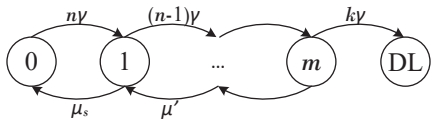

Figure 19: Markov model used for reliability analysis.

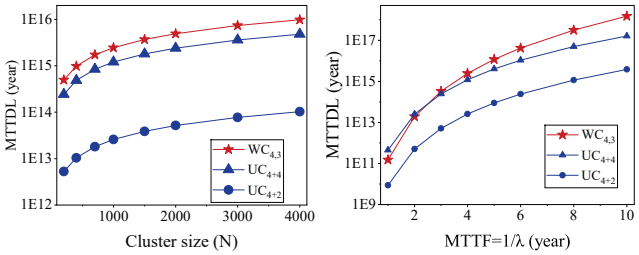

(a) Varying cluster size N. (b) Varying MTTF $1/\lambda$.

Figure 20: Sensitivity analysis on MTTDL.

A Appendix

A.1 MTTDL and Markov Model

We evaluate data reliability using the mean-time-to-data-loss (MTTDL) metric, modeled via continuous-time Markov chains following prior works [6, 27]. As shown in Figure 19, each circles corresponds to a health states of a stripe: state i indicates that i chunk(s) are lost, while the Data Loss (DL) state represents unrecoverable data loss. A stripe transitions between adjacent states at specified rates, and MTTDL is defined as the expected time for the stripe to transition from state 0 to the DL state.

The state transition rate from state i to state $i+1$ is $(n-i)\gamma$, where γ is the failure rate of each node and n is the stripe width. A stripe enters the DL state once fewer than k healthy chunks remain. For UCLRC, local parity does not fully protect the stripe: when $i \geq r$, an additional failure may directly cause data loss with probability p_i, which is empirically measured via simulation [6]. The transition rate μ_s from state 1 back to state 0 is $\mu_s = \frac{1}{T_s}$, where $T_s = \frac{CS}{\varepsilon(N-1)B}$ is the mean time to repair a single-failure stripe. Here, S is the node capacity, C is the repair traffic normalized by chunk size, CS is the total network traffic during repair, N is the cluster size, B is the per-node network bandwidth, and ε is the fraction of network bandwidth allocated to repair. The term $\varepsilon(N-1)B$ represents the total available bandwidth assuming the repair traffic is evenly distributed across nodes. Since multi-chunk failures are rare and prioritized, the repair rate μ', i.e. the transition rate from state $i(>1)$ to state $i-1$, is basically dominated by $\mu' = \frac{1}{T'}$, where T' denotes the time to detect multi-failure stripes and trigger repair [6, 27].

We configure the parameters as follows: the mean-time-to-failure (MTTF) $1/\gamma = 4$ years, $N = 1000$ nodes, $S = 16$ TB, $B = 10$ Gbps, $T' = 30$ minutes, $\varepsilon = 0.1$. The MTTDL results of evaluated codes in our experiments are shown in Table 3. Figure 20 further illustrates the sensitivity of MTTDL to variations in N and $\frac{1}{\gamma}$ for $WC_{6,3}$, UC_{4+2}, and UC_{4+4}. The results indicate that while the MTTDL of both WiseCode and UCLRC scales at a similar rate with N, WiseCode exhibits a faster growth rate as $1/\gamma$ increases. Although $WC_{4,3}$ underperforms UC_{4+4} under an extremely low MTTF ($\leq$2 years), WiseCode demonstrates superior reliability in more realistic MTTF ranges (3–5 years) [17, 28, 65].

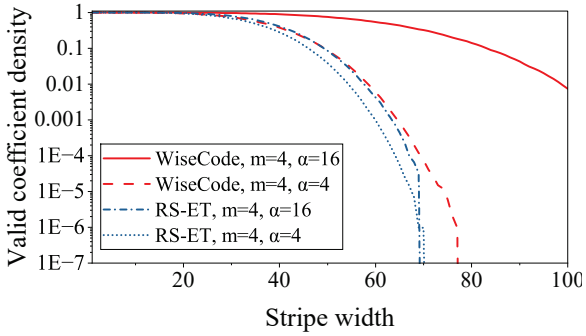

Figure 21: Density of valid coefficient combinations.

A.2 Existence of Valid Coefficients

As Table 2 summarizes the maximum stripe width achieved in our experiments, we believe that these results suggest that the theoretical ceiling for WiseCode's scalability is substantially higher. To validate this, we randomly choose up to 1,000,000 coefficient combination from GF(2^{16}) for RS-ET codes and WiseCode, calculating the density of valid assignments for each. And we observe that WiseCode has a higher probability to find valid coefficient under stripe-width configurations. As shown in Figure 21, the density of valid combinations for RS-ET codes with $m = 4$ decreases precipitously when the stripe width approaches 70. While WiseCode with $m = 4$ and $\alpha = 4$ exhibits a slightly better density curve, the density improves significantly as α increases. This improvement is driven by divide-and-conquer verification, which effectively reduces the number of coefficient constraints (§4.1) and thus render less coefficient combinations invalid.

A.3 Revisiting the Construction of WiseCode

Section 3 illustrates the template-based construction of WiseCode. Here we offer a straightforward matrix-based construction to simplify the discussions and proofs. We focus on how to directly obtain the parity-check matrix P, i.e., the entire coefficient matrix of coding equations, such that the coding equations can be collectively defined as $P \times C = \vec{0}$, where C represents all chunks.

In an (n,k,α) WiseCode built atop the (n_{msr},k_{msr}) MSR template, we have $m = n-k = n_{msr}-k_{msr}$. Define $b = n_{msr}/m$, then $\alpha = m^b$. If the $m \times 1$ coefficient vector of each sub-chunk is considered as a element, the parity-check matrix (i.e., coeffi-

cient matrix) P corresponding to all n chunks can be regarded as a $\alpha \times n\alpha$ matrix, where each of the n chunks corresponds to a $\alpha \times \alpha$ sub-parity-check-matrix (*SPCM*), i.e., Chunk_i corresponds to $SPCM_i$. Basically, each row of $SPCM_i$ corresponds to a sub-stripe, and each column corresponds to a sub-chunk. The elements of $SPCM_i$ are given as follows.

As discussed in Section 3.1, Chunk_i's parameters x and s are inherited from the template and are originally defined in Rule #2 (§2.3). The position of each element in the *SPCM* is denoted by the coordinate (r,c) starting from the top left corner, r for row and c for column. Given the base-m representation of c as $c = (c_{b-1}, c_{b-2}, \ldots, c_0)_m$, we define $c(x,s) = (c_{b-1}, \ldots, c_{s+1}, x, c_{s-1}, \ldots, c_0)_m$. We also define $\vec{\lambda} = [1, \lambda, \lambda^2, \ldots, \lambda^{m-1}]^T$. With m parameters λ_{im} to $\lambda_{(i+1)m-1}$ as specified in Section 4, the elements in the $SPCM_i$ of chunk_i are:

- $\overrightarrow{\lambda_{im+c_s}}$, if $c = r$ or $c(x,s) = r$,
- $\vec{0}$, otherwise.

We note that the conditions "$c = r$" and "$c(x,s) = r$" match the Rule #1 and Rule #2 in Section 2.3, respectively.

Lemma A.1. *Row_r of $SPCM_i$ contains 1 or m non-zero elements: If $r_s = x$, Row_r contains m non-zero elements at columns with indices $\{r(t,s) \mid 0 \le t < m\}$, with the element values specified as $\{\overrightarrow{\lambda_{im+t}} \mid 0 \le t < m\}$. If $r_s \neq x$, Row_r contains one non-zero element only at Column_r, with the element value specified as λ_{im+r_s}.*

A.4 WiseCode Repair Pattern

We prove the correctness of WiseCode repair pattern shown in Section 3.2. The key is to answer two questions: (1) For the lost chunk i, which sub-stripes are selected for decoding; (2) In a helper chunk i', which sub-chunks belong to the selected sub-stripes.

Answer for question (1). With the parameters x and s of chunk i, the α/m sub-stripes whose indices j satisfy $j_s = x$ are selected for decoding. According to Lemma A.1, each Row_j in the $SPCM_i$ contains m non-zero elements at columns with the indices $\{j(t,s) \mid 0 \le t < m\}$, therefore the Sub-Stripe_j can recover the m corresponding sub-chunks by solving the equation on Row_j. It is obvious that for any two different selected sub-stripes, their j vary at some digit j_p ($p \neq s$), therefore the two sets of $\{j(t,s) \mid 0 \le t < m\}$ have no intersection, and traversing all selected α/m sub-stripes can recover all α lost sub-chunks.

Answer for question (2). If $\text{Chunk}_{i'}$ is a sibling chunk of Chunk_i, it is obvious that it needs to contribute all α sub-chunks as helper sub-chunks, because $SPCM_{i'}$ is identical to $SPCM_i$ regarding the positions of non-zero elements, and these positions span all columns (sub-chunks).

If $\text{Chunk}_{i'}$ is not a sibling chunk of Chunk_i, we prove that in $SPCM_{i'}$, any non-zero element of Row_j only occurs within columns whose indices c satisfy $c_s = x$, i.e., having the same value range as the indices of the selected α/m rows (sub-stripes). Let the parameters of $\text{Chunk}_{i'}$ to be s' and x', then we discuss the position of non-zero elements in each Row_j based on Lemma A.1. If $j_{s'} = x'$, then the Column_c having a non-zero elements satisfies $c \in \{j(t,s') \mid 0 \le t < m\}$. In this case we have $s' \neq s$, otherwise $s' = s$ and $x' = j_{s'} = j_s = x$, which contradicts the assumption that $\text{Chunk}_{i'}$ is not a sibling chunk of Chunk_i. Therefore, any $c \in \{j(t,s') \mid 0 \le t < m\}$ satisfies $c_s = j_s = x$ because the sth digit of $j(t,s')$ is identical to j. If $j_{s'} \neq x'$, then the Column_c having a non-zero elements satisfies $c = j$, which also means $c_s = x$ because $j_s = x$. In conclusion, any non-zero element of Row_j only occurs within columns whose indices c satisfy $c_s = x$, which means that the indices c of helper sub-chunks also satisfy $c_s = x$ since each column corresponds to a sub-chunk with the same index.

A.5 Matrix-block-repetition pattern

Recall that each element of $SPCM_i$ corresponds to a coefficient vector of a sub-chunk, and there are at most m non-zero elements in each row of $SPCM_i$ (Lemman A.1). The m^b sub-chunks of chunk_i can be partitioned into m^{b-1} mutually disjoint subsets, each containing m sub-chunks, such that any sub-stripe only contains sub-chunks within a single subset. Using the sub-chunk index to describe each subset, sub-chunk_c belongs to the subset $\{c(t,s) \mid 0 \le t < m\}$, and these m sub-chunks sequentially corresponds to coefficients $\{\overrightarrow{\lambda_{im+t}} \mid 0 \le t < m\}$. The indices j of sub-stripes related to this subset of sub-chunks satisfy $j \in \{c(t,s) \mid 0 \le t < m\}$, i.e., having the same value range of the sub-chunk indices. Therefore, $SPCM_i$ of size $m^b \times m^b$ can be partitioned into m^{b-1} small matrices of size $m \times m$, each corresponding to one sub-chunk subset and its sub-stripe subset.

These small matrices have identical elements and cover all non-zero elements of $SPCM_i$. We denote each of these small matrices as elementary-parity-check-matrix (EPCM), and therefore $SPCM_i$ consists of m^{b-1} $EPCM_i$. An $EPCM_0$ in the case of $m = 4$ is as follows:

$$EPCM_0 = \begin{bmatrix} \overrightarrow{\lambda_0} & \overrightarrow{\lambda_1} & \overrightarrow{\lambda_2} & \overrightarrow{\lambda_3} \\ & \overrightarrow{\lambda_1} & & \\ & & \overrightarrow{\lambda_2} & \\ & & & \overrightarrow{\lambda_3} \end{bmatrix} \quad (1)$$

Corresponding to chunk partitioning rule in Section 4.1, concatenating SPCMs of chunks within group_s produces grouped-$SPCM_s$ ($GSPCM_s$). For each SPCM within group_s, there is an EPCM with the rows and columns indexed within the same value range $\{c(t,s) \mid 0 \le t < m\}$, and these EPCMs can be also concatenated together to produce grouped-$EPCM_s$ ($GEPCM_s$). Therefore, assuming group_s include m_s chunks, $GSPCM_s$ can be partitioned into m^{b-1} identical $GEPCM_s$, exhibiting the matrix-block-repetition pattern.

A.6 The Parity Solving and Matrix Elimination

Here are the mathematical details of Section 5.3, and we also prove Theorem 4.1 along this process. The objective of matrix elimination is to eliminate *GSPCM* of other groups, such that computing each sub-chunks within group$_s$ only needs to invert $GSPCM_s$. As $GSPCM_s$ exhibits the matrix-block-repetition pattern, the inversion of $GSPCM_s$ is further reduced to the inversion of $GEPCM_s$.

Details of matrix elimination. Define $\vec{\lambda}^{[h,t)} = [\lambda^h, \lambda^{h+1}, \ldots, \lambda^{t-1}]^T$, i.e., performing head and tail truncation on the original $\vec{\lambda}$. Then we define that substituting each element $\vec{\lambda}$ by $\vec{\lambda}^{[h,t)}$ in $GSPCM_s$ and $GEPCM_s$ produces $GSPCM_s^{[h,t)}$ and $GEPCM_s^{[h,t)}$, respectively. Now we start to separate $GSPCM_0$ from the other GSPCMs and eliminate $GSPCM_0$. Note that we may logically permute matrix rows between steps to facilitate the demonstration, which has no actual impacts on computations. Without loss of generality, we assume that the m chunks to be computed are parity chunks with indices $\{p_1, \ldots, p_m\}$, while any m other chunks follow the same procedure to perform divide-and-conquer solving. We start with the entire coefficient matrix $[P_{p_1}, \ldots, P_{p_m}]$, corresponding to parity chunks $\{C_{p_1}, \ldots, C_{p_m}\}$. The matrix elimination consists of two key operations: *row transformation* and *sub-chunk transformation*. Equation 2 demonstrates the row transformation process, with the row transformation matrix RT_0 described later:

$$
\begin{aligned}
&[P_{p_1}, \ldots, P_{p_m}] \\
&= [GSPCM_0^{[0,m)} \,|\, GSPCM_1^{[0,m)} \,|\, \cdots \,|\, GSPCM_{b-1}^{[0,m)}] \\
&\quad \text{(Group } SPCM\text{s within each group}_s \ (0 \le s \le b-1).) \\
&= \left[\begin{array}{c|c|c|c} GSPCM_0^{[0,m_0)} & GSPCM_1^{[0,m_0)} & \cdots & GSPCM_{b-1}^{[0,m_0)} \\ GSPCM_0^{[m_0,m)} & GSPCM_1^{[m_0,m)} & \cdots & GSPCM_{b-1}^{[m_0,m)} \end{array}\right] \\
&\quad \text{(Define } m_s \text{ as the number of parity chunks in group}_s.) \\
&= \left[\begin{array}{c|c} GSPCM_0^{[0,m_0)} & GSPCM_{[1,b)}^{[0,m_0)} \\ GSPCM_0^{[m_0,m)} & GSPCM_{[1,b)}^{[m_0,m)} \end{array}\right] \\
&\quad \text{(Focus on only group}_0.) \\
&\Rightarrow \left[\begin{array}{c|c} GSPCM_0^{[0,m_0)} & GSPCM_{[1,b)}^{[0,m_0)} \\ 0 & RT_0 \times GSPCM_{[1,b)}^{[0,m_0)} + GSPCM_{[1,b)}^{[m_0,m)} \end{array}\right] \\
&\quad \text{(Eliminate } GSPCM_0^{[m_0,m)} \text{ using } RT_0 \times GSPCM_0^{[0,m_0)}. \\
&\quad RT_0 \text{ represents row transformations to eliminate group}_0.) \\
&= \left[\begin{array}{c|c} GSPCM_0^{[0,m_0)} & GSPCM_{[1,b)}^{[0,m_0)} \\ 0 & A \end{array}\right] \\
&\quad \text{(Denote the bottom-right part by } A.)
\end{aligned}
\tag{2}
$$

Note 1 for proof of Theorem 4.1. Now we have decomposed the coefficient matrix $[P_{p_1}, \ldots, P_{p_m}]$ into $GSPCM_0^{[0,m_0)}$ and A, such that the coefficient matrix is invertible if and only if $GSPCM_0^{[0,m_0)}$ and A are invertible. The remaining of the proof lies in proving that A is equivalent to $GSPCM_{[1,b)}^{[0,m-m_0)}$ regarding the invertibility (See Note 2). If we can establish this equivalence, then we can continuously decompose $GSPCM_s^{[0,m_s)}$ from $GSPCM_{[1,b)}^{[0,m-m_0)}$, such that $[P_{p_1}, \ldots, P_{p_m}]$ is invertible if and only if all $GSPCM_s^{[0,m)}$ are invertible, matching Theorem 4.1.

Row transformation matrix. Since $GSPCM_0$ can be partitioned into m^{b-1} identical $GEPCM_s$, RT_0 can also be partitioned into m^{b-1} identical elementary-RT_0 (ERT_0), each eliminating $GEPCM_0^{[m_0,m)}$ using $ERT_0 \times GEPCM_0^{[0,m_0)}$, i.e., $ERT_0 \times GEPCM_0^{[0,m_0)} = GEPCM_0^{[m_0,m)}$. According to linear algebra, $ERT_0 = GEPCM_0^{[m_0,m)} \times (GEPCM_0^{[0,m_0)})^{-1}$. Each ERT_0 is of size $(m-m_0)m \times mm_0$ and one can verify that it has at most $(mm_0 + m - m_0)m_0(m-m_0)$ non-zero coefficients.

Given the original parity-check matrix equation:

$$
\begin{aligned}
&[P_{p_1}, \ldots, P_{p_m}] \times \{\text{all parity chunks}\} = \vec{R} \\
&\text{i.e., } GSPCM_{[0,b)}^{[0,m)} \times \{\text{parity chunks in group}_{[0,b)}\} = \vec{R}
\end{aligned}
$$

RT_0 also transforms the intermediate results $\vec{R}$ (see §5.3) of size ml to $\vec{R}'$ of size $(m-m_0)l$. That is,

$$
A \times \{\text{parity chunks in group}_{[1,b)}\} = \vec{R}' \tag{3}
$$

where $A = RT_0 \times GSPCM_{[1,r)}^{[0,m_0)} + GSPCM_{[1,r)}^{[m_0,m)}$.

Sub-chunk transformations. To maintain the original coding coefficients of the remaining parity sub-chunks (i.e., to transform A back to $GSPCM_{[1,b)}^{[0,m-m_0)}$), we adopt sub-chunk transformations (ST_0) such that

$$
GSPCM_{[1,b)}^{[0,m-m_0)} \times ST_0 \times \{\text{parity chunks in group}_{[1,b)}\} = \vec{R}' \tag{4}
$$

Comparing Equation (3) and (4), we have

$$
RT_0 \times GSPCM_{[1,b)}^{[0,m_0)} + GSPCM_{[1,b)}^{[m_0,m)} = GSPCM_{[1,b)}^{[0,m-m_0)} \times ST_0 \tag{5}
$$

To determine the required ST_0, we analyze the left side of Equation 5 at the granularity of ERT_0. As each ERT_0 performs the row transformation on a $GEPCM_0$, it also transforms coefficients of parity sub-chunks within other groups. We take group$_1$ for an example. In $GSPCM_1$, we select the m rows corresponding to ERT_0 and select the m sub-chunks with the same indices as these rows. One can verify that the coefficient matrix of the m selected sub-chunks within the m selected rows is a $m \times m$ diagonal matrix, whose elements are identical coefficient vectors. The coefficient vector can be

determined as in Appendix A.3, and here we assume its value to be $\vec{\lambda}$, such that coefficient matrix, denoted by $Diag_\lambda$, can be written as follows:

$$Diag_\lambda = \begin{bmatrix} \vec{\lambda} & & & \\ & \vec{\lambda} & & \\ & & \ddots & \\ & & & \vec{\lambda} \end{bmatrix}$$

Therefore, for the m selected sub-chunks and m selected rows, Equation 5 turns into

$$ERT_0 \times Diag_\lambda^{[0,m_0)} + Diag_\lambda^{[m_0,m)} = Diag_\lambda^{[0,m-m_0)} \times EST_{0,\lambda} \tag{6}$$

where $EST_{0,\lambda}$ denotes an elementary-ST_0 corresponding to $Diag_\lambda$. Recall that $ERT_0 \times GEPCM_0^{[0,m_0)} = GEPCM_0^{[m_0,m)}$, we define ERT_0^t $(0 \le t < m-m_0)$ to be the sub-matrix of ERT_0 that satisfies

$$\begin{aligned} &ERT_0^t \times GEPCM_0^{[0,m_0)} = GEPCM_0^{[m_0+t,m_0+t+1)} \\ \Rightarrow &ERT_0^0 \times GEPCM_0^{[0,m_0)} = GEPCM_0^{[m_0,m_0+1)} \\ \Rightarrow &ERT_0^0 \times GEPCM_0^{[t,m_0+t)} = GEPCM_0^{[m_0+t,m_0+t+1)} \\ \Rightarrow &ERT_0^t \times GEPCM_0^{[0,m_0)} = ERT_0^0 \times GEPCM_0^{[t,m_0+t)} \end{aligned}$$

That is to say, performing ERT_0^t on $\vec{\lambda}^{[0,m_0)}$ is equivalent to performing ERT_0^0 on $\vec{\lambda}^{[t,m_0+t)}$. Therefore, we have

$$\begin{aligned} &ERT_0^t \times Diag_\lambda^{[0,m_0)} + Diag_\lambda^{[m_0+t,m_0+t+1)} \\ =&ERT_0^0 \times Diag_\lambda^{[t,m_0+t)} + Diag_\lambda^{[m_0+t,m_0+t+1)} \\ =&(ERT_0^0 \times Diag_\lambda^{[0,m_0)} + Diag_\lambda^{[m_0,m_0+1)}) \times Diag_\lambda^{[t,t+1)} \\ =&Diag_\lambda^{[t,t+1)} \times (ERT_0^0 \times Diag_\lambda^{[0,m_0)} + Diag_\lambda^{[m_0,m_0+1)}) \end{aligned}$$

traversing t from 0 to $m-m_0$, we have

$$\begin{aligned} &ERT_0 \times Diag_\lambda^{[0,m_0)} + Diag_\lambda^{[m_0,m)} \\ =&Diag_\lambda^{[0,m-m_0)} \times (ERT_0^0 \times Diag_\lambda^{[0,m_0)} + Diag_\lambda^{[m_0,m_0+1)}) \end{aligned} \tag{7}$$

comparing Equation 6 and Equation 7 we have $EST_{0,\lambda} = ERT_0^0 \times Diag_\lambda^{[0,m_0)} + Diag_\lambda^{[m_0,m_0+1)}$. And sub-chunk transformation ST_0 is determined by traversing all ERT_0 and getting all $EST_{0,\lambda}$. Now we successfully eliminate group$_0$ and maintain the original coefficient matrix (with necessary truncation) of sub-chunks in other groups. Each $EST_{0,\lambda}$ is of size $m \times m$, and one can verify that $(EST_{0,\lambda})^{-1}$ has at most $mm_0 + m - m_0$ non-zero elements.

Note 2 for proof of Theorem 4.1. Now we have given the form of $EST_{0,\lambda}$. Recall that $A = GSPCM_{[1,b)}^{[0,m-m_0)} \times ST_0$, then A is equavilent to $GSPCM_{[1,b)}^{[0,m-m_0)}$ regarding invertibility as long as each $EST_{0,\lambda}$ is invertible. One can refer to [49] for the proof of a similar problem in the MSR-code version.

A.7 The Computational Overhead of Parity Solving and Matrix Elimination

We count the number of multiplications imposed by eliminating group$_s$. Denote the number of remaining chunks after eliminating group$_s$ as r_s. Firstly, each of m^{b-1} ERT_s imposes at most $(mm_s + m - m_s)m_s r_s$ multiplications on $\vec{R}$, totaling $(mm_s + m - m_s)m_s r_s m^{b-1}$. Secondly, eliminating group$_s$ introduces sub-chunk transformations ESTs that need to be inverted, imposing at most $mm_s + m - m_s$ multiplications for each of $r_s m^{b-1}$ ESTs (m^{b-1} ESTs for each of r_0 remaining chunks), totaling $(mm_s + m - m_s)r_s m^{b-1}$. Thirdly, when the remaining $r_s m^b$ chunks are solved, substituting them into the equation of group$_s$ takes m_s multiplications for each sub-chunk, totaling $m_s r_s m^b$. Finally, we need to solve the following equation for group$_s$:

$$GSPCM_s^{[0,m_s)} \times \{\text{parity chunks in group}_s\} = \vec{U}$$

where $\vec{U}$ is the remaining intermediate results after substituting solved sub-chunks. One can verify that each $(GEPCM_s^{[0,m_s)})^{-1}$ has at most $(mm_s + m - m_s)(m_s)^2$ non-zero coefficients, totaling $(mm_s + m - m_s)(m_s)^2 m^{b-1}$ for $(GSPCM_s^{[0,m_s)})^{-1}$, and the number of multiplications for solving this equation does not exceed this number. Note that $\sum m_s = m$, $r_s + m_s \le m$, and $mm_s + m - m_s \le m^2$. It can be easily verified that the total multiplication number is $O(m^{b+3}) = O(m^3\alpha)$.

The LogDrive: Composable Durability for Cloud-Based Shared Logs

Abstract

A growing class of systems leverages inexpensive cloud object storage as a disaggregated data plane, offloading durability and scaling to the cloud. Storing the metadata for such systems in a cloud database is too expensive; while self-managed databases are complex and fragile. Conflux provides a third option by storing a shared log on cloud storage and using it to replicate state across VMs. A key innovation in Conflux is the separation of durability from sequencing. Durability is provided solely by the novel LogDrive abstraction: a simple, low-level substrate that can be layered above arbitrary cloud storage, striped for throughput, and – unlike shared logs – composed via quorum-based replication. Sequencing is provided by the AtomicLog, which implements a conventional shared log over any LogDrive. This design allows Conflux to replicate arbitrary state machines while using RAID-like compositions of cloud storage for durability. Conflux is deployed in production at Confluent as the metadata service for an S3-based publish-subscribe system called K2. We show that Conflux can run on diverse storage services (e.g., DynamoDB, S3, S3Express) with just a few hundred extra LOC per service; as well as augment the durability of these services (e.g., with synchronous cross-region replication). Conflux unlocks new cost vs. latency trade-offs over cloud storage: for our representative workloads and latency SLAs (compared to using DynamoDB directly) Conflux-over-DynamoDB slashes metadata cost by 10X and overall cost by 3X.

1 Introduction

Cloud storage services such as S3 [8] offer scalable, elastic, and fault-tolerant data storage at inexpensive prices. As a result, stateful distributed services with rich APIs – ranging from analytical databases to publish-subscribe systems – are increasingly designed as stateless / soft-state layers over disaggregated cloud storage. In such services, the data plane resides directly on cloud storage (e.g., S3), while metadata (e.g., an index) is stored on a separate metadata service; for example, Snowflake stores data on S3 and metadata in FoundationDB [45]. The resulting services have data planes that

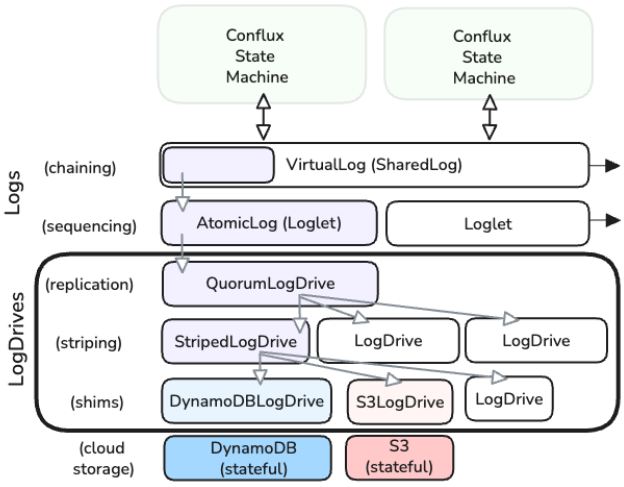

Figure 1. *LogDrives are **easy to build** as shims over cloud storage, and via RAID-like composition; they are **useful** for implementing shared logs (and SMR).*

are cheaper and simpler to build and operate, which translates to cost savings and higher reliability for end-customers.

At Confluent, we set out to build a new publish-subscribe service called K2 directly over S3, leveraging its inexpensive large writes to enable a high-throughput, low-cost product (called Freight [11]) for customers storing bulk data (e.g., observability traces) at sub-second latencies. In the K2 design, data is written directly to S3 in large, batched blobs; and the unit of metadata is a fine-grained index (an ordered list of pointers for each pub-sub topic). To store this metadata, we needed a durable yet easy-to-operate database that could support small writes (and reads) at low cost (but not necessarily low latency); and expose a convenient API for storing per-topic indexes.

Unfortunately, we found our options limited:

- Operating a stateful distributed database to store metadata is complex and difficult, typically requiring a collection of individual machines (e.g., EC2 VMs deployed via K8s [5]) to ensure durability in the presence of failures. Existing options such as FoundationDB [45], KRaft [6], ZooKeeper [37], and etcd [4] are known to be difficult to operate in production [17,

†These authors are no longer at Confluent; their contributions to this work were made while at Confluent.

28]. This complexity is exacerbated by the hybrid nature of the overall system, since the data and metadata planes can each fail in different ways; as well as the outsized impact of metadata loss on overall durability.
- Conversely, storing metadata in a cloud database (e.g., DynamoDB [32]) is simpler and safer, but prohibitively expensive for the small, frequent writes and reads found in metadata workloads. We estimated that a DynamoDB-based metadata layer would incur roughly 75% of K2's overall cost. Further, new and cheaper options can emerge and prices can fluctuate (e.g., S3Express [9] launched in 2024 and changed pricing in 2025 [12]), necessitating difficult, risky migrations between storage services to optimize cost.

In this paper, we present a new metadata store called Conflux. Conflux uses cloud storage as a shared log for State Machine Replication [49]. We apply research on shared logs [2, 18, 19, 22, 31, 44, 52] to construct a replicated state machine over a total order of commands, which in turn is stored on a shared log implemented directly on cloud storage. In this design, the shared log is a consensus engine that delegates durability entirely to cloud storage; drives down write costs by batching log-structured writes; and lowers read cost via materialized local views. By storing the shared log on passive cloud storage, Conflux aims for the benefits of RAID-like [47] composition over different storage services: striping for throughput; replication for higher availability and durability; chaining for dynamic switching of new writes; as well as tiering for migrating older writes.

However, we encountered an unexpected challenge in realizing our goal of delegating durability to arbitrary, diverse, and composable cloud storage. While shared logs can be composed via chaining and striping [18], they cannot be easily or efficiently composed via replication. The reason is the narrow, opinionated *append* interface, which allows each shared log to decide the timestamps of its new entries: when an entry is appended to multiple logs, each one can assign a different, potentially conflicting timestamp. As a result, we were unable to compose single-region DynamoDB logs into a multi-region log; or one-AZ S3Express logs into a multi-AZ or multi-region log. The absence of replication severely hobbles the value of composition (imagine RAID without mirroring!). Ironically, the property that makes shared logs compelling – the delegation of sequencing and durability to a single abstraction – also hinders their composition.

One solution is to *separate sequencing from durability*: we can introduce a low-level abstraction for durability (such as a shared address space) that is easy to compose via layering, striping, and replication; and layer the shared log above it as a shim, with a soft-state counter (as in Corfu [19]) for tracking the tail. We borrow this principle from other areas of systems: e.g., filesystems layered over block devices composed via RAID [47]. Unfortunately, this moves the burden to recovery: if the shared log layer experiences failures (e.g., if the counter appears to fail), recovering its soft state – specifically, the linearizable tail – from an address space can be difficult and expensive, particularly in a distributed setting with partial failures and concurrent writes. Adding special APIs to the address space (e.g., to fence concurrent writes and return the first unwritten entry, as in Corfu's custom storage servers) hinders its implementation over passive cloud storage and easy composition. Required is an abstraction for shared log durability that is composable, yet enables recovery.

Accordingly, we propose a new abstraction called the LogDrive. Like a conventional address space, the LogDrive exposes a numbered, random-write address space of durable registers. However, the LogDrive expects to be written (almost) in sequence: accordingly, it provides an extra *weakTail* API. The LogDrive has unusually weak semantics: e.g., individual addresses are only linearizable as long as a single value can possibly be written to them, and hence weaker than Write-Once, Conditional, or Atomic Registers [16, 24]. In addition, the *weakTail* call (as its name implies) is not necessarily linearizable; instead, it is only required to correspond to a deterministic function over a non-atomic, unordered scan. The LogDrive abstraction is *easy to implement*: the compact API and its weak semantics allow layering over existing cloud storage APIs (even without write-once or conditional-write support); and composition via single-round quorums and striping.

At the same time, the LogDrive abstraction is *powerful and useful*. We describe a new shared log design called the AtomicLog that combines the LogDrive with a soft-state counter and a windowed write discipline. The result is a full-fledged, linearizable shared log, which in turn can be used for State Machine Replication. By composing LogDrives via replication, we can augment the existing intra-region durability of cloud stores with cross-region quorums. For example, we can run a single DynamoDBLogDrive per region; and then construct a QuorumLogDrive that writes to two out of three regions before responding.

Conflux breaks new ground in a number of ways. The LogDrive (in concert with the AtomicLog) is the first solution for composing shared logs via replication; prior work such as Delos [18] stopped at composition via striping and concatenation. Earlier systems [7, 18, 19, 31] have explored disaggregated shared logs implemented over collections of custom servers, whereas Conflux uses common-denominator cloud storage APIs. Prior work such as LazyLog [44] *temporally* separates ordering and durability within a shared log for performance, whereas Conflux *spatially* separates these concerns into different layers for composability. Scalog [31] separates sequencing from durability for performance, but its sequencing layer is a stateful SMR-based metadata layer in itself.

In this paper, we make the following contributions:

- We describe the design and implementation of Conflux, the metadata service for a new S3-based publish-subscribe system called K2. Conflux uses cloud storage as a shared log, reducing the metadata cost by 10X compared to using DynamoDB directly, within a p99 write latency of 130ms; and the overall K2 cost by 3X.
- We propose a novel LogDrive abstraction that allows Conflux to easily run on diverse cloud stores (S3, DynamoDB, S3Express) and switch dynamically between them. New LogDrives are easy to build: for example, a single engineer was able to build a production-quality DynamoDBLogDrive in just a week.
- The LogDrive can be composed via replication (as well as striping): we show that this lets us construct multi-region quorums over DynamoDB, as well as multi-AZ quorums over S3Express.

2 Motivation

At Confluent, our goal was to build a Kafka [40] publish-subscribe (or pub-sub) implementation directly over cloud storage. Kafka is the *de facto* API for modern pub-sub systems, with thousands of production use cases. Applications can publish data to a topic and fetch data from it (in practice, Kafka refers to a topic as a partition and a bundle of partitions as a topic; but we match terminology with the pub-sub literature [33] by referring to a topic as a single total order). Existing implementations of Kafka are typically complex distributed systems that run directly on hardware for low latency workloads, with a resulting operational cost that is passed on to customers.

Our goal in building a new Kafka implementation was two-fold. First, we wanted to exploit high-latency but low-cost cloud storage to offer an inexpensive, bulk variant of Kafka to our customers (called Confluent Freight [11]). In particular, S3 provides cross-AZ durability for writes at a fixed cost regardless of payload size (in contrast to EC2 cross-AZ networking, which is charged per-byte), creating an opportunity to slash cost via big writes. Second, we hoped to get the ancillary benefits of running stateless logic above cloud storage, such as simpler operations and better reliability.

In this Kafka implementation (called K2), clients connect to stateless brokers (i.e., servers that implement the Kafka protocol). To publish data to a topic, a client sends it to a broker; once the broker has a large enough batch that typically spans writes to multiple topics, it issues a single write to S3 for the batch and then updates the metadata for all those topics. In this architecture, much of the heavy lifting is done by the metadata layer. Our default option for storing metadata was to build or buy a distributed database, deploy it on cloud VMs using K8s, and operate it with high reliability (e.g., matching Snowflake's use of FoundationDB [45]). However, this option would require a massive investment in time and resources, and considerably delay our time to market. Could we do better by using cloud storage for metadata as well?

Why not store Metadata directly in a cloud DB? Cloud databases like DynamoDB are powerful, reliable, and capable of handling our metadata workload: each K2 topic's metadata can simply be a key in DynamoDB. However, existing databases turned out to be prohibitively expensive: for example, our estimates suggested that we would spend 75% of our cloud cost just on metadata storage if we used DynamoDB. One reason for high cost is that the metadata workload consists of small writes to different keys (e.g., if an K2 broker combined data for 10 topics in a single S3 batch, we'd have to issue 10 separate writes to the metadata layer). A different concern relates to reads; metadata is often accessed repeatedly as clients and background processes replay the topic state. In the absence of (potentially complex) caching infrastructure, these accesses blow up read costs.

In addition, we needed fast reaction times to changes in cloud pricing and features. Unlike the data plane, which requires a minimal put/get interface from cloud storage, metadata can benefit from rich APIs for indexing. However, using such APIs would limit the portability of our code to other cloud providers, or to other storage options at the same provider if prices changed; in addition, adding new metadata APIs would require careful implementation on each backend.

Could we somehow obtain the benefits of storing metadata in cloud storage (i.e., delegating durability entirely to the cloud provider); while at the same time keep our cost low?

2.1 The Cloud is the Log!

In a shared log design, we execute multiple copies of a database on individual servers; and keep these copies synchronized via an external shared log. In principle, the log is the source of consistency as well as durability (storing the linearizable order of commands); the database is simply a materialized cache over the log. This clean, API-driven separation between the soft-state database and the durable shared log allows us to easily place the latter on cloud storage, entirely delegating durability to the cloud.

Using cloud storage as a shared log eliminates costly small writes: we can batch metadata updates for multiple topics and issue them in a single write to the shared log. Since each database server effectively has a full, strongly consistent copy of the database, we can serve reads with low cost (and low latency) without unnecessarily accessing cloud storage. In addition, we access cloud storage through a narrow API (the API of the shared log does not change over time even as we add new APIs to our database).

Unfortunately, we ran into a fundamental limitation of the shared log abstraction's *append* interface: composition via replication. Consider the task of composing a replicated shared log R over two individual shared logs A and B. Trivially, we could implement the *append* operation on R by

```
interface LogDrive {
  void write(long address, ByteBuf payload);
  ByteBuf read(long address);
  TailDesc weakTail(int K);
  struct TailDesc {
    long nonContiguousTail;
    Set<Long> holes;
  }
}
```

Figure 2. *The LogDrive API*

forwarding it to both A and B; however, there is no guarantee in the shared log API that we will obtain the same timestamp from both (such a guarantee would be difficult to obtain, given that the implementation could choose to embed internal protocol details such as membership epochs in its timestamps [7]). Further, if one of the two appends is delayed, retrying it incurs the risk of duplicate entries with different timestamps. In addition, concurrency poses a challenge: we have to issue the appends one-at-a-time, else they could arrive at the logs in different orders.

These issues can be solved if R entirely ignores the timestamps / ordering provided by A or B and instead embeds application-level timestamps into entry headers. However, playback now requires re-ordering of entries, negating the simplicity benefit of the shared log abstraction. In addition, the replicated log needs a source of these external timestamps; using an explicit sequencer turns composition into a complex, heavy-weight layer (in contrast to a light-weight, RAID-like shim that can be nested arbitrarily).

Why is composition via replication so important? Our use cases for K2 spanned the durability gamut: some applications were okay with data loss if a single AZ failed; others required multi-AZ durability within a single region; while some mission-critical use cases required zero data loss even if an entire region failed. These requirements complicated our path to using existing services like S3, DynamoDB, or S3Express for storing metadata; since S3 and DynamoDB do not currently support synchronous cross-region replication; while S3Express does not support cross-AZ replication. The ability to compose shared logs via replication would allow us to leverage the existing machinery of these services within regions (in the case of DynamoDB or S3) and AZs (with S3Express) while augmenting it with cross-region or cross-AZ replication, respectively. Even if these systems provide synchronous cross-region replication as an option (e.g., DynamoDB enabled support in mid-2025), we would have more flexibility in a compositional layer (e.g., to use different policies or placements) and retain the ability to migrate between clouds or even span clouds.

3 The LogDrive Abstraction

The LogDrive is a novel abstraction that can be easily implemented on cloud storage and composed via replication and striping. We now describe the LogDrive API and its various implementations. In later Sections, we explain the utility of the LogDrive for State Machine Replication.

3.1 The LogDrive Abstraction

The LogDrive is an address space of registers with a random *read*/*write* interface (see Figure 2). Addresses are initialized to an *unwritten* state; a *write* switches them to a *written* state. In Figure 3, we show the anatomy of a LogDrive: the *contiguous tail* ($\mathcal{T}$) is the first unwritten address before which all addresses are written; the *non-contiguous tail* ($\mathcal{N}$) is the first unwritten address after which all addresses are unwritten; and in between is a "swiss cheese" area of intermixed written and unwritten addresses. We call the unwritten addresses less than $\mathcal{N}$ the *hole-set* ($\mathcal{H}$).

Two features distinguish the LogDrive from a conventional address space. The first is the *weakTail* API, which returns a tuple with ($\mathcal{N}$, $\mathcal{H}$): the non-contiguous tail and the hole-set. Note that the caller can compute the contiguous tail $\mathcal{T}$ from the returned tuple: it is guaranteed to be the lowest address in $\mathcal{H}$, or $\mathcal{N}$ if $\mathcal{H}$ is empty. Informally, we will refer to $\mathcal{T}$ as returned by *weakTail* even though it is a derived value. Importantly, the application provides a parameter K to *weakTail*, which is the maximum possible distance between $\mathcal{T}$ and $\mathcal{N}$. The application typically knows and ensures this bound by using a windowing discipline to write to the LogDrive. As we see later, this bound is critical for implementing *weakTail* efficiently, giving the implementation license to ignore the prefix of the address space while determining $\mathcal{H}$. As long as the K bound is correct, the *weakTail* response entirely characterizes the written/unwritten status of each address in the LogDrive. Note that $|\mathcal{H}|$ is bounded by K: this API is only practical for small K.

The second distinguishing characteristic of the LogDrive is the unusually weak semantics it provides, on two dimensions. First, individual addresses are *single-value registers*: i.e., they are only linearizable for *write*/*read* operations if a single value is written to them (though the same value can be written multiple times). We rely on the application to never write multiple values to an address. In this sense, they are similar to SWMR registers [41] or write-once registers [34] but with significantly weaker semantics. Second, the *weakTail* is not linearizable; instead, it is merely equivalent to a deterministic function over an unordered, non-atomic scan (e.g., executed via parallel point reads) on the address space. This guarantee has other parallels in the literature: e.g., non-atomic collects [15] on SWMR registers and interval-linearizability [27].

Lemma (**[LD.1]** Tail-Range Guarantee)**.** *Let a weakTail operation run over a linearization span* $[t_{\text{start}}, t_{\text{stop}}]$*, such that*

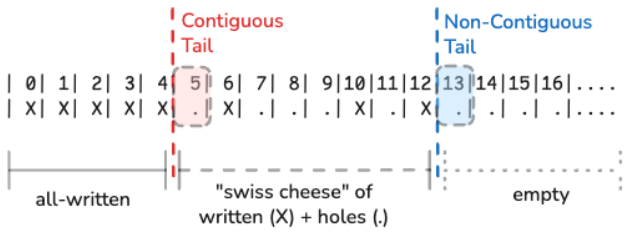

Figure 3. *The Anatomy of a LogDrive.*

$\mathcal{T}_{\text{start}}$ and $\mathcal{T}_{\text{stop}}$ denote the actual contiguous tail at those times. Then the value $\mathcal{T}_{\text{obs}}$ returned by weakTail satisfies:

$$\mathcal{T}_{\text{obs}} \in [\mathcal{T}_{\text{start}}, \mathcal{T}_{\text{stop}}].$$

Proof sketch. Consider a *weakTail* implementation that literally scans for holes by issuing point reads in parallel to the entire address space. During the scan, different addresses are sampled at different times in $[t_{\text{start}}, t_{\text{stop}}]$. Suppose $\mathcal{T}_{\text{obs}} < \mathcal{T}_{\text{start}}$. Then the scan must have observed address $\mathcal{T}_{\text{obs}}$ unwritten at some time $\tau \geq t_{\text{start}}$, which contradicts the definition of $\mathcal{T}_{\text{start}}$ as the first unwritten slot at t_{start}. Similarly, if $\mathcal{T}_{\text{obs}} > \mathcal{T}_{\text{stop}}$, then the scan must have observed all addresses $< \mathcal{T}_{\text{obs}}$ as written strictly before t_{stop}. But then $\mathcal{T}_{\text{stop}}$ cannot be the first unwritten address at t_{stop}, a contradiction. Thus $\mathcal{T}_{\text{obs}}$ must lie within $[\mathcal{T}_{\text{start}}, \mathcal{T}_{\text{stop}}]$. *Full Proof in Appendix.* □

However $\mathcal{T}_{\text{obs}}$ is not necessarily linearizable, since writes on the LogDrive can linearize out of address order: e.g., let us say we write to 1 and then 0 (causing the contiguous tail to jump from 0 to 2). A *weakTail* concurrent with both writes might return 1 if it first reads 1 as unwritten and then 0 as written. But this execution does not correspond to any total order of the two writes and the *weakTail*.

Lemma ([LD.2] Window Scan Property**).** *To satisfy weakTail semantics, it is sufficient for an implementation to first determine the non-contiguous tail linearizably; and then issue an unordered, non-atomic scan to the K-sized window of preceding addresses. The value returned by this window scan is equal to the value returned by some unordered, non-atomic scan over the entire address space.*

Proof sketch. Reading the non-contiguous tail $\mathcal{N}$ linearizably tells us that, at some instant t^* during the operation, all written addresses lie in $[0, \mathcal{N}^*)$ and all addresses $\geq \mathcal{N}^*$ are still unwritten. Under the K-window discipline, there can be at most K holes before $\mathcal{N}^*$, so the hole-set at t^* must lie entirely inside $[\mathcal{N}^* - K, \mathcal{N}^*]$, and every address $< \mathcal{N}^* - K$ is definitely written. We can therefore construct an equivalent full, unordered, non-atomic scan by (i) using the issued window reads in $[\mathcal{N}^* - K, \mathcal{N}^*]$, and (ii) using hypothetical reads issued at time t^* that returned written below the window and unwritten above it. The returned non-contiguous tail and hole-set from this hypothetical full scan exactly match those found by the window scan. *Full Proof in Appendix.* □

3.2 Primitive LogDrive Implementations

The compact API and weak semantics of the LogDrive simplify its implementation on existing cloud storage. Single-value registers are trivial to implement over any existing key-value store (even ones that do not provide conditional put operations, such as S3 prior to 2024) or even shared disks.

As a result, the only complexity in implementing a LogDrive on an existing cloud store has to do with the *weakTail* call to find its contiguous tail. In practice, we find that existing cloud stores give us efficient ways of finding the non-contiguous tail; and can scan back K entries to find the contiguous tail, as we describe:

S3: Each LogDrive is assigned a particular prefix in an S3 bucket (the combination of bucket and prefix uniquely identifies the LogDrive). Within that prefix, we reverse-encode addresses as S3 keys (e.g., so that the 0th address is lexicographically last). S3 gives us the ability to list keys in lexicographic order. Accordingly, we can list the first K keys to obtain the last K written slots, which we then invert to return the list of holes in the last K slots. By Lemma LD.2 (Window Scan Property), this is sufficient to return a correct *weakTail* response.

DynamoDB: We use composite keys to encode LogDrive entries: each LogDrive to a particular partition key, and each address is encoded as the sort key. Unlike S3, we don't need to reverse-encode, since DynamoDB lets us query items in either lexicographical order. By Lemma LD.2 (Window Scan Property), this is sufficient to return a correct *weakTail* response.

S3Express: This storage service is nearly identical to S3, except for its single-AZ durability and some differences in API semantics. One difference is that we can no longer list keys in lexicographical order [10]. To get around this, we create a directory-like hierarchical structure on the S3Express key space. We then enumerate all entries at each level of this hierarchy to route to the non-contiguous tail; and then scan backwards K entries to find the contiguous tail. By Lemma LD.2 (Window Scan Property), this is sufficient to return a correct *weakTail* response.

3.3 The StripedLogDrive

Striping the LogDrive is straightforward for writes and reads: we implement RAID-0-style striping to map from *global* addresses (on the StripedLogDrive's address space) to *local* addresses on S individual stripes. Note that a stripe here is a LogDrive instance, implemented over a cloud store as described above.

To implement *weakTail* on the StripedLogDrive, we invoke it on all stripes in parallel and wait for all responses. We pass in K/S as the parameter to the per-stripe *weakTail* calls; we require K to be a multiple of S. We convert all returned local addresses to global addresses; and then pick the maximum

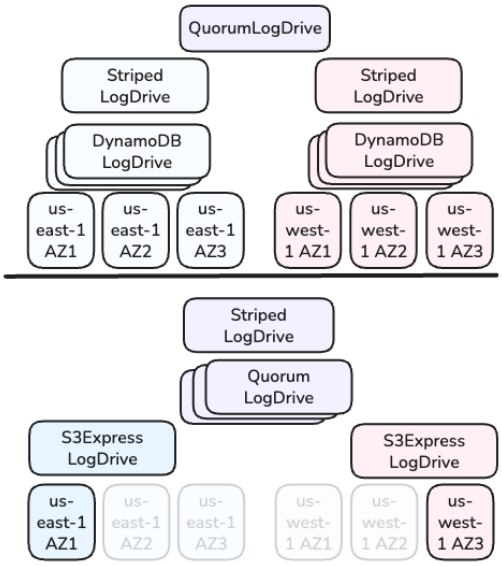

Figure 4. *Replication over Striping, similar to RAID-10 (Top); Striping over Replication, similar to RAID-01 (Bottom).*

returned global non-contiguous tail, along with the union of all the returned hole-sets.

Theorem ([SLD.1] Striped LogDrive Preserves *weakTail* Semantics)**.** *The weakTail implementation of the StripedLogDrive, described above, satisfies the LogDrive weakTail semantics: it is equivalent to the result of some unordered, non-atomic scan over the global address space within the linearization span.*

Proof sketch: The *weakTail* call on each stripe is equivalent to an unordered, non-atomic scan on its own local address space (corresponding to a stripe of the global address space). We can construct an unordered, non-atomic scan on the global address space by combining these per-stripe scans, translating each local address to its global equivalent. Picking the maximum non-contiguous tail returned across all stripes is equivalent to choosing the non-contiguous tail from that global scan; the union of all the returned hole-sets is equal to the hole-set on the global address space. *Full Proof in Appendix.* □

3.4 The QuorumLogDrive

The QuorumLogDrive (or QuorumDrive for short) replicates data across a quorum of N LogDrive replicas. Note that a replica here is a LogDrive instance, implemented over a cloud store as described above. The QuorumDrive is configured with a write quorum size Q_w, which can range from $[1, N]$.

On a *write*, the QuorumDrive forwards the command to all replicas. As an optimization, we can also hedge [29] by sending to a specific Q_w-sized subset and contact more replicas if responses are delayed. Once Q_w nodes ack, we can ack the write; as a result, writes ack in one round-trip to a write quorum. Since only one value can possibly be written to a single-value register, we avoid a two-round protocol like ABD [16] for Atomic Registers.

The *weakTail* call needs a conventional read quorum to intersect with write quorums: $Q_r = N - Q_w + 1$. At the same time, it has to "repair" writes [16] to enforce a write quorum for any observed partial writes. Practically, the *weakTail* accesses a quorum of size $Q_f = max(Q_w, Q_r)$ to invoke *weakTail* locally on each one. However, determining the global state from the responses is more involved than in striping: just because we observe a local hole at a single replica does not mean that corresponding global address was a hole at any time during the *weakTail*'s linearization span. The replica could have merely missed that write by being temporarily inaccessible.

Accordingly, we examine each slot to determine if it is a global hole. For each slot in the address space, we can determine the global written / unwritten status as follows.

1. We see that the slot is unwritten on Q_r of replicas. We mark it as globally unwritten.
2. We see that the slot is written on Q_w of replicas. We mark it as globally written.
3. We cannot determine if the slot is globally written or unwritten (i.e., we do not see Q_w written or Q_r unwritten replicas). This happens if we can only access Q_f replicas and we are unable to determine the slot's global status without the inaccessible replicas. In this case, we repair the write by copying over the value to Q_w replicas and mark the slot as globally written.

Based on our determination of the global status of each slot, we can then return a *weakTail* response.

Windowing discipline on the global address space has two implications for this algorithm. First, we can run the algorithm in $O(Q_f * K)$: we start from the highest returned non-contiguous tail and examine only the K global addresses prior to it, since everything prior to that is guaranteed (by the application, via the *weakTail* parameter) to be lower than the global contiguous tail, and hence globally written. Second, relaying K to the per-replica *weakTail* calls instructs them (in their own *weakTail* implementations) to ignore anything prior to N-K: even though they may have local holes at these addresses, the application (in this case, the QuorumDrive) knows these to be globally written.

Theorem ([QLD.1] QuorumLogDrive preserves *weakTail* semantics)**.** *The weakTail implementation of the QuorumLogDrive, described above, satisfies the LogDrive weakTail semantics: it is equivalent to the result of some unordered, non-atomic scan over the global address space within the linearization span.*

Proof sketch: A *weakTail* call issues a *weakTail* to a quorum of replica LogDrives. By the *weakTail* spec, each replica responds with a full (unordered, non-atomic) characterization of its address space. In effect, we observe the status of every address in each responding LogDrive at some (different) instant within the linearization span. Any slot that we mark

```
interface Loglet {
  Pair<LogPos, SealStatus> checkTail();
  LogPos append(ByteBuf buf); //throws if sealed
  void seal();
  LogPos prefixTrim(LogPos trimPos);
  ByteBuf readNext(LogPos min, LogPos max);
}
```

Figure 5. *The AtomicLog API (== Delos Loglet API [18]).*

as globally unwritten must have been globally unwritten at the start of the linearization span. Any slot that we mark as globally written must be globally written by the end of the linearization span. As a result, we can construct a full (unordered, non-atomic) scan of the entire global address space with a linearization point for each individual written or unwritten entry within the linearization span. *Full Proof in Appendix.* □

4 Implementing a Shared Log over the LogDrive: The AtomicLog

Thus far, we have established that the LogDrive abstraction is *easy to implement and compose*. We now show that the LogDrive is also a *useful* abstraction that can support a conventional shared log.

In particular, we implement the Loglet API from Delos [18] (see Figure 5) verbatim. The Loglet API supports linearizable *append*, *checkTail*, and *readNext* calls. It also provides a linearizable *seal* call, which ensures that subsequently linearized *append*s do not acknowledge successfully. The Loglet is required to be highly available for all calls except *append*. In particular, *checkTail* has to be highly available and linearizable with appends, effectively returning the first unwritten log position. As shown by Delos, this API can be layered under a virtualization layer that provides high availability for *append*s; and support efficient, safe, and highly available State Machine Replication in production systems. Accordingly, we start by describing the AtomicLog in this Section, which implements the Loglet API over a LogDrive; and then describe how we virtualize it for high availability.

The AtomicLog is a stateless client-side library that interacts with two components: the LogDrive and a shared, soft-state sequencer object. The sequencer supports a simple *acquireSlot* / *completeSlot* API. It does not see any data payloads and does not have to be durable or highly available. There can only be one sequencer in an AtomicLog instance; if it fails or reboots, the AtomicLog becomes permanently unavailable for appends. Accordingly, it can be implemented as an RPC service collocated on one of the AtomicLog clients.

To *append*, a client first calls *acquireSlot* on the sequencer to obtain the next slot; *writes* to the LogDrive; and then calls *completeSlot*; before acking the *append*. The state of the sequencer is a combination of a counter and a window of in-flight writes. If an incoming *acquireSlot* finds that the window is full — i.e., there are more than K slots between the contiguous tail and the non-contiguous tail – it blocks until the window opens up (i.e., a write completes that moves the contiguous tail moves forward). In turn, each *completeSlot* blocks until all prior slots are completed.

In practice, this protocol ensures that the AtomicLog writes to the LogDrive within a K-sized sliding window. For example, in Figure 3, the AtomicLog (configured with $K = 8$) has to block before writing to address 13 since address 5 has not been written yet. As a result, it enforces a bound of K on the distance between the contiguous and non-contiguous tails of the LogDrive.

In this protocol, the linearization point of an append is determined by the *completeSlot*. In other words, appends linearize in strict address order: an append returning position 5 must linearize after an append that returns position 4 and after an append returning position 6. As per the Loglet contract, the *append* is not highly available (e.g., the sequencer can fail; or clients can crash after acquiring a slot); we discuss soon how unavailability is handled at a higher layer. However, the Loglet API does require a highly available, linearizable *checkTail* that returns the first unwritten log position.

Implementing *checkTail* is trivial: we simply invoke *weakTail* on the underlying LogDrive. Surprisingly, the returned contiguous tail gives us a linearizable *checkTail* for the AtomicLog, even though the LogDrive's *weakTail* is not itself linearizable.

Theorem (**[AL.1]** *checkTail* Linearizability)**.** *The AtomicLog checkTail operation, implemented via a single weakTail on the underlying LogDrive, is linearizable with respect to append.*

Proof sketch: Appends linearize in strict address order. A *checkTail* invoked over interval $[t_{\text{start}}, t_{\text{stop}}]$ returns $\mathcal{T}_{\text{obs}} \in [\mathcal{T}_{\text{start}}, \mathcal{T}_{\text{stop}}]$ (since the enclosed *weakTail* satisfies these bounds, by Lemma LD.1). Placing the *checkTail* immediately after all appends to addresses $< \mathcal{T}_{\text{obs}}$ yields a total order consistent with real-time and with the returned value. Thus *checkTail* is linearizable wrt *append*. □

Intuitively, the LogDrive *write* / *weakTail* API is not linearizable since writes do not commit in address order, and hence it is not always possible to generate a candidate total order that satisfies returned values as well as a sequential specification; whereas *append* / *checkTail* is linearizable due to the blocking behavior of appends on prior unwritten slots.

Finally, we provide a highly available *seal* to satisfy the Loglet API. For this, the AtomicLog stores a seal bit in a designated location on cloud storage (e.g., as address 0 on a second LogDrive). Each *append* checks this bit after *completeSlot* and throws if the log is sealed, while *checkTail* checks it after the *weakTail* and returns the seal status. To *seal* the AtomicLog, we simply write to this location. As per Delos, the seal checks are not required to be atomic with the *append* or *checkTail*,

though they must not be linearized before [35]. We omit describing *readNext* and *prefixTrim* for lack of space.

Optimizing *checkTail*: The protocol described above can be inefficient since *weakTail* requires accessing cloud storage. We can drastically reduce the common-case cost and latency of *checkTail* by using a *fast-path checkTail* that goes to the sequencer rather than the LogDrive. **We only use the *weakTail* on the LogDrive as a *slow-path* once the log is sealed.** If the sequencer is unavailable, we first seal the log; and then switch to the slow-path.

We do have to be careful in this case to avoid having two sources of truth for the tail. For example, a slow-path response might see a tail X on the LogDrive; but a subsequent, non-overlapping fast-path *checkTail* invocation can return $X-1$ as the tail, resulting in a linearizability violation (for example, if the writer of entry $X-1$ went to sleep after writing to the LogDrive but before calling *completeSlot* on the sequencer).

To avoid such linearizability violations, the *checkTail* uses the fast-path sequencer-based tail check before accessing the seal bit; if the seal bit is set, the client retries the tail check on the slow-path. As a result, once the seal bit is set, all subsequently linearized *checkTail* operations return values from the slow-path.

Handling Failures via Virtualization As in Delos, we layer a VirtualLog above the AtomicLog to convert our Loglet (which does not provide high availability for appends) into a highly available shared log that can drive State Machine Replication (see Figure 6 for the full stack). Our VirtualLog is not novel: it is identical to the Delos design and implementation, storing membership (i.e., the mapping from the VirtualLog's address space to individual Loglets) in a conditional register on cloud storage. For each Loglet, we store the configuration of the corresponding AtomicLog instance (including the underlying LogDrive – or multiple layered LogDrives – as well as the endpoint of the sequencer). Above the VirtualLog, we use a conventional SMR layer similar to Delos, which stores durable snapshots in cloud storage; we describe this layer in the next section.

When the Loglet (i.e., the AtomicLog) becomes unresponsive for *append*s, we simply *seal* it; call *checkTail* to determine the switchover point; and then write a mapping to the conditional register so we can switch to a new Loglet (either another AtomicLog or an entirely different implementation) for new *append*s. Within the AtomicLog, there are two failure cases of interest. First, the sequencer can fail. Second, a client can fail after acquiring a slot (effectively making the sequencer unavailable, since *acquireSlots* can no longer complete). We treat both these cases identically; in both cases, the Loglet becomes unavailable for *append* calls. Our choices here are identical to those made in prior work (e.g., the Delos NativeLoglet).

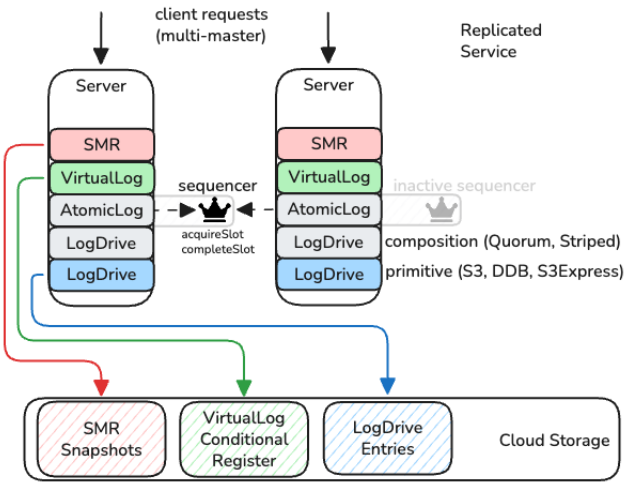

Figure 6. *SMR via LogDrives: each SMR-replicated server stores all its hard state in cloud storage. Servers do not interact via RPCs at any layer, with the exception of the soft-state sequencer in the AtomicLog.*

4.1 Discussion

Test-Driven Design: We created an extensive simulation testing framework for our shared log implementations. In this framework, we spin up a range of concurrent workloads against the shared log API in Figure 5; execute the workloads against a given target implementation of the API (e.g., the VirtualLog on an AtomicLog on a QuorumLogDrive) with failure and delay injection; and then check whether the resulting execution is linearizable.

Interestingly, this simulation testing drove many of our design insights. For example, we had initially assumed that the LogDrive would have to provide a linearizable *weakTail*; it was only after a pagination-induced linearizability violation in our S3LogDrive went uncaught in the AtomicLog sim-test that we realized we did not need *weakTail* linearizability: the AtomicLog was linearizable even if LogDrive was not. As an aside, our simulator also independently discovered a seal check ordering bug in the VirtualLog protocol described subsequently by the Delos team [35].

Low-Latency AtomicLog: As described, the AtomicLog uses the LogDrive abstraction to extract, augment, and scale durability (e.g., via quorums and striping) from external cloud storage. In one extreme, we use a primitive LogDrive (e.g., S3LogDrive) directly under AtomicLog, without further stacking. In principle, Conflux should also be able to support the other extreme, where we rely entirely on stacked LogDrives to provide durability over a non-durable primitive LogDrive.

To test this hypothesis, we implemented another primitive LogDrive: a simple, single-node LogServer that implements the LogDrive API via RPC, storing state on a local SSD

without further replication or striping. We obtain replicated durability by layering a QuorumLogDrive on top (which writes to a quorum of LogServers); and scale throughput via a StripedLogDrive. This resulting AtomicLog deployment is equivalent to a conventional shared log implemented on servers, allowing us to trade off operational overhead for lower latency within the same codebase.

5 Conflux and K2

We now describe how we built a metadata store called Conflux over the AtomicLog / LogDrive abstractions; and how we used it to power K2, a new Kafka implementation that stores data in S3 and metadata in Conflux.

5.1 The Conflux Metadata Store

Conflux has a shared log design, nearly identical to Delos [18] and borrowing from other shared log systems from research and industry. A Conflux service consists of one or more servers, each of which stores a local, single-node database (in production we use RocksDB [26]); and a single VirtualLog that each server can append to and read from. Conflux implements State Machine Replication [49] over the VirtualLog (as shown in Figure 6): updates to the service can be sent to any server; which *append*s an entry describing the update to an external shared log; and then synchronizes its local state with the shared log by calling *readNext* and applying new updates (until it executes the one it just added). Read-only queries can be served by any server, which calls *checkTail* on the shared log to establish a linearization point; and then synchronizes its local state until that tail position; before serving the query from local state. This simple protocol results in a replicated, linearizable database where both ordering and durability are delegated entirely to the external shared log, which is essentially the linearizable or strictly serializable total order of updates to the service. In principle, we can reconstruct state by replaying the shared log from the beginning on a new server; in practice, we frequently checkpoint state to cloud storage and trim the shared log, so that only a small suffix of the log has to be replayed on recovery.

By default, Conflux is a multi-master database that stores input commands (prior to execution) in the shared log and executes them (deterministically) on playback; but also supports modes where servers execute commands and append speculative outputs to the log [21]; or a single server (elected via the log itself) acts as a primary and stores non-speculative outputs in the log. In multi-master mode, reads have to wait for at least one round-trip to check the tail of the shared log; we use a "bus-stand" optimization [17] to amortize the bandwidth cost of this check, with many reads queueing up behind a single "bus" that checks the tail periodically.

Above the shared log, Conflux uses a stack of SMR layers [20]. These layers include logic for time/size-based batching and observability. The top-most SMR layer is the application, which can expose any arbitrary API. Later in the paper, we describe the specific API we implement on Conflux to support its primary use case as the K2 metadata store.

As described earlier, Conflux implements the VirtualLog abstraction from Delos, which separates reconfiguration from sequencing and durability (Figure 1 showed this separation of concerns earlier in the paper). The VirtualLog stitches together a number of Loglets into a single shared log. As a result, Conflux can switch from one Loglet to another without downtime, dynamically changing the underlying storage backend. The membership of the VirtualLog (i.e., the sequence of Loglets and the address ranges they cover) is stored in an external conditional register, which is the ultimate (and only) source of consensus in the system; in Conflux, this register is stored directly on DynamoDB (cost is not a concern since the state is small and only accessed on node reboots and reconfigurations).

5.2 The K2 Pub-Sub System

We now describe how we used Conflux to power K2, a new Kafka implementation that stores data in S3 and metadata in Conflux. K2 consists of a collection of servers called *brokers* (mirroring Kafka parlance) that implement the Kafka protocol. Clients can connect to brokers to *publish* data to a topic; and *fetch* data from the topic. As mentioned previously, Kafka uses the term 'partition' to refer to topics; but we use the classical definition of a topic as a single total order. Each broker collects incoming publish requests (across different topics) into a large batch to write to S3; and then updates metadata stored in Conflux. On a fetch request, the broker consults metadata in Conflux to retrieve the location of the requested data, and serves the data by reading S3.

Over time, brokers can access and rewrite state in S3: to switch it from the initial write-optimized format to a read-optimized one; to compact topics (i.e., remove overwritten updates to the same fine-grained key); or to build additional indexes over the topic for data lake formation. This background activity can be isolated on a separate pool of background brokers, or be collocated on the client-facing brokers.

In principle, any broker can respond to a publish or consume request for any topic. In practice, we shard the space of hashed topic IDs into ordered ranges [14], and assign different ranges to sets of brokers (typically one per AZ, to enable zone-aware routing from clients that minimizes inter-AZ data transfer costs). Affinitizing brokers to topics enables better locality within the initial write batches, which in turns results in more efficient background processing; and simplifies caching for reads. Brokers are not required to be durable – we can reconstruct the system entirely from S3 and Conflux – but do maintain soft-state caches of data.

```
interface K2MetaStore {
 long appendDataRef(TopicID id, DataRef newData);
 DataRef fetchDataRef(TopicID id, long address);
}
```

Figure 7. *Simplified subset of API exposed by Conflux to K2.*

5.3 Conflux in K2

As noted earlier, Conflux is a general-purpose SMR system that can replicate any deterministic service with an arbitrary API. To support K2, we implement a particular service called the K2MetaStore. In the remainder of this discussion, we use Conflux interchangeably with K2MetaStore (until we introduce other APIs). Figure 7 shows the subset of this API used in the critical path of publish-subscribe requests.

For each topic, Conflux stores an ordered list of pointers called DataRefs. To a first approximation, a DataRef is a pointer to some external piece of data. Accordingly, when a broker stores data in S3, it creates an S3DataRef – a pointer to a portion of an S3 object – and then sends it to Conflux, which adds it to the ordered list.

Logs on Logs: Each ordered list in Conflux can be viewed as a fine-grained shared log within a state machine, which in turn is replicated over a coarse-grained shared log. We exploit this log-on-log structure by using a common API for both layers: the ordered list of DataRefs implements a read-only subset of the API in Figure 5, as does each individual DataRef. Using a common API at different layers has a number of practical implications. For example, we were able to augment our test coverage for Conflux by reusing our sim-test framework from Section 4.1 to run against a single topic, testing the entire stack end-to-end for linearizability. Practically, a common base API for both the fine-grained application-level construct and the coarse-grained replication log allowed us to reuse code: oncall tooling, wrappers for observability, composition, and interception; reusable benchmarking logic; etc. In making this choice, we were inspired by a familiar pattern in OS design: e.g., virtual disks and physical disks.

In addition, DataRefs are not necessarily just passive pointers to S3 blobs; as shared logs, they can be backed by complex systems. This allows Conflux to delegate indexing for a prefix of the topic: e.g., to a prior Kafka deployment (for migration) or to a data lake format on S3 (for tiering cold metadata).

Sharding in Conflux: In production, we compose multiple Conflux instances into a larger, sharded instance, for scaling throughput and capacity. We use an identical sharding scheme to the K2 brokers, to maximize locality between brokers and Conflux shards (to minimize the fan-out between a broker and the number of Conflux shards it interacts with).

Re-sharding is currently done via a conventional transaction protocol that locks and moves sub-ranges of hashed topic IDs from one shard to another. We are currently exploring ways to exploit the log-like nature of the state machine

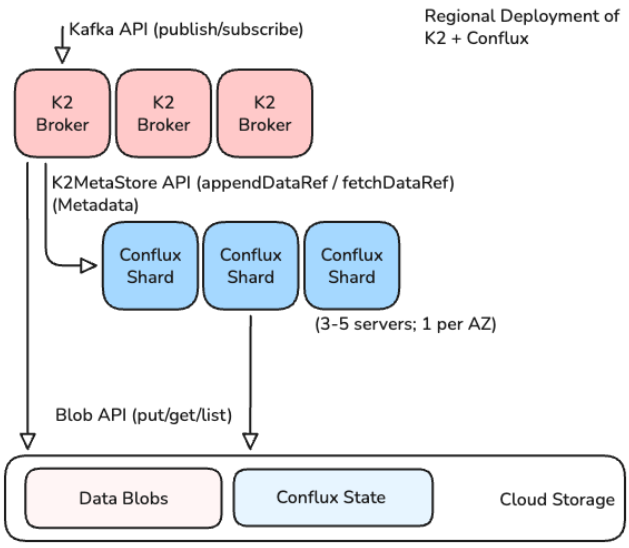

Figure 8. *K2 servers store data blobs in cloud storage and metadata in Conflux. (See Figure 6 for the structure of a single Conflux shard).*

for faster moves: e.g., we can virtualize a topic's index to span physical segments on different shards. This is similar to the shared log virtualization we use in the consensus layer, echoing Lampson's principle of "use a good idea twice" [43].

Other APIs: To support other parts of the Kafka protocol, we implemented two other separate APIs on Conflux in addition to the K2MetaStore. The first is a K2GroupService which implements the group coordinator abstraction in Kafka, responsible for managing groups of consumers fetching from a bundle of individual total orders (i.e., which Kafka calls a topic; or equivalently a bundle of conventional pub-sub topics), mapping consumers to total orders and tracking cursor offsets. The second is a K2TxService, which implements a coordinator for implementing Kafka transactions.

In production, we deploy a single Conflux service for each of our three APIs within a region. Each such regional Conflux deployment consisting of multiple shards. Each shard is replicated across multiple Conflux servers (typically one per AZ, such that we have between 3 to 5 servers, depending on the AWS region).

6 Evaluation

We present an evaluation of Conflux using a combination of production and benchmarking data. All our deployments run on AWS EC2 instances deployed via K8s [5], using EBS drives for network-attached storage. In all experiments, we have production-grade logging and monitoring enabled via Datadog [3]. In our single-region tests, each Conflux deployment consists of one server per AZ (for example, in us-west-2 we run four servers), while clients are distributed across all AZs. Since Conflux servers store only soft state, the number

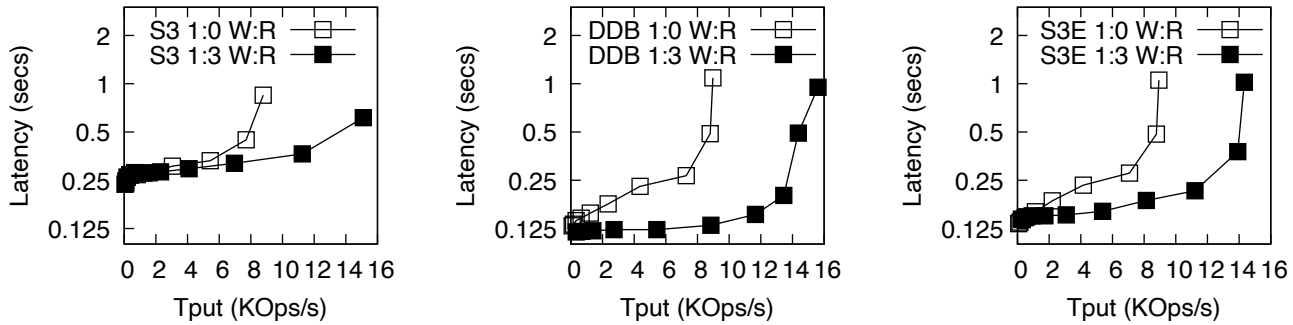

Figure 9. *Conflux can run on S3 (Left), DynamoDB with Striping (Middle), and S3Express with Quorums (Right).*

of servers has no durability implications. In our multi-region tests, we continue to run our deployment entirely on us-west-2, but synchronously mirror data to two other regions: us-east-1 (~60ms away) and eu-east-1 (~120ms away).

In our cost and latency comparisons, we include a hypothetical DynamoDB strawman for the Conflux API. We assume that each *appendDataRef* results in one write to DynamoDB; and each *fetchDataRef* is one read. In practice, implementing a production-ready shim on DynamoDB would require non-trivial engineering effort (e.g., concurrency control between competing *appendDataRef* calls); however, this simple model gives us a lower bound on achievable latency and cost.

In our production workloads, the average write size to Conflux is 165 bytes; and the write:read ratio is typically 1:3. In our benchmarking setup, we use m6g.xlarge EC2 instances; we omit details of our production servers. We use three cloud storage backends in our experiments. S3 and DynamoDB provide durability against AZ failures, while S3Express can lose data with one AZ failure.

In our setups, we vary the LogDrive used by Conflux, but use S3 to store snapshots every 10 minutes (so that the shared log does not have to be replayed from the beginning). By default, we set a batching timeout in Conflux to 100ms; and a size threshold to 60KB. The Conflux AtomicLog is configured with a windowsize of $K = 16$. All reported latencies are p99s.

6.1 Pluggability and Composability

Conflux can leverage the LogDrive abstraction to easily run on and *extract durability* from different cloud stores with minimal effort. Figure 9 shows the throughput-latency curve for different Conflux deployments, running over S3 (Left), DynamoDB (Middle), and S3Express (Right), respectively.

Interestingly, this graph also illustrates that the LogDrive can *augment the durability* of existing cloud storage: to provide an apples-to-apples comparison with S3Express (which is natively single-AZ), we layered a QuorumLogDrive over three S3ExpressLogDrives, each one in a different AZ.

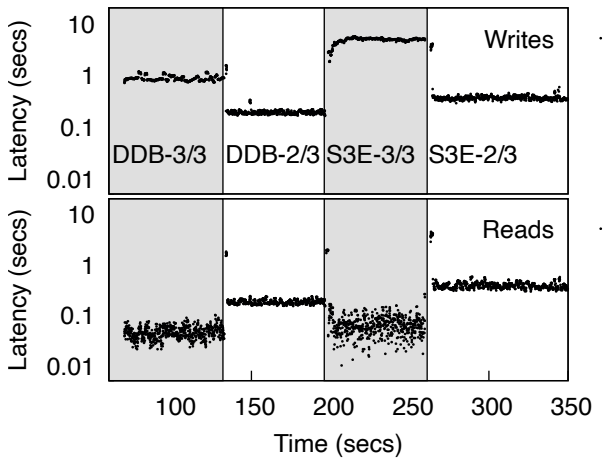

Figure 10. *Conflux reconfig: DynamoDB (3,3) quorum to DynamoDB (2,3); to S3Express (3,3); to S3Express (2,3). Replicas in us-west-2, us-east-1, eu-east-1; clients in us-west-2.*

Conflux can switch its VirtualLog between different AtomicLogs which are backed by different LogDrives. In Figure 10, we start running Conflux on a QuorumLogDrive running on a (3,3) quorum of DynamoDBLogDrive instances running in us-west-2, us-east-1, and eu-east-1; writes have to wait for all regions, but reads are cheap. We then switch to a (2,3) quorum: writes and reads are now equally fast, since they both have to reach a majority. After that we switch to (3,3) quorum of S3Express single-AZ instances (one AZ per region); and finally we switch to a (2,3) quorum of S3Express. Finally, in Figure 11, we show this (2,3) quorum S3Express configuration seamlessly tolerate an S3Express outage in us-west-2 (emulated by disable access control). These graphs illustrates that Conflux can reconfigure without downtime between different backends; obtain different durability / latency profiles via quorum sizes; augment DynamoDB (one-region) and S3Express (one-AZ) to provide multi-region durability; and tolerate regional storage failures. Table 12 shows the LOC for the various LogDrive implementations involved.

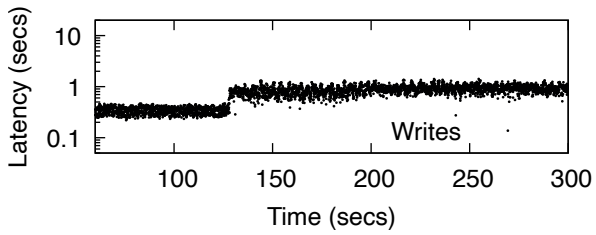

Figure 11. *Conflux S3Express (2,3): S3Express fails in us-west-2.*

Implementation	LOC
S3LogDrive	519
DynamoDBLogDrive	528
S3ExpressLogDrive	525
StripedLogDrive	194
QuorumLogDrive	325

Metadata cost	7.20	0.69	1.10	0.85
Total cost	9.57	3.06	3.47	3.22

Figure 13. *Conflux-over-DDB is 10X cheaper than DDB for metadata and over 3X cheaper overall (data plane = $2.37/hr).*

6.2 Cost

We provide a detailed cost estimate of running Conflux over the DynamoDBLogDrive, compared with using DynamoDB directly. We pick a record size of 165 bytes, matching the average observed in our production workloads. For Conflux, we include the cost of 3 EC2 instances for the Conflux deployment and the associated EBS disk cost. Our modeled workload issues 2K writes/s and 6K reads/s. We use the latest available cost information from AWS: for DynamoDB, we used on-demand capacity pricing [1] in the us-west-2 region ($0.625/M Write Request Units / WRUs, and $0.125/M Read Request Units).

Table 13 shows that Conflux-over-DynamoDB is an order of magnitude cheaper than the direct-over-DynamoDB strawman. This cost differential arises for a number of reasons. First, Conflux collects small writes in a batch and issues a single large write to DynamoDB (i.e., the append to the shared log). Since each write (regardless of size, up to 1KB) is charged independently as a WRU, batching lowers our cost significantly even though we are writing the same amount of data in both Conflux and the strawman design. Second, batching writes allows us to compress writes more efficiently (we model a factor of 5X, which is what we observe in our production workloads). Third, Conflux serves reads from a strongly consistent, full copy of the database (i.e., by playing the shared log), avoiding redundant reads to DynamoDB. We also include cost numbers for Conflux on S3 and S3Express (replicated over 3 AZs); both are more expensive than DynamoDB.

The Conflux setup we model here is identical to the one we evaluated earlier in Figure 9; accordingly, the corresponding p99 latency is roughly ~130ms. As a result, our $10X$ cost win comes with a $6.5X$ write slowdown; but the resulting latency is acceptable for Conflux's use case.

Separately, we validate that metadata is indeed a significant fraction of overall cost. To do so, we model the corresponding data plane cost assuming: (a) each data blob referenced by a metadata record is $128KB$; (b) data blobs are batched together into $5MB$ objects; (c) a $1:3$ ratio of publish to fetch. Under these assumptions, we obtain a data plane cost of $2.37 per hour. As a result, replacing a strawman DynamoDB in K2 cuts cost by more than $3X$ (see Table 13).

6.3 K2 in Production

This section shares empirical data from a production K2 deployment that shows the performance and reconfigurability benefits of Conflux. This deployment spans three AZs in us-west-2 region and uses LogDrive-on-DynamoDB with a batching latency of 100ms. The deployment consists of 114 K2 brokers, of which 108 are serving requests. We use 20 Conflux instances as shards with three servers each.

Figure 14 shows a screenshot of our production dashboard for a run with $9GB/s$ produce and $27GB/s$ fetch. Latencies are reported over 1-min intervals from each K2 broker. Produce p99 latency is about 600ms whereas fetch p99 latency is about 300ms; the 500ms numbers are due to a blocking timeout on client fetches for empty topics. Figure 15 (Left) compares data plane and metadata latency on the production run (plotting the p99 across per-server p99s). The produce latency is dominated by the latency to batch and upload data to S3 and then to sequence it via an *appendDataRef* RPC to Conflux (which has a p99 of 130ms, in line with our micro-benchmarks for Conflux-on-DynamoDB). Fetch latency is dominated by the latency to retrieve data from S3; sometimes serving a single client fetch might require reading a number of different S3 objects, which can aggravate the tail latency. In this run, the average metadata record size is around 165 bytes and we get an effective compression of around $6-7X$.

Finally, we show Conflux change backends mid-flight. Our initial deployment used S3LogDrive under Conflux. However, we discovered that S3LogDrive had suboptimal performance (as we showed in Section 6.1) as well as cost (as we saw in Section 6.2) compared to DynamoDBLogDrive. Accordingly, we decided to switch our early access service to use Conflux over DynamoDB. A single engineer implemented and

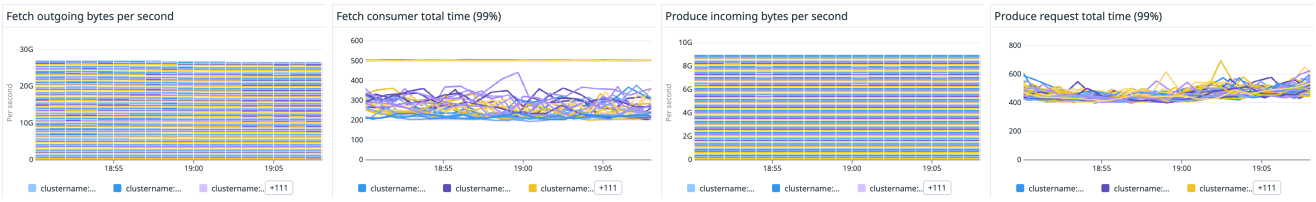

Figure 14. *Screenshot of the production dashboard for a K2 cluster serving 9GB/s produce and 27GB/s fetch throughput.*

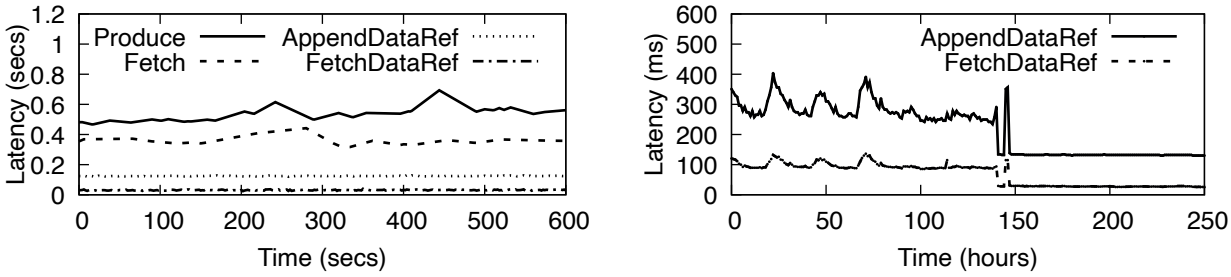

Figure 15. *(Left) Latency on K2 9GB/s produce / 27GB/s fetch production cluster (p99 across per-server p99s); (Right) switchover on an early production cluster from S3 to DynamoDB.*

deployed the DynamoDBLogDrive in about 1 week, leveraging existing simulation tests and observability wrappers. Early tests hit rate limits on DDB partition key accesses; the engineer was able to work around that by using the StripedLogDrive. Figure 15 (Right) shows a running Conflux service make the switch without downtime. Interestingly, we first switched to an incorrect table; switched immediately back to S3 (hence the spike); and then made the correct switch.

7 Related Work

As described, K2 implements large numbers of fine-grained shared logs over an S3-based data plane and the Conflux metadata layer; and Conflux is itself a database designed over a shared log. Accordingly, both K2 and Conflux are shared log designs which intersect with the literature in different ways.

Early group communication systems [23, 30, 51] provided flexible placement of sequencing and durability: e.g., sequencing could be out-of-band or in-band, fixed or moving, etc. While the theory of Paxos retained this flexibility [42, 50, 53], production-ready MultiPaxos systems [25] and later Raft [46] adopted inflexible leader-driven designs where a specific node acted as a sequencer, a storage acceptor, and a database learner.

Scalable shared logs: Initial shared logs like Corfu [19] reintroduced sequencing flexibility by separating the location of sequencing from durable storage, in a "sequence-first, write-later" design; in doing so, they scaled the throughput of a single log. Later shared log designs like Scalog [31] reversed this order to "write-first, sequence-later", shifting the burden of storing the durable sequence to a stateful metadata layer. In the same timeline, industry systems such as Kafka [40] and BookKeeper [39] focused instead on scaling to large numbers of fine-grained leader-driven logs. Given this history, K2 can be viewed as a "write-first, sequence-later" system that scales to many fine-grained logs (with Conflux acting as the metadata layer storing the durable sequence for each log).

Shared logs for SMR: At the same time, shared logs have also played a different role by providing an API for consensus, simplifying SMR-based production databases that need extreme reliability, arbitrary APIs, composability, and zero-downtime upgrades, but not massive scale or low latency [2, 18]. Conflux extends this literature by enabling these properties over cloud storage at low cost. In addition, the AtomicLog / LogDrive can be used underneath any existing SMR-based database.

Shared logs have been recently extended to serverless functions [36, 38, 48] and stream processing [54]. The ideas in Conflux could potentially allow these systems to operate directly over cloud storage. In addition, the LazyLog [44] applies the same principle of separating sequencing from durability in a slightly different way. In a sense, the LazyLog changes *when* a timestamp is assigned to an appended entry, whereas in this work we focus on *which layer* assigns the timestamp.

Streaming on cloud storage: K2 fits into a trend towards constructing high-level APIs by combining cloud storage with a metadata layer. Snowflake's database architecture [45] over S3 and FoundationDB is an early and significant example of this design pattern. Warpstream [13] is another

example of a Kafka implementation that uses S3 as its durability layer. While K2 shares this design pattern, our primary contribution is the LogDrive abstraction and its use within Conflux to provide a simple, robust, and inexpensive metadata layer over cloud storage.

8 Conclusion

Commodity cloud storage has the potential to unlock innovation at higher layers by providing durability as a service. At the same time, existing cost structures make it prohibitively expensive to build metadata layers that require small, frequent accesses. In this paper, we proposed a new system called Conflux that uses cloud storage as a shared log for replicating updates, extracting durability while slashing cost. Conflux introduces a novel shared log design that separates sequencing (via the AtomicLog implementation) and durability (via the LogDrive abstraction). The LogDrive supports arbitrary RAID-like stacking, allowing us to combine and augment existing cloud durability in new ways. Conflux is deployed at Confluent as the metadata service for K2 (which in turn powers the Freight product), driving down metadata cost by 10X and overall system cost by 3X.

9 Acknowledgments

We would like to thank Chad Verbowski, Jun Rao, and Jay Kreps for funding the K2 project and shaping its goals. Anil Sharma and Kamal Gupta were responsible for managing early iterations of the team. Hakan Hacigumus significantly impacted the project in its later stages. We would also like to thank our anonymous OSDI shepherd. Finally, this paper would not have been written without CQ Tang's advice and encouragement.

A LogDrive Proofs

A.1 Specification of the LogDrive

A LogDrive is a bounded array of $N+1$ registers, indexed by the integers $A = \{0, 1, \ldots, N\}$. Each address $a \in A$ holds either a payload from a value set $\mathcal{V}$ or the distinguished value $\perp$ indicating *unwritten*. At time t, the system state is

$$S(t) : A \to \mathcal{V} \cup \{\perp\}.$$

For simplicity, we use the Nth register as a sentinel: $S(t, N) = \perp$ for all t. We assume that this sentinel register is never written to.

Read/write semantics. Operations $\textsc{write}(a, v)$ and $\textsc{read}(a)$ are *linearizable*. That is, there exists a total order of all completed reads and writes, consistent with real-time precedence, such that:

- A write $\textsc{write}(a, v)$ takes effect at its linearization point, setting $S(t, a) = v$.
- A read $\textsc{read}(a)$ returns $S(t, a)$ at its linearization point.
- **Write-once monotonicity:**

$$S(t_1, a) \neq \perp \;\Rightarrow\; S(t_2, a) \neq \perp \qquad \text{for all } t_1 \leq t_2.$$

  Once written, an address is never unwritten.
- **Single-value assumption.** If two writes to the same address propose *different* values, the behavior is unspecified. All correctness arguments assume that executions are *well-formed*: for each address a, at most one value v is ever written to a.

Contiguous tail. At any time t, the contiguous tail is:

$$\mathcal{T}(t) = \min\{a \mid S(t, a) = \perp\}.$$

Non-contiguous tail and K-window discipline. At time t, define the *non-contiguous tail* as

$$\mathcal{N}(t) = \min\Big\{ a \in A \;\Big|\; S(t, a) = \perp \text{ and } \forall b \in A,\ b > a \Rightarrow S(t, b) = \perp \Big\}.$$

That is, $\mathcal{N}(t)$ is the first unwritten address after which all addresses are unwritten.

We say that an execution satisfies the *K-window discipline* if, for all times t,

$$\mathcal{N}(t) - \mathcal{T}(t) \leq K.$$

Thus at most K addresses in the prefix $A_{<\mathcal{N}(t)}$ are unwritten. Intuitively, this captures that the application never has more than K *in-flight* writes.

weakTail semantics. Let a weakTail(K) operation o execute during the real-time interval $[t_{\text{start}}(o),\ t_{\text{stop}}(o)]$. During this interval, o determines (via direct reads or implicit deduction) the written/unwritten status of every address. Formally, for each $a \in A$, let

$$\tau_o(a) \in [\ t_{\text{start}}(o),\ t_{\text{stop}}(o)\ ]$$

denote the time at which o observes the status of address a. Define

$$w_o(a) = \begin{cases} \text{written} & \text{if } S(\tau_o(a), a) \neq \bot, \\ \text{unwritten} & \text{if } S(\tau_o(a), a) = \bot. \end{cases}$$

The return value of weakTail(K) is produced by a deterministic function

$$F : w_o \longmapsto (\mathcal{N}_{\text{obs}}, \mathcal{H}_{\text{obs}}),$$

where:

- $\mathcal{N}_{\text{obs}} = \min\{\, a \in A \mid w_o(a) = \text{unwritten and } \forall b \in A,\ b > a \Rightarrow w_o(b) = \text{unwritten} \,\}$
- $\mathcal{H}_{\text{obs}} = \{\, a \in A \mid a < \mathcal{N}_{\text{obs}} \text{ and } w_o(a) = \text{unwritten} \,\}$ is the *observed hole set*, i.e., the unwritten addresses between the contiguous and non-contiguous observed tails.

Further, the caller can derive the contiguous tail $\mathcal{T}_{\text{obs}}$ from the return value of weakTail. Given $(\mathcal{N}_{\text{obs}}, \mathcal{H}_{\text{obs}})$, the observed contiguous tail is

$$\mathcal{T}_{\text{obs}} = \begin{cases} \min \mathcal{H}_{\text{obs}} & \text{if } \mathcal{H}_{\text{obs}} \neq \emptyset, \\ \mathcal{N}_{\text{obs}} & \text{if } \mathcal{H}_{\text{obs}} = \emptyset. \end{cases}$$

For brevity, in the remainder of the proof we will speak of weakTail as "returning" $\mathcal{T}_{\text{obs}}$, with the understanding that this value is computed in the above manner.

Intuitively, weakTail corresponds to an *unordered, non-atomic scan* in which each address a is read at least once at some time $\tau_o(a)$ within the operation interval, and the operation returns the first unwritten address beyond which all addresses are unwritten; as well as the list of holes prior to it.

A.2 Derived Properties of LogDrive

Lemma ([LD.1] Tail-Range Guarantee**).** *Let a* weakTail(K) *operation o execute during the real-time interval $[t_{\text{start}},\ t_{\text{stop}}]$, and let*

$$\mathcal{T}_{\text{start}} = \mathcal{T}(t_{\text{start}}), \qquad \mathcal{T}_{\text{stop}} = \mathcal{T}(t_{\text{stop}})$$

be the true contiguous tails at the start and end of o. Let $\mathcal{T}_{\text{obs}}$ be the observed tail returned by o, as defined in the weakTail *semantics. Then*

$$\mathcal{T}_{\text{obs}} \in [\mathcal{T}_{\text{start}},\ \mathcal{T}_{\text{stop}}].$$

Proof. By the weakTail semantics, for each address $a \in A$ there is an observation time

$$\tau_o(a) \in [t_{\text{start}}, t_{\text{stop}}],$$

and $w_o(a)$ is determined from the state at that time as written or unwritten.

Lower bound. Suppose, for contradiction, that $\mathcal{T}_{\text{obs}} < \mathcal{T}_{\text{start}}$. By definition of $\mathcal{T}_{\text{start}}$, every address $a < \mathcal{T}_{\text{start}}$ is written at time t_{start}, i.e. $S(t_{\text{start}}, a) \neq \bot$. By write-once monotonicity, once written an address never becomes unwritten, so for all $t \geq t_{\text{start}}$ we have $S(t, a) \neq \bot$. In particular,

$$S\big(\tau_o(\mathcal{T}_{\text{obs}}), \mathcal{T}_{\text{obs}}\big) \neq \bot,$$

since $\tau_o(\mathcal{T}_{\text{obs}}) \in [t_{\text{start}}, t_{\text{stop}}]$. Hence $w_o(\mathcal{T}_{\text{obs}}) = \text{written}$, contradicting the assumption that $\mathcal{T}_{\text{obs}}$ is the smallest address with $w_o(a) = \text{unwritten}$. Therefore $\mathcal{T}_{\text{obs}} \geq \mathcal{T}_{\text{start}}$.

Upper bound. Suppose instead that $\mathcal{T}_{\text{obs}} > \mathcal{T}_{\text{stop}}$. By definition of $\mathcal{T}(t_{\text{stop}})$, $\mathcal{T}_{\text{stop}}$ is unwritten at time t_{stop}, i.e. $S(t_{\text{stop}}, \mathcal{T}_{\text{stop}}) = \bot$. By write-once monotonicity, if a location is unwritten at some time, it must have been unwritten at all earlier times. Thus for all $t \leq t_{\text{stop}}$,

$$S(t, \mathcal{T}_{\text{stop}}) = \bot.$$

In particular, since $\tau_o(\mathcal{T}_{\text{stop}}) \in [t_{\text{start}}, t_{\text{stop}}]$, we have

$$S\big(\tau_o(\mathcal{T}_{\text{stop}}), \mathcal{T}_{\text{stop}}\big) = \bot,$$

and hence $w_o(\mathcal{T}_{\text{stop}}) = \text{unwritten}$. But this contradicts the fact that $\mathcal{T}_{\text{obs}}$ is the *smallest* address with $w_o(a) = \text{unwritten}$, since $\mathcal{T}_{\text{stop}} < \mathcal{T}_{\text{obs}}$. Therefore $\mathcal{T}_{\text{obs}} \leq \mathcal{T}_{\text{stop}}$.

Combining the two bounds yields $\mathcal{T}_{\text{obs}} \in [\mathcal{T}_{\text{start}},\ \mathcal{T}_{\text{stop}}]$. □

Lemma ([LD.2] Window-Scan Refinement**).** *Assume the K-window discipline holds, and that the storage layer provides a linearizable operation to read the non-contiguous tail $\mathcal{N}$. Consider a weakTail operation with real-time interval $[t_{\text{start}}, t_{\text{stop}}]$ implemented as follows:*

1. *Read $\mathcal{N}$ once, yielding $\mathcal{N}^*$, with linearization point $t^* \in [t_{\text{start}}, t_{\text{stop}}]$.*
2. *Perform an unordered, non-atomic scan only over the window $[max(0, \mathcal{N}^* - K),\ \mathcal{N}^*]$, reading each address in this window at least once at some time in $[t_{\text{start}}, t_{\text{stop}}]$, and return the set of holes in that window.*

Then the pair $(\mathcal{N}_{\text{obs}}, \mathcal{H}_{\text{obs}})$ returned by the window scan is equal to the pair produced by some full unordered, non-atomic scan whose observations all lie within $[t_{\text{start}}, t_{\text{stop}}]$.

Proof. Let t^* be the linearization point of the read of $\mathcal{N}$, so we observe $\mathcal{N}^* = \mathcal{N}(t^*)$. By the K-window discipline at t^*, the true contiguous tail $\mathcal{T}(t^*)$ lies in $[\mathcal{N}^* - K,\ \mathcal{N}^*]$, all addresses $< \mathcal{N}^* - K$ are written at t^*, and all addresses $> \mathcal{N}^*$ are unwritten at t^*. If $\mathcal{N}^* < K$, we interpret the window $[\mathcal{N}^* - K,\ \mathcal{N}^*]$ as $[max(0, \mathcal{N}^* - K),\ \mathcal{N}^*]$, since addresses below 0 are outside the array.

Construct a hypothetical full unordered, non-atomic scan as follows: for each address in $[\mathcal{N}^* - K,\ \mathcal{N}^*]$, use the actual read (time and result) performed by the window-scan implementation; for each address $< \mathcal{N}^* - K$, imagine a read at time t^* returning "written"; and for each address $> \mathcal{N}^*$, imagine a read at time t^* returning "unwritten". All these reads occur within $[t_{\text{start}}, t_{\text{stop}}]$ since t^* does, so this is a valid full unordered, non-atomic scan in the sense of our *weakTail* specification.

By construction, the non-contiguous tail in this hypothetical full scan is exactly the non-contiguous tail observed by the window-based implementation; and the set of holes observed in the full scan is also equal to that returned by the window-based implementation. Thus there exists a full unordered, non-atomic scan whose observations all lie within $[t_{\text{start}}, t_{\text{stop}}]$ and whose $(\mathcal{N}_{\text{obs}}, \mathcal{H}_{\text{obs}})$, as defined by the WEAKTAIL semantics, coincide exactly with those returned by the window-based implementation.

□

A.3 StripedLogDrive Implementation

Let $S \geq 1$ be the number of stripes. Each stripe D_i, for $i \in \{0, \ldots, S-1\}$, is an independent LogDrive instance with local address set

$$A^{\text{loc}} = \{0, 1, \ldots, N\},$$

where the local address N is a sentinel that is never written ($S_i(t, N) = \perp$ for all t), and addresses $0, \ldots, N-1$ are the real data slots. We write

$$A^{\text{real}} = \{0, 1, \ldots, N-1\}$$

for the set of real local addresses.

The global address space of a striped LogDrive is the finite set

$$A^{\text{glob}} = \{0, 1, \ldots, SN\},$$

where addresses $0, \ldots, SN-1$ are striped across the S underlying instances and address SN is a global sentinel that is never written.

For a global address $a \in \{0, \ldots, SN-1\}$ we define

$$\text{stripe}(a) = a \bmod S, \qquad \text{local}(a) = \left\lfloor \frac{a}{S} \right\rfloor.$$

Then $\text{stripe}(a) \in \{0, \ldots, S-1\}$ and $\text{local}(a) \in A^{\text{real}}$ for all $a < SN$. At time t, the global state is

$$S^{\text{glob}}(t, a) = \begin{cases} S_{\text{stripe}(a)}\big(t, \text{local}(a)\big) & \text{if } a < SN, \\ \perp & \text{if } a = SN. \end{cases}$$

Read/write semantics. A striped LogDrive supports global operations $\text{WRITE}(a, v)$ and $\text{READ}(a)$ only for $a \in \{0, \ldots, SN-1\}$, by delegating to the corresponding stripe:

$$\text{WRITE}(a, v) = \text{WRITE}_{\text{stripe}(a)}\big(\text{local}(a), v\big).$$

$$\text{READ}(a) = \text{READ}_{\text{stripe}(a)}\big(\text{local}(a)\big).$$

The global sentinel address SN is never written and is never the target of a read.

Algorithm 1 StripedLogDrive Implementation

```
1:  procedure StripedWrite(a, v)                          ▷ 0 ≤ a < SN
2:      i ← a mod S;    ℓ ← ⌊a/S⌋
3:      D_i.write(ℓ, v)
4:  end procedure

5:  procedure StripedRead(a)                              ▷ 0 ≤ a < SN
6:      i ← a mod S;    ℓ ← ⌊a/S⌋
7:      return D_i.read(ℓ)
8:  end procedure

9:  procedure StripedWeakTail(K)
10:     assert K mod S = 0
11:     K_i ← ⌊K/S⌋ for all i ∈ {0, ..., S − 1}
12:     for all i ∈ {0, ..., S − 1} in parallel do
13:         (N_obs^(i), H_obs^(i)) ← D_i.weakTail(K_i)
14:     end for
15:     T_cand ← {SN}
16:     for i ← 0 to S − 1 do
17:         if N_obs^(i) < N then
18:             T_cand ← T_cand ∪ { S · N_obs^(i) + i }
19:         end if
20:     end for
21:     N_obs^glob ← min T_cand
22:     H_obs^glob ← ∅
23:     for i ← 0 to S − 1 do
24:         for all a ∈ H_obs^(i) with a < N do
25:             H_obs^glob ← H_obs^glob ∪ { S · a + i }
26:         end for
27:     end for
28:     return (N_obs^glob, H_obs^glob)
29: end procedure
```

Disjointness Assumption. Each stripe D_i is an independent LogDrive instance with no shared state.

Lemma (**[SLD.0]** Linearizability of StripedLogDrive)**.** *StripedLogDrive READ/WRITE operations are linearizable: there exists a total order of all completed operations, consistent with real-time precedence, whose behavior matches that of an abstract LogDrive.*

Proof. By specification, each global READ/WRITE on address a is routed to a single stripe and stripes do not interfere. Since each stripe is a linearizable LogDrive, its operations admit a linearization order. Because the per-stripe histories are independent, these orders can be merged while preserving real-time precedence. The resulting total order satisfies the abstract LogDrive semantics, establishing linearizability. □

Theorem (**[SLD.1]** Striped LogDrive Refines the LogDrive Specification)**.** *Assume K is divisible by S, and that each stripe D_i is a correct LogDrive satisfying the abstract specification*

of §A.1, including the WEAKTAIL(K/S) *semantics. Then the striped LogDrive defined above:*

1. *provides linearizable* READ/WRITE *operations; and*
2. *provides a correct* WEAKTAIL(K) *implementation whose return value coincides with that of some unordered, non-atomic scan over* A^{glob} *in the sense of §A.1.*

Thus the striped LogDrive is a correct implementation of the abstract LogDrive.

Proof. Linearizability of reads and writes follows from A.3.

***Correctness of* WEAKTAIL.** Consider a striped WEAKTAIL(K) operation o with real-time interval $[t_{\text{start}}, t_{\text{stop}}]$. By the StripedLogDrive implementation, for each stripe $i \in \{0, \ldots, S-1\}$ the client invokes

$$D_i.\text{WEAKTAIL}(K/S),$$

where K/S is an integer by assumption. Since D_i is a correct LogDrive, the abstract WEAKTAIL(K/S) specification guarantees that there exists a (hypothetical) local unordered, non-atomic scan o_i over the local address space $A^{\text{loc}} = \{0, \ldots, N\}$ whose per-address observations all occur within $[t_{\text{start}}, t_{\text{stop}}]$, and such that applying the unstriped WEAKTAIL semantics to o_i yields exactly the pair $(\mathcal{N}_{\text{obs}}^{(i)}, \mathcal{H}_{\text{obs}}^{(i)})$ returned by D_i .WEAKTAIL(K/S).

We now construct a global unordered, non-atomic scan o^{glob} over the global address space $A^{\text{glob}} = \{0, 1, \ldots, SN\}$. For each stripe $i \in \{0, \ldots, S-1\}$ and each real local address $a \in A^{\text{real}} = \{0, \ldots, N-1\}$, the scan o^{glob} performs a read of the global address $A = S \cdot a + i$ at the same time and with the same return value as in the local scan o_i for address a. For the global sentinel address SN, the scan o^{glob} performs a single read at any time in $[t_{\text{start}}, t_{\text{stop}}]$, returning $\perp$. All per-address observations of o^{glob} thus lie within the interval $[t_{\text{start}}, t_{\text{stop}}]$ and are consistent with the striped LogDrive state, so o^{glob} is a valid global unordered, non-atomic scan in the sense of §A.1.

By construction, for every i and $a \in A^{\text{real}}$, the global address $A = S \cdot a + i$ is unwritten in o^{glob} if and only if the corresponding local address a is unwritten in the local scan o_i. Applying the unstriped WEAKTAIL semantics *globally* to o^{glob} therefore yields:

- a global observed non-contiguous tail

$$\mathcal{N}_{\text{obs}}^{\text{glob}} = \min\Big(\big\{S \cdot a + i \;\big|\; i \in \{0, \ldots, S-1\}, \; a = \mathcal{N}_{\text{obs}}^{(i)} < N\big\} \;\cup\; \{SN\}\Big),$$

- and a global observed hole set

$$\mathcal{H}_{\text{obs}}^{\text{glob}} = \bigcup_{i=0}^{S-1} \left\{ S \cdot a + i \;\middle|\; a \in \mathcal{H}_{\text{obs}}^{(i)} \cap A^{\text{real}} \right\}.$$

Algorithm 2 QuorumLogDrive Implementation: Write and Read

```
1:  procedure QuorumWrite(a, v)
2:      for all j ∈ {0, ..., N − 1} in parallel do
3:          send write(a, v) to D_j
4:      end for
5:      wait until ack received from at least Q_w replicas
6:      return
7:  end procedure

8:  procedure QuorumRead(a)
9:      choose any set R_r ⊆ {0, ..., N − 1} with |R_r| = Q_r
10:     for all j ∈ R_r in parallel do
11:         x_j ← D_j.read(a)
12:     end for
13:     if some x_j ≠ ⊥ then
14:         pick any non-⊥ value v among {x_j}_{j∈R_r}
15:         send write(a, v) to enough replicas to ensure at
        least Q_w written
16:         return v
17:     else
18:         return ⊥
19:     end if
20: end procedure
```

These are exactly the values computed and returned by the StripedWeakTail algorithm. Hence for this striped WEAKTAIL(K) operation o, there exists a global unordered, non-atomic scan o^{glob} whose observed non-contiguous tail and hole set coincide with the striped implementation's return value $(\mathcal{N}_{\text{obs}}^{\text{glob}}, \mathcal{H}_{\text{obs}}^{\text{glob}})$.

Conclusion. The striped LogDrive provides linearizable read/write semantics and a correct WEAKTAIL(K) implementation, and therefore refines the abstract LogDrive specification. □

A.4 QuorumLogDrive Implementation

A.5 The QuorumLogDrive

We implement a replicated LogDrive over N independent LogDrive replicas $D_0, \ldots, D_{N-1}$. For each replica D_j we assume the abstract LogDrive specification of §A.1 holds, including linearizable READ/WRITE and WEAKTAIL(K) semantics. The QuorumLogDrive is configured with:

- a write quorum size Q_w, where $1 \le Q_w \le N$;
- a read quorum size $Q_r = N - Q_w + 1$;
- a fault-tolerance quorum size $Q_f = \max(Q_w, Q_r)$.

Lemma (**[QLD.0]** Linearizability of QuorumLogDrive Reads / Writes)**.** *Under the assumptions of §A.5, the QuorumLogDrive* READ/WRITE *operations are linearizable: there exists a*

total order of all completed operations, consistent with real-time precedence, whose behavior matches that of an abstract LogDrive.

Proof. Fix an address a. Because replicas $D_0, \ldots, D_{N-1}$ are independent LogDrive instances, each replica's local READ/WRITE operations on a are linearizable with respect to its own state.

A global WRITE(a, v) sends WRITE(a, v) to all N replicas and waits for acknowledgments from a write quorum of size Q_w. We linearize this write at the real-time instant when the Q_w-th replica durably stores v at address a. After that instant, at least Q_w replicas contain v at a and, by the single-valued assumption, no replica ever stores a different value at a.

A global READ(a) selects a read quorum R_r of size $Q_r = N - Q_w + 1$ and performs a local READ(a) at each replica in R_r, obtaining responses $\{x_j\}_{j \in R_r}$. There are two cases:

- If all $x_j = \perp$, then no completed write to a can exist: any completed write would have updated a write quorum of size Q_w, and since $Q_w + Q_r > N$, the read quorum R_r would intersect that write quorum at a replica returning $v \neq \perp$. Thus the abstract LogDrive state at a is $\perp$ throughout the read's interval, and we can linearize the read at any time within its interval, returning $\perp$.
- Otherwise, some $x_j = v \neq \perp$. Let WRITE(a, v) be the latest completed write to a in the write linearization order. At its linearization point, at least Q_w replicas store v at a, and by the single-valued assumption no later write stores a different value. Since $Q_w + Q_r > N$, the read quorum R_r intersects this write quorum at some replica that stores v, so the read observes v. The QuorumLogDrive picks some non-$\perp$ value v among the x_j and optionally performs a read-repair step that sends WRITE(a, v) to additional replicas until at least Q_w replicas store v. We linearize the read at any time between the linearization point of WRITE(a, v) and the time when it has collected its Q_r responses. The subsequent read-repair writes occur after this linearization point and write the same value v, so they do not change the value of a in the abstract LogDrive and do not affect correctness.

In both cases the read's return value matches the value stored at a in the abstract LogDrive at its linearization point, and real-time precedence is preserved. Since operations on different addresses are independent and each replica is linearizable, we can take the union of these per-address linearizations to obtain a global linearization order over all READ/WRITE operations.

Thus the QuorumLogDrive provides linearizable writes and reads. □

Theorem ([QLD.1] QuorumLogDrive Refines the LogDrive Specification**).** *Under the assumptions of §A.5, the QuorumLogDrive provides linearizable READ/WRITE operations and a correct* WEAKTAIL(K) *implementation. Hence it refines the abstract LogDrive.*

Algorithm 3 QuorumLogDrive Implementation: WeakTail

```
procedure QuorumWeakTail(K)
    choose any set R_f ⊆ {0, ..., N − 1} with |R_f| = Q_f
    for all j ∈ R_f in parallel do
        (N_obs^(j), H_obs^(j)) ← D_j.weakTail(K)
    end for
    N_max ← max_{j∈R_f} N_obs^(j)
    L ← max{0, N_max − K}                ▷ window: only K slots before N_max
    ▷ Classify global written/unwritten status for slots in [L, N_max)
    for a ← L to N_max − 1 do
        cntWritten ← 0;   cntUnwritten ← 0
        for all j ∈ R_f do
            if a ≥ N_obs^(j) or a ∈ H_obs^(j) then
                cntUnwritten ← cntUnwritten + 1
            else
                cntWritten ← cntWritten + 1
            end if
        end for
        if cntUnwritten ≥ Q_r then
            globalStatus[a] ← unwritten
        else if cntWritten ≥ Q_w then
            globalStatus[a] ← written
        else      ▷ ambiguous: repair and treat as written
            pick any replica j* ∈ R_f with local written at a
            v ← value of slot a at replica j*
            replicate v to enough replicas to ensure at least Q_w written
        (e.g., send write(a, v) to further replicas)
            globalStatus[a] ← written
        end if
    end for
    ▷ Derive global non-contiguous tail and hole set from globalStatus
    N_obs^glob ← min{a | a ≥ L, ∀b > a : globalStatus[b] = unwritten}
    H_obs^glob ← { a | L ≤ a < N_obs^glob, globalStatus[a] = unwritten }
    return (N_obs^glob, H_obs^glob)
end procedure
```

Proof. Linearizability of READ/WRITE follows immediately from Lemma QLD.0. We prove correctness of WEAKTAIL(K).

Let operation o run during $[t_{\text{start}}, t_{\text{stop}}]$. It queries a quorum R_f of size Q_f and obtains from each replica $j \in R_f$ a valid local WEAKTAIL(K) observation $(\mathcal{N}_{\text{obs}}^{(j)}, \mathcal{H}_{\text{obs}}^{(j)})$, each corresponding to some local unordered scan o_j whose observations fall within o's interval.

Let $\mathcal{N}_{\max} = \max_{j \in R_f} \mathcal{N}_{\text{obs}}^{(j)}$ and $L = \max\{0, \mathcal{N}_{\max} - K\}$. By the global K-window discipline, all $a < L$ are globally written throughout o.

For each $a \in [L, \mathcal{N}_{\max})$, classify the status of a using the quorum rule:

$$\text{status}(a) = \begin{cases} \text{unwritten} & \text{if at least } Q_r \text{ replicas in } R_f \text{ report } a \text{ unwritten,} \\ \text{written} & \text{if at least } Q_w \text{ replicas in } R_f \text{ report } a \text{ written,} \\ \text{written} & \text{otherwise (after performing repair to ensure } Q_w \text{ replicas store the unique value).} \end{cases}$$

Because the address space is single-valued and $Q_w + Q_r > N$, this classification is consistent with the linearizable write-once semantics: a completed write to a implies at least Q_w replicas store the value v, so no read quorum can fail to observe v; conversely, if a read quorum observes a as unwritten, then no write quorum has completed. Repair writes only propagate existing values and occur within o's interval, so they preserve linearizability.

Define a hypothetical global unordered scan o^{glob} by assigning each address a a written/unwritten observation consistent with $\text{status}(a)$ at some time in $[t_{\text{start}}, t_{\text{stop}}]$; this is possible since each case of $\text{status}(a)$ corresponds to a quorum condition that holds at some time during o. For $a < L$, mark a written; for $a \geq \mathcal{N}_{\max}$, mark a unwritten, consistent with all local observations.

Applying the abstract weakTail semantics to o^{glob} yields exactly

$$\mathcal{N}_{\text{obs}}^{\text{glob}} = \min\{a \mid \forall b > a : \ \text{status}(b) = \text{unwritten}\},$$

and

$$\mathcal{H}_{\text{obs}}^{\text{glob}} = \{a < \mathcal{N}_{\text{obs}}^{\text{glob}} \mid \text{status}(a) = \text{unwritten}\},$$

which coincide with the QuorumLogDrive output.

Thus the implementation refines the abstract weakTail(K) specification, completing the proof. □

Timelock Drive: Isolated Time-Based Defense for Storage Systems

Jonah Rosenblum

University of Michigan

Peter M. Chen
University of Michigan

Satish Narayanasamy
University of Michigan

Abstract

Data is one of the most critical assets for organizations and individuals, yet its integrity is increasingly threatened by ransomware, data tampering, sabotage, and intentional data vandalism. While most organizations rely on backups, backups themselves are also vulnerable. Even a fully secure software system may be insufficient, as nearly two-thirds of attacks exploit human errors to steal access credentials.

