However, this may incur non-negligible overhead due to costly page faults. A finer-grained method investigated recently is zero-copy access [51, 59, 73], which allows GPUs to directly read from host memory via transaction layer packets of PCIe. According to the PCIe spec [51], up to 256 outstanding memory requests can be in flight concurrently, each accessing 32~128 bytes. This enables fine-grained and parallel data access. However, zero-copy may cause redundant transfers upon repeated access to the same data [55, 73].

Proxy Graphs. In recent years, utilizing proxy graphs has emerged as a promising alternative for processing large-scale graphs [32]. A proxy graph is a compact graph abstraction that retains computation-critical edges to preserve topological semantics of the original graph. This idea has been explored across several contexts, including reducing graph complexity for analytics and visualization [32, 38, 41, 76, 92], optimizing partition navigation in distributed environments [25, 53, 72], and relieving memory constraints in out-of-core systems [32, 85]. Existing proxy graph construction methods primarily follow three routes: (1) ***Structure-preserving Reduction***. Early methods in this direction used edge contraction, i.e., merging connected vertices, to generate coarse-grained graph representations [25, 53, 72]. While effective for regular meshes, such methods may abstract away individual vertex details. Input Reduction [38] instead removes graph components that do not affect query results in irregular graphs, e.g., vertices with no incoming or outgoing edges. While preserving exact correctness, its reduction ratio is typically constrained by the inherent connectivity of the graph (e.g., around 50% [38]). (2) ***Graph Sampling***. This line of work utilizes edge sampling techniques, such as random walk [41] and priority-based selection [92] (e.g., selecting low-weight edges for shortest-path queries), to bound proxy graph size. Wonderland [85], an out-of-core graph system, further enhances connectivity by incorporating edges that bridge weakly connected components. These sampling-based abstractions prioritize a small memory footprint; yet their lossy nature often necessitates an intensive refinement phase to ensure result accuracy. (3) ***Query-based Sketch***. To better align the abstraction with query semantics, recent methods propose constructing proxy graphs based on offline pre-evaluated queries [32, 76]. For instance, CoreGraph [32] evaluates a set of queries with sources at high-degree vertices and includes all edges on the resulting critical paths. This approach yields high accuracy (often exceeding 95%), though it involves a non-trivial generation phase.

2.3 Motivation

While state-of-the-art incremental EGA techniques achieve promising efficiency on GPUs [17, 18, 74], their performance collapses when the graph scale exceeds GPU memory capacity. To better understand these limitations and guide the design of a more efficient solution, we profile representative incremental EGA systems and identify two critical challenges and one key opportunity.

Challenge #1: The I/O Bottleneck in Data Transfer. We first break down the execution time of batch-based incremental EGA under memory oversubscription to evaluate existing data transfer strategies. As shown in Figure 2 (a), the overhead

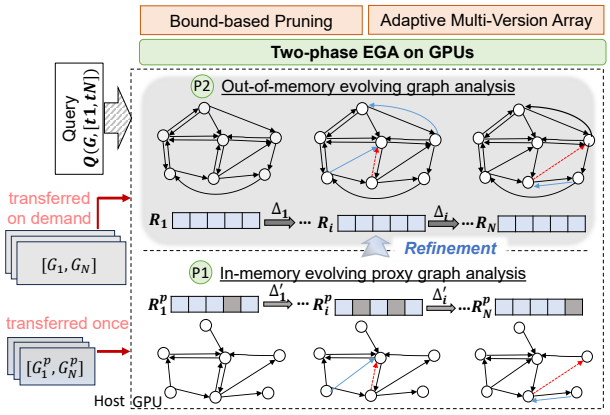

Figure 4: Workflow of EGA in POEGA.

of explicit data transfer dominates the execution, accounting for 77.6% of the total analysis time on average, and peaking at 94.4%. Implicit management strategies, zero-copy and unified memory (UM), are even worse, exhibiting significantly higher latency as shown in Figure 2 (b). These results underscore a fundamental barrier: even if an ideal policy transfers only the exact on-demand data per iteration, the heavy I/O overhead remains prohibitive for incremental analysis. This suggests that simply optimizing data transfer is insufficient; a paradigm shift to reduce the volume of required I/O is necessary.

Challenge #2: The Memory Bottleneck from Multi-Version States. While vertex-centric data is traditionally assumed to fit within device memory [51, 62, 63], this assumption breaks down under multi-snapshot concurrency. For instance, the value arrays for the Subdomain graph (used in our evaluation) across 40 snapshots consume approximately $102\text{M} \times 4\text{B} \times 40 \approx 16\text{GB}$, exceeding our GPU capacity (see §6). In practice, when co-located with graph structure data, the system encounters out-of-memory errors even earlier, typically when $N > 30$. Crucially, this scalability hurdle is overlooked by existing concurrent approaches [10, 17, 82], which assume all concurrent state arrays are memory-resident. A naive workaround involves offloading value arrays to host memory and transferring them on demand, as for graph data. Yet given the high frequency of fine-grained, atomic state updates in graph analytics, this approach incurs prohibitive transfer overheads, severely throttling the performance.

Opportunity: Exploiting Computational Underutilization. We observe that current GPU-based EGA methods suffer from severe hardware underutilization. Figure 3(a) presents the Cumulative Distribution Function (CDF) of thread utilization (defined as the ratio of active threads to total threads) when evaluating an *SSSP* query over 32 snapshots. We compare a streaming-based method, KS [70], and a batch-based approach, CG [1], both using fine-grained explicit memory management [62]. KS exhibits extreme inefficiency, with GPU usage remaining below 10% for over 60% of the runtime, primarily due to its serial snapshot processing scheme. While CG improves utilization, it still remains below 45% overall. The root cause is the sparsity of incremental workloads. As shown in Figure 3(b), the incremental analysis of a single snapshot typically activates significantly fewer vertices (one to two orders of magnitude) compared to a full re-evaluation. This creates a massive utilization gap, presenting a prime opportunity to amortize the cost of our proposed proxy-based approach by processing multiple snapshots concurrently.

3 Overview of POEGA

To enable efficient incremental EGA on GPUs, we propose POEGA, a holistic system that orchestrates a Proxy-Guided Concurrent Analysis execution model. Figure 4 provides an overview of the workflow of POEGA. Inheriting the two-phase methods of proxy graph approaches, POEGA is tailored for evolving graphs, including: (P1) *In-Memory Evolving Proxy Graph Analysis*, and (P2) *Concurrent Out-of-Memory Incremental Analysis for Snapshots*.

POEGA system accepts an evolving graph query on snapshots within a time interval $[t_1, t_N]$ and operates as follows. At P1, POEGA first transfers the *evolving proxy graph* to the GPU and then evaluates the query on it entirely within the memory, generating the approximate results $R_1^p, \ldots, R_N^p$. Guided by these results, POEGA at P2 performs exact incremental analy-

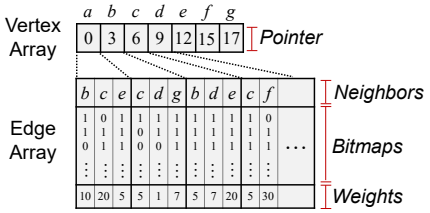

Figure 5: UnionCSR format of an evolving graph in POEGA.

sis on the full snapshots, which are outside the GPU memory and transferred only *on demand*. Thanks to our incremental-analysis-oriented evolving proxy graph (§4.1), the analysis at this phase is *deletion-free*, requiring minimal data transfers. In this phase, POEGA fuses the execution of multiple snapshots into a single kernel, which enforces data access of neighbors coalesced across snapshots (§4.2). Furthermore, the computations that can also be coalesced are identified and pruned by our novel runtime technique based on checking the bounds of values across snapshots (§4.3). Finally, to enable more snapshots to enjoy the benefits of concurrent analysis, POEGA manages the values of snapshots using Adaptive Multi-Version Array, a novel format for resolving the memory bottleneck in concurrent analysis on GPUs (§5).

Format of Evolving Graphs. We represent the evolving graph using a *snapshot-union* Compressed Sparse Row (CSR) format. Any edge that appears in at least one snapshot is stored once in this *UnionCSR* structure. Figure 5 shows this representation of the evolving graph in Figure 1. Like classical CSR format, adjacency information of the graph is maintained by (1) the vertex array, which records the start offsets of each vertex's neighbors, and (2) the edge array, which concatenates all neighbors. To differentiate edge presence across snapshots, UnionCSR associates each edge with a bitmap, where the i-th bit indicates its presence in snapshot G_i. By default, a 64-bit word is used for alignment, while additional words can be added to support more snapshots. This design enables fast GPU thread data access, akin to compact formats in prior works [12, 17]. The difference is that UnionCSR supports diverse data access interfaces by $O(1)$ bit operations, including view(G_i) for a single snapshot, view_shared(G_i, G_j) for shared subgraph, and view_diff(G_i, G_j) for the delta $G_j - G_i$. As this work focuses on enabling efficient GPU-based analytics, we assume graph updates are ingested offline and treat storage optimizations [7, 21, 65, 77] as orthogonal to ours. In fact, UnionCSR can be seamlessly generated using the standard parallel CSR computation from the durable graph storage, such as the multi-version adjacency list in GraphOne [37].

4 Proxy Graph-based EGA

The main idea of POEGA is shifting the out-of-memory irregular large-scale evolving graph processing into a two-phase processing, and solving the extra computation introduced by refinement via our efficient concurrent analysis on GPUs.

4.1 Incremental Analysis Oriented Evolving Proxy Graphs

Prior studies [32, 76] have demonstrated the feasibility of building high-fidelity approximations with a condensed structure for *static* graphs. For example, the state-of-the-art Core Graph [32] achieves over 95% accuracy with only 10% of the original edges. Starting from the approximate results on the proxy graph, the subsequent phase analysis refines the results on the full graph. Fundamentally, proxy-based approaches *trade* reduced memory I/O (by confining the bulk of access to the refinement phase) for increased total computation (processing both proxy and full graphs).

However, applying existing proxy designs to evolving graphs faces a fundamental dilemma between construction cost and approximation fidelity. On one hand, lightweight heuristics like Wonderland [85] yield low accuracy (e.g., around 50%), less effective in reducing the out-of-memory accesses in the second-stage analysis due to the iterative nature of graph processing. On the other hand, high-fidelity proxies like Core Graph are designed for static snapshots; naive reconstruction for every snapshot is computationally prohibitive (e.g., 7–14 minutes per snapshot [32]), outweighing any analytical benefits. More critically, reusing a single static proxy for an evolving sequence is inferior to structural divergence. After a series of updates, the proxy graph is no longer the subgraph of snapshots. Consequently, the second-phase analysis that processes the delta between the snapshot and the proxy graph needs to handle deletions, which are expensive to process, e.g., 2× slower than processing additions [1].

Maintained Evolving Proxy Graphs (EPG). Notice that *evolving graph changes slowly*, a well-known belief that has been used in optimizing evolving graph analytics [12, 30, 46, 70] and storage [12], we employ a single high-fidelity base proxy to capture the critical graph structure of recent snapshots and use a lightweight maintenance heuristic to adapt it computation-friendly to the second-phase refinement.

The complete EPG construction design is summarized in Figure 6. Following standard graph storage practices [42], we periodically construct proxy graph checkpoints offline. These proxy graphs are generated by evaluating queries on the top-K highest-degree vertices. For each vertex reached by a query, different from existing methods [32, 76], we select only one edge on its critical path (e.g., the shortest path from the source), thus keeping the proxy graph size complexity of $O(|V|)$. In our implementation, we empirically set K to 10 by default. To ensure sufficient structural coverage, if the resulting proxy remains below a predefined threshold (e.g., 10%) of the original snapshot size, we further augment it by evaluating other high-degree vertices that appear at a few hops from the source of the existing critical paths for the K queries.

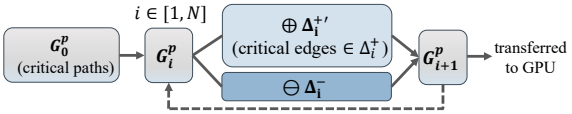

Figure 6: Design of Maintained Evolving Proxy Graph.

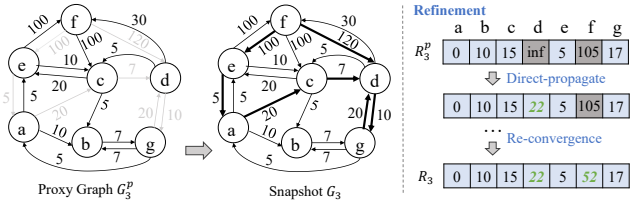

Figure 7: An illustrated example of applying refinement.

After the arrival of query Q on window $[t_1, t_N]$, we retrieve the nearest preceding checkpointed proxy graph at t_0 as the *base proxy* graph for EGA, denoted by G_0^p, where $t_0 \leq t_1$. We then apply the maintenance heuristics to map original deltas (Δ_i^+, Δ_i^-) onto G_0^p for generating subsequent proxy graphs:

$$G_{i+1}^p = G_i^p \oplus \Delta_i^+ \ominus \Delta_i^-, \quad i \in [0, N). \tag{1}$$

When the addition deltas are large, we selectively choose two types of edges from Δ_i^+ to keep the proxy graph compact while preserving fundamental structure: (1) bridge edges that connect two high-degree vertices, and (2) backup edges that connect any low-degree vertex to others.

Beyond the differences from existing work in pre-evaluation query and critical edge selection, the maintained EPG is specifically designed for dynamic scenarios with two key benefits. First, its update logic can be integrated seamlessly with the original graph's update procedure, and can even be executed concurrently to hide EPG generation latency. Second, by explicitly applying deletions, EPG remains a strict subgraph of the original graph ($G_i^p \subset G_i$). As a result, the evolving proxy graphs can effectively drive the *deletion-free* incremental analysis in the second phase, while keeping the high structural fidelity.

4.2 Two-stage Evolving Graph Analysis

P1: *In-memory Evolving Proxy Graph Analysis*. In this phase, the query is evaluated on the proxy graphs G_i^p to derive approximate results $\{R_i^p\}$ for the corresponding snapshots. After transferring the UnionCSR format of evolving proxy graphs, which is generated when creating the format of the original evolving graph, to the GPU once, this entire phase executes entirely within the GPU memory. As a result, evolving proxy graphs can be evaluated efficiently using existing in-memory EGA *incremental analysis* engines, such as streaming-based [46, 70] and batch-based [1] mentioned in §2.3. We adopt the batch-based incremental analysis method, as it aligns more with the GPU's massive parallelism.

By first analyzing the shared subgraphs of a series of proxy graphs G_c^p (via view_shared), batch-based analysis first obtains R_c^p and then incrementally processes additional edges of the proxy graphs to the shared graphs $\Delta(G_i^p - G_c^p)$ (via view_diff) to obtain R_i^p. Note that only the edge additions over the subgraph are processed in this process, where each edge e in the delta is tried once in relaxation operations (called *tracing*), e.g., in SSSP, push the value of source $e.src$ to the destination $e.dst$ if $val(e.src) + e.weight < val(e.dst)$. The affected vertices are added to the frontier to finish the convergence as the normal graph processing. Since these incremental analyses start from the shared subgraph that has no inter-dependency, we thus parallelize them using the same concurrent analysis kernel in the second phase below.

P2: *Concurrent Out-of-memory Incremental Analysis for Snapshots*. In the second phase, POEGA refines the approximate results R_i^p into precise results R_i for each snapshot G_i. This is achieved by treating the graph difference, $\Delta(G_i - G_i^p)$, as a batch of edge additions and performing an incremental analysis. Benefit from our evolving proxy graph construction ($G_i^p \subset G_i$), the incremental analysis performed during refinement is deletion-free. This process consists of two primary steps: (1) *direct-propagate* the addition delta to identify the effects of $\Delta(G_i - G_i^p)$ to R_i^p and (2) *re-convergence*, which resumes iterative processing until convergence. As introduced in existing incremental analysis designs (§2), the direct-propagate step performs a single-pass traversal over the delta edges, applying the edge function to each. An illustrated example is shown in Figure 7. After getting the approximate results for the proxy graph of snapshot G_3 in Figure 1, the direct-propagate step processes the delta edges (bold in G_3). Specifically, it applies the edge function for the delta edge (c, d) and then updates the value of vertex d to 22. Subsequently, during the re-convergence phase, this updated value is further propagated through the graph iteratively, ultimately refining the result of f. Since this refinement aligns with traditional incremental analysis [23, 66, 70], their correctness in reaching the precise value of G_i is inherently guaranteed.

Different from P1, both steps in P2 require out-of-memory graph data accesses. For the direct-propagate, since the delta size is relatively large, we use the explicit data management method [62] to transfer the data to the GPU memory to avoid the throttling performance. For the following convergences, we employ the implicit data transfers, since the incremental analysis involves a relatively small frontier size, where the implicit transfers outperform the explicit ones as they avoid the data preparation (e.g., compaction).

Coalesced Computation. Since the processing logic is the same across snapshots (for both proxy and full graph analysis), we *fuse* the analysis of multiple snapshots into a single kernel to concurrently execute them, as shown in Algorithm 1. Thanks to the UnionCSR format, this concurrent analysis

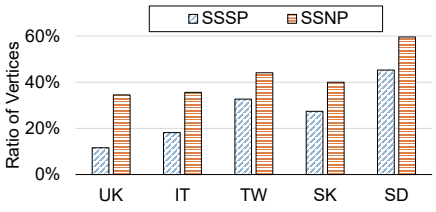

Figure 8: Inter-snapshot Redundant Computations in EGA.

Table 1: Bounds in the conditions for pruning over edge (u,v).

Alg.	Push conditions	$\bowtie$	$\mathcal{B}_{src}(val(u))$	$\mathcal{B}_{dst}(val(v))$
SSSP	$val(u)+w<val(v)$	$<$	$val^{\downarrow}(u)$	$val^{\uparrow}(u)$
BFS	$val(u)+1<val(v)$	$<$	$val^{\downarrow}(u)$	$val^{\uparrow}(u)$
SSWP	$min(val(u),w)>val(v)$	$>$	$val^{\uparrow}(u)$	$val^{\downarrow}(u)$
Viterbi	$val(u)/w>val(v)$	$>$	$val^{\uparrow}(u)$	$val^{\downarrow}(u)$
SSNP	$max(val(u),w)<val(v)$	$<$	$val^{\downarrow}(u)$	$val^{\uparrow}(u)$
WCC	$val(u)<val(v)$	$<$	$val^{\downarrow}(u)$	$val^{\uparrow}(u)$

coalesces the access to the neighbors of a vertex. Instead of issuing individual memory requests for each snapshot, threads access the neighbor union of a vertex in a single transaction (Lines 3-4). The kernel then determines edge presence in a snapshot via bitwise operations (Line 6). This reduces GPU global and out-of-memory traffic regardless of explicit or implicit data transfers. Analyzing vertex v in N snapshots in an iteration requires $|neigh(v)|$ times memory access, outperforming $\sum_{i\in[1,N]}|neigh_i(v)|$ required by separate kernels. Besides, the access to the active vertex set, i.e., frontiers of snapshots, is coalesced (Line 2) by maintaining the union of frontiers (Line 10), similar in spirit to prior static graph multi-query concurrent analysis [10,82]. Using this technique, the memory footprint is reduced, while the correctness of monotonic algorithms is not affected [82]. But since this method introduces unnecessary computations, we optionally also maintain separate frontiers if the memory budget allows.

Finally, thanks to the fused processing of multiple snapshots in one kernel, as of one snapshot, existing GPU thread scheduling schemes, such as the vertex-centric [36], warp-centric, or block-centric [75] processing, can be seamlessly applied to our concurrent analysis kernel to solve the thread mapping efficiency of graph algorithms on GPUs.

Algorithm 1 Coalesced Concurrent Analysis (G,$[1,N]$)

```
__global__ SSSP_CoalConcur(...)
1:  /* id is thread ID, warp ID, or block ID. */
2:  vid = frontier[id];
3:  for eid = G.vertexPtr[vid] to G.vertexPtr[vid + 1] do
4:      e = G.neighbors[eid];
5:      for sid = 1 to N do /* a thread or a warp of threads */
6:          if e.bmp[sid] then
7:              new_val = value[vid][sid] + e.weight;
8:              if new_val < val[e.dst][sid] then
9:                  CASMIN(val[e.dst][sid], new_val);
10:                 frontier_n ← e.dst;
```

4.3 Bound-based Pruning

In the concurrent analytics frameworks discussed in previous sections and prior works [10, 82, 87, 90], computations for neighbors, including arithmetic operations and atomic updates, are executed individually for each snapshot. This occurs even when the graph data accesses are coalesced.

However, we identify that this distinct per-snapshot computation incurs significant redundancy due to the inherent temporal locality of evolving graphs. We define *redundant computation* as edge operations that yield identical values or trigger the same control-flow outcomes (e.g., effective updates) on the same vertex across all snapshots. Our profiling shown in Figure 8 reveals that such redundancies constitute 18.2% to 59.6% of the total computations, highlighting a substantial potential for optimization.

Eliminating these redundant computations is challenging because vertices with identical converged results cannot be identified a priori. To address this, we propose a runtime pruning technique based on the **bounds of values**. This approach leverages *necessary conditions*, rather than exact conditions, to rapidly identify and prune redundant operations.

Definition 1 (Value Bounds)**.** *Let $val_i(u)$ be the converged or intermediate value of vertex u in snapshot i, where $i\in[1,N]$. We define its lower bound as $val^{\downarrow}(u)=\min_{i=1}^{N}(val_i(u))$ and the upper bound as $val^{\uparrow}(u)=\max_{i=1}^{N}(val_i(u))$.*

We now detail the bound-based pruning mechanism applied to the computations for an edge (u,v) across snapshots $G_1,\ldots,G_N$. First, we abstract the generic relaxation criterion that serves as a prerequisite for updating $val(v)$, denoted as $[val(u)\otimes w(u,v)]\bowtie val(v)$. Here, $\otimes$ represents the numerical operator that generates a candidate value, and $\bowtie$ denotes the relational operator that determines whether the candidate yields a superior result. While we formulate this using the *push* model, this logic applies symmetrically to the *pull-based* model (where v checks incoming neighbors). The specific operators for the graph algorithms evaluated in this work (§6) are listed in Table 1.

Definition 2 (Pruning Criteria)**.** *For an algorithm Q, the computations over edge (u,v) across all snapshots can be safely pruned if the following necessary condition **fails to hold**: $[\mathcal{B}_{src}(val(u))\otimes w(u,v)]\bowtie\mathcal{B}_{dst}(val(v))$ is False, where $\mathcal{B}_{src}$ and $\mathcal{B}_{dst}$ represent the specific bounds (upper or lower) determined by $\bowtie$.*

Table 1 specifies the bounds for different algorithms. The logic is as follows: if $\bowtie$ is $<$, a successful update requires the candidate value to be smaller than the current value. Therefore, we use the *lower bound* for the source u (best-case can-

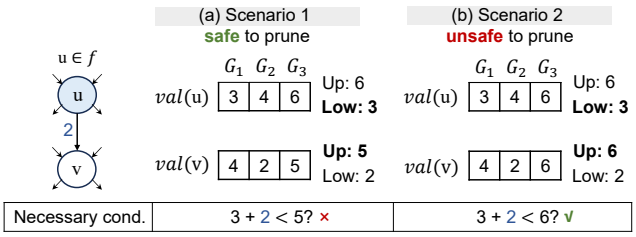

Figure 9: Pruning the push operations over edge (u, v) when concurrently serving an *SSSP* query in three snapshots.

didate) and the *upper bound* for the destination v (worst-case target). If this "best-case" fails to trigger an update, computations for all snapshots can be skipped. The inverse logic applies when $\bowtie$ is $>$.

An example of this pruning technique for SSSP is shown in Figure 9. In Case (a), the source's lower bound (after adding weight) is 5, which is not smaller than the destination's upper bound (5). This mathematical guarantee ensures that no snapshot can trigger a valid update, allowing the kernel to safely skip all N computations/comparisons for this edge. Case (b) highlights the necessary nature of this check. Although the bound condition allows the computation to proceed (i.e., no pruning), specific values in individual snapshots may still fail to trigger updates. Thus, passing the bound check implies a potential, rather than guaranteed, update.

Algorithm 2 Coalesced Concurrent Analysis with Pruning

```
__global__ SSSP_CoalConcur_Prune(...)
1:  vid = ...
2:  for eid = G.vertexPtr[vid] to G.vertexPtr[vid + 1] do
3:      e = G.neighbors[eid];
4:      if not Q.necessary(vid, e.dst, Upper, Lower) then
5:          continue; /* Bypass Redundant Computation */
6:      for sid = 1 to N do
    ... /* Lines 6-10 in Algorithm 1 */
__global__ Update_Bound(...)
14: if vid in frontier then
15:     Upper = max(val[vid][...]);
16:     Lower = min(val[vid][...]);
```

Lazy Update of Bounds. In implementation, we store the bounds of the vertices in two arrays: `Upper` and `Lower`. However, maintaining exact bounds in real-time on the GPU is expensive, as it necessitates frequent atomic updates to the global `Upper/Lower` arrays, leading to high memory contention. A key insight is that *out-of-date* bounds can still serve as a valid basis for safe pruning, even if they miss some optimization opportunities. We thus introduce a lazy update runtime technique for the bounds. As shown in Algorithm 2, instead of updating bounds immediately after the edge relaxation within each iteration, the lower and upper bounds of a vertex's values are updated only at the end of each iteration, via a separate lightweight kernel (Lines 14 to 16).

Correctness of the runtime lazy update. Using lazy bounds preserves the algorithmic correctness by analyzing the effects of out-of-date bounds of the destination ($\mathcal{B}_{dst}^{stale}$) and source ($\mathcal{B}_{src}^{stale}$) vertices separately. Without loss of generality, we assume a monotonically decreasing algorithm (e.g., SSSP), where both upper and lower bounds can only decrease or remain static.

- For the destination vertex, the pruning checks its upper bound. Since values decrease monotonically, the lazily updated (stale) upper bound is always a *conservative overestimation* of the true state (i.e., $\mathcal{B}_{dst}^{stale} \geq \mathcal{B}_{dst}^{true}$). If the pruning condition (e.g., $Candidate \geq \mathcal{B}_{dst}^{stale}$) holds for the looser stale bound, it guarantees that it also holds for the tighter true bound. Thus, a stale $\mathcal{B}_{dst}$ only leads to missed pruning opportunities, but never incorrectly prunes a valid update.

- For the source vertex, the pruning checks its lower bound. A stale lower bound implies $\mathcal{B}_{src}^{stale} \geq \mathcal{B}_{src}^{true}$, which may result in an inflated candidate value. Theoretically, this could trigger a "false positive" pruning (i.e., skipping a computation that should be performed). However, correctness is maintained by the *iterative nature* of the graph algorithm: if $\mathcal{B}_{src}^{true}$ has decreased, the source vertex u must have been updated and added to the active frontier. Consequently, this edge will be re-evaluated in the next iteration with the updated bounds. While this may slightly delay convergence, it ensures no valid updates are permanently lost.

5 Divergence-Aware Vertex State Management

While the concurrent execution design in POEGA effectively harnesses GPU compute resources, the achievable degree of concurrency remains bottlenecked by the $O(|V| \times N)$ space complexity required to maintain query states (e.g., distance values) across N snapshots. To address this issue without resorting to expensive host-device transfers or concurrency-limited execution, POEGA introduces the **Adaptive Multi-Version Array (AMVA)**, a divergence-aware storage backend that dynamically manages a hybrid scalar-vector layout.

5.1 Dynamic Data Layout

Design Goals. Existing dynamic graph formats on GPUs, including those based on Packed Memory Arrays (PMAs) [65, 94] and linked lists [21, 77], are predominantly optimized for topological mutability (e.g., structural edge insertions and deletions). However, these designs are ill-suited for the vertex state management required by incremental graph analysis, which involves massive, concurrent read-modify-write operations. Consequently, a high-performance state management design should satisfy three requirements:

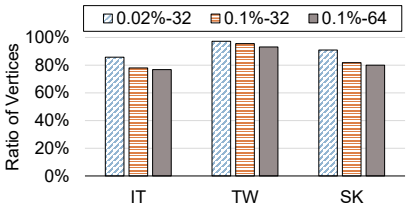

Figure 10: Inter-snapshot Equivalent Values in EGA ($|\Delta|$-N).

- **Deterministic $O(1)$ access complexity**. Data structures requiring traversal (e.g., pointer chasing in linked lists) or search (e.g., binary search in PMAs) to locate value data introduce significant latency, and exacerbate thread divergence and stall execution pipelines on GPUs, leading to severe performance degradation.
- **Spatial locality for memory coalescing**. Conventional dense arrays (as shown in Figure 11(a)) offer excellent spatial locality. Conversely, adopting formats with poor locality (e.g., hash-based structures [5]) would break memory coalescing and waste GPU memory bandwidth.
- **Minimal data movement overhead**. Dynamic structures like PMAs often require shifting contiguous memory blocks to accommodate element insertion. Such cascading data movement triggers severe write amplification and requires costly global synchronization [88]. Therefore, the proposed state management design must avoid physical data relocation or re-allocation [77].

As shown in Figure 10, empirical analysis reveals that a substantial portion of vertices (65% to 95%) maintain invariant state values across all snapshots during incremental EGA. This indicates that statically provisioning a full-version value array for every vertex is prohibitively wasteful. However, since the set of stable vertices is input and query dependent and unknown *a priori*, exploiting this redundancy requires a design that performs adaptive compaction at runtime. To satisfy the design goals, we propose the Adaptive Multi-Version Array. Specifically, AMVA employs a *dual-format* storage strategy: (i) *Scalar format*, which stores a single value shared across all snapshots for stable vertices; and (ii) *Full-version format*, which maintains a dense vector of N values for divergent vertices. Compression schemes (e.g., storing only unique values) are deliberately avoided for deterministic O(1) addressing: the current binary design ensures that states of a vertex in any snapshot can be accessed via either a direct read or a single-level redirection.

Layout. The AMVA consists of two core components:

(i) The Vertex Directory (VD). The VD acts as the primary lookup table, implemented as a linear array where the i-th element corresponds to vertex v_i. To minimize memory footprint, a *tagged pointer* scheme is employed to multiplex data and metadata within a single word (extensible to larger data types). As shown in Figure 11(b), the two Most Significant Bits (MSBs) serve as the divergence flag, while the remaining bits constitute the payload. The flag bits encode the current mode of the vertex. Across different modes, the payload stores either the shared value directly or an index offset pointing to the Expansion Buffer. More details are shown in §5.2.

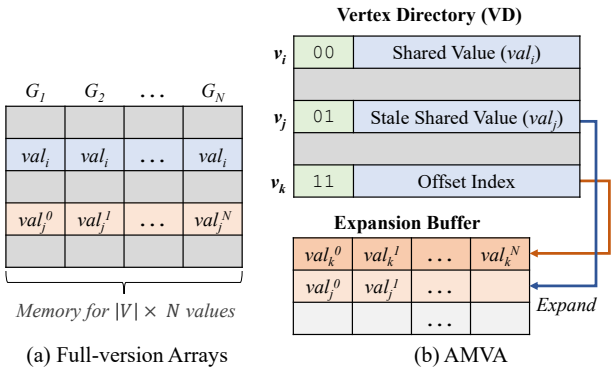

Figure 11: Vertex State Representations.