We present Timelock Drive (TD), which allows users to timelock a physical disk block for a duration during which the stored data cannot be modified by anyone, including credentialed users. We show that this enables a secure backup system where the versioning system itself is not part of the TCB. Only a small, isolated checker remains in the TCB, and we formally verify it. A critical challenge we address is maintaining metadata without overwriting prior state using a pure append-only design. We solve the performance problem of scanning logs to retrieve metadata by offloading metadata management to the untrusted host while ensuring security through integrity checks.

Our experiments show that TD incurs negligible space, performance, and storage I/O overheads compared to conventional versioning systems.

1 Introduction

Data is one of the most precious commodities owned by businesses and consumers, and safeguarding it is paramount. Unfortunately, the integrity[1] of critical data is under attack by ransomware [39, 51], data tampering and sabotage [2], and data vandalism. Ransomware in particular has become pervasive: in 2024, 67% of hospital organizations were hit [51], and ransomware attacks are projected to cost victims $265 billion annually by 2031 [39].

The most common way to defend against integrity attacks is to keep regular backups using a versioning system (VS) [8, 9, 14, 33]. Unfortunately, this defense has proven insufficient in practice because the backup system itself often shares the same vulnerabilities as the host: bugs in backup software, compromised administrator credentials, and insider attacks all allow adversaries to corrupt or delete backups [51]. In fact, recent surveys show that 95% of ransomware-hit organizations reported that attackers attempted to compromise their backups, and two-thirds of those attempts succeeded [51].

To defend against these vulnerabilities, researchers have proposed adding retention policies that prevent recently created versions from being deleted for some fixed period of time [18, 45]. Similar to the timelocked safes used in banks, such policies force attackers to wait before damaging recently written data. While a patient attacker could wait out the retention interval, forcing such delays increases the chance of detecting the intrusion before damage occurs and makes opportunistic attacks far less attractive.

Unfortunately, adding a timelock policy to a backup or versioning system is insufficient, as the VS itself may be compromised. Bugs or stolen administrator credentials allow an attacker to override or bypass the retention policy—an issue made concrete by recent trimming attacks that bypass timelock logic inside storage-side VS systems [36].

In this paper, we propose a more fundamental approach: a Timelock Drive (TD) that enforces timelocks directly on physical disk blocks. The TD exposes a simple storage interface but provides a strong security guarantee called **transient immutability**: each block becomes immutable for a fixed period after it is written to the drive, and no software component, including a fully compromised VS or administrator, can override this protection.

All accesses to TD pass through a small, isolated microcontroller, called the TD checker, which enforces the timelock constraints. The TD provides a simple storage interface that supports reads, writes, and timelock operations, while the versioning system (VS) runs on the untrusted host and is entirely outside the trusted computing base. This separation provides a clear division of responsibility: the TD guarantees that blocks cannot be modified for the timelocked duration, while the VS is free to manage data in any way as long as it does not attempt to overwrite data before its timelock expires (as such attempts will fail). Decoupling the two components greatly reduces the amount of trusted code required on the TD, and as a result, the TD checker is only about 400 lines of code. Its small size allowed us to formally verify the correctness of

[1] Confidentiality is also important, but is outside the scope of this paper.

the timelock mechanism.

A critical constraint of the TD is that it forbids overwriting any physical block during its timelock. Yet existing file systems and versioning systems depend on metadata overwrites to maintain version indices, free space, and consistency state. For example, LFS periodically updates its checkpoint region [41], and systems such as FlashGuard and S4 overwrite version metadata [18,45]. A VS running on top of TD cannot perform these updates, since any metadata overwrites would violate timelock immutability and be rejected, creating a fundamental mismatch between traditional VS design and the non-overwriting constraint imposed by a TD.

In fact, even the TD system itself is not allowed to overwrite any timelocked physical blocks; it must instead maintain and update its own metadata state without overwriting timelocked physical blocks. This leads to the central question of this paper: **Can we build both a usable TD checker and a performant versioning system on top of a storage device that forbids all overwrites for a fixed period, including overwrites of their own metadata?**

Our solution is to store TD metadata as a purely append-only log, the TD-log, on the drive. Every update creates a new log entry, which are coalesced and written at the block granularity. Each TD-log entry includes a timelock field that protects the physical addresses referenced in the entry, including the log block itself, eliminating the need for additional metadata about the metadata. While this design is non-overwriting, retrieving TD metadata from the drive requires scanning the entire log – an approach with an unacceptable overhead.

To address this, we use a **delegate-but-verify** strategy. The untrusted host maintains a full, in-DRAM cache of TD metadata, along with a cryptographic BLAKE3 hash generated by the TD checker. On each write, the host supplies the relevant metadata and hash; the TD checker verifies integrity before proceeding. The checker itself stores only a small set of freshness counters (~ 2 MB per 1 TB disk), enabling a scalable design. Because the host provides all metadata during normal operation, the TD checker never needs to read TD-log entries from disk. The on-disk TD-log is read only during recovery, which is infrequent and can tolerate a full scan. This approach yields an efficient metadata solution by trading rare recovery-time cost for non-overwrite property.

We build a secure, non-overwriting versioning system (VS) on top of an isolated TD. The VS runs entirely on the untrusted host; even if it is fully compromised, the system can always recover to a pre-intrusion state. This is because TD's transient immutability ensures that checkpoints created before the intrusion remain unmodified until their timelocks expire.

To respect TD's no-overwrite constraint, the VS records all of its metadata in TD as append-only logs. For performance, it maintains an in-memory logical-to-physical map on the host. From the TD's perspective, VS metadata and data are indistinguishable and subject to the same timelock protection.

During recovery, the only trusted input is the content stored on the TD. For each logical address, the system retrieves the most recent version written before the suspected attack time and discards those written after, thereby neutralizing spoofed entries. To make this possible, the TD provides a **time-of-lock** security guarantee: recovery can reliably determine the time-of-lock for every block, as the TD checker records each block's time-of-lock in the TD metadata log.

We implement the VS as a block device driver that can be mounted by ext4, formally verify the TD checker in Dafny [24], and prototype the TD on a Raspberry Pi interposed between the host and a storage device. Reads incur no overhead, and writes benefit from secure host-side metadata caching. Across a variety of storage traces and filesystem workloads [46], TD introduces negligible overhead (0.4% execution, 0.5% throughput for SSDs).

Our paper makes the following contributions:

- We design and implement a secure Timelock Drive (TD) that guarantees transient immutability for a physical block. All information (data and its metadata) are timelocked for the duration specified by the host (user).
- We design and evaluate a TD and VS system that does not require overwrites to timelocked data and metadata.
- We isolate the TD checker from the rest of the system, including the versioning system. It has a narrow interface and a small TCB (∼400 LoC), which enables formal verification.
- We demonstrate that TD incurs negligible performance and space overhead by securely caching TD metadata on the untrusted host.

2 Background and Threat Model

In this section, we describe a threat model for data integrity attacks and the requirements for secure backups.

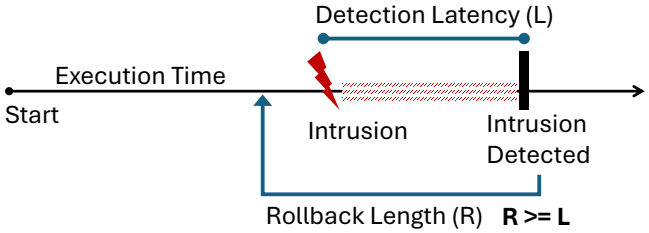

Figure 1: Recover by restoring state before the intrusion.

Figure 1 illustrates a simplified timeline of a data integrity attack and recovery using a continuous backup system. Before an intrusion, a VS periodically checkpoints data on a storage device. After intrusion, we assume that an attacker has complete control over the host software stack, including privileged users, the OS, filesystem, drivers, and the versioning system.

At some point, the intrusion is detected (in the worst case, after the attack is completed). We define the latency between

intrusion and detection as intrusion detection latency (L), as shown in Figure 1.

The fundamental property of secure backups is the ability to roll back, restoring the storage state to *before* the time of the intrusion. We refer to this as rollback length (R). To defend against intrusions, the rollback length must exceed the expected intrusion-detection latency (L).

Need for time-based defenses: A timelock adds a significant hurdle to an attacker who compromises the host system. The value of a timelock is threefold: (1) attackers are forced to wait much longer before asking for a ransom, and during this waiting period they risk being detected before they can damage stored data [3, 28, 32], (2) a safety window provides administrators with more time to discover exploits and deploy patches, (3) expensive deep scans that detect intrusions, invalid/corrupted data, etc. can run less frequently and analyze changes in system state over time. Timelocks allow administrators to trade extra storage space for greater security guarantees. With unlimited storage capacity, an infinite timelock will indefinitely prevent overwrites of protected data; more realistically, having enough capacity to store six months of old data poses a massive challenge for ransomware. According to a recent report [1] from Google, the median intrusion detection latency in 2024 was only five days, and $\geq 99\%$ of intrusions are detected within 5 months.

Isolation for Security: Isolation is a well-known security concept that reduces attack surfaces and minimizes the impact of software bugs. For example, in OpenSSH, isolating authentication logic from pseudo-terminal management and running them at different privilege levels prevents privilege escalation attacks [35]. Another example is Page Table Isolation, which separates user and kernel page-table mappings to protect against Meltdown attacks [26, 47]. Isolation is a key design principle in microkernels [5, 25], web browsers [37, 38], and hypervisors/VMs [4, 42].

Prior S4 systems [18, 45, 50] integrate time-based security checks into a VS on the storage device. Recent work has shown that vulnerabilities in version management can bypass timelock checks and delete old versions, violating the time-based defenses [36]. Our work aims to simplify the timelock primitive to the smallest TCB possible and isolate it from all other components of the secure backup system.

Orthogonal threats: Data exfiltration happens when an attacker can siphon off sensitive data, which they can use for their own gain or threaten to release for a ransom. Such attacks only require read permission. The proposed defenses [15, 27, 40] against data exfiltration are orthogonal to Timelock Drive and thus can be used in conjunction with each other. For example, time-release encryption schemes [27, 40] can prevent plaintext leakage while Timelock Drive guarantees the ciphertext can't be overwritten.

Another threat model includes physical access to the storage system. These powerful adversaries can steal the physical storage device and/or damage it beyond repair. Our work focuses on defending against digital security threats.

TD Command	Inputs	Outputs/Impact	ATA Command
read	addr	Data @ addr	(0x25) READ DMA EXT
write	addr, data, md	Write data @ addr if free.	(0x35) WRITE DMA EXT
timelock-update	addr, TD log block, TD hash	Check validity of timelock/unfreeze operations in TD log using hash. Write TD log block at specified addr.	(0x49) Unused opcode
get-next-td-hash	start-bit	Reads next block in TD metadata log, updates freshness counters, returns secure hash. Returns null at the end	(0x28) Unused opcode
identify	N/A	Disk model, serial number, geometry, etc.	(0xEC) IDENTIFY DEVICE
sync	N/A	Flushes drive buffers (write barrier)	(0xE7) FLUSH CACHE

Table 1: TD-checker Controller's Modified ATA Interface

Clock Assumptions: In this work, we assume our TD-checker has a monotonically non-decreasing clock, even across restarts/crashes. This is similar to non-volatile secure counters in trusted platform modules (TPMs) [30]. If the checker loses power, the clock stops, so all timelock mutability countdowns simply pause until power is restored. This does not weaken the immutability guarantee; it only delays deletion. This assumption is not unique to our work; all S4 systems [18, 45, 50] make the same assumptions about clocks.

3 Timelock Drive

This section presents the Timelock Drive (TD), a standard SSD or HDD whose accesses pass through a lightweight, formally verified, TD-checker controller. The TD augments traditional credential-based security with a temporal protection mechanism: once a user writes to an address and issues a timelock, that block cannot be modified by anyone, including privileged software, until the lock expires.

This section addresses the core challenge of building a performant TD checker on a storage device that blocks all overwrites for a fixed period, even of its own metadata. Section 4 describes how we build a secure backup system on top of Timelock Drive.

3.1 Timelock Drive Interface

A conventional storage device is enhanced with a formally verified TD-checker controller (Fig. 2a), which guards and mediates all access. We refer to this augmented device as the Timelock Drive (TD). It presents a narrow command interface to the host, listed in Table 1.

The **read** and **identify** commands behave like their conventional counterparts and carry no additional TD constraints.

The TD-checker permits a **write** command to a block only when the timelock constraint is satisfied. The additional parameters (md, md-hash) enable the TD-checker to validate this constraint (described later in Section 3.4).

The **timelock** operation allows users to protect a block for a duration δ, enforcing a **transient immutability** guarantee that prevents modification of the block for at least δ time.

A key interface question is when the timelock countdown should begin. If the countdown starts at the moment of timelock, the user must somehow predict how long the data will remain useful. In practice, users rarely know this. For instance,

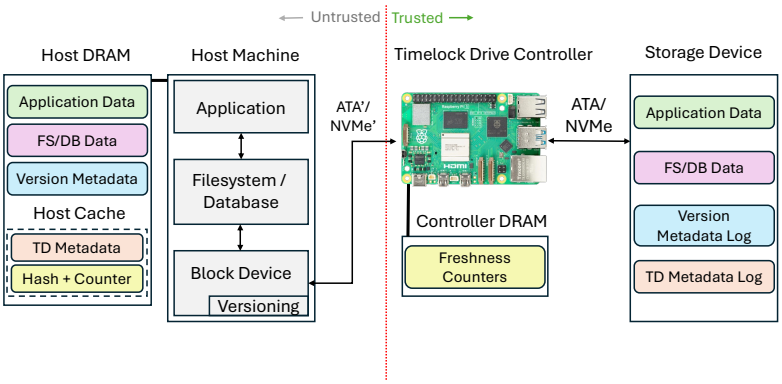

Figure 2a. Timelock Drive system overview.

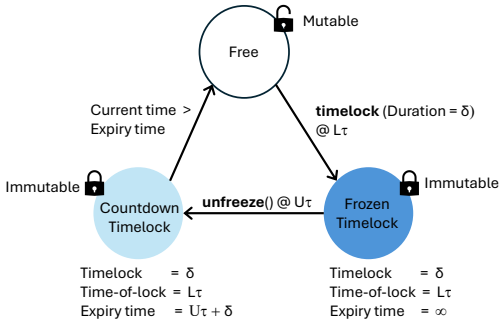

Figure 2b. States of a storage block.

the lifetime of a versioned block lasts until the next version is written; a timing that cannot be known in advance.

A simple workaround is to refresh timelocks for all live blocks before they expire, but doing so would impose heavy performance overhead. Instead, TD uses two states for a timelocked block. After a block is timelocked, it enters a frozen state in which it is protected indefinitely. Later, the user may explicitly **unfreeze** the block. Once unfrozen, TD prevents writes for the duration specified at the original timelock (δ).

This design preserves transient immutability: the block remains protected for the full timelock interval *after* being released. Even if an adversary gains control immediately after a write and attempts to unfreeze the block, they must still wait out the timelock before making any modification.

Figure 2b illustrates the finite-state machine for a disk block. A timelocked block transitions from free to frozen, disallowing further writes. When unfrozen, it moves to the countdown state, where writes remain disallowed. Once the timelock duration expires, the block returns to the free state and can be written again. The timelock operation records a time-of-lock timestamp in the block's metadata, which helps prevent adversarial spoofing during recovery (Section 4.7).

The **timelock-update** command applies timelock/unfreeze operations on a host-specified list of addresses. The motivation for bulk update is further explained in Section 3.3.

Finally, the **get-next-td-hash** command rebuilds the host's TD metadata cache after a checker reset or intrusion recovery. With the `start` bit set, the checker begins scanning the TD metadata log from the beginning; each subsequent call processes the next log block, updates the checker freshness counters, and returns the corresponding secure TD hash, returning `null` at the end of the log. The purpose of this command is discussed in Section 3.4.

3.2 Verified Trusted TD-Checker Controller

The TD-Checker controller is a small microcontroller that natively executes the timelock logic. Its inputs are storage-interface commands; in our prototype, we use the "TD-ATA" command set shown in Table 1. The controller approves or rejects each command based on the addressed block's timelock state, allowing only those that satisfy the current timelock constraints to pass through. TD is agnostic to the underlying storage medium (HDD or SSD). We adopt the ATA command interface for its simplicity and widespread use, though the design can be extended to other interfaces, including NVMe.

To support TD commands, the controller has a clock that retains its state across power cycles. The assumptions about this clock are stated in Section 2.

Small and Isolated TCB: The controller and its state (clock and metadata) are isolated from the host system, interacting only through the verified TD-ATA interface. We formally verify (Section 6) that our controller implementation satisfies TD's security guarantees, ensuring that the timelock constraint holds even if the host is compromised. All higher-system components—privileged users, the filesystem, versioning software, drivers, and the OS—are excluded from the TCB. Our verified implementation in Dafny consists of roughly ∼400 lines of code, excluding ghost statements used solely to assist verification.

3.3 Non-Overwrite TD Metadata

TD-checker relies on per-block metadata—timelock state, timelock duration, time-of-lock, and expiry time—to enforce its checks. If no metadata exists for a block, we assume it is in the free state, as is true for all blocks initially.

When a block is timelocked, its metadata is updated and persisted on the drive. This metadata must itself be timelocked; otherwise, an adversary could tamper with it and subvert future TD checks.

A natural design is to store TD metadata along with data within a disk block to timelock it. However, the TD metadata must change when the block transitions from the frozen state to the countdown state, since the recorded state and expiry time change. The controller does not continuously update metadata during the countdown; it only checks, on a later write, whether the recorded expiry time has passed. Still, the frozen-to-countdown transition requires a metadata update, which would be forbidden if the metadata block itself were

timelocked. Thus, TD needs a way to update metadata state without overwriting timelocked metadata.

We address this challenge by representing TD metadata as an append-only log. When a block is timelocked, a metadata entry is appended to the log; when the block is unfrozen, a new entry is appended rather than modifying the old one. Logically, the latest valid entry for a block determines its current TD metadata state. During recovery, the log can be replayed to reconstruct this state; during normal operation, TD avoids expensive log scans by delegating metadata caching to the untrusted host and verifying the supplied metadata, as explained in Section 3.4.

Each log entry stores the TD metadata for a timelocked disk block, and the entry is protected under the same timelock duration as the block it corresponds to. Since writes to disk are at block granularity, each log entry would require an entire block, which is space-inefficient. We solve this problem by extending the TD interface to support **bulk timelock-update**. This allows the user to apply the timelock or unfreeze transition to a list of addresses rather than a single address. While the list size could be 1, for a versioning system, bulk operations work well, as they timelock/unfreeze a set of blocks at the end of a checkpoint interval.

3.4 Delegating TD Metadata Management to Untrusted Host

TD metadata for a block must be read on every write to perform the timelock check. A pure append-only log incurs high latency overhead, since locating the latest metadata for a block requires an expensive scan of the entire log.

We can reduce this overhead by adding a metadata cache inside the TD-checker, but TD metadata exhibits poor temporal locality, so the cache would need to hold nearly all metadata to be effective. This significantly increases controller complexity, and any cache miss still triggers an expensive log scan. Storing all metadata (one metadata block per 512 addresses) consumes roughly $\frac{1}{513}$ of total device capacity – impractical for a small controller.

Instead, we let the untrusted host maintain the TD metadata cache and secure it using cryptographic mechanisms. The TD-checker computes a BLAKE3 HMAC over the metadata, the TD address, a freshness counter, and a 256-bit secret key, and gives it to the host. When writing to a block, the host (user) supplies its corresponding metadata and HMAC to the controller, which verifies the hash and freshness counter.

In fact, we let the host propose metadata updates when issuing a timelock or unfreeze command. The TD-checker's role is to validate the integrity of old metadata and the correctness of new/updated metadata, both supplied by the host.

To maintain freshness, the controller maintains a 4-byte counter for each TD metadata block and includes it in the HMAC. The host locally caches the latest TD metadata and corresponding hashes and supplies them with TD commands. This cache is not trusted: if the host supplies stale metadata or an old hash, the checker recomputes the HMAC using its current freshness counter and rejects the command.

The controller's memory requirement remains modest: it stores only the freshness counters, requiring approximately $\frac{1}{525{,}312}$ of disk capacity, or about 2 MB per 1 TB of storage. Assuming a disk write latency of 10 ms, nonstop writes to a single block would take 1.36 years to overflow a 4-byte counter, making overflows rare.

The TD metadata log is read-only when the cache must be rebuilt, such as after a power reset, a freshness-counter overflow, or intrusion recovery. In these cases, the checker generates a new secret key, disables writes, and reconstructs its freshness counters by scanning the append-only TD metadata log. The host initiates this scan by issuing `get-next-td-hash` with the `start` bit set. Each subsequent `get-next-td-hash` command causes the checker to read the next TD metadata log block, apply the metadata updates in that block to its freshness counters, and return the resulting secure TD hash to the host. When the end of the log is reached, the checker returns `null`; at that point, the host has rebuilt its cache of TD metadata and corresponding hashes.

If multiple log entries refer to the same address, the scan may return multiple hashes for that address. Only the hash corresponding to the latest processed metadata state remains valid, because each subsequent metadata update advances the checker freshness counter. Thus, a host that later supplies an intermediate metadata entry and hash will be rejected as stale.

A random-access command, such as `get-td-hash(addr)`, would be inefficient: the checker would have to scan the TD log to find the latest metadata for that address. Rebuilding all hashes after a reset would therefore require one log scan per address, yielding quadratic recovery time. In contrast, `get-next-td-hash` streams through the log once and rebuilds both the checker's freshness counters and the host's valid hashes in linear time.

3.5 Timelock Drive Policy and Use Cases

Prior solutions that embed timelock policy within the versioning system (VS) [18, 45, 50] offer weaker security guarantees due to a large TCB and lack user-controlled timelocking to prevent overwrites of a physical block. Because the timelock mechanism is intertwined with the VS, users are bound to predefined policies, and any change requires modifying an already large TCB—risking new vulnerabilities.

TD is fundamentally different. It enforces timelocks directly on physical disk blocks and exposes this capability to users through a minimal interface. The VS is built on top of this abstraction and is therefore excluded from the TCB. This separation allows users to implement their own versioning policies without affecting the TCB.

We outline several use cases for Timelock Drive, beyond conventional versioning, that are enabled only due to TD abstraction. Users with highly sensitive data (e.g., cryptocurrency keys) can store them in TD with an infinite timelock. An

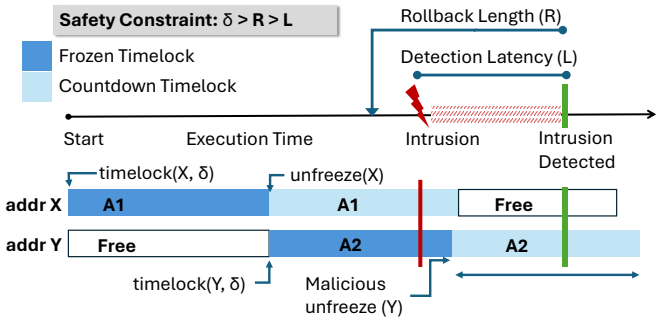

Figure 3: Secure backups using Timelock Drive

OS or middleware can automatically identify important files (based on content or type) and timelock them with durations tailored to importance. Organizations can timelock records to ensure regulatory compliance. TD can also protect logs during an attack, enabling accurate forensic reconstruction and intrusion analysis [10, 11].

While many applications are possible, we focus on one crucial use case for Timelock Drive: secure backups, which we discuss in the next section.

4 Secure Backups Using Timelock Drive

We build a secure, non-overwriting versioning system (VS) atop the isolated Timelock Drive, with the VS running entirely on the untrusted host. Even if the VS is fully compromised, TD's transient immutability preserves all pre-intrusion versions long enough to guarantee recovery to a pre-intrusion state (Section 2).

4.1 Overview

The TD-checker controller exposes an unchanged view of the physical address space to the VS (Figure 4). The VS, running on the untrusted host, then exposes a subset of the physical address space to the client filesystem[2] as the logical address space. The VS manages the placement of TD-metadata, VS-metadata, and the filesystem's data. The TD-checker does not distinguish between VS data and VS-metadata.

When the filesystem writes to a logical address, the VS allocates a free physical block, writes the new version, and timelocks it. It then unfreezes the old version so that, once its countdown timelock expires, the corresponding physical block can be reclaimed.

The VS maintains metadata mapping each logical address to its sequence of physical blocks. Conventional VS designs overwrite metadata on every disk write, but in an untrusted VS, such overwrites could allow an adversary to corrupt or erase version history during an intrusion. Thus, VS metadata must also be timelocked, requiring a design that avoids overwriting during the timelock interval. This section discusses how our VS achieves this using a pure append-only, non-overwriting log; conceptually similar to the TD-log.

A trusted recovery process reconstructs a pre-intrusion system state using only the contents of TD. Finally, we show how standard optimizations such as incremental checkpointing can still be implemented despite the constraints imposed by TD.

[2]Any system that uses a block device—filesystems, databases, object stores, etc.—can run atop TD; we use a filesystem for illustration.

4.2 Secure Untrusted Version System

When the filesystem issues a write, the VS stores the data in a free block in TD and secures it with a timelock set to the rollback length (R). Even if an intrusion happens immediately after the write, the worst an adversary can do is attempt to unfreeze the data. However, due to the timelock, TD ensures the data are protected for the duration of R. Therefore, if the intrusion is detected in less than R, the data can be recovered.

Once data are written to a physical address and timelocked, that physical address remains immutable until unfrozen. VS unfreezes that physical address only when the filesystem writes a new version to the corresponding logical address.

Figure 3 shows an example. When the filesystem writes to a logical address (A), the VS stores the data in a free block (X) in the TD, and applies a timelock of duration R. On a subsequent write to the same logical address (A), the VS writes the new version (A2) to another free physical address (Y), timelocks it, and immediately unfreezes the old version (A1) stored in physical address X. The unfrozen physical address then enters a countdown timelock state, and stays protected for the duration of R.

Version Integrity Guarantee: To establish that we will always be able to safely recover the latest pre-intrusion version for a logical address, let us consider all possible storage states at the time of intrusion for an address.

First, for physical addresses in a free state, there is no valid data and therefore no guarantee is needed.

Second, we consider addresses in a countdown timelocked state. For instance, in Figure 3, physical address X is in this state at the time of an intrusion. This physical block was unfrozen by our VS before the intrusion. While the VS is untrusted, its behavior before an intrusion is benign. Therefore, it would have issued an unfreeze command for block X only after writing a newer version (A2) to another physical block (Y). As a result, even if block X expires after the attack and loses protection, a more recent version (A2 in Y) can still be recovered for the corresponding logical address.

Finally, a physical address (Y) could be in the frozen timelock state, implying that it contains the most up-to-date version for a logical address and was not unfrozen before the intrusion. In this state, the worst an adversary can do is unfreeze the physical address shortly after the intrusion, as shown in Figure 3. This would only transition the physical address into a countdown timelock state, where it remains protected for the duration of the timelock (R). Therefore, as long as the timelock duration is set long enough to outlast the time needed to detect the intrusion, we can recover a valid version for A.

4.3 Incremental Checkpoint on TD

Creating a version for every write can greatly increase storage overhead. A conventional solution is to divide execution into epochs and take a copy of the checkpoint at the end of each epoch. An incremental checkpoint [16, 34] typically only maintains the most recent version of a logical address written within its epoch. If an address was not written within an epoch, then the checkpoint has no versions for it.

Our VS implements incremental checkpoints as follows. For each write to a logical address within an epoch, the VS allocates a new TD block and stores the version without a timelock. At the end of the epoch, the VS timelocks (for duration R) the set of blocks containing the most recent versions of all logical addresses written during that epoch. It also unfreezes old versions corresponding to these logical addresses.

The only limitation of incremental checkpointing is that, rather than always recovering to the last write before the intrusion, we roll back to the most recent checkpoint/epoch before the intrusion. We use small epoch intervals (one hour), which is negligible compared to the intrusion detection latency (weeks). Given that we may lose all versions produced after an intrusion, incremental checkpointing would additionally lose at most one epoch's worth of data, which is again negligible.

4.4 Non-Overwriting Version Metadata

We assume that an attacker can gain full control over the VS after an intrusion. To enable safe recovery, we must apply the same timelock protection to both data and the version metadata. This is a novel challenge, as all prior VS we are aware of, including "append-only" systems [9, 14, 33, 41], modify version metadata. For example, LFS periodically overwrites checkpoint regions every 30 seconds [41].

Our VS metadata maps logical addresses to physical addresses. Since we cannot overwrite the map during updates, a naive solution is to track changes in version metadata by adding additional versioning. However, to do this, we would need a second layer of metadata on top of our version metadata. Future updates encounter the same issues, necessitating the addition of a third layer of metadata, followed by a fourth, and so on. This becomes an infinite recursion problem.

We solve this recursive problem by using an append-only log that tracks the chronological updates of versions. When the filesystem writes to a logical address, the VS will create a new version and store it in a free physical address. At the same time, a new metadata entry is added to the end of the log that describes the mapping between the logical and physical addresses. When enough log entries are created (or enough time has passed), a block of log entries is stored in TD with a timelock greater than or equal to the underlying data. Each log block is linked together through a series of forward pointers with the head of the log stored at a predetermined location in the physical address space. This data structure allows us to track all changes to our metadata (versions of versions) without triggering the recursive update problem [41].

4.5 Bulk Metadata Update

Each VS metadata log entry is small, so we aggregate multiple log entries into a metadata disk block during an epoch. At the end of an epoch, the VS metadata are written to the drive. When the VS is under heavy write load, the metadata block may fill up quickly before an epoch ends. In that case, more than one metadata disk block would be written at the end of that epoch.

At the end of an epoch, VS timelocks and unfreezes a set of blocks in bulk (Section 3.3). This aggregates TD metadata and writes it to the disk only at the end of each epoch.

4.6 Crash Safety

Users rely on crash safety to recover a valid system state after sudden crashes, such as power loss [29]. Prior systems that embed timelocks into the VS do not provide explicit crash-safety guarantees or require a battery backup for each device [18, 19, 50]. This means that even with a crash-safe filesystem, prior solutions can still lose data and/or timelock protections after a crash.

A write barrier, implemented through synchronization operations such as `fsync` or disk flushes, provides a persistence-ordering point: writes issued before the barrier must reach stable storage before writes issued after the barrier are allowed to become durable. TD preserves the crash-safety guarantees of the client filesystem by forwarding filesystem writes and write barriers (ATA sync) to the underlying disk in the same order in which they are received. However, the VS also creates additional persistent state, including version metadata and TD metadata, and this state must be ordered carefully with respect to the data it describes.

For each committed epoch, the VS persists updates in three ordered steps. First, it writes the data blocks. It then inserts a write barrier before writing the corresponding version metadata. This ordering is required in any versioning system: recovery must never observe version metadata that points to data blocks that were not durably written. Second, after writing the version metadata, the VS inserts another write barrier before writing the TD metadata and timelock records. This ordering is specific to TD: recovery must not observe timelock metadata for an epoch unless the version metadata for that epoch is also durable. Otherwise, a crash could leave TD metadata durable while the corresponding version metadata is missing or stale, causing recovery to associate timelock state with stale data. Finally, after writing the TD metadata, the VS issues a final write barrier to commit the epoch. If a crash occurs before this final barrier completes, the incomplete epoch is discarded during recovery.

4.7 Spoof-free Guarantee for Recovery

Prior systems [18, 45, 50] implicitly trust their versioning software to behave correctly after an intrusion. We cannot make this assumption, as our VS is untrusted. Consequently, recovery must remain correct even under adversarial VS behavior,

including spoofing attacks carried out after the intrusion.

We assume that the intrusion time can be identified through forensic analysis, which is outside the scope of this work. Prior research provides techniques for reconstructing and analyzing intrusions [10, 11, 53]. Alternatively, one may attempt recovery under several candidate intrusion times and validate each resulting system state.

The only input our trusted recovery software depends on is the content of the timelock drive. The first step in recovery is to identify data written after the intrusion, so that it can be discarded. This immediately defeats spoofing attempts in which an intruder fabricates a new state after compromise.

We considered adding per-write "time-of-write" metadata to the TD. However, this would force a metadata update on every write, which is unnecessary because only one version per checkpoint interval is protected by a timelock.

Instead, we use time-of-lock as a proxy for determining whether a version predates the intrusion. Time-of-lock is recorded when the timelock command is issued. Any version protected by that timelock must have been written before its time-of-lock. Thus, if a block's time-of-lock precedes the intrusion time, its stored version must also precede the intrusion and is therefore valid for recovery.

As discussed in Section 4.2, versioning integrity is guaranteed for the most recent version of every logical address. During recovery, we scan the version metadata linked list (Section 4.4) to identify the most recent version for each logical address. Each log entry stores a logical address and a pointer to a physical block containing one of its versions. We determine the latest valid log entry by reading its time-of-lock. This entry provides the physical address of the most recent pre-intrusion version of that logical address.

After fully resetting all untrusted components, the VS is reinitialized using the logical-to-TD mapping constructed during recovery. The system can then resume operation safely.

4.8 Versioning System with Multiple Drives

Our work constructs a versioning system (VS) using a single Timelock Drive (TD). However, deploying this system across multiple drives managed by a single host requires additional design considerations. Because each TD maintains its own unique, unsynchronized clock, there is no universal timestamp for system-wide recovery.

To overcome this, the host VS must periodically log "recovery barriers" across all drives. To safely log a barrier, the host first issues a synchronization barrier (write barrier) to each drive. Next, it writes a special sentinel block containing a unique identifier to each drive and timelocks it. Finally, the host issues a second synchronization barrier to all drives before resuming normal execution.

With recovery barriers in place, multi-drive recovery proceeds securely. First, the intrusion time is determined with respect to a specific drive, say D. The recovery process then subtracts a small guard window from this timestamp to account for the maximum possible clock drift across the system. It then locates the last recovery barrier, B, written to drive D prior to this adjusted intrusion time. Finally, the process retrieves B's time-of-lock on every other drive. Since B is a synchronized event, its time-of-lock on each drive provides a safe, localized pre-intrusion timestamp, allowing the host to accurately roll back the state for every drive in the system.

5 Implementation

5.1 System Organization

Users create and modify files through a standard Linux ext4 filesystem. To persist these updates, ext4 issues block I/O requests to a block device driver. We implement a new block device driver using the BDUS framework [13]. This driver implements our untrusted VS and manages all version metadata. It communicates with the TD controller over sockets using the interface shown in Table 1.

We implement the TD controller logic in Dafny and formally verify the properties described in Section 6. The verified Dafny specification is transpiled to Rust and compiled with `rustc` to produce the executable TD-checker.

Our target design is a hardware microcontroller that runs the TD-checker natively and intercepts storage-interface commands directly. Because we were unable to find a commercial device that exposes this programmable interception layer, we prototype the TD controller on a Raspberry Pi.

5.2 TD Interface

TD exposes a modified ATA command interface, TD-ATA, derived from the ATA specification. TD-ATA (Table 1) extends ATA by adding fields for timelock durations to write commands—reusing reserved and obsolete bits—and by introducing two additional operations: `timelock-update` and `scan-td-log`. We include only the commands needed for our experiments, though additional ATA commands (e.g., power-management, SMART, and streaming-configuration operations) can be incorporated once proven safe.

The controller interprets each TD-ATA command, along with its supplied parameters and the current timelock state of the addressed block, to determine whether to accept or reject the command. Accepted commands are forwarded unchanged to the underlying storage device.

5.3 Metadata Layout

Our VS issues sequential writes to storage, preserving spatial locality: each new write is placed in the next free disk block, typically adjacent to the previous one. VS and TD metadata are persisted at the end of each epoch. To maintain spatial write locality, we interleave VS and TD metadata blocks as shown in Figure 4.

TD metadata log: Each metadata entry is 8 bytes. Four bytes are dual-purpose, storing either the timelock (for frozen

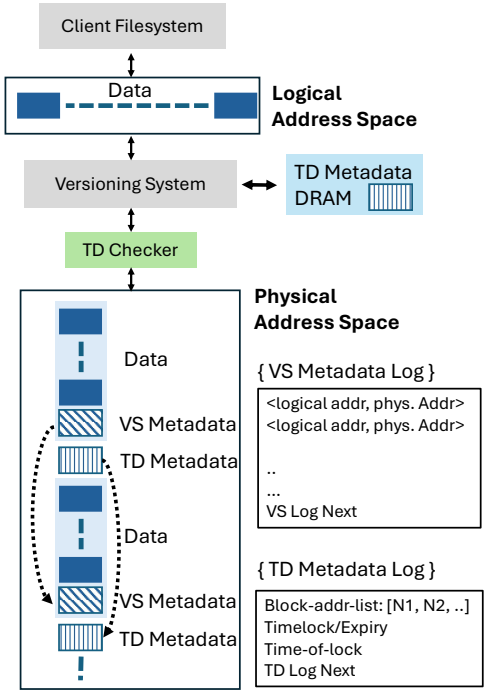

Figure 4: Address space layout.

state) or the expiry time (for countdown state). The remaining four bytes encode the time-of-lock in the upper 31 bits, with the lowest bit indicating whether frozen or unfrozen. We store metadata for adjacent addresses together, allowing $\frac{\text{BlockSize}}{8}$ entries per metadata block. With a 4KB block size, exactly 512 TD metadata entries fit in one block. Each block contains a forward pointer to the next TD metadata block.

VS metadata log: Each log entry is also 8 bytes. Thus, a 4KB metadata block stores $\frac{\text{BlockSize}-8}{8}$ entries (511 entries), reserving 8 bytes for a forward pointer to the next VS metadata block.

5.4 VS Append-Only Metadata Log

VS metadata maps each logical address to a set of TD addresses that contain its versions. We maintain this mapping using an append-only log (Section 4).

VS reserves a physical block (the *home node*) that stores the head pointer of a linked list of VS metadata blocks. Within each metadata block, we reserve 8 bytes for a pointer to the next block in the list. Before writing a metadata block, the VS preallocates a TD address for the next metadata block and records this pointer in the block currently being written.

This design introduces a subtle challenge: the current metadata block points to a future block that has not yet been written, and thus contains no valid metadata. If a crash or power failure occurs at this point, naïvely following the pointer chain would encounter an invalid block. We address this issue by relying on the time-of-lock. Metadata blocks in the linked list are written in chronological order, except for the final preallocated (but unwritten) block. During recovery, if a metadata block's time-of-lock indicates it was written *before* its parent, we conclude that we have reached the true end of the list.

5.5 Garbage Collecting VS Metadata Logs

We must periodically garbage-collect the VS metadata log. The VS performs this operation infrequently (user-defined, e.g., once per month). Before unfreezing the old list, the VS constructs a condensed log that contains only the most recent version entry for each logical address. It computes this condensed log by scanning its in-memory copy of the metadata. The VS then stores the new log in TD and timelocks it with the same duration as its underlying data. The head of the new list is written to a second predefined head-pointer location in the home node. The garbage collector alternates between these two locations.

Note that TD is agnostic to whether a block contains data or version metadata; it is isolated from versioning logic and protects both using the same mechanisms. The garbage collector responsible for freeing the old VS metadata list is itself part of the untrusted VS. To free the old list, it issues `timelock-update` commands to the TD addresses that store the old metadata, but only after writing the new log to a separate location. The old list remains immutable during its countdown timelock state. Consequently, even a fully compromised host cannot corrupt VS metadata stored on TD until its timelock expires.

5.6 Garbage Collecting TD Metadata Logs

TD metadata logs are maintained using a solution similar to the VS metadata log. The mechanism for garbage-collecting TD metadata logs is also similar to that for VS logs, with one key difference. Unlike VS metadata, a TD metadata log entry cannot be unfrozen until its corresponding data block is also unfrozen. The VS unfreezes a data block only after the application creates a new version for its corresponding logical address.

To address this constraint during garbage collection, the VS issues a write that copies the current version of a logical address to a new physical block. This action enables the VS to treat the original version as the "old version" and unfreeze its TD block. Once the data block is unfrozen, the corresponding TD metadata entry can also be unfrozen, allowing the TD metadata log to be reclaimed safely.

5.7 TD-aware Disk Block Management in VS

The VS maintains a list of physical blocks that are in the free state. Initially, this list contains all blocks. When the filesystem writes to a logical address, the VS allocates a free TD block to store the new version. The TD block holding the previous version for that logical address is then unfrozen and moved to a countdown list. Periodically, the VS scans this countdown list and returns any TD blocks whose timelocks have expired back to the free list.

Defragmentation: The VS preserves high write performance by issuing sequential writes; however, over time, the available sequential region becomes fragmented, reducing opportunities for long, efficient writes—a well-known limitation of log-structured filesystems [41]. Periodic cleaning restores sequential space by relocating live data and reclaiming fragmented segments. Unlike LFS, our VS must wait for each segment's timelock to expire before reclaiming it. A timelock-aware defragmentation daemon performs this cleaning while preserving future sequential write performance. Because all reclamations in the VS must respect timelocks, and the TDs clock remains idle while not powered on (Section 2), we note that defragmentation and garbage collection cannot make progress unless the TD is powered on.

6 Formally Verified Security Guarantees

We formally verified the following two strong guarantees for the metadata state of TD: (1) There is no way to bypass the immutability guarantee of a timelock. (2) In the event of a power outage, replaying the TD log of transactions correctly reconstructs the metadata state. To formally prove properties about TD we create a model of it in Dafny. Dafny is a programming language that supports proofs about functional correctness of code [24].

6.1 Timelock Guarantees

To guarantee timelock protections cannot be bypassed, we prove that our code exactly implements the state machine in Figure 2b. We first create an abstract model of the state machine, then prove our executable code (which operates on metadata encoded as bytes) correctly follows all states and transitions. This process, known as refinement, guarantees our code is free of exploits that allow an attacker to bypass states (e.g. skipping from Frozen Timelock directly to Free).

Proof sketch: (1) We model abstract states A and transitions from Figure 2b with the function $\texttt{transition}(A)$. (2) We create a function $\texttt{abstract}(B)$ that converts a sequence of bytes B to an abstract state. (3) We implement $\texttt{transition}(B)$ which performs byte-level operations to encode the next state. Our proof shows that transitioning at the byte level and then abstracting is equivalent to transitions at the abstract level. Formally, for any byte sequence B: $\texttt{abstract}(\texttt{transition}(B)) = \texttt{transition}(\texttt{abstract}(B))$.

6.2 Recovery Guarantees

If the system loses power, we must correctly reconstruct the timelock metadata state from the log stored on the drive. We achieve this by persisting each metadata transaction to form a transaction log. Our proof demonstrates that scanning and replaying this log produces a metadata state equivalent to the original execution.

Proof sketch: assume that replaying the log up to transaction n produces an identical metadata state to performing those n transactions. When we perform transaction n+1 during normal execution, we update the metadata state and append the transaction to the end of the log. Since (1) the replay is correct through transaction n, and (2) the replay and real-time execution of a transaction apply the same updates, appending transaction n+1 to the end of the log preserves correctness. Thus, given the same initial state, both execution paths will always produce the same final state.

Table 2: Workloads Used for Evaluating TD.

Workload	Description
VM-Enterprise [23]	Traces collected from VMs running enterprise software.
Exchange [43]	Traces collected from production mail server at Microsoft.
TPCC [20]	Traces of TPCC benchmark.
TPCE [20]	Traces of TPCE benchmark.
Finance [49]	Traces from OLTP applications at large financial institutions.
Web-Research [22]	Traces from Apache web-server managing FIU research projects.
filebench [46]	Filesystem benchmarking tool. Benchmarks used simulate a file server, a mail server, and database transactions.

6.3 Proof Assumptions

Since Dafny does not natively support raw ATA commands, we use a trusted but unverified Rust function to pass commands through to the drive. We model the transaction log on disk as a data structure containing a sequence of 4KB blocks. Each time the Rust function is invoked, Dafny updates the transaction log. As such, we assume this model accurately reflects blocks as persisted on disk. As with all computer-aided proofs, we also rely on the correctness of the theorem provers verifying our Dafny code.

7 Evaluation

Our evaluation demonstrates the efficiency of TD across a variety of workloads. We show that, for latency, bandwidth, and I/O, TD incurs negligible overhead compared to a baseline solution. Additionally, we demonstrate the value of our host-side cache by evaluating an alternative design that scans the TD log to compute the current metadata state. Lastly, we compare our solution to the widely used backup/snapshotting solution, LVM [17], to explore the storage overhead and recovery-time implications of TD .

7.1 Experimental Setup

To measure TD performance, we use the workloads in Table 2. These include a mixture of traces and benchmarking workloads that capture the behavior of enterprise software [23],

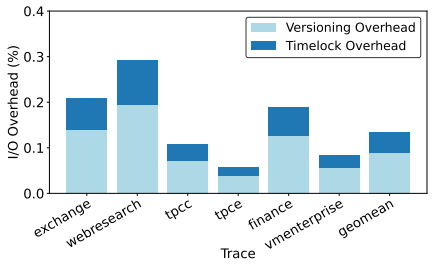

Figure 5a. Disk IO overhead.

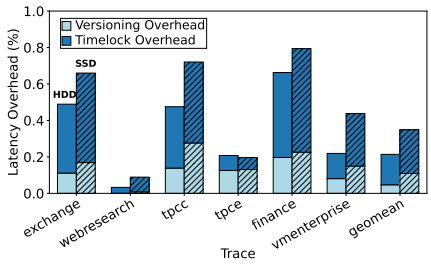

Figure 5b. Latency overhead.

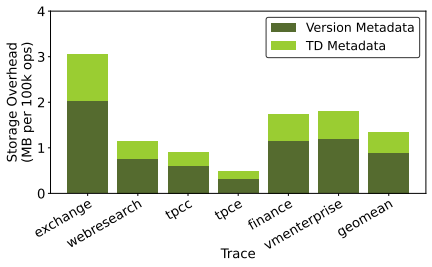

Figure 5c. Space overhead.

mail servers [43,46], web servers [22], file servers [46], and database OLTP workloads [20,46,49]. We compare runtime performance against a baseline log-structured block device. This baseline has no security or versioning features and uses the log-structure to improve random-write performance.

In production, we envision the checker logic integrated directly into the drive's controller silicon, with a negligible footprint. For our experiments, we use two configurations: one for security testing and one for performance evaluation.

The first configuration involves a prototype implementation of the TD checker on a low-end controller (a Raspberry Pi 5). The host driver communicates with the controller via Ethernet. This emulates the physical isolation between the host and checker and is used for the experiment in Section 7.2.

The second configuration collates the controller logic with the host machine. The host driver communicates with the controller logic via shared memory IPC. This is done to eliminate any potential bandwidth or latency limitations of the Ethernet connection, thus more closely measuring the overhead of TD. We use this configuration for all other experiments.

The primary storage device used in our evaluation is a 4TB Seagate ST4000DMZ04 hard disk. In experiments that explicitly mention SSD performance, we use a 1 TB Samsung MZ-77E1T0B drive.

7.2 Security Analysis

Our formal verification of the TD controller in Section 6 proves our transient immutability guarantee. To validate our secure backup system, we deploy 18 ransomware samples from well-known "families" of ransomware attacks [21]. TD successfully recovered the filesystem state for every sample.

7.3 Performance Analysis

7.3.1 Trace Evaluation:

We evaluate the latency and I/O overhead of TD via I/O traces collected from a variety of workloads found in Table 2. Before each workload, we write 1GB of data to the driver to warm up the system. We run the first 100,000 commands from each trace as quickly as possible to stress-test the I/O latency of TD. We also measure the performance of just versioning, with no timelock protections, to learn the performance breakdown.

I/O Overhead: I/O overhead is due to VS and TD metadata reads and writes. As noted earlier, these metadata are also delegated to the host, and therefore, they are only read in uncommon scenarios during recovery.

In our experiments, we conservatively version and timelock all writes. Even so, the I/O overhead stays low as seen in Figure 5a. Write-heavy traces, such as Web-Research and Exchange, incur the highest I/O overhead due to additional version and timelock metadata that must be persisted to protect the data.

Because the metadata cache is managed by the host, we do not incur additional metadata reads at runtime. Without this optimization, the I/O overhead of TD grows considerably, which we explore in Section 7.3.4.

Latency Overhead: Compared to the baseline system, the latency overhead of TD is composed of the I/O overhead, the ordering of new I/O, the cost of managing the host metadata cache (computing hashes and transferring cache blocks), and the overhead of checking the state of each block address before it is written.

As seen in Figure 5a, the I/O overhead is negligible, which is due to host-side caching. The order of I/O (contiguous versus random) can have significant performance implications. As explained in Section 5.3, VS writes version and timelock metadata contiguously with data during write-heavy periods. As a result, the additional I/O incurred by TD has minimal performance impact. Looking at the breakdown in Figure 5b, we see that the bulk of overhead in TD is due to timelock checks (ensuring blocks are free) and managing the host metadata cache. Even with the cost of timelocks/metadata management, TD achieves negligible overhead over the baseline.

We found that TD performs significantly better than LVM in terms of latency across all benchmarks, except Web-Research. LVM does not structure its data writes sequentially in a log [41], and thus suffers from random-write latency. The Web-Research benchmark is write-heavy; however, most of its writes are naturally sequential, which neutralizes the performance gap between TD and LVM.

7.3.2 Filesystem Benchmarks

To evaluate the performance of real-time workloads, we mount an ext4 filesystem onto the VS driver and run several write-intensive filebench [46] workloads. The filesystem

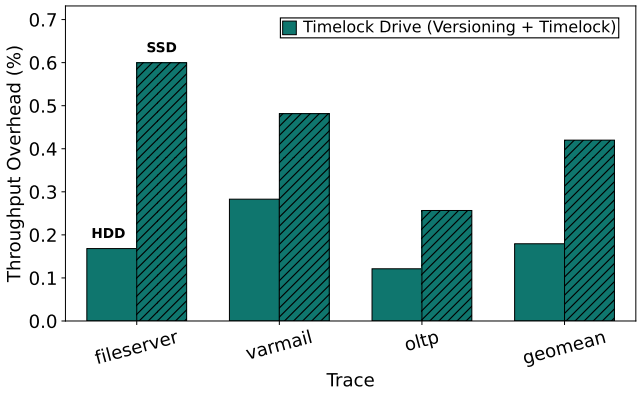

Figure 6: Throughput overhead for filebench workloads.

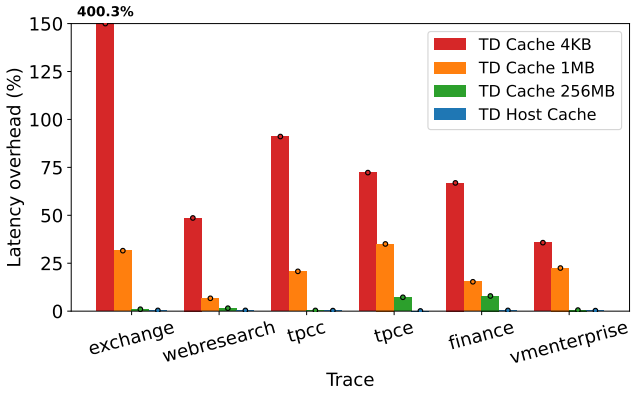

Figure 7: Cache sensitivity analysis for traces in Table 2.

used is the same for both TD and the baseline, so it does not add new overhead compared to the trace evaluation. We find, as shown in Figure 6, that, much like latency, TD incurs negligible throughput overhead.

7.3.3 Performance on HDD vs SSD

We perform all trace and filesystem benchmark experiments twice, once on an HDD and once on an SSD. Read and write operations are considerably faster on an SSD. While the absolute cost of managing versions and doing timelock related computations stays the same, they become a larger proportion of the overall runtime. As a result we see increased overhead of TD, especially in workloads with a large volume of writes. While TD is less performant on SSDs, it still maintains a modest overhead (<1%) in all workloads.

7.3.4 Delegating Caching Metadata to Host

To motivate our host-managed metadata cache design from Section 3.4, we explore an alternative design for TD that manages its own cache on the gatekeeper. In a gatekeeper-managed cache design, every cache miss requires scanning the entire timelock metadata log to compute the most up-to-date metadata state. To evaluate the performance of this design, we perform a sensitivity study with three different cache sizes (small/4K, medium/1M, and large/256M).

Due to the timelock constraint, there is no temporal locality

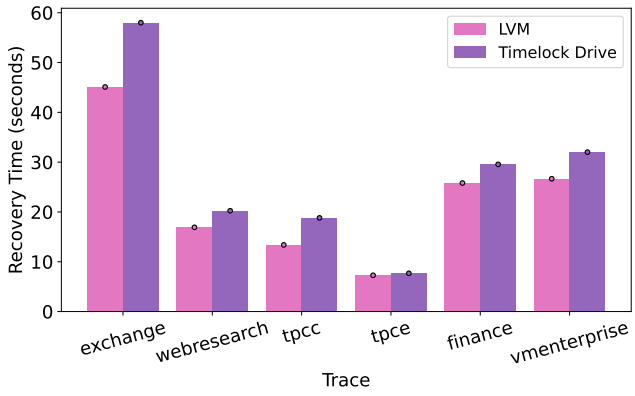

Figure 8: Recovery time for traces in Table 2 compared to LVM.

for TD metadata. As a result, for write-intensive traces, we observe frequent cache misses, each of which requires an expensive log scan. This is true even for a medium-sized cache (1 MB), resulting in over 30% overhead. Even for non-write-intensive workloads, triggering a scan moves the seek head away from the most recently read/written data. As a result, cache misses increase the amount of random disk I/O. To avoid missing the cache entirely, we need 2GB of cache for every 1 TB of storage. This is prohibitive for a microcontroller design, which is why we opt for the host-managed cache.

7.4 Efficiency of Data Recovery

We run each trace to completion, take a snapshot, overwrite every address in the trace to simulate an integrity attack, and measure recovery time for both TD and LVM. We compared our performance against LVM's snapshot feature.

Recovery in TD is proportional to the length of the version log, which is proportional to the number of writes. This scanning method is modestly slower than LVM, as shown in Figure 8. This is one of the two costs of TD's append-only log design compared to a conventional backup system.

7.5 Storage Space Overhead

TD introduces two sources of storage space overhead. The first is from TD metadata. The TD log grows dynamically as more data is timelocked. One TD metadata log block can track updates to 1020 data blocks. A second form of space overhead is version metadata. Like TD metadata, the version log grows over time as more versions are created. One version log block can track 511 logical-to-physical mappings. Both logs grow proportionally to the number of writes.

As explained in Sections 5.5 and 5.6, we perform delayed defragmentation of the log and reclaim space once the timelock protecting it expires. Looking at Figure 5c, we can see that per 100k operations, the space overhead incurred by TD is modest. The highest space overhead comes to just over 3MB for both version and TD metadata combined. We observe that for most traces, one-quarter to one-third of the log can be reclaimed, freeing up more space in the future.

LVM, on the other hand, tracks a constant amount of metadata per snapshot, which we observed to be about 2MB. Most of our traces stay under this size for the 100k operations; however, for long-running workloads with frequent writes, LVM's constant overhead is lower than ours. This is a cost we pay for a non-overwriting pure append-only system.

8 Related Work

This paper is the first to propose a versioning system while using a storage device that forbids overwrites for a fixed period. TD constructs a secure backup solution on top of an isolated timelock primitive, which was not previously known to be possible. This is challenging as the timelock drive forbids all overwrites, including metadata, for a fixed period. We also formally verify the security guarantees of TD.

Backups and Versioning. The traditional ransomware defense is data backups. Common policies include versioning [9, 14, 33], snapshotting [7], and delta backups [6, 8, 54]. These solutions are implemented in software and are thus vulnerable to common malware attacks that compromise the OS [18, 31], and are thus inadequate for ransomware defense. However, the versioning policies and optimizations they use can be implemented in TD's untrusted VS.

Several prior works use the intrinsic out-of-place write structure of an SSD to implement data versioning that defends against ransomware without trusting the OS [18, 19, 50]. These works modify garbage collection in the flash translation layer (FTL) to retain old versions of data and enable rollbacks. BVSSD [19] retains all versions indefinitely, which implements a continuous data protection policy [52, 55] inside an SSD. Storage on an SSD is finite, which is why RSSD [36] modifies FTL garbage collection to back up flash blocks to the cloud via NVMe over Ethernet before erasing them, providing the illusion of infinite capacity. To truly address capacity limitations, we must eventually reclaim space. FlashGuard [18] and Project Almanac [50] allow for garbage collection and modify the FTL to add time-delayed versioning.

The use of time as a defense in FlashGuard and Project Almanac is similar to our work, however, we differ in several key ways. Both works use time retention as a security policy in their versioning logic. Notably, these prior works include a versioning system in their TCB and overwrite metadata, whereas we do not. We are the first to show that time retention can be decoupled from versioning, and that untrusted versioning software can use the TD interface to build a secure backup system. Additionally, because both prior works implement versioning in the FTL, the entire modified firmware is included in the TCB. Verifying that changing the FTL does not introduce vulnerabilities is a significant challenge. Tripathy et al. formally verify several, *but not all*, properties of a ransomware-resistant FTL [48], improving confidence in the correctness of FTL-based solutions.

RSSD shows that prior S4 works, including FlashGuard and Project Almanac, are vulnerable to a "trimming attack" that bypasses security checks in the FTL to erase data [36]. In contrast, our work decouples versioning from the TCB, which is a non-trivial feat as explained in Section 4.4. Our isolated TD is only responsible for enforcing timelock guarantees and is separated from the FTL, making it easier to prove strong security guarantees. We prove that TD has no equivalent to the "trimming attack" [36].

Integrating versioning and timelock checks into SSD firmware makes versioning and timelock policies less flexible, thereby restricting their use cases. By excluding versioning from the TCB, our approach enables easy updates to versioning policies and optimizations in untrusted software, without altering TCB code. As a result, TD enables several uses beyond encryption ransomware, as detailed in Section 3.5. Commercial products, such as ExaGrid and Oracle, implement "retention timelocks" by enforcing retention periods in application- or service-level backup logic [12, 44]. In contrast, our solution timelocks physical blocks on disk. It isolates timelocks from versioning logic, resulting in a minimal TCB that improves security and flexibility.

Ransomware Detection and Prevention. Another line of defense is ransomware detection, which monitors I/O and data patterns to flag malicious behavior [3, 28, 32]. But even when attacks are caught early, some data is already damaged [36], and attackers can adapt to evade known heuristics. Detection accelerates recovery, but it cannot prevent data loss; it must be paired with secure backups.

9 Conclusion

While significant advancements have been made to address hardware and software security vulnerabilities, solutions targeting human errors remain limited. Given that nearly two-thirds of ransomware attacks exploit human weaknesses, there is a pressing need for defenses that do not rely solely on managing data access through user credentials.

Timelock Drive (TD) is a significant step toward achieving this goal. It is the first work to completely isolate the timelock defense, enabling the construction of a secure backup system with the smallest known TCB — one that doesn't trust the user or the VS. The TD interface is simple enough to allow formal verification, yet flexible enough to support a wide range of versioning optimizations and data retention policies. These benefits come with negligible performance and storage overhead, making TD an efficient and robust solution.

Amazon Web Services

Abstract

The Amazon Simple Storage Service (S3) is 20 years old, hosts more than 500 trillion objects, and averages over 200 million requests per second. Its API must continuously evolve and adapt to new workloads and use cases, sometimes resulting in full re-implementations like the S3 Express One Zone storage class. This highlights two conflicting requirements: ensuring that every change preserves backward compatibility and maintaining a high-paced development environment. We report on our experience combining the use of *reference models*, in a model-based testing (MBT) style, with *abstraction* to systematically explore all behaviors of the S3 API. Our approach is grounded in the abstraction of API requests and state elements, enabling systematic validation of all abstract inputs and system states. Through rigorous validation, we produce models that are sufficiently accurate to be used as de facto specifications of S3. Our tool continuously runs in the S3 development and deployment (CI/CD) cycle, validating changes, preventing regressions, and supporting the development of new features.

1 Introduction

Over the past couple of decades, cloud services have evolved from simple web-based APIs to elaborate services with dozens of features, configurations, and input and output parameters. In this work we focus on the Amazon Simple Storage Service (S3), which supports a wide variety of customer use cases and workloads that have co-evolved with S3 over its 20 years of existence. This evolution requires new code to be added and existing code to be refactored by hundreds of developers continuously. To provide for different performance, price, and availability trade-offs, the S3 API has been re-implemented multiple times, sometimes using entirely different code bases, programming languages, and hardware. Yet, to the customers, the API behavior must remain the same. We refer to the challenge of preserving the API behavior under continuous change as the *API sameness* or conformance checking problem. This challenge is the main focus of our work. We aim at validating the functional input-output behavior of the S3 API under normal sequential behavior. We focus on the sequential behavior thanks to the consistency guarantees of S3[1], which are validated through dedicated mechanisms (e.g. [BJA+21]) and are beyond the scope of this paper. In this work we execute each operation "in isolation" and focus exclusively on validating the correctness of the sequential behavior of the API.

There are two key aspects to API sameness: (i) defining what constitutes correct API behavior, and (ii) ensuring that the service implements the correct behavior. We address the first challenge by building an executable reference model for each API. Then, we propose a systematic model-based testing (MBT) approach to address the second challenge. In order to get sufficient confidence in the correctness of the service, we require the tests to achieve sufficient and measurable coverage of the behaviors of the system. For this reason we design a systematic test generation strategy to provide the inputs on which we check conformance between the model and the API implementation. While the techniques we present are widely applicable to other stateful services, for the rest of the paper we will focus on S3. Our model and input generation techniques are now used in the continuous integration and deployment (CI/CD) pipelines of S3, preventing unexpected behaviors from reaching production. We run this validation after the execution of traditional unit and integration tests, and it has so far prevented more than 300 potential regressions from being deployed.

Amazon S3. Amazon S3 is a highly available and durable cloud storage service that provides a REST (Representational State Transfer) API. It supports 96 API operations [S3D24c]. Beyond the `PutObject` and `GetObject` operations, over its evolution S3 has added support for conditional read and write operations, multiple checksum algorithms, object versioning, tagging, replication configurations, several server-side encryp-

[1] https://aws.amazon.com/s3/consistency/

tion configurations, and many more features. To illustrate the complexity of S3 APIs and the types of edge-cases involved, consider `GetObject` [S3D24b]. `GetObject` appears to be simple: it takes a bucket name and a key name, and returns the object stored in the bucket for that key name. Consider the following `GetObject` request:

```
GetObject( bucket="bucket", key="abc",
           range="bytes=0-5242880",
           checksumMode="ENABLED")
```

`range` is a standard HTTP header described in RFC-9110 [RFC22], while `bucket`, `key` and `checksumMode` are specific to the S3 API. The RFC states that an HTTP server *may* support a sequence of ranges on `GET` requests. S3 supports a single byte range and implements the behavior described in the RFC. Depending on the state, S3 returns `206` for successful cases, `404` status code if the object does not exist, or `416` if the object is empty. Successful responses will contain the requested range of bytes of the object. In S3, the headers in the success response depend on the target object. In our example: a) if the object has 5242881 bytes or less, the response will contain the full object and its checksum, b) if the object has more than 5242881 bytes, only the first 5242881 bytes will be returned with no checksum, except, c) if the object was created with a multi-part upload API, and the first part is exactly 5242881 bytes, the response will include the checksum of the part.

We now consider a different `GetObject` request to highlight how client code often depends on specific S3 error responses, not just success responses.

```
GetObject( bucket="bucket", key="abc",
           If-Unmodified-Since="2026-02-02")
```

The `If-Unmodified-Since` header is another standard HTTP header. In `GetObject`, clients use this header to retrieve the object only if it has not been modified since the specified date. S3 will reply with `200 OK` and the object data if the content has not been modified since `2026-02-02`, and with `412 Precondition Failed` otherwise. A client will likely handle these two responses differently. Client code typically uses this header as a safety mechanism to detect changes in the object content. In this case, the error response clearly signals that the assumption has been violated. Preserving the exact behavior of both success and error responses is critical to the correctness of S3's client code. More generally, clients often rely on all observable behaviors of the API; from the service provider's viewpoint, this means *every* behavior must be preserved across changes to the service.

These two examples use only five distinct parameters and already highlight the many details that affect the full behavior of each API and their importance to customers. And yet, `GetObject` has 21 input parameters and `GetObject` responses have 36 output parameters plus the content payload. In addition, there are many configurations [S3D24a] of the underlying target bucket which affect the behavior of each request, such as bucket encryption, versioning, and access policies. As we shall see in Sec. 6, there are at least 10^{25} qualitatively distinct combinations of input parameters and states for `GetObject`. Covering all these combinations is not possible without novel reductions and automation.

Our approach to conformance. This paper addresses the conformance checking problem by combining *model-based testing* (MBT) [UPL12, BJA+21] with *predicate abstraction* [GS97]. We incrementally build an executable reference model to be the de-facto specification of the underlying API. This is motivated by the need to: a) make the model accessible to developers and tools with minimal effort, b) run conformance tests between the model and API implementation in CI/CD pipelines, and c) have reproducible diagnostics for issues identified in development.

Building a reference model takes effort and one might consider using an alternative/previous version of the service as the reference model. However, this is impractical and error prone. In response to a request, an API can allow multiple valid responses (e.g. different pagination of results, errors being reported in different order). An implementation may pick one of these possibilities, and another implementation might pick a different one. As a result, two versions of the service driven by the same test inputs can diverge while both being correct. A reference model that encapsulates all allowed behaviors of the service allows us to keep independence between the implementation under test and the reference model. In fact, for S3 Express One Zone, having access to the model was instrumental in the design and development of the implementation. The majority of S3 Express One Zone APIs match the behavior of regional S3, but getting a comprehensive specification of the APIs' behavior was not easy using only the existing regional S3 implementation. S3 Express One Zone developers used our model and test generation to validate conformance with regional S3. In specific cases where S3 Express One Zone intentionally deviates from regional S3 we extended our model with the new behavior.

Ensuring conformance is practically challenging due to the complexity of the S3 APIs with their large number of parameters and dependencies on the service state. In order to ensure API conformance for all behaviors, we need comprehensive coverage of these combinations of parameters and states. We use predicate abstraction to lift the universe of concrete requests and states to *abstract requests and states*, and to explore this much-reduced abstract space in a systematic way. Developers use this approach to comprehensively validate code changes over a well-defined (sub-)space of requests and states at development and pre-deployment time. The approach identifies regressions even in subtle edge cases, within a reasonable time budget. As a result, the approach improves development velocity and gives developers confidence that all behaviors will be tested before deployment.

To summarize, we use our validation approach for:

Preventing Regressions. A difficult challenge in maintaining a large decoupled code base is ensuring that changes to one component (e.g. a bug fix) do not introduce unintended changes to the behavior of the API. We use our executable specification as an oracle to *drive input generation strategies* aimed at maximally covering the set of behaviors that may be affected by changes. We then employ differential testing [McK98] between model and implementation to detect unintended changes.

Conformance Checking. A given API might have multiple implementations, such as the S3 Express One Zone storage class launched in 2023. With S3 Express One Zone, data is stored in a different bucket type called *directory buckets*. Directory buckets support the core APIs of regular S3 buckets, but with some intentional differences (e.g., entries in `ListObjectsV2` responses are not sorted). We used our model to guide and inform the development of S3 Express One Zone for the APIs that match regular S3. Similarly, we use it in other implementations and refactors, reducing the synchronization overhead across teams.

Model-based validation. Another challenging aspect in a large stateful application is generating tests that drive server-side behaviors to deep and non-obvious paths. We build a *custom input generation strategy*, which intentionally drives the model into the necessary pre-states (and since the model is accurate, also the system state). We use knowledge about the model state to generate inputs exercising a combination of service paths that target specific behaviors.

Validation Coverage. In order to achieve these goals, we need a cost-effective way of exploring the possible inputs of the system. Generating new inputs is only helpful if they drive the service to unexplored behaviors. In the `GetObject` example, the number of combinations of 21 input parameters and numerous state configurations makes exhaustive exploration intractable. Therefore, it is critical to carefully identify the key features and scenarios that need to be validated. We address this challenge using abstraction at the level of individual request and state features.[2] An important consequence of this approach is that we can quantify the portion of the request space that a particular input generation campaign covers.

2 Overview

Unit and integration testing are widespread mechanisms used to validate software [LW90, AO17]. Unfortunately, unit tests are only as good as the quality of the scenarios and assertions that developers consider [ZHM97]. In a highly decentralized development environment, it becomes hard to establish quality metrics from individual tests in each of the components. For web services, the overall end-to-end behavior of the service API represents yet another top-level testing target, commonly known as integration-testing [MLSRC21]. In general, assessing the quality of an integration test suite is hard, and it is seldom a subject of precise and actionable metrics.

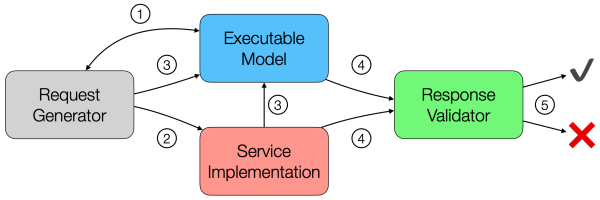

Figure 1: Model-based testing flow.

In our approach, we argue that the starting point of any effective validation technique (formal or semi-formal) is a specification of the system. Alas, when working with legacy systems, the correct level of abstraction or language for a specification is not always clear. Therefore, we make the pragmatic choice of defining a reference model as a specification, which we then use to validate the evolution or even different implementations of the system. Following the model-based testing (MBT) [UPL12] literature, we refer to the system implementation under consideration as the *System Under Test* (SUT), and use the model as an oracle in the SUT validation campaigns. Each validation campaign compares the SUT's behavior against the model on a set of inputs and highlights any discrepancies. To assess the quality of our model, and to later validate the SUT against it, we need automatic input generators that cover measurable portions of the API's input and state space. We develop a systematic input generation approach based on the model (Sec. 5). This helps us bootstrap the model when starting with a legacy system and, once the model is deemed accurate, validate evolutions of the system.

The systematic input generation is designed around three key properties:

No assertion left behind. Unlike unit testing, we do not need to write assertions. We compare every element of the responses generated by the SUT and the model. This is the strongest possible assertion on the input-output relation: equality between service and model responses.

No scenario left behind. We pair the model with automated test generation to solve the problem of test coverage and quality of integration testing. We employ input-output conformance [Tre08] validation to compare the SUT and the model (see Sec. 3).

No redundant scenario. Given the massive space of possible input requests to the API, we need to avoid redundancy. Since execution time is of the essence, our methodology avoids redundant inputs.

[2] Roughly, we consider a feature to be any of the request arguments, configurations of the bucket, or state pre-conditions that can influence the behavior of the operation.

```
while not metric.is_covered():
    test = metric.next_test(model) ①
    s_resp = service.run(test) ②
    m_resp = model.run(test, s_resp) ③
    valid = validator(test,s_resp,m_resp) ④
    report(valid) ⑤
    metric.update(model, test, m_resp)
```

Listing 1: Coverage-driven testing (pseudo).

Fig. 1 depicts the MBT strategy. There are three main components to our validation besides the implementation of the service itself. Firstly, the executable model (Sec. 3) is a simple implementation of the API. It preserves all the functional aspects of the service and ignores all the non-functional ones. This is shown in the blue box in Fig. 1. Secondly, the green box represents the response validator. This component implements the logic to *assert* whether the response of the SUT is consistent with the response generated by the model. It also allows us to select between the multiple behaviors allowed by the reference model and keep its state in sync with the SUT. Finally, the gray box corresponds to the request generator. The generator implements the algorithms that aim at maximizing our coverage metric (Sec. 5). This component ensures that all scenarios are exercised, and it is the cornerstone of our coverage-driven validation architecture.

To understand the execution flow of our tool, consider the pseudo-code in Listing 1. In the first step, the request generator queries the current state of the model and the desired coverage metric to generate the next request to execute. This is marked with bullet ① in the picture and the pseudo code. Next, in step ②, the request is sent for execution to the SUT and its response is recorded in `s_resp`. Because of the possible non-determinism in the server, the server response is sent to the model alongside with the request in step ③. To understand this, consider a simple `PutObject` interaction in the request/response excerpts shown in Listing 2. At the top we have the request issued, in this case a `PUT` request. While all fields of the requests are calculable at request generation time, that is not true for all the response fields at model execution time. In fact, the model state doesn't have the necessary information to compute the values marked in red: `x-amz-id-2`, `x-amz-request-id`, `Date` and `ETag`. The model considers these values to be non-deterministic and treats them as opaque values. While some of these values are not important to the model (for example `x-amz-id-2` and `x-amz-request-id` are used only for logging on the server side), some of them are critical for the functionality of the service, and need to be captured into the model. An example is the `Etag` value returned for stored objects. The object `Etag` is created when the object is uploaded, and can later be used in conditional operations via headers like `If-Match` and `If-None-Match`. In other cases, like the response `Date`, the model cannot compute the exact value (e.g. predict the exact time at which the server will process the request), but expects the value to conform to

Listing 2: Request/Response example. Prophecy values are in red, blue values are edited for readability.

a specific format. To simplify the response comparison, we propagate these opaque values into the model, and we take them as input for model evaluation. This is shown at step ③ where the observed response is sent as an input to the model evaluation. Care must be taken when identifying which of these values should be used in the model. For that reason, we distinguish them as *prophecies*, and prophecy values are treated specially in our model. Moving on with our execution flow, in step ④ both the model and service response are sent to the validator for checking. Finally, in step ⑤, the result of the validation is reported to the user of our tool before restarting with the next request if any. There are two possible outcomes: either the responses agree and we continue, or they don't agree, and we report them as a *deviation* to the user. The rest of the paper uses the term deviation to refer to discrepancies between model and SUT. A deviation represents an error in the model, in the SUT or in both.

2.1 Technical Choices and Assumptions

Black-box Modeling. We take a *black-box* approach to modeling and validation. We cannot afford to make assumptions about the implementation which may change in the future, or may be invalid w.r.t. other implementations of the same API. Thus, our model is agnostic to the internal implementation choices of a specific SUT, and all of our modeling is based on input/output behaviors of the service. One caveat of this approach is that the model is not able to differentiate between different *internal service states* leading to identical input/output behavior, for example those resulting from components such as caches.

Stateful REST API. We consider services that provide a REST API where the result of an operation can be influenced by preceding operations. For instance, the result of a `GetObject` is affected by a successful prior `PutObject` on the same key. Therefore, the model of the service must also be stateful and retain sufficient information about the previous operations to be able to correctly compute the response for the next request. However, in the interest of simplicity, our model is: 1. *in-memory*, meaning that the state is not durable across instantiations, 2. *single-threaded*, meaning that API calls are executed one at a time in the order that they are received by the model, and 3. *performance agnostic*, meaning it does not reflect performance requirements of the implementation, such as latency or throughput.

Non-determinism. Our target systems are mostly deterministic: given the same state, if we issue the same API call, we observe the same behavior, and the same resulting updated state. Some exceptions to this rule are: *service-generated identifiers*, which depend on internal state we cannot observe; *timestamps*, which depend on when the request is received and how long processing takes; and *transient errors*, such as `500 InternalServerError` responses triggered by hardware failures. A second form of non-determinism arises across implementations. Each implementation is free to choose the order in which to process independent request attributes, and this order affects which error is returned. The model must accommodate this variation: for each request, it returns the set of valid error responses, and a correct implementation must return one of them. We additionally require each SUT to consistently return the same error. Therefore, we learn the choices made by each SUT and then the validation steps for the SUT fail if a different choice is observed. Sec. 3 exemplifies this.

2.2 End to End Simplified Example

We illustrate our approach end-to-end through a simplified version of the S3 `GetObject` API with only three request fields: `bucket`, `key`, and `checksumMode`. We use the simplest form of bucket: a key-value store mapping keys to object blobs. Each object has an associated checksum, which can be retrieved via `GetObject` by setting `checksumMode` to `ENABLED`.

To validate that an implementation of `GetObject` behaves correctly for every distinguishable combination of request and state, we decompose the validation task into four subgoals:

(a) enumerate the set of scenarios (abstract state-request pairs) necessary to cover all API behaviors,

and for each of these scenarios:

(b) bring both SUT and model into the state required by the scenario,

(c) issue a concrete request representing the scenario against SUT and model, and

Response	Condition
`400 InvalidBucketName`	syntactically invalid `bucket`
`400 InvalidKey`	syntactically invalid `key`
`404 NoSuchBucket`	valid `bucket` but it does not exist in account
`404 NoSuchKey`	valid `bucket` and `key`, but `key` does not exist in `bucket`
`400 InvalidArgument`	`checksumMode` is a string other than `ENABLED`
`200 OK` + payload	otherwise

Table 1: Simplified `GetObject` behaviors

(d) compare the response received from the SUT with the responses admitted by the model.

We describe subgoal (d) first, since it defines what *correct* means, and then revisit (a)–(c) in turn.

Expected outcome and comparison (d). For our simplified `GetObject`, the model's behaviors are described in Tab. 1. To illustrate the non-determinism of error responses, notice that the conditions can overlap on some requests. For example, a request with an invalid `bucket` and an invalid `key` admits both `400 InvalidBucketName` and `400 InvalidKey` as valid model responses. The validator declares success whenever the SUT response is among those allowed by the model, and reports a deviation otherwise.

Input scenarios enumeration (a). Enumerating all concrete request/state pairs is intractable: bucket and key names alone range over all possible strings. The main insight of our input generation strategy is that we only need to consider inputs that lead to distinct behaviors. For instance, S3 rejects all bucket names longer than 63 characters and a few such names suffice to validate the SUT on this behavior. To formalize this, we partition the values of each API request and state feature into equivalence classes, which we call *categories*. Each category is defined via predicates over the request fields and S3 state (see Sec. 4).

To make the explanation concrete, let us denote by V_Ω the model state, and let b, k and c represent the values for the `bucket`, `key`, and `checksumMode` fields respectively. In this example, we define the abstraction function via six Boolean predicates: (i) valid_bucket_name(b) holds iff b is a syntactically valid bucket name; (ii) bucket_exists(V_Ω, b) holds iff V_Ω contains a bucket named b; (iii) valid_key_name(k) holds iff k is a syntactically valid key name; (iv) key_exists(V_Ω, b, k) holds iff V_Ω contains an object with key k in bucket b; (v) checksum_mode_present(c) holds iff the request contains the `checksumMode` field (i.e. $c \neq$ `None`); and (vi) valid_checksum_mode(c) holds iff c is a valid value for the `checksumMode` (i.e. $c \in \{$`None`, `ENABLED`$\}$).

The predicates (i), (iii), (v) and (vi) are request predicates and do not depend on the state; the remaining state-dependent

predicates relate the request with the model state. An *input scenario* is a truth assignment over the six predicates, and there are $2^6 = 64$ such assignments. However, most of these are *spurious*: existing objects cannot have an invalid bucket name or an invalid key name, a key cannot exist in an unknown bucket, and if the `checksumMode` is not present, it must be valid. We capture these constraints as a conjunction of four implications, which we call the model invariant inv_Ω (Sec. 5.1):

$$\begin{aligned}
\text{bucket_exists}(V_\Omega, b) &\rightarrow \text{valid_bucket_name}(b) \\
\text{key_exists}(V_\Omega, b, k) &\rightarrow \text{valid_key_name}(k) \\
\text{key_exists}(V_\Omega, b, k) &\rightarrow \text{bucket_exists}(V_\Omega, b) \\
\neg\text{checksum_mode_present}(c) &\rightarrow \text{valid_checksum_mode}(c)
\end{aligned}$$

We enumerate non-spurious scenarios by computing all satisfying assignments of inv_Ω. For our example, this reduces the 64 scenarios to 21: 2 success scenarios with an existing bucket, key, and checksum mode either `None` or `ENABLED`; 1 error scenario with an existing bucket, key, and invalid checksum mode; 3 error scenarios with an existing bucket and valid but non-existent key; 3 error scenarios with an existing bucket and invalid key; 6 error scenarios with a valid but non-existent bucket; 6 error scenarios with an invalid bucket.

Most input scenarios lead to error responses, and many will produce the same error on the SUT. In practice, deterministic implementations check arguments in some order and short-circuit on the first error. Suppose our SUT first performs the syntactic checks on `bucket`, `key`, and `checksumMode` in this order, and then looks for the object with the given bucket and key names in the state. Under this evaluation order, several of the 21 scenarios map to the same SUT behavior. For example, the 6 input scenarios with an invalid bucket name all produce the same response (`400 InvalidBucketName`) regardless of the state or the other field values. We call this the *first-error hypothesis* and use it to reduce the number of scenarios further (Sec. 5.2).

State setup (b). Given a non-spurious scenario, we have to bring both the SUT and model into a state that satisfies all state-dependent predicates of the scenario. For instance, every scenario where bucket_exists holds requires the state to contain at least one bucket. We address this problem with a component called API-planner (Sec. 5.3). Given the state-dependent predicates of a scenario, the API-planner returns a sequence of requests that lead from the current state to a state that satisfies the input predicates.[3] Consider a success scenario with both predicates bucket_exists and key_exists set to true. The scenario requires V_Ω to contain a bucket with a valid name, and in it an object with a valid key. Assuming the current state (V_Ω) is empty, the API-planner produces two preparatory requests: 1. `CreateBucket`(b) with a freshly synthesized valid bucket name b, and 2. `PutObject`(b, k, *payload*) to write an object with freshly synthesized valid key k and some content *payload* into bucket b. Each preparatory request is itself a test and it is processed end-to-end through our validation pipeline as described in Fig. 1. Once the planner reports that the target state is reached, we proceed to test the `GetObject` input scenario request of interest.

[3] Since we only exercise non-spurious scenarios, we only ever call the API-planner with non-contradictory predicates.

Request concretization (c). With the state in place, the last step is to pick concrete values for the request features that are consistent with the input scenario. For request predicates we sample from the category dictated by the scenario: e.g. if valid_bucket_name must be false, we sample from a pool of syntactically invalid names (too short, too long, illegal characters, ...). Instead, for state-dependent predicates we query the model state for values that satisfy them. For example, if both bucket_exists and key_exists must hold, we ask the model for an existing (bucket, key) pair, and reuse the names synthesized during state setup. Finally, the `checksumMode` is: 1. omitted from the request if checksum_mode_present is false, 2. set to `ENABLED` if both checksum_mode_present and valid_checksum_mode hold, and 3. sampled from a pool of invalid values (e.g. empty string, `DISABLED`, or some other invalid string) if valid_checksum_mode is false. The resulting `GetObject` request is then executed according to our description of step (d) above.

3 The Model

Our model is intended to serve as the de facto specification of the S3 API. As a result, service owners need to be familiar with the model code base and extend it in anticipation of changes in the service. Practically, the choice of programming language and development methodology for the model follows the same standards as the majority of our service code bases. Consequently, we implement our model in Java, and we use the standard builder tools available to engineers.

Our model implements a key-value store with additional metadata to represent details about the stored objects. For simplicity, we only store information in the model if it can be observed by subsequent API calls. For example, the model records the object's `ETag`. The `ETag` is computed when the object is created, and later `GetObject` operations for the object will return the same `ETag`. However, the model does not store the operation's request identifier (`x-amz-request-id`) since there is no way of retrieving it via API calls. Some examples of common metadata that we store in the model alongside the object key and payload are: object creation time, object tags, server-side encryption mode, encryption key for the object (if any). Each of these can affect the behavior of subsequent operations, and hence the model must have access to this information. As a concrete example, the encryption key in a `GetObject` request needs to match the one used at

creation time for the request to succeed; otherwise a `403 Access Denied` error code is returned.

We strive to reuse model code and functionality when implementing similar features for different APIs. As an example, consider the conditional operation features present in the `GetObject`, `PutObject`, `CopyObject` and `DeleteObject` APIs. These features validate the same syntactic and semantic conditions on the arguments and state of the system. Therefore, our model encapsulates the behavior of each feature in a single *trait*. This reduces the size and complexity of our model, and it makes reasoning about each individual feature uniform across all APIs that use them. As we shall see in Sec. 5, this also enables us to abstract the input generation strategy for each individual feature, which then generalizes for all the APIs that use the feature.

Non-determinism and Prophecy Variables. The model exhibits non-determinism in two ways: incorporating prophecy values from the SUT response and allowing different input validation orders. For example, consider the following `GetObject` request:

```
GetObject(bucket="non-existing", PartNumber="abc")
```

This request leads to an error response since: 1. the bucket name, while syntactically valid, does not correspond to an existing bucket and 2. the part number is not a positive integer. Different implementations can perform these checks in different orders. For instance, Amazon S3 performs the syntactic checks on the part number before checking whether the bucket exists, and replies with the error `400 InvalidPartNumber`. However, a different implementation of `GetObject` could choose to report `404 NoSuchBucket` instead. Our model generates all the acceptable error responses and the SUT response is correct if it is among the ones generated by the model. This raises the question of checking a mostly-deterministic service with a non-deterministic model. A specific SUT must be consistent in its responses and always pick the same answer among the ones allowed by the model. This property is important for customers who may have error handling routines for errors they observed during testing. If the SUT suddenly reports a different error for the same request, customers' code may break in production. We validate that each SUT keeps returning the same error by learning a partial order for each SUT. The partial order describes which error the SUT returns among the ones allowed by the model. We then use the precedence order to specialize the model for the specific SUT. This enables our tool to validate that the SUT retains the same ordering without having to build a separate model.

4 Request and State Abstraction

The effectiveness of our model-based validation rests on its ability to exercise tests that show whether the model and implementation coincide (step ① in Fig. 1). Our goal is to explore all SUT behaviors that are distinguishable from a black-box viewpoint. As anticipated in Sec. 2.2, we use predicate abstraction [GS97] to focus our validation efforts on meaningful input scenarios and, consequently, on tests that exercise distinct behaviors.

Terminology and definitions. Tab. 2 reports some terms that we use throughout the section. We use *feature* generically to refer to either an input parameter (*request feature*), or a configuration of a logical component of the state of the system (*state feature*). For example, in `GetObject` the bucket name of the request is a request feature. In contrast, state features correspond to elements of the state that influence the behavior of the API in an observable way. For example, whether a bucket name is in-use (i.e. a bucket that has been successfully created and has not been deleted yet) is a state feature.

We group together values of a feature that result in similar behavior when considering specifically that feature.[4] We define *categories* (equivalence classes) of values for a feature, with the expectation that values in the same category behave similarly. Considering bucket name as an example, a bucket name can fall into one of three equivalence classes: 1. syntactically invalid names, 2. syntactically valid names for non-existent buckets, or 3. valid names for existing buckets. Each class triggers distinct service behaviors and outputs. The equivalence classes partition the possible values of a feature. Therefore, we can exercise the relevant behaviors by selecting one value from each category instead of trying all possible values. An *input scenario* maps each feature to a corresponding category. Each input scenario is a truth assignment for a set of predicates over the request and state features of the API. Input scenarios reduce the set of all possible requests that need to be exercised to a much smaller finite set that still exercises all meaningful behaviors. This transforms an intractable exploration problem (exploring all possible values) into one amenable to algorithmic automation. We apply the abstraction across all API features and dramatically reduce the universe of scenarios to exercise while preserving comprehensive behavioral coverage. Consider the categories for bucket names as shown in Fig. 2. The left diagram in the figure shows how the space of all possible bucket names is partitioned according to the three categories. Whether a bucket name is well-formed is strictly a property of the bucket name string. Therefore, it is a request feature and no information about the state is needed to decide it. On the other hand, the existence of a bucket depends on the state and it is a state feature. We assume that for each feature, we can categorize its values such that if two values are in the same category, they drive the same SUT behavior.

For each category we introduce a corresponding predicate that holds iff the value is in the particular category. We use

[4] It is sometimes useful to think of a feature as a type, limiting the kind of values that it can accept.

Request / concrete request		Request readily executable against the service.
State / concrete state		Current state of the model / SUT.
Deviation		Request and state where the model and SUT do not agree on the response.
Feature	Request	Argument or contextual parameter that affects strictly the request. E.g. the bucket name.
	State	Contextual parameter or condition on the state that affects the request. E.g. if a bucket with a specific name exists.
Predicates	Input	Set of boolean functions / formulae over model state and action. E.g. "is_valid_bucket_name" or "bucket_exists".
	Output	Set of boolean functions / formulae over response / output. E.g. "status_code_200" or "no_such_bucket".
Input scenario		Total truth assignment over the input predicates. Denotes set of states and requests that are *equivalent* with respect to the predicates.
Projections	Abstraction	Maps a concrete request and state to the corresponding input scenario. E.g. the bucket name "ab" maps to the category of invalid buckets.
	Concretization	Function that maps an input scenario to concrete request and states in its denotation. E.g. the category of invalid bucket names maps to the concrete bucket name "bc" and others.
Category	Request	Set of values for a request feature that are equivalent w.r.t. the input predicates.
	State	Set of values for a state feature that are equivalent w.r.t. the input predicates.

Table 2: Terminology

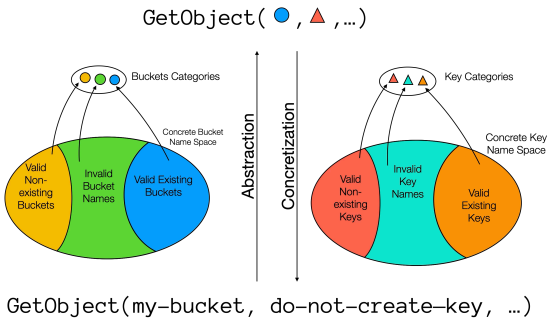

Figure 2: Request abstraction

predicates on inputs, outputs, and state elements to characterize the space of behaviors of the system. A predicate may depend on more than one request feature. S3 buckets contain objects identified by a key. Therefore, the predicate key_exists, holding only when an object with the given key exists, depends on the state of the system, as well as the request's bucket and key names.

The *abstraction* function evaluates the predicates on a particular request and state pair. The *concretization* function does the inverse: given an input scenario, it generates concrete request and state pairs, producing an executable test case. Fig. 2 depicts the process of mapping a concrete request to an input scenario and vice versa. Notice that sampling concrete requests from input scenarios is a critical building block to obtain a concrete test suite that achieves our coverage goals. We generate a set of input scenarios that achieves our coverage goal; concretization then turns each scenario into a concrete request executable on both SUT and model, thereby producing a test suite that realizes the coverage goal.

More formally, let $\mathbb{P}_I$ be the set of input and state predicates and $\mathbb{P}_O$ be the set of predicates on the output / responses. Then, $2^{\mathbb{P}_I}$ is the set of all the possible assignments to the input predicates, hence the set of all input scenarios. We say the abstraction is *adequate* iff every concretization of a given input scenario leads to outputs that correspond to the same assignment to the predicates in $\mathbb{P}_O$. In this case we say that the set of predicates $\mathbb{P}_I \cup \mathbb{P}_O$ is *fine*. Therefore, the input predicates are sufficiently precise to distinguish request-state pairs leading to distinct replies (w.r.t. $\mathbb{P}_O$). The abstraction is adequate if two request-state pairs that lead to responses that correspond to different evaluations of the output predicates $\mathbb{P}_O$ are mapped into distinct assignments to the input predicates $\mathbb{P}_I$.

To add structure to our abstract scenario space we take into account the *kind* of response (success or error) that the scenario will lead to on the SUT. This is simplified because web services reply to every request with either a success response or an error response.[5] For instance, ¬bucket_exists establishes a priori that the `GetObject` request cannot succeed, and moreover, if no other error-inducing predicates are true of the input scenario, it defines the exact error case that we will observe (in this case `404 NoSuchBucket`). This addition allows us to 1. use the model to predict whether the requests should succeed or not, and therefore focus our input generation for requests that should succeed first, and 2. define metrics on error-inducing requests, based on their proximity to a successful request. We define the distance between an error-inducing request and a success request as the number of parameters whose evaluation leads to error. We refer to this distance function as num_errors. For instance, `GetObject(bucket="1b", key="", PartNumber="abc")` induces at least three errors: the bucket name is too short, the key name is empty, and the `PartNumber` is not a number. num_errors counts the total number of error preconditions of an input scenario. We include it in our abstraction to distinguish between requests that are expected to succeed (num_errors $= 0$), requests that hit exactly one error condition (num_errors $= 1$), requests that can trigger two distinct error preconditions (num_errors $= 2$), and so on. Sec. 5.2 describes how this enables us to reduce the number of inputs that need to be validated to achieve coverage of the input scenarios via the *first-error hypothesis*.

4.1 Predicate Definition

Consider the example in Fig. 3. The picture shows three HTTP requests for key "`key`" in bucket "`bucket`". The requests specify different `If-Unmodified-Since` dates and

[5] For simplicity, we assume that 2XX HTTP responses [RFC22] are successful, and other responses (errors or informational) are considered errors.

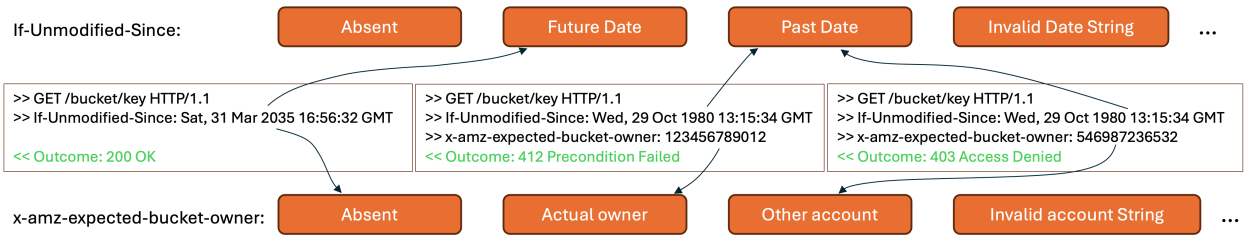

Figure 3: Abstraction example.

`x-amz-expected-bucket-owner` values. The response received for each request is shown below the request in green. The semantics of `If-Unmodified-Since` is such that: 1. if the date is in the future the header is ignored; 2. if the date is before the creation date of the object we will receive a `412 Precondition Failed`; 3. otherwise the request can succeed with a `200 OK` response if no error happens elsewhere. The `x-amz-expected-bucket-owner` header is used to ensure we only operate against a bucket owned by the specified account. If the account does not own the bucket a `403 Access Denied` error is returned. This example illustrates the importance of the abstraction: the exact choice of future date or exactly which "wrong" owner we specify does not matter. We only need to test one future date for this scenario, not all possible ones. Similarly, for the `x-amz-expected-bucket-owner` field we only need to test the actual owner, any other account as owner, and at least one other value for each of the remaining categories shown at the bottom of the figure. Importantly, the choice of category for a feature can drive different outcomes for the request, while different concrete values in the same category will produce the same responses.

Identifying Meaningful Categories. A natural question is how to determine the appropriate set of categories of each feature. For instance, should we refine the "invalid bucket names" category further? The choice of categories is driven by the following observations. 1. Whether all the values in the category result in the same behavior for the feature in question. 2. Whether a category represents values that are potentially difficult to handle, even if it may not change the observable behavior. Typical examples are control characters in strings, empty or null values, boundary conditions, etc. 3. Whether the category contains values that are relevant for the specific optimizations and design choices of the SUT. While in this case, the category may not change the observable behavior, developers with information about the SUT can provide knowledge about inputs that trigger a different SUT path.

While some of these categories are immediately derivable from observations of the system and documentation, others need expert knowledge of the system. Over time, engineers add more information to our abstraction that relates to server paths that are not distinguishable by the model, but nonetheless deserve to be validated separately. For example, the object size of a request may affect the path, while the observable behavior is unaffected. Crucially, this has no effect on the model, but in the validation strategy we may be explicitly interested in covering such cases.

5 Automated Input Scenario Generation

Our test generation strategy uses the request and state abstraction introduced in Sec. 4 to exercise a configurable set of input scenarios. A test configuration defines the predicates that we are interested in and bounds the minimum and maximum num_errors of the input scenarios. The configuration is a boolean formula over $\mathbb{P}_I$ and num_errors. The test generation procedure explores all input scenarios in the configuration by enumerating the truth assignments that satisfy the formula. When the configuration includes all the features of the API type (the formula is valid), the test generation strategy will cover all the input scenarios for that API. Since input scenarios are equivalence classes of the observable behavior of the system, executing one request for each input scenario gives us the best black-box approximation of the service execution paths according to our abstraction predicates $\mathbb{P}_I$ and $\mathbb{P}_O$.

While this goal is intuitively simple, in many cases covering the entire space of input scenarios makes the procedure exercise scenarios that are *redundant* or *spurious* as discussed in Sec. 2.2. An input scenario is *redundant* if it covers behaviors of the SUT that have been already exercised by other scenarios. An input scenario is *spurious* if there are no concrete tests that can satisfy the category combination required by the input scenario. For example, the set of input scenarios $2^{\mathbb{P}_I}$ contains inputs that combine invalid buckets with values in all categories for key names: including the category of existing keys! In S3, there cannot exist keys in a bucket with an invalid bucket name, hence the input scenario cannot be concretized. There exists no state and request pair that meets the requirements of the scenario.

Recall the goals introduced in Sec. 2.2. We want to exercise all non-spurious input scenarios in a configurable portion of the space. To that end, we first need to enumerate the relevant (non-spurious) input scenarios. Then, for each scenario, we must reach a state and generate a request that exercises it on the SUT. Therefore, for every input scenario we execute a sequence of requests. The prefix of the sequence contains the requests necessary to reach the necessary state. The last request of the sequence is the one that actually exercises the

input scenario we are interested in. We send every request to the SUT first and then we check whether the responses are admissible by sending the same requests to the model (Fig. 1). We call the process of computing the sequence of requests to exercise an input scenario *concretization*.

5.1 Removing Spurious Input Scenarios

As exemplified in Sec. 2.2, we introduce a propositional formula inv_Ω (for state invariant) to distinguish spurious and non-spurious input scenarios. We first show what inv_Ω looks like in the case of Amazon S3 and then give a more general description of its shape and how it is employed in the scenario enumeration procedure.

For this example, consider the `bucket`, `key` and `version id` features of the `GetObject` API. In this setting we define inv_Ω as the conjunction of seven implications. Implications 1 and 2 express the fact that in S3 keys exist only inside buckets, and a key can have multiple versions. Implication 3 states that every key has the null version. Then, implications 4, 5 and 6 state that only buckets, keys and version ids that are syntactically correct can exist in the state. Finally, implication 7 encodes the fact that a version id cannot be both named and null at the same time. More formally, let V_Ω be the model state and let b,k,v represent the values of `bucket`, `key`, and `version id` respectively. Consider the predicates valid_bucket_name, valid_key_name, valid_named_version, null_version, bucket_exists, key_exists, version_exists $\in \mathbb{P}_I$. Then, inv_Ω is the conjunction of the following formulae:

$$\text{key_exists}(V_\Omega,b,k) \rightarrow \text{bucket_exists}(V_\Omega,b) \quad (1)$$

$$\text{version_exists}(V_\Omega,b,k,v) \rightarrow \text{key_exists}(V_\Omega,b,k) \quad (2)$$

$$\text{key_exists}(V_\Omega,b,k) \wedge \text{null_version}(v) \rightarrow \text{version_exists}(V_\Omega,b,k,v) \quad (3)$$

$$\text{bucket_exists}(V_\Omega,b) \rightarrow \text{valid_bucket_name}(b) \quad (4)$$

$$\text{key_exists}(V_\Omega,b,k) \rightarrow \text{valid_key_name}(k) \quad (5)$$

$$\text{version_exists}(V_\Omega,b,k,v) \rightarrow \text{valid_named_version}(v) \vee \text{null_version}(v) \quad (6)$$

$$\text{valid_named_version}(v) \rightarrow \neg\text{null_version}(v) \quad (7)$$

More generally, we require the atoms of inv_Ω to be the abstraction predicates $\mathbb{P}_I$ and we require inv_Ω to denote the set of non-spurious input scenarios. An input scenario is a truth assignment over the atoms of inv_Ω, hence it makes the formula either true or false. In other words, inv_Ω is satisfied by an input scenario iff the scenario is non-spurious. Therefore, we can generate the non-spurious input scenarios by enumerating the satisfying assignments of inv_Ω. In fact, the core of the input scenario generation procedure is an *all-sat* engine that enumerates the truth assignments to the predicates $\mathbb{P}_I$. The *all-sat* procedure can be implemented using any off-the-shelf SAT solver [CKHM25]. The input scenario generation procedure takes as input the invariant inv_Ω and the test configuration. It explores all non-spurious scenarios in the given configuration by enumerating all satisfying assignments (*all-sat*) of the formula obtained by the conjunction of inv_Ω and the test configuration. The conjunction of the test configuration with inv_Ω prevents the procedure from generating scenarios that are spurious and cannot be concretized.

5.2 Removing Input Scenario Redundancy

APIs often involve many, sometimes optional, input parameters. Unfortunately, the number of input scenarios is exponential in the number of features of an API. This implies that in several cases it may be neither practical nor cost-effective to explore all input scenarios. Instead, we are interested in exploring specific aspects or features of the API. Generally, the time available for validation is bounded (e.g. in a CI/CD approval step). Therefore, we need to limit our search to fit the time budget of the development cycles. We must focus our validation on features and scenarios that are more likely to exhibit new behaviors, potentially deviating from the model. For example, consider the `GetObject` API with its 21 input parameters. For simplicity, assume we define only 2 independent predicates for each feature (i.e. 4 categories), then we have 4^{21} input scenarios for `GetObject`. Since our tool executes around 1.5×10^5 requests per hour, it would take about 2.9×10^7h to execute all `GetObject` scenarios. This simple computation shows that the predicates $\mathbb{P}_I$ alone do not sufficiently focus our exploration for all APIs. For this reason, we exploit num_errors to reduce, in a safe manner, the cases that need to be covered to identify deviations.

As exemplified in Sec. 2.2, covering all input scenarios would exercise the same behavior multiple times. This is especially true in the case of requests leading to error responses. Consider again the `GetObject` request from Sec. 3:

```
GetObject(bucket="non-existing", PartNumber="abc")
```

In Amazon S3, this request will result in a `400 InvalidPartNumber` error, indicating that the part number check took precedence over the bucket existence check. The SUT stops processing the request and immediately returns once the first error is found. The values of all other fields are ignored and don't affect the SUT behavior. We assume that error responses short-circuit the service execution, and dub this property the SUT *first-error hypothesis*. We use the hypothesis to focus our exploration policy further.

num_errors, defined in Sec. 4, helps us exploit the short-circuiting mechanism. We use it to reduce the number of requests we generate, while still exploring all SUT behaviors under the first-error hypothesis. For instance, input scenarios where more than one input would lead to error induce redundancy: one of the two inputs will get evaluated first and the other will be ignored. However, our goal is to ensure conformance between model and SUT. Therefore, we cannot just stop after exercising all requests with up to 1 error. We need to

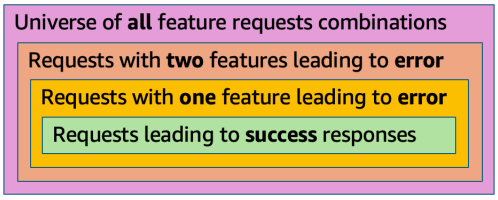

Figure 4: Space of requests by errors.

exercise requests with 2 errors to ensure the ordering in which the features are evaluated by the SUT is compatible with the model expectation. For example, all authentication and authorization checks must occur before all state-dependent checks (e.g. existence of the key). We use this strategy to organize our space exploration as illustrated in Fig. 4, where each set contains all the scenarios with up to n errors.

0-errors campaigns. These include all input scenarios leading to success responses.

1-error campaigns. These are all input scenarios that contain exactly one feature leading to error. These campaigns validate that our error reporting is accurate, and in combination with the 0-errors campaigns above, if the first-error hypothesis holds, evaluate all SUT paths for the API.

2-errors campaigns. These cover all input scenarios with exactly 2 features that should lead to an error. They validate that our model predicts the parameter evaluation precedence when more than one parameter leads to error.

Under the first-error hypothesis, any campaign with at least 3 errors exercises the exact same behaviors observed in the 1-error campaigns, and contributes nothing to the validation of the error ordering already achieved by the 2-errors campaigns.

In some instances, accurately calculating the exact num_errors for an input scenario is quite expensive. Intuitively, this requires identifying the closest input scenario leading to success, which implies considering all alterations for all predicates. While we generally keep the num_errors definition precise, for larger numbers n of num_errors we accept some requests with $m < n$ errors, if that speeds up the search. Notice that this is a safe overapproximation of the space of requests with n errors, since it only adds cases which may have less than n errors. The set will contain all scenarios with n errors.

5.3 Input Scenario Concretization

The previous sections described how we enumerate the input scenarios that achieve the desired behavior coverage. Unfortunately, we cannot directly execute an input scenario on the SUT. We must first set up the state required by the scenario and then create a corresponding request. For example, consider a `GetObject` input scenario where both bucket_exists and key_exists hold. To exercise the scenario, we first need a state with an existing bucket b and an object in b with some key k. Then, we can exercise the scenario by executing the request `GetObject(bucket="b", key="k", ...)`.

Listing 3 details the process of exercising an input scenario on the SUT and performs four main steps. First, we analyze the input scenario and extract the description of the required target state (`make_target_state`). Second, we execute the (possibly empty) sequence of operations necessary to reach the target from the current state (the while loop in `execute`). Third, we inspect the state and generate the request we need to execute (`concretize_request`). Finally, we execute this request on both model and SUT, exercising the input scenario (the last call to `test` in `execute`).

We now describe how the steps are implemented. The state required by an input scenario depends on the assignment prescribed by the scenario to the input predicates that depend on the model state. Therefore, given an input scenario we analyze its truth assignment to all predicates in $\mathbb{P}_I$ that depend on the model state and compile it into a structure we call *target state*. The target state is an abstract description of the state necessary to execute the input scenario. In the case of S3, the target state defines the number of buckets needed and, for each bucket it specifies the required configuration, keys and objects it must contain.

Given the target state, we must compute the sequence of operations necessary to set it up. As we mentioned in Sec. 2.2, that is the task of the *API-planner* component. Given the target state, the API-planner produces the sequence of actions necessary to reach the target from the current state. API-planner is a function that, given the current state of the model and the target state, generates the next action we need to perform or `None` if the current state meets the target. Recall the example from Sec. 2.2. Starting from an empty state, we want to exercise a `GetObject` input scenario where both bucket_exists and key_exists hold. The API-planner will first synthesize a valid bucket name and create a bucket with such name via the `CreateBucket` API. After successful execution of the `CreateBucket` request, the API-planner synthesizes a key name and object payload. These values are used to generate a `PutObject` request to write an object in the bucket we just created. Upon successful execution of the `PutObject`, the state has both a bucket and a key. We've now reached our desired state and the API-planner returns `None`. In order to exercise the scenario, we need to synthesize the corresponding request. In our example, we need to generate a `GetObject` request that uses the bucket and key names that we just created. We achieve this by querying the current model state for an existing bucket and key.

Importantly, the API-planner assumes the SUT and the model agree on the behavior of all *write* APIs (`CreateBucket` and `PutObject` in our example). We validate this by comparing the model and SUT responses for all requests generated by the API-planner and by running test campaigns specific for `PutObject` and the other APIs. In general, if the SUT and

```
def test(request: Request, model: Model) -> bool:
  sut_response = execute_sut(request)
  prophecies = make_prophecies(sut_response)
  model_response = model.execute(request, prophecies)
  return sut_response == model_response

def execute(model: Model, scenario: Scenario) -> bool:
  target: TargetState = make_target_state(scenario)
  request: Request = api_planner(model, target)
  while request is not None:
    if not test(request):
      raise StateSetupFailure()
    request = api_planner(model, target)
  request = concretize_request(model, scenario)
  return test(request)
```

Listing 3: Scenario concretization and execution (pseudo).

model do not agree, our validation campaigns will highlight defects either during the state-setup sequence, if SUT and model reply differently to a request generated by the API-planner, or when validating the response to the final request that exercises the desired scenario.

Listing 3 decomposes the scenario concretization process in two methods: `test` and `execute`. The `test` method simply executes the given `request` on both the model and SUT, and it returns true iff they generate the same response. As described in Sec. 3, the `prophecies` structure is used to enable the model to replicate the decisions made by the implementation (e.g. set the `Date` in the response correctly). The `execute` method sets up the state required to exercise the input scenario, generates the request corresponding to the scenario, and executes the request. The method returns true iff both SUT and model agree on the response to such request. The `execute` method first extracts the state requirements from the scenario into the corresponding target state. Then, it keeps calling `api_planner` to retrieve the next request to be executed in order to set up the state. It relies on the `test` method to execute the request on both model and SUT. If model and SUT reply differently, it notifies the caller that there has been a failure during the state setup. Once the desired state has been reached, `concretize_request` generates a request that exercises the given scenario in the current model state. Finally, it calls `test` one last time to run the request on both model and SUT and returns false iff a deviation was found.

5.4 Configuring Validation Campaigns

The input scenario generator takes as input a configuration that defines the testing campaign. The configuration defines the input scenarios of interest, explicitly defining the features and predicates that must be completely explored. We strategically define test campaigns and the corresponding configurations with the help of engineers. We define configurations that exploit knowledge about un/correlated features in the SUT. The configurations limit the combinatorial complexity of the validation campaigns and make them fit in the computational budget. For example, conditional features (`If-Modified-Since`, `If-Unmodified-Since`, `If-Match`, `If-None-Match`) are related to each other, and are also related to the freshness of the object. However, conditionals are mostly independent from other features, such as bucket configurations, and fields like `x-amz-expected-bucket-owner`. For this reason, for time budgeted campaigns, we restrict the features to be tested according to their correlation.

6 Results

Our model-based validation infrastructure is currently employed in CI/CD pipelines of S3. Tab. 3 reports the number of findings of our tool on three major initiatives within S3. Each of these findings resulted in proactive fixes and prevented the deployment of model-breaking code changes. Each finding has been manually analyzed and assigned a severity score. For each initiative the table reports the total number of findings and the number of findings with high severity.

The S3 Express One Zone storage class launched in 2023. Prior to launch, we applied our approach to all the S3 APIs that require strict compatibility with the original regional S3 implementation. For the APIs with intentional changes, we adapted our model to reflect the expected behavior on directory buckets. Using our methodology we prevented 171 deviations. Of these, 12 were of high severity. All these defects were fixed before the service launch in 2023.

Our tool is used in an ongoing multi-year rewrite of S3's frontend API service. As part of this effort, developers run it locally in their development environments, and it is also integrated into the CI/CD pipeline. Local runs typically exercise a small, specifically defined, subset of the overall tests that are run in the CI/CD steps. Over the course of the rewrite, the CI/CD steps identified 92 issues that were missed by other unit and integration tests. This enabled developers to address all of them before deploying to production.

Finally, as part of the CI/CD process in S3 we continuously check for errors and prevent them from releasing into production. To date, we identified 109 deviations, of which 24 have high severity. In the past two years, our tool helped in validating several major new feature launches such as: enabling server-side encryption by default, support for full object checksums, and conditional write operations (e.g. the `If-Match` field for `PutObject` requests).

6.1 Validation Reductions

Tab. 5 reports an overapproximation of the number of input scenarios for the `GetObject` API obtained from the number of features and categories in Tab. 4. The number of scenarios is still too large to be executed in the CI/CD pipeline. Each approval step in the CI/CD pipeline must provide feedback within a reasonable amount of time. As a starting point, we allocate a budget of three hours per validation campaign and run multiple campaigns in parallel. For this reason, in our testing setup each campaign can execute up to approximately

Implementation	# Issues	High Sev
S3	109	24
S3 Express One Zone	171	12
S3 Refactor	92	10

Table 3: Issues prevented to date.

Feature Type	Features	Categories

Encryption	`Bucket(C)`, `Key(C)`, `VersionId(C)`, `Size`, `SSECustomerKey`, `SSECustomerAlgorithm`, `SSECustomerKeyMD5`	86400	527040	1270080
Response*	`Bucket(C)`, `Key(C)`, `VersionId(C)`, `ResponseExpires`, `ResponseCacheControl`, `ResponseContent*`	279936	0	0

Table 6: Sample grouping of correlated features for validation and approximation of number of input scenarios.

432000 requests. For the features of the `GetObject` API, we defined an average of 2.4 equivalence classes that can be used in successful requests. Therefore, in an approval step we can cover the success-case combinations of about 15 features ($\approx \log_{2.4}(432000)$). Developers define the combination of features to consider based on their knowledge of the SUT and the changes they are interested in validating. We then rely on asynchronous long-running validation tasks to explore a rotating subset of the features with the goal of highlighting defects resulting from unexpected interactions between features.

We also have predefined validation campaigns, built alongside senior developers, that couple together highly correlated features. Tab. 6 reports a sample of common groupings of interest. For each group it reports the number of input scenarios containing 0, 1, and 2 errors that cover the feature combinations. Consider the first group (Ranges) in Tab. 6. We have, as in most validation configurations: `Bucket(C)`, `Key(C)`, `VersionId(C)`, where the `(C)` stands for correct categories for the group since we are interested in the object structure in this case, not bucket and key names, which are validated elsewhere. We also have features related to the size and structure of the stored object: `Size`, `PartNumber`, `Range`, and `ChecksumMode`. This results in 212400 requests, which we can execute in about 1.5 hours.

While we still don't cover all the input scenarios on every change, we highlight that the number of cases being covered is well beyond what can be achieved with manually defined tests. In addition, our approach is flexible and the scenarios being exercised can be changed via simple configuration updates.

6.2 Comparison to Property Based Testing

We compared our test generation approach to property-based testing (PBT). In the PBT setup the input generator samples each parameter from a weighted distribution and runs `GetObject` requests against randomly generated objects in an S3 bucket. We then apply our abstraction function to each request's input and output parameters and count the unique input scenarios covered. In a run of 28457 `GetObject` requests, the PBT tests exercise only 9040 unique scenarios, meaning that 19417 requests were scenarios already covered.

We obtain a similar result when targeting a specific scenario of interest. In this case we selected 3 features of `GetObject`: `bucket`, `key`, and `range`, and we allowed 2 categories for each, totaling 8 non-spurious input scenarios. The PBT generator eventually covers all 8 scenarios. However, across 10 different runs it required 3200 requests on average to do so. Instead, our scenario generation procedure directly enumerates the distinct input scenarios and deterministically generates the 8 required requests.

These simple experiments highlight the additional cost incurred to achieve the same coverage goals without a systematic way of exploring the input space.

7 Related Work

The literature more closely related to our work is on the topic of automated test generation and model-based testing. Tab. 7 organizes tools in this large research field along 4 orthogonal dimensions. 1. The *testing approach* is white-box if the tool leverages the source code of the system, and black-box otherwise. 2. The *test-generation policy* is the algorithm used to select the next test scenario. 3. The *input generation* represents the logic used to select the input value for each scenario. 4. An approach is *stateful* if the test generation considers the current state of the SUT, stateless otherwise. 5. The *oracle* is the component that performs the assertions to validate the

correctness of the observed behavior.

Grammar-based approaches, such as Grammarinator [BCD23, HKG18], exploit an explicit grammar to define the set of inputs. The space of all possible scenarios is defined by the possible combinations of derivation rules in the grammar, and the tools use randomization to explore the productions of the grammar. Unfortunately, grammar-based input generation is not well suited for stateful systems.

There is extensive literature on automated test generation for REST APIs [GZA24, KXSO22, CZPC21, MASR21, HD22]. Tools such as APIFuzzer [api], EvoMaster [Arc19], RestTestGen [VDC20, CZPC22], Schemathesis [HD22], and Fuzz4All [XPT+24] aim at testing an arbitrary REST API. Therefore, they often use comparatively weak oracles that don't enforce any specific behavior and perform only shallow checks on the response. Moreover, most of them rely on randomization or best-effort GenAI approaches for test generation, and do not provide conclusive coverage metrics on the covered space of requests.

The VIVAS framework [GGT25, FFP+23] relies on the definition of an abstraction of the system and the coverage goal is defined via (temporal) properties in the abstract space. The oracle is defined by runtime monitors [CTT19] synthesized from a set of desirable properties of the system on the abstract space. VIVAS focuses on ensuring that all traces of the system satisfy a set of properties. Instead, we focus on a simpler setting and consider the validation of a single action at a time executed in different SuT states. Our oracle is the full system model, defined directly on the concrete space, while in VIVAS the oracle is given by abstract properties.

Combinatorial Interaction Testing (CIT) [CDS08, NMT12, HWKK20, DMDS24] and tools like Tcases [tca] also organize the input space in features and categories. The tool Tcases simply generates the input scenarios. How to incorporate the scenarios into a practical testing campaign for a SuT is left to the user. Tcases employs a generate-and-filter logic to enumerate the non-spurious input scenarios. This approach does not scale to the number of features and conditions of the APIs we are interested in. Works on CIT focus on how to select a "minimal", fixed set of input scenarios to cover as many feature interactions as possible. Some of these works (e.g. [CDS08]) also account for constraints between features to eliminate spurious scenarios. Their goal is to maximize the likelihood of exercising interesting behaviors of an arbitrary system, while minimizing the size of the test suite. Instead, we target a specific system and API and ask the developers to select which feature combinations need to be validated. The combinations to cover are chosen dynamically based on the portion of the system that is under active development.

Ridge et al. propose SibylFS [RST+15] for the verification of file systems. File system operations have only a few input arguments, while we deal with tens of input request parameters. In fact, 21k tests are sufficient for SibylFS, while the simplest of our individual APIs requires upwards of 100k tests to explore its behaviors. They also identify equivalence classes to obtain a finite set of scenarios to be tested. The test generator explores the combinations of all commands where the combinatorial testing is feasible and covers all "static real-world behaviors". The generated *test scripts* are then supplemented by manually defined ones to cover remaining cases. Instead, we are interested in conclusive configurable testing campaigns that can quantify which portion of the space of input scenarios has been covered.

8 Conclusions and Future Work

We described the approach we adopted to define a high-fidelity model for the S3 API. The same approach is used to increase the confidence in the correctness of both the model and the implementation itself. The tool is under active development to support new features and implementations. It has been instrumental in preventing deployment of over 300 regressions. The tool validates code deployments in the CI/CD pipelines of S3, S3 Express One Zone, and internal rewrites.

Our approach relies on manually defined predicates that abstract the set of requests and states into abstract scenarios. We are currently working on learning/mining these predicates from service interactions and from the source code to reduce the effort required to build and maintain the model.

Abstract

High-end virtual machines (VMs) have become essential in public clouds for supporting large-scale guest applications. While conventional pre-copy live migration cannot reliably migrate such high-end VMs due to convergence problems, post-copy migration offers a viable alternative. However, high-end post-copy migration suffers from significant performance penalties, including extended downtime, prolonged post-copy duration and degraded guest performance, which stem from scalability bottlenecks in kernel memory management.

We identify the unnecessary overuse of lock protection as the root cause of scalability bottlenecks in existing approaches, which can be effectively resolved through strategic lock relaxation. To address this challenge, we propose M3U, a scalable kernel memory management approach for post-copy live migration of high-end VMs. M3U customizes lock-protected memory management operations, reducing operation overhead and minimizing critical sections. Additionally, M3U employs lock-reduced parallelism to decrease dirty page registration overhead. M3U also implements a decoupled fault handling pipeline to maximize page transfer efficiency, and utilizes fault-aware page size determination to meet minimum fault latency requirements. For pass-through devices, M3U further provides proactive identification and pre-transmission of device states, effectively eliminating 98.5% of hardware I/O page faults. Our evaluation demonstrates that M3U achieves a 47.0% reduction in downtime, an 89.6% reduction in post-copy duration, and a 4.1× improvement in guest performance.

1 Introduction

Today's public cloud infrastructure faces growing demand for deploying large-scale, resource-intensive applications—such as cloud gaming, deep learning, and large language model serving—driving the proliferation of high-end virtual machines (VMs). In this paper, we define high-end VMs as instances with substantially aggregated resources: at least 64 vCPUs, 256 GB of memory, up to 100 Gbps network bandwidth, and 600k IOPS disk performance. According to Google Cloud Platform's 2025 documentation [9], 85.7% of currently available machine types already support high-end VM configurations.

Live migration is an essential feature for cloud management, enabling transparent and seamless relocation of VMs from one physical server to another. This capability is particularly valuable for routine operations such as hardware maintenance and dynamic workload rebalancing [2, 7, 25, 28, 39, 51]. However, the increasing adoption of high-end VMs introduces significant challenges to live migration processes, as migrating these resource-intensive, high-end VMs without service interruption requires enhanced technical approaches.

Pre-copy [8, 26, 37], the predominant live migration approach in public clouds, is prone to failure when migrating high-end VMs due to the convergence problem [29, 38, 49]. The convergence problem occurs when vCPUs write dirty pages to VM memory at a rate exceeding the network transfer speed, preventing pre-copy from satisfying its stop condition. If the convergence problem persists, pre-copy live migration will fail. In fact, this problem is particularly prevalent among high-end VMs. Our analysis of over 50,000 pre-copy live migration samples from high-end VMs collected over 12 months in our cloud infrastructure reveals a migration success rate of merely 81%, with the convergence problem identified as the root cause of migration failures.

To ensure successful live migration of high-end VMs, employing a post-copy scheme [22] is essential. Post-copy addresses the convergence problem inherent in pre-copy by allowing the VM to resume execution on the target host before all memory has been transferred. The remaining dirty pages are then synchronized gradually in the background between the source and target hosts. If the VM accesses a page that has not yet been transferred, a page fault is triggered, causing the VM to block until that page arrives. Importantly, because the source VM is suspended during this process, the dirty memory set ceases to grow, which ensures that the migration

[*] Yizhe Xu, Yuan Tao and Zhibin Zhang equally contributed to this work.
[◇] Jian Li and Chao Zhang are the corresponding authors.

process will eventually converge and complete successfully.

However, post-copy live migration incurs two significant performance penalties when applied to high-end VMs—penalties stemming from their extreme resource density (e.g., large memory footprints, numerous vCPUs) and workload intensity (e.g., high memory-dirtying rates, bursty I/O). As VM resource allocations continue to scale, high-end VMs increasingly expose fundamental scalability limitations in the post-copy model. These limitations primarily manifest in two ways. **(1) Unacceptable VM switching downtime.** The post-copy model requires marking dirty memory as missing before the VM resumes on the target system. Consequently, the target system unmaps all dirty memory in page-sized units during downtime—a process termed *dirty page registration*. This operation accounts for 57–66% of the total downtime and results in excessive downtime lasting multiple seconds (§2.2). **(2) Heavy performance degradation during prolonged post-copy duration.** In post-copy migration, missing memory pages are fetched remotely and reconstructed on the target system. However, this reconstruction process introduces significant lock contention, as multiple tasks concurrently attempt to maintain cross-page-table consistency. This lock contention reduces page transfer throughput to only 9.2% of the available network bandwidth. Consequently, both per-page-fault latency and post-copy duration are substantially prolonged, leading to severe guest performance degradation—e.g., network interruption lasting over 15 seconds (§2.2).

Few prior studies have examined the performance penalties associated with post-copy live migration of high-end VMs. Recent work on Two-Dimensional Paging (TDP) Memory Management Unit (MMU) [18] attributes this challenge to scalability bottlenecks within the kernel MMU. In this paper, we define MMU as the software memory management subsystem provided by the host kernel and hypervisor, rather than the conventional hardware unit for address translation. Specifically, TDP MMU reveals severe lock contention arising from exclusive locking of the entire kernel MMU during each page fault in post-copy migration. However, as we demonstrate in §2.2, TDP MMU addresses only a limited subset of kernel MMU scalability bottlenecks and provides minimal improvements in post-copy performance.

In this paper, we present a critical observation: lock protection in standardized kernel MMU capabilities is *unnecessarily overused* in the context of post-copy live migration. This overuse of lock protection introduces scalability bottlenecks across page table management, consistency maintenance and fault handling, which collectively result in significant performance penalties in high-end VM scenarios. By strategically applying lock relaxation techniques to kernel MMU capabilities, we can minimize the critical sections protected by locks, thereby maximizing system parallelism and improving the overall efficiency of post-copy migration.

We propose Migration Memory Management Unit (M3U), a novel kernel MMU design that addresses the scalability challenges inherent in high-end post-copy migration. M3U manages VM memory and interacts with the original kernel MMU through standard system abstractions while implementing its own page-fault handler and page table management logic (e.g., page mapping/unmapping). To achieve this, M3U employs three key optimizations: **(1) First,** M3U fully preallocates VM physical memory, and maintains it statically by employing lightweight permission-bit flagging to replace costly page mapping/unmapping operations. This approach reduces critical sections and operation overhead, thereby enabling efficient parallel dirty page registration to minimize VM switching downtime. **(2) Second,** M3U implements a decoupled userfault pipeline to achieve lock-free parallel page data copying and mixed page table updating. These mechanisms collectively minimize fault latency and reduce the duration of the post-copy phase. **(3) Third,** to mitigate performance degradation caused by I/O page fault handling for pass-through devices, M3U eliminates nearly all I/O page faults through device state identification and pre-transmission.

In summary, our contributions in this paper are as follows.

- We provide detailed analyses and empirical observations on the performance penalties and kernel MMU scalability bottlenecks inherent in high-end post-copy migration.
- We introduce M3U, a scalable kernel MMU approach designed to address these scalability bottlenecks and mitigate the performance penalties associated with high-end post-copy migration.
- We present a comprehensive evaluation of M3U, demonstrating significant performance improvements over existing approaches: reducing downtime by up to 47.0%, decreasing post-copy duration by 89.6%, and improving guest service performance by 2.6–4.1×.

2 Background and Motivation

2.1 High-end Post-copy and Kernel MMU

High-end post-copy. The post-copy scheme [22] represents an appropriate choice for live migration of high-end VMs, as it effectively avoids the convergence problem inherent in pre-copy migration. Post-copy migration generally comprises two distinct phases.

- **VM switching phase.** During this phase, the VM is first suspended on the source host, and the target system restores the VM's state information (including CPU and device states) from the source. Second, *dirty page registration* marks the remaining dirty pages on the source VM as not present for the target VM. Finally, once the target system completes the restoration of all VM states, the VM is resumed on the target host. The VM downtime is incurred during this phase, as the VM remains suspended throughout the switching process.
- **Post-copy phase.** Following the VM switching phase, the remaining dirty pages are transferred to the target system

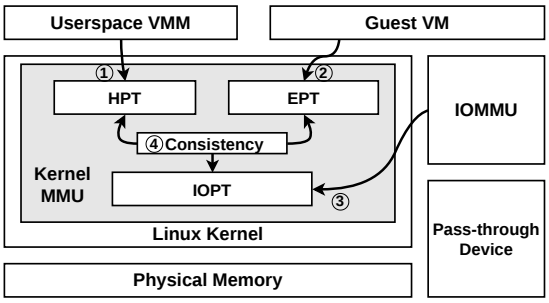

Figure 1: Kernel MMU capabilities for virtualization.

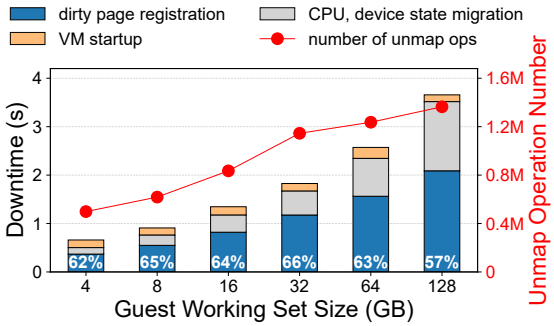

Figure 2: Downtime breakdown collected on the target during post-copy live migration of a VM with 64 vCPUs, 256 GB memory. (workload: memory random write, block size 1 KB)

through two complementary mechanisms: *demand paging* and *active pushing* [22]. Demand paging operates by immediately pulling a page from the source to the target when the target VM accesses a registered page and triggers a page fault. Concurrently, active pushing maintains a continuous background transfer of dirty pages from the source, ensuring that pages are available before they are accessed by the target VM.

Three critical migration metrics—*downtime* (the duration of VM switching), *post-copy completion time* (PCT; that is, the duration of the post-copy phase), and *guest performance degradation*—are commonly used to evaluate both performance and guest impact during post-copy live migration. For convenience, we hereafter refer to post-copy live migration of high-end VMs as *high-end post-copy*.

Kernel MMU. The core operation performed during VM migration involves identifying dirty memory pages, transferring them, and integrating them into the target VM's address space. These tasks are typically implemented using a suite of functions provided by the kernel Memory Management Unit (MMU).

As shown in Figure 1, the kernel MMU supports post-copy live migration through the following key capabilities:

① *guest memory manageability* through the Host Page Table (HPT), which enables the userspace Virtual Machine Monitor (VMM), such as QEMU [41], to allocate, deallocate, map, and unmap VM physical memory;

② *guest memory virtualization* through the Extended Page Table (EPT), which facilitates VM execution by managing Host Physical Address (HPA) to Guest Physical Address (GPA) mapping and handling vCPU page faults;

③ *Direct Memory Access (DMA) support* through the I/O Page Table (IOPT), which enables memory virtualization for pass-through devices;

④ *cross-table consistency*, which coordinates updates across the HPT, EPT, and IOPT to ensure mapping coherence, for instance, reallocating a guest physical memory page triggers synchronized updates to all corresponding page table entries.

2.2 High-end Post-copy Challenges MMU Scalability

However, these kernel MMU capabilities confront significant scalability challenges for high-end VM post-copy, which lead to unacceptable performance penalties in migration metrics.

In this section, we provide both theoretical and experimental analyses on these performance penalties. The test configuration is identical to that in §6.1. To improve address translation efficiency and overall guest performance, we utilize huge pages (hereafter referring to 2 MB pages) to manage guest memory by default. We support 1 GB huge pages but do not use them as the default option because 1 GB huge page requires large, contiguous physical memory regions, which is less practical in our deployment scenarios. The results of migration metrics are shown in Figures 2 and 3.

Unacceptable VM switching downtime. As shown in Figure 2, the migration downtime increases rapidly with the workload intensity and exceeds 3 seconds (*s*) when we increase the working set size of memory random write workload to 128 GB in the high-end VM being migrated. In our cloud, downtime at such a level counts against most of our committed Service Level Objectives (SLOs) with customers, which can lead to immediate customer complaints when their real-time workloads are interrupted.

We found that the overhead of dirty page registration accounts for 57–66% of the total downtime as a major contributor. This overhead comes from the costly unmap operations to register and mark every dirty page in guest memory as missing on the target system. As a userspace process, the migration thread cannot directly modify its own page tables. Consequently, it must rely on the kernel-provided unmap interface, which simultaneously releases physical memory and updates the HPT, as the only mechanism for HPT management (① in Figure 1). However, the unmap operation is lock-protected and mutually-exclusive in execution, which leads to scalability bottlenecks. As illustrated in Figure 2, the total cost of unmap operations scales almost linearly with total operation number. While it is acceptable for normal VMs, for high-end VMs with an extremely large quantity of unmap

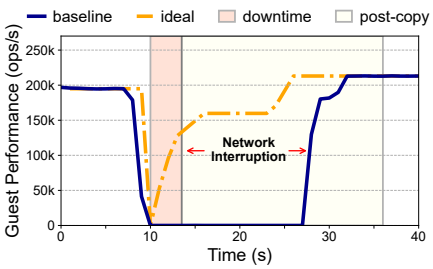

Figure 3: Guest service undergoes network interruption for over 15 *s*. (Redis, 1 thread, 24 GB working set, random SET)

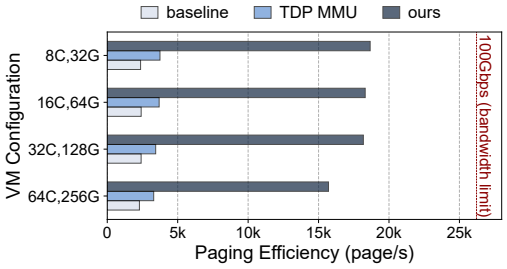

Figure 4: Paging efficiency comparison (quantified in pages per second from source to target; page size is 4 KB).

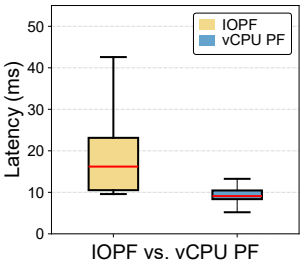

Figure 5: Demand paging latency comparison.

operations required, the overhead of dirty page registration becomes non-trivial. For instance, a VM with a 128 GB working set can trigger up to 32 million unmap operations to be done before the VM can be resumed on the target. Note that these unmapped pages must be reallocated when they are later recovered—either via active pushing or demand paging.

Heavy performance degradation and long PCT. Ideally, as shown in Figure 3, we expect post-copy live migration to bear almost no downtime and the guest to suffer minimum performance before all its remaining memory has been transferred. Contrary to our expectation, in the test shown in Figure 3, guest service experiences a network interruption for over 15 *s* even after the VM has resumed on the target host. Moreover, the PCT, defined as the duration for the VM to recover to its peak throughput after migration, exhibits significant divergence from the theoretical memory-transfer bound. As shown in Figure 3, the observed PCT is 24 *s*, whereas transferring the remaining 24 GB of memory over a 50 Gbps bandwidth (half of the host available bandwidth, explained in §6.1) would take only 3.84 *s* under ideal conditions. This results in a significantly longer effective downtime compared to that of pre-copy.

We observe that heavy guest degradation and long PCT are both caused by the low efficiency of demand paging and active pushing in dealing with the dirty pages and guest page faults at high-end scale. We show in Figure 4 that the baseline efficiency of demand paging and active pushing merely achieves 9.2% utilization of the total physical network bandwidth. With further analysis, we discover that such low efficiency is primarily caused by two conflicts between demand paging and active pushing.

Lock contention for cross-table consistency. Post-copy migration leverages the Linux userfault mechanism to handle the transferred page data for demand paging and active pushing. To safely integrate these newly arrived pages into the target's guest memory, the userfault handler must ensure cross-table consistency among the HPT, EPT, and IOPT (④ in Figure 1). The cross-table consistency is achieved in the following exclusively locked steps: a new host physical page is allocated, its content is copied from userspace to kernel, and all the three page tables (HPT, EPT, and IOPT) are updated atomically under their memory locks. These locks raise significant contention among demand paging, active pushing and vCPU page fault handling. Consequently, the userfault-driven page-in path becomes a scalability bottleneck in high-end post-copy scenarios, where a large quantity of vCPUs may concurrently fault on missing pages—leading to severe lock contention and serialized page-in operations.

Page size dilemma. In contrast to demand paging, which favors the smallest page size (e.g., 4 KB) to minimize per-fault latency due to the data movement through the Ethernet, active pushing operates as a background, bulk-transfer mechanism and thus benefits significantly from larger memory chunks. To maximize throughput and reduce overhead, we advocate using large pages (e.g., 2 MB) for actively pushed regions. This reduces the frequency of userfault invocations, page-copy operations, and page-table installations—collectively lowering control-plane overhead and improving overall paging efficiency. However, memory virtualization (e.g., by QEMU/KVM) provided by the kernel MMU enforces a *single, fixed page size* to manage the entire guest address space across the HPT, EPT and IOPT. The single page size enforcement raises conflicts between low per-fault latency and high paging efficiency required by demand paging and active pushing respectively.

A recent work, TDP MMU [18], partially resolves the lock contention in cross-table consistency by enabling parallelized EPT update. It replaces the original spinlock on the entire kernel MMU with a shared read lock, and uses atomic instructions to guarantee synchronous changes on EPT entries. However, TDP MMU cannot resolve the lock contention in the remaining operations of the userfault handler, e.g., the updating of the HPT and IOPT. In addition, TDP MMU does not provide a solution to the page size dilemma we mentioned above. Consequently, TDP MMU gains very limited improvement in kernel MMU scalability and paging efficiency as shown in Figure 4.

2.3 I/O Page Fault Performance

To meet high-end VMs' demands for high-performance networks, storage, and heterogeneous accelerators, cloud service providers adopt pass-through as a primary I/O virtualization mechanism. This approach enables guest VMs to communicate directly with devices using DMA (③ in Figure 1), bypassing the CPU and host software to achieve bare-metal level I/O performance. During the post-copy phase, DMA operations on non-present pages trigger hardware I/O page faults (IOPFs). To investigate IOPF performance, we constructed a real IOPF-enabled platform based on an existing IOPF solution [60] (also used in [21, 59]) that leverages PCI hardware support [40].

However, demand paging triggered by IOPF imposes a greater impact on guest performance than page faults triggered by vCPUs. Figure 5 shows that demand paging between these two types of page faults incurs approximately 2× average latency differences (3.21× for maximum). This performance degradation occurs because IOPF undergoes a PCIe transaction and a host interrupt before being handled by the host CPU, resulting in significantly higher latency than normal page faults (e.g., 3–80×) [56, 57]. Furthermore, IOPF handling occurs within the critical path of device DMA. Consequently, the device must suspend processing of the faulted I/O queue until the IOPF is resolved. This suspension can further lead to queue blocking and packet loss, particularly under bursty I/O workloads common in modern NICs and storage controllers. As a result, a single unresolved IOPF may stall the entire I/O queue, inducing delays that extend beyond the IOPF latency alone and directly impact guest service quality [21, 24, 59].

Our further investigation reveals that the IOPF pattern in post-copy migration exhibits a distinct temporal and structural pattern. Almost all IOPFs occur within the first few seconds after the VM resumes on the target host. These IOPFs fall into two categories: 1) Descriptor faults, triggered when the device driver accesses I/O descriptors (e.g., VirtIO virtqueue headers/descriptors) that record buffer metadata (address, length); 2) Buffer faults, caused by missing I/O data buffers. Crucially, I/O descriptors reside in driver-initialized, fixed-location control structures (e.g., virtqueue vrings) and are reused circularly during I/O processing—meaning each descriptor page faults at most once per migration. In contrast, I/O buffers are dynamically allocated by the driver per request; however, since the driver always accesses them first via CPU (e.g., to populate headers or issue commands), buffer pages are typically recovered via regular vCPU page faults—not IOPFs. As a result, descriptor faults dominate the IOPF footprint, while buffer-induced IOPFs are rare in practice.

2.4 Challenges and Insights

Kernel MMU scalability challenges. The performance analysis reveals that high-end post-copy migration introduces significant scalability challenges to the kernel MMU. These challenges stem from three primary sources:

- **HPT manageability** (① in Figure 1): lock-serialized updates to the HPT create a bottleneck, resulting in prolonged downtime.
- **Cross-table consistency maintenance** (④ in Figure 1): lock-serialized userfault handlers enforce strict synchronization requirements, which causes substantial guest performance degradation and extends PCT.
- **IOPT fault handling** (③ in Figure 1): hardware constraints in IOPF handling mechanisms limit fault processing latency, further degrading guest performance.

Key insight. The kernel MMU inherently enforces strict lock protection during HPT updates and cross-table consistency maintenance to ensure data correctness and consistency. However, we observe that *lock protection is unnecessarily overused* in numerous operations during post-copy migration (which will be elaborated in the next paragraph). Consequently, it is feasible to strategically relax lock protection in these operations to achieve better kernel MMU scalability in high-end post-copy scenarios.

The overused lock protection is primarily concentrated in three areas: physical memory allocation and deallocation, page content and table updating. **(1) First,** physical memory allocation and deallocation are essential to native kernel MMU capabilities such as map and unmap operations; however, they are entirely unnecessary for post-copy migration. We can therefore statically maintain the placement of VM physical memory during post-copy to eliminate both physical memory allocation/deallocation and the corresponding lock-protection overhead. **(2) Second,** page content updating is tightly coupled with the userfault handler through lock protection. By decoupling page data copy from the userfault handler, we can effectively eliminate this lock protection and achieve higher copy efficiency through parallel execution.

Based on these insights, we address the aforementioned challenges by designing strategic lock relaxation in kernel MMU capabilities, which comprises three components: (1) lock-reduced parallelism for HPT updates to achieve scalable HPT manageability; (2) decoupled and pipelined userfault handling to minimize lock contention during cross-table consistency maintenance; and (3) minimized IOPF occurrence (reduced to nearly zero IOPFs) rather than laboriously mitigating IOPT fault handling performance.

3 M3U Overview

We propose the Migration Memory Management Unit (M3U), a novel kernel MMU design for high-end post-copy to tackle the scalability challenges. As shown in Figure 6, M3U is a modular plugin that interacts with the original kernel MMU through standard system MMU operation abstractions. Therefore, M3U does not include invasive changes to other VMM or kernel MMU functionalities. M3U preserves the memory

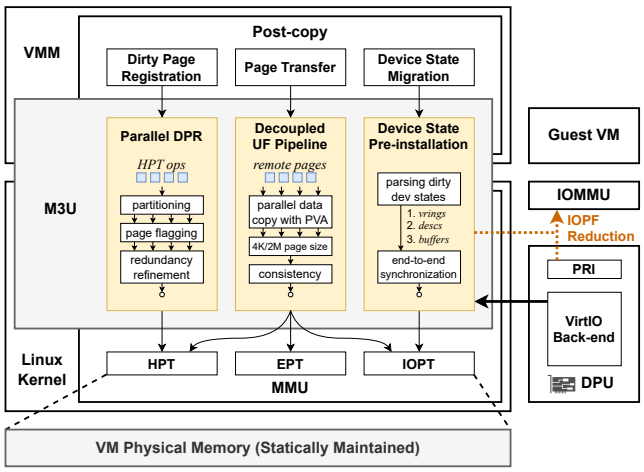

Figure 6: M3U overview.

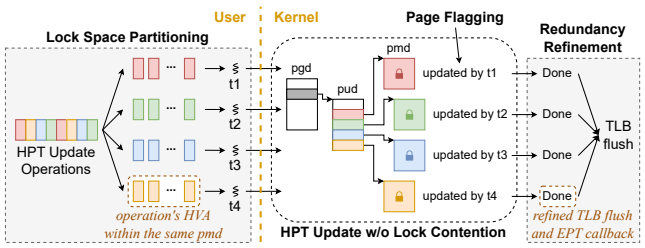

Figure 7: Lock-reduced parallelism for dirty page registration.

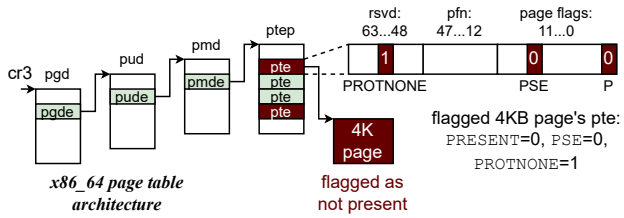

Figure 8: Illustration of page flagging.

mappings across the HPT, EPT and IOPT unchanged throughout post-copy migration, thereby significantly minimizing MMU modification overhead. As a result, MMU operations become lightweight, and their lock contention is drastically reduced. Specifically, M3U incorporates the following design components.

Parallel Dirty Page Registration. To minimize VM switching downtime, we introduce a lightweight, parallel dirty-page registration mechanism. By leveraging two key properties: (1) physical memory remains allocated throughout post-copy migration, and (2) the guest is fully suspended during VM switching, we replace heavyweight HPT operations (e.g., page mapping/unmapping) with ultra-lightweight permission flag updates, such as toggling the Present bits in HPT entries. This eliminates redundant MMU operations that incur high synchronization overhead, including physical page allocation/deallocation and cross-CPU Translation Look-aside Buffer (TLB) shootdowns, thereby dramatically reducing lock contention and enabling highly parallel memory discarding.

Decoupled Userfault Pipeline. To mitigate performance degradation and reduce PCT during VM resumption, we decouple the underlying address dependencies between active pushing and demand paging. This separation simultaneously alleviates lock contention for cross-table consistency and resolves the page-size trade-off inherent to these two paths. Specifically, we assign distinct Host Virtual Address (HVA) spaces for active pushing and demand paging. This design eliminates costly user/kernel memory copies and enables batched, pipelined HPT updates, thereby dramatically reducing lock contention. Moreover, this address space decoupling between active pushing and demand paging allows us to support mixed page sizes: large pages (e.g., 2 MB) for active pushing to maximize bandwidth efficiency, and 4 KB pages for demand paging to minimize fault latency, optimizing each path independently.

Device State Pre-installation. Rather than laboriously optimizing the inherently complex and latency-sensitive IOPF handling path, we eliminate nearly all IOPFs with simple device state pre-installation. Since descriptor faults dominate IOPFs in post-copy migration, and because I/O descriptors along with their associated I/O buffers occupy only a small memory footprint, we proactively transmit this device state to the target before VM resumption. As a result, DMA operations during the critical first few seconds after resumption proceed without triggering any actual IOPFs.

4 M3U Detailed Design

In this section, we present the M3U design details that address the scalability challenges and achieve efficient post-copy live migration for high-end VMs.

4.1 Parallel Dirty Page Registration

To improve the throughput of dirty page registration during the critical VM switching window, we propose parallel dirty page registration. The key to enabling efficient parallelism is eliminating or simplifying redundant MMU operations that cause lock contention.

Our approach rests on three core design principles: (1) Replace heavyweight HPT update operations with lightweight permission-bit flagging (e.g., clearing the Present/Writable bits), thereby keeping physical memory allocations static throughout the process; (2) Eliminate redundant MMU operations—such as page allocation/deallocation and TLB maintenance—that incur significant locking overhead; (3) Partition the VM's HPT address space to allow concurrent dirty page registration across disjoint regions, thereby avoiding inter-thread lock contention. We illustrate this design in Figure 7 and explain the details as follows.

Page Flagging. We propose page flagging (illustrated in Figure 8) to replace the heavy HPT updates (e.g., page mapping or unmapping), to make the dirty page registration

more lightweight. Page flagging refers to replacing physical memory deallocation during dirty-page registration with a lightweight 2 MB page-table splitting operation, followed by marking all 512 resulting 4 KB page-table entries with the non-present bit. Once flagged as non-present, a page becomes inaccessible to the guest VM; any subsequent VM access triggers a standard page fault, which notifies the migration process to fetch the page from the source host. Meanwhile, the discard process creates an HVA address space dirty bitmap [15] to record the absence of memory pages, with each bit representing a present/non-present 4 KB memory page.

M3U also leverages this page-flagging mechanism to preserve physical memory allocations throughout the migration procedure. This stability allows M3U to exploit a key property: the VM's physical memory (in HPTs) is fully allocated during the pre-copy phase. Consequently, when pages are later recovered via demand paging, their mappings can be restored efficiently—without requiring new physical allocations or complex remapping logic.

Redundancy Refinement. As VM stops running during VM switching and physical memory allocation remains, we can further refine two redundant locks in the HPT update to reduce lock contention: (1) the lock-intensive MMU notifier callback for erasing invalidated EPT mappings, which is unnecessary because the EPT is not constructed until VM resumption; (2) the TLB flush for every unmap operation. Specifically, since EPT is not fully constructed until userfault handling, the EPT callback in MMU notifier can be safely removed from the unmap operation without affecting system behavior. Meanwhile, VM does not access guest memory in downtime, so that we can aggregate all TLB flushes into one flush when dirty page registration is completed. To this end, the refined HPT update operation in M3U fully eliminates contention caused by redundant locks.

Lock Space Partitioning. To eliminate lock contention in parallelized HPT page flagging, we partition HPT update operations by address space. By replacing complex memory unmapping with lightweight page flagging, the only locks required during flagging are the page-table locks (e.g., PGD, PUD, and PMD in the x86_64 page table hierarchy). Other locks, such as the VMA lock, are no longer needed, since the underlying HPT mappings of HVA-to-HPA remain unchanged. As shown in Figure 7, M3U partitions the entire HVA space into disjoint 1 GB regions. Consequently, the PUD and PMD locks required to update the 512 PMD entries within each region are independent across regions.

M3U employs a worker thread pool to parallelize dirty page registration. The page-grouping worker receives dirty pages from the source system, which are transmitted in strictly increasing order of HVAs. Leveraging this ordering, the worker groups all pages that fall within the same 1 GB address boundary and assigns each group to a dedicated discarding worker. Because HPT updates within a single 1 GB region require only the corresponding PMD and PUD locks, discarding workers operating on disjoint 1 GB address ranges do not contend for the same locks, enabling effectively lock-contention-free parallelism. When all the VM pages are discarded, the page-grouping worker triggers a TLB flush to update the physical TLB buffer.

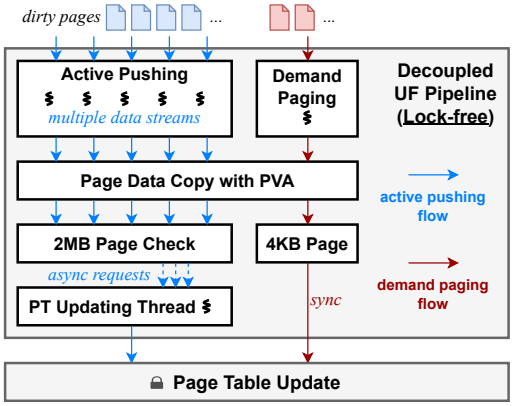

Figure 9: Decoupled userfault pipeline.

4.2 Decoupled Userfault Pipeline

To mitigate performance degradation and reduce PCT during VM resumption, we separate the address space to reduce contention and enable mixed page granularity to speed up active pushing and demand paging. Figure 9 depicts the overall design of decoupled userfault pipeline.

4.2.1 Separate Address Space

To improve the efficiency of active pushing, M3U builds an exclusive post-copy virtual address (PVA) space for statically maintained physical memory to straightforwardly recover dirty pages by direct memory copying. This direct mapping allows active pushing to recover multiple dirty pages concurrently across multiple data streams to enable high-throughput, parallel page restoration.

Post-copy Virtual Address (PVA). M3U incorporates a PVA mapping interface to directly remap the VM memory in another address space distinct from the origin HVA. With PVA, active pushing breaks the original dirty-page recovery procedure into two stages: memory data copying and cross-table consistency maintenance. First, when the active pushing on the target fetches a remote page, it directly copies the page data to guest memory with PVA. This eliminates the original costly user/kernel memory copies and lock holding during updates to the page table and page content in kernel space. Second, the active pushing clears the corresponding bit in the dirty bitmap set by page flagging and submits an asynchronous update request to a dedicated page-table-updating thread to perform cross-table consistency operations, such as synchronizing HPT, EPT, and IOPT entries. As these operations are handled exclusively by a dedicated single thread, lock contention among data stream threads is eliminated.

Multi-pushing. By leveraging an isolated PVA address space that enables concurrent memory copying, M3U integrates parallel data streams into active pushing to allow simultaneous page transfers—significantly improving paging efficiency. Each data stream is established over a dedicated socket connection and managed by migration threads on both the source and target sides. The source side dispatches dirty pages across multiple data streams for parallel transmission, while the target side concurrently receives and restores the contents of these pages. Meanwhile, a dedicated page-table-updating thread asynchronously maintains the cross-table consistency (e.g., across the HPT, EPT, and IOPT) required by all data stream threads, thereby eliminating lock contention among them. Through this design, M3U achieves highly efficient page transfer via batched, pipelined active pushing.

For demand paging, which is extremely latency-sensitive, M3U employs a dedicated data stream with a 20 Gbps throughput upper bound to handle page-fault requests, ensuring they are not blocked behind active-pushing traffic.

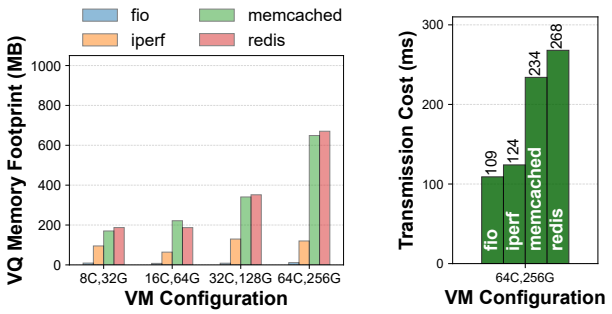
4.2.2 Mixed Page Table Updating

The decoupling of PVA from HVA simplifies the cross-table consistency maintenance so that M3U is capable of supporting mixed page sizes to balance the trade-off between active pushing and demand paging.

Demand Paging in 4 KB Granularity. M3U enforces a 4 KB page size for demand paging to minimize page-fault handling latency. As described in Section 4.1, any 2 MB HPT entry containing missing pages is split into 512 individual 4 KB page-table entries, each initially marked as non-present. When the VM accesses a missing 4 KB page, the demand-paging handler immediately fetches the page from the source and clears the corresponding bit in the dirty bitmap set by page flagging. The vCPU fault handler then sets the Present bit in the corresponding 4 KB HPT entry and installs the matching EPT entry, allowing the VM to resume execution seamlessly. By using 4 KB pages for demand paging, M3U avoids unnecessary overfetching of dirty memory and minimizes fault latency, ensuring rapid recovery of only the required data.

Active Pushing in 2 MB Granularity. M3U provides a batched HPT page-table rebuild interface that enables active pushing to recover discarded (missing) pages at 2 MB granularity. When active pushing finishes copying data and submits an asynchronous update request to the page-table-updating thread, the thread checks the dirty bitmap to determine whether all memory within the corresponding 2 MB region has been successfully retrieved from the source to the target. This 2 MB page check is performed using atomic bitmap operations and does not necessitate lock protection. Once all 512 constituent 4 KB pages of a 2 MB region are confirmed as recovered, the thread coalesces them into a single 2 MB HPT entry, replacing the individual 4 KB mappings. This optimization reduces what would otherwise require 512 separate page-table updates to just one, thereby dramatically decreasing the number of locks acquired (e.g., PMD/PUD locks) and significantly alleviating lock contention during HPT maintenance. In addition, M3U eliminates redundant transfer of 4 KB pages with an existing send-once guarding mechanism in QEMU—during post-copy, the source leverages its dirty bitmap to ensure that each page is transferred at most once [43]—thereby preventing transfer amplification.

Notably, M3U eliminates all intermediate page copies that the original QEMU must rely on when guest memory uses 2 MB page size. For the origin QEMU on the target system, it has to wait for the 512 × 4 KB pages to be transferred before it finally maps this 2 MB page. However, there is no guarantee that all 4 KB page data within a 2 MB page can be transferred strictly in order and without any loss. Consequently, each 2 MB page uses a temporary buffer to store the 4 KB page data until the 2 MB page is completely transferred, which causes an additional page copy through this temporary buffer. With PVA and mixed page size support, M3U no longer needs such intermediate page copies.



(a) Virtqueue Memory Footprint (b) Transmission Cost

Figure 10: Small total memory footprint and lightweight transmission cost of virtqueue structures, making one-time transmission of these virtqueues a feasible alternative to demand paging by IOPF handling.

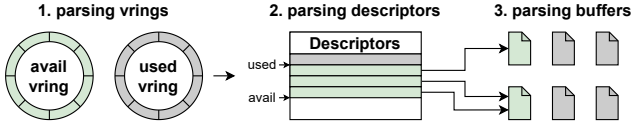


Figure 11: Parsing the VirtIO virtqueue structures.

4.3 Device State Pre-installation

Device state pre-installation eliminates nearly all IOPFs during post-copy. A critical observation on our platform is that the device states, e.g., the virtqueue structures for the VirtIO driver, remain in a small total memory footprint, regardless of the I/O pressure. Figure 10a shows various workloads (including intensive workloads for network, storage, CPU and memory) we tested for diverse I/O pressures, and the total

memory footprint of virtqueues is at most ∼671 MB. Directly transferring these virtqueues incurs very lightweight overhead considering the network bandwidth assigned for live migration. Generally, for production-level live migration practices, we assign 20 Gbps for pre-copy and 100 Gbps (the host available bandwidth, explained in §6.1) for transmission during downtime. With such network bandwidth, the transmission cost of virtqueues achieves no more than 300 milliseconds (*ms*) for the tested workloads as illustrated in Figure 10b.

As a result, transmitting all device state in a single batch is significantly more efficient than fetching it on demand via IOPFs. When all DMA-related missing pages are recovered during VM switching, the I/O buffers already present in the virtqueue become non-faulting. Subsequent I/O buffers produced after VM resumption will typically trigger a vCPU page fault, which retrieves the required memory from the source system on demand.

End-to-end Synchronization of Dirty Device States. M3U implements end-to-end functionality for capturing, parsing, exporting, and importing all dirty virtqueue structures by leveraging the VirtIO backend driver. As shown in Figure 11, M3U begins by locating the vring metadata and descriptor tables within each virtqueue. The physical addresses of these structures are recorded by QEMU during device initialization. M3U then traverses each descriptor table between the available and used ring indices to identify all active I/O buffers associated with pending or in-flight requests. The resulting dirty virtqueue state—including vrings, descriptors, and referenced buffers—is exported to the migration thread, which handles its transmission over the network to the target host. Upon receipt, the target VMM uses M3U to reconstruct and install the complete virtqueue state, completing end-to-end synchronization of dirty device state. Critically, this entire process is fully transparent to the guest OS and requires no modifications to the guest—preserving compatibility while enabling efficient post-copy device resumption.

The concrete procedure of device state migration is now as follows. After the VM and the devices are suspended on the source, the VMM performs a device draining operation that flushes all in-flight packets in devices and makes the device states consistent. During the device state migration in VM switching, the VMM leverages M3U to achieve this synchronization of device states between the source and target.

4.4 Concurrency Safety

M3U ensures concurrency safety throughout post-copy migration in two phases: (1) Externally across the source and target hosts. To perform critical VM switching, the source suspends the vCPUs and drains the devices during the downtime phase, where no concurrent VM execution is allowed, thereby ensuring data consistency. After the VM resumes on the target, non-present pages remain inaccessible to the VM until they are transferred, preventing data corruption. (2) Internally on the target host. Technically, the only new race introduced by M3U is the concurrent update of the same page by both demand paging and active pushing. To eliminate this race, the source leverages its dirty bitmap [43] to ensure that each page is transferred at most once; the target uses its received bitmap to ensure that each page and the corresponding mapping are restored at most once. This coordination mechanism across both migration hosts ensures such races never occur during post-copy, effectively preventing page data from being overwritten or corrupted. As for other inherent race conditions—such as those between concurrent faults and demand-paging requests—the hypervisor and VMM already handle them safely, eliminating any risk of data corruption.

5 Implementation

We implemented a prototype of M3U in QEMU 8.2 and Alios with Linux kernel 4.19. Our prototype supports all VirtIO driver versions; we use version 0.95 in our evaluation. The M3U prototype implementation consists of over 2,000 lines of code (LoC) in userspace and over 4,000 LoC in the kernel.

Applicability. M3U's design is applicable to both Type I and Type II hypervisors. The implementation follows the deployment setting adopted in our cloud environment, which utilizes the QEMU-KVM virtualization stack under a Type II model. KVM-based Type II hypervisors remain a mainstream solution in modern cloud infrastructures (e.g., Google Cloud [10] and AWS Nitro [54]), making this deployment setting representative of real-world practice.

M3U is highly compatible with the Linux kernel because it relies on stable standard interfaces provided by the kernel MMU for external management modules [32–35], and the kernel preserves the compatibility of these interfaces across internal feature evolutions. Therefore, M3U can be integrated into recent kernels with minimal adaptation. We have verified M3U's compatibility with Linux kernels 4.19, 5.15 and 6.6 in our cloud environment; we use the implementation with Linux kernel 4.19 in our evaluation.

Device memory management. M3U manages the VM memory separately through Linux `/dev/mmap` interfaces, so that it can interact with the original kernel MMU through standard system abstractions, while implementing its own page-fault handler and page-table management logic (e.g., mapping/unmapping).

Demand paging. Similar to QEMU's post-copy preempt feature [46], we employ a single data stream for demand paging that transfers dirty pages immediately without batching. Unlike batched transfer in active pushing for higher throughput, this allows a faulted page to be transferred with minimum latency. In addition, we refine the function calls irrelevant to post-copy during vCPU page fault handling to reduce demand paging latency.

Parallelism tuning. For parallel dirty page registration (§4.1), we assign one worker thread in the thread pool per 8 GB guest memory. The thread count is no more than 16, where it

achieves the maximum efficiency improvement.

For parallel data streams (§4.2), we implement the page transfer framework based on the QEMU multifd [44]. We employ 6-8 data streams for active pushing, while the demand paging always employs a single data stream. This practical optimal configuration (verified in our evaluation) enables the paging efficiency to reach over 70% of the physical network bandwidth on a single host server, which is generally beyond the bandwidth limit for live migration.

6 Evaluation

6.1 Platform and Workload

The evaluation platform comprises a pair of source and target nodes for live migration, with guest VMs deployed as clients on these nodes. Each node is equipped with dual-socket, 32-core Intel Xeon 8369B CPUs, 512 GB DDR4 memory, and a DPU card (PCIe Gen3 connection with 8 lanes, supporting a maximum physical network bandwidth of 200 Gbps).

M3U supports all major Linux-based guest OSes and uses Ubuntu 20.04.6 with Linux kernel 5.4 in evaluation. Our high-end guest VM is configured by default with 64 vCPUs, 256 GB of memory, and a 100 Gbps virtual network interface controller (vNIC) enabled via I/O pass-through[1]. To obtain stable performance measurements, we pin each vCPU to a separate hyper-threaded core co-located on a single NUMA socket. The host OS is statically configured to use 2 MB huge pages by default, with Transparent Huge Page (THP) [5] disabled to optimize guest performance. Correspondingly, the guest OS has huge pages disabled by default.

Baseline. For our first baseline, we begin with the community version of QEMU 8.2 and Linux kernel 4.19. We also implement pass-through I/O virtualization in the baseline using a state-of-the-art DPU-based VirtIO offloading approach [60]. To handle IOPFs, we adopt the same hardware solution employed in recent works [21, 59], which relies on the Address Translation Service (ATS) and Page Request Interface (PRI) as defined by the PCI standard [40].

For our second baseline, to demonstrate M3U's advantages in paging efficiency and PCT, we introduce the TDP MMU, a state-of-the-art approach for kernel MMU scalability (explained in §2.2). TDP MMU adoption requires a recent Linux kernel version that is incompatible with our DPU offloading virtualization platform [60]. Consequently, we deployed TDP MMU on a bare-metal machine with an identical configuration to M3U's setup, except without the DPU device, using QEMU 8.2 and Linux kernel 5.15. Since this baseline deployment does not include modifications to dirty page registration and lacks support for pass-through devices during post-copy live migration, we limit our comparison of TDP MMU and our approach to paging efficiency and PCT metrics, excluding downtime, guest performance, and I/O-related measurements.

[1]The same configuration is used in the `n4-standard-64` VM type on Google Cloud Platform, which costs 2.2K USD per month per node.

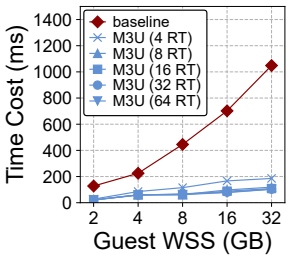

Figure 12: Dirty page registration overhead. "RT" denotes registration thread.

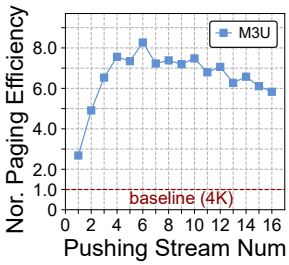

Figure 13: Normalized paging efficiency using baseline with 4 KB page size as 1.0×.

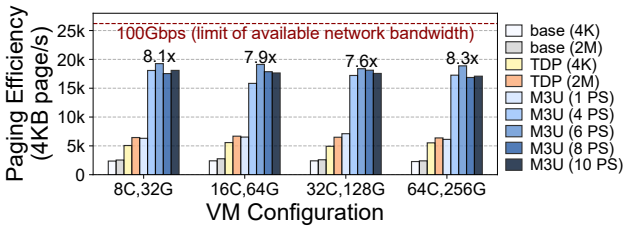

Figure 14: Paging efficiency of post-copy under different VM configurations. "PS" denotes the number of pushing streams.

To perform practical live migration, we adopt a "*hybrid*" method [23, 50]—a state-of-the-art approach that combines pre-copy and post-copy phases—which has become the standard in practice [49]. We enforce only one round of hybrid pre-copy before the live migration enters the downtime phase to highlight the performance differences between M3U and the baseline approaches during post-copy. The available network bandwidth for live migration is 100 Gbps (max 200 Gbps; 100 Gbps for guest VM, 100 Gbps for host).

Workload. In high-end VMs, we run Liblinear [14] and Llama.cpp [17] as the compute-intensive workloads. We run Graph500 [19], as well as YCSB [11] and Memtier [48] benchmarks on Memcached [36] and Redis [47] as the memory-intensive workloads. We use iperf3 [20] and FIO [6] for network and block I/O intensive workloads, respectively.

6.2 Micro-benchmark

Dirty page registration. Figure 12 demonstrates that M3U reduces the time cost of dirty page registration significantly by up to 90.2%. For all downtime-related tests, we employed memory random write operations with 1 KB block size as the workload and progressively increased the workload intensity. The test results show that M3U effectively reduces the time cost of dirty page registration by 60.0–90.2%, demonstrating better scalability across varying workload intensities compared to the baseline. Additionally, we observed that the time cost of dirty page registration plateaus at 16 worker threads; therefore, we configured this value as the default thread count for the worker thread pool.

Management of stream number. To study the scalability

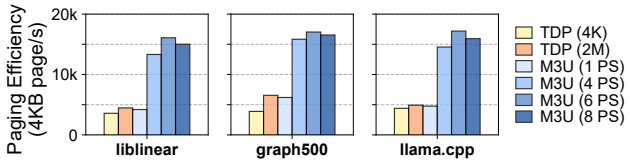

Figure 15: Comparison of paging efficiency under varying guest workloads.

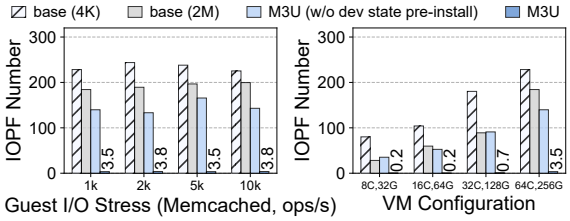

Figure 16: IOPF number under varying guest I/O stress levels and VM configurations.

of multi-pushing (§4.2) and how the number of concurrent streams should be managed, we adopt a practical evaluation on paging efficiency while systematically increasing the number of pushing streams from 1 to 16. The results in Figure 13 show that M3U achieves the highest paging efficiency with 6 pushing streams (7.6× improvement over the 4 KB baseline due to the throughput gains enabled by multi-pushing). Since the available host bandwidth is 100 Gbps, M3U with 6 streams already achieves the maximum migration bandwidth of approximately 80 Gbps. In addition, we can adjust the number of streams from 1 to 6 to almost linearly increase M3U's paging efficiency to better utilize the available migration bandwidth. As future work, we can further utilize advanced network solutions (e.g., RDMA or CXL) to reduce transmission overhead.

Paging efficiency. Figure 14 shows that M3U achieves superior paging efficiency compared to both the baseline approach and TDP MMU. The paging-efficiency upper bound derived from the physical network limit (dotted line in Figure 14) is calculated by dividing the maximum network bandwidth of 100 Gbps by the base page size of 4 KB.

Compared to the baseline approach using 4 KB page size, M3U achieves a paging efficiency improvement of 7.6–8.3× in the best case when utilizing 6 data streams for active pushing. Even with a single data stream for active pushing, M3U outperforms the baseline by 1.6–2.1× due to the performance gains enabled by asynchronous decoupling between page data copying and cross-table consistency maintenance.

Compared to TDP MMU, M3U with 6 active pushing streams delivers the most substantial improvement. Using a 4 KB page size, TDP MMU achieves a 1.4–1.6× improvement compared to the baseline, which is less than M3U with 1 active pushing stream compared to the baseline. As expected, larger page sizes enhance paging efficiency. When employing a larger 2 MB page size, paging efficiency improves by up to 1.2× for the baseline and 2.7× for TDP MMU.

In addition, to evaluate paging efficiency across diverse guest workloads, we select several resource-intensive workloads and run them continuously in the high-end VM during post-copy: (1) Liblinear (50% CPU, 20% memory), (2) Graph500 (66% memory), and (3) Llama.cpp (benchmarking llama-3-8B, 75% CPU, 20% memory). The results in Figure 15 show that, consistent with the prior results under idle conditions, using 6 active-pushing streams remains the optimal configuration across all workloads. Under this configuration, M3U outperforms TDP MMU by 3.9–4.5× with a 4 KB page size and by 2.6–3.6× with a 2 MB page size.

IOPF reduction. Figure 16 illustrates that M3U reduces the total IOPF number to 0.2–3.8 IOPFs per post-copy live migration of high-end VMs, across various guest I/O stress levels (using the Memcached benchmark) and with different VM configurations. Compared to the baseline, M3U achieves up to 98.5% reduction in IOPFs during post-copy migration by leveraging device state pre-installation.

First, as shown in Figure 16 (left), the total IOPF number for M3U remains consistently low (3.5–3.8 IOPFs per post-copy live migration) across different guest I/O stress levels. Next, Figure 16 (right) shows that M3U achieves 0.2–3.5 IOPFs per live migration across all tested VM configurations, whereas the baseline approaches' IOPF counts (with two page size configurations) scale proportionally with VM configuration due to the high-end VM's elevated memory dirty rates and larger total dirty page volumes. Lastly, even without device state pre-installation, M3U achieves fewer IOPFs overall owing to its improved paging efficiency. Similarly, the baseline using 2 MB pages incurs fewer IOPFs than the variant using 4 KB pages for the same reason.

6.3 Migration Metrics

Downtime. Figure 17 shows that M3U achieves up to 47.0% downtime reduction compared to the baseline. With lock-reduced parallelism, the overhead of dirty page registration during downtime decreases from 40.2–64.4% to 6.1–15.4%. The device state pre-installation incurs a time cost of 94–304 *ms*, which accounts for 12.7–29.0% of the total downtime. Although device state migration in M3U requires an additional 131.6 *ms* on average due to the device state pre-installation, this overhead remains marginal relative to the total downtime.

Apart from the costs associated with dirty page registration and device state migration, the remaining downtime costs between M3U and the baseline are relatively similar, primarily due to CPU state migration (0.2–1.4 *s*) and VM startup (121–169 *ms*). We attempted to reduce the cost of CPU state migration for further improvement; however, this approach proved highly challenging because CPU state migration strongly depends on the hardware-specific interfaces in QEMU-KVM.

PCT. Figure 18 illustrates that M3U delivers the shortest PCT

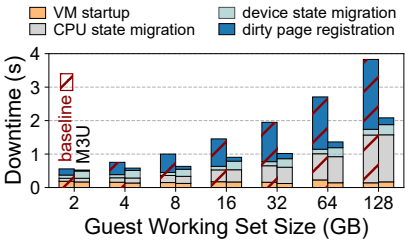

Figure 17: Downtime comparison.

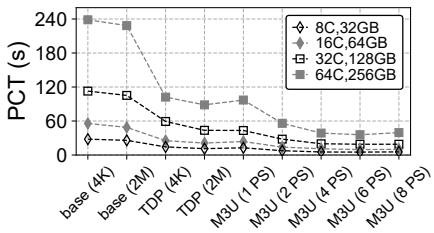

Figure 18: PCT comparison under varying VM configurations.

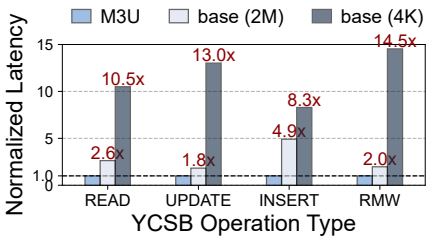

Figure 19: YCSB benchmark on guest Memcached (normalized latency).

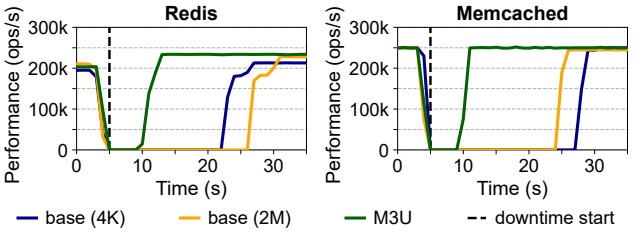

Figure 20: Memtier benchmark on guest Redis and Memcached services (throughput).

compared to TDP MMU and the baseline. We varied the total number of dirty pages across all test suites to demonstrate PCT differences. The results reveal three key findings. First, due to improved paging efficiency, M3U achieves an 85.8–89.6% reduction in PCT compared to the baseline. Even with only a single data stream, M3U reduces PCT by 33.4–55.6%. Second, TDP MMU also significantly reduces PCT by up to 55.7% compared to the baseline; however, this reduction is less than M3U's reduction with ≥ 2 data streams. Third, page size emerges as a deterministic factor for PCT reduction: TDP MMU and the baseline achieve additional PCT reductions of 25.7% and 12.6%, respectively, when using 2 MB pages. This result also indicates that M3U's fault-aware page size determination is highly effective.

Guest performance. Figure 19 shows the normalized operation latency of the YCSB benchmark on the guest Memcached service, demonstrating a substantial reduction. This evaluation encompasses four operation types that constitute all YCSB workloads (a–f) in different ratios, with the exception of the "Scan" operation, which is unsupported in Memcached. The "Read-Modify-Write" operation is abbreviated as "RMW" for clarity. The results show that M3U achieves 1.8–4.9× lower operation latency than the baseline configuration with 2 MB pages, and 8.3–14.5× lower latency than the baseline using 4 KB pages.

Figure 20 shows the real-time performance curves of the Memtier benchmark for guest Redis and Memcached services executing SET operations. To evaluate M3U's effectiveness, we quantify the service throughput degradation during the post-copy phase by the performance curve valley. The results show that M3U achieves a 2.6–4.1× reduction in throughput loss compared to the baseline approach, thereby significantly improving guest performance.

7 Discussions

IOPF elimination. M3U eliminates up to 98.5% of the IOPFs in post-copy, as tested in §6.2. The remaining IOPFs stem from non-atomic virtqueue processing in the guest VirtIO front-end (FE). Specifically, a timing window exists between (a) when the VirtIO FE allocates a buffer, and (b) when it posts this buffer into a descriptor. If live migration enters the downtime phase while virtqueue processing occurs within this interval, an IOPF will occur if the buffer is dirty, even though M3U has already performed device state pre-installation.

To completely eliminate IOPFs in post-copy migration, one straightforward approach would be to design a para-virtualized mechanism that guarantees atomic virtqueue buffer processing during the downtime phase of post-copy live migration. However, this approach introduces significant complexity and requires substantial modifications to the guest VirtIO FE. Moreover, it would make the guest VM fully aware of the ongoing post-copy live migration, thereby violating the principle of guest transparency. Consequently, M3U does not currently pursue this approach and takes this challenge as future work.

Failure tolerance. Post-copy is vulnerable to failures because the VM's memory state is bifurcated across both the source and target hosts during post-copy, and failure on either host will make the VM unrecoverable. Recently, a failure-tolerance approach for post-copy has been proposed based on the checkpoint/restore technique [16]. It is a software-based approach that M3U can adopt for failure tolerance in post-copy.

Generalizability. In brief, M3U is a fully generalizable approach for the community solutions. We discuss the generalizability by dividing the designs into two separate parts: pass-through device related and the others. For the latter part, M3U's designs do not rely on any new hardware features, which can be applied to community solutions like QEMU-KVM on commercial off-the-shelf servers as we evaluated. For the pass-through device related part, M3U's solution, i.e., the one-time transmission of device states during downtime

is device-independent, which can also be applied to diverse pass-through devices.

Overcommitment. Live migration naturally coexists with memory overcommitment, an essential property for cloud elasticity. Since the entire VM memory must eventually be transferred during migration, reclaimed memory is restored before migration proceeds. During restoration, the host hypervisor swaps in reclaimed pages and reconstructs the corresponding host-side HVA-to-HPA mappings in the background. Guest execution remains isolated from the host-side restoration because guest GVA-to-GPA mappings remain unchanged. The only interaction occurs when guest applications access reclaimed pages, where restoration introduces neither additional interference nor guest-visible overhead because both behaviors invoke the same underlying swap-in path. Consequently, migration executes with fully resident VM memory and without overcommitment, as commonly adopted in existing live migration systems. Based on this invariant, M3U prevents the target host from swapping migrated memory until migration completes, thereby eliminating additional complexity and overhead. Outside the migration period, overcommitment remains fully supported on our platform.

Applicability to Type I hypervisors. The core techniques in M3U (e.g., static memory allocation, page flagging, separate address space, etc.) also extend to Type I hypervisors, particularly to lock-protected memory management paths in the hypervisor and userspace migration components. Therefore, the design principles in M3U remain applicable across both Type I and Type II hypervisors.

8 Related Work

Post-copy live migration. The post-copy scheme [22] was introduced to reduce the total migration time and transferred data compared to the conventional pre-copy scheme. By directly switching the VM to the target host and lazily transferring all remaining memory data, post-copy effectively eliminates the pre-copy convergence problem [31, 52]. In contrast, other optimized pre-copy approaches (e.g., compression [27, 53] and CPU throttling [42]) can only mitigate, rather than eliminate, the convergence problem while simultaneously introducing host resource over-consumption or negatively impacting guest performance.

Post-copy migration is well-known for delivering poor guest service performance during extended PCT, especially when migrating high-end VMs. Previous studies have attempted to address this challenge through two primary approaches: (a) incorporating a hybrid pre-copy phase [23, 30, 50], or (b) actively and adaptively pushing dirty pages during the post-copy phase [22, 45, 52]—both we have adopted as our baseline strategy. Abe et al. [1] propose a para-virtualized post-copy approach that enables coordination between the host VMM and guest OS to identify VM's working sets for prioritized transfer. However, we do not adopt this approach because it violates the guest transparency principle. Note that the existing literature does not adequately address how this performance penalty amplifies when migrating high-end VMs, nor does it identify the root cause: specifically, the limitations of demand paging and active page pushing mechanisms, as well as the underlying scalability bottlenecks in kernel MMU.

I/O page fault. Resolving IOPFs caused by pass-through device DMA on non-present I/O pages—a common challenge in overcommitted cloud infrastructures—is a well-established research area [3, 4, 12, 13, 21, 56, 58]. Most existing studies focus on reducing the number of IOPFs or minimizing associated latency; however, they are generally constrained by performance bottlenecks or compatibility limitations. A recent approach, VIO [59], introduces an elastic pass-through mechanism that converts most IOPFs into CPU-side page faults. However, this approach does not further reduce the frequency or the cost of these page faults.

Regarding post-copy live migration, Tian et al. [55] present a VFIO-based solution that extends post-copy support to pass-through devices. Nevertheless, this approach suffers from limited device compatibility—it is specifically optimized for Intel XXV710—and introduces significant overhead from the VFIO stack. In contrast, our work adopts an IOPF handling solution based on the PRI/ATS hardware features, which ensures broad device compatibility. Notably, our work is the first study to successfully eliminate the vast majority of the IOPF handling costs during post-copy live migration.

9 Conclusion

M3U is a scalable kernel MMU design that eliminates the unacceptable performance penalties of high-end post-copy live migration. It addresses kernel MMU scalability bottlenecks in HPT manageability, cross-table consistency maintenance, and IOPT fault handling through three key techniques: (1) lock-reduced parallelism for dirty page registration, which reduces total downtime by up to 47.0%; (2) a decoupled userfault handling pipeline based on parallel data copying with a separate PVA and mixed page table updates, which reduces PCT by 89.6% and improves guest performance by up to 4.1×; and (3) identification and pre-transmission of pass-through device states, which eliminates up to 98.5% of IOPFs.

The design principles of M3U are fully generalizable to existing open-source solutions, providing clear guidance to the community on adding high-end VM support for post-copy live migration.

Compaction-Free Memory Defragmentation for Virtualization via Infinite Guest Physical Address Space

Peixin Zeng[†]*, Hao Huang*[†]*, Yanqi Pan, Wen Xia*[✉]*, Darong Yang, Jiahao Chen, Nan Zhang*
Harbin Institute of Technology, Shenzhen

Abstract

In virtualized environments, guest memory defragmentation is essential for exploiting huge-page benefits and improving application performance. However, existing approaches directly reuse host-side defragmentation and assume a limited guest physical address (GPA) space. As a result, they rely on memory compaction to defragment this constrained space, causing throughput to drop by up to 51% and latency to rise by up to 102% in YCSB-Redis workloads.

This paper proposes INFINIDEFRAG, a compaction-free memory defragmentation technique for virtualization. Our key insight is that the GPA space can be regarded as (nearly) infinite by controlling the mapping between GPA and host physical address (HPA), thereby eliminating the need for guest-side memory compaction. To realize this insight, we introduce (1) *Infinite Address Manager* that expands the GPA space while reclaiming free fragment pages; (2) *Host Memory Guard* that maintains the GPA–HPA mapping and constrains HPA usage within each VM's quota; and (3) *Scalability Optimizer* that scales GPA/HPA space management to multi-thread and multi-VM environments. Experiments on micro-benchmarks and real-world applications show that INFINIDEFRAG outperforms state-of-the-art approaches and can achieve ideal, fragmentation-free performance.

1 Introduction

Virtualization has become a foundational technology to enable resource sharing, workload isolation, and flexible deployment [32, 54]. Therefore, virtual machines (VMs) power a wide range of services, including cloud platforms and enterprise IT environments, which require efficient and scalable system designs. Among these, memory access is one of the most important optimizations to improve VM performance.

Huge page is a widely adopted technique to improve memory access performance [18, 21, 33, 35, 36, 39, 45, 47, 57]. By increasing the page size from 4 KB to 2 MB, and even to 1 GB, huge page significantly lowers the translation lookaside buffer (TLB) miss rates and page table walk (PTW) cycles. In virtualized environments, huge pages are particularly important because they substantially reduce the overhead of two-level address translation, where each memory access traverses from the guest virtual address (GVA) to the guest physical address (GPA), and then to the host physical address (HPA).

However, the effectiveness of the huge page highly depends on the contiguous physical memory, whereas memory fragmentation is a notorious problem that makes the memory discontinuous [28, 42, 48, 56]. Specifically, fragmentation arises when the memory is allocated and freed in a non-deterministic pattern, making it increasingly difficult for the page allocator to find large contiguous regions for huge page allocation.

To solve the problem, existing fragmentation mitigation works primarily focus on two dimensions: (1) *Anti-fragmentation*: optimizing allocation policies to proactively avoid fragmentation [31, 37, 40, 48, 53]. However, such static strategies are tailored to specific scenarios and fail to adapt across diverse workloads. (2) *Defragmentation*: Invoking memory compaction when contiguous regions are unavailable [2, 33, 39, 50, 57]. Yet frequent compaction incurs substantial latency spikes. Our preliminary experiments show that these approaches can reduce throughput by up to 51% and increase latency by up to 102% in YCSB-Redis workloads (§3), thus squandering the performance benefits of huge pages.

This work aims to eliminate the costly guest-side memory compaction in virtualized environments, thereby fully exploiting the benefits of huge pages. Our insight is that *the GPA space can be regarded as (nearly) infinite*[1] *by manipulating the mapping between GPA and HPA*, thereby eliminating the need for guest-side memory compaction. Existing guest systems require memory compaction because they adopt a host-like abstraction that assumes the GPA space is fixed and limited. In reality, GPA is a form of virtual memory, as the guest OS behaves like a host-side user process. Consequently, expensive compaction and page migration are unnecessary. Instead, contiguous memory can be obtained simply by expanding the GPA space and updating the GPA-HPA mapping.

We incarnate this idea by building INFINIDEFRAG, a compaction-free memory defragmentation technique. The primary challenge is how to efficiently manage the infinite GPA space while keeping the host physical memory usage within the VM's quota. To address this, we introduce an array of techniques. First, *Infinite Address Manager* provides new contiguous GPA memory by reclaiming free fragment GPA pages and expanding the new GPA region using memory trade (*i.e.,* trades fragmented pages for contiguous memory), fast reclaim, and reserved region. Second, *Host Memory Guard* maintains the GPA-HPA mapping and constrains the actual

[†] Co-first author.
✉ Corresponding Author: Wen Xia (xiawen@hit.edu.cn).

[1] Modern processors support a PB-scale address space enabled by 57-bit address width, which almost never exhausts (more details are in §3.3, §7).

host memory usage within a VM's quota using self-hosted remap and batch unmapping. Finally, *Scalability Optimizer* further improves GPA/HPA space management efficiency and scales INFINIDEFRAG to multi-thread and multi-VM environments with lockless page-bitmap updates, in-kernel remap with delayed TLB flushes, and hybrid paging.

We implement INFINIDEFRAG[2] as a module of Linux's memory management subsystem, invoked when the standard high-order allocation path cannot satisfy the new huge-page allocation requests. We evaluate INFINIDEFRAG using both micro-benchmarks and real-world applications. The results show that INFINIDEFRAG substantially outperforms state-of-the-art approaches and achieves ideal, fragmentation-free performance. For example, on YCSB-Redis workloads, INFINIDEFRAG improves throughput by 21%–105% compared to LLFREE [53], Linux with transparent huge page (THP) enabled [17], and Linux using the default 4KB pages.

In a nutshell, we make the following contributions:

- We reveal that existing guest-side defragmentation techniques incur significant overhead. The limited GPA space is the primary cause of their overhead, even though GPA can in fact be treated as an infinite virtual address space (§3).
- We propose INFINIDEFRAG, a compaction-free memory defragmentation technique to achieve lightweight defragmentation with three designs: *Infinite Address Manager*, *Host Memory Guard*, and *Scalability Optimizer* (§4).
- We implement and evaluate INFINIDEFRAG. The results show that it substantially outperforms existing approaches with ideal, fragmentation-free performance (§5, §6).

2 Background

2.1 Memory Virtualization

Memory virtualization is a fundamental abstraction in modern VMs, allowing guest operating systems (OSes) to share physical memory efficiently and transparently. By decoupling the guest's view of memory from the underlying hardware, the hypervisor provides each VM with an isolated, contiguous address space, ensuring both safety and flexibility.

Address translation in virtualization. Memory virtualization relies on a two-level address translation: guest virtual addresses (GVAs) are first mapped to guest physical addresses (GPAs), which are then translated to host physical addresses (HPAs). This design provides strong isolation and flexible management but introduces additional overhead.

Mitigating address translation overhead. Modern processors support two-level paging through *nested page tables* (NPT), such as Intel Extended Page Tables (EPT) and AMD Rapid Virtualization Indexing (RVI). EPT, in particular, maintains a second-level page table for GPA → HPA translation, supports multiple page sizes (*i.e.,* 4KB, 2MB, and 1GB), and enforces per-page read, write, and execute permissions. On each memory access, the CPU first translates GVA → GPA via the guest page table, then GPA → HPA via EPT. The results are cached in the TLB and Page Walk Cache [44], allowing fast lookups. However, on a cache miss, both guest page table and EPT should be traversed, imposing significant overhead for workloads with poor TLB locality or frequent memory turnover [39]. *In this paper, we use NPT to represent the two-level paging* (i.e., *GVA → GPA → HPA), while EPT to represent the specific GPA → HPA translation.*

[2] INFINIDEFRAG refers to the compaction-free memory Defragmentation technique using Infinite guest physical address space.

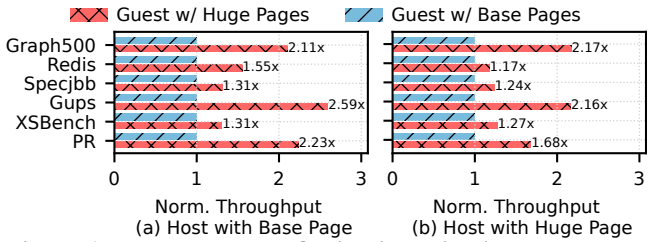

Figure 1: Huge page benefits in virtualization. *We evaluate four configurations combining huge and base pages on both the guest and the host. Experiments are conducted on Linux THP [17] without host/guest fragmentation, and the results show that guest-side huge pages yield substantial performance improvements.*

2.2 Huge Page and Fragmentation

Huge Pages. To reduce the overhead of two-level address translation and improve TLB efficiency, modern systems support huge pages (e.g., 2 MB and 1 GB on x86-64), which decrease TLB misses, shorten page walks, and boost performance—particularly for memory-intensive workloads. Specifically, in virtualized environments, hardware features such as Intel EPT allow huge pages at both the guest and host levels, reducing nested page table entries and improving translation efficiency to near-native levels. As shown in Figure 1, employing huge pages on the guest can significantly enhance performance, regardless of the host-side configuration.

However, huge pages require physically contiguous regions, but long-running systems often suffer from external fragmentation. Consequently, even with sufficient free memory, allocating huge pages becomes increasingly difficult, highlighting the need for an efficient huge page management strategy.

Huge page management in Linux. Linux originally introduces hugetlb pages [13] to support huge pages, but they are ad-hoc and non-transparent to applications. To address this limitation, the Linux kernel provides transparent huge pages (THP) [17], which automatically promotes base pages into huge pages. THP relies on a background kernel thread (*i.e., khugepaged*) to coalesce contiguous 4 KB base pages into 2 MB huge pages and may additionally promote pages during page faults when conditions permit. This design enables applications to benefit from reduced TLB misses and shorter page walks without modification. However, THP critically depends on memory compaction to obtain physically contiguous memory, which can introduce substantial latency spikes, particularly under memory pressure or fragmentation.

The fragmentation problem. As systems run, the continual allocation and release of memory inevitably create external

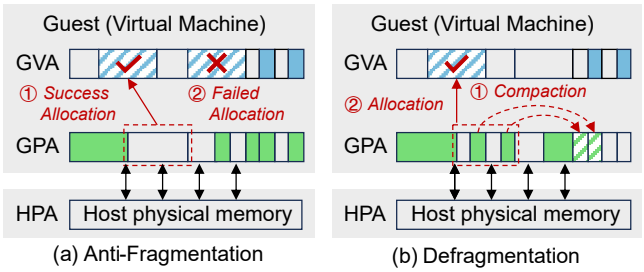

Figure 2: Deficiency of existing fragmentation mitigation techniques. *(a) Anti-fragmentation is tailored to dedicated scenarios and fails to scale across diverse workloads, while (b) defragmentation incurs substantial overhead due to page compaction.*

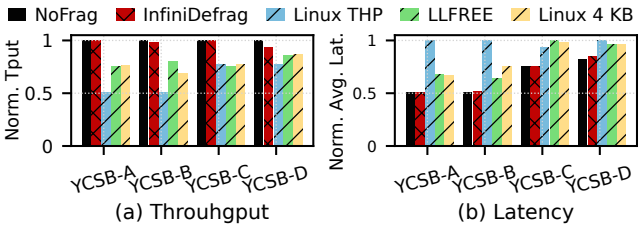

Figure 3: Performance analysis under fragmentation. *The host uses huge pages, NoFrag denotes the non-fragmented baseline using Linux THP, and experiments are conducted under the extreme fragmentation setting (§6.1). The results suggest that existing fragmentation mitigation approaches substantially deteriorate throughput and latency, sometimes even fall below Linux 4 KB.*

fragmentation, substantially reducing the availability of contiguous 2 MB pages. Consequently, THP often falls back to 4 KB pages without extra mechanisms even when the total free memory remains sufficient. Although the buddy allocator [15] attempts to maintain memory contiguity, fragmentation still prevents huge page allocations in practice. Moreover, under memory pressure, background compaction often fails to keep pace with fragmentation, leading to substantial performance degradation for workloads that depend on huge pages [28, 42].

2.3 Existing Fragmentation Mitigation Works

Existing fragmentation mitigation works fall into two categories: (1) *Anti-fragmentation*: optimizing memory allocation to avoid fragmentation; (2) *Defragmentation*: invoking memory compaction when contiguous regions are unavailable.

Anti-fragmentation. These approaches [31, 37, 40, 41, 48, 53] mitigate memory fragmentation by employing specialized allocation policies that carefully control page placement decisions to preserve large contiguous regions. For example, as shown in Figure 2a, several approaches [37, 40] co-locate objects or pages with similar lifetimes or sizes to improve spatial locality and maintain memory contiguity.

Although such proactive strategies can delay fragmentation, they suffer from inherent limitations. Specifically, (1) their effectiveness depends on heuristics or assumptions about future allocation patterns, which often fail under dynamic and heterogeneous workloads, leading to inevitable fragmentation. (2) They may also trade short-term allocation efficiency for preserving contiguous regions, leading to unnecessary memory waste for no-fragmentation scenarios. (3) They typically require modifications to allocators or applications, significantly limiting their deployability in production environments that demand transparency and backward compatibility.

Defragmentation. These techniques [2, 39, 47, 50, 56] rely on relocating movable pages to coalesce scattered free pages, thereby creating large contiguous regions (*i.e.,* Figure 2b). For example, Linux THP performs both background and on-demand compaction to facilitate 2 MB huge page allocation even under severe fragmentation, as discussed in §2.2.

However, reactive strategies introduce substantial runtime overhead. Specifically, (1) relocating pages requires data copy, page-table updates, and TLB shootdowns, which disrupt execution and often cause noticeable latency spikes. (2) Pages that are pinned, shared, or hardware-mapped are inherently unmovable [34, 48, 56], fundamentally limiting how much contiguous space compaction can recover. (3) Compaction competes for CPU cycles and memory bandwidth, and is frequently throttled under memory pressure, making it less effective when fragmentation is extremely severe.

Overall, prior works primarily mitigate memory fragmentation at the host level, with benefits indirectly inherited by guests. To our knowledge, this is the first work to design a dedicated guest-side defragmentation technique.

3 Observations and Motivations

3.1 Limitations of Existing Approaches

In this section, we begin with preliminary experiments to examine whether existing fragmentation mitigation approaches can improve the performance of foreground applications.

Methodology. We evaluate throughput and latency using YCSB [23] on Redis [16]. The host uses huge pages, and experiments are conducted under the *extreme fragmentation setting* (see details in §6.1). Moreover, we select LLFREE [53] and Linux THP [17] to represent anti-fragmentation and defragmentation approaches, respectively. We also compare against Linux with 4 KB pages and *NoFrag*, which represents Linux THP without fragmentation. Specifically, LLFREE is a memory allocator designed to replace the Linux buddy system [15], which applies heuristics to proactively reduce potential future fragmentation. Linux THP, on the other hand, relies on background huge-page promotion or foreground synchronous page compaction to defragment memory (§2.2).

Observation #1: State-of-the-art fragmentation mitigation techniques exhibit poor performance. As shown in Figure 3, both anti-fragmentation (*LLFREE*) and defragmentation (*Linux THP*) achieve only 49%–72% of *NoFrag* throughput and incur 30%–102% higher latency. In some cases, their performance even falls below that of *Linux 4 KB*, which does not exploit huge pages. These results suggest that the overhead imposed by existing fragmentation mitigation techniques outweighs the performance gains provided by the additional huge pages they produce, as further studied in the next subsection.

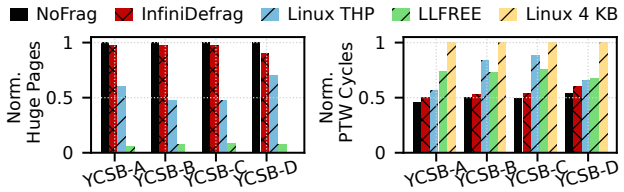

Figure 4: Huge page and PTW cycle analysis under fragmentation. *The host uses huge pages, NoFrag denotes the non-fragmented baseline using Linux THP, and experiments are conducted under the extreme fragmentation setting (§6.1). Results in subfigure (a) suggest that existing approaches fail to provide sufficient huge pages, which result in high PTW cycles in subfigure (b).*

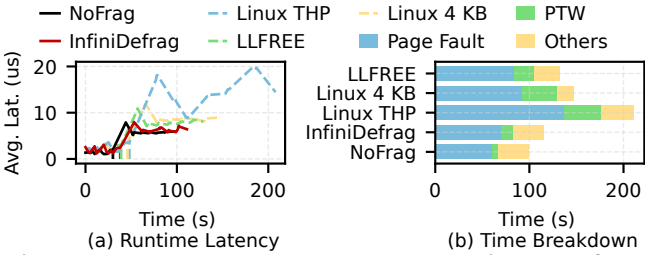

Figure 5: Latency and breakdown analysis under fragmentation. *The host uses huge pages, NoFrag denotes the non-fragmented baseline using Linux THP, and experiments are conducted under the extreme fragmentation setting (§6.1). (a) The vertical line indicates the end of the load phase, after which is the run phase. (b) Memory compaction increases the page fault time, while huge pages reduce the PTW cycles and the page fault time.*

3.2 Deficiency Analysis

We then conduct detailed experiments to demystify the deficiency of existing fragmentation mitigation approaches.

Methodology. The experimental setup follows that described in §3.1. Specifically, we: (1) measure the number of allocated huge pages to assess the ability to maintain contiguous memory regions (Figure 4a); (2) record page table walk (PTW) cycles to evaluate the efficiency of two-level address translation (Figure 4b); (3) measure real-time request latency to capture performance fluctuations over time (Figure 5a); and (4) perform time-breakdown to analyze how compaction and huge page contribute to overall performance (Figure 5b).

Observation #2: Anti-fragmentation performs poorly due to limited number of huge pages. As shown in Figure 4a, when memory becomes fragmented, anti-fragmentation (*i.e., LLFREE*) fails to provide sufficient huge pages compared to the ideal case (*i.e., NoFrag*). Although LLFREE is designed to preserve contiguous regions, it ends up allocating the fewest huge pages (*Linux 4 KB* does not have huge pages), resulting in longer *Page Fault* and *PTW* time, as shown in Figure 5b.

Observation #3: Defragmentation performs poorly due to substantial compaction overhead. Although defragmentation (*i.e., Linux THP*) is able to allocate more huge pages and reduce PTW cycles (Figure 4b), it still delivers the longest average latency—even worse than *Linux 4 KB* without huge pages (Figure 5a). The reason is illustrated in Figure 5b, where

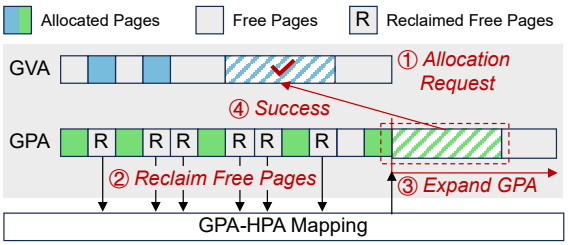

Figure 6: The Infinite GPA space. *It enables efficient defragmentation without any compaction or page migration, by simply controlling the mapping between the GPA and HPA pages.*

Linux THP exhibits much higher *Page Fault* time, either because synchronous compaction increases page-fault handling time or because background page migration increases the number of page faults. These compactions directly interfere with foreground request processing, leading to pronounced latency inflation despite the presence of more huge pages.

Thus, existing approaches face a dilemma: *increasing huge-page availability requires defragmentation effort, yet the resulting overhead can outweigh the performance benefits that huge pages are meant to deliver.*

3.3 Motivation: The Infinite GPA Space

Based on the above analysis, we pose a fundamental question: Is it possible to combine the low overhead of anti-fragmentation with the huge page ability of defragmentation?

Opportunity #1: The GPA space is (nearly) infinite. Modern systems now feature terabytes of physical memory, substantially expanding the physical address space. To accommodate this growth, recent x86 processors, including Intel Ice Lake and Sapphire Rapids, implement 5-level paging [5], thereby increasing the physical address width from 48 to 57 bits. This expansion highlights both the need for scalable memory management and the challenge of system software to efficiently exploit such a vast address space [4].

We quantify the write intensity of guest memory using the dirty-page rate, a standard metric used in prior live-migration studies [22, 30]. Existing work reports that cloud workloads often dirty memory at tens of MB/s, and 32 MB/s is the point that pre-copy migration becomes ineffective [30]. At this rate, a VM produces roughly 2.76 TB of modified memory per day. Given a 57-bit address space (*i.e.,* $\sim 1.44 \times 10^{17}$ bytes), the system can sustain about 4.7×10^4 days—over a century before exhaustion. Moreover, even under higher dirty-rate assumptions, the lifetime remains on the order of decades.

Opportunity #2: GPA-to-HPA indirection enables flexible remapping. By decoupling a VM's view of physical memory (*i.e.,* GPA) from the underlying real machine layout (*i.e.,* HPA), the virtualization layer allows the host to transparently reorganize memory pages without impacting the guest. This indirection enables defragmentation strategies that are both low-overhead and non-intrusive to guest workloads.

Insight: Compaction is unnecessary with the infinite GPA space. With the two opportunities, a VM's physical memory

(*i.e.,* GPA) can be treated as an infinite address space, mapped to host physical memory (*i.e.,* HPA) on demand. This enables compaction-free defragmentation by controlling the mapping between guest and host memory. We use Figure 6 to illustrate this approach: ① when a huge page allocation request cannot find a contiguous GPA, ② free fragment GPA pages are reclaimed, and ③ the GPA space is expanded with the updated GPA-HPA mapping, ④ thereby reserving a contiguous GPA region to succeed the request without compaction.

Note that maintaining the GPA–HPA mapping during GPA space expansion may introduce host-side fragmentation, especially in multi-VM environments. We regard it as a challenge.

Challenges. However, leveraging this insight to build a practical defragmentation mechanism raises several challenges: (1) How can the VM's infinite physical address space (*i.e.,* GPA) be efficiently managed? (2) How can actual physical memory (*i.e.,* HPA) be constrained within the VM's quota? (3) How can the system scale efficiently under multi-thread and multi-VM environments? We address them in Section 4.

4 INFINIDEFRAG Design

We propose INFINIDEFRAG, a compaction-free memory defragmentation technique. However, designing INFINIDEFRAG is non-trivial, and we first introduce our design goals:

- *Low overhead*. It should be lightweight without affecting the performance of the foreground applications (§4.2).
- *High HPA utilization*. It should ensure that the VM's actual HPA usage does not exceed the resource quota (§4.3).
- *High scalability*. It should provide high scalability under multi-thread and multi-VM environments (§4.4).

4.1 INFINIDEFRAG Overview

Components. Figure 7 presents the major components. First, *Infinite Address Manager* manages the infinite GPA space and performs compaction-free defragmentation, thereby achieving the *low-overhead goal* and addressing *Challenge 1* (§4.2). Second, *Host Memory Guard* maintains the GPA–HPA mappings to ensure that the HPA consumption stays within the VM's quota, thereby fulfilling the *high HPA utilization goal* and addressing *Challenge 2* (§4.3). Finally, *Scalability Optimizer* improves the efficiency of GPA/HPA management in multi-thread and multi-VM environments, thereby achieving the *high scalability goal* and addressing *Challenge 3* (§4.4). Moreover, INFINIDEFRAG is compatible with existing virtualization architectures, allowing traditional VMs and our VMs to run concurrently within the same environment.

Workflow. We use Figure 7 to illustrate the workflow of INFINIDEFRAG: ① When a huge-page allocation request cannot find contiguous GPA space, ② the *Page Allocator* invokes the INFINIDEFRAG module to perform memory defragmentation. First, ③ the *Infinite Address Manager* reclaims free fragment GPA pages and expands the GPA space to the same size; Second, ④ the *Host Memory Guard* reallocates HPA pages to maintain the new GPA–HPA mappings; Finally, ⑤ the newly extended contiguous GPA region is allocated to satisfy the

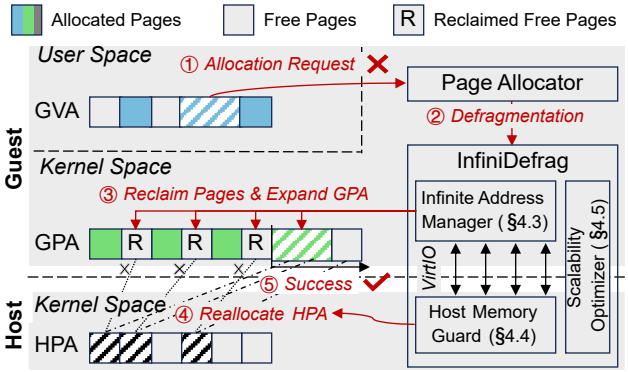

Figure 7: INFINIDEFRAG overview. *The major components are Infinite Address Manager, Host Memory Guard, and Scalability Optimizer, corresponding to our three challenges and design goals.*

huge-page allocation request. Note that INFINIDEFRAG falls back to regular memory compaction (*i.e.,* Linux THP [17]) when the GPA space can no longer be expanded. However, given the petabyte-scale address space and its century-level sustainability (§3.3), this situation rarely happens.

4.2 Infinite Address Manager

Infinite Address Manager leverages *memory trade (§4.2-1)* to manage the infinite GPA space, which consists of two components: *guest reclaimer* (§4.2-2) and *guest extender* (§4.2-3).

1. Managing GPA space through memory trade. INFINIDEFRAG adopts a simple yet efficient idea—*memory trade*, to fully exploit the infinite GPA space while minimizing system overhead, design complexity, and engineering effort.

Specifically, when the GPA space becomes fragmented and the guest OS cannot satisfy a huge page allocation request, it initiates a *memory trade* with the host via *VirtIO* [51]. *Memory trade* refers to the trade of fragmented base pages for a newly contiguous GPA region. In practice, the guest reclaims free fragment pages (via *Guest Reclaimer*) and uses them to extend the GPA space (via *Guest Extender*). The contiguous region is allocated in 1 GB block granularity. This process avoids page migration and compaction; it simply updates the host's page tables (*i.e.,* EPT). Moreover, the reclaimed pages and the expanded memory should satisfy the following equation:

$$N_{frag} * Size_{base_page} = N_{expand} * Size_{mem_block} \quad (1)$$

where N_{frag} is the total number of reclaimed pages; $Size_{base_page}$ is the size of the reclaimed base pages (*i.e.,* 4KB); N_{expand} is the number of memory blocks that will be expanded; and $Size_{mem_block}$ is the size of each memory block.

Note that *memory trade* is performed asynchronously without blocking allocation, so INFINIDEFRAG will fall back to base-page allocation until the *memory trade* completes.

2. Reclaiming GPA pages via guest reclaimer. *Guest Reclaimer* leverages the buddy-system allocator's page-allocation interface [15] to identify free fragment physical pages and forwards their page-frame numbers to the host. Specifically, it reserves these fragmented pages by invoking the allocation interface, preventing regular workloads from

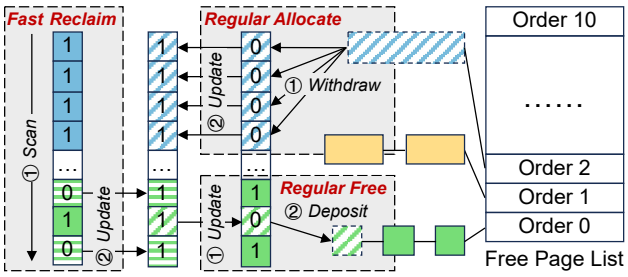

Figure 8: Fast Reclaim vs. Regular Allocation/Free. *Each dashed box is executed atomically. Note that Fast Free is unnecessary, and its workflow (if used) is similar to that of Fast Reclaim.*

acquiring them, and thus achieving logical reclamation. Moreover, *Guest Reclaimer* should coordinate with *Host Memory Guard* to unmap these pages from the QEMU process's (*i.e.,* guest OS) page table and return them to the host's page-frame allocator (§4.3), which is similar to memory ballooning [29]. These operations expose the reclaimed pages to the host, allowing them to be reassigned to other processes.

Optimizing reclamation via fast reclaim. Unfortunately, directly applying the (memory ballooning-like) Guest Reclaimer fails to meet our latency and overhead requirements because the buddy allocator has two limitations [52, 53]:

- *Low Scalability*: Allocating pages requires acquiring the zone lock, which is the bottleneck during burst allocations.
- *High Complexity*: Allocating pages requires complex bookkeeping to maintain buddy allocator free lists and update multiple data structures, increasing engineering overhead.

Therefore, we propose *Fast Reclaim* to minimize page-reclamation overhead. Inspired by Wrenger et al. [52], *Fast Reclaim* uses a bitmap to efficiently track page states. Unlike Wrenger's approach, which requires a custom allocator with extensive modifications, our design remains fully compatible with the guest OS's default buddy allocator [53].

We analyze both *Fast Reclaim* and *Regular Allocation/Free*, as shown in Figure 8. *Fast Reclaim* is triggered to reclaim free fragment pages when the GPA space needs expansion, which introduces a global bitmap to track the state of each page. Specifically, *Fast Reclaim* ① scans the entire bitmap and ② updates each bit accordingly. Moreover, INFINIDEFRAG falls back to *Regular Allocation/Free* for normal page requests. During *Regular Allocation*, it first checks whether a page in the *Free Page List* has already been reclaimed by *Fast Reclaim*. If so, INFINIDEFRAG selects another free page. If the allocation succeeds and the page was not previously marked as allocated, the guest kernel sets the corresponding bitmap bit to 1. Similarly, during *Regular Free*, INFINIDEFRAG clears the bitmap bits to 0 and deposits the pages back to the list.

Note that maintaining consistency between the bitmap and the buddy allocator does not degrade regular allocation/free performance. Newly extended pages are placed at the head of *Free Page List*, making bitmap checks rarely fail in practice (*i.e.,* only check once). Moreover, we further improve *Fast Reclaim*'s scalability by optimizing the synchronization between the bitmap and the allocator, as shown in §4.4.

3. Expanding the GPA space via guest extender. *Guest Extender* first requests additional memory resources and forwards the corresponding page-frame numbers to *Host Memory Guard* as a memory-expansion request. Once *Host Memory Guard* fulfills the request, *Guest Extender* initializes the necessary bookkeeping structures and brings the newly allocated memory online. This guest-host coordination ensures that subsequent EPT faults triggered by accesses to the newly allocated GPA space are legal and correctly handled.

Optimizing expansion via reserved region. When guest memory expands, the VM must invoke the memory hotplug interface to bring newly added pages online. This process requires initializing per-page metadata inside the guest and allocating a corresponding memory-backend device in QEMU, both of which introduce nontrivial overhead. As a result, frequent expansions can noticeably degrade performance.

To address this, we employ two optimizations. First, we expand the GPA space in coarse-grained chunks (*i.e.,* 4 GB, four memory blocks), which balances the trade-off between the cost of bringing blocks online and the frequency of expansions. Second, during system boot, the guest kernel proactively reserves a large memory region (*i.e.,* 96 GB), initializes associated metadata, and keeps it offline. In practice, the reserved region is large enough for most workloads to run for an extended period (at the hour level, §3.3), while preparing this region takes less than 1 s, making expansion rarely happens.

4.3 Host Memory Guard

Host Memory Guard performs *page reallocation* (§4.3-1) to maintain GPA–HPA mappings when the GPA space expands. We then introduce *self-hosted remap* (§4.3-2) and *batch unmapping* (§4.3-3) for the host with base and huge pages.

1. Guarding host resources during page reallocation. *Host Memory Guard* coordinates with the *Infinite Address Manager* to support free GPA-page reclamation and GPA-space expansion, which in turn introduces host-side page reallocation. To ensure that a VM's actual memory usage remains within its quota, *Host Memory Guard* should carefully control memory consumption during this process. Specifically, *page reallocation* maintains the GPA–HPA mapping while ① *unmapping* HPA pages corresponding to reclaimed GPA pages and ② *allocating* new HPA pages for the expanded GPA space.

2. Optimizing the host with base pages via self-hosted remap. When host memory is scarce, the host is unable to immediately allocate enough physical pages to satisfy a guest's memory expansion request. In this case, the host should first unmap the reclaimed pages and release them back to the host's buddy-system allocator. Later, when the guest accesses the expanded GPA space, the corresponding accesses trigger host-side page faults, and the host allocates physical pages from its allocator to resolve them. This workflow introduces two challenges to squander memory expansion efficiency:

- *Long latency*: The memory expansion request cannot be

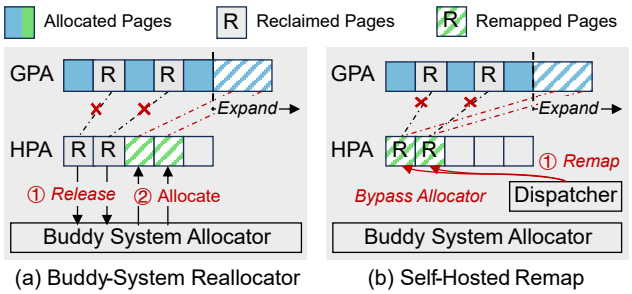

Figure 9: Self-hosted remap. *Compared to buddy system reallocator, self-host remap directly remaps fragmented pages from their original GPA locations into expanded GPA space with low overhead.*

satisfied until page reallocation completes. Because this work occurs inside the VM-exit handler, it incurs substantial latency and stalls the generation of contiguous memory.

- *Excessive complexity*: Each reallocated page goes through multiple steps—① being unmapped from the QEMU process page table, ② returned to the host buddy allocator, and ③ reallocated to serve the newly expanded GPA region.

As shown in Figure 9b, we introduce *self-hosted remap* to address this issue. The key idea is to remap reclaimed fragment pages from their original GPA locations directly into the newly expanded GPA region, bypassing the host buddy allocator and amortizing expensive unmapping operations. Specifically, when the host receives fragment pages from the guest, it no longer blocks in the VM-exit handler until unmapping completes. Instead, it records the corresponding page-frame numbers in *Page Dispatcher*. Later, when an EPT violation occurs for accesses to the expanded GPA region, *Page Dispatcher* fetches one of the recorded page frames and uses it to satisfy the page fault. Note that this technique is enabled when GPA memory is backed by host base pages.

3. Optimizing the host with huge pages via batch unmapping. When the host uses huge pages, INFINIDEFRAG falls back to regular page reallocation (*i.e.,* Figure 9a) because *self-hosted remap* performs in a 4 KB-granularity and will trigger numerous system calls to remap a huge page. Therefore, when the host receives fragmented huge pages, it unmaps them from the QEMU process's page table and returns them to the host page-frame allocator. However, reclaim requests typically arrive in a scattered pattern, and unmapping pages individually incurs substantial overhead: every operation requires a system call (*e.g., madvise* or *munmap*), acquisition of the process's address-space lock, a page-table walk, and cross-core TLB shootdowns [20]. To address this, we introduce batch unmapping. Specifically, all scattered unmapping requests are first recorded in a bitmap; the host then scans this bitmap and issues a single unmapping system call for each contiguous page range, significantly reducing unmapping overhead.

4.4 Scalability Optimizer

Scalability Optimizer scales INFINIDEFRAG to multi-thread and multi-VM environments. Specifically, we first introduce *optimized fast reclaim* (§4.4-1) to scale *Infinite Address Manager*; we then introduce *optimized self-hosted remap* (§4.4-2) and *hybrid paging* (§4.4-3) to scale *Host Memory Guard* for the host with base and huge pages, respectively.

```
KVM_MMU_LOCK(kvm);
// TLB shootdown for EPT
kvm_flush_remote_tlbs(kvm); // <-- Time cousuming
KVM_MMU_UNLOCK(kvm);
...
ptl_lock(src_ptl); // Lock src page table lock
ptl_lock(dst_ptl); // Lock dst page table lock
// TLB shootdown for host page table
flush_tlb_page(vma, addr); // <-- Time cousuming
...
set_pte_at(mm, dst_addr, dst_pte, origi_dst_pte);
ptl_unlock(src_ptl); // Unlock src page table lock
ptl_unlock(dst_ptl); // Unlock dst page table lock
```

Listing 1: Naive in-kernel remap.

1. Scaling infinite address manager via optimized fast reclaim. As shown in Figure 8, the core idea of fast reclaim is to bypass the poorly scalable kernel page allocation path by leveraging a page bitmap. Consequently, the page bitmap should be updated in several situations: (1) whenever a page is allocated or freed through the regular page allocation interface, and (2) whenever the fast reclaim interface is invoked. A straightforward way to maintain consistency between the page bitmap and the buddy allocator is to use a coarse-grained lock to protect the entire bitmap. However, such coarse-grained locking severely limits scalability and introduces substantial overhead to regular memory allocation/free operations.

Therefore, we propose a transaction-based mechanism that relies solely on hardware atomic instructions to update page-bitmap entries. (1) When different threads modify different bitmap entries, no contention or cache-line bouncing occurs. (2) For regular allocation requests (via buddy allocator) targeting compound pages of order ≤ 6, which contain at most 64 base pages, we use an atomic instruction (*i.e., atomic64_try_cmpxchg*) to test and update the corresponding bitmap entry. If it succeeds, the page is allocated; otherwise, the allocator retries with another free-list entry. Note that fast reclaim also relies on the same procedure to ensure consistency. (3) For larger allocations (order > 6), we apply a coarse-grained transaction-based approach: the allocator acquires each order-6 subpage sequentially. If any sub-allocation attempt fails, it then aborts and rolls back the entire request.

2. Scaling host memory guard with base pages via optimized self-hosted remap. INFINIDEFRAG leverages page remapping to bypass the host buddy allocator (Figure 9). A straightforward and non-intrusive way to implement it is to invoke *mremap* [9]. Unfortunately, *mremap* does not scale well with increased threads. As shown in Figure 10, its latency grows sharply with thread count, reaching $\sim$ 270 µs at 16 threads. The poor scalability stems from its need to manipulate multiple virtual memory areas (*i.e., vm_area_struct*) and frequently split the source virtual memory area, which is costly and requires mutual exclusion in concurrent scenarios.

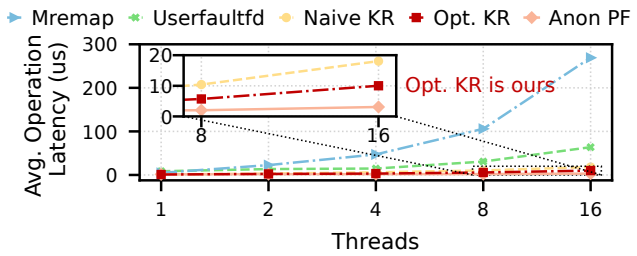

Figure 10: Page remap latency for different techniques. *The host uses base pages, and experiments are conducted under the extreme fragmentation setting (§6.1). By optimizing page remapping—from mremap, to userfaultfd, to naive in-kernel remap (KR), and finally to optimized KR — the page remap overhead is close to that of a regular anonymous page fault (i.e., Anon PF).*

We therefore explore a more efficient remapping mechanism based on *userfaultfd* [11], which is a user-space paging policy and implemented in host-side QEMU/KVM. The key advantage is that it updates only page-table entries and avoids manipulating kernel virtual-memory metadata. As shown in Figure 10, *Userfaultfd* is more scalable than *Mremap*. However, at 16 threads, remapping a single page still consumes 63 µs, which is too slow to meet SLOs. Moreover, kernel–user context switches introduce additional overhead, causing even single-thread remap operations to take up to 9 µs, which is much higher than 1 µs of a regular anonymous page fault.

Given the high kernel–user context-switch overhead of *userfaultfd*, we next introduce a lightweight kernel-based mechanism for page remapping. A naive design is to migrate the source physical page directly to the destination physical page by invoking *move_pages*, as shown in Listing 1. Nevertheless, as the thread count increases, the latency of page remapping remains high (*Naive KR* in Figure 10). Our profiling shows that with eight threads, locking and TLB-flush operations account for a substantial fraction of the remapping cost (§6.7). Each TLB flush is guarded by either the KVM MMU lock or the page-table lock, which are expensive in multi-thread environments [19, 20, 26, 38] because they require *TLB shootdown*. The shootdown further exacerbates lock contention, as all threads spin while attempting to acquire these locks.

We therefore propose ***in-kernel remap with delayed TLB flushes***. Our key insight is that *once the reclaimed GPA pages have been allocated inside the guest OS, they are logically marked as inaccessible* (§4.2). Consequently, there is no need to perform synchronous TLB flush. Instead, we can defer it asynchronously (as they will never be accessed by others), thereby avoiding lock contention. As shown in Figure 10, it scales efficiently across all thread counts, achieving performance close to regular anonymous page faults (*Anon PF*).

3. Scaling host memory guard with huge pages via hybrid paging. When the host backs VM memory using base pages, *self-hosted remap* is fairly efficient. However, when the host allocates VM memory using huge pages, reclaiming free GPA pages may introduce either internal (*i.e.,* lazily freeing fragmented base pages from a host huge page) or external (*i.e.,* directly splitting host huge pages) fragmentation on the host side, particularly in the multi-VM environment.

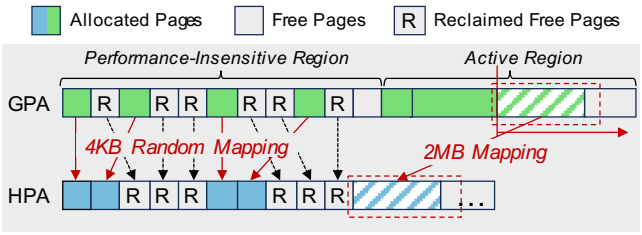

Figure 11: Hybrid paging. *Memory allocated during subsequent expansions is backed by huge pages on the host, whereas the previously allocated fragment pages are mapped using base pages.*

We introduce *hybrid paging* to address this challenge, as shown in Figure 11. Specifically, we first align GPA-HPA mappings with huge pages to maximize system performance and reduce TLB misses. For old fragment pages that are still valid and cannot be reclaimed by *guest reclaimer*, we use base pages to maintain their GPA-HPA mappings. Because these fragmented pages typically reside in performance-uncritical regions (*e.g.,* kernel objects, page cache, and other cold memory areas), we let the host perform background compaction. In contrast, performance-critical pages are allocated from the newly expanded GPA regions and backed by host-huge pages, which benefit from large GPA-HPA mappings. Therefore, *hybrid paging* avoids both host-side and guest-side fragmentation to achieve the near-ideal performance (Figure 23). Note that host-side compaction is necessary when the host uses huge pages, whereas the guest remains compaction-free during defragmentation, consistent with our insight (§3.3).

5 Implementation

INFINIDEFRAG requires coordinated changes to three layers of the virtualization stack: the guest kernel, the host kernel, and QEMU/KVM, with ∼ 7K lines of code (LoC) modified. Nevertheless, since INFINIDEFRAG operates as separate modules at each layer, it is still compatible with existing virtualization architectures, allowing traditional VMs and our modified VMs to run concurrently within the same environment. This section summarizes where each component in §4 is implemented and how the three layers interact.

Guest-side implementation. The *Infinite Address Manager* (§4.2) and the guest-side portion of *Scalability Optimizer* (§4.4-1) are implemented inside the guest kernel and extend the regular higher-order allocation path. Specifically, *Guest Reclaimer* and *Fast Reclaim* are integrated with the guest buddy allocator to identify and reserve free fragment GPA pages, while *Guest Extender* manages GPA-space expansion and memory hotplug. Moreover, the guest also maintains the page bitmap used by *Fast Reclaim* and initializes per-page metadata for newly onlined pages. From the guest's perspective, INFINIDEFRAG remains transparent to applications: it is triggered only when regular huge-page allocation fails.

Host-side implementation. The *Host Memory Guard* (§4.3) and the host-side portion of *Scalability Optimizer* (§4.4-2

Workload	Mem	Details
Gups	9.0 GB	A benchmark that updates in randomly selected locations in large memory region. [1]
Specjbb	10.0 GB	A benchmark that models a business application, stressing with compute, memory and GC. [3]
Redis	20.0 GB	An in-memory key-value store widely used for caching, real-time analytics and serving. [16]
Graph500	4.5 GB	A benchmark that evaluates graph tasks, featuring irregular memory access patterns. [6]
PR	11.0 GB	A benchmark from GAPBS, which computes node importance in large graphs. [8]
BC	11.0 GB	A benchmark from GAPBS, which measures the centrality of nodes. [8]
XSBench	5.8 GB	A Monte Carlo-based proxy application that simulates neutron cross-section lookups. [12]
Liblinear	4.5 GB	A machine learning library commonly used for training support vector machines (SVMs). [14]
CG.d	20.0 GB	A benchmark from the NAS Parallel Benchmarks, solving large, sparse linear systems. [10]
Random	7.8 GB	Issuing randomized read/write operations to produce irregular memory access patterns. [7]

Table 1: Evaluated workloads. *'Mem' is the working set size. These workloads are widely used in prior studies [39, 43, 46].*

and §4.4-3) are implemented in the host kernel. Their responsibilities are to (1) reclaim HPA pages corresponding to freed GPA pages, (2) enforce the VM's memory quota during GPA expansion, and (3) maintain GPA–HPA mappings during page reallocation. The host kernel further implements the optimized remapping path used by *self-hosted remap*, the bitmap-driven *batch unmapping*, and the host-side *hybrid paging*. When the host uses huge pages, it may still perform background compaction to recover host huge pages; However, guest-side compaction is removed from the critical path.

QEMU/KVM integration. QEMU/KVM serves as the coordination point between the guest and host implementations. QEMU provisions the memory-backend device used for reserved GPA expansion, while KVM handles the resulting EPT faults and updates the corresponding second-level mappings. Therefore, the optimized remapping (§4.4-2) and delayed TLB-flush (§4.4-3) are also implemented in the KVM-assisted host path, while QEMU provides the userspace memory backend needed to expose the expanded GPA region.

6 Evaluation

Our evaluation aims to answer the following questions:

- Does INFINIDEFRAG outperform competitors? (§6.2)
- Does INFINIDEFRAG reduce request latency? (§6.3)

6.1 Experimental Setup

Testbed. We conduct experiments on QEMU 8.2.94 with KVM enabled, using a Linux 6.10.0 host kernel. Specifically, (1) The host machine is a dual-socket server, where each socket contains a 28-core Intel Xeon Gold 6330 CPU (2.0 GHz) and 128 GB of DRAM, running Ubuntu 22.04. (2) The guest VM runs Ubuntu 20.04 and is configured with 16 vCPUs and 64 GB of memory. All modifications are applied to both QEMU 8.2.94 and the Linux 6.10.0 kernel.

Competitors. We compare INFINIDEFRAG with several state-of-the-art approaches for mitigating huge-page fragmentation (guest side only): CBMM [43], LLFREE [53], Linux Transparent Huge Pages (Linux THP) under multiple configurations, Linux using only 4 KB base pages (Linux 4 KB), and Linux THP in non-fragment settings (NoFrag). Here, *NoFrag* denotes the non-fragmented baseline under the corresponding host-page configuration used in each figure. CBMM applies adaptive policies to decide when to defragment and form huge pages, while LLFREE introduces a new kernel page allocator optimized for 2 MB page allocation. For Linux THP, we evaluate three variants: the default policy (promotion rate 1.6 MB/s), aggressive policy (16 MB/s, THP Aggr), and synchronous huge-page promotion on page faults (THP Sync).

Workloads and methodology. Table 1 summarizes the workloads used in our experiments. We choose them because (1) their working-set sizes reliably induce and expose fragmentation, and (2) they are widely used in prior studies. Moreover, we evaluate host configurations using both 4 KB base pages (THP is disabled) and 2 MB huge pages (THP is set to *always*). Due to the page limit, we omit (some) detailed analysis of the *host-side huge-page configuration*, as part of the results have already been shown in §3, and these results follow a trend similar to those of host-side base-page configuration.

Fragmentation setup. To emulate guest-side fragmentation, we follow [46] (see details in §8) with additional steps. Specifically, for each guest, we first load large files that exceed the guest's total memory capacity into the page cache, and then randomly access them for 10 minutes to disrupt LRU ordering. We further reclaim a memory region equal to the target workload's working set, triggering page replacement to evict cold pages. Meanwhile, we evaluate three levels of fragmentation.

- ***Extreme fragmentation setting.*** We logically divide the file-backed memory into 2 MB regions and randomly access 256 × 4 KB pages within each region before reclaim. As a result, the reclaimed holes are densely interleaved, so the buddy allocator can coalesce free memory only into order-0 or order-1 chunks (i.e., 4 KB or 8 KB free extents), creating severe fragmentation with almost no high-order pages.
- ***Moderate (50%) fragmentation setting.*** We access only 1–2 random 4 KB pages in each 2 MB region before reclaim. This leaves one or two "pinned" pages in every 2 MB-aligned region, preventing order-9 coalescing while still allowing the buddy allocator to merge the remaining free space into 512 KB or 1 MB blocks. We refer to this setting as *50% fragmentation* because, after reclaim, each huge-page-sized region remains coalescible only up to about half of its original size (i.e., at most an order-8 block, or roughly 1 MB), rather than a full 2 MB order-9 block.

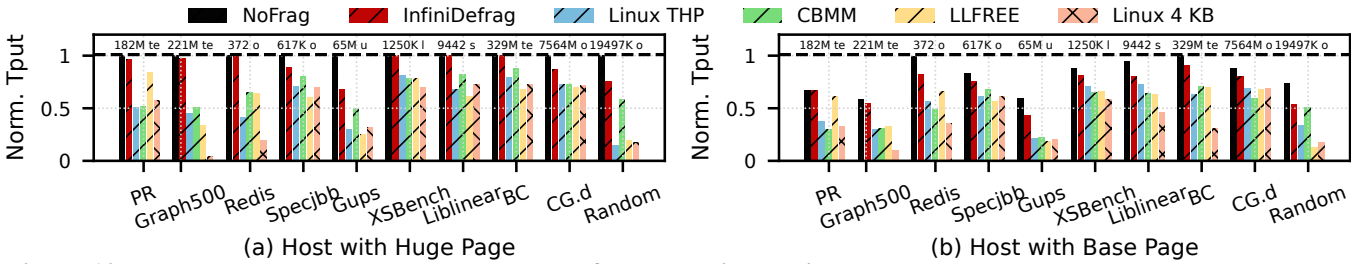

Figure 12: End-to-end throughput under extreme fragmentation setting. *All bars are normalized to* NoFrag *with host-huge configuration, enabling direct comparison between the host-base and host-huge configurations. The dashed line marks this upper bound. Moreover, the numbers above the bars report the throughput of* NoFrag *with host-huge configuration for each workload. The terms te, o, u, l, and s denote Traversed Edges, Operations, Updates, Lookups, and Samples Per Second, respectively.*

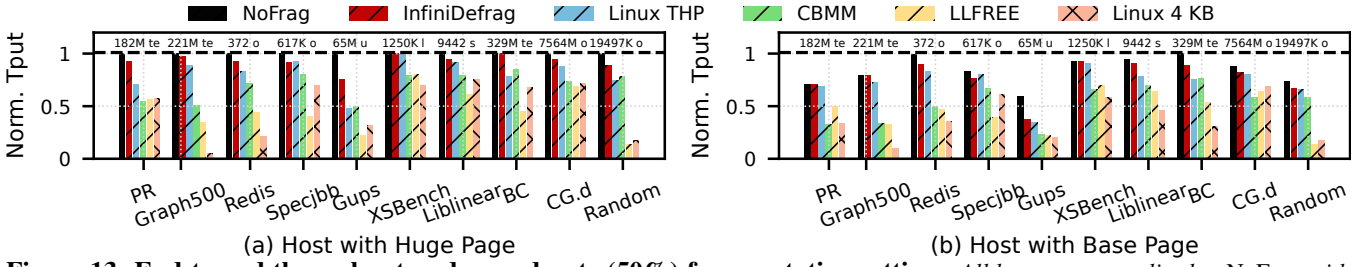

Figure 13: End-to-end throughput under moderate (50%) fragmentation setting. *All bars are normalized to* NoFrag *with host-huge configuration, enabling direct comparison between the host-base and host-huge configurations. The dashed line marks this upper bound. Moreover, the numbers above the bars report the throughput of* NoFrag *with host-huge configuration for each workload.*

- ***Light/no fragmentation setting.*** We skip the fragmentation-injection procedure above to avoid severe fragmentation. Instead, we start from a freshly initialized VM, warm up the workload, and measure after the memory layout reaches a stable state. In this setting, contiguous 2 MB regions remain widely available and all systems can obtain huge pages normally, allowing us to check whether INFINIDEFRAG introduces overhead on the normal allocation path.

Finally, we start the workload with both background compaction and THP promotion enabled. Unless otherwise stated, the main results use the extreme fragmentation setting. Note that competitors in the anti-fragmentation category (i.e., CBMM and LLFREE) are expected to mitigate the fragmentation problem during this procedure, enabling subsequent workloads to acquire more huge pages during execution.

6.2 Performance Improvement

Evaluation setup. In this section, we compare the end-to-end throughput of INFINIDEFRAG under extreme, moderate, and light/no-fragmentation settings, with all the workloads summarized in Table 1, and the host with huge/base page configurations. Moreover, all results are normalized to *NoFrag* with the host-huge configuration. This unified normalization enables direct comparison between the host-base and host-huge configurations. Note that for INFINIDEFRAG, we enable *self-hosted remap* (§4.3-2 and §4.4-2) when the host uses base pages, and *batch unmapping* (§4.3-3) plus *hybrid paging* (§4.4-3) when the host uses huge pages, separately.