(ii) The Expansion Buffer. To accommodate divergent vertices, we pre-allocate a contiguous memory block on the GPU, organized as B_{max} rows where each row contains N elements. The j-th element of a row stores the value for snapshot G_j. When a vertex transitions from scalar format to full-version format, a free row from this buffer is assigned to that vertex, i.e., *expansion*. To ensure high-throughput expansion, we utilize a **lock-free bump-pointer allocator** [64] design with managing a global atomic counter that tracks the index of the next available row. Consequently, assigning a buffer row requires only a single atomic update (e.g., `atomicAdd`).

Memory Management. POEGA adopts a flexible provisioning policy. Prior to execution, it checks if the residual GPU memory suffices for full state materialization. In unconstrained scenarios (e.g., small datasets or low concurrency), POEGA reverts to the flat full-value arrays. However, when memory bottleneck comes from vertex state management, AMVA is instantiated with a total footprint bounded by $(|V| + B_{max} \times N)$. We determine the buffer capacity B_{max} based on the remaining memory budget after allocating essential graph structures (e.g., the proxy graph, frontiers, etc.). Due to the high stability of vertex values in EGA, this pre-allocated buffer typically accommodates all divergent vertices. In cases where extreme divergence exhausts the buffer, POEGA enforces *concurrency throttling*, which restricts the batch size. We consider this an acceptable trade-off, because such high-divergence scenarios typically imply sufficient workload to saturate GPU compute resources.

5.2 Lock-Free Access Protocols

To support lock-free expansion of a vertex value, three operational modes for elements in the VD are defined using

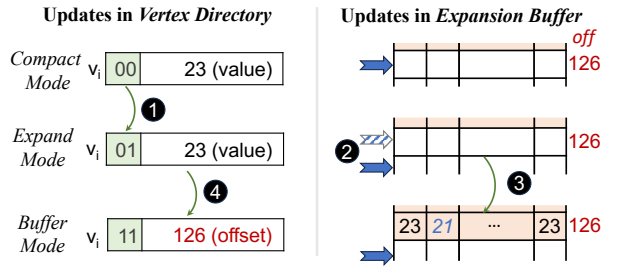

Figure 12: An illustrated example of Write-with-Expansion in AMVA. Assume that `atomicMin`(v_i, 21) is executed in the edge function during an iteration of incremental EGA.

the divergence flag (i.e., tag bits): (1) *Compact* mode (`00`), where the lower bits store the scalar shared value; (2) *Expand* mode (`01`), which indicates an ongoing expansion, where the lower bits still hold the valid but potentially stale value; and (3) *Buffer* mode (`11`), where the payload stores the offset index pointing to the expansion buffer. Based on these modes, AMVA supports three core operations on the vertex states: write(), write_expand(), and read().

Direct Write. When a thread attempts to update the state of a vertex v in snapshot G_i after verifying the push condition of edge (u,v) (e.g., $val_i[u]+w < val_i[v]$ in SSSP), the write() operation handles two specific scenarios: (i) *Buffer Mode Detected*. If the thread finds v is in the Buffer mode (tag `11`), it follows the payload pointer and directly writes the new value into the expansion buffer using an atomic operation. (ii) *Expand Mode Detected*. If v is in Expand mode (tag `01`), it indicates another thread is currently processing an expansion. The current thread waits until the mode transitions to Buffer Mode, after which it completes the write update.

Write with Expansion. When a thread attempts to update the state of a vertex v in the Compact mode, it initiates the expansion procedure and finishes the update via write_expand(). To ensure data consistency under high concurrency, we design a four-step atomic expansion protocol, as shown in Figure 12. ❶ Ownership Acquisition. The thread attempts to acquire exclusive rights to expand the values of v using an atomic Compare-and-Swap (CAS) instruction. It tries to transition the state mode from Compact to Expand while preserving the original value in the payload. Only one thread succeeds; failing threads infer that another writer has either claimed the vertex or completed the expansion, thus triggering a retry of write(). ❷ Low-overhead Allocation. The owner thread allocates a new row in the expansion buffer by performing an atomic addition of the global `counter` with the old `offset` recorded. ❸ Data Migration and Update. The owner thread expands the old scalar value (carried in the CAS payload) to all snapshot entries in the newly allocated buffer row. It then writes the new value (e.g., $val_i[u]+w$) directly into the target snapshot column i. A memory fence is issued after this step to ensure these writes are visible to all threads. ❹ Atomic Publishing. Finally, the owner commits the expansion by atomically updating the entry in the VD. The tag is flipped to Buffer mode (`11`), and the payload is replaced with the buffer index `offset`. This atomic instruction acts as the linearization point: once executed, all subsequent accesses are seamlessly redirected to the buffer.

Direct Read. When accessing a vertex state, read() first inspects the MSB of the tag: If MSB is 1 (i.e., Buffer mode), the reader thread follows the offset payload to retrieve the latest value from the buffer. If MSB is 0 (Compact or Expand mode), the value stored in the VD is consumed directly. Note that in Expand mode, the value retrieved may technically be "stale", but this will not affect the final results of incremental EGA when the target graph algorithm exhibits monotonicity.

Correctness of Stale Reads. Let d_{stale} denote the stale state read from a vertex currently in Expand mode and d_{new} denote the finalized state being written to the buffer. This vertex can be a *source* or a *destination*. (i) For source access: propagating updates derived from a source d_{stale} corresponds to processing a valid previous state of the graph. This may trigger *loose* updates (e.g., a path distance that will later be shortened), which are valid relaxations respecting the algorithmic invariants. The algorithm will eventually converge to the correct fixed point once the *tighter* d_{new} is propagated. (ii) For destination access: If a candidate update fails to improve upon d_{stale} , it is insufficient. Since the candidate update is worse than d_{stale}, the update is transitively worse than d_{new}, considering the monotonicity property (e.g., $d_{stale} \leq d_{new}$ in minimization problems). Thus, discarding the update based on d_{stale} yields the same logical outcome as checking d_{new}. In sum, the correctness of this read() operation is guaranteed.

6 Evaluation

6.1 Evaluation Methodology

Implementation. We prototype PoEGA as a graph framework written with C++ and CUDA. We integrate our framework with an open-source in-memory GPU-based static graph processing framework [57, 75]. To make a fair comparison, we incorporate this framework and UnionCSR format into all the compared systems.

Baselines. We compare PoEGA with the following systems:

- *Re-evaluation-based Approach:* **EGraph** [86], which employs a re-evaluation analytics engine and reuses the transferred shared graphs among snapshots to reduce data transfer overhead.
- *Streaming-based Incremental Analysis Approach*: including **Grapin** [74], which employs the state-of-the-art streaming-based analytics engine [20, 70] and uses zero-copy for out-of-memory accesses. We also integrate the Kickstarter engine with unified memory (**KS-UM**), which allocates the

WCC	*CASMIN*(id(d), id(s))

graph data with `cudaMallocManaged()`, and state-of-the-art explicit data transfer method Subway [62] (**KS-SW**).

- *Batch-based Incremental Analysis Approach*: we deploy **Mega** [17] on GPUs, which employs state-of-the-art *CommonGraph* [1] as analytics engines and reuses the delta transferred with Subway. We also integrate CommonGraph with unified memory (**CG-UM**) and zero-copy (**CG-ZC**).

Evaluation Platform. Experiments are mainly conducted on a server equipped with an NVIDIA RTX A4000 GPU with 16 GB memory and a 16-core Intel Xeon Gold 6426Y 2.50GHz processor with 256 GB RAM. The server runs on Ubuntu 20.04.6 with Linux kernel 5.15.0, and the codes are compiled with CUDA 12.4 with the highest optimization level. For large datasets, we extend the evaluation onto an NVIDIA A6000 Ada GPU with 48 GB memory, while keeping the remaining system configuration unchanged.

Graph Datasets. Evaluations were conducted with a set of real-world graphs from different domains. Table 2 lists these graphs with their original graph CSR sizes ($Size_{org}$) and their UnionCSR sizes ($Size_{union}$) for EGA, both with weights. All these graphs have their UnionCSR sizes exceeding the GPU memory, requiring out-of-GPU-memory graph processing. Following prior studies [45, 66, 70], we initialize and warm up the system by preloading 50% of each dataset as the base snapshot (G_0). Unless otherwise specified, all experimental results presented in this section are obtained over 32 snapshots; and each snapshot involves a delta batch of 0.1% updates, including 0.05% edge additions (randomly selected from the remaining dataset) and 0.05% edge deletions (randomly selected from the loaded portion).

Graph Algorithms. We use six types of graph queries to evaluate the graph analysis performance, including BFS (breadth-first search), SSSP (single source shortest path), SSWP (single source widest path), SSNP (single source narrowest path), Viterbi, and Weakly Connected Component (WCC). Table 3 lists their edge functions.

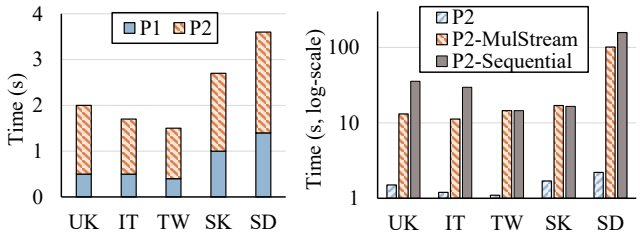
6.2 Overall Performance

Table 4 reports the overall performance of all the methods, as well as the geometric mean speedup over the baseline, EGraph. The results show that PEGA outperforms other systems across all datasets and algorithms, achieving 253.9× speedup over the baseline method EGraph. When compared with SOTA (the fastest system other than PEGA in each case), PEGA has the speedup of 6.6× on average, and at most 14.3× for SSNP on the SK dataset.

Specifically, against the streaming-based method (KS) with different GPU memory management, PEGA achieves 23.9×, 7.6×, 14.7× speedups over unified memory (UM), Grapin, and Subway (SW) in geometric mean, respectively. Besides, against the batch-based method (CG), PEGA achieves 35.8×, 25.5×, 17.0× speedups over UM, zero-copy (ZC), and Mega.

We observe that the streaming-based methods generally outperform batch-based methods, particularly when using zero-copy. This is due to the trade-off between parallelism and data efficiency. KS exploits the exact dependency tracing and result bootstrapping to minimize the data required for analysis. In contrast, CG requires much more data to support its parallel incremental analysis [17], which is even more expensive for



(a) P1 and P2 performance. (b) P2 performance under different execution strategies.

Figure 13: Two Phases Breakdown (SSSP).

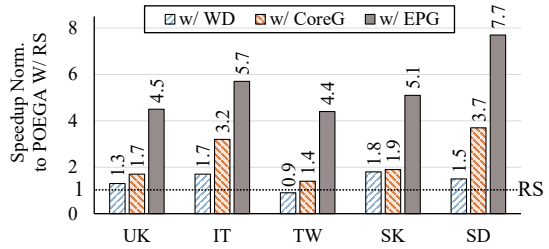


Figure 14: Effect of evolving proxy graph. Compared with POEGA integrating random sampling (RS), WD [85], or CoreGraph [32] (SSSP).

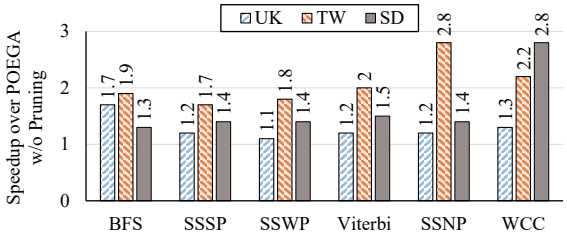

Figure 15: Effect of bound-based pruning.

the explicit data transfer (SW). The consistent speedups of POEGA over both categories confirm the effectiveness of its holistic approach for GPU memory management and parallel computation efficiency. Finally, all incremental systems show consistent speedups over recomputation-based EGraph, validating the fundamental advantage of result reuse in EGA.

6.3 Breakdown Analysis

To assess the contribution of the proposed components to the final results of POEGA, we conduct a breakdown analysis.

Breakdown of the Two Phases and Effect of Coalesced Concurrent Analysis. Figure 13(a) decomposes the execution latency of POEGA. The P1 phase, which performs in-memory EPG analysis, accounts for 24% to 39% of the total runtime, with an average of 31%. Although the P2 refinement phase remains the dominant cost, its latency is reduced to a level comparable to in-memory processing through our coalesced concurrent execution design. To further evaluate this, Figure 13(b) compares POEGA against two alternative strategies for P2: concurrent execution with CUDA stream [58] and sequential execution. Note that several techniques in POEGA, e.g., bound-based pruning, cannot be supported under a multi-stream execution. The coalesced strategy in POEGA achieves 13.6× and 21.9× speedups over these two baselines, respectively. These results validate the efficiency of data access optimization and computation reduction discussed in §4.3, and indicate that naive concurrency alone is insufficient to fully utilize GPU resources.

Effect of Evolving Proxy Graph. To evaluate the benefits of evolving proxy graph (EPG), we benchmark POEGA against three alternative proxy graph strategies: evolving proxy graph generated for each snapshot with (1) the random sampling (RS), (2) the heuristics in Wonderland (WD) [85] (e.g., edges with the least weights), both sized at 10% of E, and (3) a static Core Graph [32]. Results in Figure 14 show that EPG helps POEGA achieve average speedups of 5.4× over RS and 3.8× over WD. This is due to the higher accuracy of EPG (from 87.1% to 98.8%) compared to that of RS (10% to 26%) and WD (14% to 48%). Besides, EPG in POEGA outperforms the static core graph by 2.4×, despite the latter's high accuracy for the initial snapshot. This verifies the benefits of incremental analysis-oriented adaptation for updates. Besides, the proxy graphs in POEGA account for 12.1% to 15.9% of the original snapshot sizes, with a maintenance and generation cost of less than 0.3 seconds per snapshot. Note that this cost can be covered by the graph storage update procedure.

Effect of Bound-based Pruning. To evaluate the impact of the bound-based pruning, we disable it and then benchmark POEGA. The results in Figure 15 show diverse benefits of pruning on different graph datasets and algorithms. It improves the performance of POEGA by up to 2.8×, and by 1.6× on average. These results highlight the room for further improving the concurrent analysis by reducing redundant computations across snapshots, underscoring the effectiveness of our approach, including the lazy updates of the bounds.

Effect of Using AMVA. We evaluate the effectiveness of AMVA in scenarios where allocating full value arrays out of GPU memory (e.g., 32 snapshots of TW/SD). AMVA is compared against two alternative strategies: (1) batch-by-batch, which trades reduced concurrency to memory, and (2) zero-copy for managing out-of-memory value arrays. Results in Figure 16 show that AMVA outperforms batch-by-batch concurrent analysis up to 3.3×. This contributes to the benefits of snapshot coalescing with a higher concurrency. Notably, both AMVA and batch-by-batch analysis consistently outperform zero-copy, demonstrating the need for explicit runtime state management on GPUs.

The results in Figure 16 also present the impact of AMVA on two phases and yield two observations. First, AMVA delivers more gains at higher snapshot numbers (32 and 64), yet

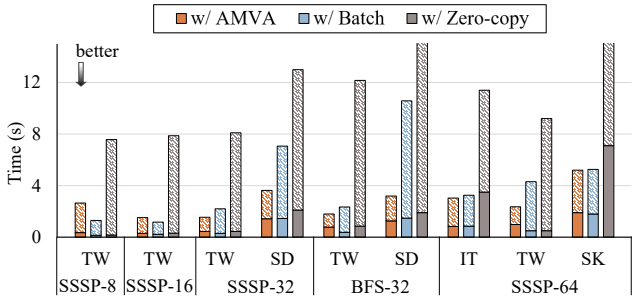

Figure 16: Effect of AMVA in two phases. Compared against reduced concurrency (batch-by-batch) and zero-copy for out-of-memory value array. (P1: Solid; P2: Patterned.)

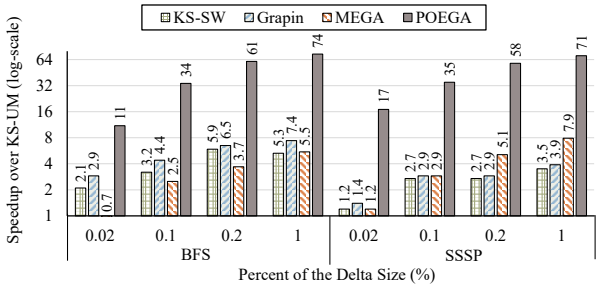

Figure 17: Effect of delta size (*SK*).

exhibits a performance degradation compared to the batch-by-batch method at smaller scales (8 and 16). This indicates that when potential concurrency is limited, the runtime overheads of AMVA outweigh its memory-saving advantages. Second, AMVA introduces a trade-off between the two phases. While it boosts P2 by up to 4.7× and 12.9× compared with batch-based and zero-copy, it results in only marginal gains, or even slight slowdowns for P1. This is because in-memory processing benefits relatively less from increased concurrency, which makes AMVA's computational overhead more visible.

6.4 Scalability

We also examine the scalability of POEGA. First, the delta batch size is set from 0.02% (0.01% add. and 0.01% del.) to 1% (0.5% add. and 0.5% del.) while keeping 32 snapshots. Speedups of POEGA and two state-of-the-art systems, Grapin and Mega, as well as the KS-SW, over KS-UM are reported in Figure 17. POEGA and batch-based incremental system Mega have consistently increasing speedups with larger delta sizes. Mega outperforms Grapin when the delta is 1% for SSSP, showing the scalability of batch-based incremental methods in terms of delta size.

We then vary the snapshot number from 8 to 64 while keeping the delta size at 0.1%. The results in Figure 18 show that POEGA generally has more benefits than other approaches across different N. Streaming-based methods, KS-SW and

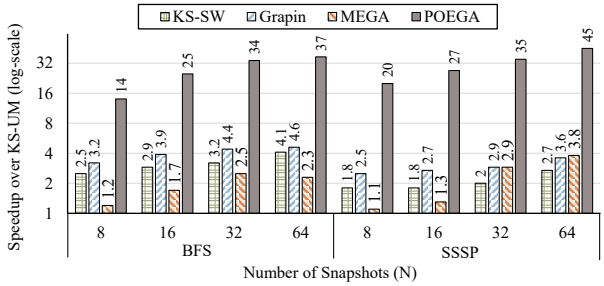

Figure 18: Effect of number of snapshots (*SK*).

Table 5: Performance results (seconds) for running over *SD* dataset on a 48GB GPU.

Systems	BFS	SSSP	SSWP	Viterbi	SSNP	WCC
EGraph	212.6	254.1	759.4	620.2	966.4	182.9
Grapin	10.9	16.0	14.1	16.1	11.3	9.7
Mega	12.0	21.4	52.9	55.4	60.5	18.6
POEGA	2.7	2.4	2.2	3.0	2.7	2.6

Grapin, have stable performance with different N, which is due to their sequential processing of delta for each new snapshot, regardless of the total snapshot numbers. KS-SW shows a fluctuating performance because it is sensitive to the effect of deletion deltas.

Results on a GPU with 48 GB memory. We further evaluate the scalability of POEGA on a GPU platform with increased memory capacity. Table 5 reports the performance of POEGA, the baseline, and the SOTA systems over the graph dataset *SD* on a 48 GB GPU. Note that despite the larger GPU memory, the runtime state and graph data of SD exceed 48 GB.

The results show that while increasing GPU memory to 48 GB improves performance for all systems, i.e., 4.2× for EGraph, 1.2× for Grapin, 2.8× for Mega and 1.6× for POEGA, the gains are sub-linear. These suggest that these systems are generally memory-bound, yet simply scaling the GPU memory size cannot fully mitigate the overhead of irregular, fine-grained out-of-memory graph data accesses typical in incremental analysis. Notably, POEGA maintains its benefits, achieving a 4.9× speedup over Grapin on SD, surpassing the 4.0× speedup observed in the 16 GB scenario.

7 Discussion and Future Work

Monotonic Graph Algorithm. POEGA currently supports graph algorithms that exhibit monotonicity, where *vertex values only change monotonically across iterations before convergence.* This property is common for a wide spectrum of iterative graph algorithms: beyond the fundamental algorithms presented in §6, it encompasses complex tasks such as graph radii estimation and minimum spanning tree. The significance of monotonicity has been extensively recognized and exploited in prior graph systems. It serves as the theoretical

foundation for for asynchronous iterative processing [62, 82], result reuse in dynamic graph processing [11, 16, 70, 83], automated parallelization [15], and iteration pruning [9, 32, 33, 80]. Furthermore, as existing studies have provided automated condition checkers to confirm whether a graph algorithm is monotonic [20], users can directly leverage them to verify whether an algorithm can be deployed in POEGA.

For non-monotonic graph algorithms, such as PageRank and Betweenness Centrality, POEGA could integrate the corresponding incremental approach, such as Graphbolt [46], to its analytics engine, while needing to adapt the bound-based pruning technique, which currently relies on the monotonicity. The efficiency of POEGA for non-monotonic graph algorithms is an open problem, and we leave the investigation of general incremental graph analysis on GPUs as our future work.

Extending POEGA to Multi-GPU Environments. Beyond single GPU, POEGA can be extended to multi-GPU scaling. In this scenario, snapshots can be distributed across multiple GPUs by batch, with each batch still using the coalesced concurrency analysis. Since the resident-memory proxy graph is compact, it can be replicated on each device to enable independent, zero-communication approximate analysis in P1. Besides, future work could exploit the distinct bottleneck profiles of POEGA's two phases to overlap P1's compute-intensive tasks with P2's I/O-intensive transfers across devices, further mitigating the PCIe/NVLink overhead.

8 Related Work

Evolving Graph Systems. Various incremental computation frameworks have been proposed. Early approaches such as Tornado [66] and Naiad [54] explore the incremental analysis concept, but only support edge additions. Kickstarter [70] designs the runtime support for the analysis to enable the capability of handling deltas with deletions, while Graphbolt [46] further supports the Bulk Synchronous Parallel semantics on the basis of Kickstarter. Tegra [30] extends streaming analysis to arbitrary time windows of the graph. CommonGraph [1] proposes to transform the expensive deletion processing into addition processing by first analyzing the common subgraphs and then incrementally reaching the full snapshots. MEGA [17] is an evolving graph accelerator that improves data reuse in CommonGraph by optimizing the scheduling of the incremental analysis. More recently, UVV [2] further reduces computations in CommonGraph by identifying vertices with stable values across snapshots. However, UVV relies on *offline* evaluation over the union of snapshots, which incurs significant overhead for large-scale, out-of-core processing. POEGA departs from this by introducing *online* stable value identification. Through a lightweight (yet safe) approximation for bound-based pruning, it achieves similar computational savings without heavy pre-processing.

A few works have explored improving the data representation of Kickstarter. Risgraph [16] optimizes for the per-update incremental analysis scenario, proposing the hash index for the adjacency list of graph data to enhance access efficiency. IncBoost [83] discusses the efficiency of dependency data representations in Kickstarter. All these systems and formats are built on multi-core or distributed CPUs.

GPU-based Graph Processing. Many GPU-based systems are designed for a specific graph algorithm [6, 26, 67, 71]. Among the general frameworks, Gunrock [75] introduces the frontier-centric model and implements a number of graph primitives. Maximum warp [27], CuSha [36], warp segmentation [35] and Tigr [57] focus on addressing GPU thread divergence issues for irregular graphs. These methods are orthogonal to the techniques of this work.

To address GPU memory oversubscription, early work Graphie [22] and GraphReduce [63] adopt the partition-based method and actively track the active vertices on partitions to avoid unnecessary partition transfers. EMOGI [51] explores efficiently employing zero-copy for graph analytics. Subway [62] proposes to transfer fine-grained partitions of the active vertices. All of these works focus on the memory oversubscription issue on the *static graphs*.

GPU-based *dynamic graph* systems are built to meet the real-time response requirement for the applications on rapidly evolving graphs. EGraph [86] proposes to share partitions among snapshots in dynamic graphs to reduce the redundant data transfer to devices. Grapin [74] adopts zero-copy for its streaming incremental engine (based on Kickstarter) and caches the hot vertices' subgraph in the GPU to reduce potential data transfer overhead. CGCGraph [68] transfers active shared partitions to GPUs while processing unshared active parts on the CPU concurrently. Aside from analytics, a parallel line of work has explored dynamic graph data structures or storage on GPUs [5, 7, 21, 65, 77].

9 Conclusion

This work presents POEGA, a framework designed to enable efficient large-scale evolving graph analytics on GPUs. It adopts a proxy-guided incremental analysis model to reduce out-of-memory IO, which first analyzes the proxy graphs and then executes global refinement. To solve the extra computations, POEGA employs an efficient concurrent analysis on GPUs, including bound-based pruning and adaptive state format to enable high concurrency. A comprehensive evaluation of POEGA demonstrates its effectiveness.

A Artifact Appendix

Abstract

This artifact provides the source code, benchmarks, and evaluation scripts for POEGA, a high-performance framework designed to enable efficient large-scale evolving graph analytics on GPUs. It includes the implementation of proxy-guided two-phase analysis, bound-based pruning, and adaptive multi-version array.

Scope

This artifact enables validation of POEGA's performance against seven compared systems mentioned in §6. Refer to the artifact's README for specific experiments.

Contents

The artifact includes core source code (`src/`), dataset preprocessing utilities (`tools/`), and the script for running all experiments (`run.sh`). The README details the full directory structure and contents.

Hosting

The artifact of POEGA is hosted at https://github.com/YunMoZhang/POEGA. Use the latest commit on the `master` branch.

Requirements

CUDA Toolkit ($\geq$ 12.4) and CMake ($\geq$ 3.18) are required. Evaluated on an NVIDIA RTX A4000 GPU and NVIDIA A6000 Ada GPU. Refer to the README for comprehensive requirements.

Pluto: High-Performance, Memory-Efficient Distributed Graph Analytics Through Advanced Mirroring

Ying-Wei Wu

Microsoft

Mattan Erez
University of Texas at Austin

Abstract

Inter-host communication poses a significant performance bottleneck in distributed graph analytics due to synchronization overheads. To mitigate this, state-of-the-art systems typically employ the full mirroring technique to replicate all potentially needed remote data and adopt a bulk-synchronous parallel execution model for coarse-grained communication. While effective for reducing network traffic, these approaches substantially increase memory footprint and constrain system parallelism. This paper introduces Pluto, a memory-efficient distributed graph analytics system based on two advanced mirroring designs: static partial mirroring and a mirror-free architecture. Nonproductive data duplication is avoided to reduce memory usage, while the work migration mechanism allows communication-computation overlap for performance improvement. For homogeneous graphs, Pluto achieves up to 3.8× speedup (harmonic mean 1.75×) compared to a full mirroring baseline and delivers up to 12× speedup (harmonic mean 1.75×) over existing open-source systems. For labeled property graphs, Pluto achieves up to 2.6× speedup (harmonic mean 1.37×) and lowers the minimum host requirement to 50%–90% of the baseline.

1 Introduction

The widespread adoption of social media and search engines has driven significant interest in graph-based analysis of social networks and web crawls. These datasets are massive, often ranging from terabytes to petabytes, making single-node storage and processing impractical. As a result, distributed frameworks are developed to partition graphs across clusters of nodes and execute in parallel.

A fundamental challenge in distributed systems is inter-node communication, which is frequently constrained by network latency and limited interconnect bandwidth. To mitigate communication costs, state-of-the-art systems [11, 14, 19, 20, 48] commonly combine the *mirroring* approach with bulk-synchronous parallel (BSP) execution. Mirroring replicates remote data to reduce communication during execution, and the BSP model combines multiple updates for coarse-grained synchronization.

While mirroring reduces communication volume, it increases memory usage. Given historically abundant memory, the prevailing practice has been to replicate all potentially required remote data, an approach we call *full mirroring*. However, with the slowing of Moore's law [33] and memory capacity scaling lagging behind data growth [6], optimizing solely for performance is no longer a sustainable solution as memory becomes the limiting resource. In our study, full mirroring incurs up to 4× memory overhead and can be even larger on highly connected graphs, questioning the long-term viability of this conventional dogma under emerging trends.

We address this challenge through two advanced mirroring designs: *static partial mirroring* and a *mirror-free* architecture. Static partial mirroring leverages *mirror heterogeneity*, the observation that not all data replication contribute productively to execution. By identifying and eliminating the nonproductive duplications, the memory usage is reduced while maintaining or even improving performance. The mirror-free architecture targets algorithmic variants that operate efficiently without any mirroring, and thus completely removes the memory overhead of data duplication. Together, the two designs cover a broad range of common graph applications.

Building on these ideas, we present Pluto, a memory-efficient distributed graph analytics system. By lowering memory requirements, Pluto enables the same applications to run on fewer nodes. In addition, Pluto migrates work to the nodes that hold the relevant data while continuing local computation, overlapping communication with computation to hide network latency and improve performance.

This work makes the following contributions:

- We identify *mirror heterogeneity* and propose a *static partial mirroring* approach that detects and avoids nonproductive data replication.
- We analyze algorithmic variants that operate efficiently without remote data replicas and design a *mirror-free*

architecture to remove duplication overhead entirely.

- We introduce an *on-demand work migration* mechanism that initiates network transfers early and overlaps communication with computation, amortizing communication costs.

- We implement these techniques on top of D-Galois [14] to build Pluto, a high-performance and memory-efficient distributed graph analytics system. Across large-scale homogeneous graphs and standard benchmarks, Pluto outperforms state-of-the-art systems by up to 12× (harmonic mean 2.5×) and delivers 3.8× speedup (harmonic mean 1.75×) over our own full mirroring baseline. For labeled property graphs, Pluto achieves up to 2.6× speedup (harmonic mean 1.37×) while enabling the same graphs to be stored on only 50%–90% of the hosts required by existing systems.

2 Background

2.1 Graph Data

A basic graph is defined as $G = (V, E)$, where V is a set of vertices and E is a set of edges. This topology-only representation, often called a *plain* or *homogeneous* graph, is widely used in academic research for algorithmic studies that focus on geometry.

The *labeled property graph (LPG)* [4], which is the most dominant data model in modern graph databases [1, 24, 31, 34, 42], augments G by associating labels and properties with both vertices and edges. Labels classify graph elements into meaningful categories, and properties attach attributes with arbitrary data structures to each element. This combination of flexibility and expressiveness allows the LPG model to represent real-world domains in a rich and intuitive manner.

2.2 Graph Analytics

This work focuses on graph analytics, a class of algorithms that analyzes the topology of graph-structured data to uncover patterns and insights.

2.2.1 Programming Models

Most graph analytics systems [11, 14, 19, 20, 28, 48] adopt a vertex-centric model: each vertex maintains a state, and each algorithm defines a local computational rule to update the vertex state with connecting edges and immediate (one-hop) neighbor values. An alternative line of work [2, 7, 8, 32] operates on the adjacency matrix representation of graphs through linear algebra. Hochan et al. report that the vertex-centric paradigm outperforms the linear-algebra-based approach across a range of graph analytics workloads [26]. Accordingly, all five benchmarks in our evaluation are implemented using the vertex-centric model.

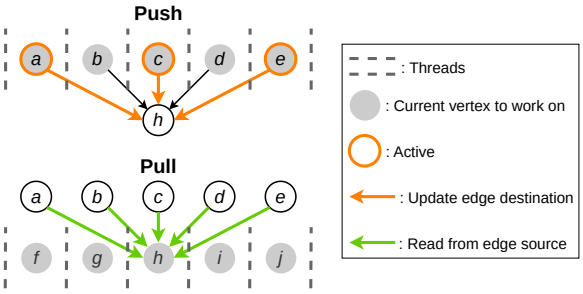

Figure 1: The push and pull update models.

2.2.2 Update Models

Fig. 1 illustrates the two primary update models used in vertex-centric programs: push and pull. In the push model, a vertex becomes active when its own state satisfies conditions specified by the algorithm and then propagates updates along outgoing edges to destinations. In the pull model, a vertex collects values from all sources of incoming edges and jointly decides whether to update its own state. Execution proceeds iteratively according to the chosen model until the graph reaches a global quiescent state with no further updates.