Throughput under extreme fragmentation. The results in Figure 12 show that INFINIDEFRAG consistently achieves the highest throughput under all the configurations. Specifically, when the host uses huge pages, INFINIDEFRAG approaches the upper bound in most workloads, indicating that it preserves most of the benefit of 2 MB guest and host mappings. When the host uses base pages, INFINIDEFRAG still outperforms all baselines, but a visible gap to the upper bound remains. This gap reflects the cost of shattered EPT mappings: although INFINIDEFRAG preserves 2 MB guest pages, scattered 4 KB host pages may prevent the host from using 2 MB EPT entries, requiring up to 512 EPT entries for a 2 MB guest region. However, even with this penalty, INFINIDEFRAG still reliably supplies 2 MB huge pages on demand and avoids the wasted compaction overhead incurred by *Linux THP*.

Throughput under moderate (50%) fragmentation. Figure 13 reports the moderate-fragmentation results under both host-huge/base configurations, which suggests that INFINIDEFRAG remains the best-performing approach in both of the two configurations. However, the throughput gap over Linux THP becomes smaller than that in Figure 12. The reason is that moderate fragmentation still leaves sizable contiguous regions (e.g., 512 KB and 1 MB blocks), making huge-page recovery easier for the baseline and therefore reducing the benefit of compaction-free defragmentation. Moreover, compared to the extreme fragmentation setting, INFINIDEFRAG with moderate fragmentation remains closer to the upper bound (i.e., NoFrag with host-huge pages) under the host-huge configuration, whereas the host-base configuration still exhibits a moderate gap due to the lack of 2 MB EPT mappings.

Throughput under light/no-fragmentation. In this setting, since all systems can obtain host-side huge pages normally and easily, all approaches achieve similar performance.

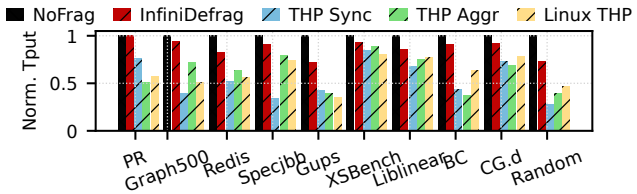

Figure 14: Throughput of different THP settings. *The host uses base pages, and experiments are conducted under extreme fragmentation. Note that other configurations have a similar trend.*

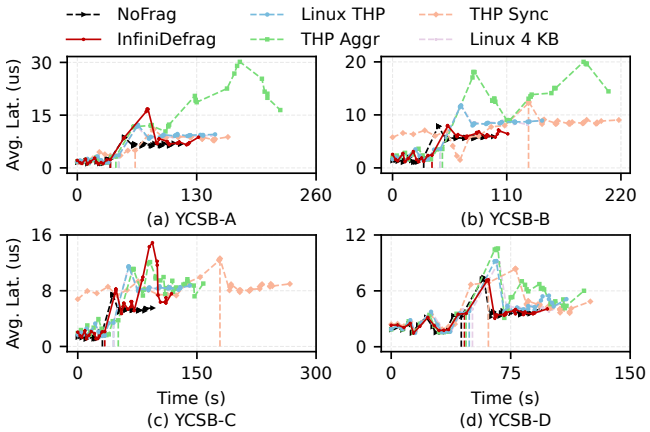

Figure 15: Latency analysis under YCSB-Redis. *We first build the database (*i.e.*, the load phase), and the vertical dashed line marks the transition to the run phase. We omit LLFREE and CBMM because their results are similar to those of Linux 4 KB. Moreover, the host uses base pages, experiments are conducted under extreme fragmentation, and other configurations have a similar trend.*

Therefore, we do not report the results under the light/no-fragmentation setting. Specifically, when fragmentation is mild, INFINIDEFRAG rarely needs to expand the GPA space, while Linux THP can recover huge pages through direct compaction with little overhead. As a result, the benefit of compaction-free defragmentation becomes small.

Throughput of different THP settings. As shown in Figure 14, INFINIDEFRAG consistently outperforms all variants of *Linux THP* across evaluated workloads. Notably, there is no single THP configuration that achieves optimal performance for every workload; both conservative (*i.e., Linux Sync*) and aggressive (*i.e., Linux Aggr*) strategies can introduce performance regressions. The reasons are further analyzed in §6.7.

6.3 Latency Analysis

Figure 15 shows the real-time latency of the YCSB workloads during both the load and run phases. We report only the results for the host using base pages under the extreme fragmentation setting, while other configurations exhibit a similar trend. The results suggest that INFINIDEFRAG consistently exhibits the lowest latency, whereas all Linux THP variants (*i.e., Linux THP*, *THP Aggr*, and *THP Sync*) exhibit poor latency and can even underperform the 4KB-only baseline (*i.e., Linux 4 KB*). Interestingly, *THP Sync* and *THP Aggr* hit their latency bottlenecks at different stages: *THP Sync* shows substantially higher latency during the load phase, while *THP Aggr* suffers from severe latency spikes during the run phase. The reason is that most memory allocations occur in the load phase; *THP Sync* triggers synchronous compaction on the allocation path, introducing high allocation latency. By contrast, *THP Aggr* performs system-wide scanning and page migrations in the run phase, heavily interfering with the YCSB-Redis workload.

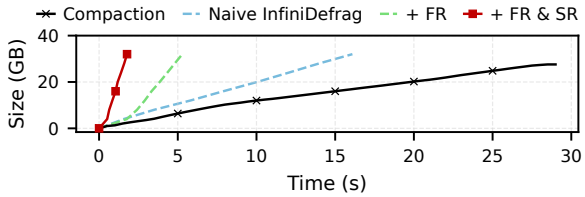

Figure 16: Defragmentation efficiency analysis. *Experiments are conducted without foreground applications. "FR" refers to fast reclaim (§4.2), and "SR" refers to self-hosted remap (§4.3). The host uses base pages, experiments are conducted under extreme fragmentation, and other configurations have a similar trend.*

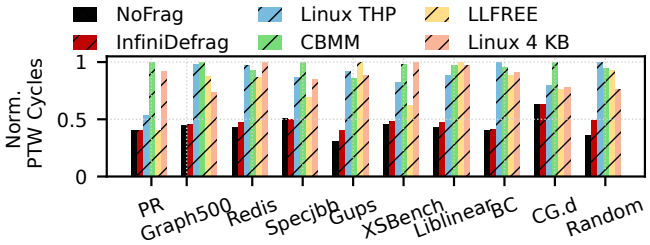

Figure 17: Comparison of page table walk cycles. *The host uses base pages, and experiments are conducted under extreme fragmentation. Although using huge pages only at the guest cannot reduce TLB miss rate, it still significantly reduces PTW cycles.*

6.4 Defragmentation Efficiency

This section measures the raw bandwidth of different defragmentation mechanisms, where bandwidth is defined as the amount of contiguous physical memory generated per second. Similarly, we report only the results for the host using base pages under the extreme fragmentation setting, while other configurations exhibit a similar trend. Moreover, we exclude those anti-fragmentation approaches (*i.e., LLFREE* and *CBMM*) because they cannot produce contiguous memory. The results are shown in Figure 16, *Compaction* (*i.e., Linux THP*) achieves 0.91 GB/s, while INFINIDEFRAG + *FR & SR* reaches nearly 20 GB/s (*i.e.,* about 19× improvement). These results demonstrate that INFINIDEFRAG can defragment memory with substantially higher efficiency.

6.5 Huge Page Analysis

Page table walk cycles. The workloads we evaluate (Table 1) exhibit highly random memory access patterns, which lead to frequent TLB misses and expensive page table walks. INFINIDEFRAG outperforms other approaches primarily because it significantly reduces the cycles spent on page table walks. Figure 17 compares PTW cycles across all approaches and, together with Figure 12, demonstrates a strong correlation between reduced PTW cycles and improved performance. The remaining gap between INFINIDEFRAG with host base

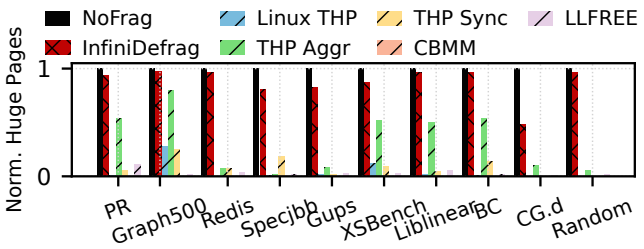

Figure 18: Total allocated huge pages. *The host uses base pages, and experiments are conducted under extreme fragmentation. CBMM/LLFREE cannot allocate any huge pages in many workloads.*

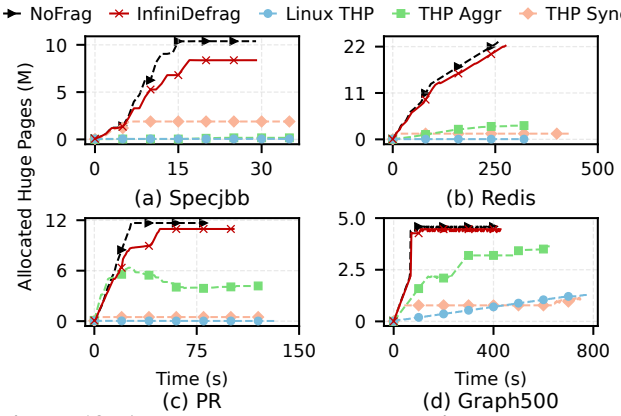

Figure 19: Allocated huge pages over time. *The host uses base pages, and experiments are conducted under extreme fragmentation. We do not evaluate CBMM and LLFREE because they cannot allocate any huge pages in many workloads (i.e., Figure 18).*

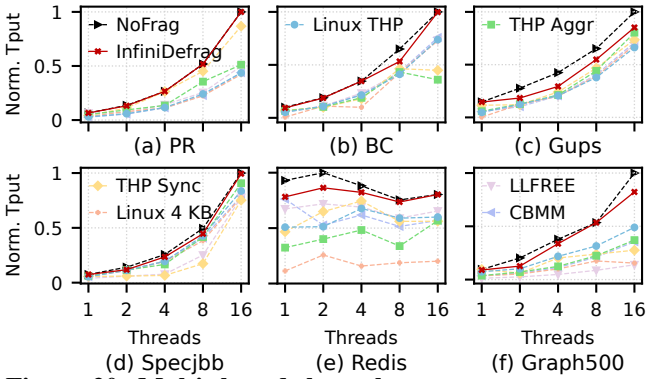

Figure 20: Multi-thread throughput. *The host uses base pages, and experiments are conducted under the extreme fragmentation setting. Note that the Redis server is a single-thread model; therefore, increasing thread counts does not improve throughput and may even degrade performance due to lock contention.*

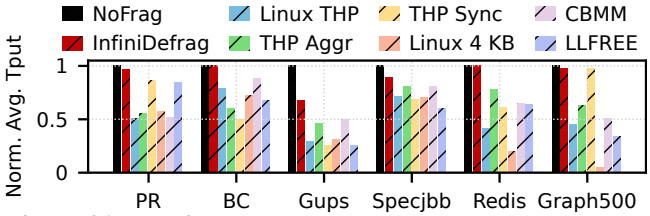

Figure 21: Multi-VM throughput. *The host uses huge pages, and experiments are conducted under extreme fragmentation. Each bar reports the average throughput. We do not evaluate the host with base pages because its performance is similar to the single-VM case (i.e., without host-side fragmentation and inter-VM interference).*

pages and the upper bound in Figure 12 is consistent with this result, as host base pages prevent the use of 2 MB EPT mappings and thus increase nested page-walk overhead.

Allocated huge pages. By mapping larger memory regions with each TLB entry, huge pages substantially reduce TLB pressure and the number of memory accesses required during a TLB miss. This reduction in PTW cycles makes huge pages a critical optimization for efficient address translation.

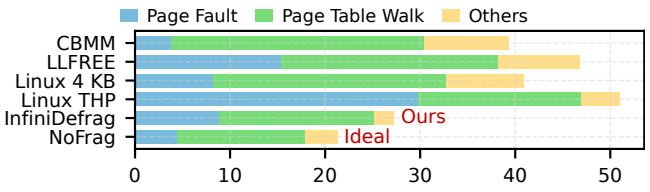
Figure 18 shows the total allocated huge pages. Under severe fragmentation, both anti-fragmentation (*i.e., CBMM* and *LLFREE*) and defragmentation (*i.e., Linux THP*, *THP Aggr*, and *THP Sync*) techniques allocate far fewer huge pages than the total working set size. In contrast, INFINIDEFRAG nearly reaches this upper bound, with the small remaining gap arising from its fallback to base-page allocation when memory trade (§4.2-1) is performed asynchronously. Although *THP Aggr* can increase the number of allocated huge pages, they still suffer from substantial throughput degradation (Figure 14) due to the high overhead of memory compaction (§6.7).

We further analyze the temporal behavior of huge page allocations across the workload's execution, as shown in Figure 19. Most workloads allocate physical memory gradually rather than all at startup, consistent with the OS's lazy allocation policy. Consequently, memory allocation continues throughout the workload's lifetime, making these workloads highly sensitive to the memory compaction overhead. Because memory compaction lies on the critical path of the page fault handler—*i.e.,* during physical page allocation—it can introduce substantial runtime overhead.

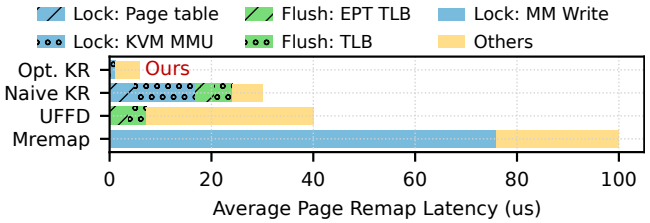
6.6 Scalability Analysis

Throughput under multi-threads. As shown in Figure 20, INFINIDEFRAG consistently outperforms competitors at all concurrency levels, demonstrating the effectiveness of *optimized fast reclaim* (§4.4-1) and *optimized self-hosted remap* (§4.4-2). Specifically, *THP Sync* fails to scale for Redis and Graph500 because synchronous compaction in the page-fault path becomes a bottleneck at high concurrency. *Linux THP* also fails to scale, as its background compaction depends on expensive page migrations, including TLB shootdowns. Note that the huge page configuration (on the host) and the moderate (50%) fragmentation setting exhibit a similar trend, and we evaluate only six workloads due to the page limit.

Throughput under multi-VMs. Figure 21 shows the average performance of three VMs, where INFINIDEFRAG outperforms competitors in most cases, demonstrating the effectiveness of *optimized fast reclaim* (§4.4-1) and *hybrid paging* (§4.4-3). Note that the multi-VM results are similar to those of the single-VM results (*i.e.,* Figure 12), indicating that there is no noticeable performance interference between VMs. Moreover, we omit the configuration where the host uses base pages or suffers from moderate (50%) fragmentation, because these



(a) Time breakdown of Gups.



(b) Time breakdown of remap under 8-thread Gups.

Figure 22: Overhead analysis of INFINIDEFRAG. *The host uses base pages, and experiments are conducted under the extreme fragmentation setting. (a) Page Fault includes memory compaction or fast reclaim. (b) Opt. KR is our optimized in-kernel remap, Naive KR is the in-kernel remap without deferred TLB flush, UFFD is userfaultfd, and Mremap is the mremap syscall (§4.4-2).*

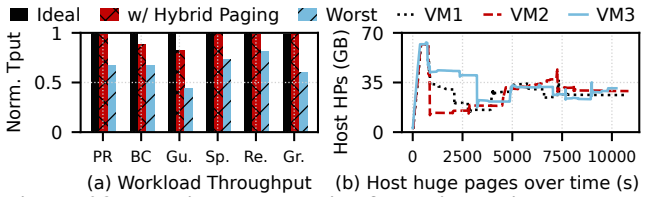
settings do not introduce meaningful host-side fragmentation or inter-VM interference; therefore, their overall performance is expected to be similar to the single-VM case.

6.7 Overhead Analysis

Infinite address manager. We first analyze *Gups* to evaluate whether *infinite address manager* introduces additional overhead, as shown in Figure 22a. The results show that INFINIDEFRAG reduces the time spent in the page-fault path and achieves near-optimal performance thanks to *optimized fast reclaim* (§4.4-1). In contrast, *Linux THP* reduces PTW cycles but spends considerable time in memory compaction (*i.e.,* increased *Page Fault*). As a result, the runtime is even longer than that of *Linux 4 KB*. Note that the host-side *Page Fault* introduced in Figure 22a is different from the guest-side anonymous page fault introduced in Figure 10.

Host memory guard with base pages. We further evaluate whether the optimized kernel remap (*i.e., Opt. KR*, §4.4-2) improves the efficiency of *self-hosted remap* and thereby minimizes the overhead of *host memory guard* when the host uses base pages. The results in Figure 22b indicate that, by safely deferring TLB flushes, *Opt. KR* eliminates nearly all lock contention overheads (*i.e.,* only reserve *Lock: KVM MMU*), thus achieving the best performance with minimal overheads.

Host memory guard with huge pages. We next evaluate whether *hybrid paging* mitigates host-side fragmentation and thereby reduces the overhead of *Host Memory Guard* when the host uses huge pages (§4.4-3). As shown in Figure 23a, *w/ Hybrid Paging* achieves performance close to *Ideal*, which represents the case where the host has sufficient free memory to provide huge pages. This prevents INFINIDEFRAG from degrading to *Worst*, which occurs when the host becomes fully fragmented and cannot provide any huge pages.



(a) Workload Throughput (b) Host huge pages over time (s)

Figure 23: Multi-VM analysis of hybrid paging. *The host uses huge pages (i.e., only this configuration has hybrid paging), and experiments are conducted under the extreme fragmentation setting. Moreover, (a) Gu., Sp. Re., and Gr. represent Gups, Specjbb, Redis, and Graph500. Ideal and Worst denote Linux THP running atop the host using all huge and base pages. (b) Each VM sequentially executes the six workloads listed in subfigure (a).*

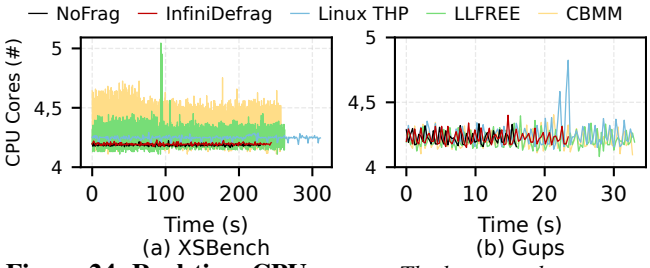


Figure 24: Real-time CPU usage. *The host uses base pages, and experiments are conducted under extreme fragmentation.*

The small remaining gap observed in *BC* and *Gups* workloads arises from two aspects: (1) reclaiming fragmented pages may require splitting nearby huge pages into 4 KB mappings; and (2) the host performs asynchronous compaction on these 4 KB pages, introducing background overhead. Because most of these 4 KB pages reside in performance-insensitive regions, their overheads have only a minor impact.

Figure 23b shows that each VM requires only 30–40 GB of huge pages. This is because host-side huge pages are primarily applied to the expanded GPA region, which largely covers workloads' working set. In addition, VMs finish with a similar time, indicating a small interference between them.

6.8 Consumed Resources

CPU usage. Figure 24 shows that INFINIDEFRAG consumes fewer CPU cores with negligible fluctuations than competitors. Under fragmented memory, Linux THP incurs compaction overhead from page faults and the background daemon. Moreover, *LLFREE* and *CBMM* consume more CPU cores to carefully control page placement decisions and preserve large contiguous regions for each allocation. In contrast, INFINIDEFRAG eliminates compaction and introduces only negligible CPU overhead when expanding contiguous memory.

Memory usage. The *fast reclaim* (§4.2-2) introduces a page bitmap that tracks page states using only 2 bits per page (one bit for free/allocation state and one bit for online/offline state). In addition, as the guest physical address space grows, the memory footprint of per-page metadata increases proportionally: each 4 KB page requires 64 bytes of metadata, amounting to roughly 1.6% of its size. Moreover, the memory overheads of all other kernel data structures are negligible.

7 Discussion

Host-side huge pages vs base pages. Using huge pages on the host reduces TLB pressure and page-table footprint, thereby improving VM performance. However, huge pages limit fine-grained control: they complicate memory reclamation, increase internal fragmentation, and disable page-level deduplication mechanisms such as KSM [27, 39, 55]. In contrast, base pages provide greater flexibility for reclamation, compaction, and deduplication, but incur higher TLB overhead. Overall, host-side huge pages deliver high performance, whereas host-side base pages offer high flexibility, and INFINIDEFRAG performs well under both configurations.

Giant page support. 1 GB giant pages provide substantial benefits for memory-intensive workloads [50]. However, Linux currently lacks transparent support for 1GB THP, and memory fragmentation makes such allocations nearly impossible in practice [50, 56]. In contrast, INFINIDEFRAG can efficiently construct large contiguous physical regions, making 1 GB page allocation far more feasible.

Unbounded GPA space expansion. We currently apply no specialized optimizations to the unbounded GPA expansion. Therefore, there are two possible problems: (1) page-metadata memory grows linearly with GPA size; one possible optimization is to recycle metadata from reclaimed pages to avoid new allocations during future expansions. (2) unrestricted expansion could eventually exhaust the 57-bit physical address space, although this would take more than a century (§3.3). A potential optimization is to retrieve earlier fragmented pages from the host while returning the expanded contiguous regions. We leave these optimizations to our future work.

Page cache reclamation. The page cache is a major contributor to guest-side memory fragmentation [42]. Therefore, we plan to leverage our *fast reclaim* mechanism (§4.2-2) to reclaim fragmented page-cache pages. By integrating page-cache reclamation into the defragmentation pipeline, we expect to further improve the availability of contiguous memory and enhance the overall effectiveness of INFINIDEFRAG.

8 Related Work

Object-level and allocator-level defragmentation. Object-based defragmentation techniques classify objects by predicted lifetimes and colocate those with similar lifetimes [24, 31, 40, 41]. Recent allocator-level techniques such as TCMalloc [31] are also hugepage-aware and improve huge-page utilization in production by steering allocations into already-backed huge pages and adaptively releasing unused subregions. Because the kernel ultimately manages memory at page granularity, these approaches operate primarily in user space and do not directly address guest physical memory fragmentation inside a VM. In contrast, INFINIDEFRAG operates at the guest-physical level and is orthogonal to such methods; the two could be combined to further improve performance.

Page-level defragmentation. Illuminator [48] targets permanent fragmentation caused by unmovable pages but does not optimize regular memory compaction, making it complementary to our approach. LLFREE [53] revisits page-frame allocation from the kernel level and provides a scalable allocator with low metadata overhead and built-in anti-fragmentation behavior for huge pages. However, it requires replacing the Linux buddy allocator, making it less compatible with existing kernel features such as compaction and NUMA balancing. Moreover, under the highly fragmented VM settings (*e.g.,* the *extreme fragmentation* setting in §6.1), its anti-fragmentation benefits become limited and it underperforms INFINIDEFRAG in end-to-end throughput (*i.e.,* Figure 12 and Figure 13).

NUMA-aware defragmentation. vMitosis [46] addresses remote page-table accesses in virtualized NUMA systems by improving translation locality, either by migrating page tables to the local node or replicating them across sockets. We do not compare against it because the two works are orthogonal: vMitosis focuses on NUMA-aware page-table placement, whereas our work targets memory defragmentation. By the way, our proposed *memory trade* (§4.2-1) can achieve NUMA-aware support by implementing at a per-NUMA-node granularity, ensuring that the GPA space expansion allocates and reclaims pages only from the corresponding NUMA node.

Architectural support for defragmentation. Some prior works [25, 49, 56] address huge-page allocation under fragmentation by introducing architectural-level optimizations, which require specialized hardware support. For example, Contiguitas [56] targets host-side physical memory contiguity. It separates movable and unmovable allocations and uses hardware support to migrate unmovable pages, thereby increasing the availability of contiguous HPA. In contrast, INFINIDEFRAG provides contiguous GPA without guest-side compaction. The two approaches are therefore complementary: a host running Contiguitas could provide more contiguous HPA memory, allowing INFINIDEFRAG's host-huge page mode and *hybrid paging* to use more 2 MB-2 MB mappings.

9 Conclusion

We propose INFINIDEFRAG, a novel defragmentation technique for virtualized environments that efficiently generates huge pages. The key insight is to treat the guest physical address space as (nearly) infinite by controlling the mapping between guest and host physical addresses, thereby eliminating the need for costly memory compaction. Extensive experiments demonstrate that INFINIDEFRAG outperforms state-of-the-art approaches, achieving near-optimal performance comparable to non-fragmented memory conditions.

Abstract

We present GOODKIT, a new framework for live virtual machine introspection (LVMI) designed for performance, scalability, and safe integration in modern cloud environments. Unlike existing approaches—such as LibVMI—which rely on heavy VM pausing, GOODKIT executes observers as lightweight VMs colocated with the VMM, enabling native-speed access to the target state while preserving strong isolation. GOODKIT introduces fine-grained, lock-aware memory–coherence mechanisms, a configurable probing subsystem for I/O and kernel-level events, and a mutualization layer that allows multiple observers to operate concurrently without degrading target performance. Across 21 real world use cases, including rootkit detection, ransomware monitoring, and scheduler introspection, GOODKIT delivers high performance (compared to LibVMI), strong isolation, and broad applicability.

1 Introduction

Virtual machines (VMs) are the basic abstraction for modern cloud computing. Tenants and providers must routinely leverage *VM introspection (VMI)* techniques to observe VM behavior, in order to detect attacks, maintain availability, and understand performance problems. A VM observer should perform the above tasks while remaining safe for the platform, and also (in many use cases) transparent to the guest. This requires three properties: *low overhead* to track frequent events, *strong isolation* from both the guest and the cloud provider, and the ability to *bridge the semantic gap* between low-level VM state and high-level system abstractions. Our goal is to design a *live VMI (LVMI)* framework that achieves all three properties in a multi-tenant (IaaS) cloud, and that can be leveraged by tenants without constraints imposed by the cloud provider.

Existing VMI systems place observers in three locations: in a separate VM, inside the hypervisor or VMM, or inside the target VM's guest OS. Hypervisor-based systems [13, 22, 23, 25, 41, 48, 50, 52] such as LibVMI [8] run the observer in a separate VM and improve isolation from the guest, but they require hypervisor changes, often pause the VM for a consistent view, and incur extra kernel to userspace crossings. Observers embedded in the VMM [24, 41] have direct access to guest memory and VMM events, but they enlarge the trusted computing base (TCB). Besides, this approach does not provide isolation guarantees between the different observers (deployed by tenants and/or the cloud provider) attached to a target VM. In-guest observers [7, 18, 32] offer native performance and no semantic gap, but a compromised guest can disable or mislead them, and they share its fault domain. No existing design provides live introspection that is fast, strongly isolated from both guest and provider, and deployable without modifying the hypervisor.

We present GOODKIT, a LVMI framework that takes a different approach. It runs one or several observers as regular guest VMs *under the same VMM process as their target VM* and maps selected regions of the target's memory into these observers under explicit policy. From an observer's perspective, introspection looks like native memory access, while still benefiting from VM-level isolation and standard hypervisor accounting. All introspection mechanisms live in user space inside the VMM and in the observer VMs. Moreover, GOODKIT does not require modifying the hypervisor (enabling quick adoption by cloud providers) nor the target guest, and is agnostic to the observers' guest OSes. To support multiple observers efficiently and safely, GOODKIT combines fine-grained access control with a mutualization layer that shares common introspection work and reduces contention on kernel data structures.

Our evaluation shows that GOODKIT retains the benefits of LibVMI-style introspection while avoiding its costs. On 14 Phoronix workloads, GOODKIT observers introduce at most a 1.06× slowdown on the target, whereas LibVMI induces slowdowns between 5.15× and 37.6× under comparable conditions. On micro-benchmarks, GOODKIT's lock-based introspection is up to 17× faster than LibVMI's pause/resume mechanism, and overall introspection latency improves by up

to 110× for some policies. Across 21 real-world use cases, including rootkit detection, ransomware monitoring, liveness monitoring, and scheduler analysis, GOODKIT provides strong isolation, stable capture rates at high frequencies, and modest implementation effort; observer code is typically 3-6× shorter than equivalent LibVMI-based implementations.
Overall, we make the following contributions:

- We identify requirements for live VMI in multi-tenant clouds: flexibility, isolation, consistency, low overhead, precise accounting, and easy deployment (§3.1).
- We present GOODKIT, an introspection framework that shares the same VMM between a target VM and its observer VM(s) and maps the target memory into each observer VM under explicit policy, without changing the hypervisor (§3.4.
- We design and implement mechanisms for lock-aware, consistent introspection, shared monitoring across observers, and VMM-side probing of VMM and hypervisor events (§4).
- We develop a GOODKIT prototype supporting Linux-based target and observer VMs on x86 machines. We evaluate GOODKIT on 21 real-world use cases and show low overhead, strong isolation, and broad applicability (§5).
- We release GOODKIT as an open-source project (Appendix A).

2 Background and Motivations

This section presents the necessary background on virtualization (§2.1), motivates the need for live VM introspection (§2.2), and discusses the limitations of state-of-the-art approaches (§2.3, §2.4).

2.1 Virtualization

Generalities. Several popular virtualization platforms (e.g., KVM [2] and Oracle VirtualBox [5]) follow a two-layer design with a *hypervisor* and a *virtual machine monitor (VMM)*. Hereafter, we focus our concrete discussion on KVM-based platforms, as they underpin some of the main public (e.g., AWS, GCP) and private (e.g., OpenStack, Proxmox) cloud infrastructures. The hypervisor (KVM in our case) runs in the host kernel and provides core virtualization primitives: vCPU execution, EPT page-fault handling, and VM isolation. It exposes a userspace API (the KVM API) but does not encode any notion of a VMM instance. Because it is part of the kernel, modifying the hypervisor is undesirable.

The VMM (e.g., Firecracker [1, 12] or QEMU [6]) runs as a userspace process and builds full virtual machines using this API. It reserves part of its address space as guest "physical" memory (see below), configures virtual devices, loads the guest OS, and manages paravirtualized I/O during execution. Since VMMs are regular userspace programs, they are the natural place to add mechanisms such as VMI support without touching the hypervisor.[1]

Memory virtualization. It involves several coexisting address spaces, each interpreted at a different layer of the virtualization stack. The *host virtual address (HVA) space* corresponds to the virtual memory of the VMM process (e.g., QEMU or Firecracker). Processes inside the guest OS use the *guest virtual address (GVA) space*. The guest OS maps GVAs to *guest physical addresses (GPAs)* using its own page tables, which represent the physical memory abstraction exposed to the guest. Finally, *host physical addresses (HPAs)* denote the actual machine memory managed by the host kernel and used by the hypervisor.

When creating a VM, the VMM allocates one or more regions in its own virtual address space (HVA), typically via `mmap()`, to hold the guest's RAM. These HVA regions do not need to be contiguous, but the VMM can present them to the guest (GPA) as a contiguous physical address space. It does so by configuring KVM's *memory slots*, each mapping a range of HVAs to a corresponding range of GPAs. For example, an HVA region *(hva1, size)* in the VMM may be exposed to the guest as *(gpa=0, size)*, creating the illusion of a contiguous physical memory layout for the guest regardless of how the VMM arranged the underlying HVAs.

KVM, in turn, maintains for each VM a second-level page table, the *Extended Page Table (EPT)* on x86, that translates GPAs to HPAs. Inside the guest, each process has its own page table maintained by the guest OS, which translates GVAs to GPAs. Thus, when the processor executes a memory access inside the guest, it performs a two-dimensional translation: a guest page walk (GVA to GPA), followed by an EPT walk (GPA to HPA). The resulting HPA identifies the actual physical page on the host. Notably, after memory slots are configured, HVAs play no role in guest execution (in the hardware translation performed on behalf of the guest). The HVA is involved only when the VMM itself accesses the guest's memory (e.g., for snapshots, migrations, or to read VirtIO ring buffers).

2.2 Live VM Introspection

VM introspection (VMI) gives cloud tenants and providers visibility into the internal state of their virtual machines. It supports three main activities: (1) *security operations*, which ensure that a guest does not execute or prepare to execute malicious code (e.g., ransomware); (2) *liveness monitoring*,

[1] Note that the terminology of the domain is not fully homogeneous. Some research papers and existing tools use the expressions *VMM* and *hypervisor* interchangeably to denote the complete virtualization stack. Some other works use *hypervisor* for the entire vitualization system and *VMM* for the subsystem virtualizing the CPU and memory [16]. In the present document, like some other authors, [12, 17, 51], we use *hypervisor* for the host kernel component (here, KVM), and *VMM* for the user-space helper process (here, Firecracker) involved in CPU, memory and I/O virtualization.

which detects crashes, deadlocks, or livelocks and triggers restart; and (3) *forensic analysis*, which examines a VM's memory after a failure to identify root causes. The first two activities typically run on live systems and often precede forensic investigation. We focus on live VMI (LVMI). §5.2 presents several representative real-world LVMI use cases.

We call an *introspection mechanism* any component that can access the internal state of a VM. An *introspection framework* is a coherent stack of mechanisms, libraries, and runtimes that together provide efficient and convenient access to VM state. An *observer* is a system built on top of such a framework to implement high-level LVMI services (for example, liveness monitoring).

2.3 LibVMI-based Observers

LibVMI [8] underpins most industry [4, 9] and academic VMI systems [23, 25, 38, 39, 41, 48, 50]. We first review how it works and then explain why it is a poor fit in live-monitoring scenarios.

Description. LibVMI is a C library that builds on KVM-VMI (KVMI) [37], Bitdefender's extension [15] of KVM for introspection. KVMI adds a kernel subsystem and a userspace library, `libkvmi`, that communicate over a UNIX socket. KVM then spawns a dedicated kernel thread that handles commands from the observer.

LibVMI offers three main classes of commands: (1) *vCPU commands*, to get/set registers, query `cpuid`/`xsave`, and pause or resume vCPUs; (2) *memory commands*, to read/write guest physical memory, adjust page permissions, and translate GVA to GPA; (3) *configuration commands*, to fetch VM/hypervisor metadata (e.g., memory size, KVM version), register events (e.g., CR3 traps), and configure monitoring at VM or vCPU level.

Impracticability for LVMI. LibVMI introduces two major costs for live monitoring:

(1) LibVMI-based tools typically *pause the target VM* to obtain a consistent snapshot of kernel data structures. These global pauses are extremely expensive in LVMI: prior work reports slowdowns up to 9x [31], and we observe similar behavior. The cost grows roughly linearly with the polling rate, which makes LibVMI unsuitable for use cases involving live VM monitoring, such as process scheduling analysis or memory overcommitment.

(2) LibVMI *never accesses guest state directly*. Every operation is routed through KVMI over a socket, causing extra user–kernel transitions and data copies. For example, writing a buffer to guest memory involves copying it from the observer to a KVMI kernel buffer, then again into guest memory.

LibVMI provides an optional cache in the observer to hide part of these costs, but caching trades freshness for speed. It is therefore unusable for most LVMI scenarios that require up-to-date state, such as the use cases in §2.2.

2.4 Limitations of Existing Designs

Existing VMI approaches adopt different placement strategies, each with distinct trade-offs in observability, isolation, performance, and deployability.

A first class of designs, often called out-of-VMM approaches [13, 22, 23, 25, 41, 48, 50, 52], runs the observer in a VM managed by a different VMM instance than the target. Most of these systems rely on LibVMI [8], which exposes a high-level API for inspecting guest state but requires hypervisor modifications. This placement provides strong isolation and clean per-VM accounting. Still, it incurs expensive cross-VMM interactions, frequent VM pauses, and high memory overhead, as each observer requires its own VMM process. Since the observer runs outside the target's VMM, it also cannot see VMM-level events such as device I/O or VM exits. `mmap()`-based variants [21, 28, 30, 40, 60] reduce memory-access cost by mapping the target's memory into the observer VMM, yet they retain key drawbacks: per-observer VMM bloat, dependence on hypervisor changes for memory sharing, and lack of visibility into VMM-level activity.

A second class of systems [24, 41] embeds the observer inside the VMM that hosts the target. The observer is compiled into the VMM process and thus has direct access to guest memory and VMM events. This yields high observability and low-latency introspection. However, it removes isolation: observer and VMM share privileges and address space, so a bug or compromise in the introspection code can bring down the entire VMM and all its guests. This design is also hard to modularize (e.g., to several, dynamically-attached observers) and prevents separate accounting of monitoring overhead.

A third class, in-target approaches [7, 18, 32], places the observer directly inside the target guest OS as an agent or kernel extension. This mitigates the semantic gap and gives very efficient access to guest state but completely forfeits isolation and trust, since compromising the target also compromises the monitor.

GOODKIT adopts a different design: an in-VMM, multi-guest architecture in which observers run as independent guest OSes under the same VMM instance as the target. This preserves the modularity and isolation benefits of out-of-VMM observers while avoiding per-observer VMM overhead, and it still allows access to VMM-level events without compiling monitoring code into the VMM. By extending the VMM (rather than the hypervisor), GOODKIT enables controlled, direct mapping of the target's memory into observer guests while keeping the hypervisor unchanged. As a result, it combines high-performance introspection with strong isolation, precise accounting, and compatibility with existing cloud deployments.

3 Overview

This section details the design requirements of GOODKIT (§3.1), explains the threat model (§3.2), and presents an overview of GOODKIT (§3.4).

3.1 Requirements

We design GOODKIT to meet the following requirements simultaneously:

(R1) ***Flexibility:*** GOODKIT must support a wide range of monitoring use cases, potentially requiring events from the guest OS, the VMM, and the hypervisor. Achieving this goal is particularly challenging because we explicitly avoid modifying the hypervisor (see R6).

(R2) ***Isolation:*** Observers must be isolated from the target guest OS, the VMM, and the hypervisor. The system must provide (i) fault isolation (a misbehaving observer must not disrupt target services) and (ii) privilege isolation (untrusted tenant observation code must be isolated from the VMM).

(R3) ***Consistency:*** Observer data must be accurate and internally consistent. For example, traversing the process list must yield a coherent snapshot even if the target modifies the list concurrently.

(R4) ***Speed and Overhead:*** The system must observe the target in (near) real time, missing no relevant events while imposing low performance overhead on the target.

(R5) ***Resource Efficiency and Accountability:*** Each observer's resource consumption must be small, accurately measurable, and attributable to the corresponding tenant for accounting and billing.

(R6) ***Adoption:*** The system must integrate seamlessly with existing cloud deployments and avoid hypervisor changes, since updating hypervisors at scale is a time-consuming, resource-intensive and security-sensitive endeavor.

Non-goals. There are several valuable directions that lie beyond the scope of GOODKIT. Although GOODKIT enables the development of introspection policies, our objective is not to propose new *policies*, for example, aimed at improving kernel-compromise detection. Similarly, enhancing detection accuracy through novel analysis algorithms is also outside the scope of this work.

3.2 Threat Model

The VMM and hypervisor are part of the Trusted Computing Base (TCB) and are assumed to be correct and uncompromised. The target guest VM may be fully compromised, for example by a rootkit or ransomware. Each observer guest is trusted by its tenant to perform legitimate introspection, but may still be faulty or malicious. A faulty or malicious observer can lie to its tenant, disrupt the services provided by the target or more generally, compromise the integrity of the (target) guest state due to the ability to modify locks or other memory regions. From the cloud provider's perspective, an observer is untrusted: it is a regular VM with the same isolation guarantees as any other tenant VM. A faulty or malicious observer thus cannot compromise other VMs.

3.3 Design Trade-Offs

In GOODKIT's design, an observer runs as an independent guest VM managed by the same VMM instance as the corresponding target VM. Compared to LibVMI, where the monitoring code executes outside of the VMM, the isolation layer is thinner but, in return, we do gain live access to the target VM memory (mapped into the observer), and also direct access to the target VM devices. Modifying the VMM rather than the hypervisor is preferable because the latter is a software layer with a complete set of privileges that must necessarily be under the control of the cloud provider, whereas the ownership of the VMM layer can be more easily offloaded to a cloud tenant. Indeed, unlike the hypervisor, the VMM runs in user mode on the host machine and there is one distinct VMM instance per (traditional) tenant VM. Besides, in real-world scenarios, modern virtualization stacks already make use of multiple sandboxing facilities as an additional level of protection against a potentially misbehaving (buggy or compromised) VMM, including limited (user) privileges and contained domains (built with features like namespaces, seccomp-bpf filters, and control groups) [12]. In our approach, such sandboxing facilities may also be leveraged for mitigating the impact of a misbehaving observer on the host and the other guests.

3.4 Architecture

We now describe how GOODKIT's design (Fig. 1) satisfies the requirements introduced in §3.1. We begin by explaining how GOODKIT runs observers as guest OSes (R2), before detailing the programming model, including the introspection API and the mechanisms for controlling and deploying observers (R1). We then present our memory–mapping scheme, which provides isolation, accurate accounting, and consistent access to the target state (R2–R5). Finally, we show how shared introspection and a purely userspace implementation of GOODKIT reduces overhead and eases adoption in existing cloud environments (R4–R6).

Observer as guest OS, enabling isolation and precise accountability (R2 & R5). In GOODKIT, an observer (A) can run either as a unikernel [36] or a full Linux guest. In our current prototype, we opted for the latter, as it provides a more general and flexible execution environment. (B) GKBUILDER launches observers as separate guests using the same KVM interfaces as for the target (1 and 2). For each observer, it sets up memory slots in the VMM process that KVM uses to build the observer's EPT (C): some slots map selected regions of the target's memory, while others are private. The

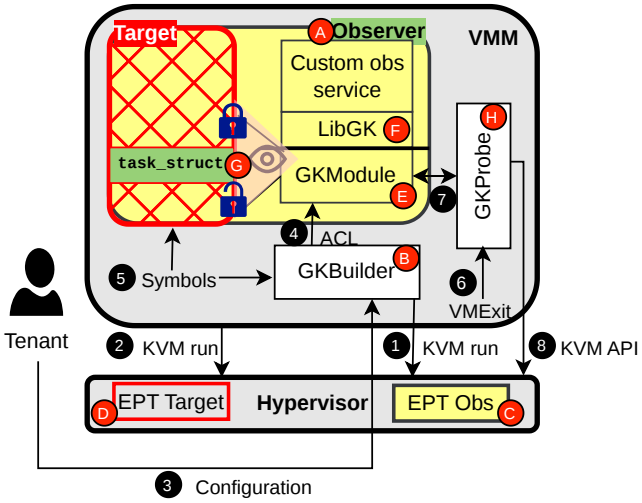

Figure 1: GOODKIT Architecture. The gray boxes correspond to existing Hypervisor and VMM layers. The white boxes correspond to new VMM subcomponents introduced by GOODKIT. The yellow boxes denote the observer's context. In this example, we use a single observer, whose purpose is to introspect a subset of the target VM's internal state, such as the list of existing processes.

target itself is assigned its own independent EPT (D). From the hypervisor's perspective, observers are ordinary guests with their own isolation and resource accounting, yet they retain controlled access to the target's memory where needed.

Introspection API, enabling flexibility (R1). GOODKIT provides a two-layer introspection API (§4.1) that supports a broad range of monitoring and analysis services (§5.2). In the observer VM, the low-level API is implemented in GKMODULE (E) and is used by kernel-space code, while the high-level API is provided by LIBGK (F) for userspace. Observation services can be implemented in the kernel, in userspace, or split across both. Userspace observers can integrate heavyweight analysis components, such as machine-learning models (§5.2, ransomware detection). Kernel-space observers, in contrast, have direct access to the target memory and to the full low-level API, including VMM communication primitives. Userspace observers interact with GOODKIT through the high-level API listed in Table 1, and can also issue requests to the VMM. This makes userspace suitable for complex code that depends on external libraries or convenient device APIs, while kernel space is better suited to low-level memory introspection. When a userspace observer needs information not exposed by the high-level API, it can delegate the low-level target-memory access to a kernel component and consume the resulting data in userspace.

Controlled introspection, enabling flexibility (R1). Tenants specify, in a YAML manifest file (3), which operations each observer is allowed to perform (§4.2). GOODKIT enforces these permissions along four axes: memory protection, introspection-API function access, symbol-table access, and probe control. GKBUILDER applies the memory-protection rules at observer boot time, and (4) GKMODULE enforces function and symbol access at runtime. These act more as guidelines than strong isolation barriers and may help building sound observers. Depending on the use cases, observers may access the target with write accesses essentially limited to the locks protecting the monitored data structures (e.g., for a rootkit detector traversing the list of processes), or also require write accesses to additional parts of the target memory (e.g., for a synchronous/active VMI scenario that places breakpoints or hooks into the target [21, 34]).

Address translation, enabling consistency (R3). Each observer receives the target's kernel symbol table (5) and uses it to locate kernel data structures. Because the target and observer use distinct page tables, these addresses must be translated. GOODKIT relies on the Linux kernel memory layout and implements seven dedicated translation functions, each covering a specific kernel memory region (§4.4). In our current implementation, the target and observer use the same kernel image so that the observer code can more easily interact with the target's kernel data-structure layout during introspection. This is not a fundamental limitation of GOODKIT; the support of decoupled kernels is left for future work. Note that, in any case (i.e., using identical or distinct kernel images for the target and observer VMs), GOODKIT, like many other VMI approaches, relies on the assumption that the observation logic is aware of the precise memory layout and intricacies of the OS kernel running in the target. Therefore, for all these approaches (including GOODKIT), a cleverly-compromised guest might evade detection by an observer if it manages to bypass some of its assumptions.

Fine-grained suspension, enabling consistency and low overhead (R3 & R4). GOODKIT preserves consistency by locking the data structure being inspected (G), instead of suspending the whole VM as LibVMI-based systems do. It assumes the OS already protects shared structures with locks. With the target's memory mapped, the observer acquires the same lock before accessing a structure, as if it were a thread within the target; concurrent updates then block on that lock. GOODKIT provides built-in support for lock acquisition (§4.5).

Shared monitoring, enabling low overhead and resource efficiency (R4 & R5). When several observers perform similar introspection tasks, such as scanning the process list, redundant work and lock contention increase overhead. GOODKIT introduces a mutualizer observer (§4.7) that centralizes these operations. Domain-specific observers register their requests with the mutualizer, which performs each operation once and distributes the results.

Only userspace components, enabling quick adoption (R6). GKBUILDER and GKPROBE (H) are implemented and run in the VMM process in userspace. GKPROBE (§4.6) monitors target-related VM exits, I/O, etc. (6) and runs provider-developed probes that can be enabled according to tenant

Table 1: A subset of GOODKIT's programming API: low-level (by GKMODULE) and high-level functions (by LIBGK).

needs, then forwards their outputs to observers (❼). Provider-developed probes are capable of implementing arbitrary operations, including (❽) invoking existing hypervisor API to capture hypervisor-level events. Its goal is to cover introspection operations that cannot be performed directly from inside observers. All changes are confined to the VMM and guest; the hypervisor remains unmodified.

4 Design and Implementation

This section presents the design and implementation of GOODKIT. While GOODKIT's design is generic, this section is based on our implementation using Firecracker as the VMM and Intel x86-64 for the CPU architecture.

4.1 Programming API

GOODKIT exposes a two-layer introspection API split between GKMODULE and LIBGK. GKMODULE provides low-level primitives in the observer kernel, including address translation, lock-aware access to target data structures, and interfaces for issuing requests to GKPROBE. LIBGK builds on these primitives to offer a higher-level userspace API for common monitoring tasks. Together, they let developers implement observation services in kernel space, userspace, or both, without handling the underlying mapping and synchronization details. A sample in Appendix B illustrates how to use this API.

Low-level API (GKMODULE). The low-level API is implemented in GKMODULE and provides basic building blocks for introspection. Its functions fall into three categories. First, it offers helpers to traverse common kernel data structures such as linked lists (line 1, first column in Table 1) and red-black trees (line 2, first column). Second, it provides memory-access utilities for address translation (line 10, first column), memory-coherence control (lines 3–8, first column), and raw memory inspection (line 13, first column). Third, it exposes system-wide control functions, including resolving kernel symbols by name (line 9, first column) and sending or receiving requests to or from GKPROBE (lines 11–12, first column).

High-level API (LIBGK). Building on the low-level functions, the high-level API implemented in LIBGK offers ready-to-use implementations of common introspection tasks, drawn from prior work [29, 40, 48]. For example, listing operations (lines 1–7, second column in Table 1), such as traversing the process list or the kernel-module list, internally rely on the linked-list traversal primitive. Several high-level functions also help validate the integrity of the target kernel code (lines 8–13, second column). In particular, in Table 1, all functions whose description begins with the verb *"Check"* are designed to detect malicious hooks or other kernel tampering.

4.2 Policy Enforcement

GOODKIT enforces fine-grained policies that limit what each observer can see and do. Some controls are implemented in the VMM (GKBUILDER, GKPROBE) and cannot be bypassed by observer code. Others are enforced inside the observer by GKMODULE; when the observer comes from a third party, its requests can instead be routed through the mutualizer observer, which applies the same checks on its behalf.

Memory protection. The memory regions visible to an observer depend on its owner and use case. For example, a memory-overcommitment observer (e.g., running Wang et al.'s V-Probe algorithm [58]) deployed by the cloud provider needs to touch only the `vmemmap` region that holds struct page entries; it should not access other parts of the guest. The YAML manifest therefore lists allowed regions and their (read/write) permissions. GKBUILDER enforces these policies when configuring shared mappings for each observer.

Probe control. Probes (described in §4.6) expose VMM- and hypervisor-level information about the target. GKPROBE treats each probe as a configurable unit: the manifest specifies which probes are enabled and, optionally, how far they may inspect guest state. For instance, `blk_probe` can either collect disk I/O request types only or also inspect read/write buffers; its configuration can restrict it to pattern collection. Because probes run in the VMM, these limits hold even if the observer is compromised.

API–function access. GOODKIT maintains an access-control list of API functions that each observer may invoke. The YAML manifest contains the allowed GKMODULE/LIBGK functions; a GKMODULE macro checks at runtime whether the caller is authorized before executing the operation. For third-party observers, the same checks can be applied in the mutualizer, which filters their requests before they reach GKMODULE.

Symbol-table access. Symbol resolution can be confined in a similar way. When needed, the manifest specifies a whitelist of kernel symbols. At runtime, the observer (or mutualizer) may resolve only these symbols; all other lookups fail with a `Symbol Not Found` error.

If no security policy is specified, GOODKIT falls back to a permissive configuration: the observer runs without restrictions, except that probes obey the default settings defined by the cloud provider.

4.3 Memory Mapping

GKBUILDER constructs the address spaces of the target and its observers and wires them together through shared memory. It allocates a contiguous region in the VMM process to back both target and observer memory, then configures KVM memory slots and EPT entries so that each observer sees its own guest-physical space with controlled mappings to the target. In this way, observers obtain direct access to target state while remaining isolated as separate VMs.

GKBUILDER first `mmap`s a large contiguous region in the VMM's virtual address space to back both target and observer memory, laid out as $\texttt{observer}_1 \mid \texttt{observer}_2 \mid \cdots \mid \texttt{target}$. For each observer, it then configures KVM memory slots that, together, form the guest-physical address space: some slots cover the observer's own core memory (allocated by the tenant), others map selected regions of the target. For instance, with 2 GB for the observer and 10 GB for the target, the observer sees 12 GB of physical memory. The precise configuration of the target memory viewed by the observer depends on the aforementioned settings but also of architecture-dependent constraints. For example, on x86, an MMIO hole typically appears near 3.25 GB, so mapping the target into the observer may require up to three slots, depending on how their ranges intersect this hole. We identify three distinct mapping scenarios, which we detail in Appendix C due to space limitations.

4.4 Address Translation

GKMODULE resolves target kernel pointers through a two-step translation: from a *Target Guest Virtual Address* (TGVA) to a *Target Guest Physical Address* (TGPA), and then to an *Observer Guest Virtual Address* (OGVA). Given an address in the target's kernel space (a TGVA), it translates it to a TGPA based on the Linux kernel memory layout, and finally maps that TGPA into the observer's own address space. This pipeline lets the observer access target kernel objects through regular in-guest pointers while preserving isolation.

TGVA → TGPA: Although one could continuously traverse the target kernel's page tables to perform address translation, this would incur substantial overhead. Fortunately, for several Linux kernel memory regions, the layout is sufficiently structured to allow more efficient translations. The Linux kernel divides its virtual address space into seven major regions [3], each with its own data types and allocation policy. GOODKIT therefore chooses the TGVA → TGPA translation method based on the region in which the address lies. The boundaries of these regions are defined by the kernel's memory layout.

(1) Text segment. This region is stored in a contiguous region in the TGPA space. Addresses in this region are translated by simple arithmetic: GKMODULE subtracts the fixed offset `__START_KERNEL_map` from the TGVA.

(2) Direct mapping region. Here, a similar optimization can take place. GKMODULE subtracts the `PAGE_OFFSET` constant from the TGVA. This region includes all contiguous allocations produced by functions such as `kmalloc()`, `kzalloc()`, `kcalloc()`, `alloc_pages()`, and `__get_free_pages()`.

(3) Vmalloc region. Addresses in this region fall within `VMALLOC_START`–`VMALLOC_END` or `MODULES_VADDR`–`MODULES_END`. These ranges cover the kernel modules area, *ioremap* mappings, and memory allocated via the `vmalloc_*` family. For such addresses, GKMODULE performs a page-table walk in the target kernel. It starts from the swapper[2] process' page table, whose page global directory (PGD) base address is exported via the `init_top_pgt` symbol, walks down the page table levels to the page table entry (PTE), and returns the corresponding physical address.

(4) Vmemmap region. Addresses in this region lie within the `VMEMMAP_START`–`VMEMMAP_END` range, which stores the `struct page` array describing physical memory. As for the `vmalloc` area, translation requires a page-table walk starting from the page table of the target's idle process. However, `vmemmap` is backed by huge pages, so the walk stops at the page middle directory (PMD) level instead of the PTE level. While `vmalloc` translation uses the PTE to obtain the physical frame, the PMD entry for `vmemmap` yields the base physical address of a memory section. The final `struct page` address (TGPA) is obtained by adding the offset of the target page within that section.

(5) Per-CPU region. These addresses correspond to per-CPU variables such as `current` (the currently executing `task_struct`) and `runqueues` (per-CPU scheduler queues). Translation uses the `__per_cpu_offset` array: GKMODULE adds the offset for the target CPU to the base address of the per-CPU variable to obtain the complete TGVA, and then translates it as in the direct mapping region.

(6) Fixmap region. This region contains statically mapped kernel addresses. Their translation uses a predefined lookup table that directly resolves virtual-to-physical mappings.

(7) Local Descriptor Table (LDT) regions. LDT-based addresses are process-specific and, in modern Linux kernels, rarely used. They can be treated as a legacy case and are typically ignored in practice.

TGPA → OGVA: At the start of the observer, the physical memory regions of the target are made available to the observer. GKBUILDER uses this information to reserve, in the observer's address space, the ranges that correspond to the target. For each of the regions, the observer allocates an in-

[2] The existence of the swapper process (also known as "idle" process), which spawns one task (i.e., idle loop) per CPU, is an invariant in the Linux kernel. This process also provides us with a stable entry point to access the kernel page table of the target.

memory descriptor. Each descriptor records the region's base address in the target (`target_base`), the corresponding virtual base in the observer (`virt_start`), and the region size.

TGPA translation to OGVA is then performed by locating the descriptor that covers the requested guest address and computing: $\texttt{OGVA} = \texttt{virt_start} + (\texttt{TGPA} - \texttt{target_base})$.

4.5 Fine-Grained Suspension

GKMODULE preserves memory coherence during introspection without the high cost of suspending the entire target VM, as in LibVMI. Instead of stopping the guest, it joins the target kernel's locking protocol: for each data structure it inspects, GKMODULE acquires the lock that protects it, so concurrent updates serialize naturally with observer accesses. Read-only objects (for example, those marked `__ro_after_init` or `const`) are accessed directly, while frequently updated structures are accessed only after taking the corresponding lock, as a regular kernel thread in the target would.

Basic idea. For any observer action that must appear as if it were performed inside the guest, the observer reuses an existing guest execution context whose participation does not affect normal execution. For example, when acquiring spinlocks, it impersonates the context of `vCPU0` (more precisely, it impersonates the target's idle task attached to `vCPU0`.) in the target and enters the same queuing and arbitration logic as a regular thread. This only adds one extra contender to the lock, while the locking protocol and scheduling behavior remain unchanged.

The Linux kernel provides two main classes of locking primitives [57]: spinning locks (spinlocks, bit spinlocks, `rwlock_t`) and sleeping locks (mutex, `rt_mutex`, semaphore, `rw_semaphore`, `ww_mutex`, `percpu_rw_semaphore`). We illustrate our approach with Spinlock, RWlock and Mutex by describing their implementations since they are the most widely used primitives in the kernel [35, 43, 54, 56].

Spinlocks. Our solution builds on the standard *queued spinlock* algorithm and reuses the per-CPU `qnodes` to place the observer in the lock queue. In Linux's queued spinlock, each waiter is represented by an MCS node [45] taken from a per-CPU `qnodes` array. Each CPU has four such nodes, one for each context: *Normal Task*, *Hardware Interrupt*, *Software Interrupt*, and *Non-Maskable Interrupt*. Normally, a CPU runs only one of these contexts at a time, so at most a few `qnodes` are in use. It is extremely unlikely that all four contexts contend for the same lock simultaneously. If this happens, the last context simply spins until a `qnode` becomes free.

In our design, an observer thread behaves like one more nested context. It uses a `qnode` in the same way as an interrupt handler, joins the MCS queue, and eventually acquires the lock in turn. Appendix D illustrates our approach through a simple illustrative scenario.

RWLocks. RW locks follow the usual semantics: at most one writer may hold the lock, whereas multiple readers may hold it concurrently. A writer blocks all other holders; when readers hold the lock, a writer sets the write-pending bit and waits for exclusive access. In Linux, contending readers and writers spin on an internal spinlock embedded in `rwlock_t`. Our observer simply uses the same queued spinlock algorithm: on contention, it joins the queue and participates in arbitration like any other entity, ensuring safe and consistent access to the protected kernel structure.

Mutexes. Mutexes are sleeping locks that can only be used in a preemptible task context. In the classic mutex algorithm, the contender is the `current` task. In GOODKIT, the observer instead impersonates the `idle` thread of the target's CPU0 as the mutex owner, since manipulating the `idle` task cannot disrupt normal service.

Lock-free data structures. Besides these lock-based data structures, Linux also uses Read-Copy-Update (RCU) protected structures, which are common in recent kernel versions. GOODKIT does not currently support RCU-specific synchronization; we discuss possible extensions in §7.2.

4.6 External Event Probing

GKPROBE is a VMM-side helper that gives observers controlled visibility and actuation at the VMM/hypervisor boundary. It lets GOODKIT offer LibVMI-style capabilities (e.g., seeing I/O activity or triggering actions) without running code in the hypervisor or modifying it.

Because many relevant events occur outside the target's memory, along the hypervisor–VMM path or inside the VMM itself, observers cannot access them directly. GKPROBE fills this gap: it runs entirely inside the VMM as a set of probes and actuators that only the cloud provider can configure. For operations already exposed by the KVM API, a probe or actuator often reduces to a simple `ioctl()` call; for events already visible in the VMM (such as VirtIO I/O operations), GKPROBE hooks into existing code paths and reports them to observers as introspection events.

Observer guests communicate with GKPROBE using VirtIO channels called *virtqueues*. An observer can produce one or several messages into a virtqueue and then trigger a hypercall, which allows notifying the corresponding VMM-level probe/actuator for processing them. Symmetrically, a probe/actuator managed by GKPROBE within the VMM can also produce one or several messages into a virtqueue and send an interrupt request to trigger the execution of a VirtIO callback inside the observer (as a response to an observer request), registered by GKMODULE, which can forward the notification to a user-space agent. The precise interaction patterns between an observer and the VMM depends on the characteristics of a given introspection scenario and the chosen probe(s). In many use cases, it is possible to leverage asynchronous communications and message batching to reduce the occurrence of hypercalls. For example, in the case of a disk I/O probe used for ransomware detection (detailed in

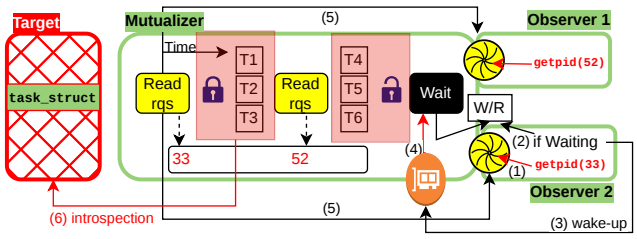

Figure 2: Mutualized introspection.

§5.2), hypercalls are only used sporadically by the observer and the VMM, respectively for submitting a set of buffers and for signaling when they are full.

4.7 Shared Monitoring

GOODKIT reduces redundant work and overhead on the target by delegating common introspection tasks to a dedicated observer, the *mutualizer*, illustrated in Fig. 2. Instead of having each observer traverse the same kernel data structures (such as list or trees of processes, VMAs, modules, etc.), client observers submit requests to the mutualizer. It checks each request against the configured policy, performs the traversal once, and shares the results, reducing CPU overhead, lock contention, and simplifying access control for third-party observers.

The mutualizer offers a configurable, iterator-based interface that treats different types of data structures uniformly. Each request specifies (i) the data structure to traverse (for example, process or module list) and (ii) the item to search for in that structure.

For communication, the mutualizer maintains a per-client ring buffer for requests and completions, and a small shared region that stores its state (`Running` or `Waiting`). When a client issues a request, it writes it into its ring buffer (1) and then checks the mutualizer state (2). If the state is `Running`, the client simply waits for the result. If the state is `Waiting`, it wakes the mutualizer by connecting to a sleeping socket via VirtIO (3). Checking the state avoids unnecessary VirtIO notifications and thus extra hypercalls and VM-Exits.

When woken, the mutualizer scans all ring buffers, groups pending requests by data structure type, and starts one worker thread per type. Each worker first acquires the corresponding lock in the target, then walks the list in fixed-size batches (6). A batch is a fixed number of structure elements (e.g., list nodes), configured at startup. After processing a batch, the worker briefly "spins and waits": it re-examines the ring buffers for new requests of the same type, merges them into its work set, and then continues from the next batch. When a requested item is found, the worker writes the result into the completion ring buffer of the requesting observer (5).

A worker stops if it scans the data structure R consecutive times without seeing any new request. Between two iterations, the mutualizer sleeps for S μs to give the target a chance to acquire the same lock (experimentally, an approximate value of 20 μs provides the best balance between responsiveness and minimization of lock contention). Once all workers have stopped, the mutualizer's main thread switches back to the `Waiting` state.

5 Evaluation

The implementation of GOODKIT consists of two parts: the VMM side and the observer side. The VMM side corresponds to 3,803 LoC (written in Rust) added to Firecracker (1,867 for GKBUILDER and 1,936 for GKPROBE), which represents 5.1% of its full code base. On the observer side, there are an additional 4,480 LoC for GKMODULE and 1,039 for LIBGK, all written in C.

Our evaluation of GOODKIT centers on the following main questions: **(Q1)** How effective and flexible is GOODKIT in a variety of use cases? (§5.2–§5.3) **(Q2)** How does GOODKIT perform compared to the state-of-the-art competitor, LibVMI (§5.4–§5.5)? **(Q3)** What overheads does GOODKIT impose on the target (§5.6)? and **(Q4)** How does the mutualizer observer improve scalability when multiple observers are running (§5.7)?

5.1 Experimental Setup

Testbed. Our experiments run on a 16-core Intel Xeon Silver 4215 at 2.50 GHz with 256 GB of RAM, running Ubuntu 20.04 and Linux 5.4.24+. All guests run Alpine Linux with a 5.10.198 kernel and the VMM is Firecracker 1.5. Unless otherwise specified, each target or observer VM is configured with 1 vCPU.

Baseline. §2.4 gave a qualitative comparison between GOODKIT and existing approaches. For the quantitative evaluation, we compare GOODKIT against LibVMI (with KVMI v7), following prior established methodology [40, 60]. State-of-the-art VMI systems are broadly based on LibVMI. We were unable to reproduce the two in-VMM instrumentation approaches [24, 41] because their source code is not publicly available.

LibVMI targets QEMU and does not natively support Firecracker. We ported LibVMI to Firecracker by reusing its QEMU logic and verified that the resulting performance matches the QEMU-based implementation (§5.4). We publicly release this port (along with the GOODKIT source code) and we provide further details in Appendix E.

Workloads. We use two dimensions of workloads: where they run (inside the target vs. inside observers) and their granularity (micro vs. macro benchmarks). Target-side workloads measure the interference of GOODKIT on guest execution; observer-side workloads act as monitoring services.

(c) Macro-benchmarks for observers.

Table 2: Workloads and benchmarks.

Micro-benchmarks are custom workloads that isolate specific GOODKIT features, inspired by prior work [40]. We introduce each target-side micro-benchmark when it first appears in the evaluation; observer-side micro-benchmarks are summarized in Table 2.a. Macro-benchmarks evaluate GOODKIT under realistic conditions. On the target side, we use fourteen applications from the Phoronix benchmark suite [47] (Table 2.b). On the observer side, we implement seven services (Table 2.c, §5.2).

5.2 Real-world Use Cases

We evaluate the effectiveness and flexibility of GOODKIT with realistic use cases. As discussed in §3.1, the novelty of GOODKIT does not lie in these use cases; they simply illustrate the range of applications it can support.

Rootkit detection. Using GOODKIT, we developed four observers to detect four open-source Linux rootkits: *Diamorphine* [42], *Adore-ng* [11], *Spy* [49], and *Sutekh* [53].

Diamorphine hooks three syscalls by overwriting their table entries with pointers to its own module. It hooks `kill()` (used to receive commands such as hide/unhide a process) and `getdents()` / `getdents64()` (used to hide processes from directory listings, including `/proc`). *Sutekh* also hooks syscalls, namely `umask()` and `execve()`, to grant root privileges to a designated process. *Spy* is a keylogger that attaches to the kernel keyboard notification chain by registering a `struct notifier_block`. *Adore-ng* modifies function pointers in the file operations structure for the `/proc` directory to hide processes and files.

Detection focuses on the kernel objects that these rootkits modify: syscall table entries (*Diamorphine*, *Sutekh*), the `struct atomic_notifier_head` for keyboard notifications (*Spy*), and the `/proc` file-operations table (*Adore-ng*). The observer checks whether these pointers reference code outside the kernel text segment, which usually means module memory. It then traverses the module list to find the module whose address range contains the suspicious function. In our experiments, the observers correctly detected all four rootkits.

Ransomware detection. Behavior-based ransomware detection either hooks filesystem syscalls in the guest [19] or inspects disk I/O at the VMM level [14, 27, 59]. We implement the second approach to showcase GKPROBE. Concretely, we reimplement *DefPunk*, a recent ML-based detector from Alibaba [59].

Our observer has two parts: a kernel module and a userspace process. The kernel module configures GKPROBE to capture disk I/O requests issued by the target. Using the probe's configurability, the observer selects which fields to collect and at what frequency. GKPROBE forwards only raw VirtIO metadata (no payload) asynchronously to the observer, keeping the probe lightweight along the guest's critical I/O path. The C structure of these records is shown below:

```
struct __attribute__((packed)) virtio_blk_probe_response {
    uint32_t type;// Request type (e.g., read, write)
    uint64_t sector;// Target disk sector
    uint32_t size;// Request size in bytes
    uint32_t disk_id;// Virtio block device id
};
```

From this stream, the kernel module derives higher-level metrics such as the total number of requests, reads, writes, write-after-read patterns (WAR), the fraction of WARs, and the number of distinct block addresses (working-set size) per time unit. Every 10 s, the userspace component classifies the target's behavior using these metrics. Because the original DefPunk model is not available, we train a linear SVM on the RanSAP dataset [26], which includes benign traces (e.g., Firefox) and several ransomware families such as WannaCry [10].

The resulting model reaches an F1 score of 0.76, comparable to the original [59]. In our tests, it raises no alarms on benign workloads and triggers at least one alert for every ransomware sample.

Liveness Monitoring. The observer plays a role similar to `mysql_safe`: it monitors the `mysqld` process inside the target. Periodically, it walks the target's process list and searches for the `task_struct` whose `comm` field matches the MySQL executable. If no such entry is found, the observer instructs GKPROBE to reboot the target.

CPU runqueue monitoring. The CPU runqueue (`struct rq`) holds the tasks about to run on a given

Use Case	Locks Types	Mem. Types	LibVMI LoC	GoodKit LoC

Table 3: Summary of locks, memory translations, and implementation effort for each observer use case. The LoCs correspond to the introspection code without includes. An example of such a code can be seen in Appendix B.

CPU. Unlike the previous use cases on global kernel structures, this one shows that GoodKit can also introspect per-CPU state. Inspecting it reveals CPU pressure and the currently running task. We use this observer to detect if a malicious or buggy process is monopolizing a CPU [55].

5.3 Internal Metrics

We analyze the observer code for our use cases to understand which kernel regions and synchronization primitives they exercise. All the GoodKit basic operations consist of either accessing the target memory (which may involve address translation and lock acquisition steps) or sending requests to the VMM probes through a VM-exit as explained in §4.6. Across all policies, the most frequently translated regions are the *direct-mapped* and *per-CPU* areas, followed by the *text segment* and *Vmalloc* region. This indicates that most introspection tasks focus on kernel code and per-task metadata. For synchronization, mutexes and read-side RWLocks are the most common, each used in 5 of the 15 policies.

During the experiments presented above, we also measured the cost of address translation and lock acquisition operations. For the former, depending on the memory type, latencies range from 45 ns in the best case (direct mapping) to 85 ns in the worst case (`vmalloc` region). The acquisition of locks without contention incurs the same overhead as within the guest: acquiring a spinlock takes approximately 29 ns, while RWLocks and mutexes take respectively approximately 26 and 36 ns.

As Table 3 shows, the implementation effort also differs markedly between GoodKit and LibVMI. Using GoodKit reduces code size by 3-6× across all policies, since the framework provides low-level introspection primitives, address-translation helpers, and coherence mechanisms.

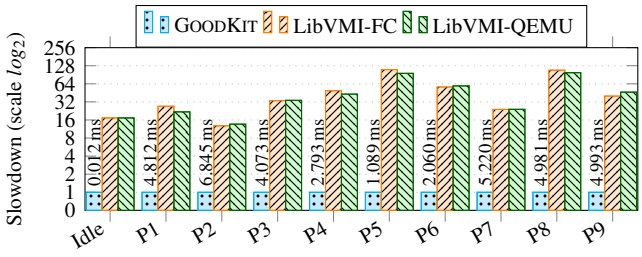

Figure 3: Introspection Turnaround Time.

5.4 Introspection Turnaround Time

We measure how long GoodKit takes to introspect the target and compare it to LibVMI. For both systems, we time the end-to-end cost to (i) resolve target kernel addresses, (ii) apply the synchronization mechanism (lock/unlock in GoodKit, pause/resume in LibVMI), (iii) collect the required information, and (iv) release the synchronization mechanism.

We use P1–P9 and the idle observers from Table 2.a. The idle observer isolates the raw cost of synchronization management. Both observer and target run with a single vCPU, and the target is idle.

Fig. 3 reports the speed up of GoodKit relative to LibVMI (all GoodKit values are normalized to 1). GoodKit is faster in every case. The idle bar shows the cost of LibVMI's `pause/resume` mechanism: acquiring and releasing a lock in GoodKit is 17× faster than pausing and resuming the guest. Locking is not the only factor. Because GoodKit observers are colocated with the VMM, they benefit from *native-speed memory access* (§5.4). This is visible in P2, where no synchronization is needed and both observers simply read the (stable) syscall table; LibVMI is still much slower. LibVMI's slowdown reaches up to 110× for P5. This is because tied to its nested loop structure that multiplies the number of `vmi-read` requests of P5.

These experiments also validate our LibVMI port for Firecracker. The slowdowns for Firecracker and QEMU versions are nearly identical, confirming that our Firecracker integration preserves LibVMI's performance characteristics.

5.5 Capture Rate

We evaluate the introspection speed of GoodKit against LibVMI using the cat-and-mouse experiment of Hongyi Liu et al. [40]. In this scenario, a kernel rootkit repeatedly corrupts the credential structures of selected processes and quickly restores them. By varying the modification frequency, we measure how often the observer catches these transient inconsistencies.

Fig. 4 shows results for attack rates up to 500 modifications per second. Above 150 modifications per second, LibVMI's capture rate drops to about 50%, and at 200 modifications per

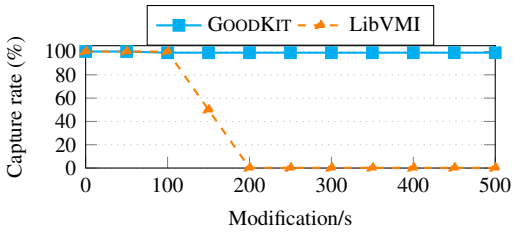

Figure 4: Rootkit capture rate of GoodKit and LibVMI in a cat-and-mouse scenario [40].

second it falls to 0.16%, showing that pause/resume cannot keep up with fast-changing kernel state. In contrast, GoodKit maintains a capture rate of 99% across the same range, thanks to its low-latency, lock-based coherence mechanism. Even at 10 million modifications per second (not shown in Fig. 4), GoodKit still achieves a capture rate of 80%.

5.6 Introspection Overhead

We now evaluate the overhead GoodKit imposes on the target, upon boot and during execution.

5.6.1 Boot Time

GoodKit starts observers inside the same VMM as the target. This increases cold-start time, which is critical in settings such as serverless computing. We evaluate three scenarios: *Parallel*, where GKBuilder launches the observer while the vanilla code builds the target; *Before Target*, where GKBuilder launches the observer first; and *After Target*, where GKBuilder launches the observer just after the target is created. In the *Parallel* configuration, we vary the number of observers from one to five.

With one observer in *Parallel*, the target boot time increases by about 1.08x-1.11x compared to the vanilla (no-observer) setup. This comes from doubling the number of `ioctl()` calls to KVM and the associated kernel-side synchronization. The overhead grows with the number of observers, reaching 1.57x for five observers; each additional observer adds roughly 1.13x-1.14x to the target build time. Thus, instantiating many observers in parallel can noticeably impact VM boot time.

In the *After Target* configuration, the target's boot time increases only by about 1.02x-1.04x. This small cost is due to parsing both configuration files and allocating memory for both guests at initialization. Importantly, this overhead does not grow with the number of observers. In the *Before Target* configuration, the target's boot time essentially doubles, since the observer is fully initialized before the target's own boot begins.

Given this overhead, users should carefully choose how they instantiate observers so they meet their application needs while minimizing overhead.

5.6.2 Execution Time

We now measure the runtime overhead imposed on the target. The target uses 14 vCPUs, and each observer runs with a single vCPU. The target executes the 14 Phoronix applications listed in Table 2.b. The baseline, normalized to 1, corresponds to running the applications without any observation. We evaluate two configurations: (i) a *single observer* and (ii) *multiple observers*. For the first configuration, we consider two representative observers—P3 (memory introspection) and *DefPunk* (VMM-level I/O events)—and we vary their observation frequency. For the second configuration, we launch the target alongside four observers: *DefPunk*, a *rootkit detector*, a *keylogger detector* (P4), and a `/proc` *file operations checker* (P6).

Single observer (P3). The second bar in Fig. 5 reports the slowdown induced by P3 on the target. Across all workloads, the P3-GoodKit observer introduces at most a 1.06× slowdown (observed on OpenSSL), which is negligible. In contrast, P3-LibVMI incurs slowdowns ranging from 5.15× to 37.6×. This substantial gap is primarily due to LibVMI's use of the *pause/resume* mechanism to ensure memory coherence, whereas GoodKit relies on lightweight, fine-grained locking.

Single observer (Deftpunk). For *Deftpunk*, we evaluate both the ransomware trace replayer from §5.2 and the `FIO-IOPS` benchmark. With GoodKit, the replayer achieves 874 I/O requests per second, matching the vanilla throughput. Under LibVMI [3], throughput drops to 747 I/O requests per second, corresponding to a **1.17× slowdown** compared to GoodKit. For `FIO-IOPS`, which is more I/O intensive than the ransomware trace, the slowdown under LibVMI is even higher, reaching **1.87**×.

Heterogeneous observers and scalability. The third bar reports the slowdown observed on the target when running the four observers simultaneously. The slowdown is approximately **1.16x** on average, which is comparable to the degradation observed with the single P3 observer earlier in §5.6.2. This experiment demonstrates that GoodKit enables efficient multi-observer introspection without significantly increasing overhead on the target.

We did not conduct the same experiment with LibVMI because LibVMI does not support multiple independent observers. If observers run as distinct processes, a pause request issued by one observer may conflict with an unpause request from another, leading to inconsistent states. Achieving coordinated behavior would require colocating all observers in a single program or implementing an external synchronization mechanism, both of which prevent running legacy observers. In contrast, GoodKit naturally supports multiple isolated observers without requiring any coordination or code modifications.

[3] We added I/O introspection support to LibVMI (see Appendix F).

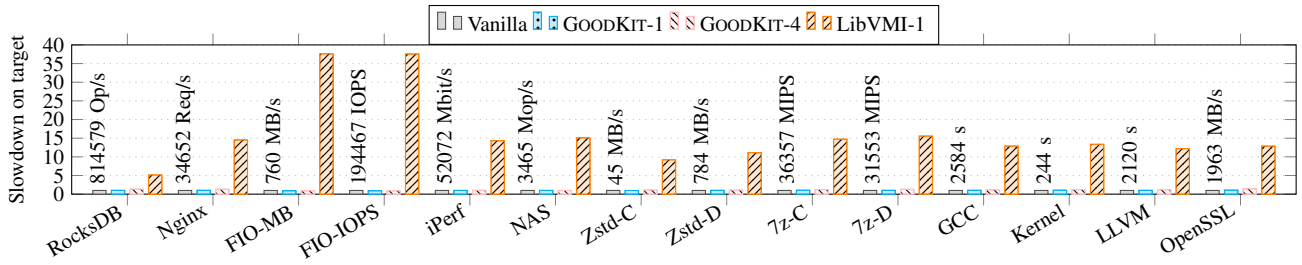

Figure 5: Overhead of GoodKit (using 1 and 4 observers) and LibVMI on the Phoronix benchmark suite.

5.7 Mutualizer Benefits

We evaluate the benefits of the *mutualizer*, which makes sense when several observers monitor the same data structures in the target. We consider both the target's and the observers' perspectives. The target runs a multi-threaded program that continuously creates POSIX threads using the `pthread` library. Each thread executes an empty function, and the main thread waits for it to terminate before creating the next one. This sustained thread creation keeps updating the kernel's thread list. Each observer repeatedly searches for a given PID in the target's thread list and performs this lookup N times.

Without the mutualizer, all observers complete their workload, but the target freezes as soon as more than one observer runs. Traversing the process list requires acquiring an RWLock in read mode, while the kernel needs the same lock in write mode to update the list when creating or terminating threads. Because observers traverse the list in a tight loop with no pause, at least one of them almost always holds the read-lock. RWLocks allow concurrent readers and do not enforce fairness between readers and writers, so the writer (the target) starves and never acquires the write-lock. The target can no longer update the thread list and eventually stalls.

With the mutualizer, this problem disappears. Only the mutualizer takes the read-lock, and it releases it after each traversal. Writers (running in the target) regularly obtain the write-lock, preventing starvation. Performance remains stable and independent of the number of observers: the target sustains approximately 35K thread creations per second, and each observer performs about 38K iterations per second. We observe the same performance when a single observer runs without the mutualizer. For comparison, a target without observers creates about 40k threads in our configuration.

6 Discussion

This section explains the position of an observer developer regarding the locks acquisition order. It also talks about how atomic variables are managed with GoodKit mechanisms.

6.1 Target's Locks Acquisition Order

The Linux kernel has a well-established locking discipline. When analyzing a complex kernel state, an observer must decide whether to follow the full locking protocol. Not following the target kernel's lock discipline may leave the system in an inconsistent state. Observer developers must carefully consider the locking strategy based on the kernel data structures they inspect and their invariants.

6.2 Atomic Variables

Atomic variables are variables that are protected by the hardware while they are being modified. This means that the coherence between two VMs that are dealing with an atomic data item is not guaranteed by the operating system, but by the hardware; this makes GoodKit-based introspection straightforward for these.

7 Limitations and Future Work

In this section, we consider some questions raised by our approach regarding the observers fault tolerance and RCU-based synchronization between an observer and its target VM.

7.1 Observers Fault Tolerance

Running observers may be malicious or faulty. While malicious observers are out of scope of this work, faulty observers should be handled to mitigate service disruption. Faulty observers can disrupt normal target execution if they acquire a target lock and then crash. To handle crashes, GoodKit may record each lock operation in a buffer shared between the observer and Firecracker, allowing the VMM to track the locks currently held by each observer. When an observer crashes, the VMM would check this shared state. If the lock map is stable, the observer holds no target lock. Otherwise, the VMM will restart the observer in recovery mode. The recovery observer would release all locks held by the failed observer, ending the disruption on the target. After recovery, the observer can either resume normal execution or shut down. A watcher may also be implemented to monitor observers that hold locks for too long. This can be done by recording the

timestamp alongside the lock map mentioned before, and have a pre defined time limit for locks holding. This has been planned as future work.

7.2 RCU-protected Data Structures

RCU (read-copy-update) [44] supports both read and write synchronization. For reads, a thread enters an RCU-protected section with `rcu_read_lock()`, obtains the current version of the object with `rcu_dereference()`, and exits with `rcu_read_unlock()`. For writes, a thread initializes a new version of the object, publishes it with `rcu_assign_pointer()`, and waits for a grace period with `synchronize_rcu()` (or `call_rcu()` for the asynchronous variant) before reclaiming old versions.

GOODKIT's current proof of concept does not implement RCU synchronization. When the observer needs to access data structures in read mode (which is likely the most dominant case), it can mimic a target reader by entering and leaving RCU reader-side sections. The main challenge comes when a reader observer needs to interact with the writer. According to the RCU protocol, a writer in the target waits until all CPUs that were executing between `rcu_read_lock()` and `rcu_read_unlock()` have left their critical sections before reclaiming old versions. An external observer is not naturally part of this protocol, so data stability is not guaranteed without additional mechanisms. Moreover, an observer performing writes cannot track the exact state of the target vCPUs in the target code execution, hindering the synchronization process.

8 Related Work

Note that we already discussed a portion of the related work in the motivation section (§2.4).

Most existing systems that address memory coherence during VMI rely on *pause-based* consistency mechanisms. Many tools depend on LibVMI [8] as their backend, and consequently adopt the strategy of pausing the target vCPUs before inspecting memory. Prior work [41] highlights several drawbacks of such techniques: latency-sensitive services may experience noticeable disruptions, and frequent pauses increase overall system jitter. Cosseron et al. [20] further demonstrated that pausing a VM induces a measurable drift between the VM's internal clock and real time, a side effect that can be detected by malware and used as a trigger to conceal or disable malicious behavior.

A different perspective is offered by TxIntro [41], which leverages Intel's Hardware Transactional Memory (HTM) [33]. TxIntro monitors the state of synchronization variables protecting kernel data structures and performs introspection within a hardware transaction. As long as the lock variables remain unchanged, the transaction proceeds, ensuring that the observed structure is read consistently; if a concurrent modification is detected, the transaction aborts and partial results are discarded. While this approach avoids explicit VM pauses, it has several limitations. First, it depends on HTM support, which is not always available or enabled on cloud platforms, e.g., due to mitigations against side-channel attacks. Second, it can only provide consistency guarantees when observing guest state that fits within the maximum read-/write set capacity of the HTM. Third, it requires hypervisor modifications, unlike GOODKIT.

Some studies, such as Virtuoso [23] and VM-Space Traveler [25], address the semantic gap by facilitating or automating the generation of introspection operations over guest kernel data structures. These efforts are orthogonal to GOODKIT and can enrich or automate its introspection API while preserving GOODKIT's isolated and efficient execution model.

BlueGuard [46] targets both hypervisor-level and VM-level introspection, whereas GOODKIT focuses exclusively on introspecting guest VMs. To achieve this, BlueGuard isolates its observer on a dedicated accelerator (e.g., a SmartNIC) and relies on DMA to access memory. However, BlueGuard exhibits two main limitations. First, DMA-based access can lead to data-coherence issues, since memory may be concurrently modified by the CPU. Second, BlueGuard requires specialized hardware accelerators, which significantly restricts its deployability in real-world cloud environments.

9 Conclusion

In this work, we introduced GOODKIT, a new LVMI framework that enables efficient, scalable, and safe introspection without relying on intrusive hypercalls or VM pausing. By colocating observers with the VMM, enforcing lightweight coherence mechanisms, and supporting flexible, modular probes, GOODKIT significantly reduces overhead while improving responsiveness and accuracy. Our evaluation shows that GOODKIT outperforms LibVMI by large margins across all scenarios, offers strong scalability thanks to the mutualizer design, and supports a wide range of real-world use cases. Overall, GOODKIT bridges the gap between practicality and performance, enabling cloud providers and tenants to deploy LVMI at scale. The GOODKIT prototype is publicly available as described in Appendix A.

Acknowledgments

We thank our anonymous shepherd and the anonymous reviewers for their insightful comments. This work was supported by the French *Agence Nationale de la Recherche* (ANR) under the DiVa project of "PEPR Cloud" (ANR-23-PECL-0004), by Inria "Défi OS", and by the CNRS MLNS2 International Research Project (IRP). Finally, we thank Baptiste Lepers and André Freyssinet for their feedback.

A Artifact Appendix

Abstract

This artifact is the prototype of GOODKIT. The code corresponds to the implemented mechanisms mentioned in the present paper. This concerns the Firecracker modification, GKMODULE and LIBGK. We also make available the Firecracker LibVMI port. This includes the Firecracker, LibVMI, LibKVMI and KVMI modifications.

Scope

This prototype allows you to make observations on a target VM. To run existing use cases, and build new live VMI (LVMI) use cases based on the existing tools. It can also serve as a basis for extended research on live VMI.

Contents

The repository contains the following:

- `firecracker-main`: A fork of Firecracker (written in Rust) with the framework's VMM integration. It allows creating/starting observers, executing probes, and managing VM–VMM communication.
- `images_builder`: Dockerfiles and scripts for building VM images, including those used in the evaluation.
- `ioctl_injector`: Userspace LIBGK code (written in C) that implements the high-level API.
- `libVMI`: Firecracker's LibVMI plugin, plus our KVMi patch adding VirtIO support for LibVMI.
- `linux-5.10.198`: Linux kernel sources (written in C) used to build the target and observer vmlinux images.
- `usecase`: Source code for the implemented use cases. The repository root also includes scripts to run experiments, a Makefile to build the project and images, and a `flake.nix` file for Nix-assisted reproducibility.

Hosting

The public link for our artifact is https://doi.org/10.5281/zenodo.20069006. It links to a Git repository.

Requirements

This artifact requires an x86 machine with KVM support capable of running Firecracker microVMs, along with the standard toolchain required to configure and compile a Linux kernel. The prototype was primarily evaluated on an Ubuntu 20.04 host running Linux kernel 5.4.24+, but it is also compatible with Ubuntu 24.04 running kernel 6.8.0. Our experimental evaluation was conducted on a 16-core Intel Xeon Silver 4215 CPU, 2.50 GHz with 256 GB of RAM. However, a 2-core CPU is sufficient to run the prototype. Finally, reproducing the experiments detailed in §5.6.2 requires at least 90 GB of RAM and 60 GB of disk space.

B Code Sample

Listing 1 is a snippet that depicts the observation of a process list. The introspection starts with a symbol lookup. The observer first gets the addresses related to the corresponding symbols (lines 2–4). Those are: the head of the tasks list `init_task`, the qnodes that reside in the per-CPU area `qnodes`, the tasks list lock that protects tasks list modifications `tasklist_lock` and the CPU areas offset array, which is subsequently used to resolved per-CPU addresses `_per_cpu_offset`.

The observer then translates the addresses to OGVA, for direct access (lines 6–8). The observer then takes the read lock on the `rwlock_t` (line 10). The `for_each_process_in_target` traverse the list of processes (lines 11–13) and translate the relevant addresses under the hood, and gives a pointer `p` on the current entry for usage. The observer then prints the process name (line 12) and releases the lock afterwards (line 14).

Listing 1: Process list traversal from an observer using GoodKit's API. The program resolves the symbol adresses using the symbol table, then grabs the protecting spinlock before walking through the list.

```
1 void process_list(struct context *vo){
2   rwlock_t *tasklock; struct task_struct *p; unsigned
      long *pcpu_off; struct qnode *qnode0; struct
      symbol_entry **syms; char *names[] = { "init_task",
      "qnodes", "tasklist_lock", "__per_cpu_offset" };
3   /* Lookup kernel symbols */
4   syms = symbols_multilookup(names, ARRAY_SIZE(names));
5   /* resolve into Observer virtual address space */
6   pcpu_off = tgva_to_ogva(syms[3]->addr, vo);
7   qnode0 = tgva_to_ogva(syms[1]->st_addr + pcpu_off[0],
      vo);
8   tasklock = tgva_to_ogva(syms[2]->st_addr, vo);
9   /* Lock, walk task list and unlock */
10  obs_read_lock(vo, tasklock, qnode0);
11  for_each_process_in_target(p, syms[0]->st_addr, vo) {
12    pr_info("Process name : %s",p->comm)
13  }
14  obs_read_unlock(vo, tasklock);
15 }
```

C Memory Slots Scenarios

KVM slots are structures that describe the physical memory layout of the virtual machine. A slot contains a range of guest physical addresses, their corresponding host virtual addresses in the VMM, and region-specific flags. Slots are used to declare the complete VM's physical memory layout to KVM. The number of KVM slots per observer depends on (i) architecture-specific physical layout constraints and (ii) the relative sizes of observer and target. On x86, an MMIO hole typically appears near 3.25 GB, so mapping the target into the observer may require up to three slots, depending on how their ranges intersect this hole. We identify three distinct mapping scenarios.

Scenario 1. Either (i) the sum of target memory and observer core memory is below 3.25 GB, or (ii) the observer core memory alone is above 3.25 GB while the target memory remains below this threshold. In both cases, the target memory occupies a single contiguous region in the observer's physical address space, so GKBuilder creates *one* KVM memory slot for the target.

Scenario 2. Either (i) the observer core memory is below 3.25 GB and the combined observer+target size exceeds 3.25 GB, or (ii) both observer and target are individually larger than 3.25 GB. Here, adding the target crosses the MMIO hole and introduces a discontinuity in the observer's physical address space. GKBuilder therefore creates *two* KVM memory slots for the target.

Scenario 3. If the observer core memory is below 3.25 GB and the target memory itself spans beyond the MMIO hole, mapping the target into the observer creates *two* distinct holes: the observer's MMIO hole and the target's own MMIO hole. In this case, GKBuilder creates *three* KVM memory slots for the target.

D Illustration of Spinlock Acquisition by a GoodKit Observer

Figure 6 shows how the observer thread W competes with two target threads, T1 and T2, for the same spinlock. (1) T2, on vCPU1, acquires the lock and enters the critical section. (2) T1, on vCPU0, tries to acquire the lock; because it is held, T1 spins and sets the pending bit. (3) T1 is added to the lock's waiting list, stored in a per-CPU (vCPU0) variable. (4) The observer thread W also tries to take the lock. (5) W spins and is added to the same waiting list for vCPU0.

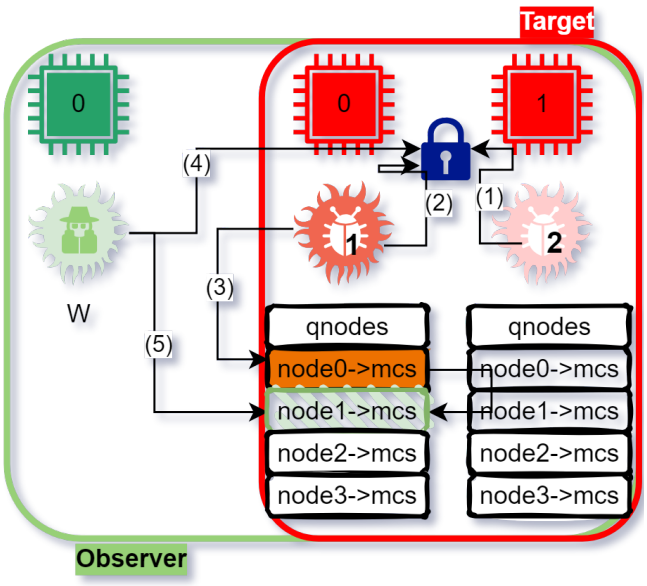

Figure 6: Remote spinlock.

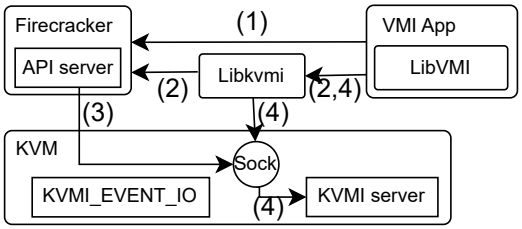

Figure 7: LibVMI usage with Firecracker.

E Porting LibVMI to Firecracker

LibVMI relies on the KVM-VMI project to provide general-purpose introspection capabilities. KVM-VMI is an extension of KVM that enables fine-grained introspection mechanisms. To perform introspection, LibVMI communicates with KVM (over the KVMI extension) through a dedicated socket.

Figure 7 illustrates how we integrated LibVMI with Firecracker. When a VMI application starts, it invokes the LibVMI initialization function, which connects to the VMM and requests the creation of an introspection socket (❶). With QEMU, LibVMI relies on libvirt's `qemu` driver for this step; however, to the best of our knowledge, no libvirt plugin exists for Firecracker. To overcome this limitation, we extended the Firecracker API to allow introspection-socket creation via HTTP requests. We also implemented a LibVMI Firecracker driver to handle (dis)connection with Firecracker.

Once the socket is created, LibVMI calls a `libkvmi` function to connect to the VMM introspection socket (❷). The KVMI protocol performs a three-step handshake to establish the connection. After the handshake completes, the VMM issues an `ioctl()` to KVM (❸) to pass the VM identifier and the socket file descriptor to KVMI. KVMI then spawns a kernel thread responsible for serving userspace KVMI requests.

From this point onward, the VMM is no longer involved in the introspection process: all communication occurs directly between LibVMI and KVM via the LibKVMI API (❹). This design ensures fairness in our evaluation.

When introspection ends, the VMI application sends a message to the VMM to terminate the KVMI session through a final `ioctl()` call.

F I/O Introspection with LibVMI

Concretely, we added a new command (`KVMI_EVENT_IO`) to KVMI, enabling a LibVMI-based observer to request that KVMI forward events corresponding to the page faults generated inside KVM when the guest attempts to access MMIO memory regions (i.e., reads or writes to memory-mapped I/O). When such an event occurs, KVMI returns to the observer the destination address. In the case of VirtIO-based devices, these addresses correspond to the in-guest VirtIO ring buffers. Using these addresses, the observer can rely on existing LibVMI memory read primitives to read and analyze the content of these buffers in order to identify the underlying disk read or write requests.

vBOIDs: Taming Chaos via Coarse-grained Scheduling Abstraction for Containers

Kaesi Manakkal[⋆], Nathan Daughety[†], Yu Sun[*], Marcus Pendleton[†], Hui Lu[⋆]

Abstract

Today's high-density container deployment often descends into scheduling chaos, where fine-grained, per-thread scheduling decisions lead to thrashing and unpredictable performance. We present vBOIDs, a container scheduling system that tames this chaos with two key techniques: a coarse-grained BOID abstraction and a two-level balancing scheme. The BOID abstraction groups tasks into larger units to dramatically reduce scheduling churn, while two-level balancing coordinates global and local scheduling to ensure efficient resource utilization without oscillation. Our evaluation shows that vBOIDs improves the throughput of containerized microservices with thousands of threads by up to 3× under highly dynamic workloads compared with existing approaches, while incurring minimal overhead and yielding negligible performance impact even in high parallel workloads. vBOIDs effectively restores order to container scheduling, delivering high performance even under chaotic conditions.

1 Introduction

Cloud runtimes now deploy thousands of containers per machine [9, 18, 33, 50]. Production systems like Alibaba's RunD host over 2,500 containers on a single node [33], and kernel-bypass runtimes like Junction pack more than 3,000 instances on a 128 GB node [18]. This growth reflects the trend of finer-grained microservices, expanding core counts, and increasingly aggressive multi-tenant consolidation [14, 20, 29, 48].

However, despite being "lightweight", container-based deployments often perform even worse than full-fledged VMs – e.g., by more than 80% ($2). This counter-intuitive result reveals a fundamental abstraction breakdown: Containers leak their internal concurrency directly to the host kernel – a single containerized microservice can expand into hundreds of *host-visible* scheduling entities, forcing Linux's Completely Fair Scheduler (CFS) [41] to manage large, dynamic runqueues. For instance, the Hotel Reservation application [21], comprising 24 microservices, generates over 500 processes/threads [1] when containerized, compared to only 50 vCPUs for VMs.

To understand the consequences, we analyze container and VM deployments under identical loads ($2). We find that while the rates of intra-core switching (i.e., time-sharing a single core) are comparable, high-density containers incur substantially higher rates of inter-core migration (i.e., moving tasks across cores for load balancing) – by an order of magnitude. Because every container thread appears directly on the host's runqueues, CFS sees frequent queue-length imbalances and performs aggressive load-balancing routines that constantly scan cores and migrate tasks to equalize state.

Each inter-core switch forces the kernel and hardware to reconstruct execution state on a new core – by issuing TLB shootdowns (via IPIs), invalidating L1/L2 caches, perturbing LLC locality, and disrupting branch-predictor and prefetching. These penalties quickly accumulate when containers generate large numbers of runnable tasks, causing the scheduler to move threads faster than hardware locality can converge – a phenomenon we term *scheduling chaos*, where a modest increase in migration rates can trigger a breakdown of hardware locality, leading to severe system inefficiency.

Existing approaches mitigate this issue through resource partitioning and smarter scheduling. Techniques such as thread pinning, cache partitioning, and CPU frequency tuning [17, 31, 32, 35, 54] carve up shared resources, while advanced scheduling and learning-based systems infer sensitivity or demand at runtime and place tasks accordingly [13, 15, 19, 26, 34, 34, 43, 53]. These techniques often reduce tail latency and noisy-neighbor effects but do not reduce the number of host-visible scheduling entities. At large scales, thousands of container threads still compete for CPU, and the resulting scheduling complexity remains a key bottleneck.

These findings reveal a core tension in high-density container deployments: Containers achieve lightweight isolation

[1] For brevity, we use "thread" thereafter to refer to both Linux processes and threads, scheduled identically by the kernel.

DISTRIBUTION STATEMENT A. Approved for public release: Distribution unlimited. Case Number AFRL-2026-0584. Dated 09 Feb 2026

by exposing internal threads to the host, forcing fine-grained per-thread scheduling, but per-thread scheduling triggers aggressive load balancing, destroying hardware locality at scale.

In this paper, we introduce vBOIDs, a coarse-grained container scheduling abstraction paired with an intermediate balancing layer embedded in the kernel scheduler. Rather than exposing hundreds of threads to the host scheduler, vBOIDs bundles each container's threads into a small number of scheduling units, i.e., BOIDS, that act as virtual CPUs. By allowing the kernel to schedule only a few BOIDS per container, vBOIDs restores a stable scheduling hierarchy, sharply reducing cross-core thrashing and preserving cache locality. In addition, a lightweight, two-level balancing mechanism coordinates load at both the global and intra-container levels: the host scheduler migrates BOIDS across cores based on aggregate pressure, while an internal balancer redistributes threads among a container's BOIDS to avoid internal hotspots. vBOIDs operates entirely within the kernel and is fully compatible with existing container frameworks, requiring no changes to applications or orchestration systems (e.g., Kubernetes [5]). As a result, containers retain their agility while gaining the stability of coarse-grained scheduling.

We implemented vBOIDs in the Linux kernel and evaluated it on representative cloud-native microservices [21, 22]. For workloads that suffer from severe scheduling chaos, vBOIDs sharply reduces migration storms and cache disruption seen under the default Linux scheduler, achieving up to 3× higher throughput while still meeting SLOs. It yields stable throughput and latency on par with the ideal – yet impractical – pinned-core setup. In highly parallel workloads that demand rapid execution across many cores, vBOIDs incurs negligible overhead: it remains lightweight while matching the throughput of the fastest unpinned configuration, demonstrating that coarse-grained scheduling does not compromise parallelism. Overall, vBOIDs restores VM-like stability to containerized execution while preserving container efficiency.

2 Motivation

Modern cloud applications increasingly consist of dozens of fine-grained microservices communicating over lightweight RPCs [8, 23, 27, 38]. This decomposition enables independent deployment, rapid iteration, and elasticity at scale, and has fueled widespread adoption of container-based execution across platforms such as Borg [52], Kubernetes [5], and ECS [11]. Containers have thus become the dominant unit of computation: they package application code, dependencies, and runtime state while sharing the host OS for isolation, scheduling, and resource management.

However, this shift toward microservice granularity creates an unprecedented amount of host-visible concurrency. Even a modest service graph can expand into thousands of runnable threads once containerized. Crucially, containers expose this internal concurrency directly to the host scheduler. Unlike VMs, which virtualize CPU resources behind a small, stable set of vCPUs, containers allow the kernel to see every runnable thread. At high density, this forces the CPU scheduler to manage thousands of scheduling entities, exercise aggressive load balancing, and migrate tasks across cores at a rate far beyond its intended operating regime.

This pattern is widespread in production. Meta operates over 18,500 active microservices across 12M+ service instances, with deep service graphs that fan out into many short RPC handlers per user request [28]. Alibaba's microservice trace covers ∼20,000 services across 10,000+ bare-metal nodes [38], and its RunD runtime hosts over 2,500 secure containers per 384 GB node, starting more than 200 per second [33]; Junction similarly packs 3,000+ kernel-bypass instances on a single 128 GB node [18]. Standard runtime stacks further inflate these counts. Microservices commonly adopt thread-per-request or thread-pool models on top of gRPC, where each blocking RPC handler occupies an entire worker for its lifetime and concurrent fan-out forces pool sizes to scale with request concurrency [49]; service-mesh sidecars (e.g., Envoy/Istio) further add a multi-threaded proxy to every pod [27]. The result is that even a single co-located service contributes tens to hundreds of host-visible threads to the kernel scheduler, independent of application logic. In addition, Function-as-a-Service (FaaS) workloads exhibit the same pattern at a finer granularity – Azure Functions' production trace reports that 50% of functions execute in under one second, with invocation rates spanning eight orders of magnitude [48]; Caladan reports up to 230,000 core reallocations/second under microsecond-scale RPCs [19], and the same scheduling chaos has independently motivated the "Wasted Cores" study [36], Google's ghOSt [26], and the upstreaming of sched_ext [24].

2.1 Scheduling Chaos

We first illustrate the scheduling chaos problem using the Hotel Reservation application from DeathStarBench [21] that models a simplified online hotel booking platform. It consists of 24 interconnected microservices that collectively implement key functionalities such as user authentication, room availability search, reservation booking, payment processing, and customer account management. Each microservice is deployed independently and communicates with others via lightweight RPCs, making the application representative of real-world, latency-sensitive, multi-tier microservices.

We compared two deployment setups: Docker containers [1] and Firecracker micro-VMs [10]. In both setups, we ensured sufficient CPU resources per microservice. For containers, we constrained CPU allocations using `cgroups` [6], assigning 1 to 4 cores based on utilization; for micro-VMs, we similarly allocated 1 to 4 vCPUs. Note that the number of

DISTRIBUTION STATEMENT A. Approved for public release: Distribution unlimited. Case Number AFRL-2026-0584. Dated 09 Feb 2026

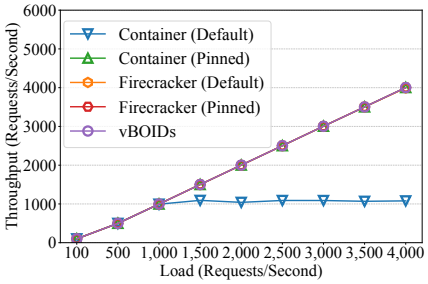

Figure 1: The throughput of Hotel Reservation as the load increases.

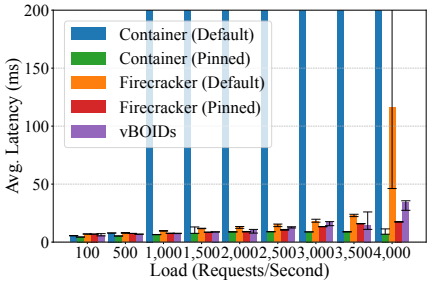

Figure 2: Average latency of Hotel Reservation under varying workloads.

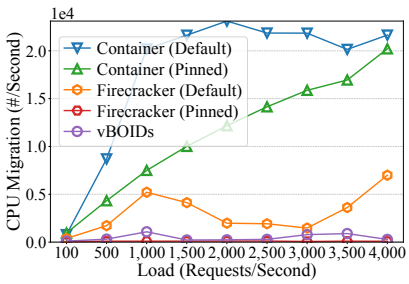

Figure 3: Process migrations of Hotel Reservation under varying workloads.

allocated CPU cores or vCPUs for each microservice was determined by (pre-)measuring its CPU utilization and rounding up to the nearest whole number to ensure sufficient resources.

We evaluated two scheduling schemes. In the `Default` scheme, the CPU scheduler, i.e., Linux CFS, freely schedules container threads or vCPUs on any available core, enabling system-wide load balancing. In the `Pinned` scheme, we manually pinned each thread or vCPU to a specific core or group of cores using CPU affinity. Although static pinning hinders load balancing, our manual pinning made sure that CPU resources remained sufficient for all microservices. It is important to note that manually pinning hundreds or thousands of short-lived threads is impractical in real deployments due to the highly dynamic nature of real-world workloads. The application ran on a server machine, equipped with two NUMA nodes, each with 32 cores (more details in §6).

Figure 1 and Figure 2 present the throughput and average latency of the Hotel Reservation application under increasing request rates. Under `Default` scheduling, the container-based deployment exhibits sharp latency spikes even at moderate load, eventually failing to meet SLOs (e.g., 200ms) as request rates increase – beyond 1k requests/second (RPS). Applying `Pinned` scheduling to containers substantially reduces latency growth and preserves stable performance across the full load range, enabling much higher sustainable throughput. In contrast, both micro-VM configurations (`Default` and `Pinned`) maintain consistently low and stable latencies across nearly all loads, with divergence appearing only at the highest request rates (around 4k RPS) – where the `Default` micro-VM configuration eventually violates SLOs.

These results highlight a clear and interesting contrast that containers are highly sensitive to CPU placement and benefit significantly from explicit core pinning, whereas micro-VMs maintain stable latency even under the default scheduler. Note that, in this paper, we chose two publicly available, widely-used microservices benchmarks – DeathStarBench [21] and Online Boutique [22] – to study the scheduling chaos problem. Both serve as conservative proxies for the production deployment – as discussed earlier, real-world deployments expose even higher host-visible concurrency, with correspondingly stronger migration storms, than what we report here.

2.2 Root Cause Analysis

To understand why containerized microservices exhibit unstable latency under `Default` scheduling while micro-VMs remain stable, we analyze microarchitectural metrics, context-switch behavior, and migration patterns at a load of 1k requests/second (Table 1), as this is the highest load on our system where all cases meet the SLO reliably.

First, Table 1 shows that `Default`-scheduled containers incur substantially higher TLB, L1-dcache, and LLC miss rates than any other configuration. In contrast, `Pinned` containers reduce misses across all levels of the cache hierarchy (e.g., L1 and LLC) as well as both dTLB and iTLB MPKI (Misses Per Kilo Instructions). Yet, micro-VMs exhibit a different pattern: although their virtualization stack introduces overhead (reflected in slightly higher LLC and TLB activity), the gap between `Default` and `Pinned` cases is small.

To further narrow down the cause, we examine context-switch behavior. An *intra-core switch* occurs when the scheduler time-slices runnable tasks on the same physical core. Microservice workloads naturally generate many such switches: short, bursty RPCs frequently block on I/O or remote calls and quickly wake up again, producing constant turnover among runnable tasks. Table 1 shows that both containers and micro-VMs exhibit similarly high intra-core switch rates, reflecting the fact that intra-core switching is driven primarily by the application's I/O-driven blocking and wake-up patterns; even in micro-VMs, the hypervisor delivers these events to the vCPUs (via VM Exits/Entries), resulting in comparable on-core scheduling activity at the host. Because these switches occur on the same core, they preserve L1/L2 cache warmth and TLB residency and avoid cross-core coordination. As a result, while intra-core switches contribute to overall scheduling volume, they impose low locality overhead.

In stark contrast, Figure 3 shows that `Default` scheduling causes containerized workloads to incur a disproportionately high number of inter-core migrations, and the rate grows

DISTRIBUTION STATEMENT A. Approved for public release: Distribution unlimited. Case Number AFRL-2026-0584. Dated 09 Feb 2026

Table 1: Running statistics for the Hotel Reservation application under the load of 1,000 requests/second. Note that cache and TLB miss numbers are reported as values normalized to the Container (Default) case.

Load (1,000 requests/s)	scheduling unit #	intra-core switches (# /second/core)	inter-core migr (# /second/core)	L1-dcache misses	LLC load/store misses	dTLB load/store misses	iTLB MPKI	CPU%
Container (Default)	495	2,677.26	315.47	1.00	1/1	1/1	1	26.25%
Container (Pinned)	495	2,698.85	117.13	0.84	0.33/0.18	0.22/0.35	0.82	13.17%
Firecracker (Default)	52	3,377.32	81.42	1.29	0.78/0.66	0.59/0.98	0.82	10.97%
Firecracker (Pinned)	52	3,558.76	1.50	1.31	0.31/0.21	0.45/0.86	0.86	9.21%
vBOIDs	52	2,535.97	16.85	0.86	0.28/0.20	0.28/0.44	0.75	10.71%

rapidly with load. Each migration moves execution to a different core (or NUMA node in the worst-case scenario), scattering working sets across cores and repeatedly discarding accumulated locality. This behavior directly elevates L1/L2 cache misses, perturbs LLC residency, and triggers TLB shootdowns, as reflected in Table 1. In addition, every cross-core move requires coordination between cores (e.g., updating runqueue state, enforcing memory-protection changes, and acquiring shared scheduler locks), further amplifying overhead. As load increases, the frequency of these migrations outpaces the hardware's ability to re-establish locality, producing the unstable execution behavior we term *scheduling chaos*. Under this, even moderate increases in request rate lead to rising tail latency and SLO violations when the system CPU utilization remains low – less than 30%.

As expected, `Pinned` scheduling substantially reduces inter-core migrations for containers – by roughly 60% at a load of 1k RPS (Figure 3) – stabilizing hardware locality and lowering cache and TLB miss rates (Table 1). This reduction manifests directly in the improved latency observed in Figure 2. However, because a container can expose hundreds of runnable threads and threads, it is difficult and impractical to pin each one to a specific physical core. Note that the existing affinity-based approach instead pins a container's all threads to a designated subset of cores. While this restricts scheduling freedom, it does not eliminate inter-core migrations: imbalances within the pinned core subset still trigger load balancing, particularly under heavy load.

Finally, `micro-VMs` exhibit different behavior. Rather than exposing hundreds of runnable entities to the host, micro-VMs present a small number of long-lived vCPUs (e.g., 52 total for this workload). Because the host scheduler sees far fewer host-visible scheduling units, runqueues remain stable and load-balancing routines have little opportunity, or need, to migrate vCPUs between cores. Consequently, both `Default` and `Pinned` micro-VM configurations incur very few migrations in Figure 3, and their cache/TLB profiles remain stable across scheduling modes. Without migration-induced disruption, micro-VMs sustain lower latencies than containerized workloads under `Default`, despite additional virtualization overhead of the guest kernel and hypervisor.

2.3 Insights

The analysis shows that the primary source of performance degradation across different configurations is excessive inter-core migrations (rather than the necessary, workload-driven intra-core switches). Like many existing approaches attempting to mitigate interference [17, 31, 32, 35, 54], thread pinning reduces migrations and restores locality but sacrifices flexibility or requires manual tuning. In contrast, micro-VMs expose only a handful of long-lived vCPUs, allowing runqueues to remain stable and maintaining hardware locality, but at the cost of full virtualization overhead.

This exposes a long-standing tension: stable placement is essential for maintaining low and consistent latency, but enforcing stability restricts dynamic load balancing, which is necessary for high resource utilization. It further raises a research question: can we decouple the granularity of thread-level execution from that of host-level migrations, thereby enabling containers to present only a handful of migration-stable units to the host while retaining their inherent flexibility and avoiding the costs of full virtualization?

3 Background

We focus on Linux's CFS, the default and widely deployed scheduler in production datacenters [37]. The core idea behind our approach – interposing a virtual scheduling abstraction between threads and physical cores – is general and can extend to emerging frameworks such as EEVDF [2] or BPF-based sched_ext [24]. However, we center our design, implementation, and evaluation on CFS, as it remains the practical substrate for most containerized cloud workloads today [52]. In the following, we provide the necessary background on CFS before introducing our solution.

Thread-granularity mismatch. The fundamental unit of execution in Linux is the thread (`task_struct`), represented in the scheduler as a scheduling entity. CFS operates on a strictly 1:1 threading model: It schedules individual threads onto physical cores based on their virtual runtime (`vruntime`). While effective for general-purpose computing, this model ignores the logical boundaries of modern containerized cloud applications. A container is simply a namespace grouping

DISTRIBUTION STATEMENT A. Approved for public release: Distribution unlimited. Case Number AFRL-2026-0584. Dated 09 Feb 2026

of hundreds of threads [6]. To the scheduler, these threads are independent actors; CFS has no structural concept of a "container" as an executable unit and cannot naturally enforce concurrency bounds – it cannot dynamically limit a container to executing on exactly N cores simultaneously (only static pinning), nor can it prevent the "split-brain" scattering of a container's threads across disjoint cores or NUMA nodes.

Task groups. In the Linux kernel, the abstract concept of a container is materialized as a `task_groups` (`cgroups` [6]). Container runtimes like Docker [1] map each container to a distinct `task_groups`. The `task_groups` aggregates the weights of its member threads to ensure proportional fairness at the group level. To limit CPU usage, the `task_groups` utilizes a "bandwidth control" mechanism. This is a temporal throttle: the kernel tracks aggregate usage and throttles all threads in the group once a global quota is exceeded. Crucially, the `task_groups` enforces temporal isolation (how much time a group gets) but lacks spatial isolation (where and how many cores a group occupies). Accordingly, `cfs_quota_us` is not a direct substitute for vBOIDs: it bounds CPU time over an interval, but not the number of cores a container can occupy concurrently. For example, a container with a quota of 2.0 CPUs can legally execute on 100 cores for 20ms (a massive burst) before being throttled. This bursty behavior degrades cache locality and induces tail latency for neighbors as we have discussed in §2. While a shorter quota period could approximate some of vBOIDs behavior, doing so would require workload-specific tuning; unless otherwise noted, our experiments use the default CFS quota and period settings.

Load balancing and PELT. For multicore systems, Linux invokes the load balancer periodically on scheduler ticks (e.g., every 1ms), whenever a CPU becomes idle, during task wakeups, or constraint changes to maintain fairness and minimize load imbalance. Migration decisions are driven by Per-Entity Load Tracking (PELT) [51], a geometric decay algorithm that implements an Exponentially Weighted Moving Average (EWMA) with a 32 ms half-life. PELT tracks the time each entity spends executing or waiting (runnable load) and aggregates these signals hierarchically – summing the load of individual threads into their parent `task_group`. During load balancing, the scheduler selects pairs of source and destination cores beyond certain load imbalances (e.g., ∼15% within a NUMA node and ∼30–50% across NUMA nodes). Then, the scheduler pulls threads from the source core runqueue to the destination core runqueue – a process called *migration*. While PELT provides an accurate view of container load, the standard load balancer still iterates over individual threads to resolve imbalances. In high-density environments, this $O(N)$ search space (i.e., total number of threads) becomes costly.