The push model only touches outgoing edges of active vertices, but the pull model scans incoming neighbors of all vertices uniformly. In multithreaded execution, push requires atomic operations at edge destinations because multiple threads may concurrently update the same vertex, whereas pull aggregates incoming neighbor values for a vertex sequentially and applies the corresponding update within a single thread. Overall, push can reduce memory operations when the number of active vertices is small, while pull can avoid contention and benefit from contiguous reads when memory activity is dense. The optimal choice typically depends on the sparsity of active vertices.

Typical graph analytics systems employ a fixed update model for the duration of execution. Ligra [39] and Gemini [48] implement hybrid strategies that adaptively switch between push and pull based on the active vertex set size per round. However, a practical implication is the memory overhead: supporting both directions efficiently requires maintaining outgoing and incoming edges simultaneously, which doubles the edge list storage.

2.3 Distributed Graph Processing

2.3.1 Graph Partitioning

The first step in distributed graph processing is to partition the graph across hosts. We follow conventions by using the term “host” to refer to each compute node and retain this

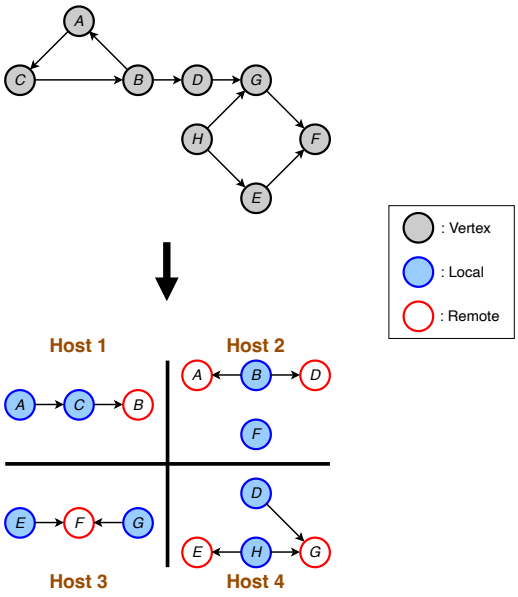

Figure 2: Example of outgoing edge-cut partitioning.

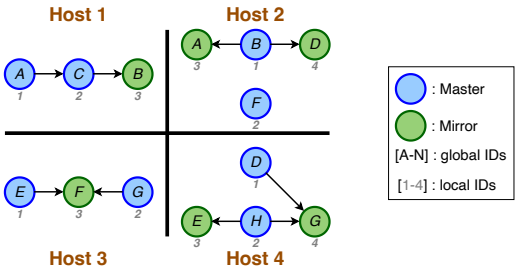
terminology throughout the paper. A wealth of partitioning schemes has been proposed and are categorized into edge-cuts [23,29,30,40,41,43], vertex-cuts [35,46], and 2D-cuts [5, 17, 18]. Evaluations in prior work [18, 21] show that no single scheme is universally optimal due to diverse graph topologies and application requirements. This paper thus focuses on the widely used outgoing edge-cut (OEC) policy.

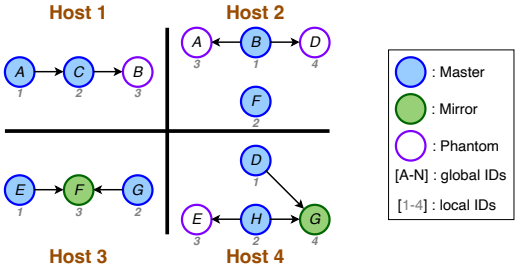
In OEC, each vertex is first assigned to a host based on a predetermined mapping, often a simple hash function. All outgoing edges of a vertex are then co-located with it on the same host. As illustrated in Fig. 2, many local edges will naturally point to remote vertices. Unlike vertex-cuts or 2D-cuts, which may split a single vertex across multiple hosts, edge-cuts maintain single ownership per vertex. This avoids ambiguity for reads and writes to remote edge endpoints, providing reproducible behavior and consistent performance across independent runs.

2.3.2 Full Mirroring

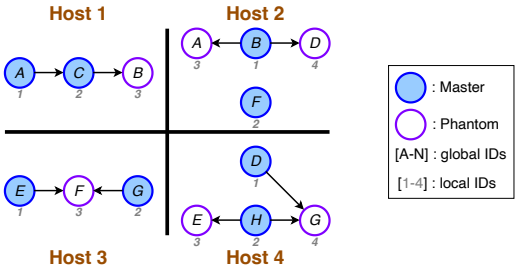
Direct execution on partitioned graphs frequently incurs remote reads and writes, which are expensive under high network latency and limited interconnect bandwidth. Modern distributed graph analytics systems [11, 14, 19, 20, 48] mitigate this with the *mirroring* technique, which replaces remote communication with local memory accesses. Each host allocates memory to replicate the vertex properties of remote edge destinations, allowing edges to read and update locally. These local replicas are commonly known as *mirrors* or *mirror nodes*, while the originally designated vertices are called *masters* or *master nodes*. To maximize communication reduction, the dogma has been to replicate all potentially required



(a) Full mirroring



(b) Static partial mirroring



(c) Mirror-free

Figure 3: Example of different mirroring techniques.

remote vertex data. We refer to this approach as *full mirroring*, which is illustrated in Fig. 3a.

2.3.3 Bulk-Synchronous Parallel

As computation proceeds, replicated mirror properties may become stale and diverge from their true values. Synchronization between mirrors and masters is required, and therefore the bulk-synchronous parallel (BSP) model [44] is commonly employed with full mirroring. Program execution is organized into rounds, and the BSP model further divides each round into two distinct phases:

- *Computation:* each host operates on its local partition using potentially stale mirror values, while multiple updates targeting the same mirror are combined.
- *Communication:* the accumulated mirror updates are sent to masters for reduction, and then reduced values are

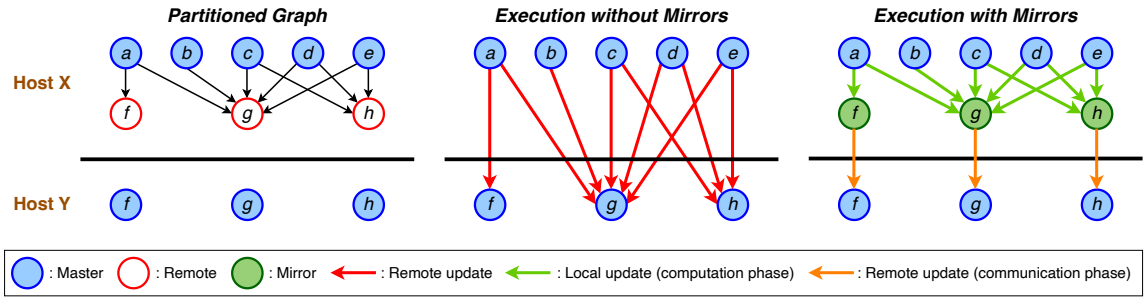


Figure 4: Example of mirror heterogeneity.

broadcast back to mirrors, restoring consistency before the next round.

This approach enables coarse-grained synchronization, minimizing network traffic while maintaining correctness.

2.3.4 Identifiers

Each vertex in the input graph is assigned a unique identifier to ensure distinction across the distributed system. These identifiers, referred to as *global IDs*, are recognized on all hosts and serve as the standard means of addressing vertices during inter-host communication. However, global IDs are often sparse, non-consecutive, and may require large data types due to their wide address space.

Under full mirroring, every master and mirror on a host maintains a piece of local memory. To optimize memory utilization, vertex data is laid out in a contiguous block using a compressed sparse row (CSR) representation. Within this structure, each vertex is assigned an offset into the local memory chunk, known as the *local ID*. Local IDs are host-specific and can be reused across hosts without conflict. Their compact and dense nature enables more efficient indexing than sparse global IDs, making them well suited for use during the computation phase.

3 Advanced Mirroring Design

We present two advanced mirroring designs that reduce memory overhead while preserving high performance under OEC: *static partial mirroring* and *mirror-free*. This section details their rationale and the supporting Pluto mechanisms.

3.1 Push Model

3.1.1 Mirror Heterogeneity

In the push model, each outgoing edge represents a potential update to a destination vertex. A mirror replicates the remote destination's properties so that updates along local edges are applied without immediate remote accesses during computation. A fixed synchronization cost is then paid during communication to propagate the accumulated local changes to the master. This reduces inter-host communication volume, alleviating network bottlenecks in distributed frameworks and thereby improving performance.

Fig. 4 illustrates the key insight of mirror heterogeneity: not all mirrors contribute equally to reducing remote communication. Each incoming edge to a mirrored destination corresponds to a potential conversion of a remote update into a local one, so the benefit generally increases with higher incoming degree. In practice, the access patterns also matter because workloads that activate only a limited subset of the graph may leave even high-degree destinations inactive. Critically, mirrors with only one incoming edge (e.g., mirror f) replace one remote update with one local update plus one remote synchronization, adding local work without reducing network traffic. Since the number of updates increases without any communication saving, these mirrors are considered *nonproductive*. Fig. 5 quantifies the fraction of nonproductive mirrors across our datasets; the tall bars highlight the importance of addressing mirror heterogeneity in system design.

3.1.2 Static Partial Mirroring

Static partial mirroring leverages mirror heterogeneity by removing nonproductive mirrors. After partitioning, candidates with a single incoming edge are identified statically and no mirror storage is allocated for them. These remote destinations without local replicas are referred to as *phantoms* or *phantom nodes*. Fig. 3b illustrates this approach: on host 4, vertex G has two incoming edges and is mirrored, whereas vertex E has a single incoming edge and is treated as a phantom. By excluding phantoms from data replication, static partial mirroring reduces memory usage and avoids unnecessary overhead while retaining the performance benefits for productive mirrors.

3.2 Pull Model

3.2.1 Mirror-Free Architecture

In the pull model, each thread pivots on one vertex at a time and sequentially reads all incoming edges. Source values are

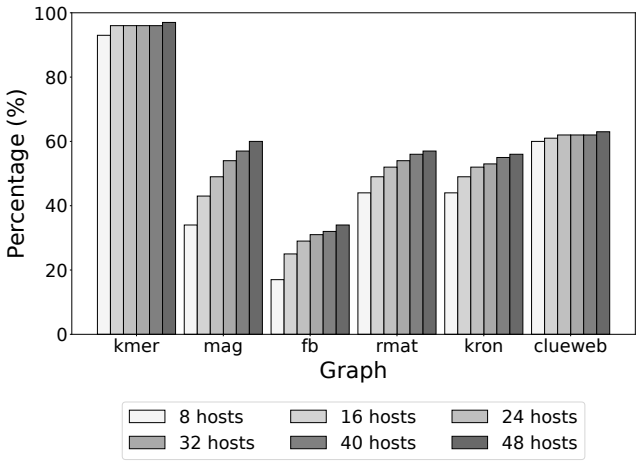

Figure 5: Fraction of nonproductive mirrors.

combined in a temporary accumulator, and the pivot's state is updated once with the accumulated result. If the pivot is a mirror, execution performs a local update during computation and later issues a remote update to the master during communication. Without the mirror, only a single remote update is issued, indicating that mirrors provide no benefit and introduce extra local work. Under OEC, outgoing edges reside with their masters on the same host, so all edge sources are masters and mirror values are never read in the pull scenario. As a result, removing mirrors completely eliminates local update overhead without increasing remote reads, which motivates the proposed mirror-free design (Fig. 3c).

3.2.2 Vertex Traversal Order

The mirror-free architecture enforces a fixed vertex traversal order that processes all masters before any phantoms in each round. This deterministic ordering allows each thread to implicitly detect the transition and switch modes exactly once: it writes updates locally while visiting masters, and then sends remote update requests while visiting phantoms. In contrast, static partial mirroring pushes updates to edge destinations that may be masters, mirrors, or phantoms. Because these destination types differ in how updates are applied, explicit vertex-type checks are required to select the appropriate interface, adding computational overhead.

3.3 Inter-Host Communication

3.3.1 Work Migration

Since phantoms do not maintain replicated data, any computation that involves a phantom requires a remote data fetch and may be followed by a remote update. This pattern substantially increases communication overhead because it introduces two-way traffic with request and response messages. To mitigate this, we introduce a work migration mechanism in which computation associated with phantoms is relocated to the owner host where the data resides [37]. This design converts bidirectional request–response exchanges into unidirectional work messages, avoiding the performance penalties of conventional remote data fetches.

In both advanced mirroring designs, only a single update and thus a single work message is associated with each phantom. All phantoms have exactly one incoming edge in static partial mirroring, while local contributions are combined in temporary accumulators before being sent in the mirror-free architecture. As a result, work migration does not introduce additional payload, and the total communication volume remains unchanged compared to full mirroring.

3.3.2 Communication-Computation Overlap

Pluto dispatches work migration messages on demand, effectively shifting part of the communication activity into the computation phase. To preserve BSP semantics, updates originating from remote hosts can only become visible to local masters after the current computation round completes. Therefore, only the network transmission is overlapped with computation, while the migrated work itself is deferred until the subsequent communication phase. By initiating communication earlier and spreading it over a longer interval, Pluto reduces instantaneous pressure on the interconnect bandwidth. Otherwise idle network resources are used for message dispatch and reception during computation, shortening the communication phase without extending computation time. Overall, this overlap between communication and computation allows Pluto to deliver lower end-to-end execution time over fully mirrored systems.

3.3.3 Address Translation

Given that all participating hosts execute the same program in a distributed system, synchronizing between masters and mirrors requires only a vertex identifier and the corresponding update. To ensure consistent interpretation across hosts, the vertex ID must be globally unique. As such, the sender translates its local ID to a global ID before transmission, while the receiver performs a global-to-local ID lookup upon message arrival. These translations can introduce non-negligible overhead.

D-Galois [14] reduces this overhead via memoization of address translation. Under BSP, synchronization between masters and mirrors occurs only during the communication phase, and all updates from a given sender to a given receiver are aggregated into a single message to improve communication efficiency. The aggregation order is fixed for each host pair, and both sender and receiver maintain an array that records the corresponding local vertex IDs in this order. This arrangement allows communication without attaching global vertex

IDs, since local IDs can be recovered by indexing the array sequentially, avoiding translation table lookups.

However, this technique does not apply to phantoms in Pluto because work migration messages are dispatched on demand during the computation phase, and their order can vary from round to round. To alleviate the high translation overhead, hosts exchange the local IDs corresponding to the masters of phantom nodes. The sender can then translate its local ID into the target host's local ID before constructing the message, allowing the receiver to bypass the global-to-local lookup and use the local ID contained in the message directly.

3.4 Dirty Phantom Identification

Full mirroring systems synchronize only dirty mirrors to minimize network traffic and achieve high performance. When a mirror receives an update, the new value is compared with the stored value to decide whether the mirror should be modified and flagged as dirty. In advanced mirroring, phantoms do not maintain persistent states, so this comparison-based flagging cannot be applied directly. Although temporary accumulators are used during computation, their contents are discarded between rounds.

In the push model, this limitation is resolved naturally because only active masters propagate updates through outgoing edges. Under static partial mirroring, each phantom has exactly one incoming edge and derives its state entirely from that source. Whenever the source master changes value and pushes an update, the destination phantom is inherently dirty and immediately migrates the associated computation to the remote owner host. No additional state is required on the phantom to determine whether the migration is necessary.

The pull model is more challenging because phantom nodes in the mirror-free architecture may receive inputs from multiple masters and must combine them. Fig. 6 shows an example where a phantom computes the minimum among its incoming masters, as in algorithms like Connected Components or Breadth-First Search. If the resulting minimum remains unchanged across consecutive rounds, the ideal behavior is to synchronize it only once, since resending the same value does not advance the global reduction. However, the lack of a replicated value prevents a phantom from directly comparing the current minimum with the previous one.

To address this, Pluto introduces an alternative mechanism to identify dirty phantoms without storing full replicas. At the beginning of each communication phase, all vertices reset a dirty bit before any remote work is applied. These bits are then set whenever a vertex's value changes, whether during the processing of migrated work or during the subsequent computation phase. A phantom transmits its temporary accumulator value for reduction only if the source vertex that currently determines this accumulated value is marked dirty. Since the update function is deterministic, unchanged inputs imply an unchanged output. By tracking which inputs have

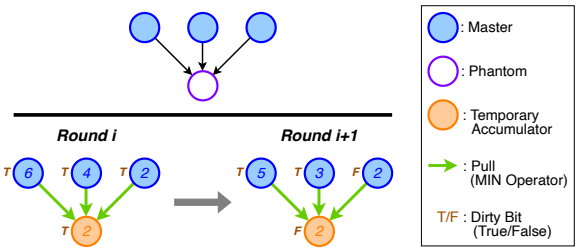

Figure 6: Example of dirty phantom identification.

changed since the last round, Pluto can infer when a phantom's output will change, regardless of the specific update operator (e.g., minimum, maximum, sum, logical operations). This design allows the identification of necessary synchronization targets while avoiding the storage overhead associated with maintaining replicated mirror states.

3.5 Backward Data Dependence

Most graph analytics applications perform only forward passes, where a destination vertex depends on the values of its sources along incoming edges. Some algorithms, most notably Betweenness Centrality, also require a backward pass, in which a source vertex is updated based on its outgoing edge destinations. In these cases, the absence of local state at phantom nodes becomes problematic because outgoing edges are co-located with their source vertices, but the computation depends on destination properties that are not replicated locally.

To support such workloads, Pluto falls back to full mirroring for the backward pass. In the current implementation, this transition is triggered on demand immediately before the backward phase begins. At that point, Pluto reinstates data replication for all phantom nodes by allocating the necessary memory and broadcasting the corresponding values from their masters. This mechanism allows Pluto to remain applicable to the full range of graph analytics benchmarks while still preserving the benefits of advanced mirroring on forward-only workloads. In our benchmarks, only Betweenness Centrality performs a backward pass and transitions exactly once from forward to backward, making this on-demand reinstatement of mirroring both practical and efficient.

3.6 Application Programming Interface (API)

Pluto follows the D-Galois parallel programming abstractions and supports a vertex-centric programming model. Fig. 7 shows push and pull implementations of Breadth-First Search using Pluto APIs.

During the computation phase, `doAll` distributes the specified node set across worker threads and invokes the given function on each node in parallel. In the push version, outgoing edges are traversed and `isPhantom` checks whether

the destination is a phantom. Computation associated with phantoms is migrated to the owner host via `sendWork`, while masters and mirrors are updated atomically using `atomicMin`.

In the pull version, masters are processed first using the non-atomic `min` operation, and dirty bits in `bitset_dist` are set to support dirty phantom identification. Phantoms then accumulate updates from incoming edges, track the source that determines the current value, and issue `sendWork` only when the contributing source is marked dirty.

After local computation finishes, the system enters the communication phase. Migrated work received from remote hosts is applied via `applyRemoteWork`, and `syncMirror` synchronizes remaining mirrors with their corresponding masters.

3.7 Memory Overhead

Prior work introduced the replication factor [14] to quantify the memory overhead of mirroring. Defined as the average number of mirrors per master, this metric captures vertex-level duplication but does not account for edges or metadata used during program execution. To directly reflect total memory usage, we propose the *aggregated memory footprint (AMF)*. As shown in (1), AMF includes both graph storage M_G and peak buffer usage M_{buf}, providing a more comprehensive measure of memory impact across different mirroring strategies.

$$AMF = M_G + M_{buf} \tag{1}$$

Pluto stores graphs in CSR format, which requires memory for vertex data M_{V_data}, edge data M_{E_data}, the edge list array M_{E_dest}, and the index array M_{E_index}. Outgoing edges of the same vertex are grouped together, with their destinations stored sequentially in the edge list array, while the index array records the position of the last outgoing edge for each vertex. These components are given in (2), where D_{vertex} and D_{edge} denote the property data size per vertex and edge in the LPG model, D_{vertex_id} and D_{index} are the sizes of the data types for vertex identifiers and edge list array indices, and N_{master}, N_{mirror}, and N_{edge} are the total numbers of masters, mirrors, and edges in the graph.

$$\begin{aligned} M_G &= M_{V_data} + M_{E_data} + M_{E_dest} + M_{E_idx} \\ \text{where } &\begin{cases} M_{V_data} = D_{vertex} \times (N_{master} + N_{mirror}) \\ M_{E_data} = D_{edge} \times N_{edge} \\ M_{E_dest} = D_{vertex_id} \times N_{edge} \\ M_{E_index} = D_{index} \times N_{master} \end{cases} \end{aligned} \tag{2}$$

Peak buffer usage is further decomposed into buffers for mirror synchronization M_{sync_buf} and buffers for work migration M_{work_buf}. The size of M_{sync_buf} is determined once the graph is partitioned, while M_{work_buf} is obtained from runtime measurements:

$$M_{buf} = M_{sync_buf} + M_{work_buf} \tag{3}$$

```
void BFS() {
  doAll(active_nodes, push);
  applyRemoteWork();
  syncMirror();
}

void push(Node src) {
  NodeData& src_dist = getData(src);
  for (Edge edge: outEdges(src)) {
    Node dst = getEdgeDst(edge);
    if (isPhantom(dst)) {
      sendWork(dst, src_dist+1);
    } else {
      NodeData& dst_dist = getData(dst);
      atomicMin(dst_dist, snode_dist+1);
    }
  }
}
```

(a) Push version

```
void BFS() {
  doAll(all_masters, pullMaster);
  doAll(all_phantoms, pullPhantom);
  bitset_dist.reset();
  applyRemoteWork();
}

void pullMaster(Node dst) {
  NodeData& dst_dist = getData(dst);
  for (Edge edge: inEdges(dst)) {
    Node src = getEdgeSrc(edge);
    NodeData& src_dist = getData(src);
    bool update = min(dst_dist, src_dist+1);
    if (update) {
      bitset_dist.set(dst);
    }
  }
}

void pullPhantom(Node dst) {
  NodeData dst_dist = UINT32_MAX;
  bool send = false;
  for (auto edge: inEdges(dst)) {
    Node src = getEdgeSrc(edge);
    NodeData& src_dist = getData(src);
    if (src_dist+1 < dst_dist) {
      dst_dist = src_dist+1;
      send = bitset_dist.test(src);
    }
  }
  if (send) {
    sendWork(dst, dst_dist);
  }
}
```

4 Implementation

Pluto is implemented on top of the D-Galois GitHub repository forked in May 2023 [13]. Implemented in C++, the integration of both advanced mirroring designs required approximately 4000 lines of code. Key implementation details are summarized below.

Communication Substrate. Inherited from D-Galois, Pluto leverages Gluon [14] as its communication substrate and uses MPI for message transport across the network. To ensure forward progress, it utilizes asynchronous MPI primitives so that multiple outstanding requests can be in flight concurrently, and the MPI handles are reclaimed once the corresponding non-blocking operations complete. Additionally, Pluto limits the number of active MPI tags in each phase of execution to improve the efficiency of message probing and handling.

Communication Isolation. Each host employs a dedicated communication thread responsible for sending and receiving messages. This thread is pinned to the core physically closest to the NIC, as specified by the system architecture, to reduce latency and improve inter-host communication efficiency. All worker threads are likewise pinned to other individual cores, and Pluto enforces a hard limit on the total number of threads to avoid oversubscription and the associated context-switching overhead.

Message Aggregation. Given the heavy network traffic generated by work migration, effective message aggregation is critical for achieving coarse-grained communication and high performance. In Pluto, work messages are continuously aggregated into buffers during the computation phase. Each worker thread independently aggregates messages destined for the same host, and the partially aggregated buffers from all workers are further consolidated before transmission. The default setting of Pluto aggregates 2^{15} messages per buffer.

Buffer Pool. Profiling reveals that frequent calls to `malloc` and `free` introduce significant overhead and can noticeably increase execution time. To address this inefficiency, Pluto preallocates a pool of fixed-size aggregation buffers that are reused throughout execution, eliminating most repeated memory allocations. When the available buffers are insufficient to meet runtime demand, the pool dynamically doubles in size to ensure scalability.

5 Experimental Setup

Configuration. Pluto is evaluated on the Skylake cluster of the Stampede3 system at the Texas Advanced Computing Center. Each compute node has an Intel Xeon Platinum 8160 processor with 48 cores running at 2.1 GHz and 192 GB of DDR4 RAM. Nodes are interconnected through an Intel Omni-Path network with a peak bandwidth of 100 Gb/s. The system runs Rocky Linux 9.5 with kernel version 5.14.0. All code is compiled with gcc 15.1.0 and the Intel MPI library 21.15.

Table 1: Graph datasets.

Graph G	Vertices $\|V\|$	Edges $\|E\|$	Edge Factor $\|E\|/\|V\|$	Max Edge Degree D_{out}	D_{in}
kmer	214M	233M	1.1	8	5
mag	244M	1.7B	7	1.3K	0.4M
fb	100M	9.4B	94	4.3K	3.8K
rmat	268M	4.3B	16	4M	0.3M
kron	1073M	17.2B	16	3.2M	3.2M
clueweb	978M	42.6B	44	7.4K	75M

Datasets. Table 1 summarizes the large-scale plain graphs used in our evaluation. The kmer dataset is a protein k-mer graph from the Graph Challenge competition hosted by the IEEE HPEC conference. The mag dataset is sourced from the Open Graph Benchmark [22] and originates from the Microsoft Academic Graph [45]. The fb dataset is generated using the social network benchmark suite from the Linked Data Benchmark Council (LDBC) [15], designed to reflect structural properties of the Facebook web crawl. The rmat and kron datasets are synthetic graphs generated using randomized generators [9, 27], with weights configured according to the Graph500 benchmark specifications [12]. Finally, the clueweb [36] dataset is one of the largest publicly available real-world web crawls.

Benchmarks. We evaluate Pluto using five representative graph analytics applications: PageRank (PR), Connected Components (CC), Breadth-First Search (BFS), K-Core Extraction (KCore),[1] and Betweenness Centrality (BC). PR runs for a fixed 50 iterations; the other applications run until convergence. Following prior work [14], the source vertex for BFS and BC is chosen as the highest-degree vertex to ensure comprehensive traversals, and the k value for KCore is set to the graph's average degree. Based on active vertex set sizes, BFS and BC use the push model, while PR, CC, and KCore use the pull model to maximize performance on Pluto. Reported results are the median of nine independent runs.

Properties. Existing LPG datasets are too small to meaningfully stress distributed systems and are therefore unsuitable for our evaluation. To approximate LPG characteristics, we assign properties to vertices and edges in the large-scale plain graphs. Property data sizes are derived from the LDBC social network graph [3, 15], which annotates entities (vertices) and relations (edges) with multiple attributes to model a real social network. We record the label distribution of masters, mirrors, and edges independently when distributing this social network graph with the CuSP partitioner [21] employed by Pluto. The collected property layouts for each configuration are then applied to the plain graphs for evaluation. Fig. 8 shows the distribution of property data sizes for the 8-host configuration.

[1] KCore does not perform the full k-core decomposition but only computes the k-core subgraph for a given k.

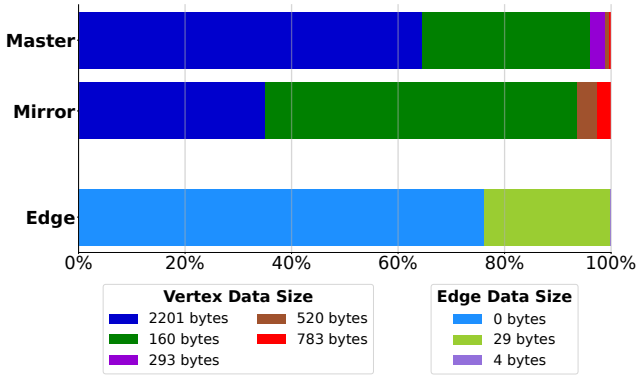

Figure 8: Distribution of property data sizes in the LDBC social network graph for the 8-host configuration.

To further study system behavior when properties are accessed, we conduct a separate set of experiments in which the traversal algorithms are extended to include predicate checks on vertex and edge properties. These setups, including property assignment and benchmark extension, enable us to capture the impact of property storage on memory locality and evaluate the effectiveness of our advanced mirroring designs on LPGs.

Systems. Pluto is compared against three state-of-the-art distributed graph analytics systems: Graphite [32], D-Galois [14], and Gemini [48]. We follow each system's recommended configuration and tune parameters to achieve the optimal performance. GraphScope [16] is excluded because it depends on Vineyard and Kubernetes for resource management, which are incompatible with the Slurm-based Stampede3 environment. We also enhanced D-Galois with the communication isolation optimization and present D-Galois$^+$ as an additional full-mirroring comparison point.

6 Evaluation

6.1 Memory Overhead

6.1.1 Aggregated Memory Footprint

Fig. 9 shows the average aggregated memory footprint (AMF) per host for Pluto under the worst peak buffer usage observed across all benchmarks. Results are normalized to a full mirroring baseline, whose average per-host memory usage is shown above the dotted line for each data model. Most data points fall below 1, indicating lower memory requirements. As expected, the mirror-free architecture generally achieves larger savings than static partial mirroring because it removes all mirrors rather than only a subset. The few exceptions arise in benchmarks such as CC and KCore that converge in very few rounds, where most progress occurs early and work migration incurs relatively high buffer usage. For other algorithms, these trends hold consistently.

The memory benefits of Pluto are substantially greater under the LPG data model. As properties are added, M_G grows sharply while M_{buf} remains roughly constant, making M_{buf} negligible in the AMF calculation in (1). The much larger vertex property sizes compared to edge properties reported in Fig. 8 cause reductions in the number of mirrors to contribute more heavily to M_{V_data} in (2). Conversely, graphs with larger edge factors in Table 1 (e.g., fb and clueweb) exhibit smaller savings because their M_G is dominated by edge-related terms (M_{E_data} and M_{E_dest}), weakening the impact of advanced mirroring that primarily reduces vertex storage. Finally, memory savings for static partial mirroring are strongly correlated with the number of removed mirrors (i.e., phantoms). As more hosts are added, the increasing fraction of phantoms in Fig. 5 aligns with the clear downward trend of normalized AMF in Fig. 9.

6.1.2 Minimum Number of Hosts

While AMF captures the total memory requirement, an important aspect of reduced memory usage in distributed processing is the ability to run on fewer hosts, which often translates to lower cluster cost. Average AMF per host (Fig. 9), however, does not reflect load imbalance due to imperfect graph partitioning. Under outgoing edge-cut, even if masters are evenly distributed, the number of co-located edges can vary significantly across hosts.

To obtain a more realistic view, we apply the LPG setup described in Section 5 to both Pluto and D-Galois$^+$ before execution. We then sweep over a range of host counts and record the minimum number of hosts required to run all LPG-extended benchmarks, as shown in Fig. 10. This procedure incorporates the load imbalance produced by the CuSP partitioner [21] and ensures that the host with the maximum memory requirement does not exceed node memory capacity and trigger out-of-memory errors. Note that the results in Fig. 9 are obtained analytically from (1), (2), and (3) without enforcing node memory capacity limits, whereas Fig. 10 reports actual feasibility on the Skylake cluster. Across our input graphs, Pluto requires only 50% to 90% of the hosts needed by a fully mirrored system.

6.2 Performance

The performance gains of Pluto shown in this section are attributed to the advanced mirroring design and its associated implementation features introduced in Sections 3 and 4. Pluto inherits optimizations from D-Galois because it is directly implemented on top of it, but does not apply optimizations from other existing systems otherwise.