4 Design of vBOIDs

The design goal of vBOIDs is to address the fundamental mismatch between the massive thread-level concurrency exposed by containers and the much coarser physical parallelism of modern multicore hardware. Our design is guided by three principles: (1) *Restore placement stability through coarse granularity:* The root cause of scheduling chaos is that containers expose too many independent migration candidates. Restoring locality requires substantially reducing the scheduler's decision space with coarser-grained placement. (2) *Minimize hot-path interference:* The Linux scheduler's hot path must remain fast and wait-free; any design that introduces per-thread coordination, shared locking, or complex data-structure traversals in this path is untenable. (3) *Preserve work conservation and fairness:* Coarse-grained placement must not strand resources. The design must maintain work conservation while avoiding static pinning (underutilization) and bandwidth throttling (temporal idling).

vBOIDs satisfies these principles by introducing a new scheduling abstraction, the BOID, along with a new scheduling layer that decouples a container thread-level execution from the kernel's core-level placement. In the reminder of this section, we first formalize the BOID abstraction (§4.1), then present the scheduling hierarchy (§4.2), and finally describe the dual-path load balancing mechanisms (§4.3).

4.1 BOID Abstraction

As shown in Figure 4, we introduce BOID, Bound Object Integrated Dispatch [2], as a coarse-grained scheduling abstraction for containers. Conceptually, a BOID functions as a container-level vCPU, aggregating the container's threads into a single, logical entity that the host scheduler treats as a schedulable unit. To operate on BOIDS, vBOIDs adds an intermediate layer to the scheduling hierarchy. Instead of scheduling individual threads, the host scheduler (CFS) schedules BOIDS onto physical cores, while each BOID acts as a vehicle for the execution of its associated threads. Structurally, a BOID is a *first-class* kernel scheduling entity (i.e., backed by `struct boid` in Figure 4) that maintains a runqueue of its assigned threads. While this resembles the hierarchical scheduling of Linux task groups (cgroups), BOIDS enforce a strict serial execution invariant: regardless of how many threads are queued in a BOID, at most one may execute on a physical core.

This serialization makes the BOID the basic unit of concurrency for a container. The number of BOIDS assigned to a container dictates its maximum degree of parallelism. A container provisioned with N BOIDS is therefore limited to N simultaneous execution contexts – mirroring the behavior of

[2] The BOID term is borrowed from Craig Reynolds' BOIDS algorithm [46], which simulates the flocking behavior of birds. We adopt this to capture BOID's flock-like migration across cores.

DISTRIBUTION STATEMENT A. Approved for public release: Distribution unlimited. Case Number AFRL-2026-0584. Dated 09 Feb 2026

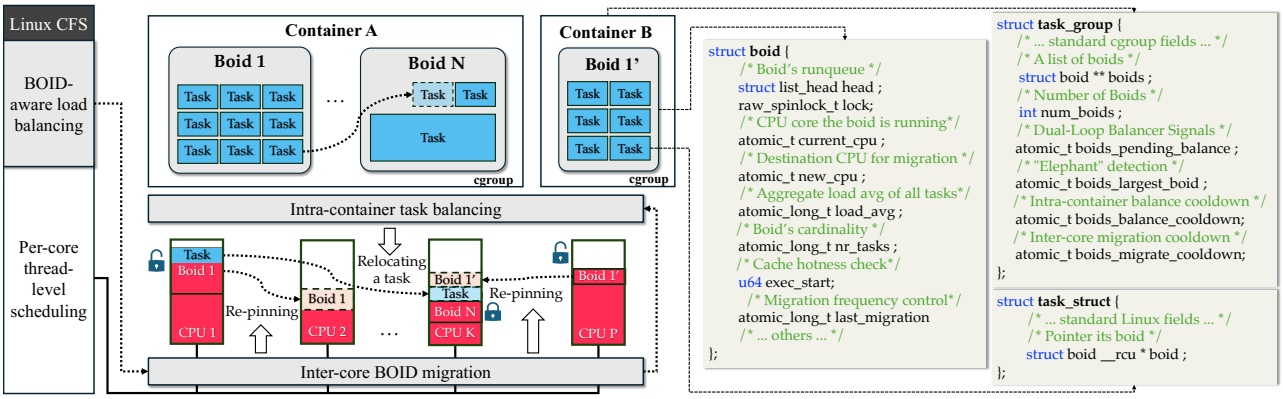

Figure 4: Architecture overview of vBOIDs (left). Key kernel data structures materializing the `boid` abstraction (right). The `boid` acts as the virtual cores (vCPUs) of containers, while `task_group` and `task_struct` are augmented to support the hierarchy.

a VM with N vCPUs. This yields a deterministic concurrency bound that eliminates the need for reactive, latency-inducing mechanisms such as CPU bandwidth quotas. Consequently, vBOIDs provides strong performance isolation by construction. In an unconstrained environment, a container with N BOIDs can utilize up to N physical cores when it has sufficient work. Under contention, the host scheduler balances load across runnable BOIDs, ensuring proportional CPU sharing at the granularity of the "virtual core" (i.e., BOIDs) rather than individual threads. Note that, vBOIDs preserves CFS's existing fairness machinery and applies it at BOID granularity: The load balancer treats BOIDs as the proportional-share entities, and per-core `vruntime` ordering still governs scheduling among threads sharing the same core. Two-level fairness properties therefore continue to hold under vBOIDs: (i) *inter-container fairness* – containers receive CPU shares proportional to their cgroup weights, summed across their BOIDs; and (ii) *intra-*BOID *fairness* – threads sharing a BOID's core compete via standard CFS `vruntime` ordering. By default BOIDs carry equal weight; they can be assigned heterogeneous weights to support fractional reservations or priorities.

4.2 Scheduling Hierarchy

While standard Linux CFS handles per-core execution and cross-core load balancing over the same set of threads, vBOIDs separates these concerns through a two-level hierarchy (Figure 4): the per-core scheduler time-shares threads assigned to each BOIDs (i.e., intra-BOID execution) on a single core, while vBOIDs's load balancer places BOIDs across cores to equalize system load (i.e., inter-BOID placement).

Intra-BOIDs execution (thread-level): At the lowest level, a BOID forms a strict execution boundary. Each BOID enforces this boundary through *dynamic affinity binding*: When a thread is assigned to a BOID (via `boids_add_task`), the kernel restricts its allowed CPU only to the physical core currently hosting that BOID. All threads whose BOIDs are mapped to a given core still compete in that core's runqueue under standard scheduling policies (e.g., `vruntime` ordering). This ensures that the hardware parallelism of a container is bounded by the number of BOIDs it is provisioned with – regardless of how many runnable threads it contains – while still preserving proportional fairness among threads sharing the same core. Notably, enforcing this invariant requires *no* changes to the scheduler's hot path; the per-core scheduler continues to select the next runnable entity on the core, guaranteed to belong to the resident BOID [3].

Inter-BOID placement (system-level): The core innovation of vBOIDs lies at the inter-BOID level, where the kernel's load balancer is extended to treat BOIDs as the atomic units of migration. vBOIDs first introduces a hierarchical load-tracking mechanism that aggregates the PELT signals (§3) of all threads within a BOID into a single, cohesive load metric (its aggregated `load_avg`). These aggregated metrics are then fed into the scheduler's existing load-balancing logic (§3), allowing the balancer to evaluate system-wide imbalance at the granularity of BOIDs rather than individual threads.

When the scheduler determines that migration is needed to equalize load, it invokes vBOIDs's *atomic migration* approach (§4.3). Instead of peeling off individual threads, the scheduler migrates the entire BOID by first atomically updating its target CPU. This operation informs the scheduler that all threads belonging to the BOID should execute on the destination core. Such BOID-level *re-pinning* is extremely lightweight and does not stall the scheduler's hot path. Threads are migrated lazily: they are removed from the source

[3] By updating each thread's allowed-CPU mask – when a thread is created or migrated – to reflect the core hosting its BOID, vBOIDs relies on the scheduler's existing CPU-selection logic. The built-in per-task CPU-admission check (`is_cpu_allowed()`), invoked during task placement (e.g., in `select_task_rq_fair()`), naturally enforces the execution boundary without requiring any changes to scheduler internals.

DISTRIBUTION STATEMENT A. Approved for public release: Distribution unlimited. Case Number AFRL-2026-0584. Dated 09 Feb 2026

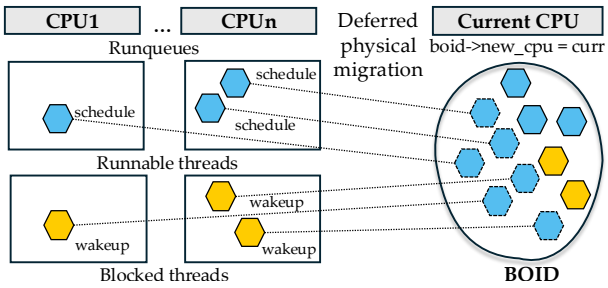

Figure 5: BOID flock-like migration.

core's runqueue and enqueued on the destination core only when they are subsequently scheduled or context-switched. Because the threads of a BOID are executed sequentially by design, the overhead of migrating the entire BOID is naturally constrained and amortized across its constituent threads.

This group-wise, atomic relocation is what gives BOIDS their flock-like behavior: placement decisions act on the collective, and individual threads simply follow the group's movement without independent negotiation. By treating the BOID as the indivisible unit of migration, the scheduler avoids the scheduling chaos of split-brain execution. The resulting hierarchy aligns the scheduler's placement decisions with the application's logical structure (i.e., BOIDS): the scheduler positions a container's BOIDS, and each BOID, once placed, carries its instruction stream on a single core.

4.3 Load Balancing

The introduction of BOIDS transforms the Linux load balancing problem from an $O(T)$ search over global threads to an $O(N)$ search over aggregate entities, i.e., BOIDS, where N represents the number of BOIDS and T denotes the number of threads – i.e., $N \ll T$. This reduction in dimensionality simplifies the scheduler's state space and yields more stable global placement decisions. vBOIDS augments Linux's default balancer with a complementary two-part migration mechanism: the *inter-core balancer* (§4.3.1) distributes BOIDS across cores to balance system-wide load, while the *intra-container balancer* (§4.3.2) distributes threads across a container's BOIDS to balance load within that container.

4.3.1 Inter-Core BOID Migration

Algorithm 1 illustrates the inter-core BOID migration logic. Traditionally, when the kernel load balancer detects a load imbalance between a source CPU (CPU_{src}) and a destination CPU (CPU_{dst}) – i.e., when `load(`CPU_{src}`) - load(`CPU_{dst}`)` exceeds the imbalance limit determined by PELT (§3) – the balancer begins scanning the runnable threads on CPU_{src}. It then migrates each movable thread (i.e., by relocating it to CPU_{dst}'s runqueue) to reduce the difference, stopping when

Algorithm 1 Inter-core BOID migration.

Require: X: source CPU; Y: destination CPU
Require: $L(X)$, $L(Y)$: load of CPUs X and Y
Require: $\theta_{\text{imbalance}} = L(X) - L(Y)$: load imbalance
Require: $\theta_{\text{imbalance}} > \theta_{\text{imbalance_t}}$ (determined by PELT §3)
Require: $L(b)$: load of BOID b
Require: $NRTasks(b)$: # tasks associated with BOID b
Require: $NRBoids$: # BOIDS in the taskgroup
Require: $R(b,X)$: residency time of BOID b on X
Require: θ_{hot}: cache-hot residency threshold
1: **for all** BOIDS b on CPU X **do**
2: **if** $\theta_{\text{imbalance}} \leq 0$ **then**
3: **break**
4: **if** $R(b,X) < \theta_{\text{hot}}$ **then**
5: **continue** ▷ Skip cache-hot BOIDS
6: **if** $L(b) > \theta_{\text{imbalance}}$ **then**
7: **if** $NRTasks(b) \geq 2$ **and** $NRBoids \geq 2$ **then**
8: CALL INTRA-CONTAINER-BALANCE
9: **if** $L(X) - L(b) > L(Y) + L(b)$ **then**
10: b.new_cpu $\leftarrow$ Y ▷ If imbalance is improved, perform migration asynchronously
11: $\theta_{\text{imbalance}} -= L(b)$

the loads converge or no additional movable threads remain. vBOIDS augments this path by evaluating BOIDS as the basic migration units, involving three main steps.

(1) *Candidate selection and locality* (line 4). The balancer first filters BOIDS based on execution history to avoid unnecessary cache disruption. For each BOID b, vBOIDS computes its residency time, $t_{res} = t_{now} - b.exec_start$. If t_{res} is below the configured hotness limit θ_{hot} (e.g., 500 μs), the BOID is considered cache-hot – its threads have recently populated the local L1/L2 caches. This BOID is thus skipped. The search is also topology-aware: a BOID is considered for migration only when CPU_{dst} lies within the same NUMA node as CPU_{src} or within the BOID's preferred node (a configurable parameter). This constraint enforces locality-preserving placement and avoids migrations that would incur unnecessary cache invalidation and NUMA penalties.

(2) *The "elephant" condition and delegation* (lines 6–8). A key challenge in coarse-grained balancing is the "elephant" BOID, i.e., an entity whose aggregate load $L(b)$ exceeds the imbalance gap between CPU_{src} and CPU_{dst} (i.e., $L(b) > \theta_{imbalance}$). Migrating such a BOID would only invert the imbalance, rather than resolve it, triggering the ping-pong effect. Instead of simply skipping these candidates, vBOIDS interprets them as a signal of *internal skew*. If an elephant BOID contains multiple runnable threads, the scheduler delegates the task-level balancing to the intra-container balancer (§4.3.2), which redistributes the BOID's internal threads across other, less-loaded BOIDS in the same container. This delegation enables vBOIDS to address fine-grained imbalance alongside the global BOID placement decisions.

(3) *Atomic actuation and convergence* (line 9-10). If a BOID satisfies the anti-thrashing condition – which guarantees that migrating it will reduce, rather than invert, the load

6: **boids_add_task**(S,t) ▷ Move task t from BOID E to S

gap – the scheduler commits to the move. The commitment is achieved using a *lazy, state-based* migration protocol that avoids taking multiple runqueue locks: Instead of immediately relocating all threads to the destination runqueue, the load balancer performs a single atomic CAS updating the BOID's target CPU state (`boid->new_cpu`). This completes the logical migration without touching per-task state.

Figure 5 illustrates this flocking-like behavior. The physical migration of threads is deferred to the context-switch path: runnable threads stay on their current runqueues, and blocked threads remain in their wakeup queues until they execute again. Upon scheduling or wakeup, each thread observes its BOID's new CPU state and migrates, causing the BOID to converge and ensuring that a thread always executes on the CPU assigned to its BOID. This two-phase mechanism allows the BOID to move atomically from the scheduler's perspective while its threads migrate asynchronously and incrementally, amortizing the cost and avoiding heavy runqueue locking. This behavior closely mirrors a VM's vCPU model, where threads execute only on the vCPU's assigned core, but differs in that BOID threads migrate lazily and independently rather than being moved as a preemptible virtual core.

Finally, the algorithm re-evaluates the load difference between CPU_{src} and CPU_{dst} (for each BOID on CPU X). If the imbalance has been neutralized ($\theta_{imbalance} \leq 0$), the search terminates (line 2), ensuring that the system performs the minimum number of migrations to restore equilibrium.

4.3.2 Intra-Container Task Balancing

By default, VBOIDS distributes threads evenly across BOIDS of a container at its initialization and when new threads are created during execution. However, as threads block, wake, and execute with varying intensity, the runnable load across BOIDS can drift over time. This imbalance breaks *work conservation* at the container level – an overloaded BOID stalls progress while underloaded BOIDS remain idle.

To address this internal skew, VBOIDS incorporates an *intra-container balancer*. Unlike VMs, which rely on a guest scheduler, VBOIDS performs this directly within the host scheduler. Unlike the default balancer, which migrates threads across arbitrary cores, VBOIDS confines redistribution strictly within the container's BOIDS. Hence, it does not reintroduce the "scheduling chaos" (§2). This intra-container balancer operates periodically or opportunistically during lifecycle events (e.g., task creation or resizing), and more importantly, cooperates with the inter-core BOID balancer.

Specifically, when a BOID is too "heavy" to migrate atomically, the inter-core balancer invokes intra-container redistribution (line 8, Algorithm 1). As Algorithm 2 further shows, once triggered, the intra-container balancer attempts to move a runnable task from the elephant BOID to the least-loaded BOID, provided two key conditions hold: (a) the load imbalance between the two BOIDS is significant enough to warrant intervention ($IB > \theta_{\text{imbalance}}$); and (b) the task is not too large, ensuring that migrating it reduces the gap rather than overshooting it ($L(t) \leq IB$). When these guards are met, the scheduler updates the task's BOID assignment (i.e., `p->boid`); the task physically migrates to the runqueue of the target BOID's core on its next wakeup or schedule event.

This pairing lets VBOIDS make progress on two fronts at once: it smooths/balances runnable load across a container's BOIDS while also reducing the size of an elephant BOID that the inter-core balancer cannot move. By shedding just enough tasks to another BOID – without overshooting – the mechanism both improves internal parallelism and turns an elephant BOID back into a migratable unit. This way, containers use their allocated BOIDS more efficiently, and BOID-level migration remains effective even under skewed workloads.

4.4 Putting It All Together

In summary, the VBOIDS architecture yields four key properties. *First*, it decouples thread execution from core placement: thread-level scheduling is handled locally preserving L1/L2 cache warmth, while expensive cross-core migrations are restricted to low-frequency and efficient structural load shifts. *Second*, it compresses the balancing state space from $O(T)$ threads to $O(N)$ BOIDS ($N \ll T$), dampening the "noise" of massive host-visible scheduling tasks and making placement decisions tractable. *Third*, its dual-path balancing approach – the inter-core balancer handles coarse-grained load drift by migrating BOIDS across cores, while the intra-container balancer corrects fine-grained skew by redistributing tasks within a container – forms a feedback system that maintains balanced utilization with minimal disruption to locality. *Finally*, it resolves the tension between isolation and utilization: unlike static pinning, which strands resources (i.e., low utilization), BOIDS remain *work-conserving* through the dual-path balancing mechanism; unlike bandwidth quotas, which enforce fairness through throttling (i.e., idling runnable tasks and in-

DISTRIBUTION STATEMENT A. Approved for public release: Distribution unlimited. Case Number AFRL-2026-0584. Dated 09 Feb 2026

creasing bursty latency), vBOIDs's concurrency bounding enforces fairness without throttling.

It is worth noticing that existing Linux task-group mechanisms control how much CPU time a container receives, but not the scheduler-visible unit of placement and migration. In contrast, BOIDS are introduced as a distinct abstraction to provide that unit: a small set of container-level virtual cores that bound concurrency and prevent thread-granularity balancing from reintroducing scheduling chaos.

5 vBOIDs Implementation

We implemented vBOIDs as a patch to the Linux 6.15 kernel, adding ∼2,000 lines of code [4] that touch the core kernel scheduler components (e.g., fair.c, pelt.c, and cgroup.c).

As depicted in Figure 4 (right), we integrate BOIDS directly into the kernel by augmenting the `task_group` structure. Each `task_group` maintains a dynamically allocated array of `struct boid` pointers. The BOID itself is a refcounted kernel object that tracks its aggregate load, current CPU, and a linked list of member tasks. To map threads to BOIDS, we modify `task_struct` to include a direct pointer to its assigned BOID. This pointer is managed via Read-Copy-Update (RCU) to allow lockless dereferencing during the scheduler's hot loop (`is_cpu_allowed`). Further, the management plane is exposed via a new `cgroup` interface file, `cpu.boids`. Writing an integer N to this file triggers a resizing operation that reallocates the BOID array and redistributes existing tasks round-robin – the existing processes within the container are distributed evenly across the new BOIDS. We determine the initial CPU affinity for a BOID based on the CPU where its first assigned process was previously resident. While integrating these data structures establishes the structural hierarchy of vBOIDs, enforcing the BOID abstraction within the scheduler's highly concurrent hot path required overcoming several challenges related to concurrency, complexity, and stability.

(1) Tunable hysteresis and locality preservation. Workloads often exhibit conflicting scheduling requirements, e.g., high-parallel tasks benefit from immediate dispatch to idle cores to minimize queuing delay, whereas latency-sensitive applications often require preserving cache locality and minimizing rebalancing overhead. To allow administrators to optimize for these conflicting goals, we introduce two tunable parameters. First, `boids_migrate_cooldown` prevents tasks from bouncing between cores during rapid interactions (by enforcing a minimum interval between migrations), which preserves cache locality. Further, `boids_balance_cooldown` stops the scheduler from overreacting to short load spikes (by throttling the frequency of load balancing events), ensuring we do not waste cycles rebalancing BOIDS for work that finishes before the migration is even complete. These parameters are enabled at the per-container level (`struct task_group`), enabling the scheduler to enforce custom migration and balancing for different workloads running on the same machine. By default, they are set to zero (i.e., no delays), which works well in most cases observed in our experiments (§6).

(2) Lazy, state-based BOID migration. A major hurdle was enforcing atomic migration without holding the runqueue locks of multiple cores simultaneously, which would induce prohibitive contention. We solved this by implementing a two-phase, flock-like lazy migration. In the load balancing path (`detach_tasks`), we do not physically move tasks. Instead, we perform a lightweight atomic CAS on the BOID's metadata (`boid->new_cpu`). The physical migration is deferred to the context switch path: we inserted a hook, `boids_post_migrate`, into `finish_task_switch`. When a thread is scheduled in, it checks its BOID's state; if the BOID has moved, the thread updates its own runqueue (`cfs_rq`) and the current cpu pointers (`current_cpu`) immediately. This allows the BOID to logically move instantly while its threads physically catch up asynchronously, eliminating the need for global runqueue locking.

(3) Zero-cost hierarchical PELT. Accurate load balancing requires aggregating the load of all threads in a BOID, but iterating over thread lists during balancing is $O(N)$. We modified the PELT update in the current PELT (§3) to perform differential aggregation (`__update_load_avg_se`). Whenever a thread's load average changes, the delta is atomically propagated to its parent BOID (`atomic_long_add`). This ensures a mathematically consistent view of aggregate demand in $O(1)$ time, without ever traversing the member threads.

(4) Lockless affinity and RCU synchronization. Enforcing strict BOID affinity (`is_cpu_allowed`) requires accessing shared BOID state during the scheduler's most performance-sensitive loops. We used RCU heavily to manage the lifecycle of BOID structures (`rcu_dereference(p->boid)`), ensuring that task placement (`select_task_rq_fair`) remains wait-free. Further, updating BOID affinity from atomic contexts (e.g., during `detach_tasks`) prevents the use of locks (`boid->lock`). Instead, we use an atomic integer to specify a BOID's current core. This primitive allows us to update a BOID's affinity atomically, ensuring no lock contention, and that the operation cannot stall the CPU.

(5) Provisioning and lightweight resizing. Provisioning BOIDS is conceptually analogous to provisioning vCPUs for a VM: the number N of BOIDS per container is workload- and deployment-dependent, and we set N to each container's expected concurrent CPU demand – the same value an operator would pick for a VM's vCPU count. Unlike VM vCPUs, however, vBOIDs allows N to be resized at runtime: the BOID array is reallocated in place, threads are re-pinned via RCU, and the operation requires neither a container restart nor thread recreation. As a result, N becomes a tunable runtime parameter rather than a deployment-time constant, and vertical

Online Boutique	moderate	moderate	moderate	11

scaling [45] – i.e., growing or shrinking a container's effective parallelism in place – becomes a lightweight operation. This makes N amenable to dynamic, load-driven adaptation; we leave a full study of such policies to future work.

6 Evaluation

Our evaluation answers a key question: *to what extent does* vBOIDs *restore placement stability and improve end-to-end performance for high-density containerized microservices?* We compared vBOIDs against various Linux configurations across a broad suite of microservice benchmarks.

Testbed. All experiments were conducted on a two-socket server equipped with two Intel Xeon Gold 6430 processors, 64 GB of DDR5 memory, and a Micron 7450 NVMe SSD formatted with ext4. Hyperthreading was disabled to avoid SMT-induced interference with a total of 64 physical cores, 32 each NUMA node. All system resources were provisioned to eliminate non-CPU bottlenecks. The machine ran Ubuntu 22.04 and our modified Linux 6.15.0 kernel, with and without vBOIDs enabled. Container experiments used Docker [1] as the container runtime; comparisons to micro-VM isolation employed Firecracker [10] configured with matching constraints for CPU and memory resources.

Workloads. We used both DeathStarBench [21] and Google Online Boutique [22] – widely used benchmarks for studying end-to-end performance in cloud-native microservices applications. DeathStarBench captures realistic service-graph compositions, request fan-out, and cross-service communication patterns typical of large-scale online services. Our experiments focus on three representative applications – Hotel Reservation, Social Network, and Media Services. Boutique [22], on the other hand, features 10 stateless services connected via synchronous RPCs and multiple aggregation points in the frontend. They collectively exercise a spectrum of CPU intensity, branching factors, and latency sensitivities, as summarized in Table 2.

Baselines for comparison. We evaluated vBOIDs against four baselines. (1) *Containers (Default):* each microservice runs as a Docker container, with CPU allocations constrained using `cgroups` and typically assigned 1–4 cores based on measured utilization; threads can execute on any available physical core (no pinning). (2) *Firecracker (Default):* each microservice runs inside a Firecracker micro-VM [10], provisioned with 1–4 vCPUs to match the container allocations; vCPUs can freely migrate across cores. (3) *Containers (Pinned)* and (4) *Firecracker (Pinned):* container threads or Firecracker vCPUs are manually pinned to specific cores or core groups using CPU affinity, ensuring the same CPU resources as those in (1) and (2). (5) vBOIDs*:* our approach, configured with the same number of BOIDS as the number of cores allocated to each container or vCPU count in the Firecracker configurations. These baselines are referenced throughout the evaluation for brevity. We collected workload- and system-level performance metrics – e.g., throughput, average and tail latency, CPU utilization, scheduling frequency, and cache activity.

6.1 End-to-End Performance

We first demonstrate the end-to-end performance using Hotel Reservation, Social Network, and Media Services under various configurations. We generated load to them using `wrk2` configured with an exponential inter-arrival distribution for requests, `20` threads, and a total of `60` connections. Each experiment ran for 60 seconds after a brief warm-up. Unless otherwise noted, we set `boids_balance_cooldown` and `boids_migrate_cooldown` to 0 to allow unthrottled balancing activity; cooldown effects are explored separately in our sensitivity analysis. To ensure fairness, resource provisioning is normalized across all configurations: the number of BOIDS, vCPUs, and physical cores is matched for vBOIDs, micro-VMs, and Docker containers, respectively.

Hotel Reservation was our motivating case (§2), where Container (Default) triggered the migration storms and locality destruction. We return to this workload to evaluate whether vBOIDs eliminates these effects in a real deployment.

Figure 1 reports end-to-end throughput under increasing RPS load (requests per second), measured only within the range where latency satisfies a 200ms SLO. As load increases, *Container (Default)* collapses early, saturating before 1k RPS. *Container (Pinned)* and both Firecracker configurations extend beyond 4k RPS due to reduced inter-core migration. vBOIDs sustains high throughput up to 4k RPS. Figure 2 shows the corresponding latency trends. *Container (Default)* exhibits sharp spikes around 1k RPS, while vBOIDs remains close to the manually pinned case, maintaining low latency through 4k RPS.

These performance trends align with the inter-core migration data in Figure 3 and micro-architectural data in Table 1, collected using `perf` over a 10-second steady-state window (for 1k RPS). First, *Container (Default)* incurs the highest inter-core migrations and cache/TLB miss rates, whereas vBOIDs dramatically reduces migration frequency and increases cache efficiency. Further, vBOIDs matches the migration behavior of *Firecracker (Default)*, recreating vCPU-like

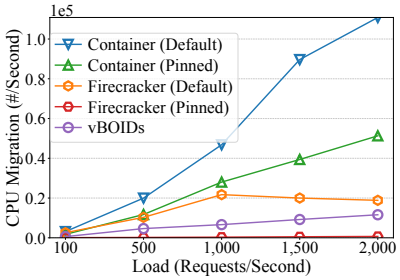

Figure 11: CPU Migrations for Media Microservices under varying workloads.

execution using BOIDS. Last, vBOIDs incurs even fewer inter-core migrations than *Container (Pinned)*, where threads remain confined to a subset of cores and still migrate frequently within that group, especially when load is high.

Overall, vBOIDs improves throughput by *over 3*× compared to *Container (Default)* and matches the performance of *Container (Pinned)* and *Firecracker (Pinned)* – all without manual pinning and while preserving full container flexibility. vBOIDs is lightweight: its overall CPU% (Table 1) is 40% of *Container (Default)* and 80% of *Container (Pinned)*.

Social Network, compared to Hotel Reservation, features a deeper, more highly branched service graph and generates a larger runnable thread set when containerized.

For throughput, as reported in Figure 6, *Container (Default)* saturates early, flattening near 2k RPS. Both vBOIDs and *Container (Pinned)* perform substantially better, sustaining close to 5k RPS, still meeting the SLO, while both Firecracker configurations follow the pinned curve till up to 3k RPS. Figure 7 captures the latency behavior. Consistent with its early saturation, *Container (Default)* experiences sharp latency spikes around 2k RPS while both Firecracker configurations can sustain till 3k RPS. In contrast, vBOIDs and *Container (Pinned)* remain stable and low-latency up to 5k RPS. Figure 8 and Table 3 explain this behavior: At 1k RPS, *Container (Default)* exhibits extremely high inter-core migrations and elevated cache/TLB miss rates, whereas vBOIDs cuts migrations by 85% and with lower cache/TLB misses.

This demonstrates that vBOIDs's coarse-grained scheduling remains effective even for deep, fan-out–heavy service graphs – not only outperforming *Container (Default)* but also surpassing both pinned and default Firecracker configurations. vBOIDs behaves just like *Container (Pinned)* in terms of performance (both throughput and latency), yet achieves this without any manual pinning. Meanwhile, vBOIDs maintains low CPU utilization, again underscoring its efficiency.

Media Services differs from the previous two workloads in that it is substantially more CPU-intensive and issues far fewer fine-grained RPCs. During execution, it rapidly spawns many short-lived threads that aim to run immediately on any available core. Hence, this workload benefits from maximizing hardware parallelism, making *Container (Default)* – with its unconstrained access to all cores – particularly effective.

Figure 9 shows that all, except *Firecracker (Default)*, scale up to 2k RPS. In Figure 10, as Media Services benefits from maximal hardware parallelism, the unpinned cases, *Container (Default)* and vBOIDs, outperform the pinned ones, *Container (Pinned)* and *Firecracker (Pinned)*, reflected in the lower latencies. vBOIDs achieves this by adaptively issuing more inter-core migrations (Figure 11 and Table 3) than those in Hotel Reservation and Social Network, enabling it to better exploit available hardware parallelism. These results show that vBOIDs delivers performance on par with the most ef-

fective configurations, even when high inherent parallelism reduces the advantage of migration control.

In summary, for workloads dominated by scheduling chaos (Hotel Reservation and Social Network), vBOIDs' coarse-grained BOID abstraction sharply reduces destructive inter-core migrations and preserves locality, achieving performance comparable to pinned configurations. In workloads with high inherent parallelism (Media Services), vBOIDs remains lightweight while matching the fastest unpinned configuration. These results show that vBOIDs delivers VM-like stability while retaining container flexibility and efficiency.

6.2 CPU Balancing and Stability

In Figure 12 (bottom), because the CPU scheduler now schedules at BOID granularity, vBOIDs exhibits VM-like per-core average CPU utilization – naturally uneven across cores due to the smaller number of schedulable units. Figure 12 (top) shows that vBOIDs's flocking-like migration behavior – where BOIDS move logically atomically but physically asynchronously – produces container-like total CPU stability, maintaining smooth, steady utilization comparable to thread-level container scheduling and avoiding the sharp oscillations seen in VMs. Together, it shows that vBOIDs combines the most desirable behaviors of VMs and native containers.

Figure 15 further presents a per-core view of CPU utilization over time under vBOIDs, with each line representing a single physical core. Individual cores exhibit natural variability driven by BOID migrations and intra-container task balancing, yet most cores remain stably clustered around 50% utilization, showing that vBOIDs maintains healthy load diffusion and remains fully *work-conserving* rather than creating persistent hotspots or underutilized cores. Consistent with this pattern, vBOIDs performs only a modest number of BOID migrations (e.g., roughly 600 over 60 s), relying instead on more frequent fine-grained intra-container task redistributions (e.g., about 16k events). This confirms that vBOIDs preserves global stability through coarse-grained BOID placement while using intra-container balancing to smooth local fluctuations without inducing system-wide oscillation.

6.3 Sensitivity and Scalability

We evaluated the impact of the inter-container balancing cooldown (`boids_balance_cooldown`) and inter-core migration cooldown (`boids_migrate_cooldown`) on two distinct workload profiles: Social Network (RPC-heavy) and Media Services (CPU-bound), as shown in Figure 13.

Sensitivity. For RPC-heavy workloads like Social Network, active intra-container balancing is essential. Because the workload is not fork-heavy, tasks are initially well distributed across BOIDS but remain long-lived, causing substantial load drift over time. Disabling balancing (`boids_balance_cooldown=-1`) or delaying it via a large cooldown degrades performance as BOIDS gradually become imbalanced. In contrast, the migration cooldown has little effect: the workload's moderate CPU intensity results in fewer inter-core migrations, leaving system behavior largely insensitive to migration throttling. Consequently, a low balancing cooldown is ideal, ensuring that vBOIDs aggressively corrects internal skew as it emerges.

In contrast, Media Services exhibit high-frequency forking of short-lived, CPU-intensive threads. This workload is largely insensitive to parameter tuning for two reasons. First, vBOIDs's placement policy assigns new forks to the least-loaded BOID, ensuring the container remains inherently balanced without requiring reactive intervention from the intra-container balancer. Second, because the workload is CPU-bound, BOIDS often remain heavy ("elephants"), which naturally suppresses inter-core migration regardless of the cooldown setting. Consequently, performance variance in this test is driven more by the high load intensity (`1.5k` RPS) and run-to-run noise than by specific scheduling parameters.

Scalability. We subjected the Social Network workload (fixed at 2k RPS) to increasing levels of background containers, simulating a high container deployment environment. We intro-

duced up to 1,000 "noise" containers, each provisioned with a single BOID and running a light workload (1–2% single core utilization). We compared VBOIDS against both default and pinned container baselines (i.e., we only pinned Social Network BOIDS, not the background container ones). As shown in Figure 14, both VBOIDS and the pinned configuration successfully maintain the target throughput even as background noise scaled to 1,000 containers, where the average latency under VBOIDS starts to increase.

6.4 Kubernetes

To evaluate VBOIDS in a production setting, we deployed the Google Online Boutique benchmark on Kubernetes [5], ramping load to 2k concurrent users via Locust [7]. The Locust workload emulates randomized user actions in the store, including product browsing, currency changes, cart views, add-to-cart operations, and checkout; these actions generate a realistic mix of read-heavy requests (e.g., `/product/<id>`, `/cart`) and state-mutating requests (e.g., `/cart`, `/cart/checkout`). In our setup, Online Boutique exposes 359 scheduler-visible units in the standard containerized deployment, which VBOIDS reduces to 31 BOIDS. We compared VBOIDS (2 BOIDS/pod) against standard unpinned pods and manually pinned pods (2 CPUs/pod). While average latencies were comparable, the unpinned baseline suffered severe tail latency degradation (p95 exceeding 4000ms). Conversely, VBOIDS matched the throughput and tail latency (under 500 ms) of the pinned configuration, achieving pinning-grade stability without manual intervention.

Resource partitioning and QoS-aware scheduling. To mitigate interference in co-located environments, prior work [13, 15–17, 31, 32, 35, 39, 55] has largely focused on resource partitioning and sensitivity-aware placement. Systems such as Heracles [35] and PARTIES [13] rely on feedback loops to

dynamically partition resources and protect latency-critical services from best-effort batch jobs. Similarly, Paragon [15] and Quasar [16] use collaborative filtering to classify workloads and avoid placing contentious applications on the same node. While these approaches reduce "noisy neighbor" interference via hardware isolation, they do not address the *scheduling overhead* itself. In contrast, vBOIDs fundamentally alters how the scheduler perceives container concurrency to prevent scheduling thrashing.

User-space and extensible scheduling. A growing body of work [18, 19, 24, 26, 29, 30, 42–44] argues for moving scheduling logic out of the kernel to support the high-frequency requirements of microservices. Systems such as Caladan [19], Shinjuku [30] and Arachne [44] implement user-space schedulers that bypass the kernel entirely to achieve microsecond-scale tail latency. More recently, Google's GhOSt [26] and the Linux `sched_ext` [24] framework utilize eBPF to delegate scheduling policies to userspace agents, allowing for rapid policy modifications. While effective, these approaches impose significant adoption barriers: they often require recompiling applications against custom libraries (e.g., Arachne and Caladan) or managing complex userspace agents (e.g., GhOSt). vBOIDs acts as a middle-ground: it retains the transparent, drop-in nature of the standard kernel scheduler, while introducing schemes to mitigate *scheduling chaos*.

Lightweight virtualization. Micro-VMs, such as Firecracker [10] and Kata Containers [4] address multi-tenancy by enforcing strong isolation boundaries [3, 4, 10, 12, 25, 33, 40, 47]. They expose a fixed set of vCPUs to the host scheduler, rather than all guest processes/threads, which naturally mitigates *scheduling chaos* and stabilizes load balancing. However, they also introduce full virtualization overhead and reduce flexibility in resource over-subscription. vBOIDs effectively extends the vCPU abstraction to native containers, providing the stability of a vCPU without the performance penalty of full virtualization or the rigidity of fixed resource constraints.

8 Discussions

vBOIDs bridges the gap between spatial partitioning (pinning) and temporal throttling (CFS quotas). vBOIDs adopts *spatial concurrency bounding* – by mapping threads onto a fixed set of migratable BOIDs, it bounds a container's parallelism – while preserving *temporal flexibility* through a two-level scheduling hierarchy. This provides pinning-like isolation benefits and quota-like fairness benefits.

However, *short-lived* microservices that rely on rapid forking pose unique placement challenges. Placing child threads on the parent's BOID maximizes locality but can temporarily bottleneck execution on a single core. Because these tasks are short-lived, they may complete before the kernel's load balancer can detect and correct the imbalance. vBOIDs mitigates this issue by adopting a parallelism-first placement policy: newly created threads are assigned to the least-loaded BOID in the taskgroup, enabling immediate load spreading and reducing transient hotspots. This design is particularly effective for bursty workloads with enough available BOIDS to absorb short-term parallelism. However, vBOIDs may be less beneficial for extremely short-lived, highly parallel workloads whose execution time is too brief to amortize placement and cache-warming effects, or when the number of provisioned BOIDS is significantly lower than the workload's instantaneous parallelism. In such cases, load spreading can be constrained by BOID availability, and the latency benefit may be reduced.

This can be further addressed via custom policies. The stable execution provided by vBOIDs offers an ideal substrate for delegating fine-grained scheduling decisions to userspace frameworks, like GhOSt [26] or sched_ext [24]. Future work could leverage this to implement custom, application-specific policies atop their assigned BOIDS, effectively insulating their internal logic from the host placement. While we currently implemented vBOIDs by modifying the kernel code (5), we are also exploring the use of eBPF or sched_ext for a more modular and easily deployable implementation.

9 Conclusion

We presented vBOIDs, a container scheduling system that restores stability to high-density container deployments by raising the scheduler's placement granularity from individual threads to BOIDS. By introducing BOIDS as container-level virtual scheduling units, vBOIDs decouples thread-level execution from host-level placement, allowing the kernel to make fewer, more stable, and more locality-preserving scheduling decisions. vBOIDs combines this coarse-grained abstraction with a two-level balancing mechanism. The inter-core balancer migrates BOIDS as aggregate units to reduce global imbalance, while the intra-container balancer redistributes tasks across a container's BOIDS to preserve work conservation and avoid internal hotspots. This design provides VM-like placement stability without requiring full virtualization, manual pinning, or rigid CPU partitioning, meanwhile preserving the flexibility and efficiency of containers that are attractive for cloud-native deployment. Our evaluation shows that vBOIDs substantially reduces migration-induced locality disruption and improves end-to-end performance for chaos-prone microservice workloads. vBOIDs's abstraction provides a practical foundation for future adaptive policies, including dynamic BOID provisioning and user-extensible scheduling.

Efficient LLM Serving on Commodity GPU Clusters with Data-Reduced Cross-Instance Orchestration

Jiangsu Du* Hongbin Zhang* Taosheng Wei Zhenyi Zheng
Jiazhi Jiang Kaiyi Wu Zhiguang Chen Yutong Lu†

School of Computer Science and Engineering, Sun Yat-Sen University

Abstract

Existing LLM serving strategies can be categorized by whether prefill and decode phases are disaggregated: non-disaggregated (NoDG) or fully disaggregated (FuDG). However, they neither fit commodity GPU clusters, which remain widely deployed as mainstream AI infrastructure. NoDG suffers from severe prefill–decode interference, while FuDG depends heavily on high-performance interconnects that such clusters lack.

We present EcoServe, an LLM serving system tailored to commodity GPU clusters. It enables a data-reduced collaboration among inference instances to mitigate prefill-decode interference, termed the partially disaggregated (PaDG) strategy. Particularly, within a single instance, PaDG disaggregates the prefill and decode phases along the time dimension to mitigate interference and enhance throughput. Next, it coordinates multiple instances and cyclically activates them to ensure the continuous availability of prefill processing, thereby rescuing latency. Thus, EcoServe's basic serving unit is the macro instance, within which multiple instances collaborate. It further incorporates an adaptive scheduling algorithm to route requests in a macro instance and a mitosis scaling approach for fine-grained capacity adjustments in online scenario.

On a 32-GPU NVIDIA L20 cluster over Ethernet, EcoServe improves goodput by 1.96×, 1.99×, 2.51×, and 2.40× when serving 30B- and 70B-scale LLMs, compared to four representative NoDG and FuDG systems, vLLM, Sarathi, DistServe, and MoonCake. EcoServe remains competitive even on an NVIDIA H100 cluster with NVLink and InfiniBand. Our code is released at https://github.com/MLSysU/EcoServe.

1 Introduction

Large language models [10, 18, 46] (LLMs) have been widely adopted in various tasks. Handling these massive LLM inference workloads requires cluster-level deployment. Recent years have witnessed the emergence of increasingly advanced GPU architectures, from H100 to GB200, offering higher compute density, larger memory bandwidth, and significantly improved interconnect capabilities. Although such devices are widely promoted and actively used in LLM research, their high cost and the slow refresh cycle of production environments imply that, in practice, commodity GPU clusters without high-performance interconnects still account for a significant share [15, 39, 47]. This observation aligns with popular LLM serving works such as Sarathi [7], DistServe [55], and FlexGen [42], all of which evaluate on GPU nodes with weak or commodity interconnects. Moreover, our study is conducted on an NVIDIA L20 cluster that provides LLM serving for a major super app of a top-tier Internet company. Consequently, efficiently serving LLMs on commodity GPU clusters remains essential.

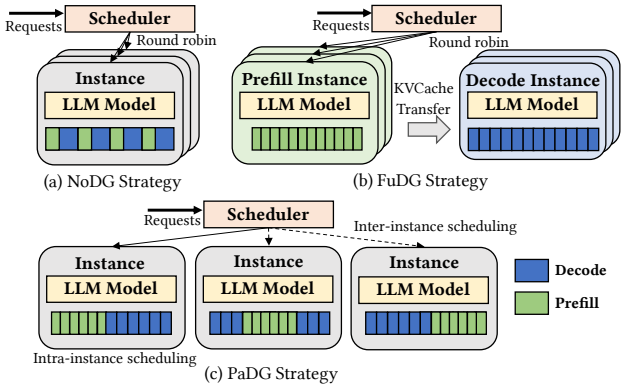

Figure 1: The NoDG, FuDG, and PaDG strategies.

LLM inference consists of two distinct phases, the prefill phase and the decode phase, each associated with a different latency SLO, time to first token (TTFT) and time per output token (TPOT). These two latency goals, together with throughput, form an inherent performance trade-off triangle. Existing cluster-level LLM inference solutions [2, 4, 7, 35, 37, 52, 55] can be categorized based on whether prefill and decode phases

*Jiangsu Du and Hongbin Zhang contributed equally.
†Corresponding author

are disaggregated: the non-disaggregated (NoDG) strategy and the fully disaggregated (FuDG) strategy. They both have severe limitations for commodity GPU clusters, either incurring severe interference between prefill and decode phases, or heavily depends on high-performance interconnects.

As shown in Figure 1(a), given that the prefill and decode phases share model weight and KV cache, the NoDG strategy [2,4,7,52], which colocates the two phases within a single instance and replicates multiple instances, appears to be a natural choice. Such colocation inevitably leads to significant inter-phase interference [35, 53, 55]. As two phases execute alternatively, prioritizing the scheduling of one phase risks violating the latency requirements of the other. This interference also harms throughput, as the decode phase cannot accumulate a sufficiently large batch size to saturate GPU resources.

As illustrated in Figure 1(b), FuDG [35, 37, 55] proposes to fully eliminate the prefill-decode interference by assigning the two phases to separate instances. However, since massive amounts of KV cache must be transferred between prefill and decode instances, it relies on hyper-clusters with powerful interconnects as the default hardware infrastructure, as exemplified by the FuDG approach in DistServe [55]. Unfortunately, high-performance interconnects like NVLINK and InfiniBand are not only costly and power-hungry, but also demand substantial technical expertise for construction and maintenance. Moreover, scaling FuDG involves adjusting both prefill and decode instances, which complicates load balancing [28].

EcoServe is designed to deliver cost-effective LLM serving on commodity clusters, without relying on high-performance interconnects. As shown in Figure 1(c), our key observation is that intra-instance scheduling, which determines when to execute prefills and decodes, should be coordinated with inter-instance scheduling, which decides when and where requests should be routed, to raise the upper bound of the trade-off triangle and fully utilize available resources. Thus, EcoServe incorporates temporal disaggregation and rolling activation to proactively schedule at intra- and inter-instance levels, so called the partially disaggregated (PaDG) strategy.

Within a single instance, the prefill and decode phases are disaggregated along the time dimension, with each phase lasting longer. By reducing prefill-decode switching frequency, it mitigates interference and achieves higher throughput. Moreover, since both phases are still in a single instance, PaDG avoids massive KV cache transmission. Next, to meet latency SLOs, it proactively coordinates multiple instances in a cyclic pattern. At any given time, at least one instance is activated to process prefills, thereby ensuring acceptable TTFT latency. A group of such cooperating instances is referred to as a macro instance.

EcoServe further includes an adaptive scheduling algorithm and the mitosis scaling approach. The adaptive scheduling algorithm guides request scheduling within the macro instance.

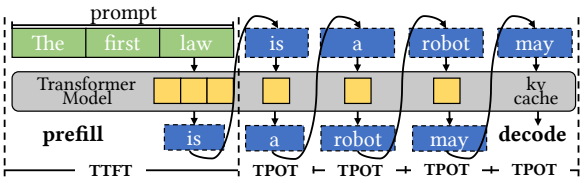

Figure 2: LLM autoregressive decoding process.

While prioritizing the maintenance of satisfactory TPOT, it identifies the most suitable instance for admitting new requests and determines the optimal number of prefill tokens that can be inserted into that instance. The mitosis scaling approach enables fine-grained control over system capacity by continuously adjusting the number of instances within multiple macro instances. A serializable proxy object is introduced to support logical migration between macro instances without interrupting execution. Our contributions are summarized:

- We present EcoServe for cost-effective LLM serving on clusters with commodity interconnects. It is based on the PaDG strategy, along with the adaptive scheduling algorithm and the mitosis scaling approach.
- We implement EcoServe in a hierarchical architecture.
- We evaluate EcoServe and compare it against four representative LLM inference systems, i.e. vLLM [4], Sarathi [7], DistServe [55], and MoonCake [37] on clusters equipped with either commodity or high-performance networks, demonstrating its superior efficiency.

2 Preliminary and Motivation

2.1 LLM Inference Characteristics

As illustrated in Figure 2, the LLM predicts the next token with the accumulated context iteratively until it encounters the end-of-sequence (EoS). By saving the key and value embedding in the memory (i.e. KV cache), redundant computations are avoided in subsequent steps, thus the inference process is divided into prefill and decode phases. A request consists of a single prefill followed by tens or even hundreds of decode steps. Modern LLMs primarily adopt the Transformer architecture [48], which leverages the self-attention mechanism to model complex dependencies in sequences. Here we conclude its computation and memory characteristics.

Distinct arithmetic intensity. Transformer's computation involves four main parts: QKV projection, QKV attention, output projection, and dim expansion and reduction. In these parts, matrix multiplications dominate computation time, while softmax and layer normalization contribute only marginally. Table 2 lists six major matrix multiplications,

Table 1: Notations.

Variable	Description	Notation
prompt_len	The length of prompt	S
generation_len	The length of generated tokens	G
batch_size	The number of batched requests	B
layer_num	The number of model layers	L
hidden_size	Input dimension of the hidden layer	H
heads	The number of attention heads	M
size_per_head	The hidden state per head	D

Table 2: Approximate arithmetic intensity (AI) of primary operations in LLMs. Negligible factors are omitted.

Operation	P/D	FLOPS	Memory Access	Approximate AI
QKV Projection	Prefill	$6BSH^2$	$6BSH+3H^2$	BS
	Decode	$6BH^2$	$6BH+3H^2$	B
Attention QK^T	Prefill	$2BS^2H$	$2BSH+BS^2M$	S
	Decode	$2BSH$	$2BSM+BH(S+1)$	1
Attention $(QK^T)V$	Prefill	$2BS^2H$	$2BSH+BS^2M$	S
	Decode	$2BSH$	$2BSM+BH(S+1)$	1
Output Projection	Prefill	$2BSH^2$	$2BSH+H^2$	BS
	Decode	$2BH^2$	$2BH+H^2$	B
Dim Expansion	Prefill	$8BSH^2$	$2BSH+4H^2$	BS
	Decode	$8BH^2$	$2BH+4H^2$	B
Dim Reduction	Prefill	$8BSH^2$	$2BSH+4H^2$	BS
	Decode	$8BH^2$	$2BH+4H^2$	B

whose arithmetic intensities are computed separately for prefill and decode using the hyperparameters in Table 1. Negligible terms (e.g., $1/H$) are omitted for approximation. Prefill intensity depends on both sequence length S and batch size B, while decode depends merely on B and requires additional KV cache loading. Thus, prefill is compute-bound, whereas decode is memory-bound.

Memory-compute trade-off. During LLM inference, limited memory capacity constrains computational parallelism, making parallel inference a potential avenue of superlinear speedup. Beyond model weights, the KV cache is the primary contributor to memory usage. In the decode phase, processing hundreds of requests simultaneously leads to substantial memory consumption. For example, in Llama-30B, a single token requires 1.52 MB of KV cache, so 128 requests with an average output of 300 tokens consume about 58.4 GB, comparable to the model weights. Moreover, since input and output lengths are stochastic and outputs remain unknown until completion, memory must be over-provisioned to avoid OOM, further complicating resource allocation.

2.2 LLM Batching Techniques

To fully utilize modern GPUs, batching is commonly adopted in deep learning workloads, where multiple samples are processed simultaneously to expose high parallelism. Regarding whether to pack prefill and decode together, modern LLM serving systems adopt either separate batching [4] or hybrid batching [7]. Separate batching handles prefills and decodes independently. Since prefills are compute-bound, even a batch size of one can saturate the GPU, whereas decodes

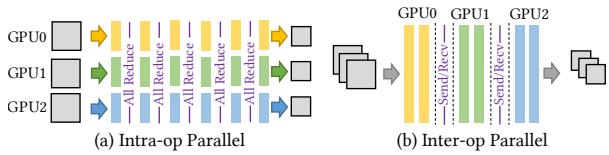

Figure 3: Intra-op and inter-op parallelism.

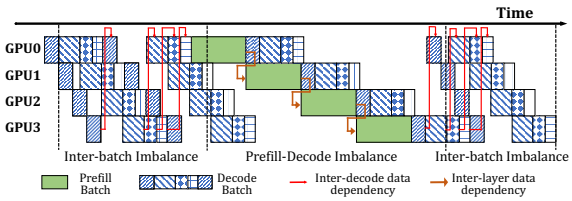

Figure 4: The inter-op parallelism with separate batching suffers from severe pipeline bubbles.

are memory-bound and require hundreds of requests to do so. By contrast, hybrid batching organizes requests of both prefill and decode phases in a hybrid batch.

2.3 Scale-up LLM Inference

To scale up both computational and memory capacity within a single inference instance, LLMs adopt several forms of parallelism, can be categorized to intra-op parallelism [12, 22, 30, 41, 43, 44] and inter-op parallelism [20, 27, 34, 53]. As shown in Figure 3, intra-op parallelism splits each layer across multiple GPUs, with model weights and KV cache evenly distributed among workers to accelerate single inference runs. It introduces frequent collective communication [13, 14].

Inter-op parallelism partitions a model layer-wise, with each device handling tens of consecutive layers. As a result, communication is limited to lightweight point-to-point transfers that occur only every few layers. The largely-reduced communication makes it a promising approach to support LLM serving, especially on commodity hardware that high-performance intra-node interconnects like NVLINK are unavailable. However, as illustrated in Figure 4, the varied input lengths and the inter-iteration dependencies in the decode lead to imbalanced and interdependent micro-batches [7, 53], causing severe pipeline bubbles.

2.4 Scale-out LLM Serving

The adoption of cluster-level infrastructure have become essential to meet the increasing demands of LLM workloads. There are NoDG and FuDG strategies.

Table 3: KV cache generation speed in the prefill instance. Here each node includes 8 GPUs and intra-op parallelism is used when a single GPU's memory capacity is insufficient.

Model	Device	Tokens/s	Data volume
Llama-30B	L20	6584.6	9.796 GB/s
Llama-30B	A800	26189.2	38.96 GB/s
Llama-30B	H100	64220.0	95.54 GB/s

2.4.1 Non-Disaggregated Strategy

NoDG [3, 4, 7] colocates prefills and decodes in a single instance, which manages the entire life-cycle of a request. In Figure 1(a), when one instance cannot handle the incoming load, the system scales out by replicating additional independent instances. NoDG supports both separate batching and hybrid batching. However, since prefills typically take much longer than a decoding step, joint scheduling causes decodes to be delayed, significantly increasing TPOT; conversely, the inclusion of decodes leads to non-trivial increases in TTFT. Thus, NoDG often exhibits low throughput as the decode phase struggles to accumulate a sufficiently large batch size to saturate the GPU under SLO constraints. To mitigate this, chunked prefill [7] divides a prefill into smaller chunks and processes over multiple iterations, but it incurs repeated KV cache accesses and heavily depends on the input-to-output length ratio. Moreover, NoDG is poorly compatible with pipeline parallelism [7, 53] due to load imbalance and interdependence.

2.4.2 Fully-Disaggregated Strategy

In Figure 1(b), FuDG [35, 37, 55] disaggregates the prefill and decode phases into separate instances, with the KV cache transferred between them. Although it avoids prefill-decode interference, it incurs data transmission [55], load imbalance [28], and complex engineering.

For data transmission, Table 3 reports the KV cache generation rate on GPU nodes (all prefill instances), indicating the volume of data to be transferred. For LLaMA-30B on a node with 8 NVIDIA A800 GPUs, the required output bandwidth reaches 39 GB/s, necessitating at least a 400 Gbps network. These represent only theoretical lower bounds; in practice, the small granularity of KV cache blocks and the complexity of interconnect topology further increase bandwidth demand. More critically, many commodity clusters were never provisioned with high-performance inter-node communication networks, making FuDG less suitable in such environments.

FuDG can be further classified into intra-node FuDG (DistServe [55]) and inter-node FuDG (MoonCake [37]), depending on whether prefill and decode instances are colocated within the same node or distributed across nodes. DistServe targets scenarios with insufficient inter-node interconnects by deploying prefills and decodes within a node and transferring KV cache via intra-node links. MoonCake designs a centralized KV cache pool and relies on InfiniBand to connect prefill and decode instances across nodes.

Besides large data transfer, FuDG suffers from load imbalance, limited parallelism compatibility, and high engineering complexity. 1) Load imbalance occurs in both computation and memory. On the computation side, continuously varying input and output lengths make it difficult to determine an appropriate number of prefill and decode instances. On the memory side, decode instances must retain large amounts of KV cache, whereas prefill instances require far less. 2) Limited compatibility with intra-op parallelism on nodes without GPU-direct links, as collective communication and KV-cache migration contend heavily for bandwidth. 3) Coordinating resources, communication, and memory across instances significantly increase engineering complexity, hindering adoption by small teams.

3 EcoServe Design

Figure 5 demonstrates EcoServe's architecture. It follows the partially disaggregated (PaDG) strategy and proactively orchestrates both intra- and inter-instance execution. Specifically, the prefill and decode phases are disaggregated along the time dimension in each instance (temporal disaggregation) to mitigate interference, while coordination is conducted across different instances to ensure continuous availability (rolling activation).

The system adopts a hierarchical architecture with three levels of scheduling, i.e. the instance scheduler, the macro-instance scheduler, and the overall scheduler. The instance scheduler manages execution within a single instance, including prefill–decode coordination, device orchestration, and compliance with higher-level directives. The macro-instance scheduler coordinates multiple instances by aggregating their execution states and dispatching requests according to profiling results and SLOs. The macro instance is a unique abstraction in EcoServe and serves as the basic unit. Finally, the overall scheduler assigns requests to macro-instances based on their capabilities. In this work, we focus primarily on the internal architecture of a macro-instance.

Furthermore, EcoServe integrates an adaptive scheduling algorithm and a mitosis scaling approach to enable the practical adoption of PaDG. The adaptive scheduling algorithm coordinates instance- and macro-instance schedulers in a master–worker pattern. The mitosis scaling approach enables capacity adjustments at the instance level rather than the coarser macro-instance level, enabling fine-grained resource utilization. To support this, a serializable proxy object is designed to seamlessly add or remove instances.

3.1 Partially Disaggregated Strategy

PaDG enables a data-reduced collaboration across instances to alleviate prefill–decode interference. It achieves this

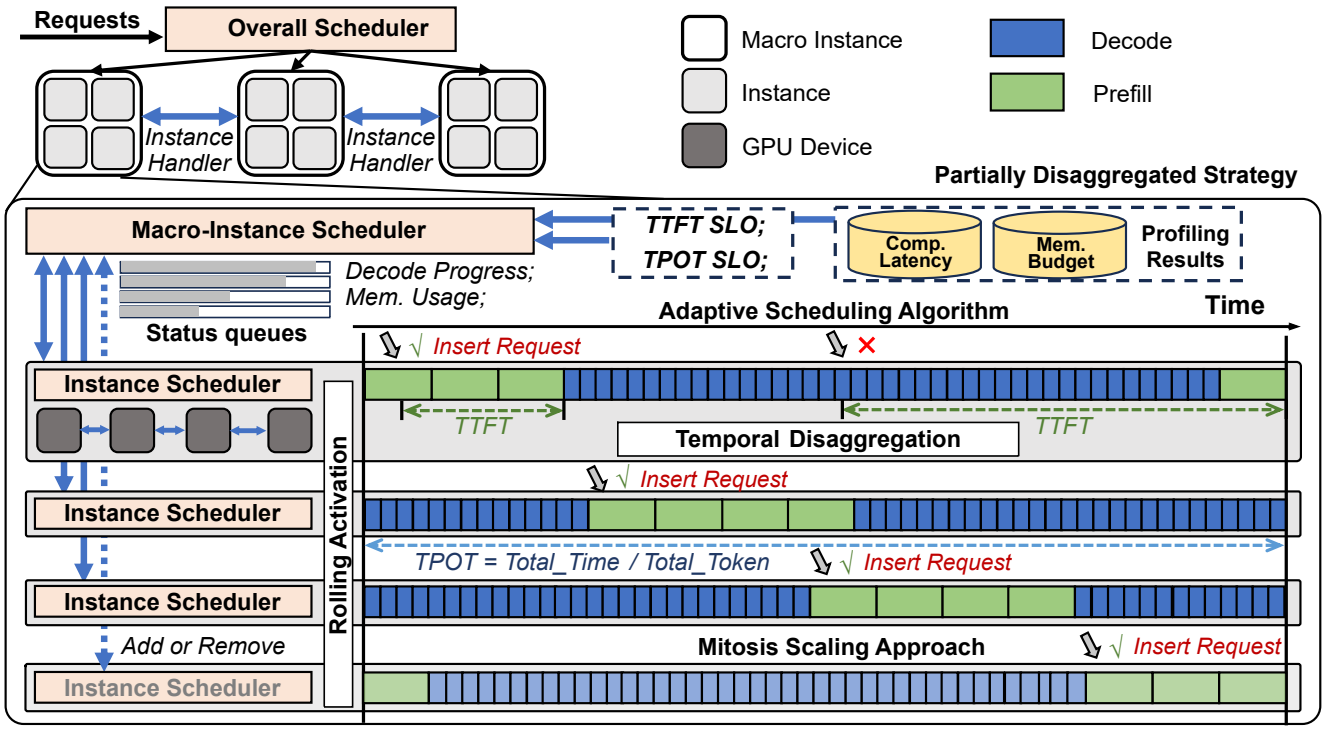

Figure 5: EcoServe adopts a hierarchical architecture in which the system consists of multiple macro-instances, and each macro-instance comprises multiple instances. The macro instance is the basic unit, within which multiple instances collaborate.

through employing temporal disaggregation and rolling activation to proactively schedule requests at both intra- and inter-instance levels.

3.1.1 Temporal Disaggregation

PaDG takes the proactive intra-instance scheduling to disaggregate the prefill and decode phases along the temporal dimension within each instance to mitigate prefill-decode interference. Unlike the FuDG strategy, which assigns dedicated prefill and decode roles to different instances, PaDG maps these roles to different time slots on the same instance. This design keeps the KV cache local and eliminates the need for explicit KV cache transmission, thereby improving on-device resource utilization and avoiding cross-instance data movement.

Since each phase occupies an instance for an extended period, intra-instance scheduling along risks degrading TTFT. As shown in Figure 5, when a new request arrives at an instance currently processing prefills, it can be immediately admitted, thereby meeting the TTFT SLO. However, if the instance is in the decode phase, the request must wait until the next prefill window, potentially resulting in unacceptable TTFT violations.

In contrast, modern LLM serving systems typically render outputs in a typewriter fashion, where the TPOT SLO can be satisfied once enough tokens are produced within a given time window. This allows decode execution, when faster than the TPOT constraint, to accumulate slack time (referred to as saved TPOT), which can then be leveraged to interrupt decodes for prefills without violating TPOT requirements.

3.1.2 Rolling Activation

Although a single instance can only remain in either the prefill or decode phase at any given time and therefore cannot immediately process newly arrived requests, rolling activation addresses this by proactively scheduling multiple instances and staggering their prefill phases over time, ensuring continuous prefill availability. As illustrated in Figure 5, instances enter the prefill phase in a cyclic pattern. From the perspective of individual requests, they are always routed to an instance currently processing prefills and can be admitted immediately. Thus, rolling activation reduces waiting time and preserves TTFT. Since output lengths are unknown, instances must continuously update their status, such as decode progress and memory usage, to the macro-instance scheduler for immediate coordination.

3.2 System Metrics for User Experience

Figure 6 illustrates the timing of both runtime and frontend. Once a token is generated, it is transmitted to the frontend, buffered, and then rendered. Classical metrics such as TTFT

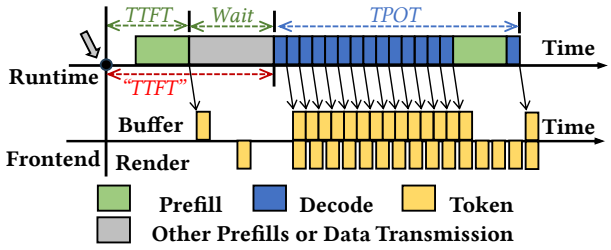

Figure 6: Runtime and frontend Timing.

and TPOT characterize latency from the runtime perspective, capturing the prefill and decode phases. However, these metrics are insufficient to capture service quality, as modern LLM serving systems handle massive concurrent requests and introduce a prefill–decode switching stage for each.

Before a request enters its decode phase, additional operations occur across all strategies, NoDG, PaDG, and FuDG. For the NoDG and PaDG strategies, prefills from other requests may occur before a given request can enter its decode phase. For the FuDG strategy, it incurs KV cache transmission overhead prior to the decode phase. Thus, the phase-switching waiting time should be recorded to provide a more comprehensive evaluation of LLM serving systems. This waiting overhead has implicitly appeared in previous work, and is frequently misrepresented.

To maintain consistency with prior work, we continue using TTFT to evaluate prefill latency. In our context, the reported TTFT consists of two components: the actual TTFT and the phase-switching waiting time. This definition represents **a stricter SLO**, as it incorporates additional overhead within the same latency bound. Accordingly, TPOT measurement begins only after the phase-switching.

3.3 Adaptive Scheduling Algorithm

The adaptive scheduling algorithm enables the macro-instance scheduler and the instance schedulers to operate in a master–worker manner, where the two levels of schedulers collaborate to coordinate scheduling decisions. From the instance scheduler's perspective, although the outcome involves disaggregating the prefill and decode phases along the temporal dimension, its scheduling policy prioritizes prefills. It continues processing active decodes, periodically updating its progress to the macro-instance scheduler, and switches to prefills upon receiving new requests from the upper scheduler.

From the macro-instance scheduler's perspective, it continuously collects status updates from all instances and dispatches requests accordingly. It traverses instances in a cyclic manner. For each incoming request, it first attempts to route it to the same instance that handled the previous request. If the instance satisfies the constraints verified by Algorithm 1, the request is forwarded. Otherwise, it checks the next available instance. To support this process, multiple public message queues are constructed on the same node as the macro-instance scheduler. Each instance periodically uploads its status to the corresponding queue, enabling the macro-instance scheduler to aggregate this information and make global scheduling decisions.

Algorithm 1: Constraint Checking Algorithm

Data: Latency constraints: S_{TTFT}, S_{TPOT}
Input: I: Statuses of all instances in a macro instance;
r: A new request

Function `CheckConstraints`(I, r)**:**
  `// 1. Check TTFT constraint`
  $t_{\text{switch}} \leftarrow$ last phase switching timestamp;
  $pending_prefills \leftarrow \{ r \in instance.reqs \mid r.arrival_time \geq t_{\text{switch}} \} \cup \{ req \}$;
  $t_{\text{total}} \leftarrow \sum(pending_prefills$ durations$)$;
  if $t_{\text{total}} > S_{TTFT}$ **then**
    return NotSatisfied;
  `// 2. Check TPOT constraint`
  $existed_decodes \leftarrow \{ r \in instance.reqs \mid r.arrival_time < t_{\text{switch}} \}$;
  $saved_tpots \leftarrow [\,]$;
  $current_time \leftarrow$ current timestamp;
  foreach $r \in existed_decodes$ **do**
    $L \leftarrow r.output_length$;
    $saved_tpot \leftarrow L \times S_{TPOT} - (current_time - r.first_token_time)$;
    append $saved_tpot$ to $saved_tpots$;
  $mean_saved_tpot \leftarrow mean(saved_tpots)$;
  if $mean_saved_tpot < t_{\text{total}}$ **then**
    return NotSatisfied;
  `// 3. Check memory capacity`
  if $req_kvcache_size > remain_memsize$ **then**
    return NotSatisfied;
  return Satisfied;

As displayed in Algorithm 1, the constraint checking algorithm is responsible for verifying that assigning an incoming request to an instance will not violate the TTFT/TPOT SLOs or exceed the instance's available memory capacity. First, the algorithm ensures that the total duration (denoted as t_{total}) will not exceed the TTFT constraint (S_{TTFT}) after adding a new request to the pending prefills during the prefill phase. The prefill duration of a single request can be predicted in advance by profiling sequences of various lengths. Next, by utilizing updated information from the instance, the algorithm calculates the saved TPOT by subtracting the required time from the achieved time. PaDG does not assume uniformly borrowing slack over the entire decoding process. Instead, slack is estimated and utilized over short decoding intervals. During each prefill–decode switch, the saved TPOT of each

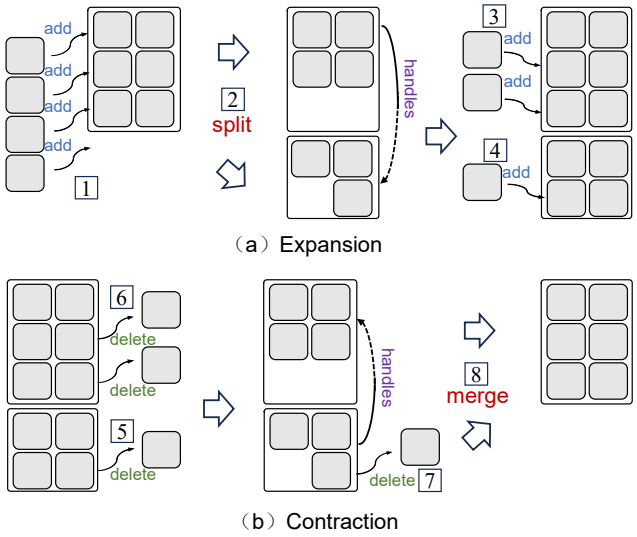

Figure 7: The illustration of the expansion and contraction processes. Here $N_l = 3$ and $N_u = 6$.

instance is locally accumulated and then consumed by incoming prefills. This localized and short-term design removes reliance on long-term prediction and improves robustness. As discussed in 3.1.1, provided that t_{total} does not exceed the saved TPOT, the TPOT constraint will be satisfied. Finally, the algorithm ensures that the total KV cache size does not exceed the remaining GPU memory capacity, preventing memory overflow.

3.4 Mitosis Scaling Approach

With the introduction of macro-instance abstraction, scaling at this coarse granularity, or relying on a single macro instance to manage all instances, would be both inefficient and inflexible. For example, as the request rate continuously increases, the macro instance scheduler must manage an increasing number of instances to meet SLOs, eventually becoming a bottleneck. Inspired by biological cell mitosis, the mitosis scaling approach adjusts capacity at the instance level, allowing EcoServe to adapt more precisely to workload fluctuations.

3.4.1 Expansion and Contraction

The mitosis scaling approach expands or contracts capacity in two steps, first by adding or removing instances within a macro-instance, and then by splitting or merging entire macro-instances. We define two hyperparameters, N_l and N_u, as the lower and upper bounds on the number of instances in a macro-instance. A small N_l causes frequent phase switching, whereas a large N_u incurs management overhead and may create scheduling bottlenecks.

Figure 7 illustrates an example of how the expansion and contraction processes are performed. The scaling is triggered either when the system fails to meet the defined SLOs or when there is sustained resource underutilization. New instances are incrementally added (step 1) until the number of instances exceeds the upper limit N_u, at which point a new macro instance containing N_l instances is split off from the original macro instance (step 2). If more instances are required, they are first added to the original macro instance until it again reaches N_u (step 3), and subsequent instances are then added to the new macro instance (step 4).

On the contrary, when the capacity becomes excessive and the contraction process is triggered, instances are firstly removed from the smallest macro instance until the number of instances in the macro instance reaches N_l (step 5). Next, instances are removed from a full macro instance (step 6). When the total number of instances across these two macro instances reaches N_u (step 7), they will be merged into a single macro instance (step 8). These removed instances will complete allocated requests before being freed. Generally, an inference system maintains multiple full macro instances, along with one or two partially filled macro instances.

3.4.2 Scaling Threshold

EcoServe decides when to expand or contract capacity by monitoring runtime signals. For expansion, the TTFT SLO attainment is adopted. When the system becomes overloaded, the TTFT SLO attainment is the first to decline and is more sensitive than TPOT SLO attainment. This is because the macro-instance scheduler routes requests only if an instance satisfies all constraints; when the system is overloaded and no instance meets these constraints, the requests become pending. These pending requests will immediately cause the TTFT SLO attainment to drop sharply, preceding degradation in TPOT SLO attainment. As demonstrated in Equation 1, EcoServe continuously tracks the average TTFTs and starts to add a new instance once it exceeds that the TTFT SLO, thereby preserving both TTFT and TPOT guarantees.

$$\frac{1}{n}\sum_{i=1}^{n} T_{\text{TTFT}}^{(i)} > T_{\text{TTFT}}^{\text{SLO}} \tag{1}$$

In contrast, saved TPOT is adopted as the signal for contraction. When the request arrival rate is low and system pressure decreases, the saved TPOT increases. For a macro-instance with n instances, we consider the reasonable range of saved TPOT to be $[T_{\text{TTFT}}, T_{\text{TTFT}} \cdot \frac{n+1}{n}]$, where the factor $(n+1)/n$ reflects the reduction in per-instance decode load if the macro-instance were hypothetically expanded from n to $n+1$ instances. Once the saved TPOT exceeds the upper bound of this interval, as shown in Equation 2, the system is over-provisioned, and EcoServe begins contracting instances.

$$T_{\text{savedTPOT}} > T_{\text{TTFT}} \cdot \frac{n+1}{n} \tag{2}$$

Table 4: Dataset Features and Corresponding SLOs.

DataSet	In_{Avg}	In_{Med}	Out_{Avg}	Out_{Med}	SLO_{TTFT}	SLO_{TPOT}
Alpaca-gpt4 [1]	20.63	17.00	163.80	119.00	1s	100ms
ShareGPT [5]	343.76	148.00	237.20	152	5s	100ms
LongBench [9]	2686.89	2736.50	101.78	19	15s	100ms

3.4.3 Flexible Instance Migration

To dynamically split or merge macro instances without reinitializing or interrupting individual instances, we design a serializable proxy object and transfer instance handles between different macro-instance schedulers. At the core of this design is the InstanceHandler metadata, which encapsulates essential information such as the instance entrypoint and its associated public message queues. When a handle is transferred between macro-instance schedulers (i.e., across processes), it is first serialized using the pickle library and then sent to the target macro-instance scheduler. The transmission process is coordinated by the overall scheduler. Upon deserialization, the target macro-instance connects with the entrypoint to obtain control of the instance, after which the instance is orchestrated into its rolling activation process. This design enables logical migration of instances across macro instances without interrupting their execution, thereby supporting more flexible and low-overhead scaling.

4 Evaluation

EcoServe adopts vLLM [4] as the single-device runtime, employs Ray to control multiple devices within each instance, and leverages ZeroMQ to synchronize instance status with the macro-instance scheduler. We evaluate EcoServe on LLMs of different scales across diverse datasets and clusters, showing its performance, scalability, and parallelism compatibility.

4.1 Experimental Setup

Cluster testbed. We conduct experiments on three clusters featuring commodity or high-performance interconnects. The primary cluster consists of 8 nodes with 64 NVIDIA L20-48GB GPUs, where GPUs are PCIe-connected and nodes communicate via 10 Gbps Ethernet. The second cluster has 2 nodes with 16 NVIDIA A800-80GB GPUs, also PCIe-connected but using a higher-bandwidth 25 Gbps RoCE interconnect. The third cluster contains 2 nodes with 16 NVIDIA H100-80GB GPUs, featuring NVLink for intra-node GPU interconnects and eight 400 Gbps InfiniBand links (one per GPU) for inter-node communication.

Model, dataset and workloads. We evaluate three representative LLM models, i.e. Llama-30B [46], CodeLlama2-34B [38], and Qwen2-72B [50]. LLaMA-30B adopts standard multi-head attention (MHA), whereas CodeLlama2-34B and Qwen2-72B adopt grouped-query attention (GQA) [8]. By sharing keys and values across query heads, GQA reduces KV cache size and mitigate FuDG transmission overhead. All experiments are conducted with BF16 precision. For applications and datasets, as shown in Table 4, we follow prior studies [24,37,55] and select three representative applications with diverse input–output length distributions.

- **Alpaca-gpt4:** [1] Instruction-following dataset with short inputs and long outputs.
- **ShareGPT:** [5] Chatbot dataset featuring relatively balanced input and output lengths.
- **LongBench:** [9] Summarization dataset with long inputs (articles) and short outputs (summaries).

We set TTFT and TPOT SLOs based solely on applications, independent of model size, and in most cases stricter than those in prior work [37,55]. Each model is paired with all datasets. To emulate realistic serving, requests arrive at a fixed rate with a Poisson distribution to introduce minor fluctuations.

Baseline. We compare EcoServe against four NoDG or FuDG systems. All baselines are built on or aligned to vLLM 0.7.3 [4] as the underlying runtime, ensuring fairness.

- **vLLM [4]:** A NoDG system with separate batching and prefill-priority scheduling, which is provided in the original vLLM implementation.
- **Sarathi [7]:** A NoDG system with hybrid batching, decode-priority scheduling, and the chunked prefill technique.
- **DistServe**[1] **[55]:** An intra-node FuDG system where prefill and decode instances are colocated within the same node. DistServe also provides a cross-node strategy that limits KV cache transmission within a node, but this is only applicable to pipeline parallelism and cannot satisfy SLOs in our setting.
- **MoonCake**[2] **[37]:** An inter-node FuDG system where prefill and decode instances may reside on different nodes. MoonCake introduces a centralized KV cache pool for transmission; even when colocated on the same node, KV cache must pass through this pool. To mitigate load imbalance, we experiment with different prefill/decode ratios and adopt the optimal one.

Metrics. Following prior work, we use SLO attainments as the evaluation metrics. Specifically, we measure system throughput at different attainment levels. Throughput is obtained by incrementally increasing the request rate until the system fails to satisfy the target attainment. Following AlpaServe [26] and vLLM [4], Poisson and Gamma distributions are used to model request inter-arrival times. The Poisson process is adopted as the default setting unless otherwise specified. It produces relatively smooth arrival patterns with

[1] https://github.com/LLMServe/DistServe
[2] https://github.com/kvcache-ai/Mooncake/tree/v0.3.2 (2025.03)

moderate variability. In contrast, the Gamma process enables controllable burstiness by adjusting the coefficient of variation and is used in bursty workload evaluations. Compared to Poisson arrivals, it generates more skewed inter-arrival times, leading to sharper fluctuations where many requests may arrive within short periods followed by idle intervals. Notably, we extend the request-sending program in the vLLM repository with multithreading support, allowing us to generate high-concurrency workloads at scale.

4.2 End-to-end Evaluation

We compare EcoServe with baselines across models, datasets, and clusters. On the L20 cluster, LLaMA-30B and CodeLlama2-34B use TP=4, and Qwen2-72B uses TP=8. To mitigate MoonCake's bandwidth limits, we deploy one instance per node, yielding 8 instances in total. On A800 and H100 clusters, LLaMA-30B and CodeLlama2-34B use TP=2 (8 instances), and Qwen2-72B uses TP=4 (4 instances). We present all evaluations with three discrete SLO attainments in Figure 8, and demonstrate two evaluation cases on the L20 cluster with continuously varying SLO attainments in Figure 9. Notably, MoonCake and DistServe fail to meet SLO attainments in some cases. In addition, DistServe cannot support Qwen2-72B with TP=8 on a single node. These cases are omitted from the results.

4.2.1 Overall Comparison

EcoServe outperforms all baselines across all evaluation cases on the L20 and A800 clusters with commodity networks, which are our primary focus. For NoDG systems, EcoServe achieves an average P90 goodput improvement of 2.01× over vLLM and 1.87× over Sarathi. As shown in Figure 9, EcoServe is more resilient at high request rates, with SLO attainment degrading more slowly than NoDG systems. For FuDG systems, EcoServe improves P90 goodput by 3.43× over DistServe and 3.41× over MoonCake. Figure 9 also shows FuDG exhibits a sharp bottleneck on commodity networks, as its interconnect bandwidth and load imbalance quickly lead to SLO violations.

On the H100 cluster with high-performance interconnects, EcoServe also outperforms almost all baselines, though with smaller margins. For NoDG systems, it gains a modest P90 improvement of 1.34× over vLLM and 1.25× over Sarathi, since the strong compute capability of H100 substantially reduces prefill–decode interference. Compared with FuDG, EcoServe still improves P90 goodput by 1.75× over DistServe and 1.24× over MoonCake, somewhat surprising, as high-bandwidth networks typically favor FuDG systems. This result is mainly due to load imbalance and engineering complexity in FuDG systems, as well as the relatively lenient latency SLOs on H100, which prevent PaDG and NoDG systems from exposing their usual bottlenecks.

DistServe colocates prefill and decode instances on the same node, causing severe imbalance, and its unmaintained prototype implementation further limits performance. MoonCake, still under active development, achieves performance comparable to EcoServe and even surpasses it on CodeLlama2-34B. Although the improved interconnect and reduced imbalance on the H100 cluster allow MoonCake to better realize its potential, we still observe intermittent pauses in prefill instances, indicating that load imbalance exists and transmission buffers quickly become insufficient.

4.2.2 Comparison across models

EcoServe demonstrates consistent benefits over NoDG systems across different model scales. In particular, it achieves average throughput improvements of 1.59×, 1.83×, and 1.76× when serving Llama-30B, CodeLlama2-34B, and Qwen2-72B, respectively. In contrast, its improvements over FuDG systems vary substantially, reaching 4.82×, 2.15×, and 1.79× on the same three models.

These differences can be explained by KV cache characteristics and model scaling effects. Llama-30B suffers the largest degradation in FuDG because its relatively larger KV cache incurs substantial inter-instance transmission overhead. In comparison, CodeLlama2-34B and Qwen2-72B adopt GQA [8], which significantly reduces KV cache size and alleviates transmission bottlenecks. Moreover, because computation grows faster than KV cache footprint as model size increases (e.g., for 72B), larger models have relatively lower KV-to-compute ratios and typically tighter latency SLOs, enabling FuDG to perform relatively better.

It is also worth noting that when serving the LongBench dataset, Llama-30B consistently outperforms CodeLlama2-34B because Llama-30B supports only a maximum sequence length of 2048, causing longer inputs to be truncated and resulting in lower actual workload.

4.2.3 Comparison across clusters

Comparing EcoServe with other systems, the gains over NoDG systems remain relatively consistent across clusters, whereas the improvements over FuDG systems vary substantially. Specifically, under P90 SLO attainment, EcoServe improves goodput over NoDG systems by an average of 1.97× on L20, 1.91× on A800, and 1.29× on H100. This mainly arises from the disparity in computational capability among the GPU devices. Since we apply unified latency SLOs determined only by the datasets, GPU devices with higher computational capability can satisfy these SLOs more easily and therefore experience less prefill–decode interference, making NoDG advantageous.

Against FuDG systems, the gains are 2.45× on L20, 4.21× on A800, and 1.50× on H100, illustrating how the relative advantages shift across clusters. This disparity can be attributed

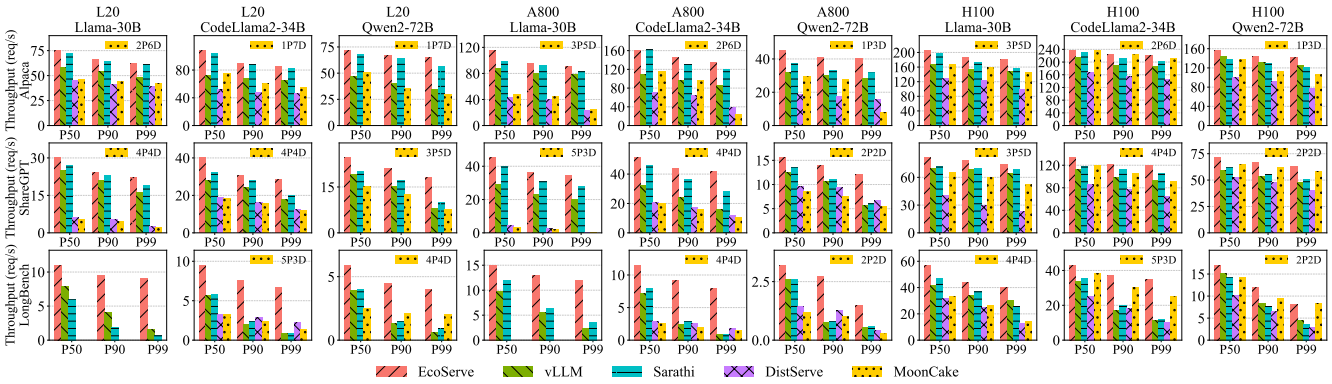

Figure 8: Evaluations across models, datasets, and clusters. The y-axis shows throughput under different SLO attainment levels.

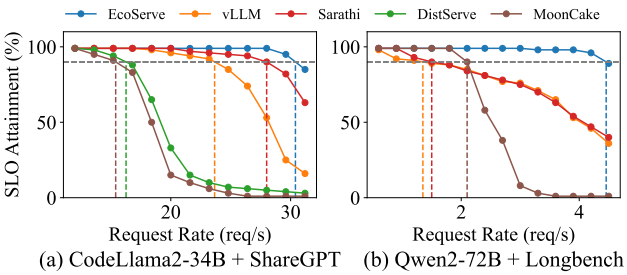

(a) CodeLlama2-34B + ShareGPT (b) Qwen2-72B + Longbench

Figure 9: Two evaluation cases on the L20 cluster with continuously varying request rates. The vertical lines indicate the maximum rate that satisfies P90 latency SLOs.

to the ratio between computational capability and network bandwidth. A higher compute-to-bandwidth ratio generally leads to larger improvements over FuDG systems since KV cache transmission becomes the bottleneck. The A800 cluster exhibits such a ratio, as its network bandwidth increases by only 2.5× compared with L20, whereas its processing capability improves by more than 4× (Table 3), making the inter-node network an even more critical bottleneck.

4.2.4 Comparison across datasets

When comparing EcoServe with other systems, the gains vary significantly across datasets due to differences in input–output length ratios. Under P90 SLO attainment, EcoServe achieves average throughput improvements of 1.19×, 1.26×, and 2.72× over NoDG on the Alpaca, ShareGPT, and LongBench datasets, and outperforms FuDG by 1.70×, 4.00×, and 2.53×, respectively.

These differences arise from how input and output lengths affect system behavior. For NoDG systems, shorter inputs reduce prefill–decode interference and repeated KV cache accesses during chunked prefill, enabling EcoServe to gain larger advantages. For FuDG systems, datasets with longer inputs and shorter outputs require more prefill instances to

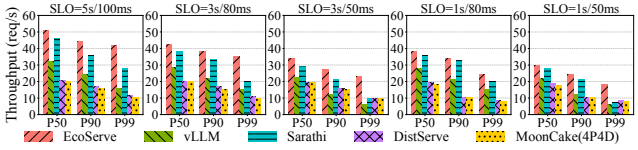

Figure 10: Evaluations under different SLOs.

generate KV cache, which increases network transmission pressure and exacerbates FuDG's bandwidth sensitivity, leading to greater improvements for EcoServe. It is also worth noting that the improvement over FuDG on LongBench would have been even higher had Llama-30B not been excluded due to execution failures.

4.3 SLO Sensitivity Study

We further evaluate SLO sensitivity by tightening the SLO from $(5s, 100ms)$ to four stricter settings: $(3s, 80ms)$, $(3s, 50ms)$, $(1s, 80ms)$, and $(1s, 50ms)$, using CodeLlama2-34B on A800 GPUs with ShareGPT.

As shown in Figure 10, as SLOs become stricter, all systems experience throughput degradation. Under the strictest $(1s, 50ms)$ SLO, EcoServe's P99 throughput decreases from 42 rps to 18 rps, a 57.1% reduction. In comparison, vLLM drops from 16 rps to 6.4 rps (60.0%), while Sarathi drops from 28 rps to 7.6 rps (72.9%), indicating that NoDG systems are more sensitive to tighter SLOs. FuDG systems, i.e., DistServe and MoonCake, show smaller relative degradation, with P99 reductions of 26.9% and 23.9%, respectively. This is because their throughput is already constrained by KV cache transmission and load imbalance under loose SLOs. Next, they show apparent robustness under stricter SLOs.

4.4 Bursty Workload Evaluation

In bursty workload evaluations, we compare throughput under both Poisson and Gamma arrival processes. To model increas-

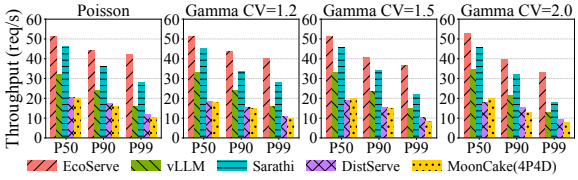

Figure 11: Evaluations under different burstiness.

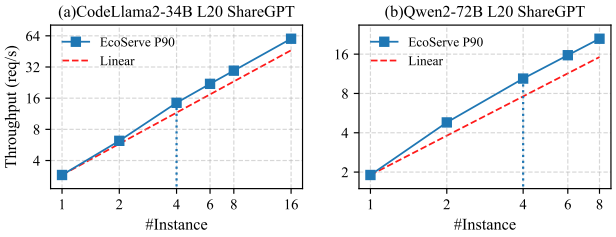

Figure 12: Static coarse-grained scaling.

ing levels of burstiness, we vary the coefficient of variation (CV) of the Gamma process as 1.2, 1.5 and 2.0, while keeping the average request rate constant. Experiments are conducted using the CodeLlama-34B model on NVIDIA A800 GPUs with the ShareGPT dataset.

In Figure 11, as workload burstiness increases, throughput degrades more significantly at higher percentiles (e.g., P90 and P99) across all systems due to burst-induced resource contention and scheduling instability, while showing almost no impact at lower percentiles (e.g., P50). Comparing these systems under P99 SLO attainment, throughput degrades by 17.3% (EcoServe), 19.5% (vLLM), 35.7% (Sarathi), 12.6% (DistServe), and 17.1% (MoonCake), respectively, as the CV increases from 1.2 to 2.0. This is because NoDG systems exhibit the weakest robustness to contention and thus suffer the largest degradation, while PaDG shows stronger resilience under resource contention caused by bursty workloads.

4.5 Scaling Capability

We evaluate the scaling capability of EcoServe from two aspects. First, we measure throughput by varying the number of instances in a macro-instance to examine static coarse-grained scaling. Second, we incrementally increase the request rate and analyze the mitosis scaling approach as the dynamic fine-grained scaling.

4.5.1 Static Coarse-grained Scaling

Static coarse-grained scaling uses CodeLlama2-34B (TP=4) and Qwen2-72B (TP=2) on the L20 cluster, with the ShareGPT dataset as the workload. Throughput under P90 SLO attainment is presented in Figure 12.

Both cases exhibit superlinear speedup initially, before reverting to linear and eventually sublinear scaling. When scaling from 1 instance (4 GPUs) to 4 instances (16 GPUs), CodeLlama2-34B achieves a 4.96× throughput increase, while Qwen2-72B reaches 5.47×. The superlinear speedup arises because EcoServe incurs minimal overhead when managing additional instances within a symmetric cluster topology. More importantly, adding instances provides greater capacity to mitigate inter-phase interference, increasing arithmetic intensity and improving GPU saturation. Assuming a macro instance contains only a single instance, the PaDG strategy actually degrades to NoDG, and two phases still switch frequently and interference severely in a single instance. This superlinear scaling effect will plateau once a sufficient number of instances is reached.

4.5.2 Dynamic Fine-grained Scaling

Fine-grained scaling uses CodeLlama2-34B (TP=4) on the L20 cluster, with the ShareGPT dataset as the workload. The request rate gradually increases from 20 to 50 requests per second in 2-minute intervals, with SLO attainments collected every 30 seconds. Based on the static scaling experiments, we set $N_l = 6$ and $N_u = 11$, since superlinear speedup disappears beyond this point and dividing a macro-instance no longer degrades performance. The system starts with 32 GPUs (8 instances) and finally uses up all 64 GPUs.

As shown in Figure 13, increasing the request rate initially results in a drop in SLO attainment, which is promptly restored once a new instance is added. This process continues until the 12th instance, where we can see that SLO attainment recovers slightly more slowly. Since the total number of instances exceeds the upper bound N_u, the system triggers a split into two macro-instances of 6 instances each. Thanks to the serializable proxy object, the split introduces only minor performance fluctuations and avoids model re-initialization. In contrast, interrupting and re-initializing an instance incurs much higher overhead. For a single instance, re-initializing CodeLlama2-34B from an L20 node's local storage takes about three minutes, and is even longer when loading weights from remote storage. Consequently, the mitosis scaling approach enables flexible, fine-grained scaling that effectively adapts to dynamic workload demands.

4.6 Parallelism Compatibility

We further design experiments to validate that FuDG is more compatible with pipeline parallelism (PP) than NoDG. As discussed in Section 2.3, PP is appealing for high-throughput inference due to its low communication overhead, but it becomes vulnerable to pipeline bubbles when prefill–decode interference is present. To evaluate this effect, we fix the TTFT SLO at 5 seconds, progressively relax the TPOT constraint, and measure throughput under different degrees of pipeline parallelism. Specifically, We evaluate CodeLlama2-34B on the ShareGPT dataset using the L20 cluster, configuring the

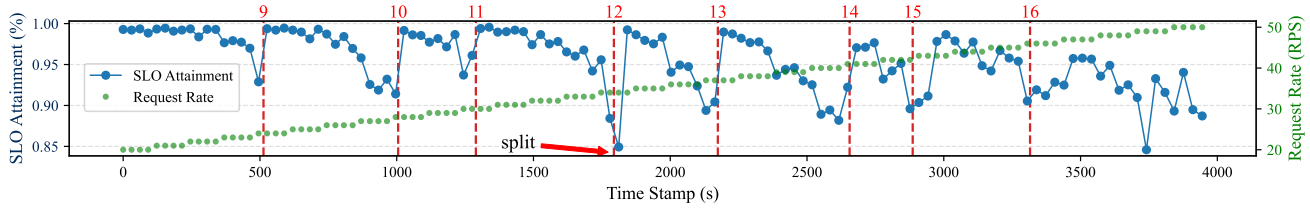

Figure 13: Dynamic fine-grained scaling experiment of CodeLlama2-34B on the L20 cluster. Here $N_l = 6$ and $N_u = 11$.

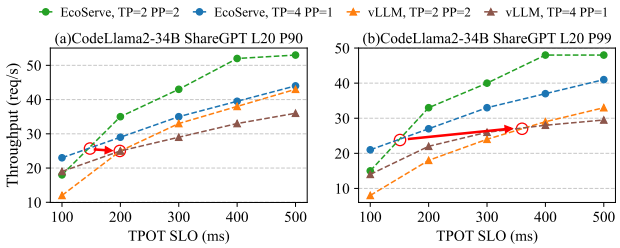

Figure 14: Pipeline parallel compatibility.

model with two settings: TP=2, PP=2 and TP=4, PP=1, which correspond to higher and lower PP degrees, respectively.

Figure 14 shows throughput as the TPOT SLO increases from 100 ms to 500 ms. The results show that EcoServe with a higher PP degree outperforms its lower-PP counterpart under tighter TPOT SLOs, surpassing that of vLLM. In other words, the performance intersection of different PP degrees occurs at a tighter TPOT constraint, and the throughput plateau achieved with PP is significantly higher than that of vLLM. These findings indicate that PaDG is substantially more compatible with pipeline parallelism, enabling PP to better reach its performance potential.

4.7 Ablation Study

We conduct an ablation study to evaluate the effectiveness of rolling activation and adaptive scheduling in EcoServe by selectively disabling them and comparing the performance.

4.7.1 Rolling Activation.

To evaluate the importance of rolling activation, we consider a variant where the next instance is selected randomly rather than following the cyclic rolling activation strategy. Experiments are conducted using all three models on NVIDIA A800 GPUs with the ShareGPT dataset. As shown in Figure 15, cyclic activation achieves higher throughput across all cases, with more pronounced gains in higher SLO attainments. This is because higher SLO attainments impose tigher scheduling constraints, leaving less slack for prefills. As a result, suboptimal scheduling strategies fail to allocate sufficient resources to meet the SLO targets. These results demonstrate that rolling activation is an effective design.

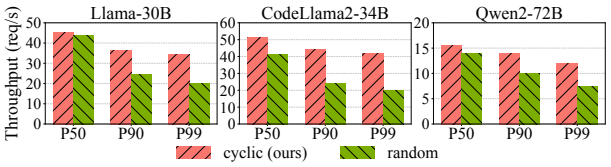

Figure 15: Ablation study of rolling activation.

Table 5: Large-scale LLM Serving Strategy Comparison.

	Goodput	Cost Effective	Load Balance	Hardware Cost	Parallelism Compatibility	Engineering Complexity
NoDG	✓	Good	Easy	Low	Low	Low
FuDG	✓✓	Poor	Hard	High	High	High
PaDG	✓✓	Excellent	Easy	Low	High	Low

4.7.2 Adaptive Scheduling Algorithm.

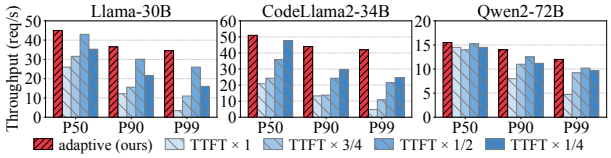

Figure 16: Ablation study of adaptive scheduling algorithm.

To evaluate the effectiveness of adaptive scheduling algorithm, We compare it with a variant that requests are routed at fixed intervals without estimating available prefill slots. Experiments are conducted across all models on NVIDIA A800 GPUs with the ShareGPT dataset. The fixed intervals are set to 1/4, 1/2, 3/4, and 1/1 of the TTFT SLO. As shown in Figure 16, while different fixed intervals lead to varying throughput, our adaptive algorithm consistently achieves the best performance, demonstrating its effectiveness.

5 Discussion

Commercial success in LLM serving hinges on adopting cost-effective strategies, which **require a careful trade-off between throughput, SLO attainment, infrastructure cost, parallelism compatibility, and even engineering complexity**. Table 5 presents a comparison between PaDG and the

existing NoDG and FuDG. In terms of goodput, PaDG is comparable to FuDG, while largely outperforming NoDG. While FuDG is designed for tight SLOs and relies on high-performance interconnects, PaDG is for cost-effective deployments that SLOs are relaxed or interconnects are limited.

Beyond hardware, PaDG also reduces load imbalance and engineering complexity. Unlike FuDG, which scales across two instance types, NoDG and PaDG scale at the granularity of individual instances, leading to simpler scaling and more balanced workloads. In addition, the lack of cross-instance KV cache transmission in PaDG and NoDG significantly lowers system complexity. From a parallelism compatibility perspective, PaDG offers further advantages. Its lower frequency of prefill-decode switching improves pipeline parallelism efficiency, while minimal data movement and reduced PCIe contention make it more suitable for tensor parallelism in commodity nodes.

NoDG, PaDG, and FuDG each have their own advantageous scenarios, and LLM serving vividly demonstrates the art of trade-offs in system optimization. NoDG is well-suited for small models, such as 7B and 13B. These models have lower computational demands, and their SLOs are easier to satisfy, making prefill-decode interference negligible. Larger models, such as 30B, 70B, and 130B, benefit more from PaDG. These models typically require parallel techniques to extend memory capacity and are still capable of meeting typical latency SLOs in a single instance. In extreme scenarios, such as ultra-large models or stringent SLOs, even minor interference can significantly degrade these metrics. In such cases, PaDG with commodity hardware becomes insufficient. To satisfy the TPOT SLO, it can be enhanced with lightweight add-on strategies (e.g., chunked prefill) or augmented with advanced hardware, while designs such as FuDG with specialized hardware may ultimately be required. More aggressive strategies are worth studying. For example, MegaScale-Infer [57] and Eaas [32] study ultra-large MoE model and disaggregates the attention and FFN modules into different instances. Moreover, these strategies incur incremental engineering costs, which also serve as a major factor.

6 Related Work

Scheduling in LLM serving. Based on whether prefill and decode phases are disaggregated, existing LLM serving approaches can be categorized into the NoDG strategy [3, 4, 7, 52] and the FuDG strategy [35, 37, 55], which are most relevant to EcoServe. Adrenaline [28] notices the load imbalance issue in FuDG and reschedules computation in prefill and decode instances.

Moreover, other studies address issues in specific inference scenarios. Flexgen [42], FastDecode [19] and Specinfer [33] enable LLM inference with limited memory capacity by employing offloading strategies. Loongserve [49] and Infinite-llm [29] targets long-context inference and optimize parallel strategy and memory utilization respectively. Moelightning [11], Pre-gated MoE [21] and Lina [25] focus on MoE models and optimize resource utilization by employing expert popularity. MegaScale-Infer [57] and Eaas [32] target ultra-large MoE model and accelerate the decode phase by disaggregating the attention and FFN modules. Liger [13] and NanoFlow [56] carefully schedules and overlaps GPU kernels from different requests to improve efficiency.

KV Cache Management. To reduce KV cache memory usage of standard MHA [48], MQA [40] and GQA [8] share key and value projections across query heads. PagedAttention [24] and vAttention [36] reduces memory fragmentation by organizing the KV cache into fixed-size blocks. To compress KV cache, H2O [54], Keyformer [6], and Liu et al. [31] find token similarity and removes redundant information. Next, Shadowkv [45], Prompt cache [17], and Ragcache [23] further explore KV cache compression and offloading strategies in long-context scenarios. AttentionStore [16] schedules KV cache across hierarchical storage tiers, while CacheBlend [51] introduces the pipelining loading with partial recomputation to use slower object stores.

7 Conclusion

EcoServe is built on the novel partially disaggregated (PaDG) strategy for cluster-level LLM serving. PaDG mitigates prefill–decode interference by enabling multiple instances to collaborate in a data-reduced manner, well suited for GPU clusters with the commodity network. EcoServe also excels in load balancing, hardware cost, parallelism compatibility, and engineering simplicity, making it a cost-effective choice.

Revisiting Pipeline Parallelism for LLM Serving

Soonjae Hwang Jeongseob Ahn

Korea University

Abstract

As the memory capacity of a single GPU is insufficient to accommodate large language models (LLMs), model parallelism has become the standard approach for serving LLMs across multiple GPUs. In online serving environments, tensor parallelism has become the de facto way in single-node multi-GPU systems because it can reduce the computation latency through parallel execution. Although pipeline parallelism can offer higher throughput, it suffers from pipeline imbalance that is exacerbated under online workloads, leading to resource underutilization and performance degradation.

In this study, we revisit pipeline parallelism for serving LLMs. Our analysis shows that computational imbalance between pipeline stages becomes exacerbated in online serving. To address these pipeline inefficiencies, we propose three techniques: two mechanisms, greedy and predictive schemes, that dynamically adjust the chunk size to mitigate prefill-induced bubbles, and a delay scheduling technique that dynamically rebalances decode workloads across pipeline stages to further reduce pipeline bubbles. We implement our techniques on top of SGLang and demonstrate that, for Qwen2.5 32B and 14B on four NVIDIA A100 40GB GPUs, pipeline parallelism with our mechanisms outperforms tensor parallelism.

1 Introduction

As large language models (LLMs) with billions of parameters have become increasingly prevalent, their inference workloads demand far more computation and memory than a single accelerator (e.g., GPU or NPU) can provide. For instance, the Llama3.1-70B [4] BF16 model requires at least four NVIDIA A100 40GB GPUs to retain its parameters. This necessitates parallel execution across multiple accelerators. In single-node multi-GPU inference, tensor parallelism has become the de facto standard [30]. By partitioning large weight matrices and attention operations across GPUs, tensor parallelism achieves low per-token latency [16], particularly with high-bandwidth interconnects (e.g., NVLink) that hide frequent all-reduce communication overhead [27]. In addition, every GPU executes the same set of operations at each step, making load balancing trivial. However, many commodity GPUs and NPUs still rely on traditional PCIe interconnects, which do not provide high-bandwidth peer-to-peer communication. In such settings, the substantial communication volume in tensor parallelism can quickly become a performance bottleneck, making it less suitable for online LLM serving.

In contrast, pipeline parallelism partitions the model along its depth, passing microbatches through sequential pipeline stages. This dramatically reduces inter-device communication and can achieve higher throughput than tensor parallelism by overlapping stage execution [11, 17], making it attractive for bandwidth constrained deployments such as PCIe.

This paper revisits pipeline parallelism to achieve high performance by effectively utilizing multiple GPUs for LLM serving. We first conduct an in-depth analysis of pipeline parallelism in the context of online serving. Our analysis identifies that computational imbalance between pipeline stages becomes exacerbated in online serving, as variability in request arrival times and input lengths leads to microbatches with different computational demands, resulting in *pipeline bubbles*. For example, if one microbatch consists entirely of decode-phase requests while another includes prefill-phase requests, the per-stage workloads differ significantly. Even when all microbatches across stages consist of decode-phase requests (e.g., decode-heavy), pipeline imbalance still occurs when one microbatch handles many decode-phase requests while another handles only a few.

To this end, we propose three techniques for pipeline parallelism to achieve high throughput while satisfying the latency requirements (e.g., SLO: Service Level Objective) for both TTFT (Time To First Token) and TPOT (Time Per Output Token). Our strategy is to leverage chunked-prefill [2], which splits long input sequences into smaller, fixed-size chunks. Since prefill computation is proportional to its input length, limiting the input with a fixed chunk size helps reduce latency imbalance across pipeline workers. However, smaller chunks lower computational throughput due to fewer tokens being

processed per iteration, leading to higher TTFT latency.

To balance this trade-off between minimizing pipeline bubbles and maximizing compute utilization, we propose two methods that *dynamically adjust the chunk size*. The first is a greedy approach, in which the LLM serving framework monitors the latency slack for both TTFT and TPOT at every iteration based on a given SLO, and incrementally increases or decreases the chunk size to balance the two phases. Specifically, when the observed $TPOT_{slack}$ is about to violate its SLO, we decrease the chunk size to reduce pipeline bubbles; when the $TTFT_{slack}$ is insufficient, we increase the chunk size to drain the waiting queue faster. This simple feedback-driven requires only minimal changes to existing serving systems.

However, the greedy approach is inherently reactive and thus limited in its ability to accurately determine the optimal chunk size under the system's current context. To overcome this limitation, we propose a *predictive dynamic chunked prefill* method that proactively selects the chunk size using a lightweight latency prediction model. The model combines offline profiling with online adaptation to account for both static and dynamic components of LLM iteration latency. Given the current system state (e.g., waiting queue, running batch, and request arrival rate), the inference serving scheduler uses this model to select the chunk size that minimizes pipeline bubbles, thereby improving goodput.

The last piece of this study is to dynamically rebalance workloads across pipeline stages, called *delay scheduling*. We find that existing implementations of pipeline parallelism typically rely on static microbatch scheduling. Once a request is assigned to a microbatch, it remains fixed for its entire lifetime [14, 37]. In decode-heavy workloads where many of the batches consist of only decode phases, such static scheduling amplifies pipeline imbalances and repeatedly causes stalls across iterations. To alleviate this, our delay scheduling examines load imbalances (i.e., # requests) at each scheduling iteration and migrates requests from the heaviest to the lightest microbatch in proportion to their computational demand.

We implement our three techniques, as well as the baseline pipeline parallelism with chunked prefill, on top of SGLang [37]. We evaluate the effectiveness of our techniques using two representative LLM models, Qwen2.5 32B and 14B, on a server equipped with four NVIDIA A100 40GB GPUs. To emulate real-world LLM request patterns, we use the `Conversation` trace from Azure [22], the `ShareGPT` trace from HuggingFace [24], and the `CNN` trace [9]. Since these are prefill-heavy workloads, we also construct a decode-heavy workload by reversing the input and output distribution of the CNN trace. We demonstrate that pipeline parallelism with a carefully tuned static chunk size already outperforms tensor parallelism in terms of goodput, TTFT, and TPOT. Our dynamic chunked prefill and delay scheduling techniques improve further: on the `Conversation` workload, they reduce TPOT and end-to-end latency by 35% and 31%, respectively, over this tuned pipeline parallelism.

2 Background

2.1 LLM Inference and Serving

LLMs typically execute inference in two distinct phases: *prefill* and *decode*. In the prefill phase, the input prompt tokens are processed through all decoder layers to initialize the attention key-value (KV) cache and produce the first output token. After this step, the request enters the decode phase, where tokens are generated autoregressively, one token at a time [29]. Each decode step reuses the KV cache and computes attention only for the newly generated token, resulting in a near-constant and significantly lower per-token cost compared to prefill. The number of decode steps (i.e., output tokens) depends on its input prompt.

Meanwhile, modern LLM serving systems commonly employ iteration-level scheduling [28, 35], where multiple requests are grouped into the same batch and processed at the granularity of iteration. The iteration-level scheduling allows new requests to join ongoing batches when GPU resources are available, and completed requests to exit early without waiting for the entire batch to finish. In online serving environments, requests often enter and exit the prefill and decode phases at different times. Batching at the iteration-level enables efficient GPU utilization by allowing requests in different phases to be processed together.

However, while iteration-level scheduling enhances GPU utilization, it can increase the decoding latency when long prefill requests are included in the same iteration. To mitigate this, Sarathi-Serve introduces the *chunked-prefill* technique, which splits the prefill phase into fixed-size chunks [2]. This approach distributes the compute load of long prompts across multiple iterations, preventing them from dominating a single iteration. The chunked-prefill approach has been widely adopted in modern LLM serving frameworks such as vLLM [14], SGLang [37], and Dynamo [19].

In online LLM serving, TTFT (Time to First Token) and TPOT (Time Per Output Token) are commonly used latency metrics to evaluate performance during the prefill and decode phases, respectively. According to the MLPerf inference benchmark [1], typical SLO targets are 2,000ms for TTFT and 200ms for TPOT. From the perspective of operating LLM-based services, it is crucial to achieve high throughput while satisfying these latency targets, referred to as goodput.

2.2 Parallelism in LLM Serving

Although each new GPU generation increases memory capacity, it still falls short of accommodating the weights of large models. For instance, serving the Llama 3.1 70B FP16 model, which requires approximately 140GB of memory, necessitates at least two H100 GPUs. A common practice is to employ model parallelism, which partitions the model across multiple GPUs. There are two primary forms of model parallelism:

tensor parallelism and *pipeline parallelism*.

Tensor Parallelism (TP) shards intra-layer tensors across multiple GPUs [25, 27]. In a transformer block, large weight matrices, such as those in attention projections or feedforward layers, are split across devices. Each GPU performs partial matrix multiplications (e.g., GEMMs) and attention operations on its shard. The partial outputs are then aggregated via collective communication primitives like all-reduce, preserving the logical semantics of the full layer. Since every GPU holds all layers in a sharded form, each forward pass involves all participating devices.

Pipeline Parallelism (PP) partitions the model by layer depth, assigning contiguous sets of layers (called `stages`) to different GPUs [11, 17]. During inference, a microbatch, a smaller split of the full input batch, is passed sequentially through these pipeline stages. While stage 0 processes microbatch i+1, stage 1 can process microbatch i, enabling concurrent execution and hiding latency through pipelining. Unlike TP, each GPU is only responsible for a subset of layers, reducing communication overhead but introducing the potential for pipeline bubbles (later discussed in detail).

In single-node multi-GPU environments, tensor parallelism has become the de facto standard for latency-sensitive online LLM serving [30]. While tensor parallelism introduces substantial communication overhead, especially compared to pipeline parallelism, this cost is largely mitigated by high-bandwidth interconnects such as NVLink [27]. However, NVLink is only available in a limited set of GPU platforms, such as NVIDIA DGX systems with A100 or H100 GPUs. Still, many GPU servers in public clouds rely on PCIe, which offers lower bandwidth. The same constraint applies to AMD GPUs and NPUs. In such environments, pipeline parallelism may offer better performance due to its lower communication requirements. Another reason tensor parallelism is often preferred is that it is generally simpler to implement and integrate, avoiding the scheduling complexity and microbatching challenges inherent in pipeline parallelism. As a result, modern LLM serving frameworks remain relatively immature in their support for efficient pipeline parallelism.

2.3 Tensor Parallelism vs. Pipeline Parallelism

To have a better understanding of the advantages and disadvantages of pipeline parallelism, we conduct a performance analysis comparing it with tensor parallelism on four NVIDIA A100 GPUs connected via PCIe 4.0 to the host. We evaluate TTFT and TPOT latency when serving Qwen2.5-32B with SGLang [37], using the Azure `Conversation` workload [22] under varying request rates. The detailed experimental setup is described in Section 5.1.

Figure 1 presents TTFT (top) and TPOT (bottom) performance for both pipeline parallelism and tensor parallelism. Pipeline parallelism achieves lower TTFT latency than tensor parallelism due to its pipelined execution across stages, which enables efficient overlap of computation during the prefill phase and accelerates the generation of the first token. However, pipeline parallelism exhibits relatively higher TPOT latency compared to tensor parallelism. This is primarily due to *pipeline bubbles* across different pipeline stages as depicted in Figure 2. We will discuss more details in the following section. As the request rate increases, these bubbles become more significant, causing pipeline parallelism to violate TPOT_{SLO}. The vertical dotted lines denote the maximum achievable goodput given latency budgets of 2,000 ms for TTFT and 200 ms for TPOT [1]. In terms of SLO attainment, tensor parallelism can sustain a 1.2× higher request rate than pipeline parallelism.

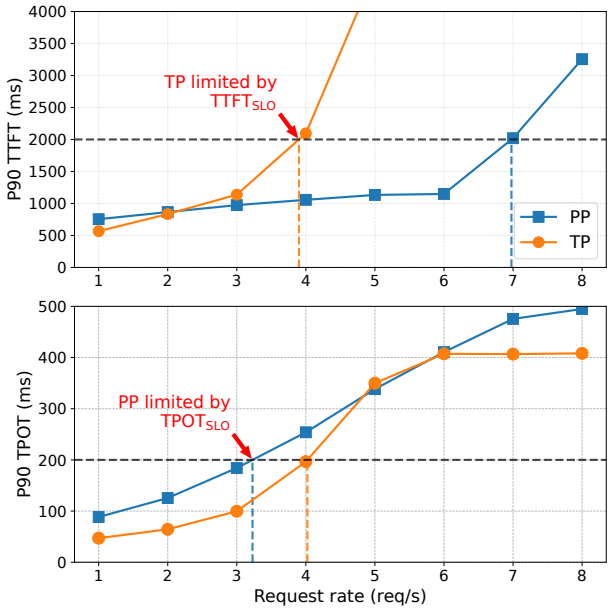

Figure 1: Performance comparison for pipeline and tensor parallelism in serving Qwen2.5-32B with the Azure Conversation workload on 4 NVIDIA A100 GPUs

3 Challenges and Proposed Approaches

This section describes challenges in serving LLMs with pipeline parallelism. First, we analyze the root cause of pipeline bubbles that lead to computational inefficiencies. Second, we provide an overview of our design approaches to reduce the pipeline bubbles.

3.1 Pipeline Bubbles in LLM Serving

The root cause of pipeline bubbles lies in computational imbalances between pipeline stages (i.e., GPU workers). Unlike model training, where inputs are fixed and predictable, online serving introduces inherent variability in request arrival

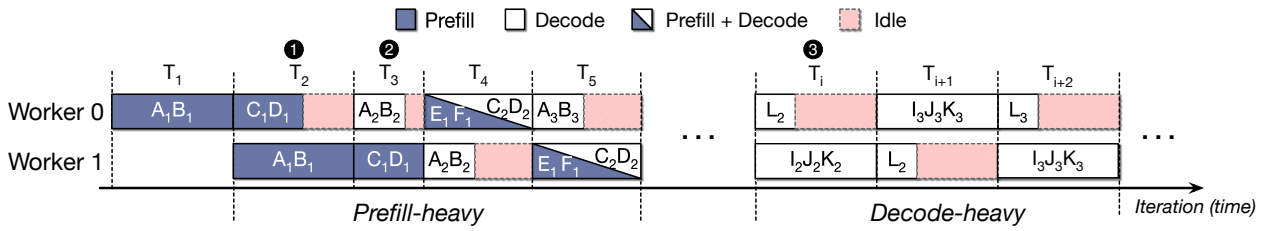

Figure 2: Three types of pipeline bubbles (The subscript indicates the iteration number.)

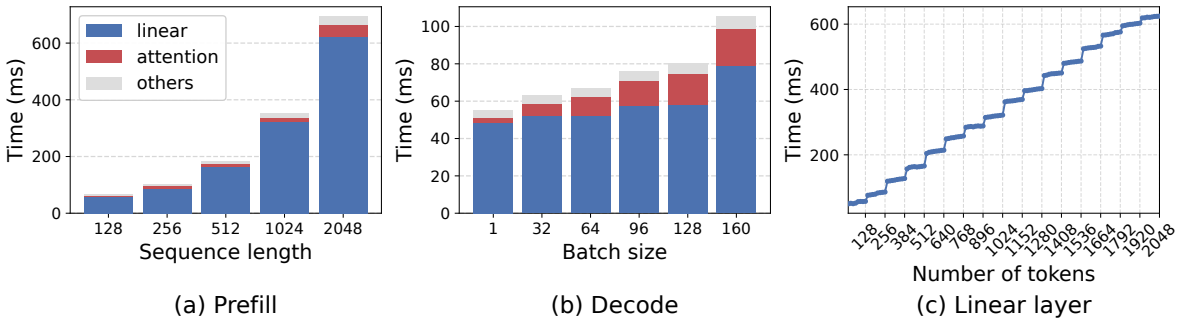

Figure 3: Performance characteristics: (a) prefill time when varying the sequence length, (b) decode time when increasing the batch size, and (c) linear operations when increasing the number of tokens

times and batch composition, making it difficult to maintain balanced compute across pipeline stages.