6.2.1 Optimal Configuration

Table 2 reports the best end-to-end execution time achieved by each system across all inputs and applications. We evaluate

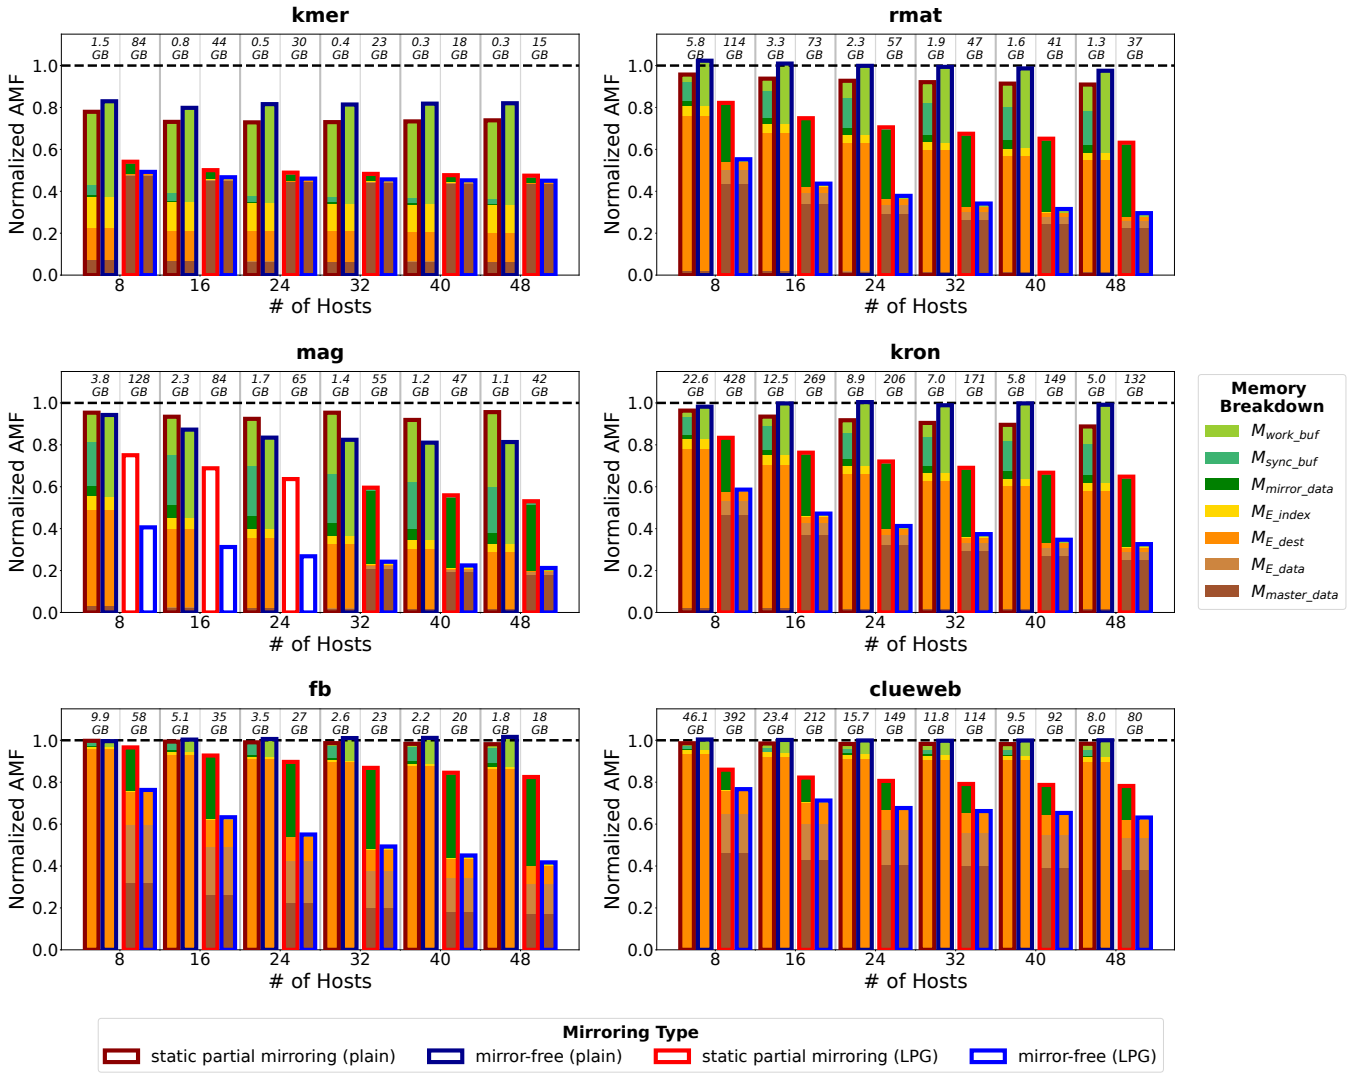

Figure 9: Average memory usage per host for advanced mirroring under the worst peak buffer requirement. The aggregated memory footprint is normalized to a full-mirroring baseline, whose average per-host usage is shown above the dotted line.

each system on clusters of 8, 16, 24, 32, 40, and 48 hosts and select the configuration that yields the optimal result. Overall, Pluto outperforms all prior works and delivers a 2.5× harmonic-mean speedup.

Graphite exhibits roughly a 20× slowdown compared to Pluto mainly because the underlying linear-algebra-based programming model requires substantially more iterations to converge than our vertex-centric approach.[2] Since D-Galois is our implementation baseline, Pluto consistently outperforms it as expected. Gemini is the fastest prior system due to its adaptive hybrid update models but still falls short of Pluto without advanced mirroring designs and the corresponding communication optimizations.

6.2.2 Strong Scaling

Since Gemini delivers the best performance among prior systems in most cases, we collect strong-scaling execution times for Pluto and Gemini to enable a direct comparison. Fig. 11 presents a subset of the results, omitting smaller graphs and some benchmarks due to space constraints. Overall, Gemini reaches peak performance at smaller cluster sizes, while Pluto exhibits better scalability as the number of hosts increases.

Gemini's advantage at small scales stems from its dual update model, which allows adaptively switching between push and pull during runtime. Many graph analytics workloads favor pull-based processing in early iterations when active vertex sets are large, and benefit from push-style execution

[2]We confirmed the setup and configuration with the authors, but the measured performance is worse than the results reported in the original paper [32]. We have also evaluated on various clusters with diverse processors, and the slowdown trend persists.

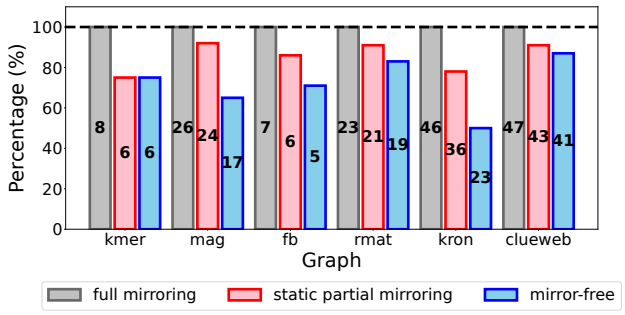

Figure 10: Minimum number of hosts required for LPG workloads.

near convergence when the active set shrinks. Pluto is thus limited by its fixed update model throughout execution. Although Pluto could adopt a hybrid approach, doing so would sacrifice memory efficiency: supporting both push and pull requires maintaining outgoing and incoming adjacency structures simultaneously, effectively doubling edge list storage (M_{E_dest} and M_{E_index}). In addition, the memory benefit of removing mirrors entirely in the mirror-free architecture would no longer apply while supporting static partial mirroring.

The high memory requirements of Gemini limit its applicability, leading to out-of-memory failures at smaller host counts for large graphs. Furthermore, Gemini exhibits weaker scalability primarily because its communication substrate is less optimized. As additional hosts are added and communication becomes the dominant cost, Gemini's performance degrades and execution time increases. In contrast, Pluto scales efficiently and outperforms Gemini as cluster sizes grow.

6.3 Advanced Mirroring Impact

Comparisons across systems depend on many factors and should not be attributed to a single feature. To isolate the contributions of advanced mirroring, we compare Pluto against D-Galois$^+$, a full mirroring baseline with communication isolation, for each graph data model.

6.3.1 Plain Graph

Under optimal configurations, Table 2 shows that advanced mirroring delivers a 1.75× harmonic-mean speedup over full mirroring across all inputs and benchmarks. Fig. 11 demonstrates strong-scaling performance for Pluto and D-Galois$^+$. The two versions converge at different rates and may reach their minimum execution time at different host counts. Fig. 12 summarizes the strong-scaling speedup of our advanced mirroring designs up to the smallest host count at which either version achieves its minimum execution time. Configurations beyond that point are excluded because adding more hosts degrades performance on one or both systems, making them neither a fair comparison nor a practical choice.

Table 2: Fastest execution time (sec) under optimal configuration. Minimum time across all systems is highlighted in yellow.

*— means the benchmark is not implemented by the original authors.

The speedup of both advanced mirroring designs follows a consistent concave-downward trend as the number of hosts increases. At small cluster sizes, computation phases are relatively long and provide ample time to cover the network traffic associated with work migration. The fraction of total execution time saved by shifting part of the communication workload into computation is therefore modest, and the speedup is limited. As additional hosts are introduced, increased parallelism shortens computation phases, improving communication–computation overlap and increasing speedup. This trend continues until an inflection point where the computation duration aligns optimally with the amount of communication that can be overlapped, yielding maximal speedup. Beyond this point, further scaling shortens computation phases to the extent that they can no longer fully hide remote work message transmission, causing spillover into the communication phase and reducing overall performance gains.

When the number of mirrors per host is small, the communication phase of full mirroring and static partial mirroring must still pay for dirty-mirror collection and the inherent network latency of inter-host synchronization. These fixed costs do not diminish with additional hosts and increasingly dominate communication time as total execution time approaches its minimum. In contrast, the mirror-free architecture can still

(c) Breadth-First Search

Figure 11: Strong-scaling execution time.

realize slight improvements because work messages are sent during computation, allowing a portion of the communication latency to be hidden. This effect explains the slight uptick in mirror-free speedup at larger cluster sizes.

Overall, the mirror-free architecture achieves higher speedup than static partial mirroring, primarily due to reduced computation slowdown and more effective communication–computation overlap. Static partial mirroring incurs extra cost from explicit vertex-type checks, whereas the mirror-free architecture avoids this overhead via a fixed vertex traversal order. In addition, since work migration applies only to phantoms, removing mirrors entirely increases the fraction of communication that can be overlapped with computation. In the ideal case, the full communication workload can be executed in parallel with the computation phase.

6.3.2 Labeled Property Graph

Fig. 13 shows the speedup of our advanced mirroring designs for LPG workloads; missing data points indicate configurations where the graph does not fit in memory according to Fig. 10. The same concave-downward trend observed for plain graphs persists under strong scaling on LPGs, but the overall speedup shrinks.

The performance benefits of the advanced mirroring designs manifest differently for LPGs due to the changed compute–communication balance. Once property predicates are added to our workloads, as described in Section 5, most of our benchmarks spend a larger fraction of time in local computation, so the portion of execution time that any communication optimization (including work migration and mirroring) can affect is smaller. Consequently, the relative speedups shrink, even though the communication phase is still significantly shortened and the underlying mechanism remains effective. This phenomenon is particularly pronounced for PR, where nearly all vertices and edges are accessed in each round. Overall, the advanced mirroring designs still deliver speedups of up to 2.6× with a harmonic mean of 1.37×.

Only kmer and mag exhibit relatively larger LPG speedups for CC and KCore. These two graphs have smaller edge factors, and both benchmarks converge within a few rounds. Fast convergence makes most progress in early iterations when work migration volume is high and spillover is more likely, where remote work message transmission cannot be fully

hidden by the computation phase and extends into the communication phase. At the same time, the lower edge factor keeps predicate-check overhead moderate. This balance allows the additional computation to compensate for spillover without dominating total execution time.

6.4 Design Features

The design features described in Sections 3 and 4 are necessary to support the high communication volume induced by advanced mirroring. Fig. 14 reports the execution time of Pluto with each feature selectively disabled (while all others remain enabled), illustrating its impact on performance. Execution times are normalized to Pluto with all features enabled, and results are reported as the harmonic mean across all inputs and benchmarks.

Buffer pools amortize memory allocation and deallocation costs by avoiding frequent `malloc` and `free` calls. Pluto benefits most from rounds with intensive work migration and continuous message aggregation, but the overall effect is diluted by near-convergence rounds with low compute intensity. The fixed vertex traversal order has limited impact because

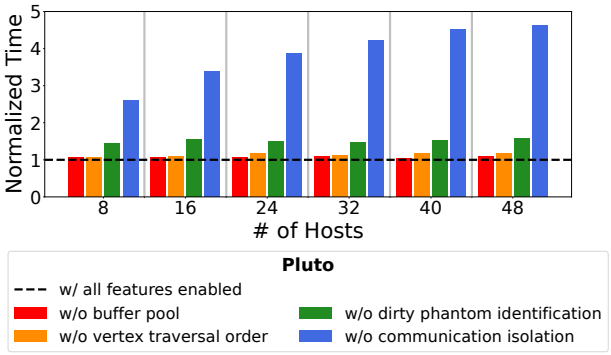

Figure 14: Impact of different design features. Execution time is normalized to Pluto with all features enabled. Results are the harmonic mean across all inputs and benchmarks.

outgoing edges are sorted based on destination local IDs to form the order of masters first, mirrors next, and phantoms last. Modern branch predictors take advantage of it to make the additional vertex-type check relatively inexpensive even without this optimization.

Since inter-host communication is the main bottleneck in distributed systems, communication-related features are the most critical for efficiency. Dirty phantom identification provides a moderate improvement by reducing the total communication volume. Disabling communication isolation causes substantial performance degradation because context switching overhead slows down the communication thread significantly, and it may be scheduled on a core farther from the NIC. Message aggregation has the largest impact on performance but is omitted from the figure: without aggregation, network traffic explodes and Pluto exceeds the 1000-second timeout limit on all experiments.

7 Related Work

7.1 Memory-Efficient Data Duplication

Pregel+ [47] also creates mirrors selectively based on vertex degree, but uses a threshold derived from a simplified cost model rather than a fixed threshold of one. Unlike Pluto, which overlaps communication and computation via work migration, Pregel+ defers all message handling (send, receive, and work processing) to the communication phase. Instead of aggregating messages on demand, it stores work messages in a large buffer during computation and scans this buffer later to identify aggregation opportunities. Because the cost model typically yields thresholds larger than one, multiple updates to the same vertex can accumulate in the buffer, leading to significant memory overhead. We also evaluated Pregel+ with our experimental setup, and Pregel+ is more than 100× slower than Pluto while sometimes fails to complete within a 1000-second timeout.

Khuzdul [10] incorporates a static data cache that selectively replicates remote data at runtime. The cache follows a *first-accessed-first-cached-with-threshold* policy and does not support eviction. Once the cache is full, subsequent requests do not incur replacement and no additional data can be duplicated. This design risks caching early-accessed vertices that may not be representative of the true hot set when the work set exceeds cache capacity. In addition, the threshold is empirically fixed at 64 without justification or sensitivity analysis. Unlike mirrors constructed deterministically after partitioning, the dynamic duplication of the data cache prevents it from undergoing the necessary preprocessing to index with compact local IDs. As a result, all vertices are referenced by their sparse global IDs in Khuzdul to avoid expensive ID translations.

7.2 Performance Optimizations Based on Vertex Degree

While static partial mirroring in Pluto targets low-degree mirrors, several prior systems apply optimizations that reduce the overheads associated with high-degree vertices to improve performance. These existing techniques are complementary to Pluto, but we do not incorporate and evaluate them due to differences in graph representations and underlying frameworks.

GPS [38] partitions adjacency lists of high-degree vertices across hosts to avoid repetitive messages and reduce communication volume. LUX [25] splits high-degree vertices across multiple hosts and uses edge partitioning primarily to balance load on multi-GPU systems. SympleGraph [49] extends Gemini with compiler-assisted enforcement of loop-carried dependencies, removing redundant computation and communication by propagating updates of high-degree mirrors in a host-to-host fashion until their masters are reached.

8 Conclusion

As real-world graph datasets continue to grow in scale, distributed graph processing systems face increasing challenges related to high memory requirements and performance ceilings. In this work, we propose static partial mirroring and the mirror-free architecture to reduce memory usage while also improving performance. Both designs are implemented in Pluto, our system which integrates a suite of optimization techniques to address the increased communication volume, preserving high scalability and throughput. Our comprehensive evaluation demonstrates that Pluto consistently outperforms state-of-the-art systems, offering a promising direction for the future of scalable distributed graph analytics.

Abstract

RedNote (a.k.a., Xiaohongshu, a global-scale social network platform) widely adopts approximate nearest neighbor search (ANNS) to power its search, recommendation, and advertising services. Due to the demanding Service Level Agreements (SLAs), we have to rely on in-memory graph-based ANNS (i.e., HNSW) to provide high throughput and low latency.

However, the ever-growing user base and content volume have led to an explosive increase in memory footprint and consequently huge CapEx and OpEx. After exploring various alternatives, we find that building a clustering-based ANNS on top of all-flash servers can be promising. Yet, we still experience severe overheads from the kernel I/O stack, a fixed pruning strategy, and slow index construction.

We present HELMSMAN, a high-performance and cost-effective clustering-based ANNS system, which combines an ANNS-oriented userspace storage stack, a leveling-learned pruning module, and GPU-accelerated pipelines of construction. HELMSMAN saves over 90% of hardware costs and enables billion-scale index (re)builds within hours. In the current production deployment, operating stably for several months, 40 machines now host ANNS workloads that previously required about 35,000 cores and 0.35 PB DRAM.

1 Introduction

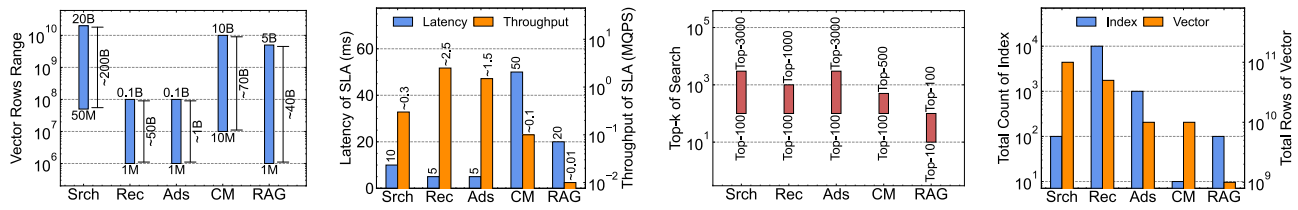
RedNote (a.k.a., Xiaohongshu) [8] is a global social media platform for users to share and interact with photos, videos, and text in the form of "notes". By 2025, the platform hosts over 300 million monthly active users and more than 80 million creators [5]. As the core infrastructure behind search, recommendation, and advertising [22, 41, 43], our approximate nearest neighbor search (ANNS) service manages hundreds of billions of embedding vectors and sustains millions of queries per second (QPS) with strict latency service-level agreements (SLAs) (e.g., 5-10 ms for real-time services).

To meet the quality of services (QoS), we previously relied on large in-DRAM graph indexes [20, 40] for high throughput and low latency. However, the scaling of users and content drastically increases the memory footprint, pushing the ANNS infrastructure at RedNote to reach the petabyte level. This incurs prohibitively high CapEx and OpEx for the existing in-DRAM ANNS infrastructure [2, 9]. We are therefore motivated to explore more cost-efficient alternatives.

The recent advancement in NVMe SSDs has made them a promising candidate given their high bandwidth and low cost per GB [18, 25, 34]. For example, a 12-drive PCIe-Gen5 SSD array [12] can deliver roughly 30% of the bandwidth of a 12-channel DDR5 memory [10], yet SSD costs about 1/40 of DRAM (i.e., 0.2 $/GB vs. 8 $/GB). While we have successfully deployed graph-based hybrid (SSD+DRAM) ANNS systems like DiskANN [49] for the more relaxed offline workloads (e.g., content moderation), using them for online services (e.g., search) remains impracticable in terms of latency and throughput SLAs. The main reason is the greedy graph traversals maintain long candidate lists (e.g., lengths can be up to 1.5× top-k), which incur many serialized I/Os and thus fail to utilize high bandwidth of SSDs.

The above observation motivates us to rethink the possibility of using clustering-based ANNS. With dependency-free I/Os issued in batches, clustering-based ANNS, such as SPANN [17], can be expected to achieve low latency that meets our SLA and also be scaled for throughput by adding more SSDs. Yet, to apply them in production remains challenging. First, under the traditional I/O stack, SPANN uses only about 20–60% of SSD bandwidth, resulting in a significant throughput gap to in-DRAM HNSW. Second, given the varying top-k of real workloads, the existing fixed pruning approach cannot sufficiently reduce redundant scans and leads to unstable per-query performance. Third, the existing single-node and CPU-only construction can take tens of hours or even days, failing to support fast rebuilds needed by frequent updates of embedding models and vectors.

Hence, to overcome these limitations, we develop HELMSMAN, a high-performance and cost-effective ANNS system using clustering-based indexes atop all-flash servers. There are three main techniques. First, we build an ANNS-oriented userspace storage backend that bypasses the kernel I/O stack, minimizing software overhead and directly orchestrating devices to match the ANNS-specific I/O patterns. Second, we develop a leveling-learned pruning module that adapts to both top-k and query distributions, while remaining compatible with SSD-friendly batched I/O. Third, we leverage GPU acceleration and dynamically allocate CPUs for index construction, enabling sub-hour builds for common-scale (e.g., 0.1B)



(a) *Total rows of vector datasets.* (b) *SLAs of performance.* (c) *Top-k value of requests.* (d) *Frequency of construction.*

Figure 1: *Characterizing ANNS of RedNote along 4 aspects: scale, SLA, top-k, and construction. Search is denoted as Srch, and others are recommendation (Rec), advertising (Ads), content moderation (CM), and retrieval-augmented generation (RAG).*

and hour-level builds for ultra-large-scale (e.g., 10B) indexes.

Our evaluations show that HELMSMAN delivers 2–16× higher throughput than existing DRAM–SSD ANNS and up to 85% of the throughput of in-DRAM ANNS, while preserving latency SLAs. We are actively rolling out HELMSMAN to our production environment. Currently, HELMSMAN can use only 40 machines with about 30-40 TB DRAM in total to sustain online traffic that previously consumed roughly 35,000 CPU cores and ∼0.35 PB of in-DRAM ANNS infrastructure, saving more than 90% device costs. The open-source proof-of-concept version of HELMSMAN and datasets fitted to real-world distributions are available at https://github.com/Red-EAD/helmsman.

2 Background

2.1 ANNS-based Services in RedNote

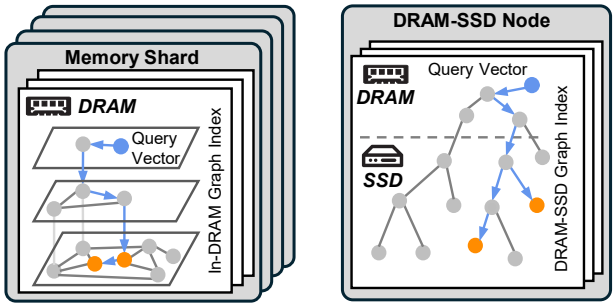
RedNote (a.k.a., Xiaohongshu) [8] is a global social platform with hundreds of millions of active users sharing and interacting with various types of content including pictures, comments and short videos on a daily basis. The proper functioning of RedNote relies heavily on the search engine, recommendation system, advertising platform, content moderation, and emerging AI services (e.g., retrieval-augmented generation for large language models). All of the above are supported by approximate nearest neighbor search (ANNS) over hundreds of billions of high-dimensional vectors with millions of queries per second. Despite all being ANNS-based, these services can have different characteristics as shown in Figure 1, such as scale of dataset (Figure 1a), the SLA of performance (Figure 1b), the top-k of requests (Figure 1c), and the index building (Figure 1d). We now further discuss them in detail.

Search. First, our search targets the full corpus (i.e., all user-generated content and web-wide data) and the index can reach up to tens of billions of vectors. In addition, the search services also follow a multi-path workflow where different recall paths cover various subsets of the corpus (e.g., texts, images, videos, and user behaviors) to ensure high accuracy. Therefore, search has the largest overall vector volume, totaling up to twenty billion vectors in practice. Second, search is directly exposed to end users, which requires an SLA of ∼10 millisecond average latency [16] under ∼300K QPS, our typical peak traffic. Third, ANNS is the first stage of the ranking pipeline in search. Thus, it requires a relatively large top-k (e.g., around 100 to 3,000) to provide sufficient candidates for downstream re-ranking models [21, 37]. Finally, because our embedding models are continuously trained with daily collected metrics (e.g., user behaviors and content popularity), we wish to rebuild (instead of in-place updating such as SPFresh [58], Quake [43] and OdinANN [23]) the entire indexes on a daily basis.

Recommendation. Unlike search, recommendation only focuses on the popular subsets of full corpus. As a result, the total vector volume is significantly smaller than that of search, ranging from 1 to 100 million vectors per index. Recommendation directly serves end users but involves more recall paths. Thus, the online request throughput can reach ∼2.5 million QPS while still requiring millisecond-level latency SLAs [33]. Moreover, post-filtering based on user-specific constraints is common in recommendation. To ensure sufficient results after filtering [63], the top-k from ANNS can be up to 1,000. Finally, embedding models are updated in batches (aggregated from minutes to hours [42, 47]) based on real-time feedback (e.g., click-through rates), leading to up to ten thousand index rebuilds per day and a cumulative rebuilt volume on the order of tens of billions of vectors.

Advertising. Embedded from products, advertising has fewer vectors, around one billion in total. Similar to search and recommendation, advertising also directly serves users and thus requires millisecond-level latency SLAs under millions of QPS [59]. In addition, advertising follows a post-filtering pipeline. ANNS retrieval is followed by scalar filtering on multiple attributes (e.g., exposure constraints and billing status), so the required top-k can be large as well (e.g., up to 3,000) [61]. Finally, for index construction, since the embedding models are modified incrementally by rates of clicks or purchases on the order of minutes, this requires that index rebuilds keep up with these real-time updates as well.

Content moderation. This maintains two types of indexes, the large allow-list corpus and the smaller block-list corpus. The allowlists consist of all content conforming to policies and values, so their indexes can reach up to 10B vectors. The block-list stores only restricted content and is typically much



(a) *In-DRAM graph indexes on distributed nodes for achieving low latency.* (b) *DRAM-SSD graph indexes on a single node for saving memory footprint.*

Figure 2: *Two solutions employed in services of RedNote.*

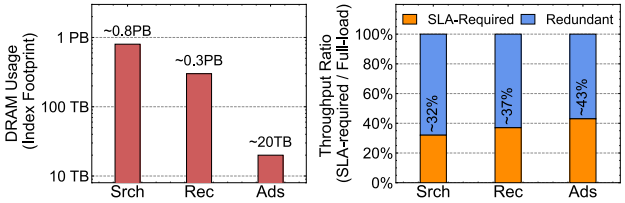
smaller (e.g., 10M vectors). Content moderation is mainly an offline workload, and new content is compared against both allow-list and block-list, then assessment models select high-risk candidates that are forwarded to manual checking. This pipeline results in more relaxed latency SLAs and lower overall throughput than the above-mentioned services [45]. Additionally, to capture restricted content with best effort, we also use relatively large top-k (up to ∼500). Since these collections change slowly, block-list indexes are rebuilt on a daily basis and the allow-list indexes are refreshed weekly.

Retrieval-augmented generation. Our ANNS also supports emerging AI applications like RAG. In RAG, ANNS is mainly used to index task-specific knowledge bases with sizes varying widely from about one million to several billion vectors depending on the applications. Since LLM inference dominates resource consumption and current models have limited context length, the SLA requirements for the ANNS stage are relatively relaxed (e.g., ∼20 ms) [29] and the required top-k is much smaller (e.g., 10-100) than other services' [44, 62]. Moreover, the underlying knowledge bases evolve slowly and the embedding models change infrequently, so index rebuilds are needed far less often than in other online workloads.

2.2 Solutions for ANNS-based Services

Graph-based ANNS offers high throughput with low latency, and is therefore widely deployed in RedNote's production services. To satisfy the strict performance SLAs of search, recommendation, and advertising, we run a large fleet of distributed memory shards that host in-DRAM graph indexes [20, 40]. The aggregated count of CPU cores already exceeds 10^5 among 4,000 nodes, spanning ∼50 clusters as of today. For scenarios with slightly more relaxed latency and throughput requirements (e.g., content moderation and RAG), we instead employ hybrid DRAM–SSD nodes with SSD-backed graph indexes [22, 49, 56] to trade some latency for a much smaller memory footprint.

In-DRAM Graph. In our production, HNSW [40], one of the state-of-the-art in-DRAM indexes, is commonly adopted.



(a) *PB-level DRAM usage.* (b) *Throughput overkill.*

Figure 3: *In our online services, latency SLAs force massive DRAM for pure in-DRAM indexes, while throughput SLAs are modest to the full-load maximum of the in-DRAM deployment.*

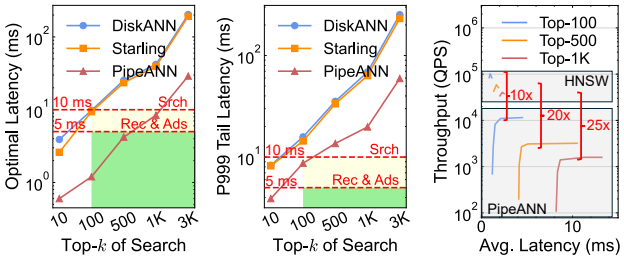
And it is widely deployed for search, recommendation, and advertising. Figure 2a shows, for a given query, the HNSW search starts from an entry node on the top layer and performs greedy best-neighbor descent layer by layer, until it reaches the bottom, where a best-first search over a candidate pool produces the final top-k results. All graph data, including neighbor lists and raw vectors, are kept in DRAM so that the critical path consists only of in-memory accesses. When a single shard cannot hold the entire index, we partition the dataset across multiple memory shards and execute search independently on each HNSW shard. The frontend then merges the partial results from all shards to obtain the global top-k answers. This design can deliver consistently low search latency and high QPS, guaranteeing QoS.

Hybrid DRAM-SSD Graph. For scenarios with more relaxed performance SLAs, such as content moderation and RAG, we employ hybrid DRAM–SSD graph indexes, as illustrated in Figure 2b. These indexes significantly reduce DRAM consumption, allowing a large-scale graph to be hosted on a single node. Representative designs include DiskANN [49] and its recent optimized variants such as Starling [56] and PipeANN [22]. They retain PQ-compressed vectors and a small set of frequently accessed vectors cached in DRAM, while storing the full-precision vectors and graph edges on SSDs to cut memory footprint. During query processing, the graph is traversed with the best-first search strategy and a beam-search procedure. The search path always advances along the edges towards the neighbor that is closest to the query. The beam-search width is translated into an I/O width that controls how many candidates are fetched from SSDs in batches, thereby improving bandwidth utilization for higher performance.

3 Motivation

3.1 Can't Afford In-memory ANNS to Scale

Over the past few years, the fast growth of RedNote's user base has driven the data volume of our stored vector corpus to be doubled annually. The more than billions of new vectors persisted each year exacts a heavy toll on the CapEx of our in-memory ANNS deployment. Figure 3a illustrates that, as



(a) *Average latency.* (b) *P999 latency.* (c) *Throughput gap.*

Figure 4: *All graph-based systems fail in replacing in-DRAM solution. DiskANN and Starling can never meet the latency SLAs. PipeANN shows an insuperable gap in throughput. Srch refers to the search business, with latency SLAs of 10 ms. And Rec & Ads refers to the recommendation and advertising, with latency SLAs of 5 ms.*

Hardware	DRAM [10]	Gen5 SSD [12]	Gen4 SSD [11]
Price ($/GB)	8 (***100%***)	0.2 (***2.5%***)	0.15 (***1.9%***)
BW (GB/s)	12 × 38 (***100%***)	12 × 12 (***32%***)	12 × 6.5 (***17%***)

Table 1: *Price and bandwidth comparisons as of Dec. 2025.*

of 2025, the in-DRAM HNSW indexes for search, recommendation, and advertising have already consumed PB-level DRAM in practice. Even just the ANN indexes of a single service (e.g., search) can now consume hundreds of terabytes of DRAM.

However, the massive DRAM usage is mostly provisioned to maintain the QoS (e.g., 10 ms average latency SLA of search). Specifically, Figure 3b shows that, out of the 100% throughput provided by in-DRAM deployments, only ∼32–43% is actually needed to maintain the required latency SLAs. Nevertheless, we still need the rest 57–68% of DRAM, not for throughput, but for the capacity to host the entire set of indexes to avoid latency spikes under workload bursts [39].

3.2 Can't Replace with Hybrid Graph

Recall that our CM and RAG services (see §2) have adopted a hybrid DRAM-SSD architecture for the graph-based DiskANN to reduce memory consumption. Given that SSDs are becoming increasingly affordable and high-performance as Table 1, it thus motivates us to consider integrating SSDs into other services (e.g., search) as well. Here, we explore the feasibility by conducting comprehensive evaluations of existing graph-based DRAM-SSD ANNS systems, including DiskANN, Starling, and PipeANN, on our standard 96-core server equipped with 12 PCIe-5.0 SSDs. Using the SIFT100M dataset [13], we target a 90% recall rate and evaluate top-k values from 10 to 3,000, which is consistent with both the BigAnnBenchmark [48] and our online services' requirements (§2.1). Unfortunately, the results are disappointing in terms of both latency and throughput.

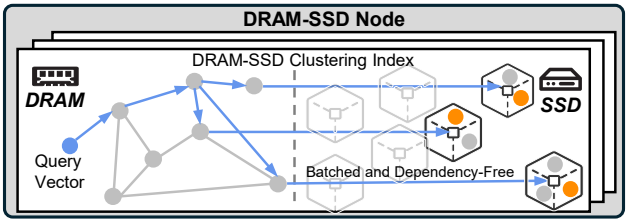


Figure 5: *DRAM-SSD clustering-based index follows the batched and dependency-free I/O pattern on the NVMe SSDs.*

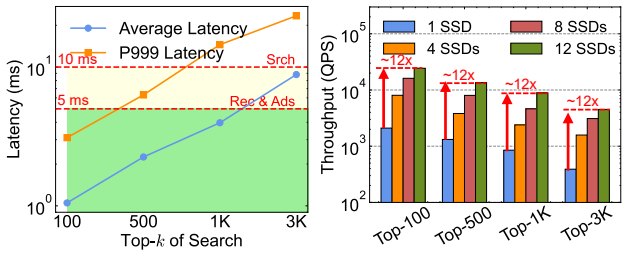
Latency. Figure 4a and Figure 4b report the mean and 99.9th percentile tail latency of the three candidates. We test them with a latency-friendly strategy by executing single-threaded queries (i.e., lowest concurrency). We can observe both DiskANN and Starling consistently fail to meet both our average and tail latency SLAs in the field (the green shaded area). PipeANN, by leveraging intra-query parallelism (i.e., multi-threaded beam-search traversal) to better utilize SSD bandwidth, achieves the lowest latency among the three but still struggles to satisfy the online SLAs at high top-k values, especially for tail latency.

Throughput. To further explore whether PipeANN can serve as a (partial) replacement, we evaluate its throughput against in-DRAM HNSW under the latency SLAs. As shown in Figure 4c, even with 12 PCIe-Gen5 SSDs providing over 30% of DDR5 DRAM bandwidth (Table 1), PipeANN's peak throughput remains 10–25× lower than that of HNSW. The root cause is that the graph-based DRAM-SSD ANNS inherently suffers from strongly serialized, dependency-chain I/Os during search (i.e., each expansion step depends on the results of previous reads). This serialized access pattern magnifies the raw latency gap between SSDs and DRAM (around 10^2-10^3). In our low-latency and high-throughput online services, this limited performance rules out the possibility of graph-based DRAM-SSD systems as a viable replacement for in-DRAM solutions at scale.

3.3 Clustering-Based ANNS Brings Hope

Failing to port in-memory ANNS with graph-based hybrid designs motivates us to reconsider another design, clustering-based DRAM-SSD ANNS. At a high level, Figure 5 shows that SPANN [17], a representative clustering-based ANNS, uses a clustered layout. The clusters' centroids are kept in DRAM, while vectors are stored on SSD as clustered posting lists. During search, it first searches the in-memory graph of centroids to identify the *nprobe* number of (e.g., 3 in Figure 5) closest partitions, then issues batched reads to fetch the corresponding posting lists, and finally computes the top-k neighbors from the loaded candidates of these lists.

Historically, this line of research was known to be latency-friendly but largely dismissed in the field due to the limited throughput [22, 51, 56]. However, the recent advance-



(a) *Near-SLAs latency.* (b) *Scalable throughput.*

Figure 6: *Based on high-bandwidth modern SSDs, the clustering-based SPANN shows nearly qualified search latency and scalable throughput under the large top-k values.*

ment in high-bandwidth NVMe SSDs (e.g., 12 GB/s from Gen5 SSD) has changed this landscape. As shown in Figure 6, using SPANN and up to 12 PCIe-Gen5 SSDs on SIFT100M, our evaluations demonstrate that, with the batched and dependency-free I/O pattern, this clustering-based design can already approach latency SLAs of online services under processing single-threaded query and achieve scalable throughput by adding SSDs. In addition, Figure 6a shows that, even when we increase top-k up to 3×10^3, SPANN nearly keeps the average and tail latency within or close to the SLAs of search, recommendation, and advertising. Moreover, Figure 6b illustrates that the throughput scales almost linearly with the number of SSDs and reaches $\sim 12\times$ speedup when using 12 SSDs, reinforcing our assumption that modern SSDs with clustering-based index can be a promising direction.

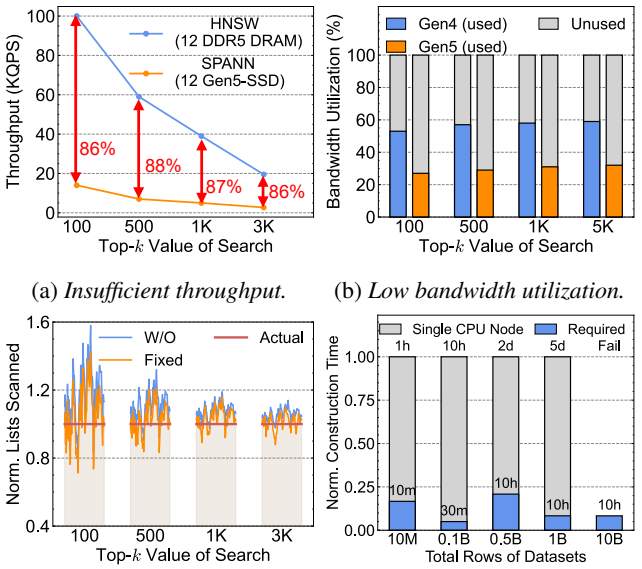
3.4 Challenges in Deploying SPANN at Scale

However, even when we pair SPANN with the array of NVMe SSDs, such a solution still cannot be directly deployed in the field. Challenges persist in both online search and offline construction. For online serving, the achieved search throughput is well below our production SLAs. Moreover, in the offline stage, the construction of indexes incurs prohibitive time overheads that must be substantially reduced.

First, SPANN cannot yet serve as a scalable replacement for the in-DRAM HNSW indexes deployed in our online stack. Under the latency SLAs of online services, even on a 96-core node with 12 PCIe 5.0 SSDs, the throughput remains insufficient. As shown in Figure 7a, there is still a throughput gap of about 86-88% between SPANN and the in-DRAM HNSW baseline.[1] This gap is largely due to insufficient utilization of NVMe SSDs' bandwidth. Figure 7b shows that SPANN uses only ~26-59% of the available bandwidth on PCIe Gen5 and Gen4 arrays, highlighting a primary opportunity to scale throughput by driving SSD bandwidth actually utilized closer to the hardware limits.

Second, SPANN's current strategy for determining the

[1]Referring to our production index-building settings, `edges` and `efConstruction` of HNSW are set as 24 and 120. SPANN is set as §5.1



(a) *Insufficient throughput.* (b) *Low bandwidth utilization.*

(c) *Un-adapted range of scans.* (d) *Long-time index building.*

Figure 7: *Clustering-based SPANN still has deficiencies. Its performance also fails to fully meet the throughput SLAs (~12%-14% of in-DRAM HNSW), due to the low bandwidth utilization and un-adapted range of scans. Furthermore, its single-node CPU-only construction of indexes incurs a heavy expenditure of time, violating the freshness of services.*

scan range (i.e., the number of loaded clusters *nprobe*) impacts both throughput and search quality. It relies on a fixed distance-based pruning rule shown in Equation 1. After locating the closest centroid c_{i1}, SPANN includes clusters $\mathbf{X}_{ij}$ in the search if distances from $\mathbf{q}$ to their centroids c_{ij} are within a $(1+\varepsilon)$ factor of the distance to c_{i1}, where ε is chosen empirically and does not adapt to query difficulty or data distribution. Figure 7c presents statistics for ~100 queries under varying top-k. The scanned range after pruning is only slightly smaller than the no-pruning (W/O) baseline, yet for each individual query, it often overshoots the range needed to reach the target recall (e.g., 90%), wasting I/O and reducing throughput; or undershoots it, causing large variance in recall and resulting in unstable search quality.

$$\mathbf{q} \xrightarrow{\text{search}} \mathbf{X}_{ij} \iff \text{Dist}(\mathbf{q}, c_{ij}) \le (1+\varepsilon)\,\text{Dist}(\mathbf{q}, c_{i1}),$$
$$\text{Dist}(\mathbf{q}, c_{i1}) \le \text{Dist}(\mathbf{q}, c_{i2}) \le \cdots \le \text{Dist}(\mathbf{q}, c_{iK}) \quad (1)$$

Finally, SPANN also faces significant challenges in offline index (re)building. As shown in Figure 7d, the existing implementation constructs the clustering structures on a standalone CPU node. When the dataset grows from ten million to tens of billions of vectors, the construction time escalates from several hours to multiple days. These construction windows are far longer than what is acceptable in our production scenarios, where embedding models and vector data are refreshed frequently. Consequently, index building also becomes a major bottleneck hindering the practical deployment of SPANN.

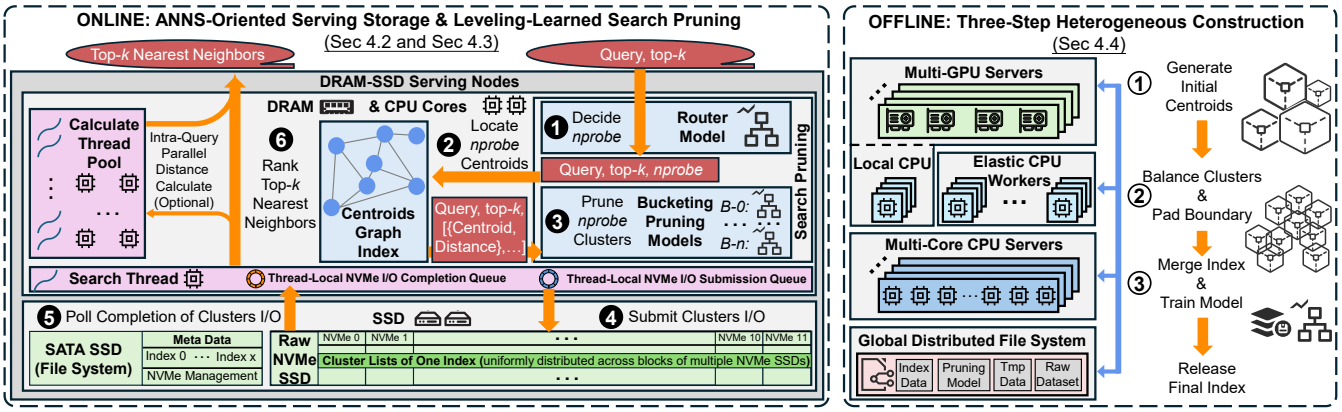


Figure 8: *Design overview of* HELMSMAN *with workflows of online search and offline index construction.*

4 HELMSMAN Design

4.1 Overview

We present HELMSMAN, a high-performance and cost-effective ANNS system using clustering-based indexes on all-flash servers. Figure 8 presents an overview of HELMSMAN, including online serving (i.e., the left half of Figure 8) and offline index construction (i.e., the right half).

Online serving. We employ all-flash servers as ANNS serving nodes where each is equipped with 12×2 TB PCIe Gen5 NVMe SSDs, 12×96 GB DDR5 DRAM, and a 96-core CPU. Recall that existing solutions such as SPANN fall short in throughput due to bandwidth utilization and pruning efficiency. We therefore redesign the storage stack and the pruning module. The key idea is eliminating overhead from I/O software and introducing adaptive learning-based models. At a high level, for each index released to serving, we use DRAM to store the centroid graph for locating nearest clusters and weights of the search pruning module (router and pruning). Meanwhile, the cluster lists are striped across raw NVMe SSDs as the granularity of logical blocks, bypassing the traditional Linux software stack. Since a single node can usually host multiple vector indexes, we use an extra SSD to store the metadata of all indexes and management of raw SSDs.

For each query with target top-k, ❶ the router model decides the *nprobe* value, ❷ then HELMSMAN uses the centroids graph index to locate the *nprobe* closest centroids, and ❸ the leveling pruning model routed at the first step further prunes the candidate clusters. ❹ The search threads submit asynchronous NVMe I/O commands for the selected cluster lists, ❺ poll completions of cluster reads on the hardware completion queue, and ❻ calculate the loaded vectors in the local thread or dispatch them to the calculate thread pool to compute distances and finally rank the top-k nearest neighbors as the result of ANNS.

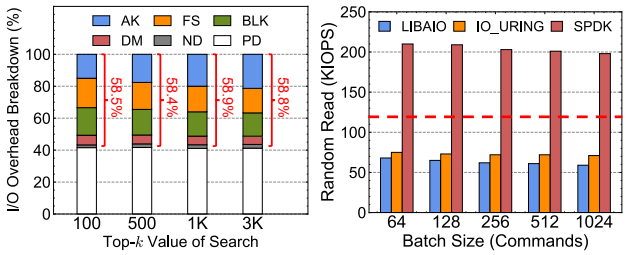
Offline index construction. To facilitate frequent index building, HELMSMAN employs multi-GPU servers to form a three-stage pipeline. Note that a major drawback in previous builds by a single node's CPUs is limited computing power and the inability to scale. Hence, we introduce GPUs to generate initial centroids and distributed nodes to accelerate balancing and padding. Backed by a global distributed file system holding the final index, pruning models, temporary data (e.g., checkpoints), and raw datasets, we orchestrate the entire construction pipeline end-to-end, achieving minute-level index building for datasets up to million-scale vectors and hour-level construction for billion-scale datasets.

In offline construction, ① multi-GPU servers run k-means to generate initial centroids from the raw dataset and save these centroids to the distributed storage. ② Then, owning initial centroids, local CPUs of multi-GPU servers or elastic CPU workers split and rebalance clusters from the initial centroids, pad cluster boundaries, and write intermediate index shards to the global distributed file system. ③ Multi-core CPU servers merge the shards, build the graph for all final centroids, train leveling pruning models, and finally materialize the index files for releasing them on serving nodes.

Design advantages. With these designs, HELMSMAN effectively solves the aforementioned challenges. First, as ❹ and ❺ of the online serving in the left of Figure 8, it bypasses the kernel on the throughput-critical I/O path (i.e., cluster-list reads) completely to exploit the high bandwidth of modern multi-SSD arrays, minimizing software overhead by directly steering NVMe SSDs to match ANNS access patterns (§4.2).

Second, as ❶ , ❷ , and ❸ of the online serving, it adaptively chooses the search range (i.e., probed clusters) on a per-query basis, achieving target recall while avoiding unnecessary I/O and computation: a trained router model predicts the recall-sufficient *nprobe*, and leveling pruning models further eliminate unnecessary scans (§4.3).

Third, as ① and ② of the offline building, to support frequent index building for incremental embedding model training and continuously evolving vector data, we utilize heterogeneous acceleration and make support for elastic scaling. Multi-GPU servers accelerate centroid generation on large-



(a) *I/O breakdown of SPANN.* (b) *Ideal IOPS per core.*

Figure 9: *SPANN's I/O path relies on the traditional Linux I/O software stack, including AK (application-kernel switching), FS (file system), BLK (block layer), DM (device mapper for RAID), and ND (NVMe driver). By issuing fixed-size 12 KB reads in batches—a new batch only after the previous one completes—we show the I/O breakdown of SPANN, and compare the performance of* `libaio`, `io_uring`, *and SPDK.*

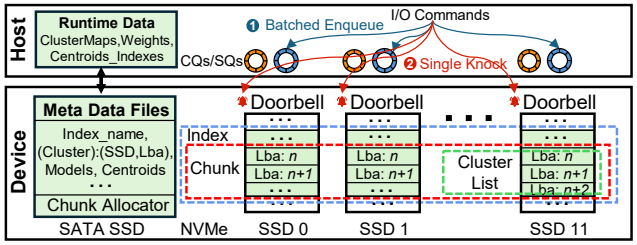


Figure 10: *Meta data as files, clusters' lists as raw blocks.*

scale datasets and we can dynamically allocate CPUs to speed up the following fine-grained index construction flexibly according to requirements (§4.4).

4.2 ANNS-oriented Storage Stack

To better serve the clustering-based ANNS indexes, we study the existing storage stack and propose an ANNS-oriented storage design. We start by analyzing the I/O behavior of clustering-based search and then discuss the corresponding design choices which take advantage of multiple NVMe SSDs with the help of the user-space SPDK driver [14].

Understanding I/O patterns. Clustering-based ANNS has two outstanding I/O patterns during online search. First, the search process tends to generate a large number of batched reads. For example, a single query can generate up to $\sim 10^3$ cluster-list loading requests when searching the top-3,000 nearest neighbors, a typical case in online search and advertising. Such massive reads can lead to a demandingly high IOPS requirement. Taking SIFT100M as an example, under a 10 ms latency SLA, computation (e.g., finding the nearest centroids, distance calculations on vectors loaded, and ranking top-k results) can already cost ~2-4 ms with only ~6-8 ms left for I/Os, which in return translates to ~120-170 KIOPS per search thread on a single core. However, the I/O stack used in SPANN can often only achieve ~30-40 KIOPS.

Second, the clusters of an index have the same size which is also the size of the issued reads. This is because, to avoid long-tail latency and the boundary error during search [17], the clustering-based index usually balances clusters' sizes below a threshold and pads clusters with boundary vectors to the same size (e.g., 12 KB per cluster for SIFT in SPANN). As a result, each cluster can have same count of pages, and each probe typically issues fixed-size reads (e.g., 12 KB from three 4KB pages) when loading the nearest clusters.

Exploring design choices. We next profile the I/O overhead of SPANN (Figure 9a) and three popular I/O stacks including `libaio`, `io_uring`, and SPDK (Figure 9b) under workloads of batched and fixed-size read patterns (i.e., the same I/O behavior as the clustering-based search) as shown in Figure 9. Results indicate that the overhead of the traditional I/O stack with `libaio` dominates the end-to-end path (up to 58% of the total) across all top-k settings, even exceeding that of accessing the SSD (i.e., *PD*, physical devices). `io_uring` shows moderate improvements over `libaio` since it does not have system calls [25]. SPDK achieves the highest IOPS by bypassing the traditional kernel stack completely. Note that these throughput numbers are all measured without considering the computation cost in Figure 9b. Given that `io_uring` and `libaio` have already failed to meet the expected IOPS, we therefore choose to build our serving storage over SPDK.

Customizing the storage stack. Adopting SPDK means dropping the support from the kernel, and we hence need to manage the data layout of indexes, the I/O control of raw devices, and the multi-device space allocation. We demonstrate our serving storage stack, as shown in Figure 10.

- *Data layout.* The index data consists of metadata and cluster lists. Metadata includes the index name, mappings of each cluster and its physical location (SSD id and LBA), pruning models, and the centroid index. Since these structures are small and can reside in memory without external reads at runtime, we simply store them as regular files on a local SSD. In contrast, the efficiency-critical cluster lists are placed directly on the logical blocks of the NVMe SSD array. Each cluster list occupies a contiguous block range of a single SSD (e.g., a cluster list uses three consecutive LBAs of SSD 11 in Figure 10), so that reading one cluster only requires a single I/O command, avoiding multiple I/Os due to crossing devices or blocks.
- *I/O control.* For the only runtime external I/O–loading cluster lists–we bypass system calls and directly submit NVMe commands to hardware queues while polling for completions. With this direct control of devices, we optimize submission at hardware granularity. I/O commands are enqueued to host-side NVMe queues in batches, and each NVMe device is notified with a single PCIe doorbell knock per batch. This eliminates hundreds of per-command PCIe round-trips (at the microsecond scale) and significantly reduces CPU overhead on the critical read path.
- *Space allocation.* Since all clusters are padded to a fixed

size, we can pre-allocate cluster-aligned regions on SSDs, avoiding fragmentation and complex file-system allocators. Hence, on raw NVMe devices, we exploit this property with a unified chunk-based free-list allocator (e.g., 64 MB per chunk) that manages SSD space for all indexes. It allocates and recycles fixed-size regions for deploying and deleting indexes at the chunk granularity. Each index then partitions its chunks into consecutive block ranges sized to a cluster list and assigns each range to a single cluster.

4.3 Leveling-learned Search Pruning

Problem and purpose. In clustering-based search, the number of probed clusters (i.e., *nprobe*) determines recall and performance. The trade-off is that an overly large *nprobe* significantly increases the I/O and computation cost due to redundant scans, while an overly small *nprobe* hurts recall.

Adapting nprobe by pruning. Many prior works such as Quake [43], Auncel [64], and LAET [36] propose early termination in pruning, which seems suitable for our adaptive adjustment of *nprobe*. However, they in fact cannot be applied to our scenario due to the lack of support for changing top-*k* of requests and the strong dependence on intermediate results. First, existing methods typically make early-termination rules for a fixed top-*k* while varying target recall. In contrast, in our services, the recall target can be predetermined from scenarios (e.g., 90% in online search) but top-*k* can vary across requests (e.g., 100-3,000 in online search).

Second, LAET also relies on intermediate features such as the distances to the current 1st and 10th neighbors after probing a subset of the nearest candidate clusters located. Similarly, Quake and Auncel need to check after each newly scanned cluster whether the recall target is met. Such iterative probe–compute–decide loops serialize cluster I/Os, and thus are unfriendly to the batched SSD reads for cluster lists, leading to reduced bandwidth utilization.

Leveling-learned search pruning. We propose the leveling-learned search pruning (LLSP) based on gradient boosting decision trees (GBDT) [2] [19,32]. First, to address varying top-*k* values, LLSP has a router model for choosing the maximum range according to the different search difficulty (i.e., the distribution of query vector and the top-*k* value) of requests. Second, it has a group of multi-level learning-based models for pruning redundant scans. At this stage, to keep batched cluster reads, we avoid using intermediate search results as features, and instead use only pre-search information: the query vector, the top-*k* value, and statistics of its distances to all nearest candidate centroids [3].

[2] GBDT is an effective architecture for pruning of online search because of its fast training (e.g., minute-level overhead for 1 million entries), low-overhead inference (e.g., ~10-30 us per prediction), and small memory footprint (e.g., only hundreds of KB per model).

[3] Feature-importance analysis shows query vectors and centroid-distance ratios can contribute nearly 50–70% of predictive power [36].

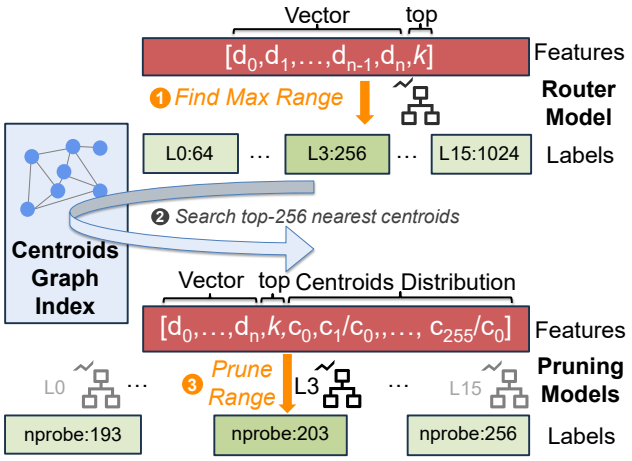

Figure 11: *Pruning workflow of search during online serving.*

Online-offline workflow. In detail, we first present the pruning process of search in online serving and then describe how the models are trained in offline building.

- *Online serving workflow.* As shown in Figure 11, we first feed the query vector and its requested top-*k* into the router model, which predicts a coarse maximum search range's level (e.g., level 3 with 256 as *nprobe* here, L3:256) as the upper bound of *nprobe*. Then the centroids graph index returns the top-*nprobe* nearest centroids. Finally, LLSP constructs pruning features from the query, top-*k*, and the centroid–distance distribution (the nearest centroid-query distance and relative ratios of the following 255 centroids' to the 1st centroid's), and applies the corresponding level-specific (i.e., level 3 here) pruning model to refine *nprobe* for batched loading nonredundant clusters from SSDs.
- *Offline training workflow.* We first set a series of range levels with increasing upper bounds on *nprobe* (e.g., 64 to 1,024 with a step of 64). From a recent time window (e.g., the previous 1 day for search, 1 hour for recommendation and ads), we uniformly sample about 1% of logged items as the training supervision. This is because most production traces show up to 90% duplication in short windows [15, 53, 54]. To avoid the overhead of brute-force ground truth, we approximate labels by running non-pruning search with a large *nprobe* (e.g., 4,096). We then train the router model by the procedure that, for each query and business-required top-*k*, finding the smallest level whose range meets the target recall and using the pair (query, top-*k*) as features and the level as label. Afterward, within each level, we derive labels for training pruning models by gradually decreasing *nprobe* from the level's maximum until recall drops to the threshold; the resulting *nprobe* is taken as the label. And the query, top-*k*, and centroid-distance distributions under the maximum *nprobe* form the feature vectors together. With the labels (i.e., actual *nprobe* minimized) and these features, we train the pruning model of each level.

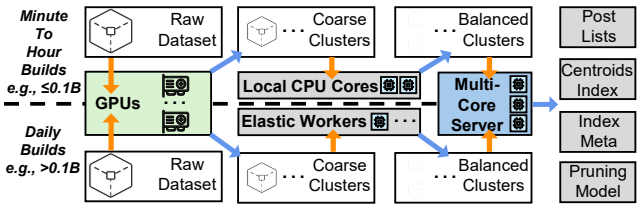

Figure 12: *Pipelines of the three-step index construction.*

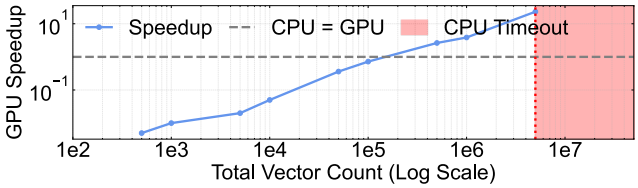

Figure 13: *The speedup ratio of GPU clustering across varying vector counts with an NVIDIA L20 vs. 48 CPU cores.*

4.4 GPU-accelerated and Elastic Building

To reduce the index construction time for million- to billion-scale datasets from days to tens of minutes, we leverage GPU-based acceleration and further design an elastic pipeline to scale the computation from a distributed CPU pool.

Procedure and issues of existing index construction. Again, we first examine the status quo (i.e., the index construction in SPANN). There are three steps. First, it applies hierarchical k-means to partition vectors into many size-bounded clusters, avoiding oversize and unbalanced partitions. Then, it performs closure multi-cluster assignment that duplicates boundary vectors, using RNG rules [52] to control redundant copies. Finally, it builds an in-DRAM graph on the centroids of all clusters for locating the nearest clusters to the query during online serving.

We can see that there are two main drawbacks in the first clustering step, which incurs the main overhead (up to ∼60-80%) of existing constructions. First, k-means on large-scale datasets incurs repeated distance calculations on high-dimensional vectors and thus places a heavy load which is beyond the capability of a CPU. Second, when vectors increase to billions from millions, it still requires multiple hours of building, requiring paralleling about 10^2-$10^3\times$ resources as data scaling. However, the current SPANN construction can only use one CPU in building and thus takes days to finish building a billion-scale index, which is unacceptable for production services.

GPU acceleration and elastic scaling. Hence, we exploit GPUs to accelerate centroid initialization and iterative balancing, and employ the elastic CPU pool to address the scaling of datasets. Figure 12 shows the workflow of our three-step index construction pipeline.

Generating coarse centroids with GPUs. First, for datasets of all scales, we use GPUs to perform coarse clustering. In this step, we do not directly split clusters down to their final size, because we found that GPU acceleration is not always effective[4]. As shown in Figure 13, GPUs provide up to orders-of-magnitude speedups on multi-million–scale and more vectors, while for small jobs (e.g., clustering on $<10^5$ 128-dim vectors), extra host–device transfers can dominate, making GPUs slower than the CPUs.

Constructing balanced posting lists. After the early clustering phase on GPUs, most clusters are already smaller than the threshold (e.g., 10^5 by default). We then use CPUs to perform fine-grained splitting and redundant padding of boundary vectors. Depending on the application scenario and dataset scale, we adopt two execution schemes.

For minute-to-hour builds of common-scale datasets (e.g., $<$ 0.1B vectors from recommendation and advertising), we employ local CPU cores to immediately finish the fine splitting and duplication with RNG checking, avoiding network transfers and extra scheduling overhead.

For search services that require daily rebuilds on larger corpora, elastic workers in online CPU clusters perform the fine-grained clustering and padding during off-peak hours, opportunistically harvesting idle resources from existing clusters under diurnal load patterns (i.e., lighter utilization at night and heavier loads during the day).

In addition, to avoid impacting real-time services, we enforce a QoS policy: whenever online and offline jobs contend for resources, online traffic always has priority and the index-building task on that node is preempted and terminated, and would retry later. To control the resulting tail latency, we further introduce task re-assignment and node eviction: once a task exceeds a retry threshold, it is reassigned to another node, and the original node is temporarily removed from the resource pool, preventing a few unstable nodes from dominating the overall construction time.

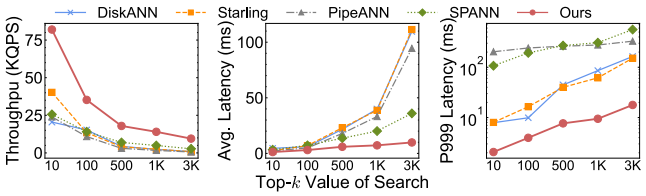
Building final index data. Finally, balanced and replicated clusters generated by both local CPUs of GPU servers and elastic CPU workers are uniformly prepared for releasing. They are consolidated on the multi-core servers to produce deployable index files, including posting lists, centroid index, metadata, and the pruning model.