3.1.1 Types of Pipeline Imbalance

Figure 2 illustrates three representative cases that lead to pipeline bubbles, assuming a two-stage pipeline and a maximum batch size of three. First, the iteration-level scheduling composes batches of requests with varying input lengths, leading to imbalanced prefill latencies. For instance, ❶ at T_2, suppose a microbatch A_1B_1 with long prompt sequences and another microbatch C_1D_1 with shorter ones. Microbatches with longer prompts spend more computation cycles during the prefill phase. In this case, `Worker 0` completes the microbatch C_1D_1 earlier, while `Worker 1` continues executing the prefill for A_1B_1. As a result, `Worker 0` cannot start the next microbatch A_2B_2 until `Worker 1` finishes its stage, leading to idle cycles. We call this *Prefill-Prefill (P-P) imbalance*.

Second, ❷ at T_3, when one microbatch (A_2B_2) consists solely of decode-phase requests while another microbatch (C_1D_1) consists solely of prefill-phase requests, the computational workload diverges sharply across stages. We call this *Prefill-Decode (P-D) imbalance*. Here, `Worker 0` handling the decode-only microbatch finishes earlier and remains idle, while `Worker 1` handling the prefill-only microbatch continues execution, further exacerbating pipeline imbalance, increasing TPOT for microbatch A_2B_2. Another P-D imbalance case is shown at T_4, where microbatch $C_2D_2E_1F_1$, assigned to `Worker 0`, includes two prefill and two decode requests, while microbatch A_2B_2 on `Worker 1` consists only of decode requests. In this case, `Worker 0` becomes the bottleneck, delaying the initiation of microbatch A_3B_3.

Third, ❸ from T_i to T_{i+2}, when all microbatches across pipeline stages contain only decode phase requests, this leads to another form of pipeline imbalance where one microbatch handles many such requests while another handles only a few. We refer to this as *Decode-Decode (D-D) imbalance*.

3.1.2 Performance Implication of Pipeline Imbalance

To precisely quantify pipeline imbalance, we analyze the performance of prefill and decode phases by varying the sequence length and batch size, respectively. First, Figure 3a shows that the prefill latency depends largely on the input sequence length, indicating that balancing the compute density of prefill stages across workers is critical. For instance, when two prefills with sequence lengths of 2048 and 128 are issued sequentially, the resulting *P-P imbalance* generates a substantial pipeline bubble, around 627ms, which consequently stalls subsequent pipeline stages.

Second, during the decode phase, the batch size (i.e., number of requests) becomes the dominant factor determining execution time, given that only a single token is processed at a time. Figure 3b shows that the decode execution time increases as the batch size grows. Although the attention operation becomes more significant in the decode phase, linear operations remain the primary source of execution time, exhibiting a distinct step-function pattern as illustrated in Figure 3c. We observe that while the performance gap between batch sizes 96 and 128 is a relatively minor 5%, this gap sig-

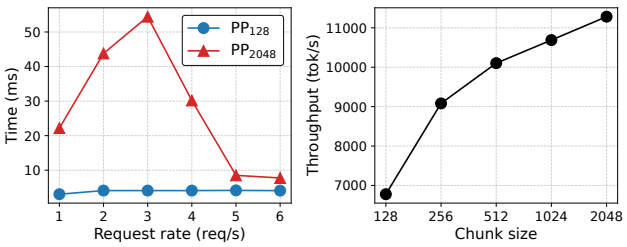

Figure 4: Pipeline bubbles and prefill token throughput according to load and chunk size (when serving Qwen2.5-32B with the Azure `Code` workload on 4 NVIDIA A100 GPUs)

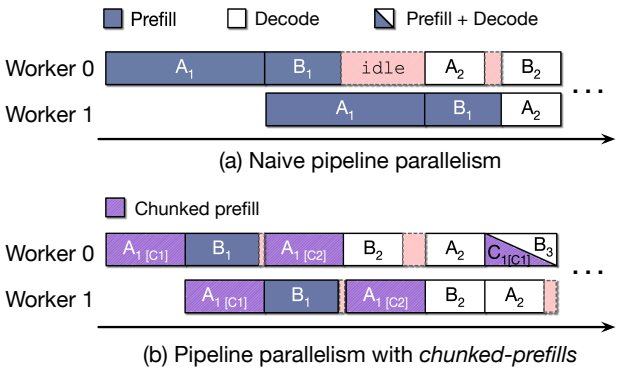

Figure 5: Reducing pipeline stalls from chunked-prefill [2]

nificantly widens to 31% for batch sizes between 128 and 160. Due to the step-function nature of linear operations [20], a batch size increase from 128 to 129 can abruptly trigger this about 31% idle time, resulting in substantial *D-D imbalance*. To mitigate such inefficiencies, microbatches for decode-only phases should be configured in multiples of 128 to align with the preferred efficiency of the underlying compute kernels.

3.2 Our Approaches

3.2.1 Chunked Prefills in Pipeline Parallelism

To reduce the pipeline bubbles caused by long prefills, a simple and straightforward approach is to leverage *chunked-prefill*, which splits the long input sequences into small, fixed-size chunks [2]. Since prefill computation is proportional to the input prompt length, limiting the prompt with a fixed chunk size helps reduce the latency imbalance across pipeline workers. Figure 4a shows the pipeline bubble time by increasing the request rate for two different chunk sizes. The large chunk size of 2,048 is determined by the compute capability of the NVIDIA A100 GPU used in this analysis. At low request rates, the chunk size of 128 results in fewer bubbles than 2,048. With a chunk size of 2,048, under low to moderate load (1~3 req/s), a few long prefill microbatches dominate the pipeline, increasing pipeline bubbles. Once the request rate reaches around 4 req/s, the pipeline is more consistently filled with incoming prefill requests, which reduces imbalance across stages. For request rates above 5 req/s, pipeline bubbles rarely occur for either chunk size because each pipeline stage remains fully utilized by the increased number of tokens.

While smaller chunk sizes help minimize pipeline stalls across the load, they sacrifice the computational throughput because the number of tokens to be processed per iteration is reduced. Figure 4b presents token throughput according to the chunk sizes. The chunk size of 128 shows significantly lower throughput than that of 2,048, leading to underutilization of GPU resources. This exacerbates TTFT performance, especially when the incoming request rate is high, as more requests are queued. Larger chunks are more effective for achieving high computational throughput.

To balance the trade-off between minimizing pipeline bubbles and maximizing GPU utilization, the chunk size must be dynamically adjusted according to system load.

3.2.2 Balancing Microbatches

Although adjusting the chunk size in prefill phases can mitigate pipeline bubbles caused by long prefills, it cannot make pipeline stages balanced in decode-heavy phases where most batches consist of only decode phases, as shown in Figure 2 ❸. In such decode-heavy phases, the computational load of each microbatch is primarily determined by the number of requests, since each request processes only a single input token. However, in existing LLM serving systems, once a request is assigned to a microbatch, it remains fixed for its lifetime [14, 37]. This static scheduling scheme magnifies imbalance and sustains pipeline stalls across multiple iterations. Note that tensor parallelism does not decompose input batches into microbatches; instead, it evenly partitions the computation of each batch across GPUs.

To address this issue, a straightforward approach is to dynamically rebalance the number of requests in microbatches across pipeline stages during iteration-level scheduling.

4 Retrofitting Pipeline Parallelism

4.1 Dynamic Chunked Prefill

Our design goal is to adaptively select a chunk size that minimizes pipeline bubbles while maintaining sufficient GPU utilization to process the current request load. Figure 5 shows that dividing the prompt (A_1) into two smaller chunks ($A_{1[C1]}$ and $A_{1[C2]}$) allows earlier stages in the pipeline to make progress, thus reducing idle time.

When determining the optimal chunk size, we treat the key performance metrics of online LLM serving, $TTFT_{SLO}$ and $TPOT_{SLO}$, as constraints. These two SLOs jointly define the feasible range of chunk sizes. Based on these constraints, our

Algorithm 1 Greedy chunk size adjustment

```
D_p ← Pipeline depth
C ← Set of possible chunk sizes (e.g., {128, 256, ...})
c ← Current chunk size
δ ← Chunk adjustment step size (e.g., 128)
KV_free ← Available KV cache memory ratio (∈ [0,1])
θ_mem ← KV memory watermark (∈ [0,1])
α, β ← Safe and critical boundaries for TTFT_slack (∈ [0,1])
γ ← Boundary for TPOT_slack (∈ [0,1])

for every D_p scheduling iterations do
    # ❶ Retrieve system metrics from the previous iterations
    retrieve_metrics (TTFT_slack, TPOT_slack, KV_free)
    # ❷ Check the available KV space
    if KV_free < θ_mem then
        c ← min{x ∈ C | x > N_run_req}
    # ❸ TPOT is violated or there is sufficient TTFT_slack
    else if TPOT_slack < 0 or TTFT_slack > α · TTFT_SLO then
        c ← c − δ
    # ❹ TTFT_slack is tight and there is sufficient TPOT_slack
    else if TTFT_slack < β · TTFT_SLO and TPOT_slack > γ · TPOT_SLO then
        c ← c + δ
```

primary objective is to minimize pipeline bubbles by selecting the smallest chunk size that can accommodate the current request load. As demand increases, the system adaptively enlarges the chunk size to improve utilization, but strictly limits this increase based on $TPOT_{SLO}$. When a TPOT violation is anticipated, our scheduler promptly reduces the chunk size to preserve responsiveness.

Meanwhile, $TTFT_{SLO}$ serves as an indicator of the current request load. When the waiting queue grows due to high request arrival rates, incoming requests are likely to violate $TTFT_{SLO}$. To mitigate this, the system increases the chunk size to increase throughput and drain the queue more quickly. However, this adjustment is allowed only as long as it does not violate $TPOT_{SLO}$. When TTFT is low, it indicates light load. In this case, the system actively reduces the chunk size. This adjustment can effectively mitigate the pipeline bubbles. This sophisticated scheduling improves resource efficiency by minimizing the idle time caused by pipeline imbalances. Based on these common optimization principles, we explore two approaches in the following sections: a greedy approach and a predictive approach.

4.1.1 Greedy approach

We first present a simple yet effective greedy method (Algorithm 1) that operates as a feedback control loop to dynamically adjust the chunk size. We maintain a discrete set of candidate chunk sizes $\mathcal{C}$ and keep the current chunk size $c \in \mathcal{C}$, initialized to the minimum chunk size (e.g., 128). We update c every D_p scheduling iterations, since a chunk size change takes effect only after a microbatch has traversed all D_p stages. We use three control parameters (α, β, and γ) that define tolerance boundaries for $TTFT_{SLO}$ and $TPOT_{SLO}$. An additional parameter, θ_{mem}, prevents out-of-memory (OOM) problems during inference.

For every D_p scheduling iterations, ❶ we compute $TTFT_{slack}$ and $TPOT_{slack}$, the remaining latency budgets for their respective SLOs, based on measured TTFT and TPOT from the previous iterations. Also, we collect the available KV memory ratio KV_{free}. Then, ❷ we perform a memory sanity check. When $KV_{free} < \theta_{mem}$, keeping a large chunk size can cause some stages to fail KV allocations. In this case, we immediately reset c to the smallest candidate that is larger than the current number of running requests. This decision prioritizes quickly draining in-flight requests, freeing KV memory, and minimizing additional bubbles.

If memory is sufficient, we then adjust the chunk size based on latency slack. ❸ When the observed $TPOT_{slack}$ indicates that the $TPOT_{SLO}$ is (or is about to be) violated, we decrease the chunk size. This reduces the pipeline bubbles caused by the prefill phase and helps ensure that the system continues to satisfy the target $TPOT_{SLO}$ for in-flight requests. In addition, when $TTFT_{slack}$ is sufficiently large, implying that the request load is low relative to the current chunk size and the system is far from the $TTFT_{SLO}$ violation. In this case, we also decrease the chunk size. This decision mitigates the *P-P* and *P-D* imbalances and significantly improves TPOT. Under light load, this adjustment has little impact on throughput because the system is not compute-saturated.

❹ When $TTFT_{slack}$ is insufficient while TPOT remains within a comfortable range, we increase the chunk size to improve throughput. This enlarges the amount of prefill computation per iteration, improving compute utilization and reducing TTFT, while preventing the violation of $TPOT_{SLO}$.

Limitation: Although our greedy approach performs reasonably well, it has structural limitations in finding the optimal chunk size. First, due to its step-wise adjustment mechanism based on reactive feedback, the greedy approach suffers from inherent latency in adaptation. It requires multiple iterations to converge on the optimal chunk size, so under rapidly changing workloads, the scheduler is constantly chasing a moving target. This inevitably leads to prolonged periods of operation in a suboptimal state.

Second, as the greedy approach relies only on latency statistics observed in previous iterations, $TTFT_{slack}$ and $TPOT_{slack}$, it leads to suboptimal chunk sizes under pipeline parallelism, where feedback is delayed by pipeline depth and skewed by larger chunks in other pipeline stages. These limitations motivate us to explore a predictive approach that estimates the iteration latency of LLM inference from the current system state, enabling accurate slack estimation.

4.1.2 Predictive approach

Overview: To overcome the limitations of the reactive greedy approach, we propose a predictive chunk size adjustment technique. This method leverages a lightweight latency prediction

model to evaluate candidate chunk sizes and select one that minimizes pipeline bubbles, thereby improving goodput.

To make this decision, given the current system state (e.g., the waiting queue and in-flight batches), our scheduler uses the prediction model to estimate the iteration latency and throughput of each candidate chunk size. The iteration latency is then multiplied by the pipeline depth to estimate the end-to-end latency under pipeline parallelism. The scheduler then establishes an upper bound on the chunk candidates by comparing the predicted latency against $TPOT_{SLO}$. Next, it derives a lower bound by comparing the predicted throughput against the minimum throughput required to satisfy $TTFT_{SLO}$. Finally, the scheduler selects the smallest feasible chunk size within these bounds to minimize pipeline bubbles.

Latency prediction model: Our latency prediction model consists of two components: offline profiling for linear layers and online adaptation for attention layers. As shown in Figure 3, iteration latency is dominated by linear layers, whose latency scales with the total number of batched tokens (i.e., chunk size), enabling accurate latency prediction through offline profiling. In chunked-prefill, the selected chunk size determines the number of tokens processed per iteration, making the input size to linear layers largely deterministic. On the other hand, attention layers account for a smaller and dynamic portion of the overall latency tied to the request composition. Since LLM inference is inherently auto-regressive, the composition of requests in the batch evolves gradually across iterations. This gradual evolution enables real-time calibration of dynamic attention latency, allowing the model to track system dynamics without introducing prediction instability.

We model the per-iteration latency, T_{iter}, as the sum of an offline component, $T_{offline}$, and an online component, T_{online}. Thus, $T_{iter} = T_{offline} + T_{online}$. The offline component models the latency of linear layers as a function of the total number of batched tokens, N_{tokens}, along with a constant runtime cost: $T_{offline} = \alpha_0 \cdot N_{tokens} + \alpha_1$. In the offline phase, we measure iteration latency across discrete batched tokens (N_{tokens}) from 128 to 2048 to compute the latency for linear layers.

For the online component, T_{online}, we model the latency of attention layers, which varies with the context lengths:

$$T_{online} = \beta_0 \cdot \sum(L_{past} \cdot L_{pre}) + \beta_1 \cdot \sum(L_{pre}^2) + \beta_2 \cdot \sum L_{dec} + \varepsilon$$

In chunked-prefill, the attention latency in each iteration depends on three quantities: the accumulated past context from prior chunks (denoted as L_{past}), the current prefill chunk (L_{pre}), and the context lengths of decode requests (L_{dec}). These contribute through three terms, prefill attention over past context ($L_{past} \cdot L_{pre}$), self-attention within the current chunk (L_{pre}^2), and decode attention (L_{dec}), with coefficients, β_0, β_1, and β_2, respectively. The residual ε accounts for unmodeled system noise.

To calibrate the parameters (β_0, β_1, and β_2), we compute the difference between the predicted and the measured iteration latency at each inference step. Based on this prediction error, we adaptively update the model parameters using the Recursive Least Squares (RLS) algorithm [8]. RLS is well-suited for our setting in two ways. First, unlike standard gradient descent, whose updates are sensitive to the scale of input features, RLS uses an internal covariance matrix to adapt to feature-wise scaling, mitigating the severe scale disparities between terms (e.g., L_{pre}^2 vs. L_{dec}). Second, a forgetting factor prioritizes recent observations, allowing the model to quickly adapt to dynamic changes such as prefill-decode interference.

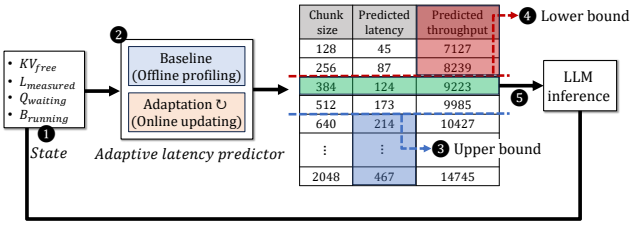

Figure 6: Workflow of predictive dynamic chunked-prefill

Online inference: Figure 6 presents how our scheduler leverages the prediction model to find the optimal chunk size. For each scheduling iteration, ❶ the scheduler first retrieves the current system state, specifically the available KV memory (KV_{free}), the measured iteration latency from the previous iteration ($L_{measured}$), the waiting queue ($Q_{waiting}$), and the running batch ($B_{running}$). It then performs a memory safety check, which is identical to that in the greedy algorithm. ❷ It updates the predictor using $L_{measured}$ and attention features (e.g., prefix and context lengths) measured in the previous iteration. The updated predictor then estimates the iteration latency for each candidate chunk size using features derived from $Q_{waiting}$ and $B_{running}$. These estimates are used to derive the predicted end-to-end latency, by scaling the iteration latency with the pipeline depth, and the expected throughput. ❸ Candidates whose predicted latency exceeds $TPOT_{SLO}$ are discarded, leaving a feasible search pool.

To determine the lower bound on the chunk size, ❹ the scheduler derives the minimum prefill throughput required to satisfy $TTFT_{SLO}$. It uses the incoming request rate and token distribution over a sliding window to compute an arrival-matching throughput, ensuring that newly arriving requests can be served in real time without growing the waiting queue. It further accounts for waiting requests exceeding a freshness threshold, calculated by dividing their total prompt length by their remaining time budget (i.e., $TTFT_{SLO}$ minus the average waiting time). The arrival-matching throughput and this additional component are summed to obtain the minimum required throughput. The lower bound is defined as the smallest chunk size whose predicted throughput meets this target.

Finally, ❺ it determines the optimal chunk size. If candidates satisfying both SLOs exist, the smallest one is chosen to minimize pipeline bubbles while satisfying the GPU uti-

lization required by the current request load. If no candidate meets the conditions, the system is considered overloaded. In this case, to prioritize draining the waiting queue, it selects the largest chunk that satisfies $TPOT_{SLO}$ to maximize throughput.

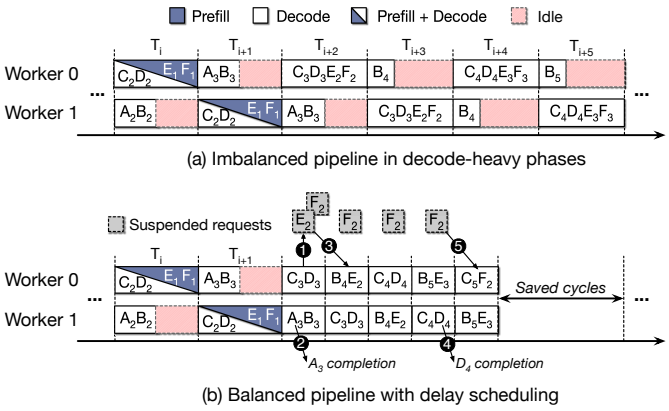
4.2 Dynamic Rebalancing

Although our dynamic chunked-prefill effectively reduces pipeline bubbles caused by prefill requests, it is ineffective when the running batch contains no prefill requests (i.e., decode-only iterations). To further reduce pipeline bubbles, we introduce a runtime scheme, called *delay scheduling*, that dynamically rebalances workloads across pipeline stages. We observe that in decode-only iterations, the number of requests is the dominant factor in computational imbalance. This arises because each request consumes only one input token at a time, resulting in nearly uniform per-request computation in the linear layers. As shown in Figure 3b, the decoding latency highly depends on the number of requests, and the linear layer takes most of the time.

When balancing microbatch sizes across pipeline stages, our delay scheduling policy aligns batch sizes with hardware-efficient batch size boundaries (e.g., 128, 256, 384). As shown in Figure 3c, processing 129 tokens costs almost the same as processing 256 tokens, so batch sizes that are slightly misaligned with these boundaries achieve little additional throughput while exacerbating *D–D imbalance*. To mitigate this, we apply a simple threshold-based preemption policy. If the number of requests in a microbatch exceeds a boundary but the overflow is within a configured threshold, we temporarily preempt the excess requests, reducing the batch size to the nearest boundary. If the overflow is larger than the threshold, we instead rebalance by aligning the batch size to the average request count across all microbatches, resuming previously suspended requests as needed to fill the gap.

The selection of which requests to preempt adapts to the current system state. When $TPOT_{slack}$ is insufficient, we preferentially preempt older requests, which can tolerate additional latency more readily. This preserves the TPOT of newer requests and reduces pipeline bubbles, lowering overall TPOT. When $TPOT_{slack}$ is ample, however, the primary risk becomes KV-cache exhaustion and $TTFT_{SLO}$ violations. In this case, we preempt newer requests instead, trading off $TPOT_{slack}$ to let older requests finish earlier and free KV memory, thereby improving goodput.

Figure 7 highlights the effectiveness of our delay scheduling approach. Although some decode-phase requests are deferred to subsequent iterations, this strategy reduces pipeline stalls, thereby improving overall completion time. At each scheduling iteration, we examine the load distribution across pipeline stages. In naive pipeline parallelism (Figure 7a), `Worker 0` executes a microbatch containing $C_3D_3E_2F_2$ while `Worker 1` processes a smaller microbatch A_3B_3 at T_{i+2}, leading to significant imbalance and idle periods. In contrast,



(a) Imbalanced pipeline in decode-heavy phases

(b) Balanced pipeline with delay scheduling

Figure 7: Reducing pipeline stalls with delay scheduling

with delay scheduling (Figure 7b), ❶ request E and F are temporarily suspended to rebalance the pipeline. Although their decoding phases E_2 and F_2 are postponed, this reduces pipeline stalls across stages. ❷ Once request A completes at T_{i+2}, ❸ the suspended decode-phase E_2 can be resumed, forming a microbatch B_4E_2. Similarly, ❹ after request D finishes, ❺ the suspended decode-phase F_2 is resumed. As the pipeline stages become more balanced, the overall latency is significantly improved.

Figure 8: Input and output length distributions

5 Evaluation

5.1 Experimental Setup

Environment: We run all experiments on a server with four NVIDIA A100 (40GB) GPUs, one 128-core AMD EPYC 9754 CPU (2.25 GHz), and 768 GB of RAM. Each GPU is connected to the host system via PCIe 4.0. We use PyTorch v2.5.1 [3], CUDA 12.4 [18], and FlashInfer [34]. We implement our proposed techniques as well as the baseline pipeline parallelism with chunked prefill on top of SGLang 0.4.1 [37].

Models and workloads: We select two popular LLM models, Qwen2.5 32B and 14B [32]. All the models are BF-16 formatted versions. To mimic real-world workloads, we use three real-world traces, including Azure Conversation [22], ShareGPT [24], and CNN [9], and a synthetic trace for evaluating decode-heavy workloads by reversing the input and output distribution of the CNN trace [9]. Figure 8 shows the input and output length distributions of the traces.

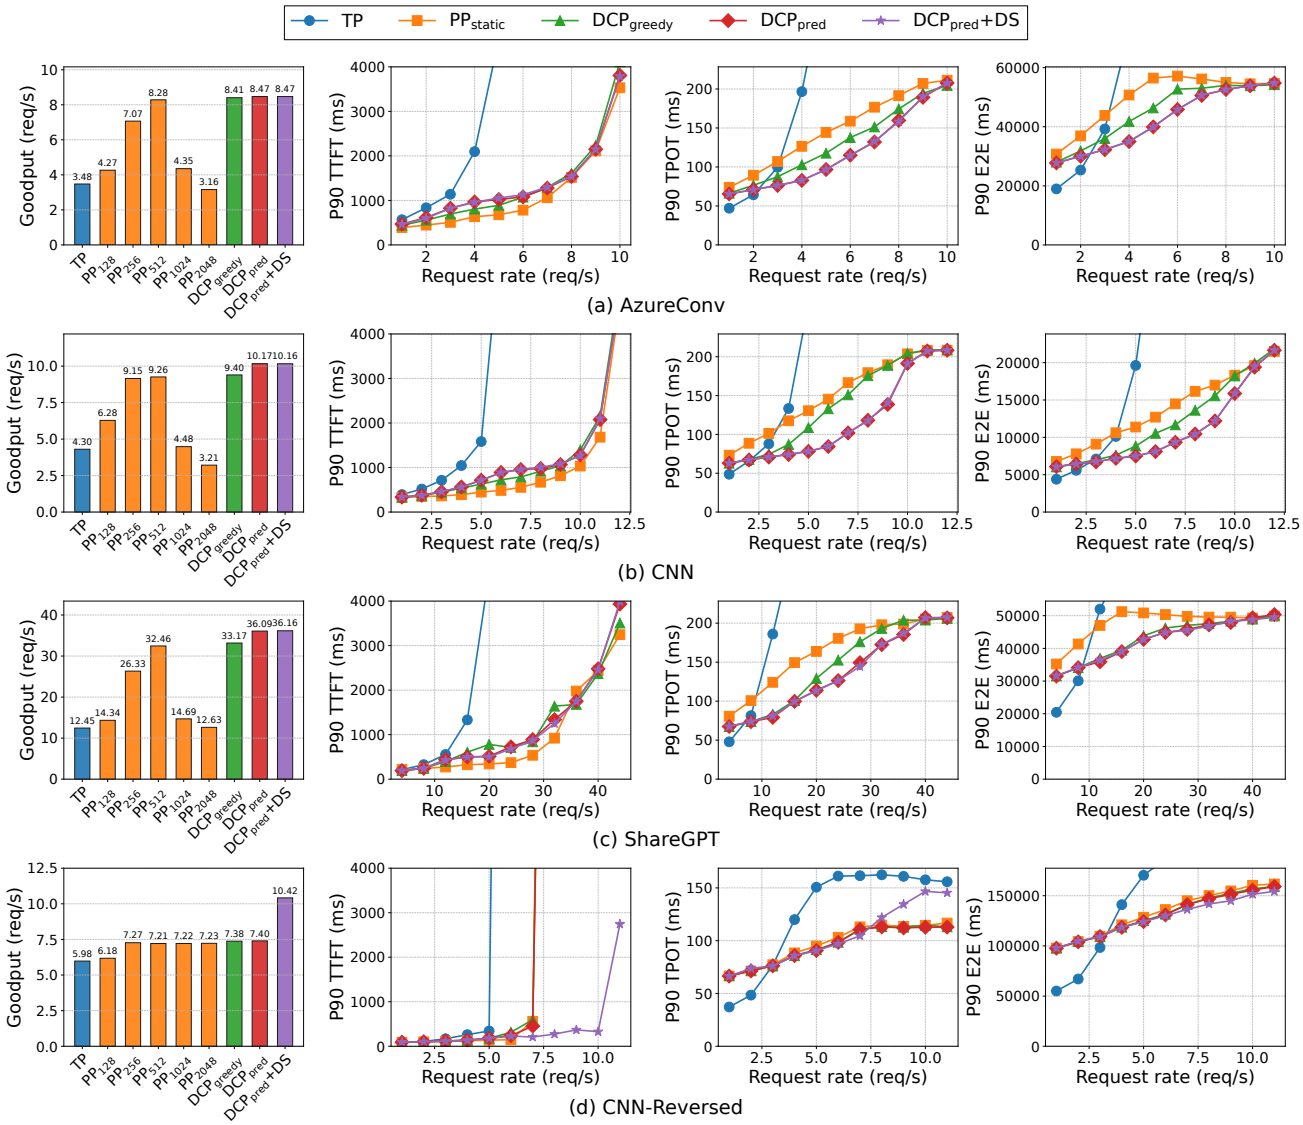

Figure 9: Goodput, TTFT, TPOT, and E2E latency for Qwen2.5-32B

Comparisons: Our baselines are tensor parallelism (**TP**) and pipeline parallelism (**PP**). We explore our three design options: dynamic chunked-prefill (**DCP**) with the greedy approach (**DCP$_{\text{greedy}}$**) and the predictive approach (**DCP$_{\text{pred}}$**), and the integration of the predictive DCP and delay scheduling (**DCP$_{\text{pred}}$+DS**).

Metrics: We use goodput as our primary evaluation metric, defined as the highest request rate at which both the 90th-percentile (P90) TTFT and TPOT satisfy their SLOs. In accordance with MLPerf guidelines [1], we set the latency budgets for TTFT and TPOT to 2,000ms and 200ms, respectively. Our primary objective is to maximize this goodput. Once we achieve comparable or sufficiently high goodput levels, we then shift our focus to latency minimization. We closely examine the P90 values for TTFT, TPOT, and end-to-end (E2E) latency to compare the latency behavior across designs.

5.2 Experimental Results

5.2.1 Goodput and latency

Figure 9 shows the goodput, TTFT, TPOT, and E2E latency as we increase the request rate for Qwen2.5-32B. To emulate realistic user traffic, we generate request arrivals according to a Poisson process, a standard model for interactive user-facing services. For tensor parallelism, we use the default chunk size of 2,048 [2, 31]. For the TTFT, TPOT, and E2E latency plots, we report only PP$_{\text{static}}$, configured with the chunk size that achieves the highest goodput for each workload. The `AzureConv`, `CNN`, and `ShareGPT` workloads exhibit prefill-heavy behavior, leading to *Prefill-Prefill* and *Prefill-Decode pipeline imbalances*, whereas `CNN-Reversed` is decode-heavy and thus suffers from *Decode–Decode pipeline imbalance*. On `AzureConv`, `CNN`, and `ShareGPT`,

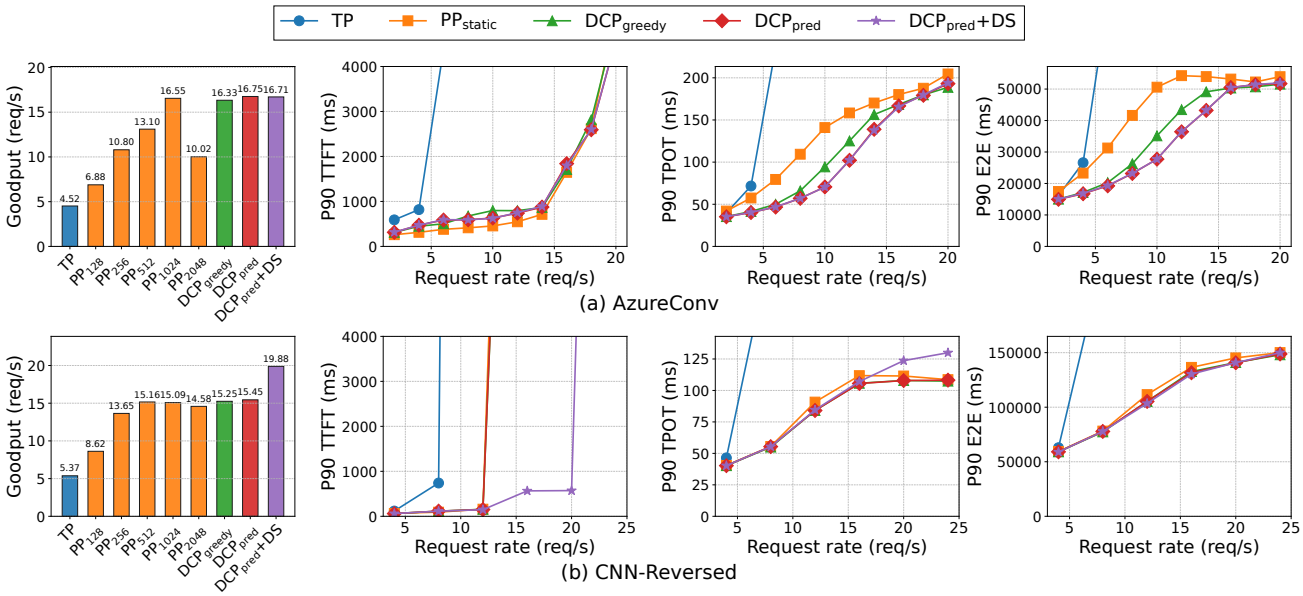

Figure 10: Goodput, TTFT, TPOT, and E2E latency for Qwen2.5-14B

a chunk size of 512 achieves the highest goodput, while `CNN-Reversed` reaches its peak goodput with a chunk size of 256, indicating that the optimal chunk size is workload-dependent. Also, this indicates that once we select the appropriate chunk size, pipeline parallelism delivers higher goodput than tensor parallelism because it substantially reduces pipeline imbalance.

However, PP_{static} cannot adjust the chunk size at runtime as the load (request rate) changes, and thus continues to suffer from pipeline bubbles. Our two dynamic chunked prefill (DCP) techniques address this limitation. Compared to PP_{static}, both DCP variants slightly increase TTFT but have a negligible impact on goodput, while substantially improving TPOT and E2E latency by reducing pipeline bubbles.

For `AzureConv`, DCP_{greedy} reduces TPOT and E2E latency by up to 19% and 18%, respectively, whereas DCP_{pred} achieves 35% and 31% reductions. The reactive nature of DCP_{greedy} fundamentally limits how aggressively it can exploit favorable operating points. Consequently, it nearly matches DCP_{pred} in goodput, but it shows a smaller latency reduction. We observe similar trends in the other prefill-heavy workloads. Compared to PP_{static}, on `CNN`, DCP_{greedy} reduces TPOT and E2E latency by 27% and 28%, respectively, whereas DCP_{pred} achieves larger reductions of 42% and 36%. On `ShareGPT`, DCP_{pred} achieves reductions of 36% and 24%. These results indicate that predictive chunk size selection provides more consistent reductions across workloads than the greedy one.

We also evaluate our delay scheduling (DS), which rebalances work across microbatches (DCP_{pred}+DS). For prefill-heavy workloads, *D–D pipeline imbalance* rarely occurs, so delay scheduling is rarely triggered. On the other hand, for decode-heavy workloads where input sequences are short but outputs are long, delay scheduling is frequently activated and further reduces E2E latency on top of DCP_{pred}. For `CNN-Reversed`, our delay scheduling can drastically reduce the TTFT latency, leading to higher goodput compared to our dynamic chunked prefill and the two baselines. Once requests are processed quickly, we can promptly reclaim their KV memory, which in turn reduces TTFT.

We also evaluate our techniques on Qwen2.5-14B. Due to space constraints, Figure 10 reports results for two representative workloads, `AzureConv` (prefill-heavy) and `CNN-Reversed` (decode-heavy). Overall, we observe similar performance trends to those of Qwen2.5-32B. For `AzureConv`, a chunk size of 1,024 achieves the highest goodput. Compared to Qwen2.5-32B, the desired chunk size is changed. Our dynamic chunked prefill techniques achieve the highest goodput and lower TPOT and E2E latency. Compared to PP_{static}, our greedy and predictive approaches reduce the TPOT latency by up to 40% and 50%. Although our delay scheduling (DCP_{pred}+DS) has little effect on the prefill-heavy workload, it reduces TTFT and median E2E latency for the decode-heavy workload. While the 32B model shows a P90 E2E latency reduction at high request rates, the 14B model shows no visible reduction. Nonetheless, the improved median latency shows the effectiveness of our delay scheduling.

5.2.2 Performance analysis

We analyze how effectively our techniques reduce pipeline stalls and imbalance across stages. Figure 11 shows the cumulative distributions of per-iteration latency for (a) `AzureConv`, (b) `CNN`, and (c) `CNN-Reversed`. For each workload, we de-

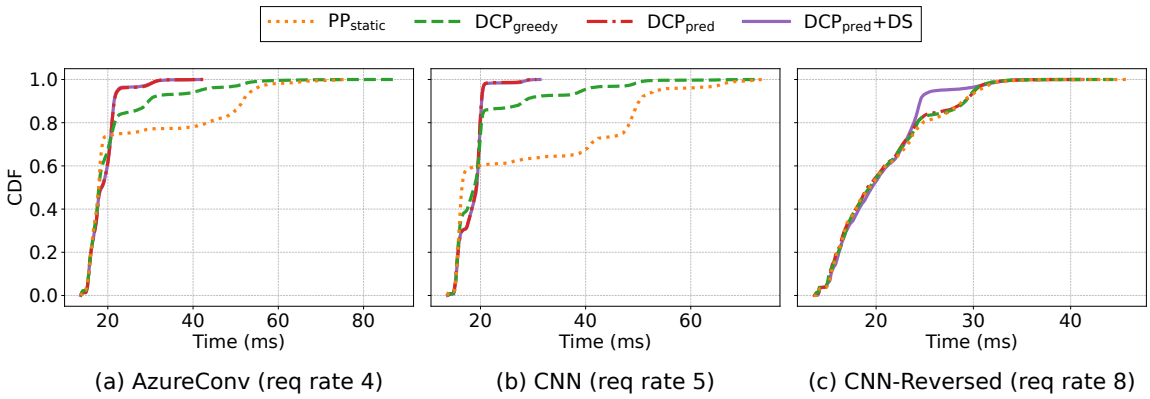

Figure 11: CDF of iteration latency for (a) AzureConv, (b) CNN, and (c) CNN-Reversed

rive the distributions from the runs in Figure 9 at average loads of roughly 4, 5, and 8 requests per second, respectively.

For the `AzureConv` workload, the 90th-percentile iteration latency drops from 51.68ms with PP_{static} to 29.56ms with DCP_{greedy} and further to 21.53ms with DCP_{pred}. At the 99th percentile, DCP_{pred} achieves 30.94ms compared to 65.34ms with PP_{static}, yielding a 2.11× improvement that significantly reduces tail latency. This suggests that DCP_{pred} more efficiently concentrates iterations within this lower bound and thereby minimizes pipeline bubbles. For `AzureConv`, *decode-decode pipeline imbalance* is negligible. Therefore, DCP_{pred}+DS is rarely triggered and results in behavior similar to DCP_{pred}.

The `CNN` workload exhibits a similar performance behavior to `AzureConv`. DCP_{pred} substantially shortens per-iteration latency, yielding a noticeable performance improvement over PP_{static}. Although DCP_{pred} shows slightly higher latency than PP_{static} below the 50th percentile, starting around the 60th percentile DCP_{pred} becomes faster and its advantage grows increasingly large toward the tail.

For the `CNN-Reversed` workload, the short input sequences and long outputs leave much less room for control via our DCP schemes. As a result, PP_{static}, DCP_{greedy}, and DCP_{pred} exhibit only marginal differences. On the other hand, with delay scheduling the 90th-percentile iteration latency drops to 24.53ms, whereas PP_{static} shows 28.94ms. This behavior confirms that decode-heavy workloads structurally suffer less from pipeline bubbles than prefill-heavy ones, but also that our DCP techniques alone cannot fully eliminate imbalance.

5.2.3 Goodput under varying SLOs

We evaluate how our proposed techniques perform under increasingly tight SLO budgets. Figure 12 shows goodput for Qwen2.5-32B and Qwen2.5-14B under `AzureConv` and `CNN-Reversed` workloads with varying SLO scales. On the x-axis, SLO Scale of 1.0 corresponds to 2,000 ms for TTFT and 200 ms for TPOT. The y-axis represents goodput, the maximum stable request rate satisfying these SLOs. Both TP and PP baselines use a default chunk size of 2048. PP generally outperforms TP, except for the 32B model under `AzureConv`, where the high compute costs dominate, diminishing PP's advantage in reducing communication overhead. We therefore focus on comparing our proposed approaches against the PP baseline. Since our two dynamic chunked prefill variants, DCP_{greedy} and DCP_{pred}, achieve similar goodput across SLO scales, we refer to them collectively as DCP unless otherwise specified. At the strictest SLO scale of 0.2 for the 32B model, even the smallest possible chunk violates the TPOT constraint, reducing the goodput of all PP-based systems to zero.

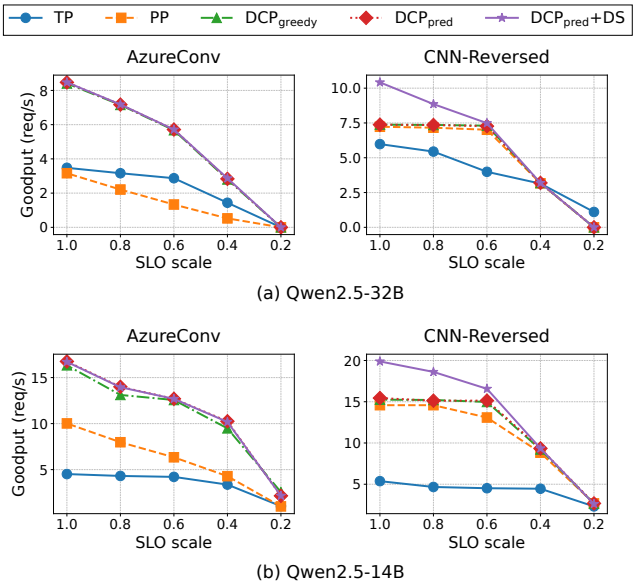

Figure 12: Goodput comparison of Qwen2.5 32B and 14B under various SLO constraints.

DCP effectively mitigates the *P-P* and *P-D* pipeline imbalances inherent in the prefill-heavy `AzureConv` workload, significantly outperforming the PP baseline. Notably, the rela-

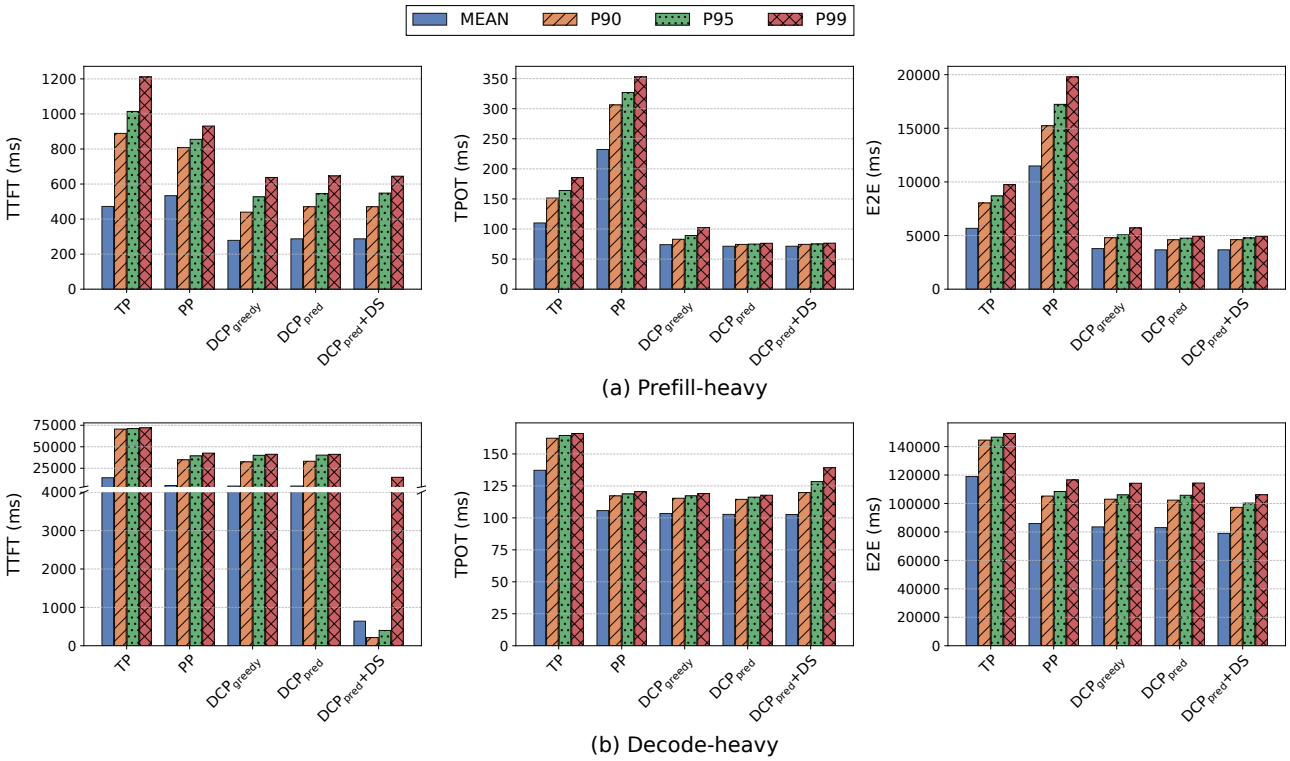

Figure 13: TTFT, TPOT, and E2E latency for (a) prefill-heavy and (b) decode-heavy synthetic workloads. Input and output lengths are uniformly sampled from [512, 1024] and [32, 64] tokens for (a), and from [32, 64] and [512, 1024] tokens for (b).

tive improvement of DCP over PP grows as SLO constraints tighten. As the SLO scale decreases from 1.0 to 0.4, the improvement increases from 2.7× to 5.4× for the 32B model, and from 1.7× to 2.4× for the 14B model. This highlights DCP's robustness under increasingly tight latency constraints. Meanwhile, delay scheduling (DS) provides no additional benefit for this prefill-heavy workload.

By contrast, in the decode-heavy `CNN-Reversed` workload, the goodput of the PP baseline remains nearly constant as the SLO scale decreases from 1.0 to 0.6. With minimal prefill tokens, violations are primarily driven by KV cache exhaustion that triggers abrupt TTFT spikes, making goodput insensitive to moderate SLO tightening. While DCP provides limited benefits due to the small prefill fraction, DS plays a crucial role by resolving the *D-D* pipeline imbalance inherent to decoding operations, yielding up to a 1.4× goodput improvement for both the 14B and 32B models over the PP baseline. However, as the SLO tightens below 0.6, DS effectiveness drops sharply since the system hits the TPOT limit before accumulating enough requests to meet its activation threshold.

5.2.4 Synthetic prefill-heavy and decode-heavy cases

To further analyze the performance benefits and limitations of each scheme, we construct synthetic workloads by uniformly sampling sequence lengths. For a prefill-heavy workload, input and output lengths are sampled from 512 to 1024 and 32 to 64 tokens, respectively; the ranges are swapped for a decode-heavy workload. Figure 13 presents TTFT, TPOT, and end-to-end latency when serving Qwen2.5-32B under prefill-heavy and decode-heavy workloads at 5 and 14 requests per second, respectively. These rates represent the point at which the PP baseline begins to violate the SLO constraints.

In the prefill-heavy workload, both TP and PP baselines achieve similar TTFT, but PP suffers much higher TPOT and end-to-end latency than TP due to severe pipeline imbalances. Meanwhile, our two DCP methods show lower latency than TP and PP across all metrics by reducing these imbalances. This indicates that mitigating *P-P* imbalance is more critical than using larger chunks to improve GPU utilization, even if smaller chunks reduce batching efficiency. The two DCP variants achieve nearly identical mean latency, while DCP_{pred} further reduces P99 TPOT and end-to-end latency by 25% and 13% over $\text{DCP}_{\text{greedy}}$, respectively, showing its advantage in reducing tail latency. Delay scheduling has little effect in this prefill-heavy case because the dominant bottleneck comes from the prefill-induced pipeline bubbles.

In the decode-heavy workload, PP achieves lower latency than TP across all metrics, reducing mean TTFT, TPOT, and end-to-end latency by 2.82×, 1.30×, and 1.38×, respectively. Both DCP variants perform similarly to PP, since *P–P* and *P–D* imbalances rarely occur in decode-heavy workloads.

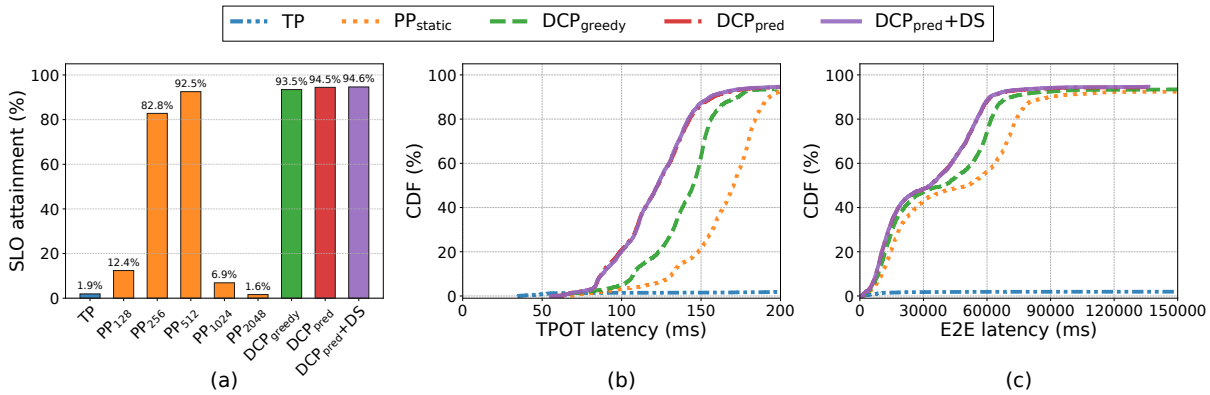

Figure 14: Performance of real-trace using Azure Conversation [22]: (a) SLO attainment, (b) TPOT latency CDF (conditional on $TTFT_{SLO}$), and (c) E2E latency CDF (conditional on all SLOs) for Qwen2.5-32B

Meanwhile, delay scheduling (DS) effectively reduces *D-D* imbalance, lowering TTFT and end-to-end latency. Specifically, DS significantly reduces the TTFT latency compared to DCP and PP, resulting in lower end-to-end latency. Once *D-D* imbalance becomes severe, DS preempts short-context requests in the batch to expedite the completion of long-context requests, reclaiming their KV memory earlier and allowing more pending requests to be served. As a result, DS reduces end-to-end latency by 4,062ms on average and 8,088ms at P99 compared to DCP_{pred}. However, these preempted requests incur higher TPOT, making P99 TPOT 15% worse than DCP_{pred}.

5.2.5 Performance of real-world trace

We evaluate our techniques using a real-world workload trace from `AzureConv`. Specifically, we replay the first 15 minutes of the trace. As the original load is already high, we scale the request arrival rate down to 0.9× its original value, so that the SLO attainment of $\text{PP}_{\text{static}}$ is approximately 90%.

Figure 14 presents (a) SLO attainment, (b) TPOT CDF for satisfying TTFT_{SLO}, and (c) E2E latency CDF for requests satisfying both TTFT_{SLO} and TPOT_{SLO}. TP achieves only 1.9% SLO attainment due to its substantial communication overhead. With the default chunk size of 2,048 tokens, pipeline parallelism (PP_{2048}) performs even worse, with SLO attainment of just 1.6%. On the other hand, $\text{PP}_{\text{static}}$, whose chunk size is selected via an offline search, achieves 92.5% SLO attainment. The workload is prefill-heavy, so our delay scheduling scheme is not activated.

While the overall SLO attainment of $\text{PP}_{\text{static}}$ and DCP is similar, DCP more effectively eliminates pipeline bubbles and shifts a larger fraction of requests into lower-latency regions. Among the two designs, $\text{DCP}_{\text{greedy}}$ yields slightly worse performance than DCP_{pred} due to the inherent limitations of its heuristic. In real-world traces, high load appears in short bursts rather than being sustained. Thus, choosing a fixed chunk size based on peak load (as in PP_{static}) is inefficient. When the load drops, the large chunk size underutilizes pipeline stages and reintroduces pipeline bubbles during normal low-load periods. If the TPOT_{SLO} is set to 150 ms, $\text{DCP}_{\text{greedy}}$ and DCP_{pred} achieve 3.06× and 4.14× higher attainment than PP_{static}, respectively. In terms of E2E latency, $\text{DCP}_{\text{greedy}}$ and DCP_{pred} complete 1.3× and 1.6× as many requests within 60,000ms as $\text{PP}_{\text{static}}$.

Model	MAPE (%)	Pred. time (ms)	Size (KB)
ALP (Baseline)	15.85	0.000136	0.363
+ Prefix Attn	12.21	0.001027	0.408
+ Prefill Attn	9.69	0.001570	0.474

DNN (2-layer, BN)	2.56	0.046407	570

Table 1: Comparison of latency prediction models

5.2.6 Analysis of latency prediction models

To understand the effectiveness of the proposed adaptive latency prediction (ALP) model, we perform an in-depth analysis of its prediction accuracy and computational cost. As described in Section 4.1.2, ALP accounts for latency variations in attention layers, which are inherently dynamic and cannot be predicted by offline profiling alone. We first evaluate how each component of ALP contributes to prediction accuracy, starting from an offline profiling method that models only the latency spent in linear layers and progressively adding the prefix, prefill, and decode attention terms, as well as residual terms. We measure Mean Absolute Percentage Error (MAPE) on a real-world `AzureConv` workload.

Table 1 presents the effectiveness of each ALP component. Since the offline profiling method does not account for the latency spent in attention layers or runtime noise, it shows

a relatively large prediction error. As we add each attention component, the model better predicts the latency contributed by attention layers, and MAPE gradually decreases. Finally, adding the residual ε term compensates for runtime noise that the attention terms cannot explain, achieving the lowest prediction error among the variants. Although prediction time and model size grow as the model becomes more sophisticated, both remain negligible.

We also evaluate three ML-based techniques for iteration latency prediction: linear regression using NumPy's `linalg.lstsq` [7], a decision tree ensemble using LightGBM [13], and a simple DNN with two linear layers and batch normalization. We train linear regression with the same features used in ALP's online adaptation phase, and additionally provide request-level statistics, such as the number of requests per microbatch and the average and maximum number of tokens per request, to the decision tree and DNN models. Although the decision tree ensemble and DNN achieve slightly lower MAPE than ALP, the improvement is marginal: ALP's MAPE is only 0.70 percentage points higher than that of the DNN model. This small accuracy gap does not lead to meaningful end-to-end performance improvements in TTFT or TPOT. In addition, these ML-based techniques require an offline training phase, whereas ALP performs lightweight online adaptation without pre-training. Therefore, ALP provides a more practical choice for LLM serving systems.

6 Related Work

There have been significant efforts to develop efficient LLM serving frameworks on modern GPUs. ORCA was an early and influential system that introduced iteration-level scheduling and selective batching techniques to effectively utilize GPU cores, achieving substantial performance gains [35]. More recently, chunked-prefill [2, 10] was proposed to enhance iteration-level scheduling under prefill-heavy workloads by splitting long prompts into smaller chunks, thereby alleviating TPOT latency. These techniques have been widely adopted in production frameworks such as vLLM [14], SGLang [37], TensorRT-LLM [28], and Dynamo [19]. In addition to the scheduling enhancement, managing KV-cache on GPU, CPU, and storage has also been widely studied to avoid the recomputation cost of attention [5, 12, 33, 36].

For multi-GPU environments, prior research has examined a range of parallelism strategies, including tensor parallelism [25, 27], pipeline parallelism [11, 17], and expert parallelism [15, 26] in MoE models to maximize hardware efficiency. In practice, tensor parallelism has become the de facto choice for single-node, multi-GPU LLM serving due to its predictable load balancing and low per-token latency, especially when supported by high-bandwidth interconnects. AlpaServe [16] extended this by combining statistical multiplexing with model parallelism to dynamically allocate GPU resources according to workload characteristics, improving throughput in multi-tenant settings. ExeGPT [21] further refined resource allocation with constraint-aware scheduling, jointly optimizing for latency, throughput, and GPU utilization in LLM inference.

However, despite these efforts, the interference between the prefill and decode phases causes significant bubbles in pipeline parallelism. To mitigate this, phase-disaggregated serving [22, 23, 38] isolated these phases on separate GPUs. While this design reduces interference, it introduces nontrivial overheads, including model weight duplication and high-bandwidth requirements for KV cache transfer. To avoid such overheads, unified serving with chunked-prefill [2] remains a practical choice, yet static chunking yields non-negligible pipeline bubbles. While recent dynamic chunking approaches [6] prioritized SLO compliance, they overlooked the structural constraints of pipeline parallelism, leaving pipeline bubbles unresolved. This highlights the need for a pipeline-specific dynamic chunking strategy that effectively eliminates bubbles under varying workloads.

7 Conclusions

This paper investigated the inefficiencies of pipeline parallelism in LLM serving and proposed scheduling techniques to mitigate pipeline imbalances. Our greedy and predictive chunk size adjustment schemes effectively improved pipeline performance in prefill-heavy workloads, while a dynamic rebalancing scheme further alleviated imbalance in decode-heavy workloads. We evaluated both individual techniques and integrated designs on the Qwen2.5 32B and 14B models using several real-world workloads. Experimental results demonstrated that pipeline parallelism with the proposed techniques outperforms tensor parallelism in terms of goodput for single-node, multi-GPU environments.

Acknowledgments

Abstract

Large language models (LLMs) are becoming critical to a variety of public services, motivating sovereign AI initiatives that seek to serve models on infrastructure they control. Yet much of this infrastructure is built as HPC clusters optimized for batch jobs rather than interactive, always-on inference services. Existing LLM serving engines efficiently execute requests on GPUs, but rely on an external control plane (e.g., Kubernetes in cloud environments) for service discovery, routing, health monitoring, and load balancing. In HPC environments, these primitives are often unavailable: resources are managed by schedulers such as Slurm, allocations are transient, compute nodes may be unreachable from outside the cluster, and GPU capacity is fragmented across heterogeneous clusters and administrative domains.

We present OpenTela, a user-space orchestration overlay that turns existing fragmented HPC clusters into a unified, cross-institutional serving platform. OpenTela provides fault-tolerant service discovery via a CRDT-based gossip network, a unified API over heterogeneous cluster managers and serving engines, and a heterogeneity-aware scheduler, all in user-space without root privileges or cluster reconfiguration. OpenTela has been deployed for over 22 months, serving 13 million requests and 15 billion tokens across 142 models to over 1000 researchers across multiple institutions. We open-source the system and release an anonymized production trace to facilitate further research into real-world LLM serving workloads, and provide a replicable blueprint for other sovereign AI initiatives to harness their own federated GPU infrastructure.

1 Introduction

As large language models (LLMs) are increasingly being integrated into critical digital infrastructure for public services such as administration [48], healthcare [7, 61], and education [14], governments and organizations need more control over how these models are developed and served. While commercial AI providers like OpenAI and Anthropic provide convenient access to state-of-the-art models, organizations using these models lack insight into how the models were trained — and hence the biases they contain. Users also have no control over the availability of these models and how they evolve over time (e.g., OpenAI can suddenly decide to stop serving a particular version of a model). Hence, many governments and organizations are investing heavily in *sovereign AI infrastructure*: compute clusters, data pipelines, model development research, and operational platforms that they can control, inspect, and govern [4, 24, 49, 64].

This shift has triggered large-scale public investment in AI-oriented supercomputing infrastructure. For example, Switzerland has invested in the Alps supercomputer, a geo-distributed cluster of over 10,000 NVIDIA Grace Hopper GPUs for open science [44]. Japan's ABCI 3.0 provides 6,128 NVIDIA H200 GPUs for AI [49]. The European Commission plans to build 19 AI Factories and up to five AI Gigafactories backed by a €20 billion investment [16]. The UK government has committed up to £2 billion to deliver new AI supercomputers [28]. Canada, Singapore, South Korea, the United States and many others are also investing in building and broadening access to AI compute [24–27].

Making sovereign AI useful in practice requires more than training models on this infrastructure. These models must also be served efficiently, reliably, and continuously to users. Model serving requires substantial compute, often exceeding the cycles spent on training [17, 67].

Yet the infrastructure being built for sovereign AI often consists of HPC clusters, which are designed for throughput-oriented batch jobs rather than interactive, always-on services like LLM inference. Model serving requires load balancing, dynamic service discovery, persistent endpoints, fault-tolerant request routing, and elastic scaling. LLM serving engines such as vLLM [38] and SGLang [75] assume that an external orchestration layer (e.g., Kubernetes) will provide the surrounding service functionality. However, in HPC environments, resources are usually managed by batch schedulers, such as Slurm [73], that give users a set of nodes for a bounded time window (e.g., up to 12 hours), with no persistent endpoints across job re-invocations or control plane to route external traffic to model replicas. Replacing Slurm with Kubernetes

is non-trivial as HPC workloads depend on features such as topology awareness, MPI integration, and established operational policies. Running a separate Kubernetes partition avoids disrupting existing workflows, but rigidly partitions scarce GPUs between batch and serving workloads, which could leave idle capacity in one partition while there is demand for the other [1, 65].

Furthermore, to deal with highly dynamic GPU availability within each HPC cluster (e.g., see Figure 1) and the bursty load patterns of LLM inference, it is often beneficial to pool resources across clusters to smooth both effects: idle GPUs at one site can absorb demand from another, and aggregating requests across clusters can improve batching efficiency. However, cross-cluster serving is challenging as clusters are often administered separately and may run different schedulers, expose different network policies, contain heterogeneous GPUs, and differ in data sovereignty guarantees.

We present OpenTela, a thin user-space overlay that turns fragmented HPC resources into a unified LLM serving platform. OpenTela runs on top of existing cluster managers such as Slurm and Kubernetes, providing LLM serving primitives entirely in user space, such that it does not require root privileges, cluster reconfiguration, or changes to user workflows. OpenTela exposes a unified OpenAI-compatible API across heterogeneous serving engines, including vLLM and SGLang, that it can run as transient Slurm jobs, long-running Kubernetes services, and diverse GPU hardware. Its decentralized gossip network backed by a CRDT-based registry provides service discovery, health monitoring, and fault-tolerant routing without assuming a central coordinator. A heterogeneity-aware placement policy helps map models to available GPUs, while ensuring that requests are only routed to model instances that a user trusts.

We deploy OpenTela to provide a catalog of open-source and community-developed models to researchers in the Swiss AI Initiative, an initiative that trains and serves open foundation models, such as Apertus [30]. OpenTela unifies multiple geo-distributed clusters with different hardware and resource management stacks, including Slurm-managed and Kubernetes-managed resources. Researchers interact with a single API endpoint, while OpenTela handles authentication, usage tracking, routing, and node lifecycle management across the underlying infrastructure. OpenTela has been operational for over 22 months. During this period, it has served more than 13 million requests and 15 billion tokens across 142 models to over 1000 researchers across multiple institutions. We open-source OpenTela at https://github.com/eth-easl/opentela and release an anonymized production trace spanning July 2024 to October 2025 at https://huggingface.co/datasets/eth-easl/swissai-serving-trace. Unlike prior public traces that typically cover a small number of models or short time windows, our trace captures a long-running, multi-model, research-oriented LLM serving workload with both popular open-weight models and a long tail of community-developed models.

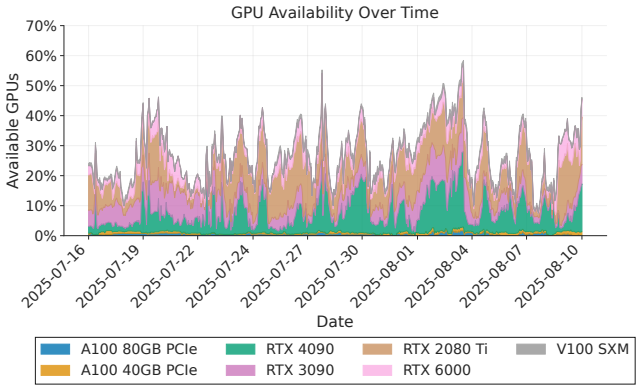

Figure 1: Percentage of idle GPUs from ETH HPC Cluster.

2 Background and Motivation

LLM serving engines are not serving platforms. Modern LLM serving engines, such as vLLM and SGLang, provide the execution layer for inference. They load model weights, manage KV caches, batch requests, schedule prefill and decode work, and expose an API endpoint for submitting prompts. These engines have made it substantially easier to run open-weight models efficiently on GPUs. However, an inference engine is not a complete serving platform. A shared LLM service must also provide a control plane around the engine: clients need a stable endpoint, the system must discover which replicas are currently serving which models, requests must be routed and load-balanced across replicas, failed replicas must be removed from the service, users must be authenticated, and operators need visibility into model availability and resource usage. In cloud deployments, these functions are often provided by Kubernetes or a proprietary orchestration system of a commercial provider. In contrast, most sovereign AI initiatives make GPU capacity available in HPC environments, where these features are lacking [41].

HPC schedulers. Slurm [73] is the most common workload manager across the top supercomputers [56]. Slurm's design reflects its origins in batch scientific computing workloads: it allocates nodes for a fixed wall-clock duration, prioritizes raw throughput over interactivity, and treats each job as a transient process with no expectation of persistent state. This works well for AI training jobs and batch data-processing pipelines. However, LLM serving requires clients to discover and route requests to model replicas. A Slurm job can launch an inference engine, but the resulting endpoint is tied to a particular allocation and compute node. When the job ends, is preempted, or is relaunched elsewhere, the endpoint changes or disappears. The scheduler does not provide a persistent service name, an external routing layer, a model registry, or a mechanism for replacing a failed replica with a healthy one.

Simply replacing Slurm with Kubernetes to leverage its orchestration primitives for LLM serving is often impractical

as many other jobs rely on Slurm features such as topology-aware scheduling and native MPI job launch [1, 65]. Another option is to partition HPC resources into a Kubernetes-managed component and a Slurm-managed component. However, this makes it more difficult to flexibly re-balance resources across the two clusters, which can lead to under-utilization and unnecessary queuing delays as the load on each cluster dynamically changes over time.

Federating HPC clusters. A single GPU cluster is often not enough to provide reliable and efficient LLM serving. GPU availability changes over time as resources are consumed by training jobs, released by completed jobs, and reserved for maintenance. Figure 1 shows this effect in an ETH GPU cluster: the fraction of idle GPUs varies over time and across GPU types. At the same time, our trace analysis in §6 shows that inference demand is bursty and model popularity shifts as users evaluate new models. Pooling resources across clusters can improve availability and utilization. Idle GPUs at one site can absorb demand from another, and aggregating requests across users and institutions can increase batching opportunities for popular models.

However, cross-cluster LLM serving introduces several challenges. The participating clusters may be administered by different organizations, run different schedulers, expose different network policies, contain different GPU types, and offer different data governance guarantees. Compute nodes may not be directly reachable from outside the cluster. Most importantly, there may be no single privileged coordinator that all sites are willing or able to operate. In the next section, we describe how to overcome these challenges.

3 OpenTela Design

To bridge the gap between HPC infrastructure and LLM serving workloads, we propose *OpenTela*: a user-space orchestration overlay that turns fragmented compute resources into a unified LLM serving platform. OpenTela *providers* contribute compute resources and deploy inference engine jobs while OpenTela *consumers* submit inference requests through an API frontend. OpenTela does not replace the underlying cluster manager in each cluster it federates. Instead, a provider launches OpenTela alongside an existing serving engine, such as vLLM or SGLang, on resources obtained from a local cluster manager (e.g., a Slurm allocation or a Kubernetes deployment). Once an OpenTela job is launched, the node running the job joins OpenTela 's peer-to-peer network, advertises its hardware and model metadata to other nodes, and becomes available to serve requests.

3.1 System Requirements

We design OpenTela around four key requirements:

R1: Non-invasive deployment. OpenTela must run with ordinary user permissions, on top of existing cluster managers, without requiring root access, scheduler modifications, or cluster reconfiguration. This allows researchers and operators to contribute resources from Slurm or Kubernetes environments without changing existing HPC workflows.

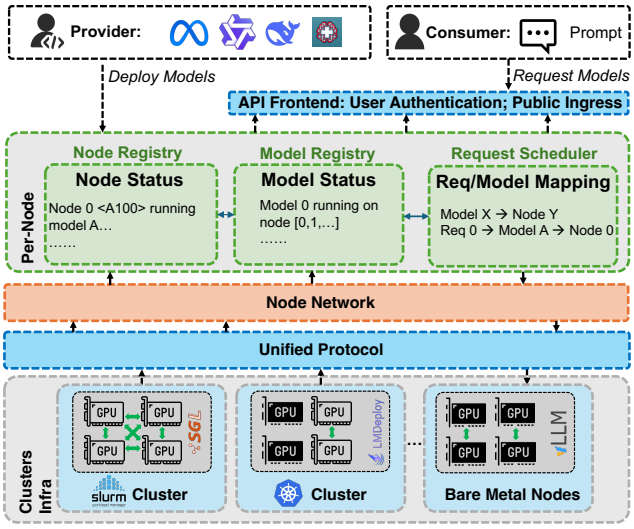

Figure 2: System architecture of OpenTela Serving.

R2: Service abstraction over transient resources. OpenTela must turn short-lived allocations and independently launched serving processes into a persistent service abstraction. It must provide service discovery, model and node registries, health monitoring, load balancing, and request routing even as nodes join, leave, fail, or are preempted.

R3: Federation without a centralized coordinator. OpenTela must operate across independently administered clusters with no shared privileged control plane. The system must maintain an eventually consistent view of available nodes and models, tolerate network partitions and node churn, and avoid making a central store a single point of failure.

R4: Heterogeneity- and trust-aware request routing. OpenTela must support diverse GPU types, serving engines, model variants, and deployment environments. It must also ensure that requests are routed only to providers authorized by the user or institution, preserving data-governance constraints even when other resources are available.

3.2 System Overview

Figure 2 shows the system architecture that OpenTela adopts to meet the above requirements.

Cluster infrastructure. OpenTela is designed to unify *geo-distributed* clusters that may consist of *heterogeneous* hardware. Each cluster may differ in hardware characteristics (GPU memory capacity and processing power, network bandwidth) and software environments (cluster manager, serving frameworks supported, CUDA versions).

Unified ML serving protocol. Most LLM serving engines expose an OpenAI-compatible API [50], which allows OpenTela to sit above them without modification. OpenTela adopts this interface as its foundation and extends it with infrastructure-level endpoints that the OpenAI API does not provide. Specifically, OpenTela exposes additional endpoints for querying real-time node status, model registry state, and

provider metadata, allowing operators and consumers to inspect the state of the serving platform directly without requiring access to individual nodes. For security, these endpoints are strictly read-only and expose the CRDT registry state without permitting external modification, preserving the integrity of the distributed states.

Node network. The node network is the transport layer that connects every OpenTela node into a single peer-to-peer fabric, regardless of which institution or cluster manager it belongs to. We build this layer with libp2p [39], which provides three key features our setting requires: peer addressing and discovery, encrypted peer-to-peer channels between any two peers, and connectivity establishment across NAT boundaries. Together, these make cross-institutional federation feasible: nodes on different clusters can locate one another, establish encrypted channels, and reach each other across private networks without any centralized broker. This is needed in our setting, as HPC nodes typically have only outbound connectivity and cannot accept inbound connections from outside the cluster. The node network establishes secure channels between two such nodes through hole punching when both can reach a common rendezvous peer, or through a circuit relay on a publicly reachable peer otherwise. Both modes use only the outbound connections that compute nodes are already permitted to make, and require no changes to institutional network policies. A new node joins the network by contacting one or more bootstrap peers. If all bootstrap peers are temporarily unreachable, the node retries with exponential backoff until connectivity is restored. Once connected, the node uses the Kademlia DHT [45] to discover other peers and exchanges state with them through a randomized gossip protocol layered on top of these peer-to-peer connections.

Registry. The registry is the state layer on top of the node network. It maintains a consistent global view of available nodes and models across institutional boundaries without a central coordinator. Our design of the registry considers that HPC nodes frequently join and leave as allocations expire or are preempted from scavenger queues, and that no central coordinator can be assumed to serialize state updates. OpenTela represents the registry as a Growth-only Map (G-Map) conflict-free Replicated Data Type (CRDT) [58], whose merge semantics are commutative, associative, and idempotent, guaranteeing convergence without coordination. Each entry in the map represents a node in the network: the key is a unique identifier assigned at node creation, and the value is a tuple containing the node's lifecycle state and its metadata payload. State updates propagate over the gossip protocol described above, and every node maintains a full local replica that it reads without further network round trips. To prevent unbounded registry growth as nodes join and leave over time, OpenTela applies a two-tier garbage collection policy: evicted nodes are first removed from the application-level view after a configurable retention window (24 hours by default), and CRDT-level tombstone markers are compacted periodically thereafter. The registry exposes two views derived from the same underlying state. The *Node Registry* tracks hardware availability and lifecycle state for each node, and the *Model Registry* maps models to the nodes currently serving them. Both views are queried locally on whichever node receives the query: every OpenTela node holds a full replica and answers from it without contacting any centralized catalog. In practice, consumers do not query the registry directly. The API frontend reads its local replica when routing each inference request, and the same replica backs the read-only HTTP endpoints described earlier, which expose registry contents for inspection by users and operators.

Service scheduler. While users can manually assign nodes to serve specific models, OpenTela also has a centralized *service scheduler* that can automatically optimize model placement to balance performance requirements with resource availability and cost efficiency. We describe the default policy in §3.5, but operators can substitute their own.

API frontend. OpenTela's API frontend runs as a regular OpenTela node that participates in the gossip network like any other but is reachable at a public IP address so that consumers can submit requests without running their own node. We call it an *ingress node* as it is the entry point through which external requests enter the gossip network. Alongside the standard OpenTela node functionality, the API frontend also runs a user-facing service that manages client connections and handles authentication, usage tracking, and the request-response lifecycle. The user-facing service and the ingress node can also run on separate hosts, as long as the former can forward authenticated requests to the latter. Because the ingress node holds a full local replica of the CRDT registry, it performs the candidate selection and routing described in §3.4 without contacting any external coordinator.

User interface. To ease access, OpenTela provides a web-based dashboard that allows users to browse the real-time catalog of actively served models alongside their hosting hardware, manage API keys, and validate model behavior through an interactive chat interface.

3.3 Trust Model

Allowing users to run arbitrary models and serve the requests of other users introduces security concerns. If any node can join the network and claim to serve any model, users have no guarantee that the node will execute inference correctly or keep the input data confidential. OpenTela addresses these concerns at two points in the serving path.

Membership admission control. Only signed OpenTela binaries can join the network. Each release is signed by maintainers, and unsigned or tampered binaries fail the join handshake and never appear in the CRDT registry.

Client-side filtering. When a user submits an inference request, they may specify a set of trusted provider IDs in the request metadata. The ingress node filters the candidate set from the CRDT registry to retain only nodes whose provider

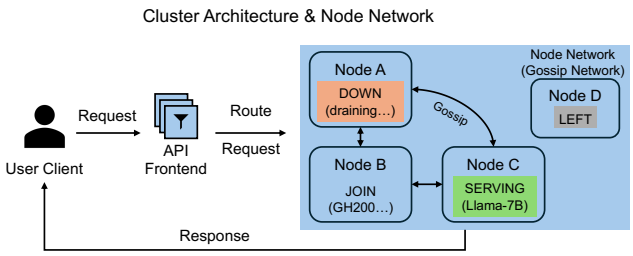

Figure 3: Workflow example of OpenTela.

IDs appear on this allowlist before applying load balancing. Requests are never dispatched to providers that the user has not explicitly allowed. This places trust management in the hands of the user, which is appropriate for a research environment where institutional relationships are known, but it requires users to maintain and update their allowlists correctly.

These mechanisms still have limitations. OpenTela attests binaries at the software level: peers verify a signature over the binary at load time, proving the file on disk matches what OpenTela maintainers signed. However, the provider, as the root user on the node they contribute, can replace the serving engine with a modified build that records every request or captures the prompts on the loopback interface between the OpenTela process and the serving engine. None of these produces externally observable artifacts that OpenTela can currently detect. Hardware-backed attestation through confidential computing would close this gap by running the serving code inside a hardware-encrypted enclave that the host root user cannot read, and by producing a remote attestation that cryptographically identifies the code executing inside the enclave. Clients could then require proof that their request was handled by a specific audited binary rather than trusting the provider's claim. We consider this a direction for future work.

3.4 Workflow Example

Life of a node. A node progresses through four strictly ordered states: `JOIN` $\prec$ `SERVING` $\prec$ `DOWN` $\prec$ `LEFT`. When a provider contributes a node to OpenTela, it initiates the `JOIN` process by contacting a known *bootstrap peer*, defined in the cluster configuration. The node registers its metadata (i.e., hardware specification) with the network. OpenTela uses a randomized gossip protocol for membership management: upon connection, the node exchanges state with the bootstrap peer, and this membership information propagates rapidly across the network. Within a few gossip rounds, the system converges and all peers update their local registries to include the new node.

After a node has joined the network, it begins the lifecycle of a model/service, entering the `SERVING` stage. The node deploys a specific model (either explicitly configured by the provider or dynamically assigned by the service scheduler). To announce availability, the node updates its local CRDT state with a service record containing the model identifier, the node's unique *session ID*, and optionally the *provider ID*. When the model is served with non-default configurations, such as lower precision or shorter context windows, it is the provider's responsibility to add this information to the model identifier. This metadata is automatically replicated to all peers, enabling other nodes to discover the new service endpoint and include it in their routing tables.

The `DOWN` stage is triggered if there is a local health check failure: when the per-node OpenTela process detects that the serving subprocess has terminated, it explicitly transitions to `DOWN` and propagates this state to all peers. `LEFT` marks permanent eviction and is triggered after the node exceeds the heartbeat grace period without recovery. The system applies a two-stage detection policy before escalating to `LEFT`: a node that fails liveness probes is first marked as *suspected* and excluded from the routing candidate set, but no irreversible state change is committed. Three independent probe paths must all fail before suspicion is declared, and a suspected node can self-refute by broadcasting a liveness update before the suspicion timeout expires. Only after this grace period elapses is the node permanently evicted. Since the merge function $\sqcup$ selects the entry with the highest lifecycle state, the network converges to the most recent fully-specified configuration for every node without any central reconciliation step. A node that recovers after eviction rejoins under a new session ID through the normal `JOIN` $\rightarrow$ `SERVING` lifecycle.

Life of an inference request. Figure 3 shows the life of a request. To schedule the request, the ingress node queries its local CRDT replica to identify candidate nodes that are serving the requested model. OpenTela routes requests based on the unique *session ID* and *provider ID* associated with each node. The system filters the initial candidate set against the user's specified *trusted providers*. Any node whose provider ID is not in the user's allowlist is pruned from the candidates pool. From the remaining authorized candidates, a specific session ID is selected via a load-balancing strategy, and the request is dispatched to that node's API endpoint. By default, the ingress node selects a session ID uniformly at random from the authorized candidates, with round robin and weighted random selection (e.g., weighted by reported GPU class) as alternative options. This decentralized approach ensures high availability and fault tolerance, as the system can dynamically route traffic across all compliant nodes, continuing to function even if individual nodes go offline.

Request-level fault tolerance. OpenTela performs best-effort retries by re-routing failed requests to an alternative node, up to a configurable maximum retry count. For non-streaming requests, this retry is transparent to the client. Streaming requests are handled differently: if a node fails or the network connection is interrupted after the stream has begun, OpenTela cannot resume generation on a different node easily, because LLM inference is non-deterministic and the partial response cannot be replayed from an arbitrary continuation point using the standard serving API. Clients issuing streaming requests must therefore implement their own retry

logic at the application level.

Scheduling policy customization. OpenTela decouples scheduling policy from request routing mechanics, allowing operators to integrate custom scheduling policies into the system. At the request-scheduling stage, a policy implements a three-method interface: `Pick` selects a worker from the trust-filtered candidate set for the current request, `OnRequestStart` and `OnRequestEnd` bracket each request so that load-aware policies can track in-flight work. Richer signals, such as the hardware of each candidate node, can be read from the local CRDT state. At the fleet level, OpenTela provides the building blocks for an external control loop: every node exposes the full status of the fleet, including the nodes in the network, their available hardware, the models they serve, and which nodes are idle. A controller can therefore poll any node, identify spare capacity, and decide which models to deploy where. For example, consider integrating Helix [46], which serves LLMs over heterogeneous GPUs and networks by routing each request along a path derived from a max-flow optimization. Its two components naturally map to OpenTela's design: the `Pick` method implements the max-flow-based selection logic, while the model-placement decision becomes a fleet-level controller that launches and terminates serving engines.

3.5 Model Placement and Scheduling

OpenTela allows users to manually specify which nodes in the cluster will serve which models. However, these decisions can be difficult for users to make. Users will often request the highest-end GPUs for their jobs to maximize performance, but these devices are usually also the most expensive and their availability is often scarce due to high demand. OpenTela therefore provides a scheduler that users can invoke when there are idle resources to fill and models waiting to be served. The scheduler decides which models should run on which nodes, and is a pluggable component so operators can swap in their own policy if needed. The scheduler runs whenever there is a model to place across more than one available hardware configuration, typically as new resources become available or as observed workload statistics drift.

In our current deployment, OpenTela does not reclaim compute nodes from running models during periods of low load, and does not repurpose them toward more popular models, because doing so makes the system less predictable for users. Resource reclamation happens only through the underlying cluster manager (e.g., Slurm timeouts or preemption). When unallocated resources do appear, OpenTela uses them to serve popular models, but resources that are already allocated to a running model are left in place even when underutilized. OpenTela also does not currently change parallelism configurations or other execution settings once the model is running. Reconfiguration requires the user to stop the model instance and redeploy it with the new settings.

Default scheduling policy. The default scheduling policy in OpenTela minimizes mean end-to-end latency over a heterogeneous resource pool. We formulate it as a constrained optimization problem. Consider a heterogeneous cluster $\mathbf{D} = \{d_1, \ldots, d_N\}$, where d_n denotes the count of available GPUs of type n. We serve M distinct model types, indexed by m, with incoming workloads $\mathbf{W} = \{w_1, \ldots, w_M\}$. Each workload w_m is defined by a tuple $\langle \lambda, \mu_{in}, \mu_{out} \rangle$ representing arrival rate and input/output length distributions, which are collected and monitored by the API frontend. The scheduler determines two key decision variables:

1. **Allocation matrix ($\mathbf{A} \in \mathbb{R}^{M \times N}$):** Where $a_{m,n}$ is the number of type-n GPUs allocated to model m.
2. **Parallelism strategy ($\mathbf{P} = \{p_1, \ldots, p_M\}$):** Where p_m defines the data and tensor parallelism configuration for model m.

The optimization objective is formulated as:

$$\min_{\mathbf{A},\mathbf{P}} \quad L(\mathbf{W}, \mathbf{A}, \mathbf{P}) \tag{1}$$

where $L(\cdot)$ represents the mean end-to-end latency over the workload $\mathbf{W}$ under allocation $\mathbf{A}$ and parallelism strategy $\mathbf{P}$.

Solving Eq. 1 requires an efficient method to evaluate $L(\cdot)$ for any candidate configuration. The typical approach of profiling jobs on different hardware configurations is accurate but not scalable, particularly for clusters that may have highly heterogeneous hardware, such as the cases we consider. Instead, we use a *serving simulator* to analytically estimate performance.

The serving simulator takes model specifications (e.g., architecture, parameter count), hardware characteristics (e.g., GPU type) and request workloads (e.g., arrival times, input/output lengths) as inputs. The simulation operates in two stages, extending the analytical method of `LLM-Viewer` [74] from single-request analysis to multi-request serving scenarios. (**1**) We first enumerate all operators in the model, such as the $\mathbf{q}, \mathbf{k}, \mathbf{v}$ linear projections, self-attention computations, feed-forward layers, etc. For each operator, we estimate its execution time on the target hardware. In our current design, we estimate execution time using the roofline model [6, 71], taking into account the operator's computational intensity and the hardware's peak performance and memory bandwidth. This analytical model, though not as accurate as empirical profiling, provides a unique advantage in our environment as it does not require offline profiling, making it adaptable to new models, new hardware, and diverse serving environments, such as model or KV cache quantization, varying sequence lengths and batch sizes, etc. (**2**) In the second stage, we simulate the concurrent execution of the input workload. Based on the operator latencies derived in the first stage, the simulator models system behaviors including continuous batching, model parallelism, and scheduling policies. The simulator outputs key metrics like latency and throughput, which drive the

service scheduler's deployment decisions. However, we acknowledge that the accuracy of the simulator is limited by the assumptions of the roofline model and the complexity of real-world serving optimizations. Our simulator does not currently model many optimizations, such as chunked prefill [3], prefill and decode disaggregation [2], prefix caching, etc., which can significantly impact performance. We consider improving the accuracy of the serving simulator a key direction for future work.

These simulation results parameterize our objective function, allowing us to evaluate the specific trade-offs inherent in Eq. 1. The scheduler uses *Constraint Programming* (CP) [55] to solve the optimization problem, which excels at exploring discrete combinatorial spaces through constraint propagation, making it ideal for our resource allocation problem. We enforce three key constraints to ensure feasible deployments:

C1: Global Resource Capacity. The total allocation for each GPU type n cannot exceed availability:

$$\sum_{m=1}^{M} a_{m,n} \leq d_n, \quad \forall n. \tag{2}$$

C2: Memory Feasibility. To prune the search space, we ensure any assigned GPU type n has sufficient memory (mem_n) to host the model weights and KV cache (M_m):

$$a_{m,n} \cdot \text{mem}_n \geq M_m, \quad \forall (m,n) \text{ where } a_{m,n} > 0. \tag{3}$$

C3: Parallelism compatibility. For each model type m, the parallelism strategy p_m specifies a configuration $\langle \psi_{\text{DP}}^{(n)}, \psi_{\text{TP}}^{(n)} \rangle$ for each GPU type n where $a_{m,n} > 0$, representing the data parallelism [40] and tensor parallelism [47, 60] degrees, respectively. The configuration must satisfy:

$$a_{m,n} = \psi_{\text{DP}}^{(n)} \times \psi_{\text{TP}}^{(n)}, \quad \forall (m,n) \text{ where } a_{m,n} > 0, \tag{4}$$

ensuring that the $a_{m,n}$ GPUs of type n allocated to model m are exactly partitioned into $\psi_{\text{DP}}^{(n)}$ data-parallel replicas, each employing $\psi_{\text{TP}}^{(n)}$-way tensor parallelism.

4 Implementation

Our implementation of OpenTela consists of approximately 7K lines of Go. We choose Go because of its strong support for concurrency, cross-platform compatibility, and a rich ecosystem of libraries for building distributed systems. OpenTela uses `libp2p` [39], a modular network stack, to construct the peer-to-peer network that underpins the decentralized architecture. OpenTela provides a `Gin` [19]-based API endpoint that exposes RESTful endpoints for accessing the internal status and functionalities of the system. The complementary API frontend is implemented using `FastAPI` [18].

OpenTela is distributed as a pre-built command-line tool. To deploy a model, users simply encapsulate their existing inference commands (e.g., `vllm` or `sglang`) within the OpenTela CLI. For instance, a user can start a node by running: `otela start --process vllm serve [model_name]`. Alternatively, users can start a node without a pre-defined model by running `otela start`. In this mode, the node registers its available hardware resources with the network, allowing the service scheduler to assign models to the node later.

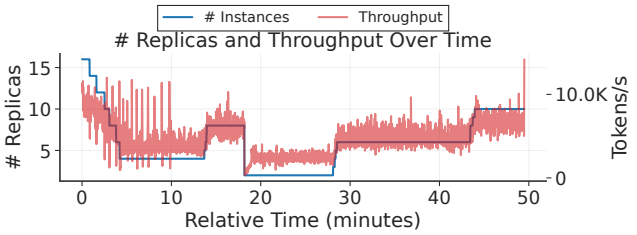

Figure 4: OpenTela's ability to recover from node failures over time.

5 System Evaluation

In this section, we evaluate the fault-tolerance and performance of OpenTela with benchmark workloads, while in §6, we will analyze the real workloads on the deployed system. Our evaluation aims to answer the following key questions:

Q1: Control plane overhead of OpenTela. How much latency does OpenTela's user-space control plane add to each request, and does this overhead remain stable as request load increases?

Q2: Elasticity and fault-tolerance. Can OpenTela maintain service continuity and scale throughput proportionally in a dynamic environment with node failures and additions?

Q3: Placement efficiency. How does our heterogeneity-aware placement strategy compare to standard heuristics in terms of aggregate cluster throughput?

Q4: Simulation accuracy. Does the serving simulator accurately capture relative hardware performance differences to guide scheduling decisions?

Experiment setup. We conduct our experiments on a heterogeneous environment composed of NVIDIA GPUs, ranging from datacenter-grade accelerators (GH200, H100, A100) to consumer-grade hardware (RTX 3090). This diversity allows us to evaluate OpenTela's ability to handle hardware heterogeneity. We use OpenTela to serve popular open-source LLMs with varying parameter sizes: `Qwen/Qwen3-1.7B`, `Llama-2-13b`, `CodeLlama-34b`, and `Llama-3.3-70B-Instruct`. Unless otherwise stated, request arrival times follow a Poisson process, with input and output token lengths sampled from Normal distributions derived from real-world traces collected from our deployment (see more details about traces in §6).

Control-plane overhead. We measure the per-request overhead introduced by OpenTela's control plane to quantify the cost of operating as a user-space overlay above the serving engines. We decompose each request's lifecycle into five control plane stages alongside the LLM inference performed by

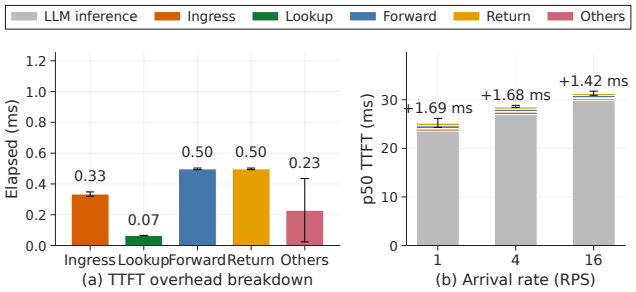

Figure 5: Control plane overhead of OpenTela. (a) Per-stage cost for a single request. (b) p50 TTFT decomposition at arrival rates of 1, 4, and 16 RPS with 256 input tokens.

the serving engine, and benchmark these components on a deployment serving `Qwen/Qwen3-1.7B` on 1 GH200 GPU, with Poisson arrival rates of 1, 4, and 16 RPS, and report the time spent in each stage.

Figure 5a reports the per-stage overhead breakdown for serving a 1.7B model. *Ingress*, which covers request reception and dispatch at the ingress node, takes 0.33 ms, and *Lookup*, the CRDT-based candidate selection at the ingress node, takes less than 0.1 ms, confirming that the local replica supports fast selection decisions without contacting a central coordinator. The dominant costs are *Forward* and *Return* at around 0.5 ms each, reflecting the network hops between the ingress and serving nodes. *Others* contributes a residual cost of less than 1 ms, which includes the handoff to the serving engine and other processing. Figure 5b shows how these costs contribute to the overall time-to-first-token (TTFT) at different arrival rates, with the control plane overhead remaining stable and contributing around 10% of the total TTFT, while the majority of the latency is due to LLM inference. As the model size grows, the relative impact of the control plane overhead shrinks, since prefill latency scales with model size while the control plane overhead remains fixed. For time-per-output-token (TPOT), only the *Return* hop contributes per token, and as the other stages are amortized over the lifetime of the request, the resulting per-token overhead is sub-millisecond, which is negligible compared to the decoding time of each token. In a wide-area deployment with the ingress node in Frankfurt and the serving node in Switzerland, OpenTela adds ~3.5 ms to TTFT over invoking the model directly on the serving node. The network round-trip accounts for ~3.1 ms, leaving only ~0.4 ms attributable to OpenTela's routing.

We also measure how quickly state changes propagate through OpenTela's gossip network. We trigger an event at one node (either a node joining the network or an existing node starting to serve a new model) and measure the elapsed time until each remaining node has applied the corresponding update to its local registry. At cluster sizes from 8 to 128 nodes, 50% of nodes converge in 7 to 13 ms, 75% within 26 ms, and 95% within 1 second. The slowest node shows a tail of several seconds, reaching around 10 seconds with 128 nodes in the network. This tail reflects how long full cluster convergence takes, but it does not block request routing: the ingress node dispatches requests to the new endpoint as soon as its own replica reflects the update, independent of when the rest of the cluster converges.

In addition, we measure the message bandwidth overhead introduced by OpenTela. On the data plane, forwarding a request from the ingress node to the serving node adds a fixed header cost of around 450 bytes on the request path and 120 bytes on the response path, independent of the payload size. On the control plane, the background traffic scales with the mesh size rather than the request rate: an idle node exchanges only liveness messages, and its per-node traffic grows roughly linearly from 1 KB/s at 10 nodes to 8 KB/s at 50 nodes. Updates to the shared registry are more expensive: each CRDT write (e.g., a node joining or registering a model) raises per-node traffic from 1 KB/s at idle to 40 KB/s when 10 nodes re-register every 3 seconds. However, these spikes are transient and do not affect request processing, since the control plane operates asynchronously in the background.

Cross-cluster overhead. The measurements above isolate per-request cost within a single cluster. OpenTela also adds overhead at the network layer through its tunneling fabric, which becomes relevant once requests cross cluster boundaries. HPC compute nodes typically sit behind login-node gateways with no inbound connectivity and tight egress policies, so any cross-cluster path requires a tunneling layer that OpenTela provides as part of its node fabric. To quantify this cost, we measure pairwise latency and throughput between our deployment clusters and representative client locations across Switzerland and Europe.

Figure 6 reports measurements through OpenTela. Parenthesized values give direct `ping` and `iperf` results for paths where the two endpoints can establish a direct connection. Entries without parentheses correspond to paths where direct communication is not possible, and OpenTela establishes connectivity through hole punching and circuit relay. On paths where direct measurement is possible, OpenTela's tunneling adds at most 15 ms above the 19 ms direct baseline (Clariden→JSC, from 19 ms to 34 ms) and reduces throughput by up to 16% (OCI-2→OCI-1, from 503 to 423 Mbps).

Elasticity and fault-tolerance. To evaluate OpenTela in a dynamic HPC-based environment, where nodes may join or leave the network at any time, we deploy OpenTela on a system with at most 64 GH200 GPUs, serving a continuous stream of inference requests while varying the available worker pool by randomly terminating nodes in the system during the experiment. Figure 4 reports the throughput (in tokens/s) alongside the number of active replicas over time. OpenTela's throughput (red line) adapts proportionally, on average, to the number of active replicas (blue line), showing that OpenTela can effectively adjust to changes in compute capacity without manual intervention. Furthermore, despite the abrupt termination of nodes, we observed zero user-facing HTTP errors during the entire experiment. This confirms

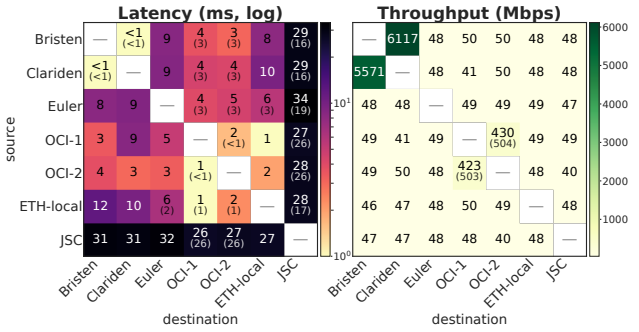

Figure 6: Network conditions across HPC clusters. Left: latency (ms, log scale), right: throughput (Mbps). Parenthesized values are direct `ping` or `iperf` baselines when reachable directly without hole punching. Unparenthesized entries use OpenTela's tunneling via hole punching and circuit relay.

Table 1: We compare how OpenTela vs. a memory-proportional heuristic policy allocate hardware for different models running in a cluster of 24 A100s and 32 GH200s.

	13B	34B	70B
MemP	4×A100	16×A100	32×GH200+4×A100
Ours	6×A100	16×GH200+10×A100	16×GH200+8×A100

that our decentralized registry maintains service continuity even under high churn rates, successfully routing requests to remaining healthy nodes while the cluster topology stabilizes.

Placement strategy. We evaluate the effectiveness of our placement strategy by comparing it to a memory-proportional policy, *memP*, inspired by HexGen [36], which represents a standard heuristic. It allocates GPU resources proportional to the memory demand of different models, defined as the product of the average request arrival rate and the model parameter size. We synthesized a workload modeled from real-world traces collected from OpenTela, consisting of three distinct models with varying sizes and load characteristics: `Llama-2-13b`, `CodeLlama-34b`, and `Llama-3.3-70B-Instruct`. Requests for each model follow a Poisson arrival process with average rates of 110, 185.5, and 221 req/s, respectively. We sample input and output sequence lengths from Normal distributions, with mean input lengths ranging from approximately 600 to 1170 tokens, and mean output lengths ranging from 64 to 530 tokens. Table 1 shows the placement allocation that each policy decides when given a budget of 24 A100 and 32 GH200 GPUs. Figure 7 compares the performance of the two placement decisions. The memP baseline prioritizes the largest model (70B) and overprovisioning it with GH200 and A100 GPUs. This does not leave enough resources for the 34B model, resulting in lower aggregate performance. In contrast, our heterogeneity-aware strategy balances allocation across model and GPU types. We do not claim that our policy is globally optimal. Our goal here is simply to highlight the importance of explicitly modeling system heterogeneity to improve resource utilization.

Simulator validation. Figure 8 compares real and simulated end-to-end latency on H100 and RTX 3090 GPUs across three configurations that vary input length, output length, and batch size. The simulator's absolute latency estimates deviate from real measurements by up to 10%, primarily due to accumulated errors in decode time estimation. The simulator captures relative performance more accurately, predicting the H100 speedup over RTX 3090 within 6% of measured values across all configurations. This shows the simulator can help OpenTela make heterogeneity-aware scheduling decisions.

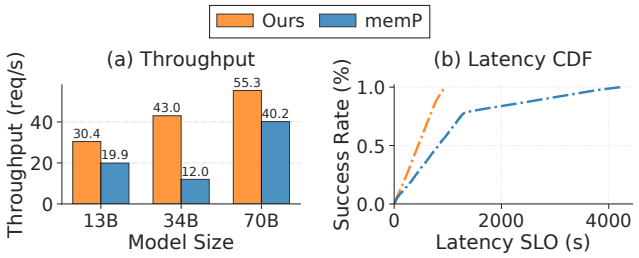

Figure 7: Throughput and latency comparison between our placement method and the memory-proportional approach.

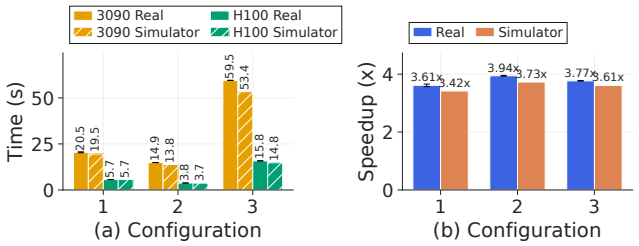

Figure 8: End-to-end performance of H100 and RTX 3090, measured on real hardware and predicted by our simulator. Each configuration is specified as (input length, output length, batch size), with lengths in tokens: **(1)** (1024, 1024, 1), **(2)** (2048, 512, 4), **(3)** (512, 2048, 8). (Left) Absolute latency in seconds. (Right) Speedup of H100 over RTX 3090.

6 Swiss AI Deployment and Trace Analysis

OpenTela is currently deployed as the serving backbone for the Swiss AI Initiative, a multi-institutional open-science research initiative for developing and providing access to open-source frontier AI models. At the time of writing, we have been operating OpenTela for over 22 months. It has served billions of tokens to over 1000 researchers across multiple institutions. We first discuss our cluster setup and then describe the anonymized trace dataset that we collected over a 16-month period (§6.1). We then characterize the LLM serving workloads from this trace (§6.2).

Cluster setup. The Swiss AI deployment spans three subclusters within the Alps supercomputer at CSCS, each with distinct hardware and management stacks. *Bristen* is an x86-64 cluster equipped with A100 GPUs, managed by Slurm, and used primarily for smaller-scale and development workloads. *Clariden* is a large-scale Slurm cluster equipped with GH200 superchips, used for production inference at scale. *Breithorn* is a small Kubernetes-managed cluster, also equipped with

GH200 superchips, intended for long-running, dedicated serving. Despite their administrative independence, all three sub-clusters participate in a single OpenTela node network. Compute nodes in all three sub-clusters sit behind network address translation (NAT) and cannot be reached directly from outside CSCS, so we run an OpenTela node on another CPU-only Kubernetes cluster as the public ingress point. Within CSCS, inter-cluster latency remains under 1 ms with multi-Gbps throughput between sub-clusters (Figure 6). Researchers and users interact with OpenTela's unified API endpoint without awareness of which sub-cluster handles their request.

Operational model. Researchers with Slurm access contribute nodes to the shared pool by wrapping their serving commands in the OpenTela CLI. The Breithorn Kubernetes partition hosts a small set of models that the community has designated for continuous availability (currently the Apertus family of open-weight models [30] developed within the Swiss AI initiative, along with a small number of other popular open models). The remaining models are served on-demand from Slurm allocations on Bristen and Clariden, with node lifecycle managed through the gossip network as described in §3. The API frontend runs as a persistent service on Breithorn and serves as the ingress node of the gossip network. It handles authentication via institutional credentials, usage tracking, and request routing across all three sub-clusters.

6.1 Trace Overview

We release the anonymized trace dataset collected from July 2024 to October 2025 to facilitate future research on AI serving system infrastructure. This dataset includes over 13 million requests, with over 15 billion tokens processed. For each request, we recorded its timestamp, model identifier, aggregate input and output token counts, and sampling parameters (e.g., temperature, maximum tokens). Due to privacy and compliance requirements, we neither use nor disclose the actual content of both input prompts and output responses in our traces. However, we do analyze prefix sharing and token reuse characteristics using the approach first described in Mooncake [53], which involves irreversibly hashing the input tokens and putting 16 consecutive tokens into a single hash bucket. A bucket ID will be equal to another if and only if the 16 tokens in both buckets are identical. We hash the bucket ID so that no information can be inferred from the ID. Hence, our trace does not include any user-identifiable information. We still allow users to bypass the usage tracking in cases where it is necessary to ensure data compliance.

In Table 2, we summarize key differences between our traces and existing public traces. Most existing traces focus on a single or very few models (often a popular closed-source LLM such as GPT-3.5 or GPT-4) while our trace includes a diverse set of real-world models, with over 142 different models being requested. Among those models, 46 are existing open-weight models that are publicly available, while the remaining 96 models are custom-trained models developed within our researchers and users community. We omit ShareGPT from this comparison because it exists in several unofficial versions and consists of conversation sessions from proprietary models without timestamps or other request-level metadata. Additionally, our traces span a longer period of time, allowing us to analyze long-term trends in model usage and request patterns.

Trace	Span	Schema	# Models	LLM
BurstGPT [69]	121 days	T, M, I/O	2	✓
Azure 1 [51]	days	T, I/O	1	✓
Azure 2 [62]	weeks	T, I/O	1	✓
Azure 3 [54]	weeks	T, I/O	1	✓
Mooncake [53]	-	-	1	✓
ChatLMSys [22]	days	M, I/O	4⋆	✓
Azure MAF [57]	days	T, M⋆	multiple⋆	✗
Ours	16 months	T, M, I/O	142	✓

Table 2: Trace characteristics summary. T: timestamp, M: model, I/O: input/output tokens, ⋆: not inference, just function invocations. Number of models only counts unique models.

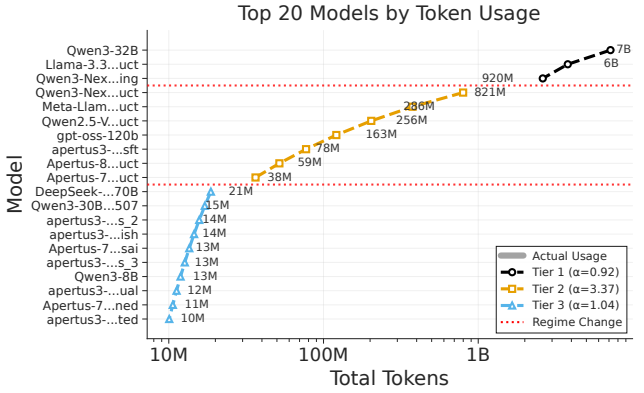

Figure 9: Overall model token usage. Each bar represents the total token consumption (input + output) for a specific model, ranked from highest to lowest usage.

6.2 Workload Characterization

Model usage distribution. Figure 9 shows the total token consumption of the top 20 models, including both input and output tokens per model, ranked from highest to lowest. We observe a multi-tier power-law distribution. The first tier consists of the top 3 models, which account for a significant portion of total token usage. These models are general-purpose LLMs that are used for various tasks. The second tier consists of multi-modal models (notably *Qwen-2.5-VL*) and also models that researchers in the Swiss AI initiative are particularly interested in evaluating (e.g., *Apertus* models, which are trained within the Swiss AI community [30]). The third tier consists of a long tail of models that are used infrequently, often for specialized tasks or by niche user groups.

Key Takeaway 1: Serving systems must efficiently support a skewed workload distribution, handling both popular general-purpose models and a long tail of diverse, niche models.

Per-model request burstiness. Next, we characterize

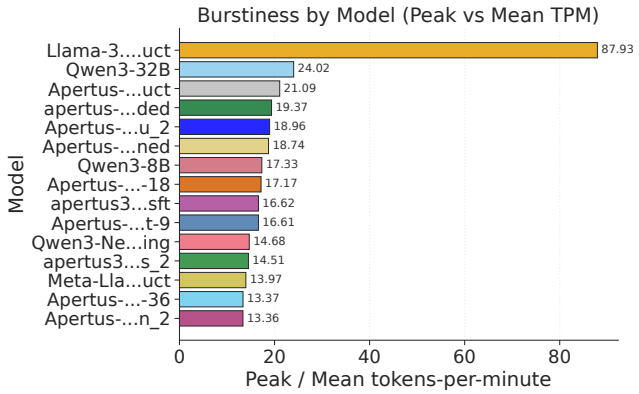

Figure 10: Peak-to-average request rate ratio per model during their active minutes.

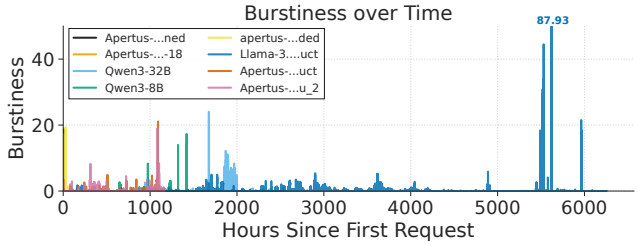

Figure 11: Burstiness over time for several representative models. Burstiness is defined as the ratio of instantaneous TPM to the model's average TPM over active periods. Timelines are aligned to the first request at $t = 0$.

model request burstiness along two dimensions: Magnitude and temporal dynamics. We define the *instantaneous burstiness* as the ratio of the instantaneous tokens per minute (TPM) to the model's average TPM. We then quantify the overall *burstiness magnitude* as the peak of this ratio. We compute the average TPM strictly over active minutes (minutes with at least one request) to avoid artificially inflating the ratio due to periods of inactivity. Figure 10 reports the magnitude, ranking models by their burstiness magnitude to highlight the most extreme bursty workloads. Overall, we observe extreme volatility across the board. Even among the top 15 most bursty models, the lowest burstiness exceeds 13, while the most bursty model reaches a ratio of over 80. This indicates that average request arrival rates underestimate peak loads. For example, Figure 11 shows the temporal request invocation dynamics for a variety of models, with timelines aligned to each model's first request ($t = 0$). This reveals when load spikes occur relative to the start of a model's operation.

Key Takeaway 2: Dynamic resource allocation and elastic scaling are essential, as static provisioning based on average rates does not satisfy peak demands while provisioning for peak would underutilize resources. Similar burstiness occurs in other real-world traces, such as ShareGPT and BurstGPT [69].

Input / Output Length Distribution. The distribution of input and output sequence lengths has significant implications for resource planning and management. We analyze the distribution of input and output token lengths of four models with highest request counts: *Llama-3.1-70B*, *Llama-3.3-70B*, *DeepSeek-R1-Distilled-Llama70B*,*Qwen-32B*. Figure 12 shows the empirical CDF of input (left) and output (right) token counts for these four models, with dotted vertical lines marking the aggregate P50, P95, and P99 across all requests. Input distributions are similar, with most prompts falling between 10^2 and 10^3 tokens, except for *Deepseek-R1-Distilled-Llama70B*, which shows a flat CDF below 10^3 tokens before a sharp jump near 10^4, indicating a dominant workload of long, fixed-length prompts. Output distributions diverge more sharply: *Llama-3.1-70B* and *Llama-3.3-70B* have a large fraction of requests producing only 1–2 tokens, consistent with classifier or guardrail traffic, while *Qwen-32B* follows a smooth sigmoid centered around 10^2–10^3 tokens.

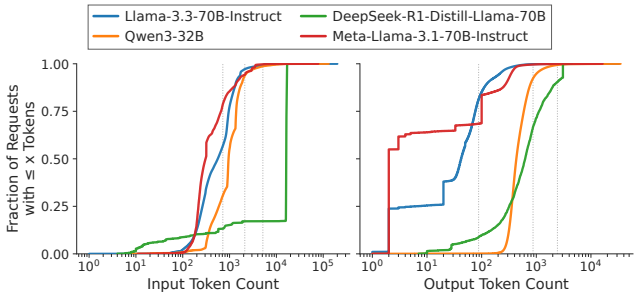

Figure 12: Cumulative distribution of token lengths for the analyzed models.

Key Takeaway 3: Output length distribution varies significantly across models. For non-reasoning models, a substantial fraction of requests produce only a few output tokens, particularly for classifier or guardrail traffic, motivating optimizations such as PrefillOnly [21]. Reasoning models, on the other hand, concentrate on longer output sequences with no comparable short output fraction. This highlights the importance of applying different optimizations for different model and workload characteristics.

Input / Output ratio characteristics. A request's resource footprint depends heavily on its structure: Input-heavy requests strain compute during the prefill phase, while output-heavy requests consume memory bandwidth during the decode phase. Therefore, we analyze how the output sequence lengths of requests compares to the total (input + output) sequence lengths. Figure 13 plots the output token ratio for `Qwen3-32B`, over three months. As shown in Figure 13, the workload is far from uniform: the ratio of output tokens to total tokens fluctuates over the three-month period.

Key Takeaway 4: Interference between compute-bound prefill and memory-bound decode stages is a critical issue in production LLM serving. This highlights the importance of optimizations such as chunked prefill [3] and prefill-decode disaggregation [34, 51, 63, 76] to mitigate this interference.

Prefix sharing characteristics. Beyond the structure of

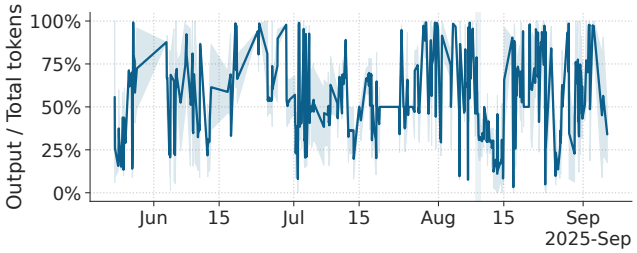

Figure 13: Output token ratio distribution for `Qwen3-32B` over three months.

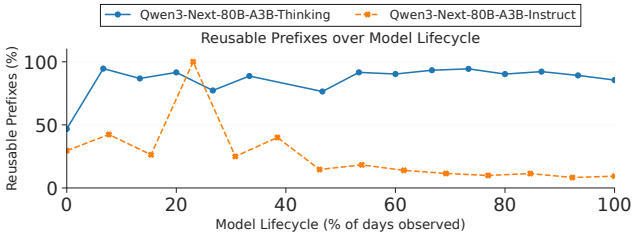

Figure 14: Reusable prefix ratio over model lifecycles for two representative models.

individual requests, we investigate the computational redundancy *across* requests. We analyze the token reuse ratio, defined as the fraction of input tokens overlapping with recent history, to identify opportunities for avoiding re-computation. Figure 14 shows how usage patterns differ between model types. The reasoning-heavy *Qwen3-Next-80B-A3B-Thinking* has a large reuse ratio exceeding 90%. This implies that the dominant workload for this reasoning model consists of deep, iterative multi-turn sessions where users build progressively on a shared context. In contrast, the standard *Instruct* variant shows a modest reuse ratio of $\sim$ 15%, reflecting the usage pattern of independent, single-turn queries. This suggests that much of the prefill computation in reasoning models may be redundant. This motivates KV-cache management optimizations like `LMCache` [11], which amortizes the quadratic attention costs inherent in long-context, iterative workflows.

Key Takeaway 5: Our analysis of *Qwen3-Next-80B-A3B-Thinking* suggests that reasoning models, particularly when used in iterative, multi-turn sessions, might exhibit high prefix reuse ratios. This suggests that optimizations focused on prefix caching and KV-cache management [11] could be particularly beneficial for amortizing the quadratic attention costs in these workloads.

Latency Distribution. Figure 15 shows the cumulative distribution of end-to-end latency (E2E, left) and output token counts for reasoning and non-reasoning requests. We observe that reasoning requests exhibit substantially higher E2E latency than non-reasoning ones, with a P95 of 173.58 s, more than 5.5$\times$ higher than the P95 of non-reasoning requests (30.77 s). The output token distribution shows the source of this gap: non-reasoning requests produce short outputs for a substantial fraction of the workload, with a median of 87 tokens and P95 of 828 tokens, while reasoning requests

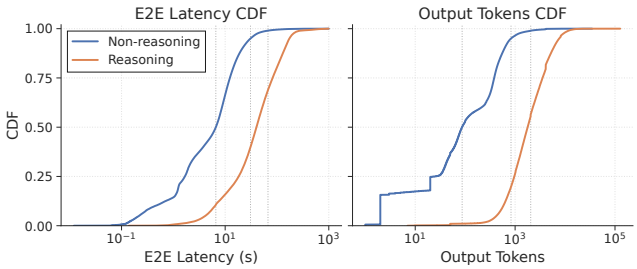

Figure 15: Cumulative distribution of end-to-end latency (left) and output token counts (right).

routinely generate much longer outputs, with a median of 1,782 tokens and P95 of 7,628 tokens, roughly an order of magnitude higher than non-reasoning requests.

Key Takeaway 6: Service Level Objectives (SLOs) must be differentiated to accommodate reasoning models, applying distinct timeout and retry policies that account for their significantly higher latency tails compared to standard models. To actively guarantee SLOs, systems could implement "reasoning budget" [43, 70] that dynamically caps the computational depth of reasoning traces to fit within time windows, or SLO-aware model selection [9, 35] where the system dispatches queries to the appropriate models, or SLO-aware model serving [10].

7 Discussion

We reflect on our experiences designing, implementing, and operating OpenTela for real users (§7.1). We then share some observations on emerging workload patterns driven by reasoning models (§7.2). Finally, we discuss the limitations of our current design and outline directions for future work (§7.3).

7.1 Lessons learned

Flexibility and interoperability as first-class citizens. We observed that researchers often have varying preferences for serving engines and hardware capabilities, and that the flexibility to adapt to different hardware and software environments is crucial for the deployment and adoption of OpenTela. In the context of LLM serving, the widespread adoption of the unified OpenAI-compatible interface across these serving engines provided a standardized abstraction layer. This allowed us to design OpenTela to be engine-agnostic by default. Furthermore, we evaluated whether Kubernetes-based orchestration would be a better fit for our use case. However, given our reliance on Slurm-based HPC clusters for GPU resources, we found that integrating with existing HPC infrastructure provided a more seamless experience for our users.