5 Evaluation

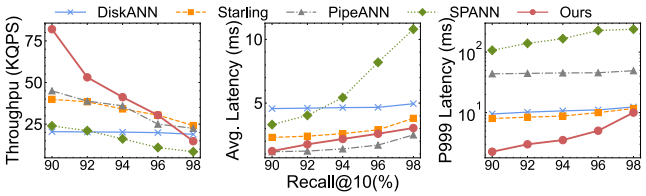
In this section, we conduct extensive experiments to evaluate the practical impacts of HELMSMAN, summarized as follows:

- HELMSMAN achieves 2-16× throughput of baselines, and can meet latency SLAs to replace in-DRAM HNSW (§5.2).
- HELMSMAN achieves 1.6-7.5× SSD bandwidth utilization of other DRAM-SSD systems, yielding up to 87% improvement by simply upgrading SSDs (§5.3).
- Under the same average recall, HELMSMAN ensures that >80% of queries individually meet the target recall by near 30 percentage points over SPANN (§5.4).

[4] At present, the development our GPU K-means is based on Faiss.



(a) *Performance across various top-k of search, under recall = 90%.*



(b) *Performance as the top-10 search, under various recall rates.*

Figure 14: *Comparisons about throughput, average and tail latency under different top-k and recall, using SIFT100M.*

- GPU acceleration enables constructing 0.1B-vector indexes within 1 hour. And by elastically scaling resources, 10B vectors can be built within 10 hours (§5.5).
- HELMSMAN can reduce DRAM usage by over 90% and improve throughput-per-dollar by 8.3× for the serving deployment (§5.6).

5.1 Setup

Dataset	Scale	Dim.	Total size	Top-*k* Range
SIFT	0.1B&10B	128	12 GB&1.2 TB	10–3,000
RedSrch	0.5B&10B	64	30 GB&0.6 TB	100–3,000
RedRec	0.1B	64	6 GB	100–1,000
RedAds	20M	128	2.5 GB	100–3,000
RedCM	0.1B	64	6 GB	100–500
RedRAG	4M	1024	4 GB	10–100

Table 2: Statistics of the evaluated datasets.

Workloads. We evaluate on the public SIFT and five production datasets, as shown in Table 2. SIFT10B is created by 10× replicating SIFT1B. Real datasets span 4M–10B vectors from our main services mentioned. Similarity metric is the L2 distance. For SIFT, we uniformly generate query top-*k* values ranging from 10 to 3,000, while for other datasets, top-*k* values are sampled from our real production traces.

Baselines. We compare HELMSMAN with DiskANN, Starling, PipeANN, SPANN, and HNSW. For DRAM-SSD baselines, we use their released implementations. We tune beam widths of graph-based systems (16 for DiskANN and Starling, 32 for PipeANN, unless otherwise specified) to achieve their optimal performance, since multi-SSD setups offer sufficient bandwidth. We set DRAM budget as 25% of the size of raw datasets [22]. For HELMSMAN and SPANN, we reduce the replication factor to 4, with centroids accounting for 8% of the total scale, thereby setting the DRAM:SSD ratio to 1:20 to match the hardware capacity. We include in-DRAM HNSW that is widely used in production for low-latency services, which serves as a strong performance reference for purely memory-resident deployments but with higher DRAM cost.

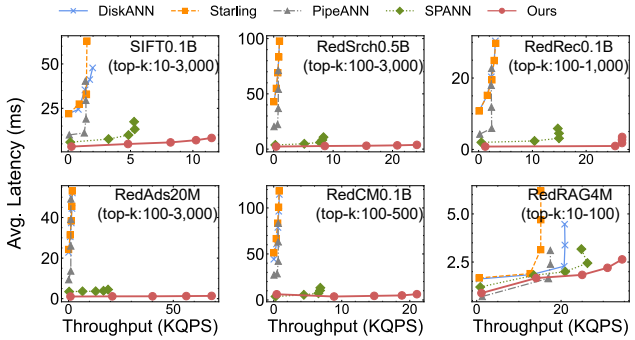


Figure 15: *Trends of throughput and average latency.*

Specifications. All DRAM–SSD tests are conducted on our testbed equipped with the 96-core AMD EPYC 9654 CPU, 12×96 GB DDR5 DRAM, 12×1.92 TB PCIe-5.0 NVMe SSDs. In-DRAM distributed HNSW uses our standard configuration with 32-core CPUs and 256 GB DDR5 DRAM to hold shards, a configuration commonly adopted in production.

5.2 Search Performance

End-to-end performance. Overall, HELMSMAN achieves the best end-to-end efficiency across a wide range of top-*k* and recall targets, as shown in Figure 14.

Varying top-k (Figure 14a). With recall fixed at 90%, HELMSMAN sustains the highest throughput on SIFT0.1B across all top-*k* values. As top-*k* increases from 10 to 3,000, its throughput degrades more slowly than that of other DRAM-SSD systems, while average latency stays within 10 ms and P99.9 latency remains well below 20 ms. For graph-based baselines (DiskANN, Starling, PipeANN), larger top-*k* forces longer greedy walks due to larger candidate lists. Starling improves top-10 performance via optimized layout but is less effective for large top-*k*. The reason is that, as top-k increases, the search depth of graph-based search grows significantly. For example, for top-1000 on the SIFT0.1B, both the candidate queue length and the number of search hops increase substantially to around 1,500 or more. The number of accessed SSD pages also rises significantly, which leaves little room for gains from layout reordering of Starling. Meanwhile, SPANN is constrained by the traditional I/O software stack. Consequently, both throughput and latency for baselines deteriorate rapidly.

Varying recall (Figure 14b). Fixing top-*k* at 10, HELMSMAN delivers competitive throughput at 90-96% recall and keeps clear advantages when recall enters the high-accuracy regime. Both average and tail latency grow smoothly with the recall, and HELMSMAN maintains sub-10 ms average latency

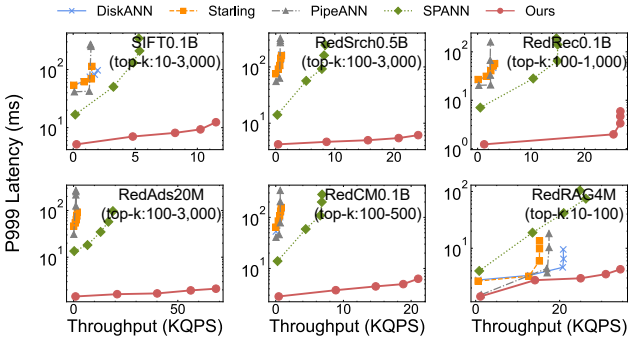

Figure 16: *Trends of throughput and P999 tail latency.*

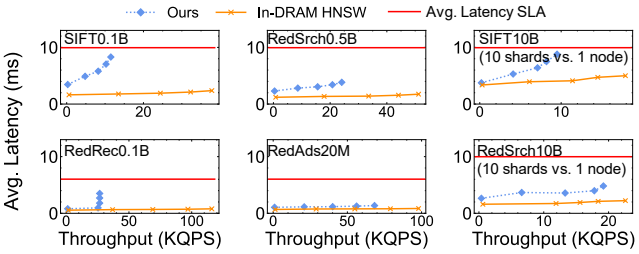

Figure 17: *Comparison with in-DRAM HNSW deployments.*

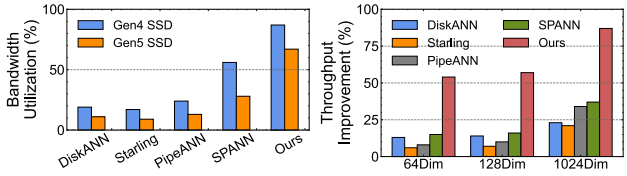
and the lowest P99.9 latency across the entire recall range.

Throughput vs. latency. We evaluate workloads from generated SIFT and productions with service-specific top-*k* and a 90% recall target, ramping threads until all systems saturate.

Throughput vs. average latency. As shown in Figure 15, graph-based systems can incur ∼120 ms average latency at only 0.5-3 KQPS because large top-*k* requires long greedy walks for longer length of candidate lists (e.g., 4,000 for top-3,000). SPANN benefits from high-bandwidth SSDs, and HELMSMAN further pushes the frontier, achieving up to 30× throughput while keeping average latency within 5-10 ms.

Throughput vs. tail latency. For P99.9 latency (Figure 16), graph-based systems and SPANN exhibit steep tail blow-ups once saturated. By clustering-based search and our customized I/O stack, HELMSMAN maintains up to an order-of-magnitude lower P99.9 latency, keeping it around ∼10 ms.

Comparisons with in-DRAM deployments. Figure 17 shows results. When HNSW fits in the same 96-core node (20M–0.5B datasets), HELMSMAN achieves about 25–70% of the throughput of in-DRAM HNSW deployments at 90% recall, while always satisfying the average-latency SLAs. For the 10B-scale SIFT and RedSrch, the production HNSW uses 10 shards with a total of 2.5 TB DRAM and 320 CPU cores (standard 32-core, 256-GB nodes). In contrast, HELMSMAN reaches roughly 47-85% of their throughput under the same SLA using a single 96-core machine with only 160–330 GB of DRAM. HELMSMAN meets SLAs with modestly higher latency, but reduces CPU usage by about 3–4× and DRAM consumption by nearly an order of magnitude.



(a) *I/O Bandwidth utilization on PCIe-4.0 and PCIe-5.0 SSDs.* (b) *Improvements by upgrading SSDs from PCIe-4.0 to PCIe-5.0.*

Figure 18: *Impacts of different generations of NVMe SSDs.*

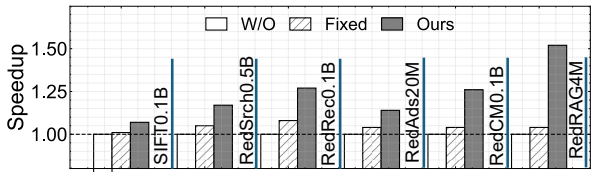


Figure 19: *Performance speedup by the pruning module.*

5.3 Storage I/O Impact

Bandwidth utilization. As shown in Figure 18a, on RedSrch0.5B, we measure the bandwidth utilization of a 12-SSD array with both PCIe-4.0 [11] and PCIe-5.0 drives [12]. Graph-based systems utilize less than 20% of SSD bandwidth, while clustering-based SPANN also merely reaches about 55% (Gen4). In contrast, HELMSMAN pushes utilization to ∼85% on Gen4 and ∼70% on Gen5, showing that its batched, device-direct I/O path is much closer to the device limits.

Gains from hardware upgrades. In Figure 18b, we then report throughput gains when upgrading SSDs from PCIe 4.0 to 5.0 on 64-dim RedSrch, 128-dim RedAds, and 1024-dim RedRAG workloads. Graph-based systems (DiskANN, Starling, and PipeANN) improve by only 10-30%, and SPANN by up to 40%, indicating they are largely I/O-latency- or software-stack-bound. In contrast, HELMSMAN gains about 55% at 64- and 128-D and 87% at 1024-D, demonstrating that its performance scales more efficiently with available bandwidth.

5.4 Pruning Efficiency

For the public SIFT dataset, we randomly sample 1M vectors as the training set and use 10% of them as queries; for production datasets, we extract 110K consecutive queries from online logs, use the first 100K as the training set, and reserve the last 10K as queries, consistent with our production scenario. By default, we set the number of iterations to 500 and the learning rate to 0.2.

Performance gains. Our pruning module consistently accelerates search across all datasets, as shown in Figure 19. Compared with the non-pruning baseline, it yields 1.1–1.6× throughput, and still provides 5–25% higher throughput than the fixed pruning policy. The benefit is most pronounced on RedRAG4M because its workloads use small top-k values (i.e., 10–100), where the optimal search range (i.e., *nprobe*) tends to fluctuate more, leading to more redundant scans.

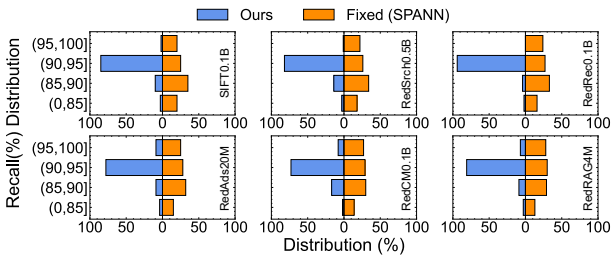

Figure 20: *Search quality improved by the pruning module.*

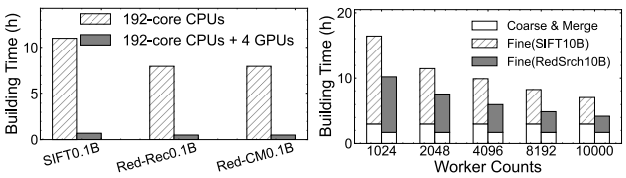

(a) *Comparison of single node.* (b) *Speedup from elastic scaling.*

Figure 21: *Acceleration of GPUs and distribution.*

Accuracy gains. As shown in Figure 20, LLSP also leads to a more stable search quality under the same average recall. In contrast to the fixed policy, which fails to meet the target recall for over 40% of queries, our method ensures that over 80% of queries meet the target recall (i.e., 90%), effectively reducing low-recall outliers across all six datasets.

Dataset	Model	Feature Importance
RedSrch	Router	*Query*:67.3% *k*:32.7%
	Pruning	*Query*:34.3% *k*:15.2% *Centroids*:50.5%
RedRAG	Router	*Query*:74.1% *k*:25.9%
	Pruning	*Query*:48.3% *k*:7.8% *Centroids*:43.9%

Table 3: Feature importance of leveling-learned pruning.

Feature importance. We further show the importance of different features in the leveling-learned pruning model in Table 3. RedSrch0.5B and RedRAG4M are chosen as representatives of production datasets with different dimensions and top-*k* ranges. RedSrch has a larger top-*k* range (100–3,000) and smaller dimension (64), while RedRAG has a smaller top-*k* range (10–100) and larger dimension (1024). Results show that the query features (e.g., query coordinates and distances to centroids used during pruning) are important for both router and pruning models, indicating that the local distribution of queries is a key factor for determining the search range and pruning ratio. Meanwhile, the importance of top-*k* is higher for the router model than the pruning model, which is reasonable since the router determines the search range (i.e., *nprobe*) based on the target top-*k*, while the pruning model further prunes clusters within the smaller selected search range.

5.5 Construction Evaluation

GPU acceleration. On a single 192-core node, CPU-only construction of 0.1B-scale indexes takes about 9–12 hours. Offloading the coarse clustering stage to 4 NVIDIA L20 GPUs reduces the total build time to within an hour, as shown in Figure 21a (up to ∼10× speedup), transforming hours-long offline jobs into minute-level builds for high-freshness services (e.g., recommendation and advertising).

Elastic scaling. For 10B-scale datasets, using GPUs for coarse clustering and single-node merging for final indexes (i.e., Coarse & Merge), we further parallelize the fine-grained balancing stage (i.e., Fine) across an elastic CPU cluster. Increasing the number of CPU workers from 1,024 to 10^4 cores reduces end-to-end building time from over 16 hours to about 4–7 hours, as shown in Figure 21b, enabling hours-level reconstruction of billion-scale indexes.

5.6 Cost Efficiency

System	DRAM (GB, $)	Gen5 SSD (GB, $)	Throughput (KQPS)	Storage Eff. (QPS/$)
HNSW	123, 1K	N/A	51	51
PipeANN	8, 64	260, 52	0.8	7
SPANN	8, 64	162, 32	8.4	88
Ours	8, 64	162, 32	24	**250**

Table 4: Comparison of cost efficiency on RedSrch0.5B.

System	DRAM (TB, $)	Gen5 SSD (TB, $)	Throughput (KQPS)	Storage Eff. (QPS/$)
HNSW	2.5, 20K	N/A	23	1.2
Ours	0.16, 1.3K	3.2, 0.6K	19	**10**

Table 5: Comparison of cost efficiency on RedSrch10B.

System	Cloud Price (norm. price / hour)	Build Time (hour)	Offline Cost (norm. cost)
HNSW	1 (96 Core)	1.5	1.5
Ours	1.3 (96 Core + 4 GPU)	1.3	1.7

Table 6: Comparison of construction cost on RedSrch0.5B.

Cost efficiency of online serving. We compare storage cost and throughput on search workloads to show online serving costs. On RedSrch0.5B (Table 4), under production top-*k* workloads, PipeANN sustains only 0.8 KQPS, yielding 7 QPS/$, even lower than in-DRAM HNSW (51 QPS/$). SPANN reaches 88 QPS/$, while HELMSMAN further improves to 250 QPS/$ (5.4× over HNSW, 2.9× over SPANN). On RedSrch10B (Table 5), by replacing a 10-shard HNSW deployment using ∼2.5 TB DRAM with each single node using 32 cores and 256 GB DRAM, HELMSMAN boosts cost efficiency from 1.2 to 10 QPS/$ (8.3×) by saving 90% of DRAM usage at an additional SSD cost of only $0.6K.

Cost efficiency of offline building. In addition to comparing our offline building time with the CPU-only SPANN, we also estimate the single-node CPU-GPU construction cost of HELMSMAN and CPU-based HNSW we deployed previouly by comparing the normalized cloud price of CPU-only and CPU-GPU instances [4]. As shown in Table 6, our GPU-accelerated construction achieves similar cost compared with CPU-only HNSW building, because of higher price of GPU instances but shorter build time. And as the GPU-based clustering implementation is developing [60], we expect the cost of clustering-based indexes' construction to further reduce, making it more cost-effective.

6 Deployment

6.1 Deployment Status

At the time of publication, HELMSMAN has been rolling out as a unified ANN layer in RedNote's production. We use HELMSMAN to support all services, and all-flash servers are gradually replacing previous in-DRAM deployments across search, recommendation, advertising, and other vector services in the coming months. Currently, with only ∼40 all-flash servers-each with 0.7–1.1 TB DRAM and 12 NVMe SSDs-HELMSMAN already sustains online workloads that previously required about 35,000 CPU cores and ∼0.35 PB DRAM in in-DRAM deployments. In the offline construction phase, HELMSMAN can leverage up to 10,000 CPU cores from online clusters during low-traffic periods (e.g., late-night hours) to accelerate large-scale builds. Looking forward, RedNote plans to migrate the majority of in-DRAM deployments onto HELMSMAN, with projected infrastructure cost savings on the order of tens of millions of dollars per year.

6.2 Operational Lessons and Future Work

Performance bottlenecks stem from local hotspots of queries and SSDs' die-level conflicts. In most indexes, the overall deployment remains smooth and stable. When SSD bandwidth and CPU utilization remain unsaturated, latency stays within SLAs and throughput scales with additional search threads. However, in the early stage of trial operation, for a few recommendation indexes, adding CPU cores failed to increase throughput, even though SSD bandwidth remained below 20%. Log replay shows that transient query bursts can target the same nearest clusters and logical blocks, causing internal chip conflicts [31] and high-latency SSD accesses. To mitigate this, we place a few redundant copies of the cluster lists on NVMe SSDs, which reduces conflicts and raises the throughput ceiling by 1.5–2×, while incurring only a minor extra SSD space overhead.

Memory bandwidth becomes the bottleneck before external I/O bandwidth is fully utilized. In our all-flash deployment, 12 Gen5 SSDs provide roughly 140 GB/s aggregate external I/O bandwidth, but only about 70% can be utilized in practice. The bottleneck is the limited effective memory bandwidth of modern 12-channel DDR5 servers, typically around 300–350 GB/s, which must serve SSD-to-DRAM transfers, DRAM-to-CPU rereads, and nearest-centroid search. Consequently, adding more SSDs brings limited benefit once memory bandwidth is saturated, as observed in our early more SSDs equipments (e.g., 20 Gen5 SSDs experiments). This imbalance is likely to worsen as modern CPUs expose enough PCIe lanes (e.g., 128-160 lanes [1]) to attach over 32 Gen5 SSDs, providing external bandwidth beyond what current memory systems can sustain. For the commercially available devices, the direct I/O-to-cache techniques such as Intel DDIO [6] and AMD SDCI [3] may mitigate this issue, but currently these methods only work for network devices and their SSD ecosystem remains immature. We think that extending such support to SSD-based systems might be a promising future direction. At the same time, recent studies [27, 28, 57] have used GPUs to overcome the limitations of CPU compute power and host memory bandwidth, while also taking advantage of the increasingly abundant external I/O bandwidth provided by NVMe SSDs. We plan to explore their optimizations in our future deployments.

Large top-k can be more important than extremely high recall. In production search, recommendation, and advertising systems, first-stage ANNS is typically used as a candidate generator rather than the final decision maker. Since single-vector similarity only provides a compressed semantic signal, downstream stages usually apply post-filtering based on scalar attributes, or rescore the retrieved candidates using richer features and the original content, such as text, images, and videos [21, 37, 63]. Therefore, in our workloads, retrieving a large candidate pool, e.g., top-k from 100 to 1000 at around 90% recall, is often more valuable than pursuing extremely high recall such as 98–99.9% for small top-k requests. The latter can substantially increase ANNS search cost but brings limited end-to-end business gain, because downstream stages mainly benefit from having enough valid and diverse candidates to filter and rescore, rather than from marginal improvements in the vector recall of a small candidate set. This suggests that future ANNS systems should be evaluated not only by recall@10 [48], but also by performance under large top-k, which better matches multi-stage pipelines.

In-place updates remain challenging. Dynamic updates are important for freshness in vector data management, especially to keep up with the near-real-time and streaming training of embedding models. In a typical 0.1B-scale recommendation workload with hourly rebuilding and ∼25–30 KQPS of search, fully replacing periodic rebuilds with in-place updates would require roughly 25–30 KOPS of updates (i.e., insertions and deletions) while concurrently serving online search. This is beyond the update and search throughputs of recent state-of-the-art large-scale dynamic ANNS systems [23, 58]. Therefore, supporting both high-rate updates

and high-performance search remains a challenging direction. Our current deployment adopts a hybrid design [24,26,50,55]: the main SSD-resident index is periodically rebuilt, recent insertions are maintained in an auxiliary in-memory index e.g., (HNSW and IVF), and deletions are tracked by a tombstone bitmap. Queries search both indexes, merge candidates, and filter tombstoned vectors. This preserves freshness with modest complexity, but still incurs extra memory usage and unavoidable rebuild costs.

7 Related Work

DRAM-SSD ANNS. DRAM–SSD ANNS includes graph-based systems (e.g., DiskANN [49], Starling [56], PipeANN [22]) and clustering-based designs (e.g., SPANN [17, 58]). Though graph-based schemes are popular for issuing fewer I/Os than clustering-based search, our findings show that SSD latency and serial access can make them slower than clustering on modern SSDs with the near-DRAM bandwidth [25,34,35], particularly for top-k up to the thousands in production [21,37,63]. Hence, we integrate clustering methods with high-bandwidth NVMe SSD arrays.

Pruning for ANNS. Quake [43], LAET [36], Auncel [64], and ANSMET [38] study pruning and early stopping for in-DRAM ANNS, where the search can iteratively check intermediate results and terminate once convergence-like conditions are met. However, such fine-grained, stateful control conflicts with SSD-friendly batched I/Os, which prefer issuing large sequential reads without per-step feedback. Therefore, instead of these intermediate-result-based methods, we propose our pruning module trained on historical traces, which predicts search ranges without relying on intermediate states.

Acceleration of index building. CAGRA [46], RAFT [7], ParlayANN [41], and Faiss [30] accelerate ANNS index construction and clustering using highly parallel graph builders and heterogeneous acceleration. We adapt several of their techniques (e.g., GPU-based k-means and parallel graph construction) in our offline index-building pipelines.

8 Conclusion

Our experience at RedNote shows that, under industrial workloads with large top-k queries, graph-based ANNS on SSDs suffers from long, latency-bound search paths and loses competitiveness. In contrast, pairing high-bandwidth NVMe arrays with the clustering-based search allows DRAM–SSD designs to approach in-DRAM performance (both throughput and latency) while greatly reducing hardware cost. HELMSMAN demonstrates this path in practice, combining a custom storage stack, adaptive pruning, and fast elastic construction to deliver cost-effective, high-performance ANNS at scale.

Acknowledgment

We thank all anonymous reviewers and our shepherd, Asaf Cidon, for their valuable feedback and helping us improve our paper significantly. We also thank engineers at Xiaohongshu Inc. for their efforts in deploying HELMSMAN in production. This work was conducted by Yuchen Huang and Baiteng Ma during their internship at RedNote Engine Architecture Department. Erci Xu is the corresponding author. WiseCode: Breaking the Scalability Barriers of Wide-Stripe Vector Codes

Sijie Cai, Guangyan Zhang*, Xiao Niu
Tsinghua University

Abstract

Wide-stripe erasure codes, with tens to over a hundred data chunks per stripe, offer high reliability at low storage overhead. Existing wide-stripe designs that are based on scalar codes (e.g., LRCs in Google and Azure) reduce *repair traffic* but increase *storage overhead*. Although vector codes are theoretically optimal in both metrics, they face severe scalability barriers in wide-stripe deployments.

We present WiseCode, *the first practical and scalable wide-stripe vector-coding approach* that achieves both efficient repair and ultra-low storage overhead. WiseCode overcomes three key scalability barriers through innovations in coding structure, coefficient selection, and coding algorithms. It introduces a template-unfold structure design that avoids sub-packetization blowup, a repetition-minimized search strategy that reduces coefficient search cost, and a two-stage coding algorithm that enables efficient encoding and decoding.

Evaluations on Ceph with ∼100-wide stripes and 1.04–1.06 storage overhead show that WiseCode increases repair throughput by 1.41×–2.18× compared to Google's UCLRCs at equal storage overhead, and also delivers higher throughput even at 2% lower storage overhead. WiseCode retains this advantage when combined with advanced repair-scheduling methods, consistently outperforming UCLRCs.

1 Introduction

Storage systems rely on redundancy mechanisms to tolerate routine device failures [1–4]. As data volumes grow exponentially [5], reducing storage overhead while preserving data reliability becomes increasingly important. In large-scale clusters managing exabytes of data, even a 1% storage overhead reduction saves millions of dollars in capital, operational, and energy costs [6]. This demand has driven the shift from replication to erasure codes [7–16] and now motivates *wide-stripe erasure codes*, or "wide codes" [6, 17, 18]. An (n,k) erasure code divides data into k data chunks and encodes them into $m = n-k$ parity chunks, forming a stripe with storage overhead of n/k (typically ≤ 1.5). Wide codes further reduce overhead by keeping m small while enlarging k. For example, moving from $(11,8)$ to $(106,100)$ reduces storage overhead from 1.375 to 1.06, without sacrificing reliability (§2.1).

Since data recovery is performed online, wide codes should quickly restore lost data [19–21] and minimize interference with foreground workloads [22–24]. Network and I/O resources are often the primary bottlenecks during recovery [24, 25], so reducing *repair traffic*—the amount of data accessed and transferred during recovery—is essential.

Achieving both *low repair traffic* and *ultra-low storage overhead* remains challenging in wide-code designs. Erasure codes fall into two categories: scalar and vector. Scalar codes, such as RS codes [18, 26] and Locally Recoverable Codes (LRCs) [6, 17, 27–30], operate at chunk granularity. RS codes satisfy the *Maximum Distance Separable (MDS)* property, achieving the optimal storage efficiency for a given reliability, but require reading k chunks to repair one; LRCs reduce repair traffic using *local parity* but increase storage overhead. Thus, **scalar codes cannot simultaneously optimize repair traffic and storage overhead.**

Vector codes [31–38], including Clay [34] and RS-ET [36], divide each chunk into α sub-chunks and organize them into α sub-stripes, where α is referred to as the *sub-packetization level*. Each sub-stripe defines a *coding equation* that specifies the relationship among its sub-chunks, allowing it to decode multiple sub-chunks independently. This enables repairing a lost chunk by decoding a small subset of sub-stripes, substantially reducing repair traffic while preserving the MDS property. As shown in Figure 1, implementing a vector code involves three key steps: (1) designing the *coding structure* that specifies sub-chunk variables in each sub-stripe's equation (with unknown coefficients), (2) selecting coefficients that ensure decodability under any 1 to m-chunk failures, and (3) developing efficient encoding/decoding algorithms.

In wide-stripe deployments (e.g., $n \approx 100$), vector codes face three **scalability barriers**:

1. *Sub-packetization blowup.* $(104, 100, \alpha)$ Clay codes require $\alpha = 4^{26}$ to achieve low repair traffic, making them

*Corresponding author: gyzh@tsinghua.edu.cn

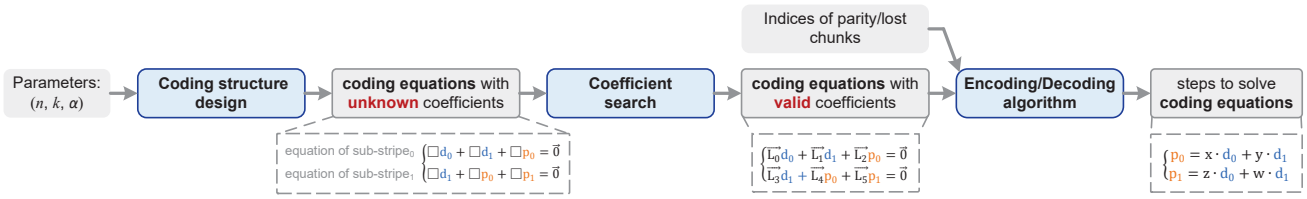

Figure 1: Three steps to realize vector codes—from coding structure design to coefficient search and coding algorithm.

impractical for deployments. RS-ET codes use smaller α but incur over 50% higher repair traffic than Clay codes.

2. *Prohibitive coefficient search.* For $(106, 100, 216)$ RS-ET codes, verifying one coefficient combination takes over 1,000 hours to check 1.7B failure cases. Moreover, many combinations must be tested before finding a valid one.

3. *High computational overhead.* Standard generator-matrix-based encoding achieves only 97 MB/s throughput for $(106, 100, 216)$ vector codes on our testbed, versus several GB/s for $(106, 100)$ scalar codes.

We propose WiseCode, *the first practical and scalable wide-stripe vector-coding approach* that achieves both low repair traffic and ultra-low storage overhead. WiseCode breaks the three scalability barriers via innovations in coding structure design, coefficient selection, and coding algorithms.

Template-unfold structure design. WiseCode takes a narrow MSR (Minimum Storage Regenerating [39]) stripe as a *template* and repeatedly instantiates it to form a wide-stripe structure while preserving the template's α and m. This allows each lost chunk to be recovered by reading sub-chunks from only a subset of sub-stripes. WiseCode selects the widest MSR template under a device-dependent α limit (higher on SSDs than HDDs for the same chunk size) to simultaneously avoid excessive data fragmentation and minimize instantiations that inflate repair traffic. This design achieves near-optimal repair traffic and minimum storage overhead without incurring sub-packetization blowup.

Repetition-minimized coefficient search. WiseCode reduces redundant work in coefficient search using two complementary techniques. *Divide-and-conquer verification* partitions chunks into disjoint groups and verifies decodability only for intra-group failure cases (i.e., all lost chunks lie within the same group), greatly reducing the verification scope while guaranteeing decodability for all failure cases. *Neighborhood-prioritized retry* generates a new candidate for retry by modifying only a small subset of coefficients in a rejected combination, preserving the decodability of most previously-verified failure cases. This significantly reduces per-candidate verification cost and accelerates retries, enabling n up to several hundred with $4 \le m \le 8$ over GF(2^{16}), whereas existing vector codes typically limit n to a few tens.

Two-stage encoding. Motivated by the observation that the generator matrix is much denser (up to 21×) than the sparse coefficients in the coding equations, WiseCode employs a *two-stage encoding* design. The *data aggregation* stage multiplies data by the sparse coefficient matrix to produce an intermediate vector; the *parity solving* stage then computes parity from the intermediate vector by solving the coding equations. WiseCode further optimizes both stages by extracting common operations during data aggregation and decomposing parity solving into computation-efficient steps using a divide-and-conquer strategy. This reduces multiplications from $O(km\alpha^2)$ to $km\alpha + O(m^3\alpha)$, cutting up to 94.6% of multiplications and improving throughput by 5.5×–22.4× in our experiments.

We integrated WiseCode into Ceph [8] as an erasure-code plugin. Evaluations on Ceph with stripe widths near 100 and storage overheads of 1.04–1.06 show that WiseCode delivers a strictly better tradeoff between repair performance and storage overhead than Google's UCLRCs [6], the state-of-the-art wide codes. At equal storage overhead, WiseCode increases repair throughput by 1.41×–2.18× compared to UCLRC; even with 2% lower storage overhead, it reduces repair traffic by 14.4% and improves repair throughput by 6.8%. When combined with the RepairBoost [21] repair-scheduling framework, WiseCode also increases repair throughput by 1.56×–2.38× compared to UCLRC, demonstrating consistent advantages under advanced scheduling.

2 Background and Challenges

2.1 Background

In an (n, k) erasure code, user data are divided into k equal-sized data chunks and encoded into $m = n - k$ parity chunks, forming an n-chunk *stripe* with storage overhead n/k. These n chunks are placed across independent failure domains (e.g., disks, hosts, racks) to tolerate multiple failures. A stripe with m parity chunks satisfies the MDS property [40] if any m lost chunks can be recovered. MDS codes have the minimum storage overhead for a given fault tolerance requirement.

Wide codes. Wide codes increase n while keeping m small (e.g., $n \ge 80$ and $m \le 8$ [6]) to reduce storage overhead without sacrificing reliability. For example, expanding RS codes

from $(11,8)$ to $(106,100)$ reduces storage overhead from 1.375 to 1.06, while increasing MTTDL (mean time to data loss, analyzed via a Markov model; see Appendix A.1) from 3.0×10^{11} to 5.4×10^{16} years. In large-scale storage clusters, degraded stripes are reported to be dominated by single-chunk failures (99.2% at Google [6], 98.08% at Facebook [22]). Moreover, modeling with a Binomial distribution [41, 42]—assuming an independent failure rate of 1/(4 years) and a repair rate of 1/(30 minutes) [17, 27, 28]—demonstrates that a stripe with $n = 100$ resides in a single-chunk failure state for over 99% of its total degraded duration. Therefore, existing wide-code designs (e.g., LRCs) primarily optimize single-chunk repair [6, 17].

Scalar and vector codes. Scalar codes treat each of the k data chunks as one variable and generate m coded variables, each corresponding to a parity chunk. Vector codes divide each chunk into α equal-sized sub-chunks and treat them as independent variables, increasing the number of variables in the encoding operation by a factor of α.

Limitations of wide-stripe scalar codes. Wide-stripe scalar codes (e.g., LRCs) reduce repair traffic by adding *local parities* on top of global parities, but this increases storage overhead. Consequently, they cannot achieve efficient repair and ultra-low storage overhead simultaneously.

2.2 Scalability Barriers of Vector Codes

In wide-stripe deployments, vector codes face three scalability barriers.

Sub-packetization blowup for minimal repair traffic. Minimizing repair traffic in vector codes comes at the cost of rapidly increasing α. MSR codes achieve optimal repair traffic [39] with $\alpha \geq m^{\lceil \frac{n}{m} \rceil}$ [43], causing severe and often impractical data fragmentation in wide stripes. For example, $(104,100,\alpha)$ Clay codes [34] require $\alpha = 4^{26}$. In practice, storage systems must cap α to limit I/O overhead from data fragmentation, which inevitably increases repair traffic. For example, when $\alpha = 64$, which corresponds to 64 MB chunks and 1 MB sub-chunks, RS-ET [36] and Hashtag+ [37] codes incur over 50% more repair traffic than the optimal bound. It is therefore challenging to design a coding structure that reduces repair traffic without incurring sub-packetization blowup.

Prohibitive search cost for valid coefficients. Two factors make coefficient search intractable: (1) *Expensive per-candidate verification*. A valid coefficient combination must ensure that every $m\alpha \times m\alpha$ coefficient matrix corresponding to any m-chunk failure case is invertible. In a $(106,100,216)$ RS-ET stripe, this requires checking 1.7 billion 1296×1296 matrices, each taking 2.4 ms on our testbed, totaling 1,130 hours. (2) *Frequent rejects*. Any failed invertibility check discards a candidate, and wide stripes have many independent failure cases, causing extremely high reject rates. With coefficients randomly selected from GF(2^{16}), $(76,72,\alpha)$ or wider RS-ET stripes fail to find any valid combination within 10 million trials in our experiments. The candidate space grows exponentially with the number of coefficients, making exhaustive enumeration infeasible.

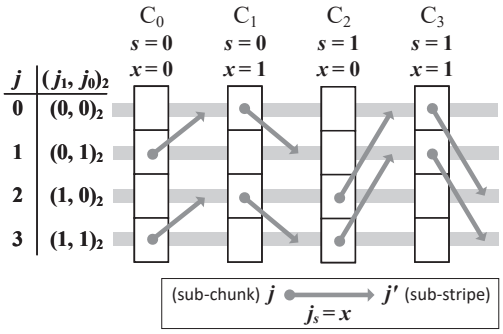

Figure 2: Coding structure of a $(4,2)$ MSR code with $\alpha = 4$. Columns correspond to chunks, each containing 4 sub-chunks. Rows correspond to sub-stripes, each annotated by index j. Rows depict Rule #1 and arrows depict Rule #2.

Excessive encoding cost using the standard method. Standard encoding, multiplying data by a generator matrix, works well for scalar codes [44, 45] but is too costly for vector codes. In the $(106,100,216)$ vector code (§5.1), each column of the generator matrix has up to 126 nonzero entries (vs. 6 in a $(106,100)$ scalar code), dramatically increasing the number of multiplications and lowering encoding throughput to 97 MB/s on our testbed (vs. several GB/s for the scalar code). This motivates developing encoding algorithms that restore computational efficiency.

2.3 MSR Coding Structure and Repair

We introduce the state-of-the-art MSR codes with the lowest sub-packetization levels $\alpha = m^{\lceil \frac{n}{m} \rceil}$ [34, 43, 46], which form the basis of WiseCode.

Coding structure. Each chunk (data or parity, determined by storage systems) is divided into α sub-chunks, and the stripe is organized into α sub-stripes. The sub-chunk to sub-stripe assignment follows two coding rules:

Rule #1. *Sub-Chunk$_j$ of each chunk belongs to Sub-Stripe$_j$ ($0 \leq j < \alpha$).*

Rule #2. *Sub-Chunk$_j$ of Chunk$_i$ also belongs to Sub-Stripe$_{j'}$ when $j' \neq j$. To compute j', express j in the base-m representation as $j = (\ldots, j_2, j_1, j_0)_m$. Let $s = \lfloor \frac{i}{m} \rfloor$, and $x = i \bmod m$. Then replace j_s with x to obtain $j' = (\ldots, j_{s+1}, x, j_{s-1}, \ldots)_m$.*

In Figure 2 for a $(4,2)$ MSR code, rows depict Rule #1 and arrows depict Rule #2. Take Sub-Chunk$_1$ of Chunk$_0$ as an example. Rule #1 assigns this sub-chunk to Sub-Stripe$_1$. Rule #2 sets $i = 0$, $j = (0,1)_2$, $s = 0$, and $x = 0$. This gives $j' = (j_1, x)_2 = (0,0)_2 \neq j$, so the sub-chunk also belongs to Sub-Stripe$_0$.

Coding equations and coefficients. Each sub-stripe defines a linear relation among its sub-chunks, expressed as a

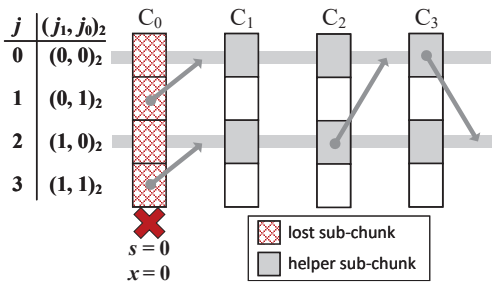

Figure 3: Repair pattern of Chunk_0 in a $(4,2)$ MSR code. Only Sub-Stripe_0 and Sub-Stripe_2 are decoded during repair.

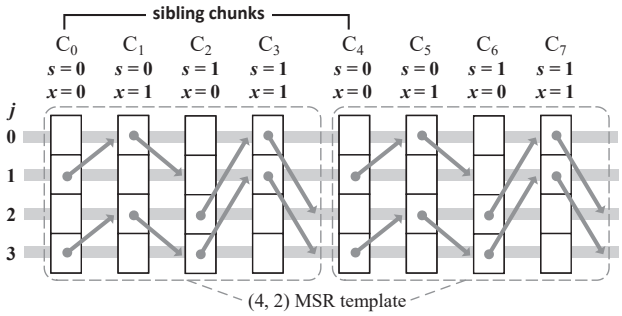

Figure 4: Constructing an $(8,6,4)$ WiseCode stripe using a $(4,2)$ MSR code as the template.

coding equation: $\vec{L}_0 c_0 + \vec{L}_1 c_1 + \cdots = \vec{0}$, where c_i represents a sub-chunk, and $\vec{L}_i$ is an m-element *coefficient vector* over a finite field (e.g., GF(2^8) [34]).

Single-failure repair pattern. Each sub-stripe can recover up to m lost sub-chunks. A lost chunk i is recovered by decoding α/m sub-stripes whose indices j satisfy $j_s = x$, where s and x are defined in Rule #2. Each such sub-stripe contains m lost sub-chunks. Each of the $n-1$ healthy chunks contributes one helper sub-chunk to each selected sub-stripe, incurring the total repair traffic (normalized by α) of $(n-1) \times \frac{\alpha}{m} \times \frac{1}{\alpha} = \frac{n-1}{m}$, which is optimal [39].

Figure 3 shows the repair pattern for Chunk_0 in the $(4,2)$ MSR code. With $s = 0$, and $x = 0$, Sub-Stripe_0 and Sub-Stripe_2 are the two sub-stripes whose indices satisfy $j_s = x$. Sub-Stripe_0 recovers Sub-Chunk_0 and Sub-Chunk_1 of Chunk_0, while Sub-Stripe_2 recovers the remaining two lost sub-chunks. In total, 6 healthy sub-chunks across these two sub-stripes are accessed as helper sub-chunks.

3 Template-Unfold Structure Design

This section presents the template-unfold structure design (§3.1), explains how it achieves near-optimal repair traffic for single-chunk failures (§3.2), shows how it reduces multi-chunk repair traffic (§3.3), and presents the dedicated chunk placement strategy (§3.4).

3.1 Code Construction via Template Unfolding

An (n,k,α) WiseCode constructs the coding structure in two steps: (1) It first selects a (n_{msr}, k_{msr}) MSR code ($n_{msr} < n$) as a *template*, which has the same parity count m and sub-packetization level α with the target coding structure; (2) It then *unfolds the template* by repeatedly instantiating it into multiple *instances* and concatenating sub-stripes with the same index across instances to scale the stripe width, while preserving m and α of the template.

Figure 4 illustrates the coding structure of an $(8,6,4)$ WiseCode where $m = 2$ and $\alpha = 4$, using a $(4,2)$ MSR code as the template. The template is instantiated twice, once for $\text{Chunk}_{0\sim3}$ and once for $\text{Chunk}_{4\sim7}$, with identical sub-chunk to sub-stripe assignments. We refer to chunks from different instances that occupy the same position in the template as *sibling chunks* (e.g., Chunk_0 and Chunk_4). Each chunks inherits the parameters s and x specified by Rule #2 (§2.3) from the template, and sibling chunks share identical s and x.

To generate the n chunks, the (n_{msr}, k_{msr}) template is instantiated $\lceil \frac{n}{n_{msr}} \rceil$ times—so each chunk has $\lceil \frac{n}{n_{msr}} \rceil - 1$ sibling chunks—producing a total of $\lceil \frac{n}{n_{msr}} \rceil \cdot n_{msr}$ chunks. WiseCode supports flexible n by retaining only the first n chunks and treating any remaining chunks as logical zero chunks, which are omitted from physical storage.

While n and k can take arbitrary integer values, α is discrete because the underlying (n_{msr}, k_{msr}) MSR code only supports α in the form of $\alpha = m^{\lceil \frac{n_{msr}}{m} \rceil}$. In practice, WiseCode imposes an upper bound on α by dividing the chunk size (e.g., 64 MB$\sim$1 GB [9, 11]) by an appropriate sub-chunk size (e.g., 1$\sim$4 MB on HDDs and 128 KB on SSDs [47]). WiseCode then selects the MSR template with the largest n_{msr} among those whose α remains within the bound, and sets $k_{msr} = n_{msr} - m$. This design mitigates the I/O overhead from data fragmentation and minimizes instantiations that inflate repair traffic (§3.2).

At this stage, (n,k,α) WiseCode has specified the sub-chunks in each of the α sub-stripes. Each sub-stripe defines a coding equation, where sub-chunks in this sub-stripe appear as variables and the coefficients are specified in Section 4.

3.2 Single-Chunk Failure Repair

An (n,k,α) WiseCode repairs a lost chunk by decoding α/m sub-stripes, each recovering m lost sub-chunks. Their indices j satisfy $j_s = x$, where s and x are the parameters of the lost chunk, inherited from the template (§3.1).

Figure 5 illustrates the repair pattern of Chunk_0 in the $(8,6,4)$ WiseCode. Both Sub-Stripe_0 and Sub-Stripe_2 contain two lost sub-chunks, and decoding them suffices to reconstruct all lost sub-chunks. Each healthy chunk, except Chunk_4, contributes only two helper sub-chunks, while Chunk_4 must

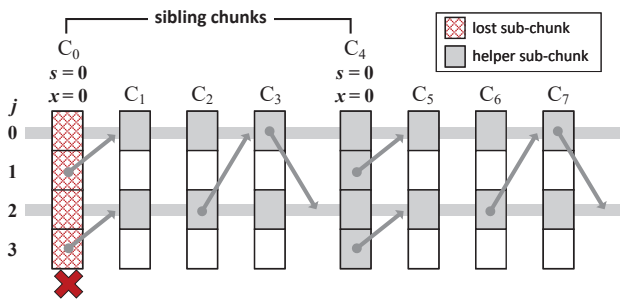

Figure 5: Repair pattern of Chunk_0 in the $(8,6,4)$ WiseCode. Only Sub-Stripe_0 and Sub-Stripe_2 are decoded during repair.

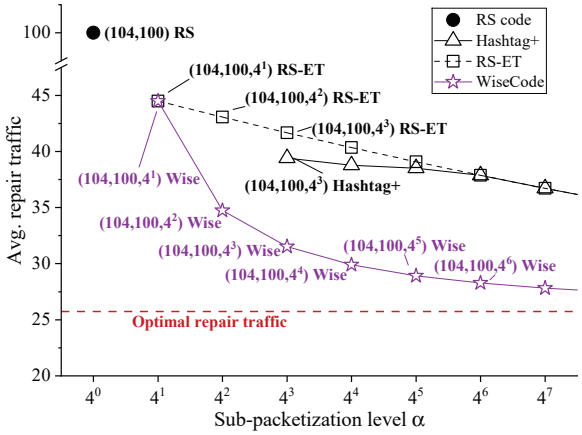

Figure 6: Trade-off between α and repair traffic for $(104,100,\alpha)$ WiseCode, HashTag+, and RS-ET codes.

contribute all 4 sub-chunks as helper sub-chunks. This is because Chunk_4 is a sibling chunk of Chunk_0, which means sub-stripes used to recover Chunk_0 also span the entire Chunk_4.

Generally, the repair pattern of Chunk_i in (n,k,α) WiseCode consists of two parts (proof in Appendix A.4):

❶ Non-sibling part: each healthy chunk that is not a sibling chunk of Chunk_i contributes 1 helper sub-chunk per sub-stripe, totally α/m helper sub-chunks whose indices i satisfy $i_s = x$, where s and x are the parameters of Chunk_i.

❷ Sibling part: each healthy chunk that is a sibling chunk of Chunk_i contributes m helper sub-chunks per sub-stripe. In total, all α sub-chunks serve as helper sub-chunks. □

Traffic analysis. Assuming Chunk_i has z sibling chunks, the repair traffic (normalized by α) is calculated as:

$$\left((n-1-z)\frac{\alpha}{m}+z\alpha\right)\cdot\frac{1}{\alpha}=\frac{n-1}{m}+\frac{m-1}{m}z$$

where the first term $\frac{n-1}{m}$ matches the optimal repair traffic [39], while the second term $\frac{m-1}{m}z$ reflects the overhead introduced by template unfolding.

Since each chunk has $z=\lceil\frac{n}{n_{msr}}\rceil-1$ sibling chunks (§3.1), increasing n_{msr} decreases z and thus reduces repair traffic. However, a larger n_{msr} also increases $\alpha=m^{\lceil\frac{n_{msr}}{m}\rceil}$, exacerbating data fragmentation. To balance this trade-off, WiseCode maximizes n_{msr} under a given upper bound of α (§3.1), thereby *achieving near-optimal repair traffic while mitigating data fragmentation*.

Figure 6 illustrates the trade-off between sub-packetization level (α) and repair traffic in $(104,100,\alpha)$ WiseCode under varied α. With a 64 MB chunk size and 1 MB sub-chunk size, $(104,100,64)$ WiseCode incurs only 22.3% higher repair traffic than the optimal, while with a 512 MB chunk size and 128 KB sub-chunk size, $(104,100,4^6)$ WiseCode incurs only 9.9% higher repair traffic.

Compared with two representative vector codes, HashTag+ [37] and RS-ET [36] codes, WiseCode converges to the optimal repair traffic more rapidly as α increases, achieving 19.3-25.3% lower repair traffic when $4^2\le\alpha\le4^7$ (noting that HashTag+ codes do not support $\alpha=m$ or $\alpha=m^2$). This advantage stems from coding design differences: HashTag+ requires decoding more sub-stripes, while RS-ET accesses more helper sub-chunks per sub-stripe, both of which increase repair traffic.

3.3 Multi-Chunk Failure Repair

Although multiple-chunk failures are rare, there is a growing concern that their likelihood increases in wide stripes in a certain degree [6]. When multiple-chunk failure occurs, WiseCode selects the *minimum subset of sub-stripes* to recover all lost sub-chunks. It uses a greedy strategy, iteratively selecting sub-stripes that maximize *recovery capability*—the number of lost sub-chunks they can recover—until all lost sub-chunks are recoverable.

In each iteration, WiseCode first calculates the recovery capability of the currently selected sub-stripes using a flow model. In this model, each sub-stripe sends up to m flows to the its lost sub-chunks, and any lost sub-chunks that receives at least one flow is considered recoverable. Thus, computing the recovery capability reduces to a max-flow problem. After obtaining the current recovery capability, WiseCode enumerate unselected sub-stripes and adds the sub-stripe that yields the largest increase in recovery capability.

In this way, only a subset of sub-stripes are selected for recovery, thereby significantly reducing the number of helper sub-chunks. For example, in the case of double-chunk failures, $(104,100,64)$ WiseCode incurs an average repair traffic of 66.68, compared to 100 in $(104,100)$ RS codes.

3.4 Fault-Tolerance and Placement Strategy

WiseCode designs its chunk placement policy in two steps: first, it enforces a hard durability constraint to guarantee data persistence against correlated failures; subject to this con-

straint, it then optimizes chunk co-location to minimize cross-rack network traffic.

Uniform fault-tolerance guarantee. Unlike LRCs—where local parities provide less protection than global ones and certain failure patterns involving no more than m chunks remain unrecoverable—WiseCode is designed to achieve the maximum fault-tolerance level, i.e., the MDS property. This property ensures WiseCode can recover from the loss of any m chunks (see §4), thereby provides a uniform fault-tolerance guarantee. This uniformity significantly simplifies chunk placement against correlated failures. For instance, to protect against rack-level correlated failures, a placement policy only needs to ensure that no more than m chunks of the same stripe are placed within a single rack, regardless of their specific chunk indices.

Rack-aware placement. Subject to the constraint that no more than m chunks reside within a single rack, WiseCode leverages its template-unfold design to minimize cross-rack traffic in hierarchical network topologies, where cross-rack bandwidth is typically much more constrained than intra-rack bandwidth [48]. Specifically, when repairing a lost chunk, sibling chunks contribute their entire data, while non-sibling chunks contribute only partial data. WiseCode exploits this asymmetry by grouping sibling chunks within the same rack whenever possible, thereby maximizing intra-rack data exchange and minimizing cross-rack transfers. For example, compared to random placement, rack-aware placement can save 18.9% cross-rack repair traffic for $(106,100,216)$ WiseCode.

4 Repetition-Minimized Coefficient Search

This section presents the repetition-minimized coefficient search, which combines two techniques: divide-and-conquer verification to reduce per-candidate verification cost (§4.1), and neighborhood-prioritized retry to minimize both the overhead of each retry and the number of retries (§4.2).

4.1 Divide-and-Conquer Verification

Given a candidate coefficient combination, WiseCode verifies the decodability of all failure cases in a *divide-and-conquer* manner. It first partitions chunks into disjoint groups and classifies all failure cases into two categories: *intra-group* failure cases where missing chunks lie within the same group, and *inter-group* failure cases where missing chunks span multiple groups. It then verifies decodability only for the intra-group ones, while safely skipping verification for the inter-group ones. This strategy is enabled by the coefficient design and the chunk-partitioning rule, as detailed below.

Coefficient design. In an (n,k,α) WiseCode, coefficients are generated from mn distinct parameters, denoted λ_0 to λ_{mn-1}. Each Chunk$_i$ is associated with m parameters, specifically λ_{im} to $\lambda_{(i+1)m-1}$. For Sub-Chunk$_j$ of Chunk$_i$, WiseCode

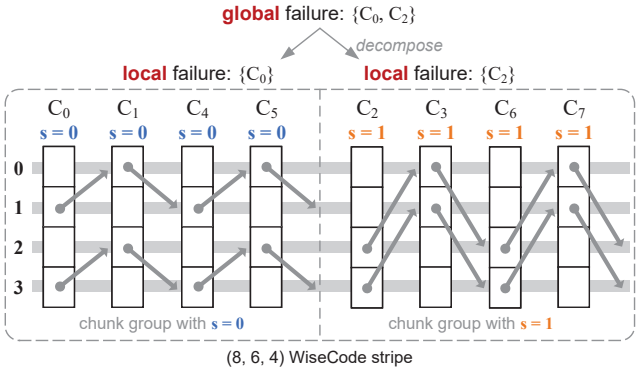

Figure 7: The chunk-partitioning rule groups chunks by s, decomposing a global failure into multiple local failures.

selects the parameter $\lambda = \lambda_{im+j_s}$, where s and j_s are defined in Rule #2 (§2.3). The coefficient vector is then constructed as $\vec{\lambda} = [\lambda^0, \lambda^1, \cdots, \lambda^{m-1}]^T$ and applied to all variables corresponding to this sub-chunk in the coding equations.

Chunk-partitioning rule. WiseCode partitions chunks by their parameters s, forming groups where all chunks share the same s value. Since $s = \lfloor i/m \rfloor$ for $0 \le i < n_{msr}$ (§2.3) takes $\lceil n_{msr}/m \rceil$ distinct values, the chunks are thus partitioned into $g = \lceil n_{msr}/m \rceil$ groups. As shown in Figure 7, in an $(8,6,4)$ WiseCode where $n_{msr} = 4$ and $m = 2$, chunks are partitioned into $g = 2$ groups corresponding to $s = 0$ and $s = 1$.

Below, we explain the correctness of divide-and-conquer verification. An inter-group failure case, referred to as a *global failure case*, can be decomposed into multiple *local failure cases*, each confined to a single group. As shown in Figure 7, in an $(8,6,4)$ WiseCode stripe, a global failure case {Chunk$_0$, Chunk$_2$} is decomposed into two local failure cases, {Chunk$_0$} and {Chunk$_2$}. We prove that global failure cases can be safely omitted from verification through Theorem 4.1 and Theorem 4.2.

Theorem 4.1. *A global failure case is decodable if and only if all corresponding local failure cases are decodable.*

Proof sketch. The proof follows a similar approach to prior theoretical work on MSR codes [49]. The key idea is to decompose the coefficient matrix of a global failure case into multiple sub-matrices, each corresponding to a local failure case, such that the overall matrix is invertible if and only if all sub-matrices are invertible (Appendix A.6). □

Theorem 4.2. *Every local failure is a subset of some m-chunk intra-group failure. If this m-chunk failure case is decodable, the local failure case is also decodable.*

Proof. Every local failure involves fewer than m lost chunks, and by adding chunk(s) from the same group we obtain the corresponding m-chunk intra-group failure. If that m-chunk failure is decodable, then any subset of its lost chunks—including the current local failure—is also decodable. □

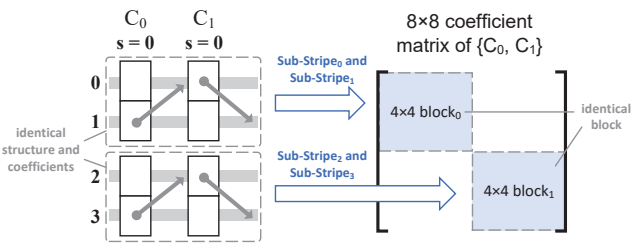

Figure 8: Coefficient matrices for chunks within a group exhibit a matrix-block-repetition pattern.

Consequently, WiseCode only needs to verify all m-chunk intra-group failure cases, totaling $g \times \binom{n/g}{m}$ cases—a small fraction of all $\binom{n}{m}$ possible failure cases. For example, in a $(106, 100, 216)$ WiseCode where $g = 3$, only 5.2 million failure cases ($\sim$0.3% of all failure cases) require verification.

Matrix size reduction. WiseCode also reduces the size of matrices to be verified according to a useful structural property under chunk partitioning: the coefficient matrix associated with chunks within a single group exhibits a *matrix-block-repetition pattern*. Specifically, it contains α/m identical diagonal matrix blocks, each corresponding to a set of m sub-stripes, with all sub-stripe sets sharing identical coding structures and coefficient assignments (Appendix A.5). As shown in Figure 8, the coefficient matrix of $\{\text{Chunk}_0, \text{Chunk}_1\}$ in the $s = 0$ group consists of two identical matrix blocks, one for Sub-Stripe$_0$ and Sub-Stripe$_1$, and another for the remaining sub-stripes. Therefore, WiseCode verifies invertibility by checking only a single matrix block rather than the entire matrix, reducing the computation cost to m/α of the original.

Overall, WiseCode significantly accelerates verification by reducing both the number of failure cases and the size of matrices to be verified. For example, in a $(106, 100, 216)$ stripe, WiseCode requires verifying only 5.2 million matrices of size 36×36, which can be completed within 3 minutes, achieving a speed-up of over $20,000\times$ compared to 1130 hours required by RS-ET code.

4.2 Neighborhood-Prioritized Retry

If a candidate coefficient combination fails verification, the search continues exploring new candidates until a valid one is found. To reduce retry overhead and accelerate convergence to valid solutions, WiseCode employs a *neighborhood-prioritized retry* strategy. Instead of resampling all coefficients, it updates only a small subset of coefficients while retaining the verified ones, generating a *neighborhood* of the rejected candidate. This localized adjustment preserves the decodability of most previously-verified failure cases, thereby avoiding redundant verification work.

To track which coefficients are retained, WiseCode treats each chunk's coefficients as a chunk-level *entry*, managed

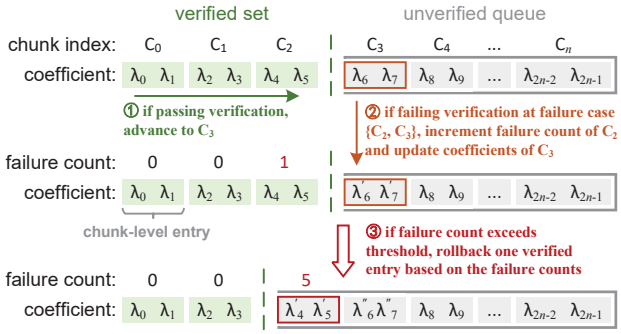

Figure 9: Three actions in each neighborhood-prioritized retry step: (1) advance, (2) update, and (3) rollback.

through a *verified set* and an *unverified queue*. A chunk is considered (un)verified if its coefficients are (un)verified. The unverified queue, initially containing all entries ordered by chunk index, is manipulated through *advance* and *rollback* operations described later. In each step, WiseCode updates only the coefficients of the entry at the front of the unverified queue, marking its corresponding chunk as the current one.

To determine which failure cases require verification, WiseCode groups chunks using the chunk-partitioning rule (§4.1) and identifies the group containing the current chunk. It then verifies only failure cases that involve the current chunk and any $m-1$ verified chunks within the same group. Failure cases involving only m verified chunks require no repeated verification since their coefficients remain unchanged. WiseCode also maintains a *failure count* for each verified entry, reflecting its contribution to failed verifications and guiding rollback decisions.

As shown in Figure 9, each search step operates on entries parameterized by λ (§4.1) and performs one of three actions:

1. **Advance**. If all required failure cases pass verification, WiseCode moves the current entry to the verified set and proceeds to the next unverified entry (or terminates if none remain);

2. **Update**. If verification fails, WiseCode increments the failure counts of involved verified entries and randomly re-samples the λ values of the current entry for retry;

3. **Rollback**. If any failure count exceeds a threshold, WiseCode randomly selects a verified entry (weighted by its failure count), updates its coefficients, moves it to the front of the unverified queue, and resets all failure counts.

Search overhead. WiseCode reduces both per-candidate verification cost and retry count, since failure cases composed entirely of verified chunks require no verification and never trigger retry. We conduct repeated experiments to compare the search overhead of the neighborhood-prioritized strategy with a naive baseline, *exhaustive enumeration*, which re-samples λ values for all entries and retry the verification of all failure cases whenever a candidate is rejected.

Table 1: Comparison of exhaustive enumeration (Baseline) and neighborhood-prioritized retry (Ours) in pre-candidate verification time, retry count, and total search time.

Stripe configuration	Verification time		# Retry		Total search time	
	Baseline	Ours	Baseline	Ours	Baseline	Ours
(104, 100, 16)	36.0 ms	2.49 ms	279	117	5.93 s	3.78 s
(104, 100, 64)	22.3 ms	0.78 ms	42	34	1.10 s	1.14 s
(105, 100, 25)	861 ms	66.0 ms	> 1.6e6	2047	> 24 h	131 s
(105, 100, 125)	819 ms	16.5 ms	> 1.6e6	312	> 24 h	21.0 s
(106, 100, 216)	2113 ms	163 ms	> 6.3e5	2403	> 24 h	341 s

Table 2: Maximum stripe width achievable from coefficient search over GF(2^{16}), for given m and α.