Need for more expressive abstractions. While the OpenAI-compatible interface simplifies interaction, it obscures critical execution details like model quantization levels and context limits. This creates ambiguity when users have strict expectations regarding numerical precision and other parameters critical for model quality. To mitigate this, we currently require model providers to adhere to strict naming conventions (e.g., explicitly tagging quantization bits in

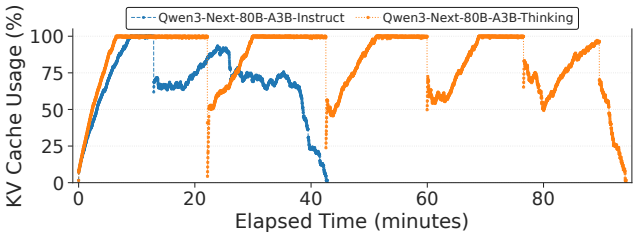

Figure 16: KV cache usage comparison between reasoning and non-reasoning models.

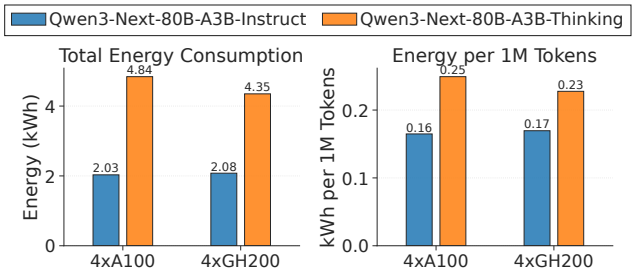

Figure 17: Power consumption of reasoning and non-reasoning models.

model names) to ensure transparency. This highlights a gap in current LLM serving protocols: the lack of a protocol for negotiating model quality of service beyond simple identifiers.

Importance of proper systematic modeling. Early iterations of OpenTela relied on a centralized database for tracking GPU worker availability. We found that enforcing strong consistency for metadata operations created a significant scalability bottleneck. The pivotal lesson was transitioning from ad-hoc state tracking to a formal algebraic model that represents the cluster state as a conflict-free replicated data type (CRDT). By modeling the system state as a monotonic lattice, we were able to decouple node interactions and adopt an eventually consistent model. This shift eliminated the central coordinator entirely, enabling the system to remain available even during network partitions.

Introspection, monitoring and human intervention. Debugging in a decentralized environment is inherently challenging due to the lack of direct access (e.g., SSH) to worker nodes. Consequently, we shifted our design philosophy from attempting to recover to fail-stop semantics. Instead of attempting complex runtime recovery, OpenTela relies on strict health checks, and upon detecting fatal anomalies (e.g., NCCL timeout), a node automatically evicts itself from the cluster to preserve global system integrity. To aid post-mortem analysis, we proactively collect logs to a sink before termination.

7.2 Implications of Reasoning for LLM Serving Systems

We also conduct some preliminary experiments to motivate future work on making serving systems more workload-aware and hardware-aware. In particular, since we notice that OpenTela often serves reasoning and non-reasoning variants of models, we explore the serving system implications of reasoning by running representative public benchmarks.

KV cache pressure. Reasoning models tend to produce longer outputs, which consumes additional memory compared to their non-reasoning ("Instruct") model counterparts. Figure 16 compares the KV cache usage for the *AIME 1983-2024* [68] benchmark. The non-reasoning model shows a dynamic usage pattern with rapid reclamation cycles, finishing in $\sim$ 40 minutes. In contrast, the reasoning model extends execution to $\sim$ 95 minutes and has a distinct sawtooth pattern: sharp, sustained increases represent the accumulation of transient state during chain-of-thought reasoning, followed by sharp drops upon sequence completion. *The high cost of regenerating transient "reasoning" states requires sophisticated memory management, such as offloading KV caches to secondary storage during preemption rather than discarding and recomputing them.*

Energy consumption. The longer execution time and higher memory usage of reasoning models inevitably increases energy costs. Figure 17 quantifies this impact on A100 and GH200 architectures for the *AIME 1983-2024* benchmark [68]. We find that reasoning models are not just slower but also consume more energy. The reasoning variant consumes over 2$\times$ the total energy of the non-reasoning baseline (rising from $\sim$ 2.0 kWh to $\sim$ 4.3 kWh). Crucially, the *energy cost per token* also jumps by $\sim$ 56% (from $\sim$ 0.16 to $\sim$ 0.25 kWh per million tokens). This non-linear scaling stems from a compound effect: The model generates more tokens (volume), and as the context window expands, the quadratic complexity of self-attention makes every subsequent decoding step more computationally intensive. Furthermore, we compare the energy consumption across two GPU architectures. While GH200s deliver superior raw performance, their energy consumption is on par with A100s for the same workload. We attribute this to two factors associated with this particular workload. First, the workload is memory-bound by the KV cache, restricting the batch sizes and preventing full saturation of GH200's compute units. Second, the sparse activation of MoE models exacerbates this by requiring more memory capacity while demanding relatively less compute. This aligns with previous findings [12, 15]. *Future serving systems could improve energy efficiency for reasoning models by applying memory optimizations, such as KV cache compression or offloading, as the workload is constrained by memory capacity rather than raw compute power.*

7.3 Limitations and Future Work

While OpenTela successfully bridges the gap between HPC infrastructure and model serving, operating a decentralized user-space overlay at this scale has revealed limitations.

Protocol expressiveness and quality of service (QoS). As discussed earlier, the adoption of a unified, OpenAI-compatible interface simplifies client integration but abstracts away critical configuration nuances; a client cannot easily request specific trade-offs, such as lower precision for lower

latency or guaranteed precision without relying on rigid naming conventions. We propose extending the serving protocol to support QoS negotiation. Future versions of OpenTela will allow clients to specify constraints (e.g., quantization $\geq$ 4-bit, specific GPU type) in the request metadata, and the system will route requests to nodes that satisfy these constraints.

Availability. OpenTela currently operates on a best-effort basis and does not provide strong availability guarantees. We plan to introduce tiered service levels. By categorizing resources based on their expected stability (e.g., differentiating between stably owned partitions and volatile scavenger queues), the scheduler could route critical workloads to more stable nodes, while batch processing tasks can exploit volatile, lower-priority capacity to maximize cluster throughput without compromising reliability for high-priority users.

Cross-node serving optimizations. Several recent serving optimizations that would benefit our workload are not yet supported in OpenTela. KV cache reuse works only when a request lands on a node already holding the relevant prefix, and prefill and decode disaggregation [51, 76] is unsupported because the OpenTela router treats each request as an atomic unit. A global KV cache layer [11] across the mesh and prefill-decode disaggregated deployment are both future work.

8 Related Work

Heterogeneous LLM serving. Heterogeneous LLM serving refers to systems that utilize a mix of GPU types with varying hardware characteristics—such as differing computational and memory capacities—to optimize resource utilization and cost-efficiency. Several recent works [29, 33, 37, 52, 66] have addressed this domain. Petals [5] is the first open-source system that allows users to serve LLMs on a set of decentralized hardware. HexGen [36] introduces asymmetric partitioning and designs advanced scheduling techniques to deploy generative inference in heterogeneous and decentralized settings. SkyServe [42] leverages spot instances across different regions and clouds to ensure availability for AI models serving, but does not focus on distributed HPC environments. LLM-ServingSim [13] adopts a trace-driven performance modeling approach and provides a simulation framework to evaluate the performance of heterogeneous LLM serving systems. ThunderServe [34] addresses the distinct computational characteristics of the prefill and decoding phases by deploying them on heterogeneous GPUs matched to their respective workload requirements. Similarly, Helix [46] formulates the optimization of heterogeneous GPU and network connections as a max-flow problem, utilizing mixed-integer linear programming to determine optimal model deployment, SageServe [32] formulates the optimization strategies as an optimization problem and solves it with integer linear programming (ILP). Collectively, these works demonstrate that the strategic utilization of heterogeneous resources significantly enhances the cost-efficiency of LLM serving. Unlike existing works on single-model serving, our service scheduler jointly addresses model heterogeneity (varying LLMs) and GPU heterogeneity (varying hardware specifications) for multi-model deployment.

Multi-tenant LLM serving. Another line of research focuses on serving multiple models concurrently to maximize resource utilization. AlpaServe [40] reveals that model parallelism can be used for statistical multiplexing of multiple models, and designs a serving system that determines efficient placing and parallelizing strategies. MuxServe [22] introduces a flexible spatial-temporal multiplexing system that identifies optimal colocation strategies for multiple LLMs. When the multiple models are fine-tuned from a shared base model, DeltaZip [72] exploits the shared weights and compresses the deltas to improve serving efficiency. If the fine-tuning is performed using parameter-efficient methods (e.g., LoRA [31]), Punica [8] and S-LoRA [59] design specialized serving systems for serving adapters efficiently. In contrast, OpenTela focuses on the challenges arising from both model and hardware heterogeneity, as well as administrative burdens in large-scale deployments, particularly on HPC environments.

Federated research infrastructure. OpenTela is similar in spirit to federated testbeds such as PlanetLab [20] and CloudLab [23], which pool resources across institutions for systems and networking research. OpenTela focuses on LLM serving and operates as an overlay on existing HPC clusters rather than dedicated testbed hardware.

9 Conclusion

As open-source models proliferate and organizations seek greater control over their AI stack, serving infrastructure needs to operate across HPC clusters with heterogeneous hardware and dynamic resource availability. Decentralized orchestration overlays such as OpenTela offer a convenient alternative to centralized cloud-native control planes. OpenTela unifies fragmented and heterogeneous compute resources across diverse clusters into a single LLM serving platform, providing service discovery, fault-tolerant routing, heterogeneity-aware scheduling, and a unified serving interface on top of existing LLM inference engines, all while operating entirely in user space. Our deployment in the Swiss AI Initiative shows that this approach is practical at scale: OpenTela has served more than 15 billion tokens across 142 models to over 1000 researchers from multiple institutions.

Acknowledgements

Beyond the authors, dozens of engineers and student assistants have contributed to the design, implementation, and deployment of OpenTela. We are grateful to Aryan Ahadinia, Elia Palme, Stefano Schuppli and the rest of the Swiss AI team and the Swiss Supercomputing Center (CSCS), in particular Joost VandeVondele and Thomas Schulthess, for their support. We thank Prof. Chaojian Li, Foteini Strati, Cedric Renggli, anonymous reviewers, and our shepherd for their insightful feedback and suggestions. This work was supported as part of the Swiss AI Initiative by a grant from the Swiss National Supercomputing Centre (CSCS) on Alps.

Abstract

Hybrid LLM inference systems exploit both GPU and CPU for computation and memory but are bottlenecked by the CPU's lower computational capabilities. Recent approaches leverage activation sparsity by offline partitioning FFN neurons into "hot" (frequently activated) and "cold" (rarely activated) sets. This approach retains critical computations on the GPU, yet static partitioning struggles to adapt to runtime activation changes, leading to suboptimal throughput.

We present KAIROX, an adaptive GPU–CPU hybrid inference system that addresses these limitations through online neuron balancing, a mechanism that dynamically redistributes neurons between the GPU and CPU based on activation patterns. To realize this, KAIROX introduces a Live Pipeline designed to prefetch neurons by predicting next-layer activation patterns. Furthermore, leveraging activation locality, we develop a Temporal Activation Momentum cache policy to prioritize neurons with sustained utility while minimizing transient, wasteful transfers. Finally, an Adaptive Neuron Balancer modulates the balancing intensity according to runtime resource conditions, maintaining an optimal equilibrium between competing system bottlenecks. For standard completion on consumer-grade PCs, KAIROX improves end-to-end throughput by up to 7.57×, 3.70×, 6.35×, and 3.76× over llama.cpp, PowerInfer, Neuralink, and Q-Infer, respectively. Across all evaluated settings, it achieves geomean speedups of 3.15× and 3.93× over llama.cpp on two representative PCs and around 2.1× over the three sparse baselines.

1 Introduction

Large Language Models (LLMs) have achieved remarkable success across diverse domains [10, 48, 59]; however, their substantial memory and computational requirements limit deployment primarily to cloud infrastructures [30]. While cloud-based inference remains dominant, deploying LLMs on edge devices such as personal computers is becoming increasingly important [6,34,57]. Local deployment offers significant advantages, including stronger data privacy protections [55] and reduced operational costs in practice [45].

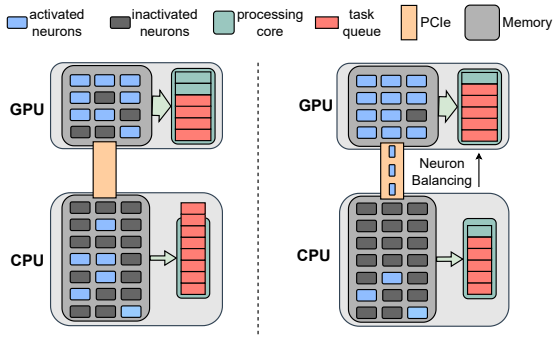

Figure 1: Two strategies for leveraging activation sparsity to compute only activated neurons (i.e., subsets of FFN weights stored in GPU or CPU memory). Left: static placement without runtime adjustment. Right: online neuron balancing with dynamic neuron transfers between the CPU and GPU.

However, the scale of modern LLMs continues to exceed the memory budgets of typical consumer hardware, making efficient on-device inference a fundamental challenge. For example, running a 13-billion-parameter model in standard FP16 precision requires more than 26 GB of VRAM—surpassing the 24 GB available even on high-end consumer GPUs such as the NVIDIA RTX 4090 [32].

To address this memory bottleneck, parameter offloading has become a widely adopted solution, wherein a portion of model weights is stored in host memory [2, 38]. In such architectures, the CPU typically performs computations on the offloaded weights, and the results are then merged with GPU-produced outputs. Frameworks such as llama.cpp [14] generally implement this using layer-wise offloading. However, because CPU computational capability is substantially weaker than that of the GPU, the CPU frequently becomes the system bottleneck, leading to increased inference latency.

Recent research provides a promising direction for alle-

*Work done while at Hong Kong University of Science and Technology.

viating this bottleneck through **activation sparsity** [28, 39, 43, 60]. For a given input, only a small subset of neurons—corresponding to specific rows or columns of the weight matrix—contributes to the output. These sparse activation patterns can be reliably predicted using lightweight predictors analogous to Mixture-of-Experts (MoE) gating [61]. By computing only the activated neurons, systems can substantially reduce both computation workload and memory footprint, thereby expanding the design space for hybrid inference. State-of-the-art activation-sparse inference frameworks, such as PowerInfer [41], leverage this property by statically placing frequently activated neurons on the GPU and rarely activated ones on the CPU based on offline profiling. As shown in Figure 1(left), the system computes only the neurons predicted to be active at runtime during inference.

However, static placement derived from offline profiling becomes inadequate when activation patterns shift or expand—such as during semantic drift or batch inference. These shifts cause many "cold" neurons (those residing on the CPU) to become active, turning the CPU into the dominant bottleneck. In practice, this limitation leads to early throughput saturation (e.g., at batch sizes of 4 or 8) and high variance in TPOT (ranging from 50 to 200 ms even at batch size 1), underscoring the inefficiencies of static placement in practice.

A natural solution is to shift from static placement to online neuron balancing, where neuron workloads are continuously redistributed across the GPU and CPU according to the activation patterns (see Figure 1(right)). While this approach can alleviate the CPU bottleneck, it introduces three tightly coupled system challenges: **how to achieve efficient balancing with computation overlap,** given that redistributing neurons across devices incurs substantial transfer latency and layer-wise dependencies provide limited opportunities to hide these transfers behind computation; **how to prioritize sustained neurons and avoid transient, wasteful balancing,** since activation patterns may fluctuate rapidly and simply redistributing each newly activated neuron risks repeatedly moving short-lived neurons, wasting scarce bandwidth and evicting more valuable ones; and **how to adaptively control balancing intensity under runtime resource constraints,** as aggressive balancing reduces CPU pressure but risks saturating the I/O path, whereas conservative balancing preserves bandwidth but leaves the CPU overloaded. These challenges make effective online neuron balancing fundamentally difficult.

To address these challenges, we propose KAIROX, an adaptive GPU–CPU hybrid LLM inference system for consumer-grade hardware. KAIROX enables efficient and adaptive online neuron balancing through three key designs:

Live Pipeline. The primary obstacle for dynamic redistribution is I/O latency: moving activated neurons from host memory to the GPU introduces delays, and strict layer-wise dependencies constrain opportunities for overlapping these transfers with computation. KAIROX mitigates this by predicting the activation pattern of layer $i+1$ immediately after the Attention block of layer i, allowing balancing actions to begin earlier and overlap data movement with ongoing computation. Neurons are further grouped and reordered based on co-activation patterns to improve PCIe utilization.

Locality-Aware Neuron Balancing. Even with prefetching, balancing bandwidth must be used judiciously. Activation patterns often contain short-lived spikes that trigger wasteful transfers and evict useful GPU-resident neurons. To avoid such thrashing, KAIROX leverages activation locality and introduces Temporal Activation Momentum (TAM), a lightweight policy that captures the temporal persistence of activations. TAM enables KAIROX to identify neurons with sustained utility, prioritizing their movement toward the GPU while suppressing transient ones that provide little benefit.

Adaptive Neuron Balancer. Effective online neuron balancing must reconcile CPU workload with balancing-induced I/O overhead—two competing bottlenecks during inference. KAIROX addresses this challenge through a runtime feedback mechanism that adjusts balancing intensity based on real-time resource availability. When the system becomes CPU-bound, unused I/O capacity emerges, creating an opportunity for KAIROX to migrate more computation to the GPU. Conversely, when the system becomes I/O-bound, excessive balancing saturates the transfer path; KAIROX then reduces balancing intensity to alleviate I/O pressure. This adaptive control strategy enables the system to sustain an efficient operating point under diverse runtime conditions.

Our contributions are summarized as follows:

- We design a hybrid inference pipeline that uses an adjacent predictor to relax sequential dependencies and overlap computation with data transfer, reducing exposed I/O latency during online neuron balancing.
- We propose Locality-Aware Neuron Balancing based on Temporal Activation Momentum, prioritizing sustained neurons while avoiding I/O waste on transient ones.
- We introduce an Adaptive Neuron Balancer that adjusts balancing intensity to real-time CPU and I/O availability, effectively managing the competing bottlenecks.
- We implement KAIROX on top of llama.cpp [14]. On diverse consumer-grade PCs, KAIROX improves standard-completion throughput by up to 7.57×, 3.70×, 6.35×, and 3.76× over llama.cpp [14], PowerInfer [41], Neuralink [50], and Q-Infer [29], respectively.

2 Background

2.1 LLM Inference & Activation Sparsity

The inference of LLMs consists of two stages: prefill and decoding. In prefill, the model processes the input sequence in parallel to generate the first output token. In decoding, the model operates auto-regressively, generating one token at a time until a termination token is produced or a maximum length is reached. LLMs adopt a stack of Transformer

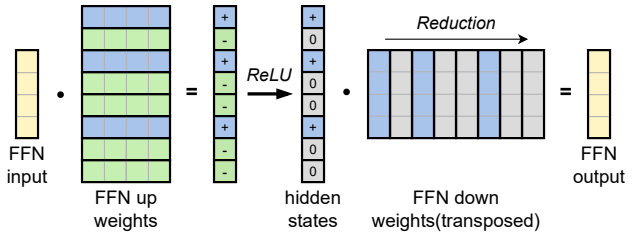

Figure 2: Illustration of activation sparsity in the up- and down-projection layers of a ReLU FFN. Activated neurons are shown in blue for visual clarity in the example below.

layers [48], each composed of an attention block and a Feed-Forward Network (FFN) [3]. While attention captures contextual dependencies, the FFN—implemented via an up-projection, an optional gated projection [36], a non-linear activation, and a down-projection—performs non-linear feature transformations. FFN blocks account for approximately 70% of parameters (e.g., 66.6% in OPT-6.7B [59] and 72.4% in LLaMA-3 8B [17], excluding embeddings), and contribute roughly 60% of prefill computation and 80% of decoding computation. Consequently, FFNs constitute the primary computational and memory bottleneck in LLM inference.

Activation Sparsity. Extensive prior work [26, 39, 40, 51] shows that LLMs exhibit substantial activation sparsity, most prominently in FFN blocks and primarily induced by the non-linear activation function (e.g., ReLU [1] or SiLU [11]). A large portion of neurons—corresponding to rows or columns of the weight matrices—produce negative or near-zero values after the first projection and are subsequently suppressed by the activation function. Figure 2 illustrates this sparsity pattern within an FFN block; for clarity, a standard projection (up- and down-projection) is shown, though the same behavior extends to gated variants. Recent studies reveal three key properties of activation sparsity: context specificity [28], where the set of activated neurons varies with the input and cannot be determined before inference; power-law distribution [41], where only a small subset of neurons is strongly activated while the majority remain inactive; and neuron co-activation [2], where neurons exhibit highly correlated activation patterns across architectures and datasets. Moreover, these works [2, 28, 41] show that FFN sparsity can be accurately predicted using lightweight predictors—analogous to MoE gating—enabling substantial reductions in computation and memory costs during LLM inference.

2.2 Resource-Constrained Inference

Deploying LLMs on edge devices (such as personal computers) has attracted increasing attention [6, 34, 57]. Compared with cloud-based solutions, local deployment offers advantages in data privacy [55], inference cost [45], and latency [20]. However, the large memory footprint of modern LLMs remains a fundamental bottleneck. For instance, a 13B model in FP16 requires at least 26 GB of memory for weights alone, exceeding the capacity of high-end consumer GPUs such as the NVIDIA RTX 4090 (24 GB) [32]. To address this constraint, recent work has explored model compression, especially quantization [22, 27], as well as system-level techniques such as offloading [18]. We categorize existing edge-inference systems by their execution strategies.

GPU-Only Inference. GPU-only frameworks primarily rely on the GPU for computation while alleviating memory pressure by offloading a portion of model weights to CPU memory or secondary storage and transferring them to the GPU on demand. Early systems such as FlexGen [38] adopt coarse-grained offloading strategies, using linear programming to schedule block-level weight swaps. While effective for high-throughput batch processing, these methods incur substantial latency for single-batch inference. In contrast, recent approaches including Deja Vu [28] and Neuralink [50] exploit activation sparsity and neuron co-activation to enable fine-grained parameter loading. By transferring only contextually relevant parameters, they significantly reduce I/O overhead and accelerate inference on memory-constrained GPUs.

Hybrid Inference. Heterogeneous frameworks leverage both GPUs and CPUs for inference. Modern CPUs support high-performance instruction sets (e.g., AVX-512, ARM NEON) that accelerate matrix operations, providing a computational resource for LLM workloads. Widely used systems such as llama.cpp [14] adopt coarse-grained layer partitioning, statically assigning selected layers to the CPU for storage and computation. This layer-wise split placement introduces synchronization barriers and often leads to GPU "bubbles"—idle periods caused by the slower execution of the CPU and the strict sequential dependencies inherent in LLMs. Empirical results from llama.cpp show that CPU computation can still account for more than 90% of total inference latency. In contrast, emerging frameworks such as PowerInfer [41] adopt fine-grained, sparsity-aware offloading based on the power-law distribution of activations. By assigning frequently activated neurons to the GPU while placing infrequently activated neurons on the CPU, these systems align computational tasks with device strengths and achieve substantial improvements in inference efficiency.

3 Motivation

While state-of-the-art activation-sparse inference methods [41] have significantly improved efficiency over traditional coarse-grained approaches, they remain constrained by inherent hardware bottlenecks. This motivates the need for a more adaptive execution model under resource constraints.

3.1 Bottlenecks in Resource-Constrained Inference

We analyze representative fine-grained approaches and identify two dominant bottlenecks: I/O latency in GPU-only systems and excessive CPU overhead in heterogeneous systems.

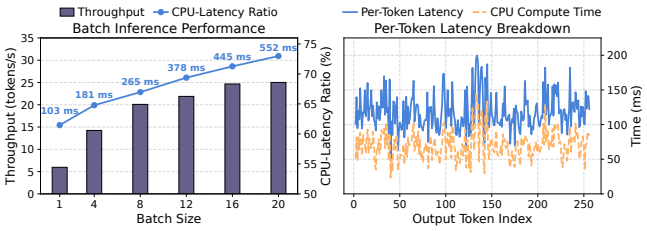

Figure 3: Illustration of the CPU bottleneck under static placement in heterogeneous systems. Left: throughput and CPU computation time under increasing batch size. Right: TPOT and CPU computation time across a 256-token decoding sequence at batch size 1. Both experiments were conducted on an NVIDIA RTX 3080 Ti.

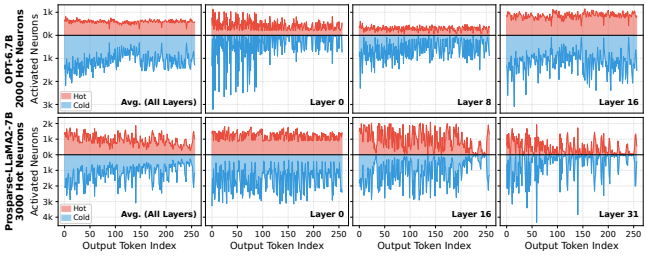

Figure 4: Examples of hot- and cold-neuron activation counts across output tokens under semantic drift, shown for OPT-6.7B and Prosparse-LLaMA2-7B at multiple layers.

Massive I/O Latency in GPU-Only Systems. In GPU-only systems with on-demand weight fetching (e.g., offloading FFN blocks to system memory), I/O latency becomes the primary bottleneck. Because computation must wait for weight transfers to complete, substantial computational bubbles form. Prior work shows that I/O can account for over 75% of generation time in sparsity-based systems such as LLM-Flash [2]. Although Neuralink improves access locality, the latency remains fundamentally constrained by physical bandwidth. As a result, prolonged I/O stalls severely underutilize the GPU, while modern CPUs remain largely idle, making this approach inefficient under resource constraints.

CPU Bottleneck of Static Weight Partitioning Systems. To improve hardware utilization, modern heterogeneous systems (e.g., PowerInfer [41]) statically assign neurons to either the CPU or GPU. The GPU executes frequently activated hot neurons, while the CPU handles rarely activated cold neurons. Although this eliminates runtime weight loading and reduces I/O overhead, it assumes that the hot–cold neuron split remains stable during inference. In practice, activation patterns drift, causing the workload to shift toward the slower CPU and resulting in significant performance degradation.

1) Workload Expansion in Batch Inference: In batch scenarios, concurrent prompts scale the workload linearly, overwhelming the CPU's limited parallelism. Crucially, while the CPU saturates, the GPU retains ample parallel headroom that could absorb this excess load, yet static placement fails to utilize it. When batch size grows from 1 to 20, throughput rises only modestly, while CPU latency increases sharply

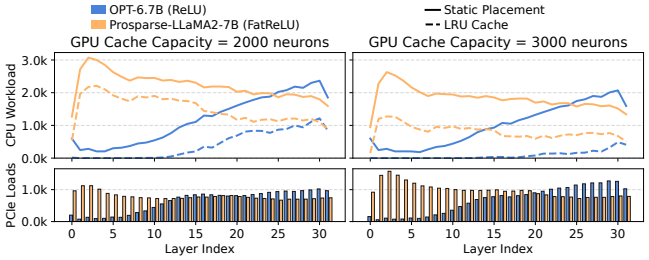

Figure 5: CPU workload and PCIe loads under static placement and an LRU neuron-balancing policy, shown for two sparse models under GPU cache capacities of 2,000 and 3,000 neurons. Solid lines denote static placement, and dashed lines denote the LRU policy.

from 102.8 ms to 551.7 ms. This static allocation turns the CPU into a dominant bottleneck, diminishing sparsity benefits and severely impacting tasks like speculative decoding that demand fast batch verification.

2) Activation Fluctuation in Generation: Activation sparsity also fluctuates substantially during token-by-token generation. Small shifts in semantic context can increase activations among cold neurons on the CPU, forcing the CPU to handle a larger portion of the computation. We quantify the semantic drift of two representative single-prompt decoding runs from two models in Figure 4. Under static placement, cold neuron activations fluctuate substantially per token (e.g., cold activations shift between adjacent tokens from nearly zero to over 3,000 in Layer 0 of OPT-6.7B). Across these representative runs, cold-neuron activations repeatedly form bursty intervals rather than isolated spikes, confirming that semantic drift is a persistent runtime phenomenon even at batch size 1. Although fluctuations also occur on the GPU side, its superior parallelism absorbs them with negligible overhead. In contrast, the same fluctuations saturate CPU workload due to its limited parallel compute capacity. As shown in Figure 3(right), TPOT varies from roughly 50 ms to nearly 200 ms within a single 256-token sequence, and CPU compute time ranges from around 30 ms to nearly 150 ms. These fluctuations persist throughout the sequence, revealing static placement's inability to follow dynamic activation patterns and resulting in unstable latency and degraded user experience.

3.2 A Strawman for Online Neuron Balancing

Both failures stem from the same root cause: static neuron placement. Once runtime activation patterns diverge from the offline profile, many computations are incorrectly routed to the CPU in most cases, creating unnecessary workload imbalance. A natural remedy is to migrate these computations back to the GPU. Our preliminary results (shown in Figure 5) show that even a simple LRU-style reload policy—loading activated neurons from the CPU to the GPU and evicting the least recently used ones—substantially reduces CPU workload with only modest PCIe overhead. For example, provisioning a small GPU cache of just 2,000–3,000 neurons yields

a notable decrease in CPU computation while keeping data transfers manageable. These observations demonstrate that limited, targeted neuron reloading can effectively trade I/O for reduced CPU computation, motivating a dynamic hybrid inference that we term online neuron balancing.

To make this idea concrete, we present a strawman system—a minimal yet illustrative design that operationalizes online neuron balancing. The strawman integrates frequency-aware static placement with simple runtime I/O control. During initialization, offline profiling identifies frequently activated neurons to pre-place on the GPU. During inference, an on-demand balancing policy detects activated cold neurons and migrates as many as the GPU cache can store, using a lightweight eviction policy (e.g., LRU). As shown in Figure 5, dynamically balancing even fewer than 1,000 neurons—despite each layer containing 11,008 neurons in Prosparse-LLaMA2-7B or 16,384 in OPT-6.7B—can substantially reduce CPU workload and stabilize execution efficiency. This strawman serves as a conceptual baseline that illustrates both the feasibility and the benefits of dynamic neuron placement.

Although this strawman theoretically overcomes the limitations of static placement by adapting to activation changes, it also reveals how the three high-level challenges of online neuron balancing manifest concretely in practice:

Challenge 1: How to achieve efficient balancing with computation overlap. Simply redistributing neurons at runtime introduces substantial transfer latency, but the strict sequential dependencies in LLM inference leave limited opportunity to hide this latency. In particular, the sparsity predictor depends on the output of the attention block to determine the activation pattern for the subsequent FFN block. As a result, the system must wait for transfers to complete after prediction, placing non-overlapped I/O directly on the pipeline. Meanwhile, integrating this dynamic balancing into a heterogeneous system—where CPU and GPU already execute concurrently—further increases pipeline complexity.

Challenge 2: How to prioritize sustained neurons and avoid transient, wasteful balancing. As shown in our analysis of activation fluctuation, activation patterns can shift rapidly within short context windows. A simple balancing policy risks repeatedly transferring cold neurons that are activated only momentarily ("one-hit wonders"), resulting in wasted I/O: scarce bandwidth is spent on neurons with minimal long-term utility, potentially evicting more valuable neurons already resident in the GPU cache.

Challenge 3: How to adaptively control balancing intensity under runtime resource constraints. I/O latency and CPU computation present fundamentally opposing bottlenecks: reducing CPU workload by balancing more neurons to the GPU increases I/O cost, while minimizing I/O leaves more computation to the slower CPU. Further, due to continuous fluctuations in resource availability and the dynamic I/O demand induced by the balancing policy, the optimal operating point shifts under different runtime conditions.

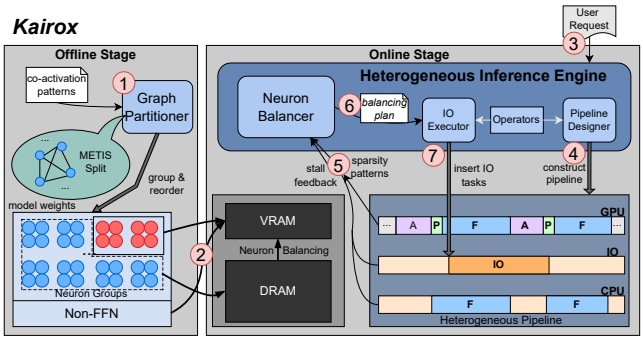

Figure 6: System overview of KAIROX.

Table 1: Summary of key notations and hyperparameters.

Symbol	Description
	Notations
n	Neuron index
g	Neuron group index
N	Total number of neurons per layer
M	Total number of neuron groups
GS	Group size (number of neurons per group)
w_{ij}	Co-activation weight between neurons i and j
$G=(V,E)$	Neuron co-activation graph
t	Generation step (token index)
$A_t^{(n)}, A_t^{(g)}$	Activation state of neuron n and normalized activation intensity of group g at step t
$S_t^{(n)}, S_t^{(g)}$	TAM momentum score of neuron n and group g at step t
	Hyperparameters
λ	TAM decay factor controlling balancing inertia
$\lambda_{\min}, \lambda_{\max}$	Lower and upper bounds of the decay factor
α	Adjustment rate for λ per decoding step
ε	Discrimination margin for loading threshold
τ_{load}	Neuron group loading threshold, $(1-\lambda)+\varepsilon$
K	GPU cache budget (top-K groups retained)

4 System Overview

To address the aforementioned challenges, we propose KAIROX, an adaptive GPU–CPU hybrid inference system. As illustrated in Figure 6, the system workflow operates in two stages. In the Offline Stage, the Graph Partitioner profiles co-activation patterns to group and reorder neurons into optimized clusters (①); we detail this process in subsection 5.2. These neuron groups are then initially distributed between VRAM and DRAM (②) to establish an efficient memory layout for runtime access.

The Online Stage is triggered by a user request (③). Upon initialization, the Pipeline Designer constructs a heterogeneous pipeline (④), as described in section 5. As inference proceeds, the engine executes an iterative optimization cycle: the Neuron Balancer continuously analyzes sparsity patterns and pipeline stall feedback (⑤) to synthesize real-time balancing plans (⑥) using the policies in section 6 and section 7. Acting on these directives, the IO Executor inserts asynchronous I/O tasks (⑦), driving a continuous loop that adapts resource allocation and overlaps data transfer with computation for each subsequent token. Table 1 lists the notation and hyperparameters.

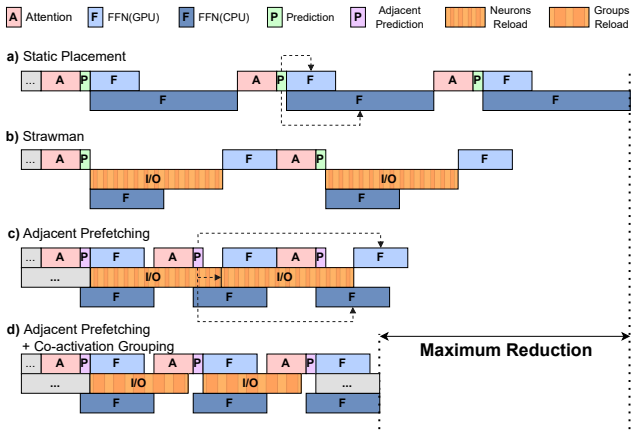

Figure 7: Comparison of heterogeneous pipelines for leveraging activation sparsity: (a) static placement; (b) the strawman design; (c) adjacent prediction; and (d) co-activation grouping & reordering.

5 Live Pipeline

We begin by constructing a basic heterogeneous pipeline similar to static neuron placement, where the CPU and GPU perform sparse computation concurrently. During online inference, the hybrid inference engine interprets computation tasks as a dependency graph and partitions them into backend-specific subgraphs. These dependencies, registered by the pipeline designer, form a Directed Acyclic Graph (DAG) that enables potential overlap across backends. A representative example is split-FFN execution: once the sparsity pattern is determined, the engine launches sparse kernels on both CPU and GPU to process their respective activated neurons, after which CPU outputs are merged back into the GPU, as illustrated in Figure 7(a).

In the strawman system, balancing-related I/O occurs strictly between sparsity prediction and FFN computation, as shown in Figure 7(b). This sequential dependency creates a substantial pipeline bubble, stalling computation on both CPU and GPU. To reduce this exposed I/O latency, we optimize balancing along two complementary dimensions: (1) hiding transfer latency via adjacent prediction and prefetching, and (2) improving bandwidth utilization through neuron co-activation grouping and reordering for transfer efficiency.

5.1 Adjacent Prediction

To hide I/O latency, KAIROX introduces adjacent prediction. This design is motivated by the empirical observation that intermediate hidden states in consecutive layers exhibit high cosine similarity, a stability that arises from the residual connections in Transformer blocks. Experiments show that the cosine similarity between adjacent layers reaches approximately 98%, indicating that the previous layer's hidden state can reliably predict the next layer's activation pattern with minimal accuracy loss. As illustrated in Figure 7(c), the predictor for layer i+1 uses the output of the attention block at layer i to forecast the activation sparsity pattern of the FFN block at layer i+1. This adjacent prediction creates a time window—spanning FFN layer i and the attention block of layer i+1—during which the I/O transfer for layer i+1 can be initiated without introducing stalls. We adopt a one-layer lookahead rather than a multi-layer lookahead because the computation and transfer durations for an individual layer are comparable. A multi-layer lookahead would yield redundant overlapping windows and significant accuracy degradation as similarity drops over larger layer gaps (e.g., 85% across two layers and 65% across four), while also introducing unnecessary complexity in boundary case management, as mentioned in the next paragraph. Therefore, single-layer adjacent prediction optimally balances overlapping efficiency with predictor accuracy, significantly reducing exposed I/O latency.

A special case arises at the first layer (Layer 0), which lacks a preceding layer for adjacent prediction. To avoid a pipeline stall at the beginning of each decoding step, we preload the required neurons during the CPU-side token sampling phase. This design leverages Activation Locality (section 6), which indicates that activation patterns remain stable across adjacent tokens. While processing the final layer for token t, we use the predicted activation pattern of Layer 0 for token t to identify and prefetch the neurons needed for Layer 0 of token t+1. By overlapping this prefetching with the final FFN computation and sampling of the current token, we eliminate the otherwise unavoidable stall at the start of the next decoding step.

A further advantage of adjacent prediction is its ability to overlap the prediction stage with CPU computation. In Figure 7(a), sparsity prediction is strictly serialized before sparse FFN execution and accounts for roughly 10% of total GPU computation time. In Figure 7(c), however, this overhead is hidden behind concurrent CPU workloads, rendering its contribution to end-to-end latency negligible.

Table 2: PCIe bandwidth (GB/s) under different hidden dimensions and neuron group sizes. The PCIe 3.0 and PCIe 4.0 results correspond to models with hidden sizes of 4096 (typical for 7B model) and 5120 (typical for 13B model), respectively.

GS	1	4	8	16	24	32	Theo.
PCIe 3.0	3.3	6.8	8.7	10.2	10.8	11.1	16
PCIe 4.0	5.8	13.7	17.8	20.9	22.3	22.8	32

5.2 Co-activation Grouping & Reordering

In LLM architectures, a single neuron occupies only a small memory footprint (e.g., $\approx$ 8 KB for a hidden size of 4096). Prior studies show that transferring weights at such fine granularity leads to severe underutilization of PCIe bandwidth due to small, fragmented reads and a large number of I/O operations. As shown in Table 2, single-neuron transfers achieve only 21% and 18% of theoretical peak bandwidth on PCIe 3.0 and PCIe 4.0, respectively. To overcome this limitation, we adopt a graph-partitioning strategy that clusters neurons with

high co-activation probability.

Problem Formulation. We formally model the neuron-grouping task as a weighted graph partitioning problem with a capacity constraint. Let $G = (V, E)$ be a dense undirected graph where V denotes a set of N neurons. Each edge (i, j) is associated with a weight $w_{ij} \geq 0$, representing the co-activation frequency (or correlation strength) between neurons i and j. Given a fixed group size GS (with GS dividing N), the objective is to partition the neurons into $M = N/GS$ disjoint groups of size GS. The goal is to maximize the total intra-group edge weight, ensuring that neurons frequently activated together are collocated and thus transferred as a unit. For descriptive purposes, we express this objective as the following binary linear programming for the grouping problem:

$$x_{ig} = \begin{cases} 1, & \text{if neuron } i \text{ is assigned to group } g, \\ 0, & \text{otherwise,} \end{cases} \tag{1}$$

$$\max \quad \sum_{g=1}^{M} \sum_{i<j} w_{ij} x_{ig} x_{jg} \tag{2}$$

$$\text{s.t.} \quad \sum_{g=1}^{M} x_{ig} = 1, \quad \forall i \in V, \tag{3}$$

$$\sum_{i=1}^{N} x_{ig} = GS, \quad \forall g \in \{1, \ldots, M\}. \tag{4}$$

This formulation corresponds to a variant of the graph partitioning problem, which is known to be NP-hard. Consequently, in the offline phase, we collect activation statistics to construct the weight matrix W and employ the METIS graph-partitioning tool [16] to efficiently approximate the optimal grouping strategy. In practice, this end-to-end grouping and reordering requires less than 10 minutes for a single layer.

Granularity Trade-offs. The group size GS serves as a critical hyperparameter. Larger groups improve bandwidth saturation by enabling more sequential PCIe transfers, but they introduce over-fetching because an entire group must be loaded even when only a subset of its neurons is activated. Conversely, smaller groups provide higher data efficiency but reduce PCIe utilization. We analyze the choice of GS in section 8. Furthermore, the mismatch between neuron-level sparsity prediction and coarse-grained group-level transfers necessitates a group-granularity scoring policy (section 6) to determine which groups to load. This optimized grouping strategy effectively reduces I/O latency (see Figure 7(d)) and mitigates pipeline stalls.

6 Locality-Aware Neuron Balancing

The efficacy of dynamic neuron balancing depends on a policy that minimizes thrashing while navigating the trade-off between I/O latency and CPU computation.

To design an effective balancing policy, we first conduct an empirical analysis of neuron activation traces. Although our system ultimately operates at the group level (as described in subsection 5.2), we present the analysis at the neuron granularity for clarity. We collected more than 400,000 activation sequences from multiple models across diverse datasets, with each sequence comprising 256 generation steps.

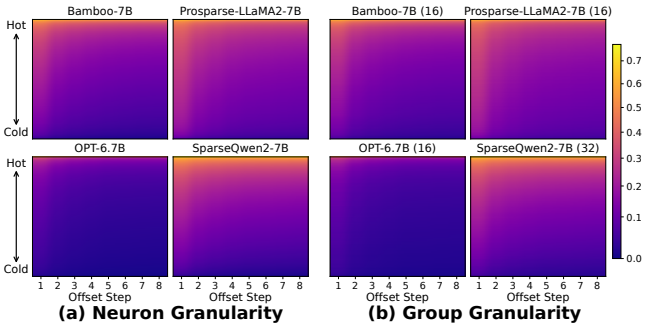

Figure 8: Heatmap of conditional reactivation probability for neuron and group granularity: (a) neuron granularity and (b) group granularity. The x-axis denotes the decoding-step offset δ (1 to 8 steps). The y-axis shows neuron or group indices sorted by activation frequency (hot to cold). The color intensity visualizes the conditional reactivation probability.

We formally define the event $A_t^{(n)}$ as the activation of neuron n at generation step t. To characterize the temporal recurrence of activations, we compute the conditional probability $P\left(A_{t+\delta}^{(n)} \mid A_t^{(n)}\right)$, which measures the likelihood that neuron n is reactivated at a temporal offset of δ steps after activation at step t. Figure 8 presents a heatmap visualizing this probability distribution of four representative sparse models. The horizontal axis denotes the time lag δ from 1 to 8, while the vertical axis lists neuron indices sorted by their global activation frequency in descending order.

Our analysis reveals an empirical observation of activation dynamics: a currently active neuron exhibits a high probability of being reactivated within the next few steps. This indicates that activations form continuous temporal clusters rather than isolated random events. These findings demonstrate the principle of Activation Locality: once a neuron is activated, it is highly likely to remain active for a subsequent sequence of tokens before becoming inactive again. We refer to this duration as the Activation Window. The window length varies substantially; although reactivation probability generally decreases with increasing δ, the decay rate is inversely correlated with global activation frequency. In particular, "cold" neurons (the bottom 70%) exhibit rapid decay, with their reactivation probability falling below 0.2 when $\delta > 2$.

Standard cache-inspired policies fail to adapt to these Activation Locality patterns. Least Recently Used (LRU) is overly sensitive to transient noise. As shown in our analysis, "cold" neurons often manifest as "one-hit wonders" with extremely short activation windows. Under LRU, a single incidental activation can promote a cold neuron to the most recently used position, potentially evicting a hot neuron that is only briefly

silent, leading to pollution and thrashing. Conversely, Least Frequently Used (LFU) suffers from history lag: it aggregates counts across the entire generation history, making it slow to respond to semantic transitions. When the context shifts, LFU tends to retain neurons associated with the previous context, failing to track the emergence of newly important neurons.

To reconcile long-term activation frequency with short-term recency effects, we introduce *Temporal Activation Momentum (TAM)*, a lightweight metric that quantifies the instantaneous "temperature" of a neuron. Inspired by the Hawkes process [23] in temporal point process modeling, TAM treats neuron importance not as a static count but as a time-decaying intensity function. Formally, the momentum score $S_t^{(n)}$ of neuron n at step t is updated recursively as follows:

$$S_{t+1}^{(n)} = \lambda \cdot S_t^{(n)} + (1-\lambda) \cdot A_t^{(n)}, \qquad \lambda \in [0,1), \tag{5}$$

TAM captures the Activation Window pattern observed in our analysis: when a neuron activates persistently, $S^{(n)}$ increases rapidly, raising its balancing priority and promoting its retention on the GPU. When the semantic context shifts and the neuron becomes inactive, $S^{(n)}$ decays exponentially, allowing the system to phase out outdated neurons smoothly.

However, directly relying on TAM may inadvertently promote "one-hit wonders"—cold neurons that activate once in isolation without forming a sustained Activation Window. To avoid unnecessary I/O, we impose a threshold constraint and, at the neuron level, treat only those neurons whose momentum scores exceed $\tau_{\text{load}} = (1-\lambda)+\varepsilon$ as balancing candidates. The term $1-\lambda$ corresponds to the theoretical momentum acquired by a cold neuron ($S_t^{(n)} \approx 0$) after a single isolated activation; thus, scores near this value typically indicate one-hit wonders. The hyperparameter ε provides an additional discrimination margin. By setting τ_{load} slightly above this baseline, isolated spikes are prevented from triggering balancing actions. The same thresholding principle is later applied to group-level scores in lines 10–15 of Algorithm 1.

Figure 8(b) shows that the principle of Activation Locality extends naturally to the co-activation level. To align with our grouping strategy (subsection 5.2), we generalize TAM from individual neurons to neuron groups by replacing the binary activation state $A_t^{(n)}$ with a normalized intra-group activation intensity $A_t^{(g)}$. The corresponding group score $S_t^{(g)}$ provides a unified scoring function for memory management. In practice, the system retains the top-K scoring groups in the GPU, where K is determined by the available GPU memory budget.

7 Adaptive Neuron Balancer

To address Challenge 3—the coupled bottleneck arising from the inverse relationship between I/O latency and CPU workload—we observe that static balancing policies are fundamentally insufficient. An aggressive policy reduces CPU workload but risks saturating PCIe bandwidth (I/O-bound), while a conservative policy alleviates I/O pressure but leaves substantial computation to the CPU (CPU-bound). Because the optimal balance varies with hardware characteristics and runtime I/O load, it cannot be predetermined.

20: **return** $\mathcal{C}_{t+1}, \{S_{t+1}^{(g)}\}, \lambda$

To overcome this limitation, we extend TAM into a feedback-driven balancing policy by incorporating a runtime control loop. In this design, the decay factor λ introduced in section 6 is no longer a fixed hyperparameter, but a dynamic control variable that modulates the system's balancing intensity according to real-time resource conditions.

In our momentum formulation, λ governs the inertia of the score updates and, consequently, the turnover rate of the GPU-resident neuron set. A high λ introduces strong inertia by emphasizing historical activations, making it difficult for cold neurons to accumulate sufficient momentum to exceed the loading threshold. This yields a conservative balancing policy that suppresses reload intensity. In contrast, a low λ reduces inertia, allowing momentum scores to respond quickly to recent activations. This heightened sensitivity increases the mismatch between currently high-scoring groups and the GPU-resident set, triggering more aggressive balancing actions that reduce CPU workload at the cost of increased I/O overhead. During inference, the hybrid inference engine monitors pipeline stalls to identify the dominant bottleneck. We incorporate a negative feedback loop (formalized in Phase 1 of Algorithm 1) to dynamically adjust the value of λ:

- **I/O-Bound:** If stalls are primarily caused by I/O delays,

the system detects excessive data-transfer pressure. In response, it increases λ by a factor of $(1+\alpha)$, strengthening momentum inertia and enforcing a more conservative balancing policy to reduce overall I/O load.

- **CPU-Bound:** if stalls originate from CPU computation, the system infers that the CPU is overloaded. It then decreases λ by a factor of $(1-\alpha)$, assigning greater weight to recent activations relative to historical momentum. This increases balancing intensity, reducing CPU workload by exploiting available I/O overlap.

We initialize λ to a moderate value (e.g., 0.5). Within the first few generation steps, the feedback-driven mechanism quickly converges λ toward—or maintains it near—an equilibrium that balances the two coupled bottlenecks. Because a static optimal configuration rarely exists under varying input contexts, this dynamic tuning enables KAIROX to adapt continuously to runtime fluctuations, including semantic shifts and changes in available hardware resources.

The complete balancing policy is formalized in Algorithm 1. It integrates Feedback-Driven Tuning and Temporal Activation Momentum within each layer's decode step once activation sparsity is predicted, automatically reconciling hardware constraints with Activation Locality.

The resulting balancing decisions are efficient ($O(1)$) and integrate seamlessly into the runtime system. We implement the updates with customized CUDA kernels (section 8), keeping end-to-end overhead negligible.

8 Implementation

We implemented KAIROX on top of `llama.cpp`, adding approximately 5,700 lines of C++ and CUDA code. In the offline stage, we collected over 400,000 activation patterns from the C4 dataset [35]. These patterns were used to train the adjacent predictors and to construct an undirected weighted graph for neuron grouping and reordering, which was subsequently partitioned using the METIS [16] graph-partitioning tool.

Priority-Aware Stream Management. To coordinate the heterogeneous pipeline, KAIROX employs three primary CUDA streams: a computation stream within the inference engine for kernel executions, and two I/O streams managed by an internal I/O Executor—one critical I/O stream for essential transfers (e.g., merging FFN results) and one reload stream for neuron-loading tasks. An asynchronous thread in the I/O Executor maintains a task queue for reload operations. When a critical I/O task arrives, the executor preempts queued reload tasks, allowing essential transfers to bypass the queue and execute immediately, thereby preventing pipeline stalls and ensuring stable end-to-end latency.

Customized Kernels. We developed optimized sparse CUDA and AVX kernels for activation-sparse inference. The feedback-driven TAM policy uses custom CUDA kernels that fuse `XOR` and `AND` operations for efficient group-level activation updates and set-difference computations. We also integrate a CUDA `argsort` kernel to rank neuron groups by momentum score. Because high-performance argsort is most efficient on inputs below 1024 elements, we constrain the neuron group count M to this threshold, keeping balancing latency negligible while integrating seamlessly with the online neuron balancing pipeline.

9 Evaluation

9.1 Experiment Setup

Hardware. We conduct all experiments on two representative consumer-grade PC configurations.

- **PC-Low**: NVIDIA RTX 3080 Ti (12 GB, 136 TFLOPs), Intel Xeon® E5-2680 v4 with execution capped at 12 threads, 64 GB host memory, and PCIe 3.0 (16 GB/s).
- **PC-High**: NVIDIA RTX 4090 (24 GB, 330 TFLOPs), AMD EPYC 7542 with execution capped at 16 threads, 128 GB host memory, and PCIe 4.0 (32 GB/s).

Models and Workloads. We evaluate a range of sparse LLMs, including OPT-6.7B/13B, OPT-30B-Q8/Q4, and OPT-66B-Q4 (ReLU); Prosparse-LLaMA2-7B/13B (derived from LLaMA-2; FatReLU); Bamboo-7B (derived from Mistral; dReLU); SparseQwen2-7B (derived from Qwen2; dReLU); and ReLUFalcon-40B-Q8 (derived from Falcon; ReLU) [39, 42, 43, 47, 59]. The suffixes "Q8" and "Q4" denote INT8 and INT4 quantization, respectively. All models are tested using a fixed subset of real-world user prompts randomly sampled from ShareGPT [46], ensuring consistent, diverse, and reproducible workloads. Additionally, we reuse the dense GEMM kernels from llama.cpp for the prefill stage, as the dense kernels are better optimized for large-batch computation.

Baselines. We compare KAIROX with four representative systems: llama.cpp [14], PowerInfer [41], Neuralink [50], and Q-Infer [29]. Llama.cpp serves as a widely used local inference baseline. PowerInfer is a state-of-the-art sparsity-aware framework; because it relies on an older version of llama.cpp, we port it to the same updated backend used by KAIROX for a fair comparison. Neuralink is an on-device activation-sparse system that eagerly loads all activated neurons onto the accelerators for computation. Because it is designed for smartphones and is not open source, we reimplement its core mechanism on top of KAIROX for evaluation. Q-Infer is a GPU–CPU hybrid inference system designed for high-end GPUs and large-batch LLM serving. Since it also uses runtime reloading, we evaluate it under the same setting as KAIROX for a direct comparison under identical constraints.

9.2 End-to-End Performance

We first evaluate throughput using a generation batch size of 1, reflecting a typical usage scenario for local LLM deployments. For consistency, we cap the maximum output length at 512 tokens and the maximum context size at 1024 tokens.

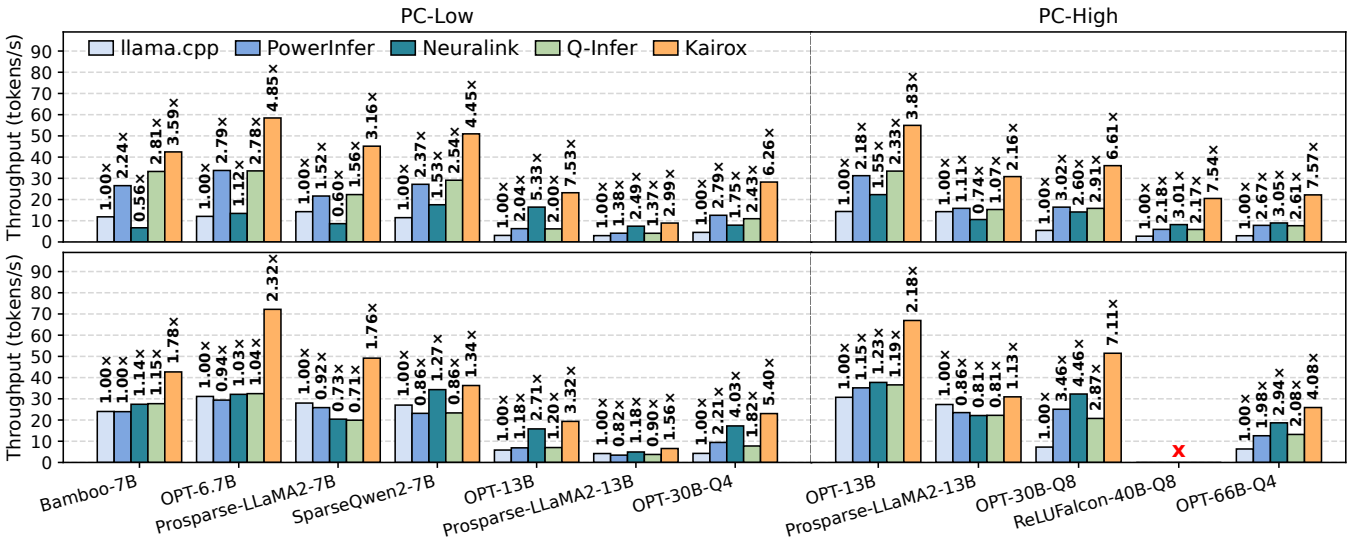

Figure 9: End-to-end performance of decoding. Top: standard decoding. Bottom: speculative decoding.

As shown in Figure 9, KAIROX consistently outperforms all baselines across models and hardware configurations. For standard completion, the speedup over llama.cpp reaches up to 7.53× on PC-Low and 7.57× on PC-High, with geomean gains of 4.45× and 5.00× across models, respectively. Relative to the sparse baselines, the geomean gains range from 2.08× to 3.06× on PC-Low and from 2.36× to 2.58× on PC-High, while the corresponding best-case gains reach 3.70×, 6.35×, and 3.76× on PC-Low and 3.46×, 2.91×, and 3.48× on PC-High over PowerInfer, Neuralink, and Q-Infer, respectively. The gains are largest on OPT models, whose stronger sparsity and shorter cold-neuron activation windows—reflected in the darker regions of Figure 8—allow TAM to filter transient one-hit-wonder activations more effectively. As a result, the GPU cache is reserved for neurons with genuinely long activation windows. Neuralink's relative performance ranges from near parity to multiple-fold gains because it is sensitive to cache hit rate, per-step activation volume, and GPU cache size. When the cache is large, it reloads a larger portion of activated neurons to make full use of the cache, introducing substantial I/O stalls (e.g., Bamboo-7B on PC-Low and Prosparse-LLaMA2-13B on PC-High). Q-Infer, despite using rebalancing, does not outperform PowerInfer in our setting. Because it is designed for large-batch serving, it focuses on current-round activations and may load short-lived cold neurons while missing persistently activated ones, leaving the system CPU-bound with extra scheduling overhead. By contrast, KAIROX leverages the activation locality property described in section 6 to ensure that high-value neuron groups consistently dominate the GPU cache, effectively reducing CPU workload and wasteful transfers.

To evaluate throughput scalability at higher batch sizes, we test Speculative Decoding—a widely used edge-acceleration technique in which a draft model proposes candidate tokens that are verified in parallel. All evaluations use 5 draft tokens, and ReLUFalcon-40B-Q8 is excluded because no compatible draft model is available. While we faithfully report cases where low acceptance rates reduce absolute gains, our analysis focuses on relative batch-processing efficiency against baseline systems. Under this setting, KAIROX continues to outperform all baselines, achieving geomean speedups of 2.23× and 2.91× over llama.cpp on PC-Low and PC-High, respectively. Relative to the sparse baselines, the geomean gains range from 1.53× to 2.11× on PC-Low and from 1.53× to 1.88× on PC-High. In this setting, llama.cpp occasionally outperforms PowerInfer and Neuralink because dense batched GEMMs can surpass sparse kernels when irregular memory access and index overhead outweigh sparsity benefits. Larger batch sizes also increase CPU workload, exposing bottlenecks in static systems. Neuralink can outperform other reloading-based baselines in some cases because its aggressive reloading absorbs part of this additional CPU workload. By contrast, Q-Infer still underperforms PowerInfer in most cases, as speculative-decoding batch sizes remain too small for its policy to reliably identify and retain high-value neurons. Nevertheless, KAIROX remains consistently superior; for example, on PC-Low with OPT-30B-Q4, it achieves speedups of 5.40×, 2.44×, 1.34×, and 2.97× over llama.cpp, PowerInfer, Neuralink, and Q-Infer, respectively.

9.3 Performance Analysis

We further examine the factors contributing to KAIROX's performance advantages over baseline systems.

Effectiveness of Adaptive Neuron Balancer. First, we compare CPU computation burden (measured by CPU latency), I/O pressure (measured by reload latency), and overall throughput under three balancing policies: a simple **Top-K**

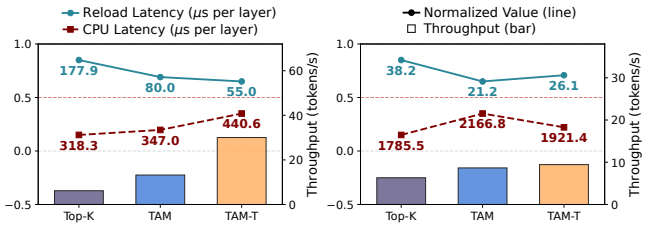

Figure 10: Comparison of CPU latency, I/O latency, and throughput under three reload policies. Left: Bamboo-7B on PC-Low. Right: Prosparse-LLaMA2-13B on PC-Low. CPU latency and reload overhead are normalized.

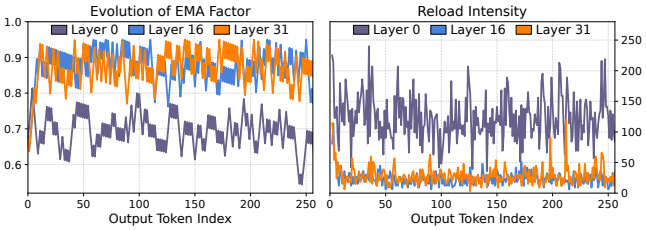

Figure 11: Evolution of the decay factor λ and the corresponding reload intensity, sampled from Bamboo-7B on PC-Low. Left: decay factor λ. Right: number of reload I/O tasks per step.

strategy that reloads the most activated neuron groups, a **TAM** scoring policy with a fixed λ, and **TAM-T**, i.e., TAM with feedback-driven tuning, as shown in Figure 10.

Under the Top-K policy, large numbers of cold neuron groups—isolated "one-hit wonders"—are indiscriminately transferred to the GPU. Although this approach nominally reduces CPU computation, the excessive reload latency induces severe stalls that negate any potential gains. Introducing a static TAM policy significantly filters out such one-hit wonders, reducing reload latency—the primary bottleneck—by approximately 1.8× to 2.2× and substantially improving throughput. Finally, the TAM-T policy dynamically navigates the inverse trade-off between I/O latency and CPU computation. In I/O-bound scenarios (e.g., Bamboo-7B on the PC-Low), the policy detects I/O-induced stalls and enforces a more conservative reloading intensity. Conversely, in CPU-bound scenarios (e.g., Prosparse-LLaMA2-13B on the PC-Low), it increases reloading intensity to alleviate CPU workload, thereby optimizing overall throughput.

Second, Figure 11 shows how the evolution of the decay factor λ regulates reloading intensity via the decoding process. Immediately after initialization, the balancer identifies the dominant bottleneck and converges toward a stable equilibrium. For example, during steps 1–7 at layer 31, λ increases monotonically, indicating an I/O-bound state that necessitates a conservative balancing. This adjustment rapidly reduces I/O volume and restores system harmony. Throughout generation, λ continues to adapt dynamically to real-time workload fluctuations. Distinct micro-oscillations emerge around specific thresholds—most notably during steps 65–85 at layer 0 and steps 130–150 at layer 16 & 31—signaling that the system has

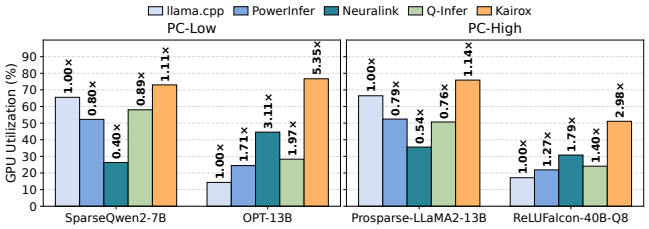

Figure 12: GPU utilization across baselines and KAIROX for representative models on PC-Low and PC-High.

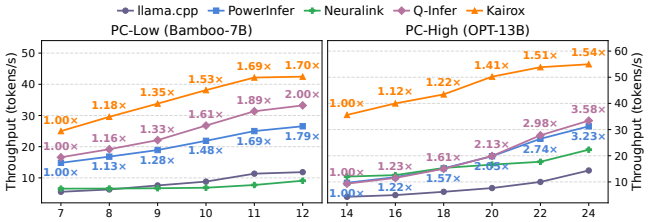

Figure 13: Throughput under varying GPU memory budgets. Left: PC-Low with Bamboo-7B. Right: PC-High with OPT-13B.

located a temporary optimal point where neuron transfers and CPU computation are effectively balanced. At layers 16 & 31, λ stabilizes around 0.85, reflecting a conservative balancing strategy. As shown in Figure 11(right), this corresponds to consistently low I/O intensity, remaining below 75 reloads per step. In contrast, the lower λ value observed at layer 0 triggers a more aggressive reloading policy, resulting in substantially higher I/O volume per decoding step.

GPU Utilization. We use NVIDIA Nsight Systems [31] to measure GPU utilization, a key indicator of pipeline efficiency and hardware stalls. As shown in Figure 12, KAIROX consistently outperforms all baselines, achieving up to 5.35× and 2.98× higher utilization on PC-Low and PC-High, respectively. This improvement reflects a more efficient execution pipeline in which the GPU remains active rather than idling. In contrast, llama.cpp exhibits pronounced utilization fluctuations determined by the degree of layer offloading. When most layers are offloaded to the GPU (e.g., Prosparse-LLaMA2-13B on PC-High), consistent kernel execution raises utilization to 68%; when memory constraints limit offloading (e.g., OPT-13B on PC-Low), utilization falls below 20%. Although activation-sparse inference frameworks generally outperform dense baselines in such settings, KAIROX still surpasses PowerInfer. This advantage stems from adaptive neuron balancing and a highly optimized pipeline that dynamically rebalances computation while overlapping CPU execution and I/O with GPU kernels to reduce stalls. GPU utilization is ultimately limited by residual non-overlappable I/O, cross-device synchronization, and system-level overheads such as CPU scheduling and token processing. In resource-constrained edge environments, these factors cap practical utilization at around 70% in our settings, which is already near saturation.

Performance under Various GPU Memory Budgets. Figure 13 shows that KAIROX consistently outperforms all base-

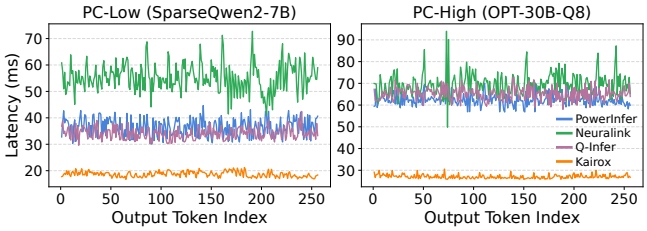

Figure 14: Per-token TPOT latency across models and systems. Left: SparseQwen2-7B on PC-Low. Right: OPT-30B-Q8 on PC-High.

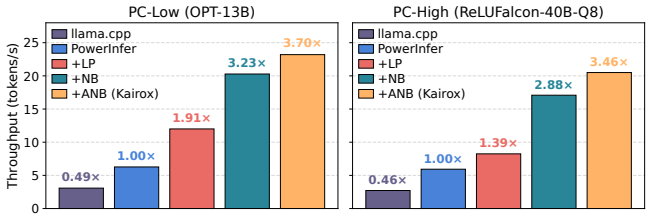

Figure 15: Contribution of each component in KAIROX, shown as throughput across incremental system variants.

lines across configurations, demonstrating strong resilience under constrained GPU memory budgets. As available GPU memory shrinks, static strategies leave more workload to the CPU, creating severe performance bottlenecks. Under these tighter budgets, KAIROX maintains a throughput of around 25 tokens/s on PC-Low with only 7 GB of VRAM when running Bamboo-7B (total memory footprint of approximately 14 GB). On PC-High, KAIROX under a 14 GB budget even surpasses all baselines operating at their full 24 GB budget, highlighting the effectiveness of its adaptive balancing under tight memory constraints. Q-Infer outperforms PowerInfer on Bamboo-7B but yields only marginal gains on OPT-13B, as its reloading policy struggles to identify high-value neurons in models such as OPT that exhibit a higher proportion of one-hit-wonder activations, as shown in Figure 8.

TPOT Latency Variability. We further evaluate per-token latency variability on a representative decoding sequence, as shown in Figure 14. Neuralink exhibits the most severe fluctuations: its TPOT trace closely follows the cold activation drift in Figure 4 because its aggressive reloading policy transfers all activated neurons without filtering, causing I/O latency to rise directly with cold activation volume. PowerInfer, as a static placement system, avoids these I/O-induced spikes but still suffers from CPU-side latency fluctuations as cold-neuron workload shifts across tokens. Q-Infer halts reloading once computation is required, avoiding the I/O-induced spikes seen in Neuralink. However, because it does not prioritize persistently activated neurons, high-value neurons may not be loaded before the I/O window closes, leaving the system CPU-bound with TPOT variability comparable to PowerInfer. KAIROX achieves the lowest and most stable TPOT across the sequence, demonstrating its robustness under dynamic activation patterns and different hardware configurations.

9.4 Ablation Study

We conduct an ablation study to quantify the contribution of each optimization component. Using llama.cpp as the primary baseline, we first observe that PowerInfer—which incorporates activation-sparse inference—achieves speedups of 1.43× and 1.61× under our evaluation settings. Building on this baseline, we incrementally integrate our dynamic optimizations in three stages and measure the resulting throughput improvements, as illustrated in Figure 15.

Table 3: End-to-end generation throughput (tokens/s) on non-ReLU architectures, comparing PowerInfer, Neuralink, Q-Infer and KAIROX. The suffixes "-Low" and "-High" indicate the hardware configurations used in each evaluation.

	Qwen2-7B (SiLU)-Low	LLaMA2-13B (SiLU)-Low	Falcon-40B (GeLU)-High
PowerInfer	16.46	3.97	9.86
Neuralink	12.95	3.02	7.83
Q-Infer	15.28	3.98	8.84
KAIROX	**21.96**	**5.07**	**10.53**

First, we apply the **Live Pipeline (+LP)** to maximize the overlap between I/O operations and heterogeneous execution. Second, we introduce online **Neuron Balancing (+NB)**, initially employing a fixed decay factor ($\lambda = 0.5$). Finally, we implement feedback-driven **Adaptive Neuron Balancing (+ANB)** to dynamically adjust λ in response to system constraints. The inclusion of LP yields throughput gains of 1.91× and 1.39× by effectively overlapping computation and communication. Notably, +NB contributes the largest performance gain, boosting throughput to 3.32× and 2.88×; this substantial leap underscores the critical importance of runtime dynamic neuron balancing in alleviating CPU bottlenecks. Ultimately, the constraint-aware tuning provided by ANB achieves peak speedups of 3.70× and 3.46×. These results demonstrate that while pipeline overlapping provides a solid foundation, dynamic neuron reloading acts as the primary driver of performance improvement, effectively unlocking the potential of hybrid inference.

9.5 Non-ReLU Models Performance

While activation-sparse inference methods typically achieve substantial acceleration on models with high activation sparsity, they often struggle with non-ReLU architectures (e.g., GeLU-based models). In non-ReLU models, a larger fraction of neurons are activated at each step due to reduced sparsity. Under static split strategies such as PowerInfer, this significantly increases the CPU workload. For Neuralink, the higher activation density triggers excessive indiscriminate reloads, rendering the system I/O-bound. Unlike competing systems, KAIROX retains its performance advantage even under high activation density. As shown in Table 3, KAIROX consistently outperforms all baseline systems across mainstream non-ReLU architectures. These results demonstrate the ro-

bustness of KAIROX and highlight potential opportunities for future research into inference optimization for less sparse or non-sparse model architectures on edge devices.

9.6 Sparse Inference Analysis

KAIROX employs lightweight predictors to skip computation for inactive neurons. Since only predicted neurons are computed, predictor accuracy directly affects downstream performance. In this section, we analyze predictor accuracy, its impact on the sparse inference system, and the underlying mechanisms behind this behavior.

Predictor Accuracy. Figure 16 illustrates predictor metrics across different layers. The recall ratio, defined as the fraction of ground-truth activated neurons that are correctly predicted, remains consistently high at 90%–99%. The precision ratio, defined as the fraction of predicted neurons that are confirmed as active in dense computation, is relatively lower. Specifically, the predictors are recall-prioritized: we deliberately sacrifice precision to maximize recall, reducing false negatives at the cost of additional false positives. This ensures that the vast majority of truly activated neurons are captured, preserving model performance.

Predictor Overhead. In our experiments, predictor execution accounts for approximately 5–10% of per-layer inference time when measured in isolation with NVIDIA Nsight Systems. However, the effective overhead introduced by the predictors is only 1–2% of end-to-end system latency, thanks to the dedicated Live Pipeline design described in section 5. Since the predictors execute on the GPU, the execution time of the predictor for layer $i+1$ is completely hidden behind the concurrent CPU-side MLP computation of layer i. The only unavoidable overhead occurs at the first layer, where the predictor and MLP computations must be serialized. As a result, predictor latency scales sub-linearly with the number of model layers, and its relative contribution diminishes in larger models. This overlap opportunity also allows us to use larger predictors for better accuracy than would be practical in systems where predictor latency is a critical bottleneck.

Model Downstream Performance. To evaluate the feasibility of KAIROX's sparse inference, we compare it against standard dense inference across several mainstream benchmarks, as shown in Table 4. The results indicate that KAIROX preserves model accuracy, with an average degradation of less than 0.5% across downstream tasks. This deviation falls within the expected statistical variance of the underlying models. Notably, our analysis shows that false negatives—neurons incorrectly classified as inactive—typically produce output magnitudes near zero. Consequently, omitting them has negligible impact on the layer's feature representation, maintaining the correctness of sparse inference.

10 Related Work

GPU–CPU Hybrid Inference. GPU–CPU hybrid inference has become a common strategy for running LLMs whose weights exceed GPU memory budgets. Representative systems such as llama.cpp [14] and PowerInfer [41] rely on static partitioning across the GPU and CPU, whereas more recent work explores runtime-adaptive reloading. Q-Infer [29], for example, is positioned toward server or high-end-GPU settings, where the goal is to maximize throughput under richer resources and larger-batch workloads. Accordingly, it focuses on current-round activations when deciding which CPU-resident weights to reload. This short-horizon policy can migrate transient "one-hit-wonder" cold neurons and incur extra transfers, but such overhead can often be amortized by the substantial computation available in large-batch serving. In contrast, KAIROX targets resource-constrained consumer PCs, where exposed transfer latency and CPU bottlenecks dominate once runtime activation drift invalidates static hot/cold placement. KAIROX therefore emphasizes not only which activated CPU-resident neurons should migrate back to the GPU, but also when such migration is worthwhile and how aggressively rebalancing should proceed under shifting CPU-bound and I/O-bound conditions.

Quantization. Quantization [8, 15] mitigates memory constraints by reducing model-weight precision to INT8 [9, 52], INT4 [13, 56], or even lower bit-widths [5, 49, 54] while maintaining acceptable accuracy. This technique is orthogonal to KAIROX, as we integrate INT8 and INT4 quantization support into KAIROX (section 9), enabling larger models to run

on limited hardware. Although quantization substantially reduces I/O volume by decreasing data-transfer size, it leaves the computational workload largely unchanged. Consequently, quantization often shifts the dominant system bottleneck from being I/O-bound to being computation-bound.

Mixture of Experts (MoE). MoE models introduce sparsity at the expert-selection level by routing each token to a small subset of FFN experts [4,61]. This differs from KAIROX, which targets fine-grained neuron-level sparsity inside FFN computation under GPU–CPU memory constraints. KAIROX does not directly replace MoE serving systems, and our implementation does not optimize expert routing or expert-level placement. However, the two forms of sparsity are complementary: once an expert is selected, its internal FFN computation can still exhibit activation sparsity, and KAIROX's neuron-level balancing could be applied within selected experts to reduce CPU-side work under limited GPU memory, presenting further opportunities for acceleration on edge devices [62]. Supporting full MoE inference would require integrating expert routing, expert-level placement, and neuron-level balancing, which we leave to future work.

Mobile Inference Systems. Deploying LLMs on mobile devices, such as smartphones, represents another important direction in edge computing. Unlike the consumer PC architecture targeted by KAIROX, mobile devices typically employ Systems-on-Chip (SoC) with Unified Memory (UM). UM enables the CPU and accelerators (e.g., NPUs, TPUs) to access a shared physical memory space, effectively eliminating explicit data-transfer overhead. Recent works such as llm.npu [53] and Smallthinker [44] exploit this property to optimize on-device inference.

LLM Serving Systems. LLM serving systems are typically deployed in cloud data centers and are designed to maximize throughput under high concurrency using abundant computational resources [30]. Research in this domain primarily focuses on efficient Key–Value (KV) cache management (e.g., vLLM [21], Mooncake [33], LMCache [7]) and distributed parallelism strategies [12, 19, 58]. LoRA-based serving systems such as CaraServe [24], S-LoRA [37], and TOPPINGS [25] represent another direction, focusing on efficient multi-adapter serving. However, these systems assume the base model fits entirely within GPU memory, with CPU involvement limited to lightweight adapter management. This makes them not directly applicable to the setting targeted by KAIROX, where the base model itself must be partitioned across the GPU and CPU under constrained GPU memory.

11 Conclusion

We presented KAIROX, an adaptive hybrid LLM inference system for consumer-grade PCs. KAIROX builds on activation sparsity to enable efficient **online neuron balancing** through a live pipeline, locality-aware neuron balancing, and feedback-driven tuning. Together, these designs navigate CPU and I/O bottlenecks, providing a foundation for low-latency hybrid LLM inference on resource-constrained hardware.

A Artifact Appendix

Abstract. The artifact for KAIROX includes the modified `llama.cpp` source tree, the KAIROX implementation, comparison-system runners, and scripts for building, benchmarking, and summarizing results. It is designed to let artifact evaluators validate the released implementation and check selected end-to-end throughput trends from the paper under representative consumer-PC configurations.

Scope. The required artifact-evaluation path focuses on availability and selected performance validation. Specifically, the artifact checks that KAIROX builds and executes correctly; that the short `simple_validation` path runs `llama_cpp`, `kairox`, and `neuralink` on one validation model for the selected hardware profile; and that the full `e2e_performance` path reproduces selected Figure 9 trends by comparing KAIROX against the included baselines under matching models, hardware profiles, and generation modes. The paper also compares against PowerInfer and Q-Infer, but those external repositories are outside the required artifact-evaluation path.

Contents. The artifact repository contains the modified `llama.cpp` tree with KAIROX, the top-level driver `bench_models.sh`, the per-backend runner `test_kairox.sh`, the build helper `compile_kairox.sh`, the fixed prompt set `prompts.txt`, the log parser `parse_bench_logs.py`, and the detailed guide `ARTIFACTS_EVALUATION.md`. Model weights are not stored in the repository; evaluators download the required GGUF model files separately from the SPIF model release.

Hosting. The artifact repository is hosted publicly at https://github.com/Anhelor/kairox.cpp. The repository is intended to remain readable throughout artifact evaluation and contains the software path needed for the required runs, except for external model weights and standard container or dependency downloads described in the guide.

Requirements. The paper evaluates two consumer-grade profiles: PC-Low, using an RTX 3080 Ti with 12 GB VRAM, 12 benchmark CPU threads, and PCIe 3.0 x16; and PC-High, using an RTX 4090 with 24 GB VRAM, 16 benchmark CPU threads, and PCIe 4.0 x16. The closest reproduction uses matching GPUs, Docker, NVIDIA Container Toolkit, an NVIDIA driver compatible with CUDA 12.8, and sufficient disk space for source, build outputs, logs, summaries, and selected GGUF model files. Different CPUs, memory bandwidth, PCIe generations, drivers, or model subsets may change absolute throughput, so the artifact emphasizes matching comparisons within the same profile.

A.1 Installation

Evaluators clone the artifact repository, prepare a model directory, and enter a CUDA 12.8 development container with GPU access. Inside the container, they install the standard build dependencies, verify that the GPU is visible, and download either the full SPIF GGUF model set or a smaller validation-only subset for the selected profile. The exact host and container commands, including optional smaller downloads for PC-Low and PC-High validation, are provided in `ARTIFACTS_EVALUATION.md`. No separate upstream `llama.cpp` checkout is required because the artifact repository already contains the modified tree.

A.2 Experiment Workflow

The artifact provides two workflows. The short `simple_validation` workflow is a smoke test that builds the release binaries and runs completion and speculative decoding for `llama_cpp`, `kairox`, and `neuralink` on the profile's validation model: Prosparse-LLaMA2-7B for PC-Low and Prosparse-LLaMA2-13B for PC-High. It is invoked as `bash bench_models.sh low simple` or `bash bench_models.sh high simple`.

The full `e2e_performance` workflow runs the validation path followed by the selected throughput experiments. It uses a maximum context size of 1024 tokens and a maximum output length of 512 tokens, matching the paper's Figure 9 setup. It is invoked as `bash bench_models.sh low full` or `bash bench_models.sh high full`. Logs are written to `low_logs/` or `high_logs/`; evaluators can inspect each log's final `benchmark summary` block or run `parse_bench_logs.py` to generate Markdown and CSV summaries.

A.3 Expected Results

The `simple_validation` run passes if the build succeeds, all backends finish without runtime errors, logs are written, and each log ends with a `benchmark summary` block. The full `e2e_performance` run passes if the parser can summarize the logs and KAIROX reports a higher `decode mean` than the included comparison systems for matching profile, model, and generation mode. Because speculative decoding is sensitive to acceptance rate and hardware differences, exact throughput can vary; the expected result is the same relative trend under matched conditions rather than bit-for-bit reproduction of every number in the paper.

ADAngel: Accelerating Arbitrary-Precision Quantized LLMs with Adaptive Computing Mapping

Yao Liu, Wenjie Wang, Yifei Feng, Bo Peng, Jianguo Yao, Haibing Guan
Shanghai Jiao Tong University

Abstract

Arbitrary-Precision Quantization (APQ), which uses asymmetric bit-widths for weights and activations (e.g., W4A8), is a prevalent technique for LLM inference because of its excellent accuracy-performance balance. APQ transforms the general matrix multiplications (GEMM), the core of LLM computation, into mixed-precision GEMM (mpGEMM) whose two operand matrices have different quantization bit-widths. However, we identify that the computation paradigms of mpGEMM in current APQ LLM inference systems are suboptimal because the shapes and bit-widths of mpGEMM tasks in APQ LLM are highly variable, whereas existing static and workload-unaware paradigms can only accelerate mpGEMM tasks with the same or similar shapes and bit-widths.

Based on this finding, we propose ADAngel, a framework for creating a workload-adaptive mpGEMM computation core for target LLMs. The theoretical foundation of ADAngel is the DPR (Decomposition-Partial Product-Reconstruction) computation model, which enables systematic generation of a diverse portfolio of mpGEMM algorithms by specifying different bit-partition schemes. Guided by this model, ADAngel constructs a Computation Strategy Set comprising several highly optimized mpGEMM kernels, and exhaustively analyzes the strategy set to create an Oracle Policy Map, which enables a lightweight dispatcher to select and execute the optimal kernel for runtime mpGEMM tasks with negligible overhead. Our evaluation shows that the ADAngel-specialized engine achieves up to a 5.10× speedup in decode throughput over llama.cpp; while in the prefill stage, it demonstrates its adaptivity by delivering speedups ranging from 1.17× to 2.38× over TensorRT-LLM in Time-To-First-Token (TTFT).

1 Introduction

Large Language Models (LLMs) [9, 21, 30, 35] are increasingly being deployed on edge devices [19, 20, 25] to enhance the capabilities of edge intelligent tasks and agents. Unfortunately, edge devices are constrained by design limitations in chip area, power consumption, and cost, resulting in significantly inferior computing and memory/storage capabilities compared to cloud-scale infrastructure. Deploying full-scale LLMs on edge devices is inefficient or often infeasible because of limited hardware resources. Post-training quantization (PTQ) [15, 31, 33, 36] is a mainstream model compression technique that is widely adopted for edge-side LLM deployment. It quantizes the weights or activations of trained LLMs to reduce data bit-width and computational complexity, thereby enabling efficient inference on edge devices. Arbitrary-Precision Quantization (APQ) [3, 14, 26] quantizes weights and activations into different bit-widths, such as W4A8 (4-bit weights and 8-bit activations), thereby achieving a fine-grained trade-off between inference speed and quality. APQ results in LLMs' general matrix-matrix multiplication (GEMM) or general matrix-vector multiplication (GEMV) having operands with different bit-widths (mixed-precision bit-widths). However, existing edge computing units or accelerators lack native hardware support for operations with asymmetric bit-width operands.

To enable existing edge devices to support inference for APQ LLMs, padding [11, 17], lookup table (LUT) [18, 22, 32], and bit-disaggregation [39] techniques have been proposed. Padding techniques upcast low-bit-width weights to match the bit-width of activations, ensuring compatibility with existing edge computing units (e.g., executing W4A8 operations on INT8 Tensor Cores by upcasting weights to 8-bit). LUT-based approaches precompute the products of high-bit-width activations and low-bit-width weights, storing them in a lookup table. During inference, results are directly fetched from the LUT to avoid asymmetric GEMM and GEMV operations. Bit-disaggregation decomposes weights and activations of varying bit-widths into 1-bit representations, reconstructing the mixed-precision computation using 1-bit GEMM and GEMV kernels. Zeng et al. [39] leverage 1-bit Tensor Cores of NVIDIA Ampere GPUs to accelerate bit-level GEMM and GEMV. Due to the memory overhead and hardware support requirements, LUT-based methods exhibit lower efficiency than padding and bit-disaggregation on edge devices.

However, our investigation reveals that relying solely on

padding or bit-disaggregation fails to accommodate the computational heterogeneity in LLM inference, thereby hindering the inference speed of APQ LLMs on edge devices. Specifically, (1) **Computational heterogeneity between prefill and decode:** LLM inference consists of two phases, prefill and decode. Prefill processes long-sequence prompts, and compute-intensive GEMM is the primary workload. Decode generates tokens sequentially based on Key-Value Cache (KV Cache), and memory-bound GEMV is the dominant operation. Padding and bit-disaggregation techniques demonstrate suboptimal adaptability for the computational and memory patterns of these two stages, resulting in unstable inference performance.

(2) **Intra-Prefill computational heterogeneity:** The arithmetic intensity of GEMM in the prefill phase increases with the sequence length. Our analysis indicates that bit-disaggregation incurs lower overhead for short sequences, while padding demonstrates superior efficiency for long sequences. A static strategy fails to adapt to these dynamic workload variations.

(3) **Intra-Decode computational heterogeneity:** Batching is a typical method adopted to improve decode parallelism. We observe that with increasing decode batch size, the Linear layers transition towards higher arithmetic intensity, thus requiring adaptive strategy selection.

(4) **Computational heterogeneity in quantization bit-width:** The quantization bit-widths of weights and activations affect the GEMM's arithmetic intensity. Bit-disaggregation outperforms padding at ultra-low bit-widths. Conversely, padding proves more effective for higher bit-widths.

The root cause of these suboptimal behaviors of existing algorithms is the fundamental mismatch between the static, one-size-fits-all nature and the computational heterogeneity inherent in APQ LLM inference. Essentially, this heterogeneity stems from both runtime dynamics and intrinsic model structures. Most importantly, dynamic shifts in sequence length and batch size drastically alter the M dimension. As shown in Figure 1, for a given N and K, the optimal algorithm changes as M varies. Furthermore, variations in N and K also significantly affect the optimal strategy, as they change the arithmetic intensity and workload characteristics of GEMM. In practice, these effects are further shaped by the tiling mechanisms used in existing GEMM algorithms. Existing static paradigms fail because they cannot adapt to the shifting operational characteristics.

To this end, we propose ADAngel, an adaptive computing mapping system designed to accelerate APQ LLM inference on edge devices. At the heart of ADAngel lies the DPR (Decomposition-Partial Product-Reconstruction) computation model, a unified theoretical abstraction that formalizes diverse software adaptation algorithms (e.g., padding, bit-disaggregation) of mixed-precision GEMM (mpGEMM) into a single, generalized description. Guided by DPR, we systematically derive a diverse Computation Strategy Set to

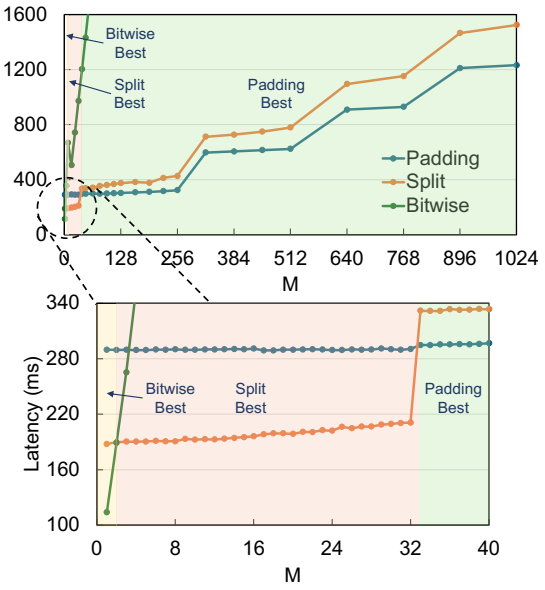

Figure 1: **The performance of three static computation strategies** (Split is our novel strategy, and Bitwise is based on bit-disaggregation) under different M for a typical W4A8 mpGEMM task in LLMs (N = 4096, K = 6144).

cover the spectrum of computational heterogeneity comprehensively. Then, in an offline phase, ADAngel exhaustively profiles these DPR-derived strategies across the target workload space defined by the target LLM to construct an Oracle Policy Map. This map is then embedded into a lightweight dispatcher, enabling the engine to dynamically select and execute the optimal kernel for every mpGEMM task at runtime with negligible overhead. For Arbitrary-Precision Quantized Models (e.g., W4A8), ADAngel natively accelerates the underlying mpGEMM operations, delivering maximum performance.

In summary, our main contributions are as follows:

(1) We are the first to perform a systematic analysis and characterization of the computational heterogeneity in APQ LLM inference, revealing the fundamental sub-optimality of static approaches.

(2) We propose the DPR (Decomposition-Partial Product-Reconstruction) computation model, a unified theoretical abstraction that establishes bit-level decomposition as a first principle to systematically generate a series of computation strategies for effective mpGEMM acceleration.

(3) We design and implement ADAngel, a methodology for constructing a workload-adaptive computation core for any given LLM through exhaustive offline profiling on several computation strategies derived by the DPR model.

(4) We conduct an extensive evaluation demonstrating that the ADAngel-specialized engine consistently outperforms state-of-the-art frameworks on both edge and data-center GPUs, with particularly large gains in long-prefill cases.

2 Background

2.1 LLM Quantization

The rapid advancement in LLMs (Figure 2, left) enhances model accuracy while substantially increasing computing and storage requirements. For example, deploying DeepSeek-R1-70B with FP16 precision consumes over 140GB of memory, requiring at least two modern high-performance NVIDIA H100 [4] GPUs with 80GB capacity. This poses significant challenges for deploying LLMs on low-cost edge devices with limited computing and memory/storage resources. Post-training quantization (PTQ) [15, 31, 33, 36] reduces memory/storage and computing costs by converting weights or activations from high-precision (FP32/FP16) to low-precision (INT8/INT4). It has become a mainstream approach for edge-side LLM deployment. Although quantizing model weights or activations enables LLM inference on edge devices, low-bit-width precision reduces model accuracy.

Existing studies [27, 37, 42] demonstrate that LLM weights exhibit high redundancy, making them amenable to low-bit-width quantization. In contrast, quantizing activations is more challenging, as low-bit-width activation representation significantly degrades LLM's quality. Arbitrary-precision quantization (APQ) [3, 14, 26] preserves LLM quality while minimizing resource demands by quantizing weights to low-bit-width representations and maintaining high-precision formats for activations, as shown in Figure 2 (Middle). In this paper, APQ refers to arbitrary weight-activation bit-width combinations, such as W4A4, W4A8, and W3A8. This usage differs from recent any-precision LLM approaches that support multiple model sizes or precision configurations from a shared representation [23]. However, APQ introduces asymmetric bit-widths between weights and activations. Current edge devices generally lack native or efficient support for asymmetric-bit-width GEMM/GEMV, requiring padding [11, 17], LUT [18, 22, 32], or bit-disaggregation [39].

Existing studies [27, 37, 42] demonstrate that LLM weights exhibit high redundancy, making them amenable to low-bit-width quantization. In contrast, quantizing activations is more challenging, as low-bit-width activation representation significantly degrades LLM's quality. In this paper, APQ refers to arbitrary-precision quantization, where weights and activations may use arbitrary and potentially asymmetric bit-widths within a deployed model, such as W4A8. This usage focuses on the execution of mixed-bit-width GEMM/GEMV operators. It differs from recent any-precision LLM approaches, which aim to support the deployment of multiple models or multiple bit-width configurations from a shared representation [23]. APQ preserves LLM quality while reducing resource demands by quantizing weights to low-bit-width representations and keeping activations at relatively higher precision, as shown in Figure 2 (Middle).

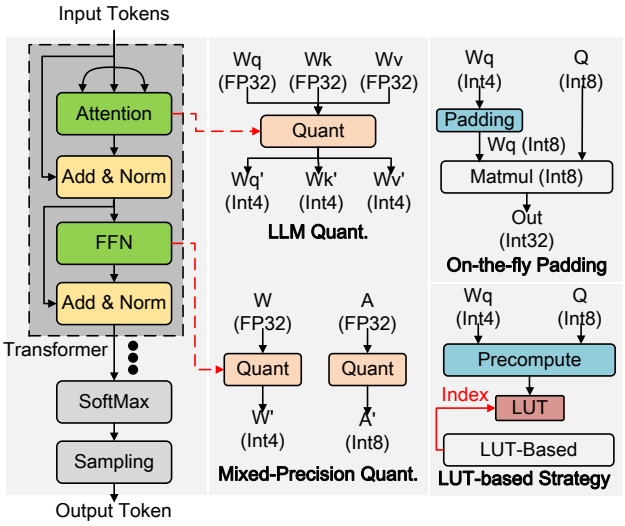

Figure 2: (1) Left: Decoder-only LLM architecture; (2) Middle: LLM quantization and Arbitrary-Precision Quantization (APQ); (3) Right: Padding and the LUT-based strategy in APQ LLM inference.

2.2 Padding and LUT in APQ LLM Inference

As shown in Figure 2 (Right), existing solutions [11, 17] widely adopt padding to implement APQ LLM inference on edge devices. It transforms low-bit-width weights to match activation bit-widths, then performs computation using conventional GEMM/GEMV operators. Although padding enables APQ LLM inference on edge devices, it introduces additional overheads: (1) the weight padding operation incurs additional cost: If it is performed online, it introduces runtime bit manipulation overhead that reduces the achievable effective compute throughput; If it is performed offline and the padded weights are stored in global memory, it leads to extra storage and memory access overhead; (2) it still executes computation on expanded high-bit-width weight representations rather than the original compact low-bit-width weights, thereby increasing computational cost.

Some researchers [18, 22, 32] propose the LUT-based strategy for direct asymmetric-bit-width GEMM/GEMV execution to avoid padding. Specifically, it precomputes the products of high-bit-width activations and multiple low-bit-width weights, and stores them in the LUT. Results are retrieved directly from the LUT instead of performing actual computations during LLM inference. However, constructing a LUT for each weight-activation bit-width combination introduces a significant memory footprint. Therefore, this paper focuses on padding and bit-disaggregation as the main software mapping strategies for GEMM/GEMV in APQ.

2.3 Bit-Disaggregation GEMM and GEMV

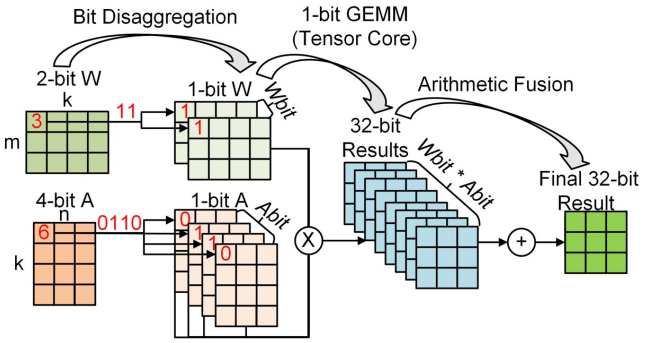

Figure 3: W2A4 GEMM bit-disaggregation workflow.

Bit-disaggregation is a mathematical approach for directly executing GEMM and GEMV with asymmetric bit-widths. As shown in Figure 3, it first disaggregates the weight matrix $[K,N]$ and the activation matrix $[M,K]$ into $WBit \times [K,N]$ and $ABit \times [M,K]$ 1-bit matrices (bitplanes) via bit-level disaggregation, where $WBit$ and $ABit$ represent the bit-width of weights and activations. Next, pairwise multiplications are performed between the 1-bit weight and activation matrices, yielding $WBit \times ABit$ result matrices. Finally, the $WBit \times ABit$ result matrices are combined into the final output. Equation 1 formally captures the bit-disaggregation process described above. It increases the number of GEMM and GEMV operations by a factor of $WBit \times ABit$, while also introducing additional combination overhead. Zeng et al. [39] leverage 1-bit Tensor Cores in NVIDIA Ampere architecture GPUs to accelerate 1-bit GEMM and GEMV, thereby optimizing the inference speed of APQ LLMs that adopt the bit-disaggregation strategy.

$$Result = \sum (2^0 W^{WBit-1} + ... + 2^{WBit-1} W^0) \times (2^0 A^{ABit-1} + ... + 2^{ABit-1} A^0) \quad (1)$$

3 Motivation

Although padding and bit-disaggregation enable APQ LLM inference on existing edge devices, our measurements show that using either alone fails to effectively capture the computational heterogeneity in LLM inference, which leads to suboptimal inference performance. To better understand this, we next analyze this heterogeneity along four dimensions.

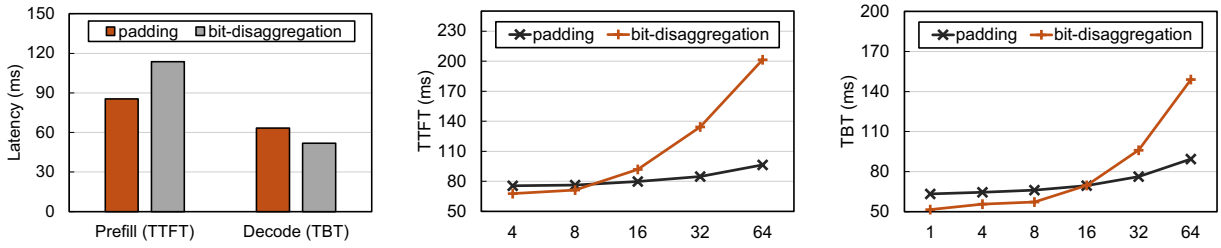
We deploy Llama-2-7B on the edge GPU of NVIDIA Jetson AGX Orin [20] using FasterTransformer [6]. The model adopts W4A8 quantization (4-bit weights and 8-bit activations). To support W4A8, FasterTransformer's GEMM and GEMV operators are reimplemented using padding and bit-disaggregation. In particular, to avoid the runtime overhead of on-the-fly weight format conversion, padded weights are precomputed and stored in global memory.

Computational Heterogeneity Between Prefill And Decode. Figure 4a presents the prefill and decode latency of the model when using padding and bit-disaggregation approaches, under the following configuration: prefill length = 32, generated sentence length = 10, and batch size = 1. Prefill latency is measured as Time To First Token (TTFT), while decode latency is recorded as Time Between Tokens (TBT).

The results show that TTFT with the padding method achieves lower TTFT than bit-disaggregation during prefill. In contrast, the decode TBT with bit-disaggregation is better than padding. The underlying reason is that prefill is typically more compute-intensive, where computation tends to dominate the performance. Bit-disaggregation significantly increases computational overhead, leading to poor performance. In contrast, decode corresponds to an I/O-intensive regime, where performance is primarily limited by memory traffic. In this case, bit-disaggregation achieves better performance mainly because it preserves a compact low-bit-width weight representation and reduces effective memory traffic. **Observation 1: Using only padding or bit-disaggregation fails to address the computational heterogeneity between prefill and decode, leading to suboptimal APQ LLM inference performance.**

Intra-Prefill Computational Heterogeneity. We increase the prefill length from 4 to 64 and measure the TTFT for Llama-2-7B's prefill. As shown in Figure 4b, the TTFT exhibits a monotonic increase with growing prefill lengths for both padding and bit-disaggregation approaches. We observe a crossover at a prefill length of 8: bit-disaggregation achieves a lower TTFT for short lengths (≤ 8), while padding demonstrates superior efficiency beyond this threshold. This crossover reflects the same compute-memory tradeoff observed between prefill and decode, but now within the prefill phase itself. For short prefills, the workload remains small, so the overhead introduced by loading expanded weights cannot be sufficiently amortized, making bit-disaggregation more favorable. As the prefill length increases, the GEMM becomes increasingly compute-intensive and the extra computation overhead of bit-disaggregation becomes its bottleneck. In this regime, padding achieves better TTFT because it incurs lower runtime computational overhead. Although the crossover point appears at prefill length = 8 in our experiments, it is not universal and can vary across model architectures, quantization bit-widths, and batch sizes. **Observation 2: Relying solely on padding or bit-disaggregation individually cannot fully account for the computational heterogeneity within prefill in APQ LLM inference.**

Intra-Decode Computational Heterogeneity. Next, we investigate the computational heterogeneity within decode. Figure 4c presents the TBT of Llama-2-7B decode with padding and bit-disaggregation for batch sizes 1∼64. The performance crossover point between padding and bit-disaggregation occurs at batch size = 16 in our experiments, although this point is not universal and can vary across model architectures

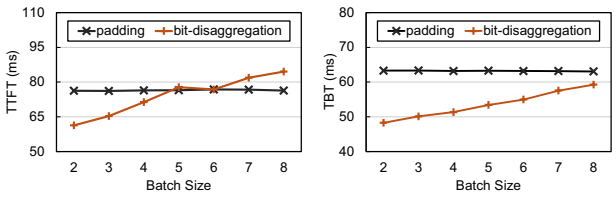


(a) Prefill and Decode (b) Prompt Length (c) Decode Batch Size

Figure 4: The computational heterogeneity between prefill and decode, intra-prefill computational heterogeneity, and intra-decode computational heterogeneity.

and quantization bit-widths. The underlying reason is the workload heterogeneity within decode. As the batch size increases, the decode workload gradually shifts from a memory-sensitive regime toward a more compute-intensive regime. For small batch sizes, performance is primarily limited by memory traffic, making bit-disaggregation more favorable because it preserves a compact low-bit-width weight representation and reduces memory access overhead. As the batch size increases, the computational overhead introduced by bit-disaggregation becomes increasingly significant, and padding achieves lower TBT due to its lower runtime processing overhead. **Observation 3: Using only padding or bit-disaggregation cannot fully adapt to the workload heterogeneity within decode in APQ LLM inference.**

Computational Heterogeneity in Quantization Bit-Width. Finally, with the activation bit-width fixed at 8 bits and the weight bit-width varying from 2 to 8 bits, we evaluate the prefill TTFT and decode TBT at prefill length = 32, generated sentence length = 10, and batch size = 1 for both padding and bit-disaggregation methods. Figure 5 demonstrates that TTFT and TBT remain stable with the padding method as the weight bit-width increases. This stability occurs because the padding method follows a similar execution pattern across different weight bit-widths in these settings. In contrast, bit-disaggregation progressively introduces more accesses to the weights and 1-bit matrix computations as weight bit-width increases, resulting in increased TTFT and TBT. **Observation 4: Neither padding nor bit-disaggregation alone can capture the computational heterogeneity introduced by the quantization bit-width in APQ LLMs.**



(a) Prefill (b) Decode

Figure 5: **Computational heterogeneity in quantization bit-width**. The activations are fixed at 8-bit quantization, while the weights vary from 2-bit to 8-bit. The x-axis represents the weight quantization bit-width.

4 Design

4.1 Overall Architecture

Our preceding analysis reveals that workload-unaware computation paradigms are fundamentally suboptimal for APQ LLM inference, failing to address the widespread computational heterogeneity of mpGEMM in LLM inference. To achieve high-performance inference, therefore, a new workload-adaptive paradigm for mpGEMM is needed, whose adaptivity is predicated on two core principles: (1) **Optionality**, the availability of a diverse portfolio of kernels that leverage hardware resources differently, and (2) **Optimality**, the capability to select the optimal kernel for each specific task.

To realize this paradigm, we propose **ADAngel**, a workload-aware framework, which is designed to accelerate APQ LLM inference, as shown in Figure 6. The theoretical foundation of ADAngel is the ❶ **DPR** (Decomposition–Partial Product–Reconstruction) computation model, which provides a unified form to both express and implement a diverse spectrum of mixed-precision GEMM strategies. Guided by the DPR model and hardware characteristics, we first define a set of three canonical strategies (Padding, Split, Bitwise) and perform deep, manual optimizations on their kernel implementations to form the high-performance ❷ **Computation Strategy Set**. Subsequently, the ❸ **Strategy Dispatcher** exhaustively evaluates these strategies offline on every potential workload within any given target LLM. This yields an oracle policy map which maps workloads to strategies, enabling the Strategy Dispatcher to perform zero-overhead, adaptive strategy selection at runtime when the LLM inference engine needs to execute mpGEMM/mpGEMV.

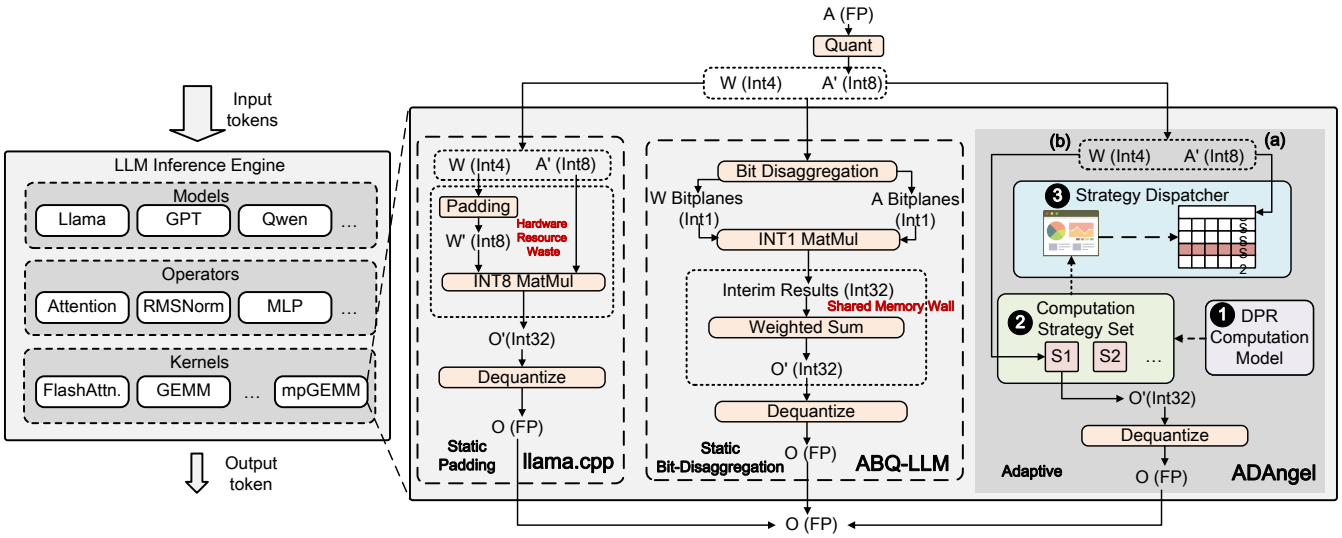


Figure 6: **The Overview of ADAngel**. In contrast to traditional static approaches, namely llama.cpp (which incurs hardware resource waste due to weight upcasting) and ABQ-LLM (which hits a shared memory wall during prefill due to bit-disaggregation, detailed in Section 6.2), ADAngel is built upon the ❶ DPR Computation Model. By analyzing hardware architecture, ADAngel constructs a ❷ Computation Strategy Set based on DPR constructs and employs a ❸ Strategy Dispatcher to map each mpGEMM task to the optimal computation strategy during APQ LLM inference. As indicated by the dashed paths (offline stage), ADAngel designs the strategy set under DPR guidance and evaluates these strategies on the target LLM to generate a dispatch table. As indicated by the solid arrows (runtime stage), ADAngel (a) retrieves the appropriate strategy based on the problem size and bit-width of the mpGEMM task, and (b) invokes the corresponding kernel to complete the computation.

4.2 DPR Framework

The performance upper bound of an adaptive system is fundamentally determined by the quality and diversity of its available strategies. Based on this principle, our framework requires a rich portfolio of high-performance computation strategies to be effective. The **DPR** (Decomposition–Partial Product–Reconstruction) computation model serves as the theoretical cornerstone for this task. That is, the strategies in our Computation Strategy Set are designed under the guidance of the DPR model, and the computation kernels dispatched and executed at runtime are concrete instantiations of it. DPR formally deconstructs any mixed-precision matrix multiplication into three logical stages: the framework first decomposes the input matrices into multiple components based on their bit-level representation; next, it performs matrix multiplication on these components to obtain a series of partial products; finally, it accurately reconstructs the final result via a weighted summation.

We now formally define this three-stage process. Given an activation matrix $X \in \mathbb{Z}^{M\times K}$ with bit-width $XBITS$ and a weight matrix $W \in \mathbb{Z}^{K\times N}$ with bit-width $WBITS$, our DPR framework computes the mpGEMM result $Y = XW \in \mathbb{Z}^{M\times N}$ as follows:

Decomposition. Its goal is to transform matrices X and W to corresponding physical tensors $\{X_{i,phys}\}$ and $\{W_{j,phys}\}$, which are uniformly typed and ready for computation by hardware accelerators like Tensor Cores in the next stage. It encapsulates two sub-steps: logical bit-partitioning and physical representation mapping.

We begin with defining an operation **logical bit-partition**: For a matrix A with $ABITS$ bit-width, based on a given bit-partitioning scheme:

$$P_A = (q_1, q_2, \ldots, q_m), \text{where} \sum_{i=1}^{m} q_i = ABITS, \tag{2}$$

the value of any element x in A is precisely expressed as a weighted sum of the corresponding elements x_i:

$$x = \sum_{i=1}^{m} x_i \cdot 2^{\text{shift}(i)}, \text{ where shift}(i) = \sum_{j=1}^{i-1} q_j. \tag{3}$$

Thus matrix A can be precisely expressed as a weighted sum of matrices A_i:

$$A = \sum_{i=1}^{m} A_i \cdot 2^{\text{shift}(i)}, \text{ where shift}(i) = \sum_{j=1}^{i-1} q_j, \tag{4}$$

then $\{A_i\}$ is the **logical bit-partition** of A based on the given bit-partitioning scheme P_A.

In the logical bit-partitioning step, respectively, $P_X = (q_{X1}, q_{X2}, \ldots, q_{Xm})$ and $P_W = (q_{W1}, q_{W2}, \ldots, q_{Wn})$ are applied to X and W, generating their logical partitions $\{X_s\}_{s=1}^{m}$ and

$\{W_t\}_{t=1}^{n}$. By applying different bit-partitioning schemes, this step provides a high degree of flexibility, allowing us to conceptually decompose matrices into logical components of arbitrary bit-widths. However, the underlying hardware acceleration units, particularly Tensor Cores, are not general-purpose multipliers. They are highly specialized computation engines, optimized for a fixed set of symmetric input precision pairs. This creates a mismatch between the flexibility of the logical decomposition at the software level and the rigid constraints of the hardware execution units. For instance, a 4-bit logical component and an 8-bit logical component cannot be multiplied directly by any single, native Tensor Core instruction.

To bridge this gap, the Physical Representation Mapping stage is an essential step. Its core mission is to unify all potentially heterogeneous logical matrices onto a single, homogeneous computation data type that is natively supported by the hardware. This is achieved through our Hardware-Aware Promotion Principle. The process first determines the maximum bit-width across all logical partitions, $b_{\max}$. It then promotes this value to the smallest, natively supported hardware precision that can accommodate it. Let H denote the set of natively supported hardware precisions on the target platform (e.g., $H = \{1,4,8\}$ on our target platform), then the final target bit-width can be expressed as

$$b_{\text{target}} = \min\{h \in H | h \geq \max\{q_{X1}, \ldots, q_{Xm}, q_{W1}, \ldots, q_{Wn}\}\}. \tag{5}$$

Subsequently, every logical matrix A_i (representing any W_s or X_t) is physically realized into a tensor $A_{i,phys}$ by promoting it to this target bit-width. This ensures that all tensors entering the computation stage are of a uniform, hardware-supported precision.

The resulting physical tensors from the decomposition stage are stored contiguously in memory, which maximizes bandwidth through coalesced accesses and allows us to fuse multiple partial product computations into a single kernel launch (e.g., computing $X_1 \times W_1$ and $X_2 \times W_1$ simultaneously), significantly reducing dispatch overhead.

Partial Product Computation. The output of the Decomposition stage is a set of hardware-ready physical tensors, $X_{s,phys}\}$ and $\{W_{t,phys}\}$, which all share a uniform bit-width, b_{target}. Therefore, each partial-product computation operates on operands with the same physical bit-width, allowing it to directly invoke symmetric-precision matrix-computation units, such as INT1, INT4, or INT8 Tensor Cores. The goal of the Partial Product Computation stage is to perform the actual matrix multiplication on these prepared tensors. Specifically, this stage executes $m \times n$ multiplications on the pairs of physical tensors to yield a series of partial product matrices, Y_{st}:

$$Y_{st} = \text{ComputeOp} < b_{target} > (X_{s,phys}, W_{t,phys}). \tag{6}$$

This stage's computational homogeneity ensures all operations are mapped to a single type of native hardware instruction (e.g., IMMA or BMMA) on the Tensor Cores, which facilitates mapping to a uniform hardware path.

It generates $m \times n$ partial product matrices, each of dimension $M \times N$. Crucially, the elements of these matrices are 32-bit integers (int32). This high precision is dictated by the architecture of the Tensor Cores, and exposes a fundamental performance trade-off: a more fine-grained decomposition (larger m or n) results in a proportionally larger memory footprint for these int32 intermediate results. This increased pressure on on-chip resources (especially shared memory) can constrain the achievable parallelism and occupancy of the GPU, a cost that can completely offset the inherent latency and throughput advantages of lower-precision Tensor Cores.

Reconstruction. In the final stage, our objective is to compute the result matrix Y. With the distributive property of multiplication, the product $Y = XW$ can be expanded from their logical decompositions into a weighted sum of partial products:

$$\begin{aligned} Y = XW &= (\sum_{s=1}^{m} X_s \cdot 2^{\text{shift}(s)})(\sum_{t=1}^{n} W_t \cdot 2^{\text{shift}(t)}) \\ &= \sum_{s=1}^{m}\sum_{t=1}^{n} X_s W_t \cdot 2^{\text{shift}(t)+\text{shift}(s)}. \end{aligned} \tag{7}$$

In summary, the DPR computation model provides a formal and principled foundation for mixed-precision GEMM. It establishes a clear methodology to deconstruct a complex, heterogeneous computation into a series of simple, hardware-aligned homogeneous operations.

4.3 Computation Strategy Set

The purpose of the Computation Strategy Set is to provide ADAngel with a broad and high-performance portfolio of computation strategies. Although the representational capacity of our DPR model provides a vast theoretical design space for this set, a significant portion of these strategies are practically inefficient. This inefficiency stems from the redundant promotion overhead introduced by our Hardware-Aware Promotion Principle when a strategy's logical bit-width does not align with the discrete precisions natively supported by the GPU's Tensor Cores.

To make this concrete, consider a W4A8 matrix multiplication where the activation partition is fixed at $P_A = (8)$. A weight decomposition of $P_W = (2,2)$ is provably suboptimal compared to the trivial $P_W = (4)$ scheme, because the $(2,2)$ scheme decomposes the work into two separate W8A8 GEMM operations, effectively doubling the computational workload.

Therefore, our method is to prune the design space by minimizing the promotion overhead, which is achieved by aligning the decomposed bit-widths with the native Tensor Core precisions. Based on this principle, we designed three families of computation strategies.

Throughput-Oriented: Padding. This strategy's philosophy is to achieve the highest possible computational throughput. It is formally expressed in our DPR model by a trivial partitioning scheme (i.e., $P_A = (ABITS)$) which maps the computation to the lowest-precision native hardware unit capable of accommodating the largest operand (e.g., INT8 Tensor Cores). Since it corresponds to a trivial partitioning scheme, the computation is not decomposed into multiple logical components, and no explicit reconstruction of partial products is required at runtime, resulting in lower overhead and higher effective throughput closer to the hardware peak.

Memory-Oriented: Bitwise. This strategy prioritizes memory efficiency. It corresponds to the finest-grained decomposition scheme in our DPR model (i.e., $P = (1,1,\ldots,1)$), replacing conventional arithmetic with a large number of simple bit-logic operations. This avoids the expansion overhead of padding, but introduces massive additional partial products and reconstruction overhead. Since it does not incur the extra weight memory traffic caused by padded operand representations, it is often more efficient in memory-bound scenarios.