Code configuration		m=4	m=5	m=6	m=7	m=8
WiseCode	$\alpha = m$	232	80	48	35	27
	$\alpha = m^2$	464	160	96	70	54
	$\alpha = m^3$	696	240	144	105	81
HashTag+	$\alpha = m^3$	87	39	25	19	17
RS-ET	$\alpha = m$	72	46	30	28	24
	$\alpha = m^2$	65	40	34	25	26
	$\alpha = m^3$	68	45	31	20	15

Both strategies use 20 threads that verify different candidates in parallel. The neighborhood-prioritized retry synchronizes the candidate across threads whenever any thread advances or the failure count (aggregated across threads) of any verified entry exceeds the rollback threshold, which is set to 1000. All coefficients and λ parameters are defined over the finite field GF(2^{16})[1]. We measure the per-candidate verification time, retry count, and the total search time, averaged over 10 independent runs (Table 1). For $(104, 100, 16)$ and $(104, 100, 64)$ stripes, our method accelerates per-candidate verification by up to 28.6× and reduces retry count by up to 58%, while the total search time remains comparable due to additional synchronization overhead. For stripes with larger m—$(105, 100, 25)$, $(105, 100, 125)$, and $(106, 100, 216)$—our method finishes the search within 6 minutes, whereas the baseline fails to find valid solutions within 24 hours due to excessive retries.

Scalability in stripe width. We evaluate WiseCode's scalability by targeting a large stripe width of 1000 and measuring the maximum number of verified chunks—denoted as n^*—achieved with 20 threads within a 24-hour search period. At this point, the first n^* chunks have been verified, enabling any stripe of width n' ($n' \leq n^*$) to be constructed by the first n' chunks. For comparison, HashTag+ and RS-ET codes adopts a similar neighborhood-prioritized retry strategy, but without divide-and-conquer verification.

As shown in Table 2, WiseCode enables stripe widths up to several hundred with $4 \leq m \leq 8$. The achievable stripe width increases with α, because a higher α enlarges both n_{msr} and the group count $g = \lceil n_{msr}/m \rceil$, reducing intra-group failures and thereby accelerating the search. In contrast, HashTag+ and RS-ET are restricted to stripe widths of only a few tens, since the absence of divide-and-conquer verification forces them to check too many failure cases, significantly impeding the search process.

Existence of valid coefficients. Prior studies [35, 36] address the finite field size required to guarantee the existence of valid coefficients. For example, to ensure a valid coefficient assignment, a $(70, 66, 4)$ RS-ET code requires a field size $\geq 2(\binom{n-1}{k-1} - \binom{\lceil n/\alpha \rceil - 1}{\lceil k/\alpha \rceil - 1})$, which equals 1.7e6. However, as shown in Table 2, $(70, 66, 4)$ RS-ET code is successfully supported by GF(2^{16}) with a field size of 65536, suggesting that existing theoretical bounds are overly conservative. While determining the maximum stripe width supported by a given finite field remains an open problem, the results in Table 2 strongly suggest that the theoretical ceiling for WiseCode's scalability is substantially higher; we provide further empirical analysis in the Appendix A.2 to validate this inference.

5 Two-Stage Encoding Framework

This section presents the two-stage encoding framework that requires much fewer multiplications than standard generator matrix encoding (§5.1) and explains how it extracts common operations during *data aggregation* (§5.2) and decomposes *parity solving* into computation-efficient steps, followed by extending these optimizations to the decoding process (§5.3).

5.1 Design Overview

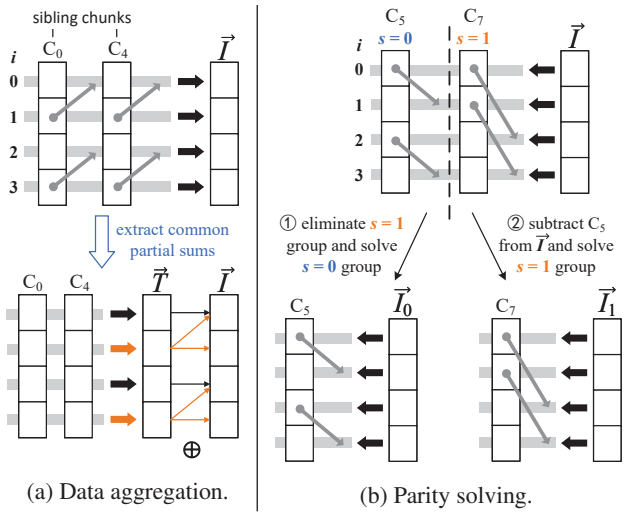
Once the parity chunks are designated, the coding equations can be expressed in matrix form as $C_D \times D + C_P \times P = \vec{0}$, where D and P denote the $k\alpha$ data sub-chunks and $m\alpha$ parity sub-chunks, and C_D and C_P are the corresponding $m\alpha \times k\alpha$ and $m\alpha \times m\alpha$ coefficient matrices, with C_P guaranteed invertible (§4). The standard encoding approach [45, 50] constructs the generator matrix $G = -{C_P}^{-1} \times C_D$ and computes $P = G \times D$.

However, the standard encoding approach is costly for WiseCode. In a $(106, 100, 216)$ WiseCode stripe, encoding with G requires 17–126 multiplications per data sub-chunk (depending on which chunks are designated as parity), while each coefficient vector in the coding equations contains only $m = 6$ elements. We make the following observation.

Observation 5.1. *The number of multiplications incurred by the nonzero entries in G far exceeds the number of coefficients in the coding equations.*

Motivated by this observation, WiseCode reduces multiplications—the dominant cost relative to additions—by multiplying each data sub-chunk only by its own coefficient vector and introducing a two-stage encoding framework:

[1]This choice balances coefficient design requirements and arithmetic complexity: GF(2^8) limits the stripe width to $256/m$ because coefficient design requires mn unique parameters (§4.1) but GF(2^8) provides only 256; GF(2^{32}) decreases multiplication throughput by 51.6% compared to GF(2^{16}).



(a) Data aggregation. (b) Parity solving.

Figure 10: Encoding scheduling: (a) extracting common data sums to eliminate redundant aggregation operations; (b) solving parity chunks using a divide-and-conquer strategy.

1. **Data aggregation**. Within each sub-stripe, data sub-chunks are multiplied by their m-element coefficient vectors and summed position-wise, producing an m-element aggregated-result vector. Concatenating the aggregated-result vectors from all α sub-stripes yields an $m\alpha$-element intermediate vector $\vec{I}$ that satisfies $\vec{I} = C_D \times D$.
2. **Parity solving**. After replacing $C_D \times D$ by $\vec{I}$, the parity sub-chunks P are then solved from the resulting coding equations $C_P \times P = -\vec{I}$.

This framework enables WiseCode to extract common operations across sub-stripes during data aggregation and follow a divide-and-conquer manner to process parity solving.

5.2 Extraction of Common Data Operations

During data aggregation, when a data sub-chunk contributes to multiple sub-stripes, it is multiplied by the same coefficient vector across those sub-stripes, as dictated by the coefficient selection (§4.1), yielding identical multiplication-result vectors. Moreover, sibling chunks follow the same coding structure, so sub-chunks with the same index across sibling chunks map to the same set of sub-stripes. Leveraging these properties, WiseCode extracts common partial sums from the multiplication-result vectors of sibling chunks, enabling their reuse across sub-stripes.

We illustrate the process of data aggregation using an $(8,6,4)$ WiseCode stripe (Figure 10a), where Chunk_0 and Chunk_4 are data chunks and form a pair of sibling chunks. Sub-chunks in each row are multiplied by their respective m-element coefficient vectors and summed to obtain an m-element common partial sum $\vec{T}$ for this row. The resulting $\vec{T}$ is then accumulated into the corresponding positions of $\vec{I}$ according to the sub-chunk to sub-stripe mapping. To minimize memory traffic, each element of $\vec{T}$ is added to $\vec{I}$ immediately after it is computed, avoiding temporary storage of $\vec{T}$ in memory. The remaining chunks are processed together with their sibling chunks (if any) in the same manner to complete the computation of $\vec{I}$.

Cost analysis. By extracting common partial sums, each of the $k\alpha$ data sub-chunks is multiplied by its m-element coefficient vector only once, leading to a total of $km\alpha$ multiplications. From the coding rules (§2.3), we observe that a fraction $(m-1)/m$ of all sub-chunks participate in two sub-stripes instead of one. Consequently, this method reduces the number of multiplications during data aggregation by $(m-1)/(2m-1)$.

5.3 Divide-and-Conquer Parity Solving

During parity solving, directly computing $P = -C_P^{-1} \times \vec{I}$ is prohibitively expensive because C_P^{-1} can be up to $10\times$ denser than C_P. Instead, WiseCode uses a divide-and-conquer strategy that operates on sub-matrices with sparse inverses. Parity chunks are partitioned into groups using the same chunk-partitioning rule as §4.1, which correspondingly partitions C_P into sub-matrices. As discussed in Section 4.1, each sub-matrix exhibits a matrix-block-repetition structure with nonzero entries confined to the matrix blocks, and its inverse preserves this sparsity[2]. WiseCode therefore performs matrix elimination and inversion at the sub-matrix granularity, using each sparse inverse to independently and efficiently solve the corresponding parity group.

Figure 10b illustrates this process for an $(8,6,4)$ WiseCode stripe. Chunk_5 and Chunk_7 are parity chunks and belong to groups with $s=0$ and $s=1$, respectively. To solve the $s=0$ group, WiseCode first eliminates the $s=1$ group via linear transformations (Appendix A.6), leaving only the $s=0$ sub-matrix and a transformed vector $\vec{I}_0$ (from $\vec{I}$). It then inverts this sub-matrix and multiplies it with $\vec{I}_0$ to obtain the $s=0$ group $\{\text{Chunk}_5\}$. After subtracting the contribution of Chunk_5 from $\vec{I}$ to produce $\vec{I}_1$, only the $s=1$ group remains unknowns. WiseCode applies the same procedure to solve the $s=1$ group $\{\text{Chunk}_7\}$.

In general, when parity chunks span multiple groups, WiseCode recursively eliminates groups until one remains, solves that group, and continues solving the remaining groups sequentially as the recursion unwinds.

Cost analysis. The divide-and-conquer parity solving incurs $O(m^3\alpha)$ multiplications (Appendix A.7), compared to $O(m^2\alpha^2)$ for directly computing $P = -C_P^{-1} \times \vec{I}$. Overall, the two-stage encoding process performs $km\alpha + O(m^3\alpha)$ multiplications, whereas the standard approach that directly computes $P = G \times D$ requires $O(km\alpha^2)$. WiseCode processes sub-chunks at a default 4 KB granularity (e.g., an 8 KB sub-chunk is processed as two 4 KB units), and therefore requires

[2]Since each matrix block appears independently and identically, we can invert them block-wise while preserving the repetition structure.

an additional $m\alpha\times$4KB of memory (within 5 MB in our experiments) to store the $m\alpha$-element intermediate vector $\vec{I}$ and other temporary results.

Extending to Decoding. During decoding, healthy chunks are treated as data chunks and aggregated using the same data-aggregation stage. Lost chunks are then partitioned into groups and recovered using the same divide-and-conquer parity-solving strategy.

6 Implementation

To demonstrate WiseCode's portability, we integrate it into Ceph [8, 51], a widely used open-source distributed storage system (§6.1). Because Ceph's native workflow is not adaptable to advanced repair scheduling, we also combine WiseCode with several representative scheduling methods to illustrate its compatibility with prior techniques (§6.2).

6.1 Ceph Erasure-Code Plugin

Although WiseCode introduces several coding-level designs, deploying it in an existing storage system requires only two essential operations: (1) identifying helper sub-chunks during repair, and (2) performing encoding or decoding using its dedicated algorithms. The coefficients obtained (§4) are stored in the system configuration, avoiding any runtime search.

To simplify integration with existing storage systems, we package WiseCode as an erasure-code plugin with two core functions: one identifies the required helper sub-chunks for given lost chunks, and the other performs encoding or decoding over available chunks. The finite field arithmetic for encoding and decoding is implemented with AVX-512 instructions [52], following GF-Complete [50]. We integrate this plugin into Ceph v17.2.5 with only ∼400 lines of C++ glue code, enabling Ceph's OSDs (Object Storage Daemons) to invoke the wrapped functions.

6.2 Integration with Repair Scheduling

Degraded read. We accelerate degraded reads using partial-parallel repair [19] and repair pipelining [20], two *intra-stripe scheduling* methods that select relay nodes to perform partial repairs[3] in parallel. With WiseCode, a node storing a non-sibling chunk of the lost chunk cannot serve as a relay because it would need to transmit a full-chunk partial result rather than a subset of sub-chunks (§3.2), increasing repair traffic. We therefore restrict relay selection to nodes storing sibling chunks, while keeping each method's original scheduling logic between the relays and the target node unchanged. Non-relay nodes simply distribute their helper data evenly across the relays and the target node.

[3]Partial repair produces a partial result using a subset of helper data (treating other helper data as zeros); summing all partial results recovers the lost chunk. WiseCode, being linear, supports this naturally.

Full-node repair. We accelerate full-node repair using RepairBoost [21], an *inter-stripe scheduling* method that reorders transmissions across stripes to improve network utilization and runs atop any intra-stripe scheduling method—partial-parallel repair, repair pipelining, or conventional repair (without relays). With WiseCode, RepairBoost only needs to account for the lower traffic contribution of non-sibling chunks than sibling chunks of the lost chunk, estimating network utilization using weighted rather than uniform traffic.

All methods are implemented in a ∼6.9K-line C++ prototype comprising a coordinator that issues repair tasks and multiple agents that execute repair operations, with gRPC [53] for inter-node communication.

7 Evaluation

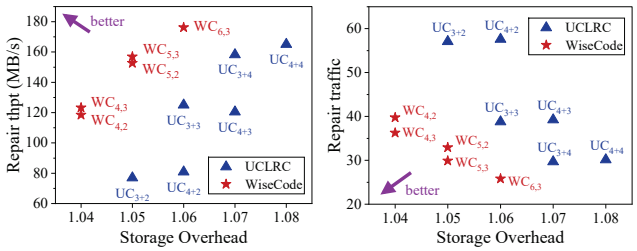
7.1 Methodology

We evaluate WiseCode against UCLRC (Uniform Cauchy LRC [6]), the state-of-the-art wide codes. We first use Ceph as the development platform, implementing both codes as erasure-code plugins for fairness, and examine offline and online repairs triggered by manually disabling one storage node. We measure repair throughput (repaired-data size divided by repair time), foreground I/O latency during online repair, and normal-write and degraded-read latencies without background repair. We then evaluate both codes with representative repair-scheduling techniques: RepairBoost [21] for full-node repair, and three strategies for single-chunk degraded reads—conventional repair (CR), partial-parallel repair (PPR) [19], and repair pipelining (RP) [20].

Code configurations. We configure UCLRC with (n,k,r,p), where r and p denote the numbers of global and local parities, to control storage overhead, repair traffic, and reliability (measured via MTTDL; see Appendix A.1). Both WiseCode and UCLRC use $k=100$, with remaining parameters varied to explore design trade-offs. Table 3 summarizes all configurations. UC_{r+p} denotes a $(100+r+p,100,r,p)$ UCLRC, and $\mathrm{WC}_{m,b}$ denotes a $(100+m,100,m^b)$ WiseCode.

Testbed. Experiments run on a cluster of 161 ecs.hfg6.large instances [54] on Alibaba Cloud. Each instance has 2 vCPUs and 8 GB RAM. Among them, 120 serve as storage nodes, each with a 100 GB elastic SSD (∼170 MB/s bandwidth), one is the monitor, and 40 act as clients. All instances connect via a 1 Gbps network.

System and workload settings. On Ceph, we use 512 placement groups [55] for balanced chunk distribution. Storage is prefilled using YCSB [56] with 4000 records (1.46 TB). During online repair, each client issues YCSB requests with read:write ratios of 50:50 (YCSB-a), 100:0 (YCSB-c), and 0:100 (YCSB-w), as summarized in Table 4. We emulate light and heavy loads using 10 and 40 clients. For evaluations with repair scheduling, 1000 stripes are randomly placed across the cluster before repair. RP is configured with a 32 KB slice



(a) Offline repair throughput. (b) Measured repair traffic.

Figure 11: Repair throughput and measured repair traffic during offline repair on Ceph.

size following prior work [20].

Chunk-size settings are listed in Table 5. In Ceph experiments, UCLRC uses a 4 MB chunk size; we avoid larger chunks (e.g., 8 MB) because Ceph performs client I/O at full-stripe granularity, which becomes very large under wide stripes and can trigger Out-Of-Memory failures on Ceph's OSDs in our testbed, particularly when multiple requests target the same OSD concurrently. For repair-scheduling experiments, UCLRC follows prior work [20, 21] and uses 64 MB chunks. WiseCode derives its chunk size from the corresponding UCLRC configuration, rounding up to the nearest multiple of $\alpha \cdot 4$ KB to satisfy 4 KB sub-chunk alignment, and this adjustment does not bring any unfair performance advantage.

7.2 Overall Performance with Ceph

Offline repair. Figures 11a and 11b show offline repair throughput and repair traffic (total network traffic divided by size of repaired chunks) versus storage overhead, averaged over 5 independent runs. The results show that WiseCode achieves a strictly better throughput-overhead tradeoff than UCLRC. With storage overhead 1.06, $WC_{6,3}$ achieves 2.18× and 1.41× the repair throughput of UC_{4+2} and UC_{3+3}, respectively. With storage overhead 1.05, $WC_{5,3}$ outperforms UC_{3+2} by 2.04× in the repair throughput. These throughput gains stem from WiseCode's reduced repair traffic, which enables faster recovery under the same network bandwidth.

Multi-dimensional Pareto Improvement. Figure 12 illustrates the joint improvements in storage overhead, reliability, and repair throughput. Unlike MTTDL analysis in Table 3, which assumes full network bandwidth utilization during repair, the repair rate used in the reliability model for this figure is derived from the observed repair throughput and node capacity in our testbed. Results show that, with a consistent overhead of 1.05, $WC_{5,2}$ offers two orders of magnitude higher MTTDL and 1.98× higher repair throughput compared to UC_{3+2}. $WC_{6,3}$ outperforms UC_{4+4} by offering 2% lower overhead, 1.81× higher MTTDL, 14.4% lower repair traffic, and 6.8% higher repair throughput against UC_{4+4}. We further conduct an iso-MTTDL comparison by interpolating UCLRC results along log-linear curve (mapping log MTTDL to linear throughput) within the same overhead configurations. Our analysis shows that with the same MTTDL, $WC_{5,2}$ offers 1.53× higher repair throughput with 1% lower overhead, or 1.11× higher repair throughput with 2% lower overhead compared to UCLRC.

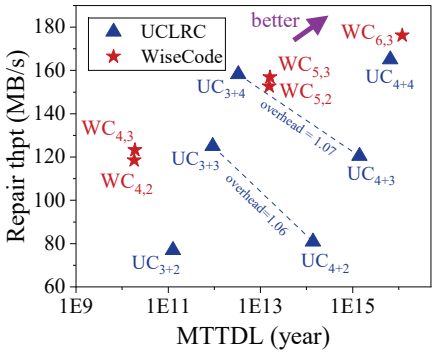


Figure 12: Joint comparison of storage overhead, MTTDL and repair throughput between WiseCode and UCLRC.

Online repair. Figure 13 plots average foreground I/O latency versus background repair throughput. At equal storage overhead, WiseCode improves both metrics: $WC_{6,3}$ delivers 36%–102% higher repair throughput and 11%–27% lower I/O latency than UC_{4+2}. Even against UC_{4+4}, which has 2% higher storage overhead than $WC_{6,3}$, $WC_{6,3}$ attains 27.7%–45.6% higher repair throughput with comparable I/O latency (within ±5%), except under YCSB-c with 40 clients, where it yields 38% higher throughput with 10% higher latency.

Normal-write and degraded-read latencies. Figure 14 shows normal-write (YCSB-w) and degraded-read (YCSB-c) latencies, each averaged over a 3-minute run. All codes exhibit similar performance (within ±5%), indicating that WiseCode introduces negligible read/write overhead, except a 6% latency increase for $WC_{5,3}$ (YCSB-c, 40 clients) and 7% for $WC_{6,3}$ (YCSB-c, 10 clients). These deviations stem from WiseCode's chunk-size rounding (Table 5), which causes Ceph to pad zeros and inflate I/O. In practice, this effect can be eliminated via precise chunking techniques [9, 27].

7.3 Performance with Repair Scheduling

Full-node repair. Figure 15 shows full-node repair throughput versus storage overhead, averaged over 5 independent runs. We present results using CR as the intra-stripe scheduling strategy for RepairBoost, as it consistently outperforms PPR and RP for both WiseCode and UCLRC in our experiments. The results show that WiseCode achieves a strictly better throughput-storage tradeoff than UCLRC, exhibiting the same performance advantages observed in the Ceph experiments. For example, with storage overhead 1.06, $WC_{6,3}$ achieves 2.38× and 1.56× the repair throughput of UC_{4+2} and UC_{3+3}, respectively. Even against UC_{4+4}, $WC_{6,3}$ achieves 13.6%

Table 3: Evaluated codes with their storage overhead, theoretical repair traffic for a single-chunk failure, and MTTDL. UC_{r+p} denotes a $(100+r+p, 100, r, p)$ UCLRC, and $WC_{m,b}$ denotes a $(100+m, 100, m^b)$ WiseCode.

Code	UC_{3+2}	UC_{3+3}	UC_{3+4}	UC_{4+2}	UC_{4+3}	UC_{4+4}	$WC_{4,2}$	$WC_{4,3}$	$WC_{5,2}$	$WC_{5,3}$	$WC_{6,3}$
Storage overhead	1.05	1.06	1.07	1.06	1.07	1.08	1.04	1.04	1.05	1.05	1.06
Repair traffic	51.50	34.33	25.75	52.00	34.67	26.00	34.75	31.52	28.42	25.60	21.59
MTTDL (years)	2.51×10^{10}	1.69×10^{11}	6.38×10^{11}	2.59×10^{13}	2.64×10^{14}	1.20×10^{15}	3.47×10^{9}	3.82×10^{9}	2.83×10^{12}	3.14×10^{12}	2.46×10^{15}

Table 4: Workloads used in the Ceph experiments.

Workload	R/W ratio	# Records	# KV pairs	Value size	Total
YCSB-a	50%/50%				
YCSB-c	100%/0%	4000	400	10^6 B	1.46 TB
YCSB-w	0%/100%				

Table 5: Chunk sizes used in the two sets of experiments.

Chunk size (KB)	UCLRCs	$WC_{4,2}$	$WC_{4,3}$	$WC_{5,2}$	$WC_{5,3}$	$WC_{6,3}$
Ceph	4096	4096	4096	4100	4500	4320
Repair-scheduling	65536	65536	65536	66000	66000	65664

higher repair throughput, despite 2% lower storage overhead.

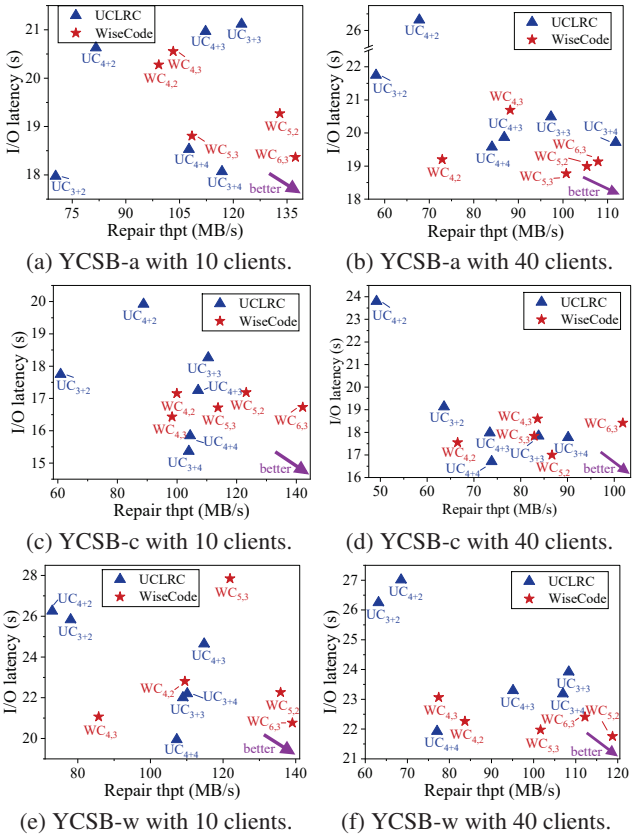
Single-chunk degraded read. Figure 17 shows single-chunk degraded-read latency, averaged over 10 independent runs. The results show that WiseCode's improvements vary across the three methods. For example, at equal storage overhead, WiseCode reduces degraded-read latency by 32%–55% compared to UCLRC under CR, due to its 37%–58% lower repair traffic. Under PPR, WiseCode and UCLRC achieve comparable latencies. In contrast, under RP, WiseCode incurs 117%–200% higher latency than UCLRC because the relay-selection constraints limit scheduling flexibility (§6.2).

The potential increase in pipelining latency represents an acceptable tradeoff for two primary reasons. First, this overhead only impacts foreground degraded reads, while WiseCode significantly enhances background repair throughput, which shortens the degraded window and directly improves MTTDL. Second, the performance impact is minimal given the rarity of failure states. Modeling with either Binomial distribution or Markov chain indicates that a stripe resides in degraded states for less than 1% of its total lifetime. This translates to a negligible impact on aggregate read performance, especially for warm and cold storage where accesses are infrequent and latency-insensitive [57].

7.4 Ablation Study of Two-Stage Coding

We measure WiseCode's computational overhead by encoding and decoding a stripe from k in-memory chunks using a single thread. Coding throughput is defined as the stripe size divided by the coding time, averaged over 10 independent runs, with chunk sizes matching the Ceph experiments.

We evaluate four variants to isolate each optimization: (1) **baseline**: generator-matrix encoding; (2) **+framework**: two-stage encoding framework only; (3) **+stage-1 opt**: framework plus data-aggregation optimization; (4) **+full opts**: all optimizations enabled (parity-solving optimization added).



(a) YCSB-a with 10 clients. (b) YCSB-a with 40 clients.

(c) YCSB-c with 10 clients. (d) YCSB-c with 40 clients.

(e) YCSB-w with 10 clients. (f) YCSB-w with 40 clients.

Figure 13: Foreground I/O latency and background repair throughput during online repair on Ceph.

As shown in Figure 16, the two-stage framework and the data-aggregation optimization increase throughput by 2.6×–3.0× and 2.0×–5.0×, respectively. The parity-solving optimization provides an additional 1.5×–1.8× speedups for $WC_{5,3}$ and $WC_{6,3}$. Overall, the two-stage encoding approach achieves 5.5×–22.4× throughput over the baseline.

7.5 Applicability to Diverse Hardware

Applicability to HDDs. While our cloud testbed uses SSDs, as in production wide-stripe deployments such as VastData [58], we also evaluate WiseCode's applicability to HDDs, which remain prevalent for their lower cost per byte [59]. We examine HDD read bandwidth during repair, where read operations dominate (95%–97%) but may be slowed by data fragmentation incurred by sub-packetization.

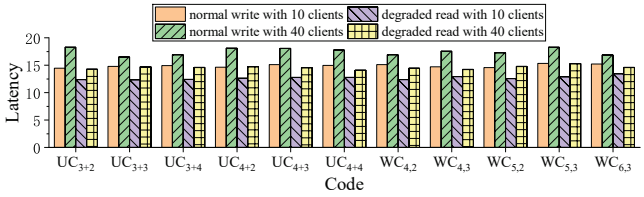


Figure 14: Normal-write and degraded-read latencies on Ceph.

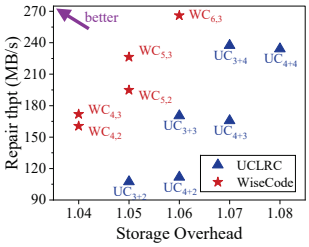

Figure 15: Full-node repair throughput with RepairBoost.

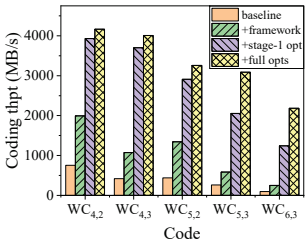

Figure 16: Coding throughput.

For example, during the repair process of $WC_{4,2}$, each helper chunk exhibits one of three read patterns with different percentages: repeatedly reading 1 sub-chunk and skipping 3 (44.2%), reading 4 consecutive sub-chunks (44.2%), or reading all 16 sub-chunks (11.6%).

We emulate these read patterns on a 7200 RPM HDD using *fio* [60] (iodepth = 8), measure per-pattern read bandwidth, and compute the percentage-weighted average, as shown in Figure 18. The results show that fragmentation reduces read bandwidth, but WiseCode still match raw network bandwidth with practical chunk sizes (e.g., 12 MB or 64 MB), ensuring that HDDs are not the bottleneck in the read-transfer pipeline [21]. Under the 1 Gbps (∼125 MB/s) network in our testbed, $WC_{4,2}$ requires 12 MB or larger chunks, and $WC_{6,3}$—despite its higher sub-packetization level—requires 64 MB or larger, both easily satisfied by the 64 MB–1 GB chunk sizes used in production [9, 11].

Applicability to faster network. Production nodes typically pair high-bandwidth network (e.g. 10+ Gbps) with high-density disk arrays (e.g., 36–216 HDDs [61]) to maximize network utilization. For instance, the Amazon D3.8xlarge instance [62] pairs 25 Gbps network with 24 HDDs, while the Tencent Cloud DA4m.32XLARGE512 instance [63] pairs 100 Gbps (50 Gbps full-duplex) network with 48 HDDs. For these big-data-oriented instances, WiseCode's repair improvement remains highly applicable because the aggregate storage bandwidth typically exceeds the network capacity. Specifically, as WiseCode achieves over 130 MB/s per disk (with 64 MB chunks), a disk array with 24 HDDs can provide over 25 Gbps of aggregate I/O, which matches the 25 Gbps network and does not become a bottleneck. Furthermore, given its high coding throughput (> 2000 MB/s), WiseCode can process 10+ Gbps network traffic using only a single dedicated CPU thread without incurring computational bottleneck.

8 Related Work

Wide codes. Most wide-stripe solutions are based on LRCs [6, 17, 27, 29, 30], which reduce repair traffic but sacrifice the MDS property. WiseCode is the first wide-stripe vector code that achieves near-optimal repair traffic while preserving the MDS property. VAST [58] designs a wide-stripe locally decodable code, but its design details remain undisclosed.

Vector codes. Clay codes [34], Butterfly codes [32], and other MSR codes suffer from sub-packetization blowup in wide stripes. Zigzag codes [64] alleviate this only for $m = 2$, offering insufficient reliability in wide stripes. HashTag+ [37] and RS-ET [36] codes avoid sub-packetization blowup but incur higher repair traffic than WiseCode and face the scalability barrier in coefficient search. WiseCode cannot yet support the flexible sub-packetization levels of RS-ET codes due to limitations of current MSR templates; future work will explore new template designs to enable this.

Repair scheduling. Prior work [19–21, 24] optimizes repair transmission schedules to better utilize network resources and accelerate repair. WiseCode is complementary: it reduces repair traffic itself and can be combined with these scheduling techniques through appropriate adaptions, as discussed in Section 6.

9 Conclusion

By breaking three scalability barriers, we present WiseCode, the first practical and scalable wide-stripe vector-coding approach that achieves near-optimal repair traffic and ultra-low storage overhead (e.g., 1.04–1.06) in large-scale storage clusters. Experimental results show that WiseCode delivers a strictly better tradeoff between repair performance and storage overhead than Google's UCLRCs.