Balanced: Split. On hardware platforms that provide native INT4 acceleration, there exists an intermediate alternative between Padding and Bitwise. Instead of using trivial partitioning or 1-bit decomposition, the weights and activations can be partitioned into a small number of hardware-aligned chunks that are as large as possible while not exceeding 4 bits (e.g., $P_W = (x), P_A = (4,4)$ for WxA8, where $x \leq 4$).

This strategy achieves a middle ground: compared to Padding, while both of them increase memory traffic by widening operand representations, Split incurs less overhead by using narrower widths (e.g., 4-bit vs. 8-bit in W2A8); compared to Bitwise, it reduces the number of partial products, and lowers both the reconstruction overhead and the intermediate-result memory footprint. The advantage of Split over Bitwise primarily stems from the reduced intermediate memory footprint. In Bitwise, a W_bA8 GEMM is decomposed into $8W_b$ bit-plane pairs, so the intermediate int32 storage for an output tile of size $T_M \times T_N$ scales as $4 \cdot (8W_b) \cdot T_M T_N$ bytes. In contrast, Split uses a much coarser partitioning (e.g., decomposing the activation into two 4-bit components), resulting in only $4 \cdot 2 \cdot T_M T_N$ bytes. Thus, Split reduces the intermediate-result footprint by a factor of $4W_b$; for W4A8, this corresponds to a 16× reduction, from 32 int32 partial products to 2. Since these intermediate int32 results typically need to be buffered (e.g., in shared memory) before the Reconstruction stage, this reduction directly lowers shared-memory pressure, improves resident CTA count and effective memory bandwidth, and thereby enables better performance than Bitwise under middle-M workloads.

To make the application of our three strategies concrete, we now instantiate them for a W4A8 mixed-precision task. The selection of the bit-partitioning scheme for each archetype, and the resulting hardware computation path dictated by our DPR model, are summarized in Figure 7.

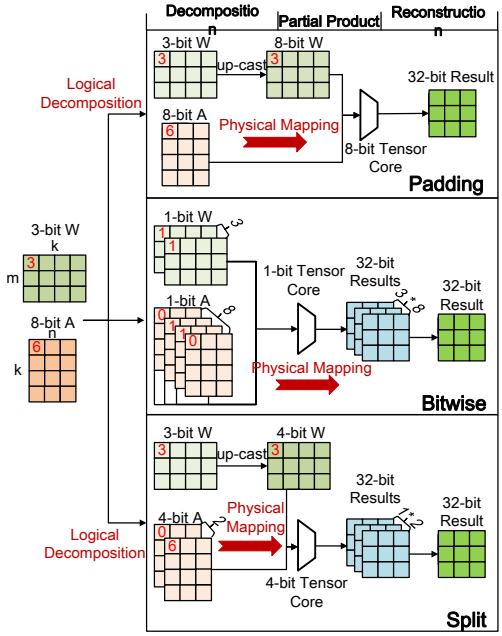

Figure 7: **Visualizing the DPR Framework**. For a canonical W4A8 task, how different Logical Decompositions and Physical Mappings, guided by our DPR model, result in three distinct hardware-aligned computation strategies.

For the above three strategy prototypes, high performance in practice also depends on efficient kernel-level implementations. We highly optimize all kernels in our strategy set, as detailed in Section 5.

In summary, guided by the theoretical principles of our DPR computation model, we have designed and implemented three distinct, highly optimized computation strategies that constitute our Computation Strategy Set. This portfolio of kernels provides the rich and diverse action space that is the essential foundation for ADAngel's adaptivity.

4.4 Strategy Dispatcher

The final component of the ADAngel framework is responsible for fulfilling the Optimality requirement: selecting the best-performing kernel from our Strategy Set for any given task. Our approach is grounded in a key insight: for a specific LLM, the variety of its constituent GEMM operations is highly constrained. This observation makes an exhaustive offline profiling approach not only feasible but also optimal. Therefore, our design consists of two phases: an offline policy construction phase that performs the analysis to generate an oracle policy map, and a lightweight online table-driven dispatch phase that executes mpGEMM tasks with the best strategy selected by the policy map.

We analyze the GEMM workload space within a target LLM. While the M dimension of a GEMM is dynamic, the N and K dimensions are static, determined by the model's archi-

tecture (e.g., hidden dimension). Consequently, the number of unique GEMM "types" (defined by static N and K dimensions) is small and finite. For instance, our analysis shows that an entire Llama-3-8B model inference involves only about 4 unique types of GEMM operations.

This bounded problem space makes an exhaustive, offline profiling approach conceivable, but its practical feasibility depends on the storage cost of the resulting lookup table. We quantify this cost as follows: storing function pointers for 4 unique GEMM types across a comprehensive range of $M = 1 \sim 8192$ (requiring 8 bytes per pointer) results in a total size of approximately 256 KB. This trivial memory footprint confirms that our empirical performance oracle approach is not only theoretically sound but also eminently practical.

The oracle policy map is constructed through an exhaustive, empirical profiling process executed once per target LLM and hardware platform. To achieve this, we first define the complete workload space by performing a static analysis of the target model's architecture to identify its finite set of unique GEMM "types", and then sweeping across a comprehensive range of the dynamic M dimension. For every point in this space, we benchmark each kernel from our Computation Strategy Set, using high-precision timers after a sufficient warm-up period to ensure accuracy. The kernel with the lowest average latency for each specific task is recorded, creating the oracle policy map: a simple key-value structure that maps a workload to a function pointer for its empirically proven optimal kernel.

The runtime behavior of the Strategy Dispatcher is simple and efficient. Upon receiving a GEMM task, it performs a direct lookup in the pre-computed oracle policy map using the task's shape as a key. This retrieves and immediately invokes a pointer to the empirically proven optimal kernel.

This dispatch mechanism, being a simple table lookup, is what provides ADAngel's two decisive advantages: guaranteed optimality (relative to our offline analysis) and negligible runtime overhead.

5 Implementation

We implemented the ADAngel framework in C++ and CUDA 12.6 with over 15k LOC. Our implementation first involved engineering the Computation Strategy Set: a portfolio of kernels where Padding and Split are built upon CUTLASS [8], and Bitwise is a custom BMMA-based implementation. With this optimized portfolio established, we then constructed the Strategy Dispatcher's policy through an automated, exhaustive offline profiling process. Finally, we integrated these components as an mpGEMM backend into FasterTransformer for end-to-end evaluation.

High-Performance Kernel Engineering. To ensure our strategy portfolio is highly competitive, we engineered each kernel family for maximum performance. The Padding and Split strategies were built on top of the CUTLASS 3.1.0 library. In our implementation, we restrict Split to weight bit-widths ≤ 4, since it no longer reduces weight memory traffic relative to Padding when the weight bit-width exceeds 4. In Split, weights are offline promoted to 4-bit and stored in a packed layout. At runtime, the 8-bit activation is decomposed into two 4-bit components and packed into a stacked $2M \times K$ matrix. Then, it is multiplied with the offline-packed weights via a single $(2M, N, K)$ CUTLASS GEMM, yielding a stacked $(2M, N)$ int32 intermediate. A lightweight merge kernel then completes the Reconstruction stage and dequantization. In contrast, the Bitwise strategy was implemented as a custom CUDA kernel based on BMMA instructions. We inherited the highly optimized weight layout from ABQ-LLM [39] to maximize memory coalescing, and applied selective kernel fusion (e.g., fusing the activation quantization and Decomposition stage) to reduce global memory traffic.

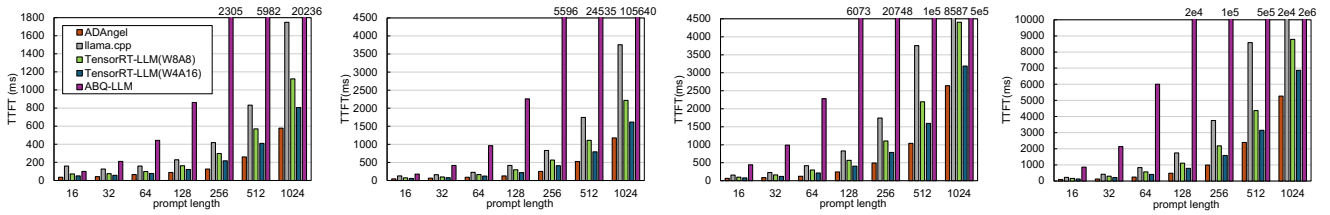
Offline Policy Construction. The Strategy Dispatcher's policy was constructed by an automated Python script that orchestrates the entire profiling workflow. It benchmarked every kernel in our strategy set across a comprehensive range of sequence lengths in the target LLM, using CUDA events for precise latency measurement. By selecting the lowest-latency kernel for each potential workload, this process generated the Oracle Policy Map. In FasterTransformer, we observed that Llama-3-8B involves 4 distinct (N, K) combinations. To construct the dispatch table on the NVIDIA Jetson AGX Orin for W4A8-quantized Llama-3-8B, we profiled these (N, K) combinations over $M \in [1, 8192]$ to cover the potential workloads. This incurs a one-time profiling cost of about 5.7 hours and a peak memory footprint of about 1.7 GB. This time cost can be further reduced by pruning the search space, since Figure 1 shows that Padding exhibits a clear advantage in the large-M regime. In addition, previously profiled entries can be reused across the same models or layers that share the same hardware platform.

End-to-End Framework Integration. To evaluate real-world performance, we integrated our ADAngel computation core into NVIDIA's FasterTransformer. We further implemented support for the widely used model Llama-3-8B within our FasterTransformer-based testbed. The integration is modular, requiring only redirecting the framework's standard mpGEMM calls to our ADAngel dispatcher.

6 Evaluation

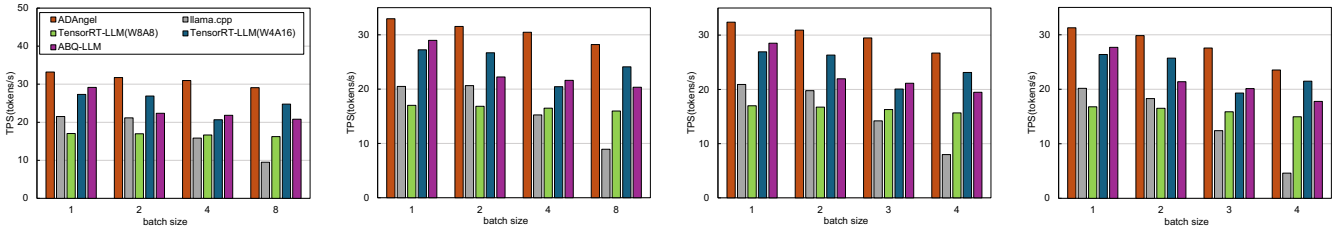
6.1 Experiment Setup

Platform. Experiments were conducted on an NVIDIA Jetson AGX Orin Development Kit 64GB, featuring an Ampere-architecture GPU (sm_87) and 64GB unified memory. We used the NVIDIA JetPack 6.1 [7] software stack (CUDA 12.6). The power mode of Orin is MODE_50W. Our entire testbed is built upon FasterTransformer, and we implemented W2A8,



(a) Llama-3-8B, batch size = 1 (b) Llama-3-8B, batch size = 2 (c) Llama-3-8B, batch size = 4 (d) Llama-3-8B, batch size = 8

Figure 8: **Prefill Stage Performance Comparison**. ADAngel significantly reduces the TTFT across various input sequence lengths, demonstrating its superiority in compute-bound scenarios.



(a) Llama-3-8B, pl = 128 (b) Llama-3-8B, pl = 256 (c) Llama-3-8B, pl = 512 (d) Llama-3-8B, pl = 1024

Figure 9: **Decode Stage Performance Comparison**. ADAngel achieves substantially higher TPS during the auto-regressive generation phase, showcasing its efficiency in memory-bound, low-latency operations.

W3A8, W4A8 and W5A8 versions of Llama-3 within this testbed. To validate the generality of the ADAngel methodology, we applied ADAngel to a data-center-class NVIDIA A100 GPU [5], generating a new, A100-specific engine.

Models. We used a representative modern LLM: Llama-3-8B.

Baselines and Our System: (1) ABQ-LLM [39], serves as a representative framework for bit-disaggregation-based mpGEMM. (2) llama.cpp [17]. This serves as an optimized, end-to-end baseline utilizing online padding mpGEMM routines. (3) TensorRT-LLM. As a recognized high-performance inference framework, TensorRT-LLM serves as a strong baseline. Since the current version for the Orin platform lacks native W4A8 support, we employ W8A8 (SmoothQuant) and W4A16 (AWQ) quantization methods for a comprehensive comparison. (4) QServe. Its W4A8KV4 configuration is a powerful solution for cloud inference but is currently unsupported on Orin. To address this, we compare ADAngel with QServe on an A100 80GB GPU to evaluate the scalability of our approach. (5) ADAngel. This is our main proposal. All mpGEMM operations in our testbed are handled by our ADAngel-specialized computation core.

Evaluation Metrics: We report (1) Time-To-First-Token (TTFT) to measure the latency of the Prefill stage, and (2) Tokens Per Second (TPS) per request to measure the throughput of the Decode stage. All presented results are the average of multiple runs following a warm-up period to ensure stable and accurate measurements.

6.2 End-to-end Evaluation

Prefill. Figure 8 illustrates the end-to-end prefill latency (TTFT) across varying prompt lengths from 16 to 1024. ADAngel consistently establishes superior performance, achieving a peak speedup of 448.69× over ABQ-LLM and a speedup ranging from 1.17× to 2.38× over TensorRT-LLM.

Compared to TensorRT-LLM configurations, ADAngel surpasses the W4A16 baseline by leveraging the superior arithmetic throughput of INT8 Tensor Cores over FP16, and exceeds the W8A8 baseline by virtue of a lightweight system architecture that eliminates the significant runtime overheads inherent in the TensorRT-LLM framework.

In the short-prompt regime, the workload remains memory-sensitive. However, the mpGEMM kernel in llama.cpp exposes only limited CTA-level parallelism under its persistent stream-k scheduling, and does not implement an asynchronous global-to-shared-memory pipeline. As a result, memory latency cannot be effectively hidden, making the kernel substantially less efficient in this regime. In contrast, our Bitwise and Split kernels contain asynchronous pipelining to overlap memory accesses with computation, thereby achieving higher efficiency. For instance, at bs = 1 and pl = 32, ADAngel reduces latency by 65.9% compared to llama.cpp (43 ms vs. 126 ms).

As the workload transitions to the compute-bound long-sequence regime, the bit-disaggregation approach (ABQ-LLM) consumes up to 32× more shared memory per thread block compared to padding-based approaches. This bottleneck, identified as the Shared Memory Wall, severely restricts

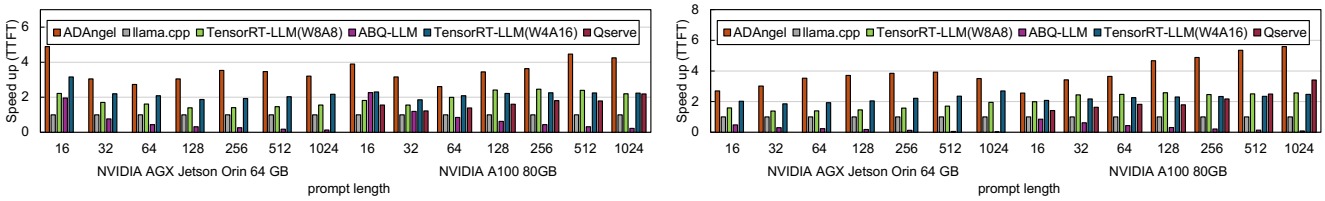
Figure 11: **Cross-precision decode performance on Jetson AGX Orin**. TPS comparison under W2A8, W3A8, and W5A8 across representative prompt lengths.

GPU occupancy due to excessive intermediate accumulation states. Consequently, although ABQ-LLM is the SOTA framework for decoding and short-sequence prefill, it becomes practically unusable in this setting: at bs $= 8$ and pl $= 1024$, its TTFT surges to approximately 39.4 minutes. The root cause of the Shared Memory Wall is induced by the storage of int32 intermediate states. Our profiling reveals that this heavy shared memory consumption saturates the SM resources, restricting the hardware scheduler to launch only 3 thread blocks per SM, with each thread block computing only an 8×48 output tile. Such low occupancy effectively nullifies the massive parallelism advantage of the GPU. In contrast, ADAngel adaptively switches to the appropriate kernel to circumvent this latency explosion, maintaining the latency within seconds (5.27 s) and achieving a substantial 448.69× speedup.

ADAngel performs well across the evaluated representative sequence lengths. Since it covers all potential M values induced by sequence-length variations within the target range, we infer it to handle sequence length oscillations effectively.

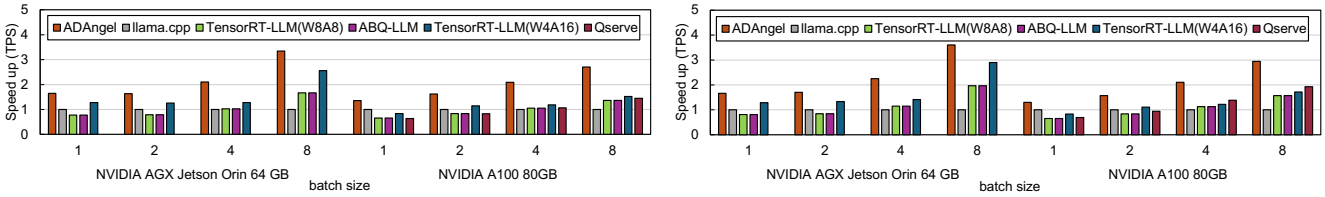
Decode. Figure 9 reports the decode throughput (TPS, tokens per second) across batch sizes from 1 to 8, where ADAngel consistently establishes superior performance. In the critical single-batch regime ($M = 1$), ADAngel achieves a 1.95× speedup over TensorRT-LLM W8A8 by eliminating two fundamental inefficiencies: it bypasses the physical bandwidth redundancy of using 8-bit weights, and simultaneously removes computational redundancy, where static padding kernels constrained by fixed INT8 Tensor Core shapes (typically $M = 16$) leave $\frac{15}{16}$ (93.75%) of compute cycles idle due to zero-padding. As the batch size scales ($M = 2 \sim 8$), while pure bit-disaggregation (ABQ-LLM) also circumvents these redundancies, it does so at the cost of excessive shared memory usage and instruction bloat; in contrast, ADAngel's Split strategy strikes an optimal balance between eliminating re-



(a) Llama-3-8B, batch size = 1

(b) Llama-3-8B, batch size = 4

Figure 12: **Prefill Stage Performance Speedup Across Hardware Platforms**. All results are normalized to the llama.cpp baseline on each respective platform (i.e., llama.cpp = 1.0×). ADAngel consistently outperforms both baselines.



(a) Llama-3-8B, prompt length = 64

(b) Llama-3-8B, prompt length = 512

Figure 13: **Decode Stage Performance Speedup Across Hardware Platforms**. All results are normalized to the llama.cpp baseline on each respective platform. ADAngel maintains its performance leadership on both the Orin and the A100 across all tested batch sizes.

dundancy and minimizing memory cost, thereby avoiding the resource bottlenecks encountered by bitwise methods and ultimately surpassing TensorRT-LLM W8A8 by 1.82× on average.

We further analyze the memory footprint of ADAngel to understand its resource trade-offs. Under a setting of bs = 8, prompt length = 1024, and generating 128 tokens per sequence, ADAngel achieves a peak memory usage of 18.80 GiB (≈ 31.5% of the device memory on Orin). This includes 14.96 GiB for model weights, 1.125 GiB for the KV cache, and 896 MiB for the ADAngel GEMM workspace, with the remaining memory attributed to runtime buffers and framework overhead. We materialize all decomposed weights in global memory to trade additional memory usage for inference performance, particularly in regimes where memory capacity is not the primary bottleneck.

6.3 Cross-Precision Evaluation

To demonstrate the generality of ADAngel across different precision combinations, we extend our evaluation to W2A8, W3A8, and W5A8 configurations. As shown in Figure 10, ADAngel consistently delivers superior prefill performance, outperforming both llama.cpp (by an average of 3.43× in TTFT) and ABQ-LLM (achieving up to 200.00× speedup in TTFT) across all evaluated bit-width combinations, confirming its robust adaptivity.

As weight bit-width increases, pure bit-disaggregation methods (ABQ-LLM) suffer from a severe TTFT expansion during long-sequence prefilling due to the proportional growth in bit-level matrix operations. ADAngel effectively curtails this latency by dynamically dispatching heavy compute workloads to the Padding strategy. Simultaneously, it maintains optimal decode throughput (TPS) by leveraging the Bitwise and Split strategies in memory-bound regimes, achieving a peak speedup of 7.35× over llama.cpp in TPS, representing the best end-to-end performance.

Notably, under the W5A8 configuration, the Split strategy becomes no longer effective. Consequently, ADAngel's TTFT speedup on short prompt lengths is less pronounced than in the W2A8 and W3A8 regimes (e.g., 92 ms in W5A8 vs. 65 ms in W2A8 at pl = 64). Nevertheless, ADAngel still yields significant performance gains over ABQ-LLM by adaptively switching away from Bitwise in large-M regimes.

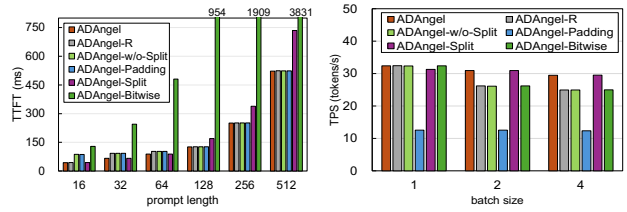
6.4 Generality Evaluation

Although ADAngel is primarily designed for resource-constrained edge scenarios, such as intelligent cockpits and robotics, the increasing adoption of arbitrary-precision quantization in cloud inference highlights its potential contribution to server-grade GPU efficiency. Figures 12 and 13 demonstrate this platform scalability by extending our evaluation to the NVIDIA A100 GPU (80GB). While QServe could not be executed on the Jetson AGX Orin due to a lack of support, we successfully deployed it on the A100 to enable a direct comparison. QServe employs strategies such as progressive group quantization tailored for high-throughput optimization; while

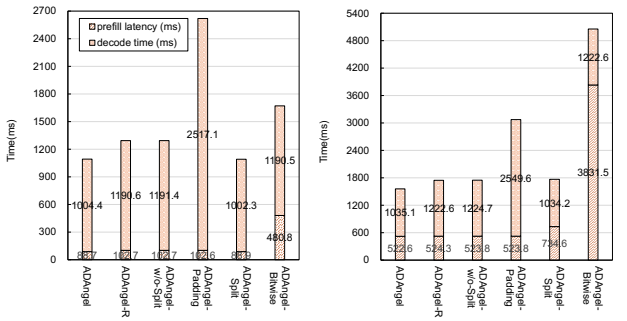
the associated overheads of these strategies are effectively hidden by massive parallelism in large-batch scenarios, they remain exposed in small-batch regimes. In contrast, ADAngel's adaptive approach successfully identifies performance bottlenecks in these specific scenarios and dispatches more suitable computation strategies, achieving speedups of 2.12× in TTFT and 1.72× in TPS relative to QServe. Furthermore, thanks to its hardware-aware adaptive mechanism, ADAngel maintains its performance advantage over TensorRT-LLM, llama.cpp, and ABQ-LLM on the A100 platform.

6.5 Ablation Study

To evaluate the specific contributions of our fine-grained dispatching mechanism and diverse strategy portfolio, we constructed three distinct ablation baselines:



(a) Prefill Stage, bs = 2 (b) Decode Stage, pl = 512



(c) Total Time, bs = 2, pl = 64 (d) Total Time, bs = 2, pl = 512

Figure 14: **Performance breakdown and ablation study of ADAngel compared with different variants**. (a) Time to First Token (TTFT) across varying prompt lengths with batch size bs = 2. Note that ADAngel-Bitwise suffers from high latency in longer sequences. (b) Generation throughput (TPS) across different batch sizes with pl = 512. (c) & (d) Breakdown of total end-to-end latency (prefill latency vs. decode time) for short sequences (pl = 64) and long sequences (pl = 512) at bs = 2, with 32 tokens generated. ADAngel achieves the lowest total latency by balancing prefill and decode efficiency.

(1) ADAngel-*: To disentangle the contribution of our core adaptive methodology from the benefits of low-level kernel optimizations, we evaluated systems using a single static strategy, denoted as ADAngel-*, where (*) represents the specific fixed strategy used (e.g., ADAngel-Padding). This serves as a control group to isolate the gains attributed solely to dynamic scheduling.

(2) ADAngel-R: To assess the necessity of our fine-grained dispatcher, we compared ADAngel against a strong rule-based baseline. This variant employs a static heuristic based solely on M: mapping tasks with $M \in [1,8]$ to Bitwise, $M \in (8,32]$ to Split, and $M > 32$ to Padding.

(3) ADAngel-w/o-Split: To evaluate the criticality of our diverse strategy portfolio, we implemented an ablated variant that excludes the Split strategy from the candidate pool.

As shown in Figure 14, ADAngel maintains a consistent performance advantage across all ablation settings. In extreme regimes where the optimal strategy is static such as long-sequence prefilling, ADAngel correctly identifies the optimal kernel with negligible dispatch overhead (total < 3 ms).

Specifically, ADAngel-R achieves gains over static Padding by selecting Split at pl = 16 during prefill and Bitwise during decode; however, due to ignoring the dimensional heterogeneity introduced by N and K, it underperforms the full ADAngel system in decode scenarios (bs $= 2 \sim 4$), highlighting the critical need for fine-grained kernel selection that considers the full (M,N,K) for every GEMM.

Furthermore, ADAngel-w/o-Split, operating on a restricted strategy set, defaults to Padding behavior in prefill to avoid the latency explosion of the Bitwise strategy, yet sacrifices the significant speedup opportunities at pl $= 16 \sim 64$ provided by Split. Similarly, in the decode phase (bs $= 2 \sim 4$), although it outperforms static Padding, it still lags behind ADAngel due to the absence of the Split strategy.

Since the benefits of ADAngel manifest across different phases, we conducted an end-to-end evaluation simulating typical intelligent cockpit scenarios (instruction parsing and short QA: generating 32 tokens with bs = 2 and pl $= 64/512$). The measured total latency demonstrates that ADAngel outperforms almost all ablation baselines across all scenarios, leveraging its effective fine-grained adaptive mechanism and a rich set of computational strategies.

7 Related Work

Post-Training Quantization (PTQ) is a key technique for compressing LLMs. Seminal methods like GPTQ [12] use second-order information for error compensation, a direction refined by works like HQQ [1]. To handle outliers, AWQ [16] protects salient weights via scaling, while other works preprocess weights via smoothing (MagR [40]) or orthogonal transformations (e.g., QuIP [2]), learn the error with adapters (e.g., QLoRA [10]), or dynamically correct errors at runtime (DecDEC [24]). To further enable integer-only hardware, another line of work performs weight-activation quantization. SmoothQuant [34] pioneered this by migrating activation difficulty to the weights, paving the way for advanced methods that reorder activations (RPTQ [38]) or reshape distributions with learnable transformations (FlatQuant [29]). While

these methods produce accurate quantized models, ADAngel addresses the critical downstream challenge of executing the resulting complex GEMM workloads with maximum, workload-adaptive efficiency.

Kernel-Level Acceleration for mixed-precision GEMM is the domain most directly related to our work. Prior art in this domain has primarily explored two major directions: software adaptation for general-purpose hardware, and the design of direct hardware accelerators. The majority of work focuses on software adaptation, which aims to optimally map these complex operations onto existing hardware. One prominent approach is to develop highly-specialized, static kernels for specific precision pairings, as exemplified by Marlin [13], which provides a state-of-the-art W4A16 GEMM kernel for NVIDIA GPUs. A different software approach, seen in frameworks like llama.cpp [11, 17], performs on-the-fly data transformation; its kernels employ techniques like online padding and native integer vectorization, where low-precision weights are unpacked and converted to a compatible format just-in-time for computation. Alternative software methods reframe the problem entirely, either leveraging bit-logic operations as in ABQ-LLM [39], or replacing multipliers with memory lookups as seen in LUT-based methods like T-MAC [32]. In contrast, the direct hardware design approach proposes new accelerator architectures. For instance, MixPE [41] designs specialized multiplier-less processing units using shift-and-add operations, while BitFusion [28] introduces a methodology to dynamically fuse bit-level processing elements.

8 Conclusion

In this paper, we identified and characterized the fundamental computation heterogeneity in arbitrary-precision LLM inference, revealing the inherent limitations of static, workload-unaware approaches. To address this, we proposed ADAngel, a framework that leverages our DPR computation model and an exhaustive offline analysis to construct a specialized, workload-adaptive computation core for any given LLM. Our extensive evaluation demonstrates that the ADAngel-specialized engine significantly outperforms state-of-the-art inference frameworks, establishing that principled, workload-adaptive specialization is an essential paradigm for unlocking the full performance potential of low-precision hardware in edge LLM inference.

Abstract

GPU architectures have continued to grow in complexity, with recent incarnations introducing increasingly powerful fixed-function units for matrix multiplication and data movement to accompany highly parallel general-purpose cores. To fully leverage these machines, software must use sophisticated schedules that maximally utilize all hardware resources. Since realizing such schedules is complex, both programmers and compilers routinely employ program transformations, such as software pipelining (SWP) and warp specialization (WS), to do so in practice. However, determining how best to use SWP and WS in combination is a challenging problem that is currently handled through a mix of brittle compilation heuristics and fallible human intuition, with little insight into the space of solutions. To remedy this situation, we introduce a novel formulation of SWP and WS as a joint optimization problem that can be solved holistically by off-the-shelf constraint solvers. We reify our approach in Twill, the first system that automatically derives optimal SWP and WS schedules for a large class of iterative programs. Twill is heuristic-free, easily extensible to new GPU architectures, and guaranteed to produce optimal schedules. We show that Twill can rediscover, and thereby prove optimal, the SWP and WS schedules manually developed by experts for Flash Attention on both the NVIDIA Hopper and Blackwell GPU architectures.

1 Introduction

Driven by the insatiable appetite of machine learning for performance, recent GPUs continue to expand the scale and capabilities of fixed-function units for matrix multiplication (GEMM), called Tensor Cores (TCs) on NVIDIA GPUs, and bulk data movement. As these fixed-function units become more powerful, the relative performance ratios of data movement and FLOPS between general-purpose and fixed-function matrix units change dramatically, often by multiplicative factors. Additionally, the interfaces for targeting fixed-function units routinely undergo significant alterations across generations, ranging from modifications to where data can be placed, to how many threads are required to issue operations, and even to the model of asynchronous execution. Consequently, every program targeting TC GPUs may have a different optimal *schedule* for each architecture generation to fully leverage the available general-purpose and fixed-function units [26, 32, 38].

A common solution to this performance portability problem for iterative programs is *software pipelining* (SWP) [6, 7, 24]. SWP permits programmers to write a simple loop to describe a computation, which a compiler can then automatically transform to exploit instruction-level parallelism within and across iterations to derive a schedule that maximizes utilization of all the functional units. Importantly, when compiling the same loop for different machines, the compiler will tailor a custom schedule based on the underlying constraints for each architecture to ensure that the same program runs efficiently in all settings [6]. To realize a particular SWP schedule, the compiler must synthesize a new loop, but the requirements imposed by new TC GPUs, such as the need for many threads to cooperatively issue TC operations [2, 3], preclude the use of a standard sequential loop to express most schedules.

To realize SWP schedules for TC GPUs, both compilers [5, 13, 25, 35–37] and developers [27, 33] have adopted *warp specialization* (WS) [10, 11] as a programming paradigm. Instead of the standard data-parallel style of GPU programming that assigns the same computation to each thread, in WS, subsets of threads called *warps* collaboratively execute different parts of a program, exchanging data through common memories and synchronizing where necessary. While WS is a necessary program transformation for achieving SWP schedules for TC GPUs, it comes with performance trade-offs (e.g., extra communication and synchronization) that obscure how best to deploy it in practice.

Currently, approaches for both SWP and WS on TC GPUs are derived either by human intuition [27, 32, 38] or through compiler heuristics [13, 35, 37]. Moreover, the interaction

*Equal contribution.
†This work was done at NVIDIA.

between SWP and WS is poorly understood, with no technical framework for reasoning about the optimality of combined solutions. The hazards of this situation can be observed in the case of Flash Attention [17, 18], where a year transpired between the release of Hopper and the development of Flash Attention 3 [32], which proposed a custom SWP schedule and WS strategy for Hopper, wasting countless compute cycles on critical inference workloads in the interim.

To rectify this situation, we show that the problems of determining the best SWP schedule and WS strategy can and should be solved simultaneously. We observe that determining a SWP schedule to maximize resource utilization can be reduced to a traditional *modulo scheduling* problem [24,31], that can be solved *optimally* [21,34], yielding the maximum possible throughput for any given machine model. We then explain why WS is a dependent program transformation that must be jointly considered to compute realizable SWP schedules for recent TC GPU architectures. We extend the approach of modulo scheduling to formulate the problem of determining an optimal SWP schedule and WS strategy as a unified constraint satisfaction problem that can be solved holistically by off-the-shelf Satisfiability Modulo Theories (SMT) solvers [9].

To demonstrate our approach, we introduce Twill[1], a system that automatically discovers optimal SWP schedules and WS strategies from high-level, tile-based descriptions of loops with simple control flow. Twill generates optimal schedules for different GPU architectures simply by altering machine-specific constraints corresponding to the easily quantifiable costs of various GPU operations. In contrast to all existing systems that perform SWP and WS of which we are aware [13, 35–37], our implementation is heuristic-free, easily extensible to new GPU architectures, and guaranteed to yield an optimal schedule for a large and important class of iterative programs (i.e., singly-nested loops without additional control flow). The specific contributions of this work are:

- A mapping of the problem of constructing a SWP schedule for TC GPUs to modulo scheduling.
- A constraint-based formulation of SWP and WS as a joint optimization problem.
- Twill, a system that implements our approach and discovers optimal SWP schedules and WS strategies for real programs.

We evaluate Twill by applying it to the Flash Attention algorithm and derive schedules for both the NVIDIA Hopper and Blackwell architectures. We show that Twill can automatically generate schedules that match the proposed algorithms in Flash Attention 3 [32] and Flash Attention 4 [38] from a high-level description of attention. We then implement these schedules and show that the resulting programs can come within 1% of the performance of hand-tuned implementations from libraries like cuDNN and Flash Attention.

[1]Twill is a textile weave that interlaces warp and weft threads in a distinctive diagonal pattern.

2 Background on GPU Architecture

NVIDIA GPUs consist of a number of independent processors called streaming multiprocessors (SMs). Each SM contains independent functional units to support general-purpose floating-point or integer arithmetic, as well as load and store units for memory operations. SMs also contain several kinds of memory including a register file for storing thread-local data, a software-managed scratchpad called *shared memory* that can be accessed by all threads on an SM, and an off-chip *global memory* that can be accessed from any SM.

An SM executes groups of 32 threads called *warps*. Warps execute in a *single instruction, multiple threads* (SIMT) model: every thread in a warp has its own instruction stream, but only a subset of threads that agree on a common instruction to execute will issue in a given cycle, while the remaining threads are masked off and prevented from executing. Each thread executes *in-order*: if a thread's next instruction is blocked on an unresolved dependency or synchronization, it cannot issue any further instructions. Hopper and Blackwell SMs have four *execution contexts* that can host active warps, so at most four warps can issue instructions each cycle. When there are more warps than execution contexts, the SM's *warp scheduler* dynamically selects up to four ready warps from which to issue instructions.

Modern GPUs augment this architecture by incorporating asynchronous accelerators for operating on entire tiles of data. Tensor Cores (TCs) for accelerating the performance of GEMM operations were first introduced in the Volta architecture [4]. More recently, the Hopper architecture [3] introduced the Tensor Memory Accelerator (TMA) unit for asynchronously moving tiles of data between global and shared memory. Since they operate over large tiles, a single TMA or TC instruction may execute for thousands of clock cycles, in stark contrast to most floating-point or integer arithmetic instructions which often only execute for tens of cycles.

The Blackwell architecture [2] is similar to Hopper, but with two important enhancements. The Blackwell TC supports larger tile sizes with higher throughput, and each SM contains a new kind of memory called Tensor Memory where inputs to the TC may be sourced and accumulators stored. Performing general computations on Blackwell TC accumulators requires explicit data movement from the Tensor Memory into the register file. While conceptually straightforward, these modifications induce large perturbations in how programs must be structured for peak performance on Blackwell.

3 Scheduling for Tensor Core GPUs

Software pipelining (SWP) [7] reorders the operations in a sequential program to maximize utilization of the available functional units by exploiting instruction-level parallelism (ILP) within and across loop iterations. We use modulo scheduling [24,31] to compute pipelined SWP schedules, and

Figure 1: Modulo scheduling a simplified Flash Attention expressed in a tile-based manner. The machine costs are for Hopper, where `GEMM` and `EXP` on a tile have roughly the same cost. Modulo scheduling recovers the Flash Attention 3 [32] pipeline.

Section 3.1 introduces standard terminology using the running example shown in Figure 1. The figure shows how to pipeline a simplified version of Flash Attention [18]. The code (Figure 1a), instruction cost information (Figure 1b), and a dependency graph (Figure 1c) go through two intermediate steps (Figures 1d and 1e) before yielding the pipelined code in Figure 1f. In this example, SWP is necessary for maximal TC utilization because the program exposes the latency of the exponential due to the data dependence on the result prior to the second matrix multiplication (Figure 1g). However, as we discuss in Section 3.2, it may not be possible on recent architectures for a single thread of execution to manifest this pipelined schedule. To address this issue, we describe in Section 3.3 how to realize an optimal pipelined schedule by distributing operations across multiple executing threads using WS, and the compilation challenges it induces.

3.1 Modulo Scheduling

Modulo scheduling [21,24,31] is a popular class of algorithms for SWP that transforms a given loop such that it achieves maximum throughput (iterations finishing per unit time) while simultaneously abiding by the data dependencies of the input program and capacities of the underlying machine. In modulo scheduling, the input loop is described as a dependence graph $G = (V, E)$ where V is the set of instructions in the loop and E defines dependencies between the instructions. We assume that G describes a singly-nested loop without control flow. In Twill, each instruction represents a tile-level operation that utilizes resources from the entire SM; dependence graphs of this form can be extracted from standard tile-based programming models (see Section 5).

Associated with each $v \in V$ is a *resource reservation table* (RRT) that indicates the functional unit(s) used during the execution of v. RRT$[v]$ is a 2-D integer array where each column corresponds to a kind of functional unit, each row corresponds to a clock cycle in the execution of v, and the entry gives the number of instances of f that are occupied by v at that clock cycle of its execution. The total number of instances of f on the machine, called the capacity of f, is given by a machine description D. RRTs for each operation in the running example and a machine description D are shown in Figure 1b; both instructions take a single cycle to execute, but they occupy different functional units. For simplicity we assume each functional unit can be scheduled and execute an instruction every cycle; on a real machine, functional units often take longer to execute some instructions than others and have limits on how often they accept new instructions. For TC GPUs that operate on large tiles of data, the abstraction of an RRT is still valid at a coarser granularity of computation, where a "cycle" might represent a coarser granularity of time. We describe how to cope with the problem of determining time granularity in Section 5.2.

Every edge $e \in E$ is a tuple (u, v, d, δ), where u is the source and v is the sink of the data dependence. The *clock cycle delay* $d \geq 0$ indicates that v must be issued at least d cycles after

u is issued. Finally, $\delta \geq 0$ is the *iteration delay*, indicating that the instance of v from loop iteration i must be issued at least d cycles after the instance of u from iteration $i-\delta$. For example, an edge with $\delta = 1$ indicates that the dependence between u and v is *loop carried* to the very next iteration. The dependence graph for the attention example is shown in Figure 1c, where the edges from S and P have $d = 1$ (from the corresponding RRTs) and $\delta = 0$, while the loop-carried dependence on O has $\delta = 1$. To simplify the exposition, we use variable names (which are unique) instead of instruction names in the figures. Together, the RRTs of each instruction (Figure 1b) and the dependence graph G (Figure 1c) are the inputs to modulo scheduling.

When run on a given loop, modulo scheduling finds an *initiation interval* I and *modulo schedule* M, from which the pipelined loop is constructed. I corresponds to the rate at which new loop iterations are issued (or finished), and is thus inversely related to the throughput; $I = 1$ is the minimum possible and means that a new loop iteration is launched every cycle. M maps each instruction to the clock cycle at which it must be issued, counting from the beginning of its iteration (hence the name "modulo"). If $M(v) = k$, then v will be issued at clock cycles $k, I+k, 2I+k, \ldots$ in the pipelined loop. A choice of M and I is valid when it ensures that the pipelined loop satisfies all dependence edges in E and keeps all functional units within capacity.

A valid modulo schedule for the running example is shown in Figure 1d. It is accompanied by the *modular RRT*, a data structure similar to the RRT that indicates the functional unit usage in the steady state of the pipelined loop. In the modulo schedule, both P and O were delayed one cycle later than an optimal schedule for just a single iteration. $M(P) = 1$ and $M(O) = 2$ would be valid per the data dependencies but invalid per the modulo RRT because O would conflict with S for the TC since $0 \equiv 2 \pmod 2$. A variety of algorithms have been developed to construct M and I for a given dependence graph G, including greedy [24, 31] algorithms and optimal [21, 34] algorithms that leverage Integer Linear Programming ($\mathbb{Z}$LP). Optimal algorithms yield modulo schedules with the smallest possible I, and thus the highest possible throughput.

Once a modulo schedule M and initiation interval I have been found, they can be used to synthesize a program that executes the schedule. A standard way [6] to realize a modulo schedule is with a sequential loop that consists of: 1) a *prologue* that primes the loop, 2) a *steady state* containing the repeatedly executing loop body, and 3) an *epilogue* that drains the loop. To construct these three components, we let L be the *length* of M, i.e., the number of cycles in M. The software-pipelined loop is constructed by overlapping $\lceil L/I \rceil$ copies of M, each copy offset by I cycles from the previous copy. The pipelined loop can then be read off from this staggered schedule: the first $(\lceil L/I \rceil - 1) \cdot I$ cycles correspond to the prologue, the next I cycles correspond to the looping steady state, and the remaining cycles are the epilogue that drains the pipeline. Placing the modulo schedule for the running attention example is shown in Figure 1e, where blue and purple correspond to different copies of the schedule, and the dashed box gives the steady state. Once the schedule has been constructed, it can be used to generate code. Generated pseudocode for the running example is shown in Figure 1f. An in-order execution as written in Figure 1a completes 1 loop iteration every 3 cycles (Figure 1g), while the pipelined execution completes 1 iteration every 2 cycles after the prologue (Figure 1h).

Applying modulo scheduling to the running Flash Attention example yields the exact pipeline developed by experts in Flash Attention 3 [32] from only a high-level description of the algorithm and machine.

3.2 Code Generation Challenges

For GPUs prior to Hopper, the modulo scheduled tile-level program in Figure 1f could be lowered to single-threaded code executing in a SIMT fashion, where each data-parallel thread would execute the same program on disjoint subsets of the tile of data. Unfortunately, most modulo schedules computed for the functional units of a Hopper or a Blackwell GPU cannot be realized as a single-threaded program in the standard style. There are four confounding factors that regularly thwart single-threaded code generation. First, and most commonly, the scale of TCs in recent GPUs requires multiple warps to cooperatively issue large GEMM computations. Most GPU compilers are built on sequential intermediate representations (e.g., LLVM and PTX) and are therefore ill-equipped to generate code for cooperative warps.

A second issue stems from the propensity of modulo schedules to increase the working set size of computations to keep live variables from multiple iterations of a program on-chip concurrently. The combination of this natural memory pressure of modulo schedules in conjunction with the larger quantities of data needed to feed bigger TCs makes it challenging to keep the working set of a computation on-chip. Most GPUs have a strict upper bound of 255 registers per thread and spilling data out of the register file often incurs a significant performance penalty as the spilled data is unlikely to remain in cache. Many single-threaded realizations of modulo schedules for recent GPUs struggle to achieve peak performance due to the cost of spilling.

A third complication is that some operations, such as transfers through the multi-tiered GPU memory hierarchy, have high variability in their execution times. While traditional modulo scheduling suggests using an upper bound on such costs [6], there is an implicit assumption that this upper bound is roughly the same order of magnitude as other operations in the schedule. However, operations like TMA transfers that move tiles of data between global and shared memory may have more than an order of magnitude difference between the fastest and slowest possible execution times for the same transfer. While these operations are performed asynchronously, the

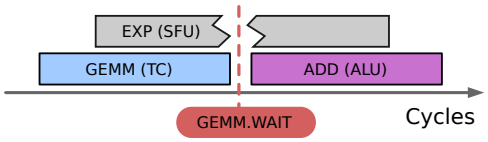

Figure 2: Visualization of three operations using different functional units scheduled on the same warp. The blocking sync after `GEMM` interrupts the concurrent issue of `EXP`.

high dynamic range of potential latencies can foil attempts to place synchronization instructions during code generation. In particular, overestimation results in under-utilization, while underestimation results in pipeline stalls during execution.

Finally, the fixed-function units on Hopper and Blackwell have asynchronous interfaces that require explicit blocking synchronization to consume results. Since GPU threads have *in-order* instruction issue, blocking synchronization interrupts the instruction issue of any concurrently scheduled operations on the same warp. An example is in Figure 2, where a modulo schedule requires an addition to consume the result of a `GEMM`, while executing an independent `EXP` concurrently. Note that all three occupy independent functional units. Executing all operations from the same warp suffers degraded performance as the `GEMM.WAIT` interrupts instruction issue for `EXP`.

Each of these four factors influence code generation for modulo schedules to differing degrees depending on the properties of the particular program. Combating them in practice necessitates a new approach to code generation.

3.3 Warp Specialization

Warp specialization [10,11] (WS) is a programming paradigm that offers a solution to the code generation challenges encountered when trying to realize a modulo schedule on GPUs. A warp-specialized program assigns operations to different warps while ensuring that the warps cooperatively execute the entire computation. WS is possible due to the hierarchical grouping of threads within an SM. Since warps are SIMT, a warp's performance is maximized when all threads in the warp issue the same instruction, and minimized when the threads *diverge*. However, unlike threads, warps are independent from each other and pay no penalty for control divergence.

While WS is commonly viewed as a separate optimization, our insight is that WS is useful precisely because it directly addresses all of the code generation problems for SWP presented in Section 3.2. First, WS naturally reasons about warps cooperating and can ensure that subsets of warps cooperatively issue TC operations. Second, by splitting the computation across many warps, the computation can access the register resources of many threads, yielding greater flexibility for fitting the large working sets demanded by SWP on-chip. Third, variable-latency operations can be separated onto dedicated warps, instead of needing to be statically scheduled alongside (and interfering with) fixed-latency operations. Finally, splitting operations across warps allows some warps to issue instructions while others are blocked on synchronization.

Since WS addresses the challenges of generating code for SWP, it has gained significant adoption by both compilers [5, 13, 25, 35–37] and programmers [27, 32, 38]. However, there are two complications. First, WS is not free and comes with trade-offs involving communication of data between warps and synchronizing access to both shared data and hardware resources. Currently, all automated approaches that we are aware of depend upon ad-hoc heuristics to decide these trade-offs [13,35,37]. These heuristics often involve canonical warp "roles" (e.g., loader and compute warps), or treat warps as parallel "agents" to whom work can be dispatched. Without a technical framework for understanding the optimality of these heuristics, it is difficult to know if programs generated using them are achieving peak performance.

The other significant complication to this approach is that, even with WS, it might not be possible to synthesize a program that actually achieves a modulo schedule. For example, despite spreading a computation across as many warps as possible in an SM, it still might be impossible to fit the working set demanded by a modulo schedule in the register file. Consequently, treating the computation of the modulo schedule and code generation using WS as two independent steps in compiling a program can lead to sub-optimal code in practice. To ensure that a modulo schedule can actually be realized, the constraints for code generation using WS need to be directly incorporated into the optimization process in conjunction with those for traditional modulo scheduling.

4 Joint Optimization Problem

We now demonstrate how to solve the optimization problem of finding a modulo schedule and a WS strategy simultaneously. The joint optimization problem is to take an input program $G = (V, E)$ and produce a modulo schedule with the minimum initiation interval along with a WS strategy capable of realizing the schedule. The result is a modulo schedule M^*, initiation interval I^* and warp assignment A^*, where A^* is an assignment of every $v \in V$ to a warp (or warps).

We approach this problem in two main steps. First, modulo scheduling is used to derive an initial modulo schedule M and initiation interval I that achieve the maximum throughput while respecting the data dependence and functional unit constraints. Then, M and I are used to seed a system of constraints that are supplemented with constraints for WS. The system of constraints can then be solved by an SMT solver to discover an M^* and A^* with the same I that respect the requirements of both modulo scheduling and WS.

We use M and I to define an initial straight-line program Q over which the constraint system is formulated. Q is obtained using the code-generation procedure of modulo scheduling from Section 3.2. Recall that $\lceil L/I \rceil$ copies of M are overlapped, each offset I cycles from the previous, resulting in a prologue, steady state and epilogue. Our insight is that we can

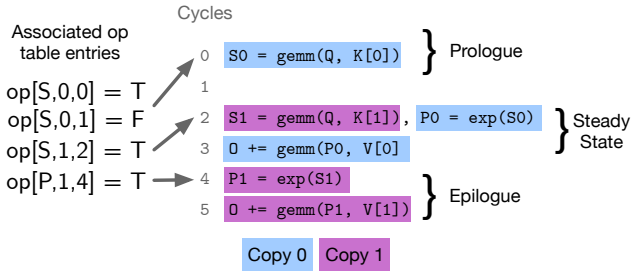

Figure 3: Straight-line code analyzed by Twill's joint formulation. Sample op table entries are to the left.

$$\forall v,i \quad \sum_t \mathrm{op}[v,i,t] = 1 \qquad \text{(UNIQUENESS)}$$

$$\forall v,i \in [1,\lceil L/I \rceil),t \quad \mathrm{op}[v,0,t] \Rightarrow \mathrm{op}[v,i,t+i\cdot I] \qquad \text{(CONSISTENCY)}$$

$$\forall v,i,t \quad t+\mathrm{cycles}(v) > T \Rightarrow \neg\mathrm{op}[v,i,t] \qquad \text{(COMPLETION)}$$

$$\forall i,t,(u,v,d,\delta) \in E,\ t' \in [0,t+d) \quad \mathrm{op}[u,i,t] \Rightarrow \neg\mathrm{op}[v,i+\delta,t'] \qquad \text{(DEPENDENCE)}$$

$$\forall t,f \quad \sum_{v,i,c \in [0,\mathrm{cycles}(v))} \mathrm{op}[v,i,t-c]\cdot \mathrm{RRT}[v][f,c] \le \mathrm{cap}(f) \qquad \text{(CAPACITY)}$$

Figure 4: Constraints enforcing a valid modulo schedule.

assume that the steady state executes exactly once, allowing us to treat the three parts as a straight-line program with length T. This assumption is sound, because it is permissible for the steady state to execute exactly once, and complete, because steady state executions are identical, and greatly simplifies the constraints by obviating the need for any loop analysis. An example program Q derived from the modulo scheduled example in Figure 1 is shown in the right half of Figure 3.

4.1 Modulo Scheduling with Constraints

The goal of the joint problem is to find a modulo schedule M^* that may be distinct from M but achieves the same initiation interval. To do so, Twill must be able to modify M, necessitating a *reimplementation* of modulo scheduling in the form of SMT constraints. Instead of modifying M directly, this reimplementation allows the modification of Q to Q^* such that Q^* has the same initiation interval and length as Q, but may be the result of a different modulo schedule. The constraints to do so are given in Figure 4. We define a 3-D boolean array such that $\mathrm{op}[v,i,t]$ indicates that operation $v \in V$ of iteration $i \in [0,\lceil L/I \rceil)$ was scheduled at clock cycle $t \in [0,T)$ in Q^*. The uniqueness constraint enforces that every operation is scheduled exactly once. The consistency constraint ensures that Q^* is obtainable from some modulo schedule. The completion constraint requires all operations to finish before the last clock cycle T of Q^*. Finally, the dependence and capacity constraints function identically to the corresponding constraints in modulo scheduling. We elide guards for brevity, but assume that constraints referencing $i \notin [0,\lceil L/I \rceil)$ are not emitted. Additionally, references to $t \notin [0,T)$ of op are mapped to false. A satisfying assignment of op induces a valid Q^* and M^*, where $M^*(v) = t$ iff $\mathrm{op}[v,0,t]$.

$$\forall t,m \quad \sum_{v,i} \mathrm{live}[v,i,t]\cdot \mathrm{footprint}(v,m) \le \mathrm{capacity}(m) \qquad \text{(MEMORY CAPACITY)}$$

$$\forall v \quad (\exists (v,u,d,\delta>0) \in E) \Leftrightarrow \mathrm{live}[v,\lceil L/I \rceil - 1,T] \qquad \text{(INIT)}$$

$$\forall v,i,t \quad (\mathrm{live}[v,i,t] \wedge \mathrm{op}[v,i,t]) \Rightarrow \neg\mathrm{live}[v,i,t-1] \qquad \text{(LIVEPROP-1)}$$

$$\forall v,i,t \quad (\mathrm{live}[v,i,t] \wedge \neg\mathrm{op}[v,i,t]) \Rightarrow \mathrm{live}[v,i,t-1] \qquad \text{(LIVEPROP-2)}$$

$$\forall v,i,t \quad (\neg\mathrm{live}[v,i,t] \wedge \bigvee_{(v,u,_,\delta)\in E} \mathrm{op}[u,i+\delta,t]) \Rightarrow \mathrm{live}[v,i,t-1] \qquad \text{(DEADPROP-1)}$$

$$\forall v,i,t \quad (\neg\mathrm{live}[v,i,t] \wedge \bigwedge_{(v,u,_,\delta)\in E} \neg\mathrm{op}[u,i+\delta,t]) \Rightarrow \neg\mathrm{live}[v,i,t-1] \qquad \text{(DEADPROP-2)}$$

Figure 5: Memory Allocation Constraints.

4.2 Memory Aware Constraints

To ensure that the working set of a modulo schedule can remain on-chip, we introduce additional constraints that enforce memory capacity, narrowing the set of valid instances of Q^*. These constraints assume that Q^* is in static single assignment form (SSA) [8, 16], where variables are defined once and have lifetimes that end at the last use. We define a second boolean array $\mathrm{live}[v,i,t]$, where $\mathrm{live}[v,i,t] = 1$ when the result of the i'th instance of v is live at time t. Using live, defining the memory capacity constraint is straightforward and shown in Figure 5, where the memory footprints and capacities are defined by the input graph and machine model. The non-trivial component of memory capacity is setting up the constraints defining $\mathrm{live}[v,i,t]$; this component cannot be discharged to an external analysis, because changes to Q^* affect when different values are live. These constraints are shown in Figure 5, and are derived from classic backwards dataflow algorithms for liveness [6]. There are three groups of liveness constraints: initial conditions, propagation of liveness, and propagation of deadness. Initially, only the loop-carried results of the last copy of each instruction are live at the last clock cycle of Q^*, i.e. at time T. Liveness is then propagated backwards through the straight-line program: if an operation's result is live at time t, it is live at time $t-1$ unless it was scheduled at time t. Deadness is propagated in a similar way, where if the result of an operation is dead at time t, it stays dead at time $t-1$ unless a user of the operation is scheduled at time t.

$$\forall v \quad \sum_{w} \text{opw}[v,w] = 1 \qquad \text{(WARP UNIQUENESS)}$$

$$\forall v \quad \text{variable_latency}(v) \Leftrightarrow \text{opw}[v, W_{vl}] \qquad \text{(VARIABLE LATENCY)}$$

$$\forall t, w \quad \sum_{v,i} \text{live}[v,i,t] \cdot \text{opw}[v,w] \cdot \text{regs}(v) \leq \text{reg_limit}() \qquad \text{(REGISTER LIMIT)}$$

$$\forall (u,v,d,\delta) \in E, t, i, w, w' \neq w, s \in [0, \text{spillcost}(u))$$
$$\text{op}[u,i,t] \wedge \text{opw}[u,w] \wedge \text{opw}[v,w'] \Rightarrow$$
$$\neg \text{op}[v, i+\delta, t+d+s] \qquad \text{(CROSS-WARP SPILLS)}$$

$$\forall (u,v,_,_) \in E, t, w, i, o \neq v$$
$$\text{op}[v,i,t] \wedge \text{opw}[v,w] \wedge \text{blocking}(u,v) \Rightarrow$$
$$\forall i', t' \in [t - (\text{cycles}(o) - 1), t],\ \neg(\text{op}[o,i',t'] \wedge \text{opw}[o,w]) \qquad \text{(CONCURRENCY)}$$

Figure 6: Warp Assignment Constraints.

4.3 Warp Assignment Constraints

Finally, we introduce constraints that influence WS decisions, shown in Figure 6. We define another boolean array $\text{opw}[v,w]$, indicating whether operation v has been assigned to warp w; opw directly defines the final warp assignments A^*. Similar to op, we define a uniqueness constraint, stating that every operation must be assigned to exactly one warp. This constraint is naturally extended to operations that span multiple warps, such as the warp-group level operations on Hopper and Blackwell.

The first constraint is the assignment of operations with variable and statically-unknown latencies. These operations are assigned to a designated warp W_{vl}, separating them from the scheduling and placement of instructions with statically-known and fixed latencies. The second constraint enforces the register limit on each warp; the constraint is similar to the capacity constraint in Figure 5, but scopes the summation to each warp. This constraint forces a partitioning of V to stay within register limits. However, data in the registers of warp w cannot be accessed on warp w' unless the data is transferred (or *spilled*) through the shared memory. When data is spilled across warps, a valid schedule must include the cost of the transfer when scheduling the consuming operation; this additional delay is captured by the *cross-warp spill* constraint. We assume the cost of cross-warp communication is provided as an annotation on nodes in G. This constraint forces a trade-off between memory capacity, latency and the costs of cross-warp spills. The final constraint is the *concurrency* constraint, which captures the effects of blocking synchronization interrupting the issue of concurrently scheduled operations. Certain edges (u,v) are designated as *blocking* edges, indicating that blocking synchronization is required by v before the results of u are accessible. The concurrency constraint states that if an operation v, assigned to warp w and scheduled at time t, requires blocking synchronization from an incoming dependence, then no other operation can be scheduled to run on w when v starts; this forces concurrent operations to either be placed onto different warps or scheduled at different times. While elided for brevity, the implementation includes a similar constraint for cross-warp spills, as transferring register data through shared memory requires blocking synchronization.

The entire system of constraints captures all the challenges presented in Section 3 that can make a desired modulo schedule impossible to implement in practice for recent GPUs. By describing the space of solutions holistically with a unified system of general constraints, we force the constraint solver to reckon with all aspects of the scheduling problem simultaneously. Furthermore, as new machines are released, constraints can easily be added, removed, and modified to reflect the challenges presented in future architectures. Therefore our approach provides a flexible framework for finding optimal solutions to the joint problems of modulo scheduling and WS.

5 Implementation

To reify our approach, we introduce Twill, a system that computes joint SWP and WS strategies for Triton [35] programs. Twill extracts dependence graphs from a mid-level Triton intermediate representation (IR) called TTGIR, which is a tile-based, SSA IR with arithmetic on tiles and explicit data movement. These graphs serve as the input program to Twill's optimization process as described in Section 4. Users of Twill must also inform it of the target GPU architecture. The target architecture is used to estimate costs of instructions and data movement (discoverable via documentation [1] or direct measurement), and to enable architecture-specific modeling, such as declaring available memories or denoting operations that require blocking synchronization.

As described in Section 4, Twill computes an initial modulo schedule by formulating it as an $\mathbb{Z}$LP problem [34] and dispatching it to the CBC solver [20]. Twill then uses the resulting modulo schedule and initiation interval to seed the system of SMT constraints. Twill discharges SMT queries to the quantifier-free linear integer arithmetic (QFLIA) theory of the Yices2 SMT solver [19]. Once a modulo schedule and warp assignment have been discovered, Twill uses standard code generation techniques to emit software-pipelined IR, annotating each instruction with the warp (or warps) that should execute it. The resulting IR can either be consumed by downstream compilers that implement a specified WS strategy (e.g., Tawa [13] or Cypress [37]), or used by an expert as reference for a manual implementation.

Algorithm 1 Twill's Search Procedure

```
1:  procedure TWILL(G)
2:      I ← 0
3:      while true do
4:          I ← I + 1
5:          M ← OPTIMAL-MODULO-SCHEDULE(G, I)
6:          if M = failure then
7:              continue
8:          L ← LEN(M)
9:          while ⌈L/I⌉ = ⌈LEN(M)/I⌉ do
10:             (M*, A*) ← SWP-AND-WS(G, M, I, L)
11:             if (M*, A*) = failure then
12:                 L ← L + 1
13:                 continue
14:             return (M*, I, A*)
```

5.1 Handling Unsatisfiability

Twill must handle the case when the constraint system is unsatisfiable. Unsatisfiability indicates that some resource limitation or concurrent interaction is preventing a modulo schedule with the initial initiation interval I from being achieved. Similar to standard approaches in modulo scheduling [24], if the constraints are unsatisfiable, Twill uses modulo scheduling to find a new candidate schedule M' with initiation interval $I+1$, which is then used to seed the system of constraints for another solution attempt. By searching monotonically from the smallest possible initiation interval, we ensure discovery of the highest throughput schedule that solves the constraints. In addition to searching over candidate values of I, Twill also searches over increasing values of L (the total schedule length) that do not affect $\lceil L/I \rceil$ at a given I. This search is depicted in Algorithm 1.

5.2 Cost Normalization

A critical component of Twill's implementation is *cost normalization*, which renders the optimization problems solved by Twill tractable. Consider the cycle counts computed from publicly available documentation [1] for a 128x128x128 GEMM on Hopper—roughly 1000 cycles. A reasonable dependence graph $G = (V, E)$ may contain many instructions with similar cycle counts. Optimal algorithms for modulo scheduling and Twill's joint formulation are not just exponential in $|G|$, but exponential in $\sum_{(u,v,d,\delta)\in E} d$. Therefore, directly using estimated cycle counts results in intractable $\mathbb{Z}$LP and SMT problems.

Our solution relies on the observation that multiplying every cycle count in a SWP problem by a positive integer results in a new problem isomorphic to the original. It is not the cycle counts that matter, but the *ratios* between cycle counts. Therefore, we want to obtain new, smaller cycle counts whose ratios are as close as possible to ratios of the original cycle counts. Cost normalization encodes this intuition as an $\mathbb{Z}$LP problem (separate from the one for modulo scheduling).

Let the list of integers C be the original cycle counts. We want to derive a new list of integers C' such that $C[i]/C[j] \approx C'[i]/C'[j]$ for all i, j. This is formalized as a constraint by introducing a variable F that bounds the change in ratios. We also bound the sum of C' from above and below, the latter to avoid the degenerate solution of all zeros:

$$\forall i, j \quad -F \leq C[i] \cdot C'[j] - C[j] \cdot C'[i] \leq F$$

$$1 \leq \sum_i C'[i] \leq U$$

U is a user-defined integer parameter that controls the exact trade-off between resolution of costs and running time of the subsequent algorithm that actually calculates a modulo schedule. Smaller values of U result in lower resolution (i.e., larger change in ratios) and lower running times. Finally, the $\mathbb{Z}$LP objective is to minimize F. Twill uses the SCIP solver [22] to find solutions because it was considerably faster than the CBC solver [20] at such problems. In our experiments, we pick $U = 300$ and find that SCIP is able to find the global minima in under 500 ms in all cases. Early in the development of Twill, we relied on an ad-hoc approach that divided each cycle count by a fixed integer, followed by rounding to obtain integer values. We found it difficult to keep this approach consistent, even for the same program on different GPUs. In contrast, framing cost normalization as an $\mathbb{Z}$LP problem offers a principled solution and is necessary for discovering optimal schedules.

5.3 Variable Latency Optimizations

As discussed in Section 3.2, approximating the execution time of variable-latency operations with a high dynamic range can cause imprecision in static scheduling. While Twill offloads variable-latency operations onto separate warps so they may be dynamically scheduled, further optimizations are possible for variable-latency operations in the target loop dependence graph that have no incoming data dependencies. We refer to these variable-latency operations as *streaming* operations. On separate warps, streaming operations can run ahead of the main software pipeline and complete several iterations before their results are needed. To reflect this, we assign streaming operations zero latency in our cost models, allowing dependent operations with statically-known latencies to be precisely scheduled. We then expose the pipeline depths for these streaming operations as parameters that may be tuned by an external auto-tuning system; exposing such parameters for dynamic tuning is commonplace among existing TC GPU programming systems [5, 15, 27, 33, 35, 37]. Many critical compute-bound kernels contain streaming variable-latency operations (like TMA loads of input tiles), warranting optimization of this important case.

5.4 Limitations and Future Work

Currently, our implementation of Twill only supports singly-nested loops without additional control flow. This limitation could be lifted through the use of hierarchical reduction techniques from the software pipelining literature [24], which we leave as future work. While Twill derives an optimal pipeline with respect to the constraints presented so far, the tile size is not automatically determined by Twill, and must therefore be selected by a human or a higher-level auto-tuning system. As we will see in Section 6.4, the solution times of Twill's joint problem range from tens of seconds to a few minutes. Fast solution times are a non-goal of our approach; we trade-off solution times for an optimality guarantee. We envision a system like Twill serving as a developer aid or as an offline optimization tool used prior to deployment, rather than being run continuously during interactive development. Despite this being a non-goal, in practice we find the solvers used by Twill to be highly optimized and capable of producing competitive search times as we will demonstrate.

6 Evaluation

We do a thorough evaluation on two important kernels from the machine learning literature, and show that Twill is able to derive SWP and WS strategies for *multiple generations* of NVIDIA GPUs automatically and from first principles. Twill is the only system we are aware of that is capable of doing so without heuristics tailored for each GPU generation. We then implement these strategies and show the achieved performance is competitive with hand-tuned implementations (Sections 6.2 and 6.3). Finally, we discuss the search times of Twill (Section 6.4).

6.1 Methodology

Kernel selection. We focus our evaluation efforts on compute-bound kernels that require utilizing both the TC and general-purpose functional units on the SM. Hence, we focus on the critically important forward and backward passes of Fused Multi-Head Attention, which have received significant human effort in developing SWP and WS strategies [32, 38]. The backward pass requires a significantly different loop structure than the forward pass and thus demonstrates Twill's flexibility in discovering different strategies.

Evaluation Platforms. We evaluate Twill on NVIDIA Hopper and Blackwell GPUs. We use a NVIDIA H100 SXM5 80 GB and a NVIDIA B200 180 GB. All experiments use CUDA 13.0. Search times were recorded on a single core of a Intel Xeon Platinum 8570.

Experimental Setup. Twill schedules dependence graphs extracted from Triton programs. Initially, we intended to use Twill within Triton and let Triton generate code from Twill's SWP and WS strategies. However, there are many additional (and orthogonal to Twill) critical decisions and optimizations that must be performed correctly to achieve high performance on modern GPUs. We found that Triton made many incorrect decisions during code generation, such as in memory allocation, data layout conversions or synchronization placement. As a result, Triton was either unable to successfully compile Twill's pipelines, or resulted in poorly performing code. To demonstrate the performance of schedules found by Twill, we instead "hand-compile" Twill's pipelines into CUDA C++. This process involved translating the pipelined and warp-annotated IR emitted by Twill into CUDA that implemented the specified strategy while allowing us to correctly make the remaining (and orthogonal) lowering steps. Automating all of these remaining steps in an optimal manner requires significant engineering and further research; as such, it is out of scope for this work.

6.2 Attention Forward Pass

The forward pass of FMHA has been the focus of significant optimization over multiple generations of GPU hardware through the Flash Attention (FA) algorithms [17, 18, 32, 38]. We focus on FMHA on Hopper and Blackwell, targeted by Flash Attention 3 (FA3) [32] and Flash Attention 4 (FA4) [38] respectively. For both architectures, novel SWP and WS strategies were required for peak performance and were discovered by humans months after each architecture was released. We demonstrate that Twill automatically rediscovers the same strategies across different architecture generations.

We started with the Triton tutorial [29] implementation of FA, a high-level implementation of FA without additional optimizations. A Triton program describes the decomposition of work for each SM. For Twill's joint approach to SWP and WS, we sub-tile the computation for the TC instruction sizes of the target hardware. This sub-tiling allows Twill to control scheduling and warp assignments at the appropriate level of granularity; Triton's IR only implicitly reasons about the decomposition of tiles onto multiple warps. We discuss these results in depth, focusing on each architecture in turn.

6.2.1 Hopper

FA3 [32] introduced two main techniques for optimizing FMHA on Hopper. The first technique was a software pipelining schedule for the main loop that extracts one GEMM into the loop's prologue so that latency of the exponential is not exposed (seen in Figure 1). The second technique was called *ping-pong scheduling*, which schedules the GEMM from one sub-tile while the exponential from another sub-tile executes, again increasing TC utilization. We show how Twill automatically derives both optimizations.

Figure 7 contains results for different implementations of

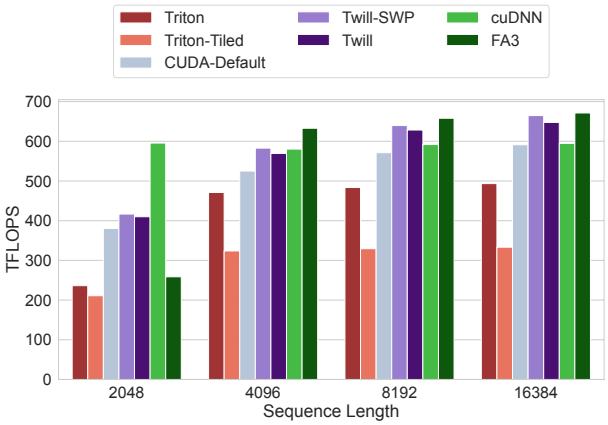

Figure 7: Hopper FP16 Non-Causal Forward Attention. (BATCH=4, NUM_HEADS=32, HEAD_DIM=128)

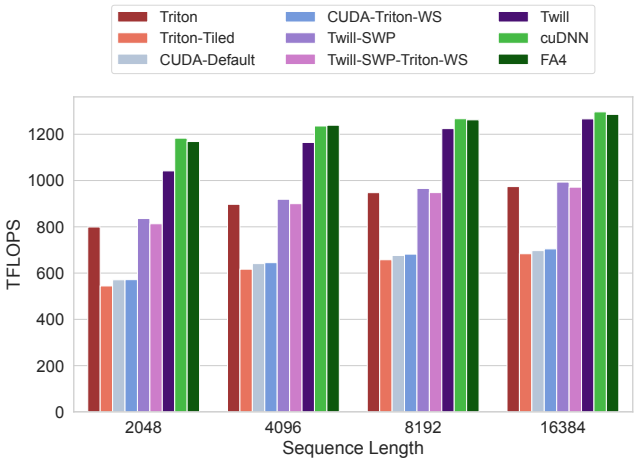

Figure 8: Blackwell FP16 Non-Causal Forward Attention. (BATCH=4, NUM_HEADS=32, HEAD_DIM=128)

forward FMHA on Hopper. The bars "Triton" and "Triton-Tiled" report the performance of Triton executing the tutorial implementation of FA and the sub-tiled version. As discussed in Section 6.1, Triton makes many suboptimal decisions during compilation. The "CUDA-Default" bar reports the performance of our "hand-compilation" of Triton IR into CUDA C++, which yields a moderate speedup over Triton. The first Twill result we discuss is the "Twill-SWP" bar, which just uses Twill's modulo scheduling (i.e., only running OPTIMAL-MODULO-SCHEDULE in Algorithm 1) to software pipeline the main loop and applies Triton's WS strategy, which puts loads from global memory on a separate warp than the rest of the computation. This results in a significant performance boost, coming within 1% of the official FA3 implementation at the 16384 sequence length. If algorithms like modulo scheduling were used within systems like Triton, this component of FA3 would not have needed human discovery. Finally, the "Twill" result uses Twill's joint formulation of SWP and WS (i.e., running the entirety of Algorithm 1). Twill's functional unit capacity constraints recover the ping-pong scheduling strategy described in FA3: since only one operation may use the TC at a time, Twill skews groups of warps so that one issues exponentials while the other uses the TC. Twill discovers the software pipeline used in FA3, but applies it only to one warp group, determining this to be sufficient to saturate the functional units. While the final implementation of this version performed slightly worse than Twill-SWP, the two initially performed equivalently (roughly 645 TFLOPS), but an orthogonal optimization (TMA multicasting) benefited the modulo-scheduled implementation more. On Hopper, multiple warps are interleaved dynamically to issue work into the TC and other functional units, naturally gaining ILP and lessening the burden on the quality of static instruction scheduling. We will see next that this is no longer true on Blackwell.

6.2.2 Blackwell

Blackwell requires substantially different SWP and WS strategies than Hopper due to a faster TC and a larger set of required synchronization operations (Tensor Memory loads and stores). The set of Blackwell results is shown in Figure 8.

As for Hopper, we include Triton results for the tutorial and sub-tiled versions. Our direct translation of Triton IR to CUDA performs worse than Triton on Blackwell because Triton's Blackwell backend heuristically applies the FA3 SWP strategy. When we apply modulo scheduling and Triton's WS strategy for Hopper, we match Triton's performance, but are far from the best implementations.

Twill's joint optimization of SWP and WS finds a strategy that performs significantly better than Triton and competitively with cuDNN and FA4. In fact, the discovered strategy is exactly the same as proposed by FA4 [38]! Twill's strategy combines a different software pipeline than Hopper with specific warp assignments and cross-warp communication. Twill's WS strategy is shown in Figure 9, using a visualization generated by Twill for the actual dependence graph obtained from Triton IR for this program. Twill places variable-latency operations (green) and TC GEMMs (pink) onto separate warps, softmax calculations for each sub-tile onto two different groups of warps (blue and orange), and accumulator rescaling operations for both sub-tiles onto a third group of warps (yellow).

This strategy does not comport to conventional warp roles like "loader" and "compute" warps. The reasoning behind this strategy is opaque without considering the associated software pipeline. The pipeline hoists the first GEMM for each sub-tile out of the loop like FA3. In the main loop, the pipeline schedules the exponential for one sub-tile during the GEMMs for the other sub-tile (like ping-pong scheduling), all while the sub-tile's accumulator is being rescaled. The rescaling is moved to a third group of warps because reading accumulators from Tensor Memory requires blocking

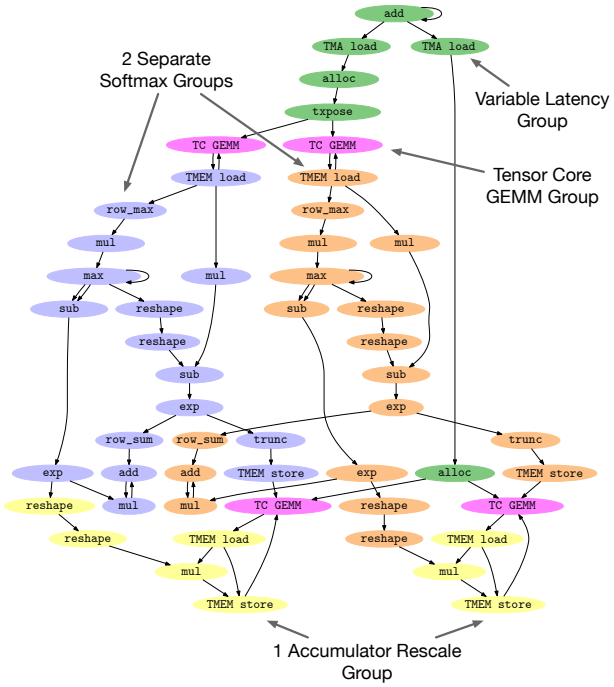

Figure 9: Twill's dependence graph showing the discovered forward WS strategy for Blackwell. Colors indicate instructions assigned to the same group of warps.

synchronization; placing it on the warp issuing exponentials disrupts the pipeline. However, moving the rescaling to a third group of warps incurs cross-warp communication, as it needs data produced by the softmax warps — Twill schedules around this latency and synchronization. Our implementation of this schedule comes within 2% of FA4 on the 16384 sequence length.

We now return to other kernel variants in Figure 8. Triton has heuristics to replicate the FA4 strategy by moving accumulator rescaling to a separate group of warps. Applying these heuristics to our purely software-pipelined implementation ("Twill-SWP-Triton-WS") or our default translation ("CUDA-Triton-WS") yields no benefit, showing that jointly considering SWP and WS is critical for peak performance.

The final compelling component of our Blackwell results are modifications which render the SMT problem unsatisfiable for the smallest I which makes the $\mathbb{Z}$LP succeed in Algorithm 1, forcing a search over larger values of I and L. These modifications include:

- Reducing the number of warps.
- Using the tutorial Triton implementation directly. Without sub-tiling, the instruction granularity is not fine enough for interleaving.
- Prohibiting cross-warp communication.

The variety of unsatisfiable configurations demonstrates the complexity of the search space for finding high performance SWP and WS strategies. Twill provides a technical framework for reasoning about and navigating this complex search space

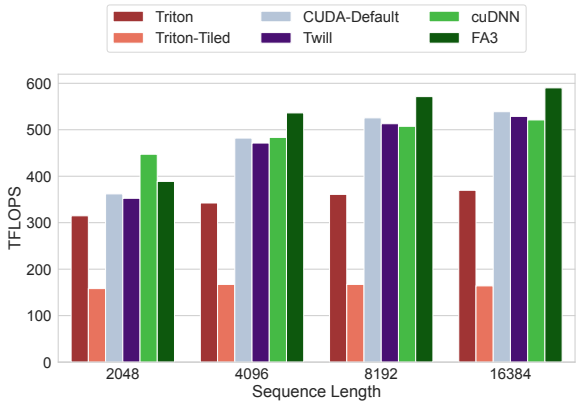

Figure 10: Hopper FP16 Non-Causal Backward Attention. `(BATCH=4, NUM_HEADS=32, HEAD_DIM=128)`

while guaranteeing optimal results.

6.3 Attention Backward Pass

We now move to the backward pass of FMHA. The backward pass is significantly different from the forward pass, requiring different SWP and WS strategies. We did not use the Triton tutorial implementation of the backward pass, as it uses a work-inefficient two-pass algorithm. Instead, we implemented the single-pass backward algorithm as described in FA3 [32] in Triton, allowing us to directly compare against cuDNN and the reference FA implementations. The single-pass algorithm consists of five GEMMs and one exponential, followed by an atomic reduction into global memory. Similar to the forward pass, we also implement a sub-tiled version of the algorithm.

6.3.1 Hopper

Hopper results are shown in Figure 10. Similar to forward on Hopper, our port of Triton IR into CUDA achieves a performance boost over Triton and performs competitively with cuDNN on the highest sequence length. Backward attention on Hopper is register constrained, and thus FA3 [32] does not construct a software pipeline that exploits ILP across iteration boundaries. Twill found a similar schedule: it exploited ILP within a loop iteration but could not do so across iterations due to register capacity. Twill's findings confirm that the developers of FA3 did not miss potential performance with their software pipelining strategy. We believe the reference FA3 implementation beats ours by 11% on the 16384 sequence length by using a slightly larger tile size (80x128), allowing for the use of larger GEMMs. Triton only supports power-of-two tile sizes, so we were not able to construct IR with the same tile size, but there is no fundamental reason that Twill cannot handle tile sizes that are not powers of two.

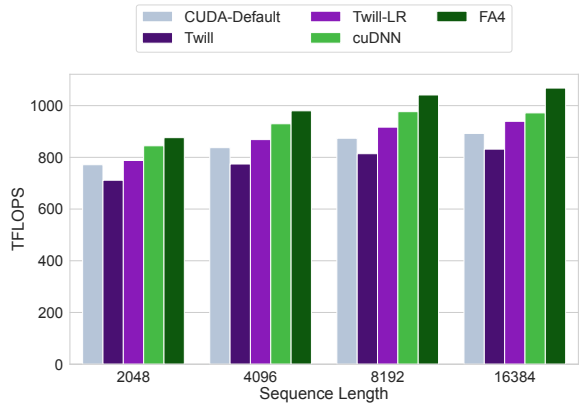

Figure 11: Blackwell FP16 Non-Causal Backward Attention. `(BATCH=4, NUM_HEADS=32, HEAD_DIM=128)`

6.3.2 Blackwell

Blackwell results are shown in Figure 11. Triton was unable to generate code for Blackwell, as it is currently unable to construct Tensor Memory allocation strategies that contain aliasing. The FA4 strategy for Blackwell [38] uses three groups of warps: two groups read accumulators from Tensor Memory to apply exponentials, and the last group stages accumulators in shared memory for the outgoing atomic reduction. Twill finds a different strategy using only two groups of warps which ping-pong between performing exponentials and staging reduction data ("Twill"). Despite our own inspection confirming the schedule should fit within the register-per-thread budget, `ptxas` was unable to register allocate this code without significant register spilling in the main loop, degrading performance. We then ran Twill with a reduced register-per-thread budget and three groups of warps, and it found the essentially same strategy as FA4. `ptxas` succeeded register allocating this version, yielding the small speedup over the default implementation ("Twill-LR"). Additionally, this configuration achieved a smaller initiation interval (Table 1) than the first strategy. This example shows the tightly-knit nature of the optimization space. It is difficult to reason about the usage of registers and warps in a separable manner; the necessary joint reasoning is best performed by automatic solvers.

The overall difference between Blackwell backward implementations is relatively small; the high throughput of the Blackwell TC renders the single-pass algorithm bandwidth-bound, limited by the completion of the atomic reduction at each iteration. However, Twill finds a similar SWP and WS strategy that hides some exposed latency present in a direct port of the Hopper backward strategy. We believe the remaining performance differences to be from orthogonal optimizations around memory layouts and instruction selection in the well-tuned reference implementations.

6.4 Search Time

While optimizing search time is not a primary goal of Twill, we measured it to demonstrate that solutions can be found in reasonable intervals of time that are comparable with existing solutions. Search times for all experiments are shown in Table 1 along with the minimum and final values of I and L. "SWP time" and "SWP-and-WS time" in the table refer to the total time spent in calls to OPTIMAL-MODULO-SCHEDULE and SWP-AND-WS in Algorithm 1 respectively. Twill's search times range from tens of seconds to a few minutes, which is reasonable for an offline system that provides an optimality guarantee for performance-critical kernels that will ultimately be deployed at scale. These times are competitive with existing solutions such as PipeThreader [14], which exhaustively searches a proposed space of SWP schedules. PipeThreader reports discovering the Hopper strategy for the forward pass in 315 seconds while Twill discovers the same strategy in 28 seconds, an order of magnitude faster. Our speedup over PipeThreader demonstrates that, despite their generality, modern ILP and SMT solvers are highly efficient at searching over and pruning large search spaces rapidly. We contrast PipeThreader with Twill in more detail in Section 7.2.

One final interesting observation is the difference in minimum and final values of I discovered by Twill for the backward B100 kernel. The larger final value of I demonstrates the existence of a kernel on a particular machine for which it was impossible to discover a WS strategy for the initiation interval predicted purely by modulo scheduling. This validates our claim from Section 3.3 that SWP and WS should always be handled jointly when determining an optimal schedule, as combinations of kernels and target machines clearly exist that necessitate a holistic approach and it is impossible to predict in advance when they might occur.

7 Related Work

7.1 Tensor Core GPU Programming

The combination of widely varying expertise in GPU programming and the desire for diverse and high-performance machine learning computations has led to a large ecosystem of programming systems for targeting TC GPUs. We provide a survey of this space of systems.

Below deep-learning frameworks like PyTorch [30] or JAX [12], domain-specific languages (DSLs) like Triton [35], Pallas [5] and CUDA Tile [15] provide abstractions for operating on tiles of data. The compilers for each language are then responsible for generating efficient code, often achieving moderate to high performance. Slightly lower-level DSL's like TLX [25] and TileLang [36] also expose tile-based programming models, but provide more control over optimizations. Gluon [28] is a Triton extension that exposes the Triton low-level intermediate representation (IR) to the program-

Benchmark	Total time (s)	SWP time (s)	SWP-and-WS time (s)	Min I, Min L	Final I, Final L
Fwd H100	28	3	25	40, 60	40, 60
Fwd B100	18	1	17	14, 27	14, 27
Bwd H100	84	2	81	30, 38	30, 41
Bwd B100 LR	48	15	32	15, 32	15, 33
Bwd B100	242	41	201	15, 32	20, 33

Table 1: Twill search time and results. Note: values of I, L are incomparable across programs due to cost normalization.

mer. Gluon programmers gain some automation from further lowering of this IR, but retain control over optimizations like memory allocation and WS. Cypress [37] is a task-based programming model that allows programmers to express the decomposition of computation and data across the GPU. Cypress provides a separate mapping interface to control performance-sensitive decisions without affecting correctness. Finally, systems like ThunderKittens [33] and CUTLASS [27] provide the developer complete control, leaving no performance-sensitive decisions to an automated system.

7.2 Software Pipelining

Pipelining for CPUs. Software pipelining is a classic and well-understood optimization for CPUs, critical for extracting enough instruction level parallelism to saturate the machine. Even for modern out-of-order processors, software pipelining can improve instruction throughput by filling the processor's reorder buffer with independent instructions. Compaction-based [7] pipelining algorithms logically unrolled the target loop until a fixed-point pipeline is discovered. Modulo scheduling [24, 31] pipelining algorithms model steady state resource usage with a modulo table data structure. Modulo scheduling algorithms are amenable to the derivation of optimal solutions through the use of Integer Linear Programming [21, 34]. Twill shows how to adapt traditional modulo scheduling techniques for Tensor Core GPUs.

Pipelining for Tensor Core GPUs. ALCOP [23] does SWP of loads with compute, and is therefore insufficient to derive pipelines that overlap compute operations, like FA3.

PipeThreader [14] finds an SWP strategy by defining a space of programs and then searching over it, profiling each candidate to find the fastest. In contrast, Twill takes a constraint-based approach where the space is implicitly defined by the constraints and the search is executed by highly-optimized solvers. Moreover, Twill does not rely on profiling—our approach is static and instead relies on publicly available specifications to estimate operation latencies. A comparison of the search times of Twill and PipeThreader is presented in Section 6.4. Apart from higher search times, because PipeThreader relies on the conventional, heuristic approach to WS involving the creation of producer and consumer warps, it cannot derive the Blackwell warp specialization strategy. Finally, perhaps the most important distinction between Twill and PipeThreader is that PipeThreader cannot provide any optimality guarantees for the schedules it finds.

7.3 Warp Specialization

The GPU programming technique of WS was introduced before NVIDIA GPUs contained TCs. CUDA-DMA [10] leveraged WS to separate data movement between global and shared memory from computation, achieving higher memory bandwidth. Singe [11] partitioned combustion chemistry computations across warps to shrink the register-level working set of each warp, allowing large chemical reactions to be simulated without spilling.

Since Hopper, WS has become ubiquitous in high-performance TC kernels. Programming systems for TC GPUs offer many different layers of control around WS. High-level systems like Triton [35], Cypress [37] or Tawa [13] heuristically define a WS *strategy*, and then automatically transform the source program to implement chosen strategy. Mid-level systems like TLX [25] allow specifying a WS strategy through source-level annotations, and then implement the strategy through transformation algorithms within the compiler. Finally, low-level systems like Gluon [28], ThunderKittens [33] or CUDA C++ require users to both define a WS strategy and realize it in low-level code. Twill focuses specifically on the problem of defining a WS strategy, which all other existing systems perform through machine-specific heuristics or by relying on programmer intuition.

8 Conclusion

We presented Twill, a system that discovers optimal SWP and WS strategies for Tensor Core GPUs. Twill presents a novel joint formulation of SWP and WS that can be offloaded to $\mathbb{Z}$LP and SMT solvers, deriving the complex strategies that experts have found by hand for multiple generations of GPUs. We additionally show that approaches that consider these optimization strategies separately are unable to achieve peak performance.

Abstract

Spatial dataflow accelerators are a promising direction for next-generation computer systems because they can reduce the memory bottlenecks of traditional von Neumann machines such as CPUs and GPUs. They organize computation around explicit, compiler-managed data movement over on-chip networks, allowing operands to be forwarded directly between processing elements and reducing reliance on high-latency, bandwidth-limited global shared memory. However, their performance depends strongly on how workloads are mapped to hardware. Naive mappings can perform poorly, and most users rely on hand-tuned vendor libraries. Thus, despite their potential for high performance, energy efficiency, and cost efficiency, limited programmability remains a major barrier to wider adoption.

This paper presents *TileLoom*, an MLIR-based end-to-end framework that compiles tile-based programs, such as Triton kernels, onto spatial dataflow architectures. Unlike compiler frameworks that focus on optimizing code generation *within* a single tile, *TileLoom* distributes tile instances across spatially distributed cores and exploits the on-chip network and distributed memories to increase data reuse and reduce communication. *TileLoom* introduces a hardware representation that captures interconnect topology, memory hierarchy, and compute capabilities, enabling both architecture-specific optimizations and support for diverse spatial dataflow targets. In experiments on two generations of Tenstorrent systems, *TileLoom* achieves performance comparable to vendor libraries on various kernels.

1 Introduction

Modern high-performance workloads, especially deep learning workloads, are highly data-intensive [5, 15]. For many of these workloads, the main bottleneck is not compute, but memory bandwidth [12, 27, 43, 70]. As process technology scales, we can place more arithmetic units on a chip, but off-chip memory bandwidth and capacity do not scale at the same rate [7, 46]. Each DRAM access costs much more energy than an arithmetic operation [22]. On-chip SRAM also becomes relatively more expensive in area and power as we move to smaller technology nodes [18, 22]. Together, these trends make it hard for conventional, memory-centric von Neumann architectures such as CPUs and GPUs to keep their compute units busy.

Spatial dataflow architectures are emerging as a strong alternative. Systems such as Tenstorrent [3], Cerebras [8], Graphcore [26], SambaNova [55, 58], Groq [1, 2], Meta's MTIA [14], AWS's Trainium [6], and Tesla's Dojo [19] organize computation around explicit, often software-controlled data movements over on-chip networks and buffers, reducing reliance on large shared caches and high-latency off-chip memories. When data is passed from core to core over short on-chip wires, the energy per bit and latency can be much lower than going back and forth to a shared cache or off-chip memory [4, 21, 22]. Figure 1 shows a representative spatial dataflow accelerator architecture from Tenstorrent: a 2D grid of cores, each typically a SIMD or vector engine, often with a matrix unit, plus a local scratchpad, connected by a packet-switched mesh NoC. 64 cores can concurrently access their local scratchpads, yielding an aggregate peak bandwidth of roughly 24.5 TB/s—substantially higher than the 6 TB/s L2 bandwidth of the NVIDIA H100 [60]. This abundant per-core bandwidth significantly alleviates memory bottlenecks for bandwidth-bound operators.

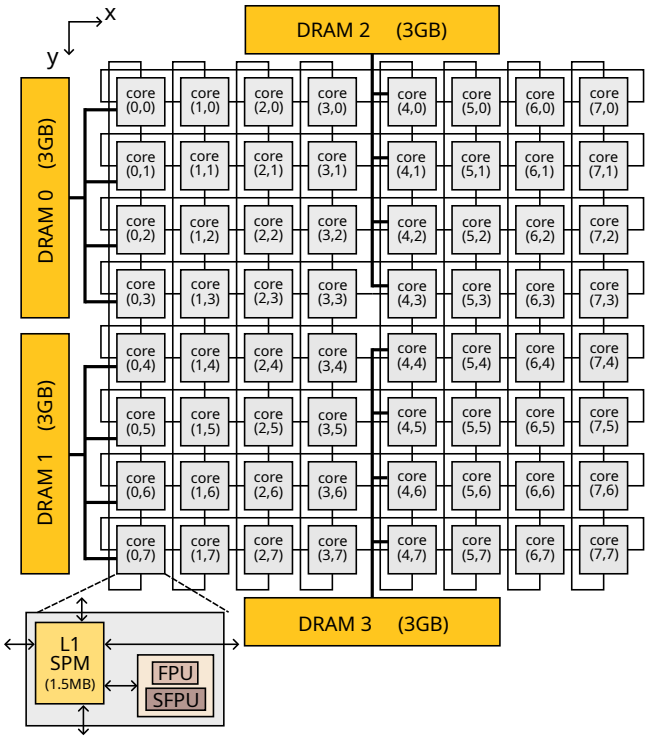

Figure 1: An example 2D-mesh spatial dataflow architecture, modeling Tenstorrent-Wormhole system.

While the structure of spatial dataflow accelerators can provide high efficiency, it also creates a serious programmability problem [16,48,56]. Performance depends heavily on how the workload is mapped: which cores execute which parts of the computation, how data is partitioned across local memories, and how traffic is scheduled on the network [17,38,56,71,73]. A naive mapping can cause severe load imbalance, network congestion, underutilized cores, or excessive off-chip memory traffic, resulting in poor performance and energy efficiency [17,38,71,73]. As a result, compiling high-level programs onto dataflow architectures is challenging, and non-experts struggle to write efficient low-level programs for them. Instead, users rely on vendor-provided, hand-optimized libraries by experts that implement a small set of popular kernels, such as matrix multiplication, convolutions, and attention, with carefully engineered mappings [11,28,34,36,45]. This dependence limits both portability across architectures and the ability to experiment with new kernels or model structures [11,34,45].

A common abstraction for parallel accelerators is the grid–block–thread model popularized by CUDA's grid-of-thread-blocks interface [30,49]. The programmer decomposes the problem into blocks and launches a grid of block instances across the device; each block, such as a CUDA thread block or OpenCL work-group, performs the same computation on a different region of the input or output tensor, and the grid covers the full problem domain [29,49]. Similar grid-based tiling models appear in high-level systems such as Halide and TVM [10,57], which treat tile shapes and launch configurations as schedule parameters and search over them to improve locality and parallelism.

On conventional, memory-centric architectures such as GPUs, the grid level is managed by hardware [30,47,49]: a hardware scheduler dynamically assigns blocks to Streaming Multiprocessors (SMs), and a shared cache hierarchy implicitly captures most data reuse across blocks [25,47]. This leaves little room for compilers to control grid-level placement, execution order, or communication. By contrast, the block–thread level is software-defined: the compiler or programmer decides how work within a block is mapped onto threads, warps, and intra-SM resources. CUDA exposes fine-grain control over thread organization, shared-memory layout, and synchronization, but exploiting it well requires careful tuning and detailed knowledge of GPU microarchitecture. To make this block-level programming more accessible, languages such as Triton [61], TileLang [66], CuTile [50], Tilus [13], and Taichi [23] let users express kernels in terms of high-level tile operators that define the work of a single block, while their compilers lower these operators onto intra-core or intra-SM resources.

Spatial dataflow accelerators change this picture. These architectures distribute compute and scratchpads across large arrays of processing elements connected by a high-bandwidth on-chip network, often without a large, unified cache that automatically exploits cross-core reuse [33,54,63]. Instead of offloading communication and placement decisions to hardware caches and schedulers, they expose richer inter-core programmability to software. Achieving good performance therefore requires a compiler or programmer to decide not only how to implement the tile program on a single core, but also how to place tile instances across cores and schedule them in time so that data can be forwarded or multicast efficiently over the NoC [33,51,63] and memory system. This inter-core programmability creates an enormous mapping design space: valid mappings are combinatorially large, and different mappings expose different reuse patterns and communication costs [51,54]. In today's systems, these decisions are baked into vendor-specific compilers and libraries [9, 54, 58, 63, 64, 75], which encode architecture-specific strategies for placement, routing, and pipelining, but are time-consuming to develop and do not generalize easily to new kernels, models, or hardware generations.

By giving more control to software, spatial dataflow architectures are harder to program but can simplify hardware and improve efficiency. Crucially, **as the hardware becomes more transparent to software by exposing explicit cores, networks, and memories instead of opaque caches and schedulers, dataflow architectures become more predictable than memory-centric architectures.** With sufficient hardware information, **a compiler can more easily**

reason about the performance of different schedules and deduce good static mappings. Building on this insight, we propose ***TileLoom*, a compiler framework that supports end-to-end execution of tile-based programs on spatial dataflow systems.** Our goal is to let users write kernels in a tile-wise language, such as Triton, while the compiler maps the logical grid onto the physical array of cores, schedules tile execution in time, and orchestrates data movement and reuse over the NoC and distributed memories. In other words, *TileLoom* takes on responsibilities typically handled by hardware schedulers and runtimes on GPUs, moving these decisions to compile time for spatial dataflow systems. To support a broad range of dataflow architectures, *TileLoom* introduces a hardware description that models interconnect topology, memory hierarchy, and compute resources. Given this description, the compiler searches for mappings that balance load, improve data reuse, and respect network and memory constraints across architectures. We evaluate our approach on Tenstorrent systems and show that it can match or outperform vendor-provided handwritten libraries on key kernels.

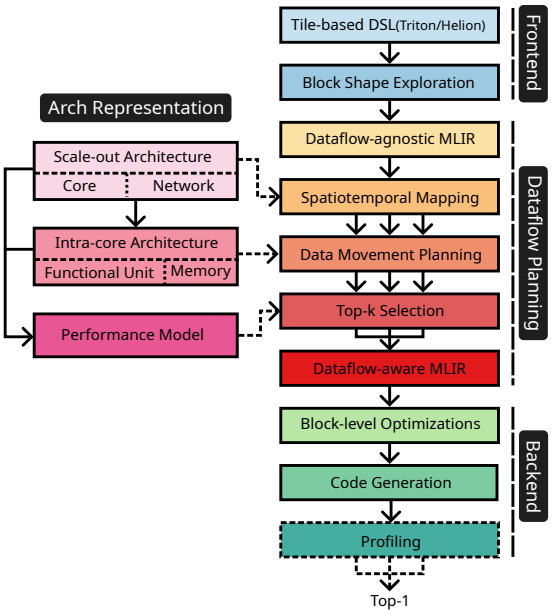

Figure 2: *TileLoom* framework overview.

2 Framework

2.1 Overview

TileLoom compiles a kernel written in a tile-based DSL (currently supporting Triton and Helion) into an executable for a target spatial dataflow architecture.[1] As shown in Figure 2, the compiler stack is organized around three main components: a front-end that lower tile-level kernels into a standard dataflow-agnostic MLIR representation that we propose; a dataflow planning stage that decides spatiotemporal mappings, data movements and generate candidates in a standard dataflow-aware MLIR representation; a back-end that generates hardware-specific executables for each core, all guided by the multi-level architecture representation and performance model.

The **front-end** takes as input a tile-level kernel and a description of how that kernel is scaled out over the full problem (the launch grid). It explores candidate *block shapes*: tile sizes and layouts, similar to the conventional auto-tunning process, and constructs corresponding programs. These candidate programs are then lowered into an MLIR-based intermediate representation and passed through normalization passes so that they share a common structure suitable for the dataflow planning pipeline. At this point, the computation is represented in a uniform, dataflow-agnostic IR affine + linalg + scf + arith): it encodes the tile and grid structure, but does not yet commit to any particular mapping onto the hardware.

The **dataflow planning** stage determines how this logical grid of tiles is realized on the target architecture. Guided by the hardware description, *TileLoom* explores spatiotemporal mappings of tile instances onto cores and time. For each candidate mapping, it performs data reuse analysis to identify which tiles can share data over the NoC or be reused over time via buffering, and it derives concrete data-movement plans: where each tensor tile is allocated, when it is copied, and how it is broadcasted or shared over the buffers. Together, the spatiotemporal mapping and the data-movement plan generate a design space of potential optimal dataflow planning candidates.

To model arbitrary dataflow architectures, the **architecture representation** is proposed, which provides the key inputs to both the dataflow planning search and the performance model. The scale-out (inter-core) description captures the spatial structure of the core array and interconnect, and guides spatiotemporal mapping decisions. The intra-core description captures the local memory hierarchy and compute resources, and guides decisions about where data is stored and how it is staged. *TileLoom* combines both levels of abstraction to generate **a performance model** that estimates the cost of different data-movement plans, taking into account memory bandwidths, NoC capabilities, and per-core compute throughput. The performance model is used to select the top candidates from the dataflow design space.

After dataflow planning stage, the IR is *dataflow-aware*: memory allocations, copies, and communication endpoints are concretized according to the chosen mapping. After chosing the top candidates from the design space, the **block-level optimization and code generation** stage compiles the dataflow-aware program that runs on each core into the vendor's existing back-end to generate an executable for each core. This corresponds to the existing compilers that compile tile-based

[1]The source code is available at https://github.com/ecolab-nus/loom-dataflow.

DSLs to block-level program.

TileLoom uses an optional two-step selection strategy to provide better support for various architectures: the automatically generated performance model (using the architectural information) first ranks candidate dataflow plans and selects the top-k mappings statically, and these k candidates are then profiled on the real hardware to choose the final mapping (which bridge the small details not covered by the architecture representation). This combination of model-guided search and hardware validation enables *TileLoom* to produce high-quality mappings while remaining portable across different spatial dataflow systems, especially when micro-architectural details are missing and hence causing inaccuracy in the hardware modeling.

2.2 Spatiotemporal Mapping

Input representation. A unified dataflow-agnostic MLIR representation is required before the dataflow planning pipeline. We assume this representation produced by the front-end, we will cover the implementation details of the Triton front-end in Section 3.1. An example of this MLIR for a matrix–multiplication kernel is shown in Listing 1. The block size and the strides for the input and output matrices are fixed by the front-end. The 2D output space is partitioned over two grid dimensions, `x` and `y`, which scale over the m and n dimensions of an $m \times k \times n$ matrix multiplication (an output-stationary tiling).

Scaling out across tiles is represented by an `affine.parallel` loop over `%block_id_x` and `%block_id_y`. Inside this loop, an `scf.for` loop iterates over the k dimension and accumulates into the same output tile, representing the sequential execution within one block over one output tile. The front-end is required to "affinize" the address arithmetic for memory operations, so every load and store address is an affine function of the tile indices and intra-tile indices. The tile-wise computation itself is expressed with `linalg` operations; this portion of the program is left unchanged during dataflow planning and is later lowered by the back-end.

The purpose of spatial–temporal mapping is to decide how the iteration space of the `affine.parallel` loop—the logical multidimensional tile grid—is assigned to physical cores and to time. To preserve locality, *TileLoom* uses *tiling-based* mappings: contiguous regions of the iteration space are mapped to contiguous spatial regions of the core array or to contiguous temporal regions in the execution schedule.

Schedule representation. On a 2D-mesh architecture like the one in Figure 1, spatial–temporal mapping produces the loop structure shown in Listing 2. The outermost `affine.parallel` loop now iterates over hardware spatial dimensions x and y, each of size 8. These indices correspond directly to the cores in an 8×8 2D mesh. After mapping, this loop represents code that actually runs in parallel across cores; its semantics have changed from a logical grid of parallelizable work-items to the physical parallel core indices.

The next `affine.for` loops iterate over `%tx` and `%ty`. These loops enumerate *waves* of tiles assigned to the same hardware array, i.e., temporal dimensions across blocks. Each wave assigns a batch of logical tiles to the available spatial cores, and the order of these waves determines the temporal schedule with which tiles traverse the array. The innermost `scf.for` remains a purely sequential loop within each core's program.[2]

Design space. The mapping from the original parallel dimensions to spatial and temporal dimensions defines the dataflow of the kernel. Under our tiling-based scheme, the design space is characterized by three coupled choices.

First, each original parallel dimension can be mapped to zero or more spatial dimensions. Mapping a parallel dimension to a spatial dimension corresponds to tiling the loop by the size of that spatial dimension and introducing a new outer `affine.parallel` loop over the hardware index.

Second, when a parallel dimension is tiled by multiple spatial dimensions (for example, by both x and y), the order in which tiling is applied matters. Different tiling orders induce different spatial layouts of tiles on the mesh and different execution schedules, and therefore expose different opportunities for spatial reuse and different communication costs.

Third, once all available spatial dimensions have been used, the remaining parallel dimensions become temporal dimensions implemented as loops over waves, (i.e. changing the rest of `affine.parallel` to `affine.for`), for instance the `%tx`↩ and `%ty` loops in Listing 2. These temporal loops and their order determine how tiles are batched onto the array over time and in what order they revisit each region of the global iteration space, which in turn affects temporal reuse and the shape of NoC traffic.

TileLoom enumerates candidate spatial–temporal mappings by exploring combinations of these choices. Each mapping fixes a concrete loop nest structure, which the subsequent analyses use to reason about data placement, reuse, and communication.

2.3 Data Reuse and Memory Operations

Different spatial–temporal mappings expose different opportunities to reuse data across time and across cores. *TileLoom* first analyzes these opportunities and then decides how to allocate data to memories and when and where to issue copies as broadcasts over the NoC or as loading from global memories.

Reuse analysis on affine accesses. For a fixed spatial–temporal mapping (Section 2.2), the loop nest contains: spatial loops (`affine.parallel`) over hardware core indices; temporal loops (`affine.for`) over waves of tiles, and sequential loops (`scf.for`) inside each core, as shown in Listing 2.

[2]This sequential loop is also temporal, but we use "sequential" to distinguish intra-core sequencing from inter-tile temporal dimensions.

            memref.copy %reinterpret_cast_0, %alloc : memref<64x64xf32, strided<[512, 1], offset: ?>> to memref<64x64xf32>
            %5 = bufferization.to_tensor %alloc restrict writable : memref<64x64xf32> to tensor<64x64xf32>
            %6 = affine.apply affine_map<(d0, d1) -> (d1 * 32768 + d0 * 64)>(%block_id_y, %arg8)
            %reinterpret_cast_1 = memref.reinterpret_cast %arg1 to offset: [%6], sizes: [64, 64], strides: [512, 1] : memref<*xf32> to memref<64x64xf32, strided<[512,↩
        1], offset: ?>>
            %alloc_2 = memref.alloc() : memref<64x64xf32>
            memref.copy %reinterpret_cast_1, %alloc_2 : memref<64x64xf32, strided<[512, 1], offset: ?>> to memref<64x64xf32>
            %7 = bufferization.to_tensor %alloc_2 restrict writable : memref<64x64xf32> to tensor<64x64xf32>
            // Tile-wise computation, omitted
            linalg.xxx;
            linalg.yyy;
            scf.yield %9 : tensor<64x64xf32>
        }
    }
}
```

Listing 2: Loop structure after spatial–temporal mapping.

```
affine.parallel (%x, %y) = (0, 0) to (8, 8) {
  affine.for %tx = 0 to %grid_dim_x ceildiv 8 {
    affine.for %ty = 0 to %grid_dim_y ceildiv 8 {
      scf.for %k {
        // tile-wise computation
      }
    }
  }
}
```

The front-end expresses all memory accesses as affine functions of these loop indices. For each access, *TileLoom* inspects which induction variables appear in its affine expression. If an access does not depend on a spatial index such as `%x`, then the accessed tile is identical for all cores along that dimension and is spatially reusable there. If an access does not depend on a temporal loop variable such as `%tx`, then the same tile is used across all iterations of that temporal loop and is temporally reusable there. If the access depends only on sequential indices, then reuse is purely intra-core. *TileLoom* records this information as reuse annotations on the memory operations.

Spatial reuse and broadcasts. We begin from a conservative baseline in which every core loads its tiles directly from global memory (for example, an L2 cache or DRAM) in the innermost loop, with no explicit sharing across cores.

If a load has no spatial reuse then the tile is unique to each core, so the load must remain a per-core global memory operation. If a load is spatially reusable along one or more spatial dimensions, *TileLoom* can reduce global traffic by replacing many per-core loads with a smaller number of global loads, followed by broadcasts over the NoC.

In the simplest case, if a tile is reusable only along a single spatial dimension, a designated producer core (or a small group of producers) loads it once from global memory and forwards it along that dimension (for example, along each row of the mesh), while receiving cores buffer their local copies. When a tile is reusable along multiple spatial dimensions, there are several concrete ways to realize that reuse. One option is to first duplicate the tile across all rows (or columns) and then perform independent one-dimensional broadcasts along the parallel dimensions; another is to propagate the tile in a wavefront-style pattern that sweeps across the array. These choices expose different tradeoffs between NoC traffic, latency, and local buffer usage. Listin 3 shows one example candidate of the matrix multiplication mapped to the 2D-mesh example architecture (Figure 1 with a 2D dataflow where the A tiles are broadcasted for each row of cores through the horizontal links of the NoC and the B tiles for each column of cores through the vertical links (we will present the notion of network resources later in Section 2.4). The broadcast information is associated to the load instructions as annotations.

TileLoom does not fix a single strategy: it uses the network description from the hardware representation to enumerate the broadcast patterns that are legal, for each spatially reusable load, a small set of candidate implementations ranging from direct per-core global loads to one-dimensional and multi-dimensional broadcasts. *TileLoom* enumerate all the possibile combinations of all memory operations that creates a design space. Their different hardware costs will be taken into account later by the performance model to select the best ones.

Listing 3: Spatial Reuse

```
affine.parallel (x,y) = (0,0) to (8,8) {
  affine.for tm = 0 to M_waves {
    affine.for tn = 0 to N_waves {
      scf.for tk = 0 to K_tiles {
        load A[tm*8+x, tk]  {type="broadcast", resource={%noc_h}}
        load B[tk, tn*8+y]  {type="broadcast", resource={%noc_v}}
        // ...
      }
    }
  }
}
```

Temporal reuse and loop hoisting. Temporal reuse is realized by choosing the loop level at which a load (or broadcast) is issued. At this point, the loop order is fixed by the spatial–temporal mapping; but we can hoist loads outward so that the same tile is reused across more iterations, at the cost of retaining it longer in a local buffer.

Consider the simplified GEMM-like loop nest below in Listing 4 left, treated as one candidate loop order, `tm` → `tn` → `tk`: the access `A[tm, tk]` depends on `tm` and `tk`, but not on `tn`, so tiles of `A` are temporally reusable across the `tn`↩ loop. If we hoist the loads of `A` outside the `tk` loop, we must buffer all tiles `A[tm, *]` for the current `tm`. Because the address depends on `tk`, hoisting across `tk` enlarges the buffered region from a single tile `A[tm, tk]` to the entire strip `A[tm, 0..K_tiles-1]`. Hoisting further outward, above `tn`, keeps the same buffered strip but reuses it across all values of `tn`, as shown in Listing 4 right:

```
affine.for tm = 0 to M_tiles {
  affine.for tn = 0 to N_tiles {
    scf.for tk = 0 to K_tiles {
      load A[tm, tk]
      load B[tk, tn]
      // ...
    }
  }
}
```

```
affine.for tm = 0 to M_tiles {
  load A[tm, *]
  affine.for tn = 0 to N_tiles {
    scf.for tk = 0 to K_tiles {
      load B[tk, tn]
      // ...
    }
  }
}
```

Listing 4: Loop structures before and after hoisting.

In general, hoisting a load across a loop that the access does not depend on increases reuse without increasing the size of the buffered region, because the accessed tile is the same for all iterations of that loop. Hoisting across a loop that the access does depend on expands the buffered region in proportion to the extent of that loop, because more distinct tiles must be kept live simultaneously. *TileLoom* applies these rules to enumerate, for each load or broadcast, all legal hoisting levels. For each level it computes the required buffer footprint and discards options whose footprint exceeds the capacity of the hardware model.

Temporal vs. Spatial. Temporal reuse and spatial reuse are orthogonal. A tile can be reused only temporally (loaded once per core and reused across iterations), only spatially (broadcast once and immediately consumed), or in both ways (broadcast once and then reused across several temporal iterations). In all cases, the decision can be viewed as picking when a tile is first loaded or received and how long it remains live in local storage under a fixed loop order.

Combining these choices for all loads yields a concrete allocation and copy mapping: a description of which memory each tile resides in at each point in time and which NoC transfers occur. This schedule can be represented by a loop sctructure with annotations as shown a simplified example in Listing 5. Each memory load is annotated with the target buffer, the type of load (using NoC for broadcasting or simple global load), and the NoC resources required. *TileLoom* prunes mappings that violate memory-capacity constraints and passes the remaining candidates to the performance model, which evaluates their compute, memory, and network costs and selects the top-k mappings for back-end profiling.

Listing 5: Example dataflow-friendly MLIR snippet before selection for matrix multiplication kernel on the example 2D-mesh architecture.

```
affine.for tm = 0 to M_tiles {
  alloc A {target_buffer=%L1, size=K_tiles*block_M*block_K}
  load A[tm, *] {type="global", resources={%noc_h, %noc_v}}
  affine.for tn = 0 to N_tiles {
    alloc C {target_buffer=%L1, size=block_M*block_N}
    scf.for tk = 0 to K_tiles {
      alloc B {target_buffer=%L1, size=block_K*block_N}
      load B[tk, tn] {type="broadcast", resources={%noc_h, %noc_v}}
      // tile-wise computations
      load C
      linalg.matmul ...
      linalg.exp ...
      linalg.sqrt ...
    }
    store C {type="global". resources={%noc_h, %noc_v}}
  }
}
```

2.4 Hardware Representation

TileLoom is designed to target multiple dataflow architectures. To make mapping decisions, the compiler needs a structured description of the hardware: how cores are arranged in space, where memories are placed, how components are connected, and what compute resources are available at each location. *TileLoom* captures this information in a multi-layer hardware representation stack. Different layers of this stack are consumed by different stages of the compiler passes.

We encode this representation in a custom MLIR dialect, `df`. The dialect provides operators that describe the scale-out structure of the machine (cores and interconnects), the memory hierarchy and its connectivity, and the intra-core compute units. The performance model and the mapping passes process the program and the hardware description written this dialect together, rather than hard-coding any particular architecture.

Scale-out architecture. At the top level, the `df` dialect describes the spatial layout of cores and the on-chip interconnect. The following operators are needed:

`df.spatial_dim(size)` declares an abstract spatial dimension, used to index and replicate hardware components. Spatial dimensions naturally represent arrays of parallel resources such as cores or memories.

`df.core(scaleout, scalein)` declares a set of cores indexed by the dimensions listed in `scaleout`; the `scalein` of the operation contains the compute components that live inside each core (optional argument, used at a lower abstraction level, described later).

`df.interconnects(components, map, bandwidth)` declares a network (set of links) that connects a set of components according to an affine map `map` and `bandwidth` specifies the bandwidth per link.

These operators are used to describe the scale-out architecture used in the spatial–temporal mapping. For our example 2D-mesh architecture (Figure 1), we can describe it with:

This fragment describes an 8×8 array of cores connected by horizontal and vertical rings (or a torus). The modulo in the affine maps encodes wrap-around links. The spatial–temporal

Listing 6: 2D mesh with abstract scale-out.

```
%x = df.spatial_dim 8
%y = df.spatial_dim 8
%cores = df.core { scaleout = (%x, %y) }
%noc_h = df.interconnects %cores, %cores { map = affine_map<(d0, d1) -> ((d0 + 1) mod 8, d1)>,bandwidth = 28 }
%noc_v = df.interconnects %cores, %cores { map = affine_map<(d0, d1) -> (d0, (d1 + 1) mod 8)>, bandwidth = 28 }
```

mapping pass uses this scale-out description to map the logical tile grid onto physical cores (Section 2.2), and the performance model uses the `df.interconnects` operators to estimate communication cost and traffic congestion of the memory operations (Section 2.5).

Memories and data movement. When planning data movements (Section 2.3), *TileLoom* must reason about concrete buffers and how the network feeds data into them. To do so, the scale-out description is refined with explicit memories.

`df.memory(scaleout, size, bandwidth)` declares a set of memories indexed by the `scaleout` dimensions. Each instance has the given capacity and per-port bandwidth.

`df.mux(dst, bandwidth, srcs, map)` declares a 1-to-N connectivity between `dst` components and `srcs`, with topology specified by an affine `map`. This operator captures fan-out connections such as "each core can access its local scratchpad" or "groups of cores share a DRAM channel".

A lowered version of the 2D-mesh description that includes L1 memories and DRAM is shown in Listing 7:

Listing 7: 2D mesh with scale-out cores, scratchpads, and DRAM.

```

%x = df.spatial_dim 8
%y = df.spatial_dim 8
%cores = df.core {scaleout=(%x, %y)}
// Per-core scratchpad memories.
%L1 = df.memory {scaleout=(%x, %y), size = 1499136, bandwidth = 60}
// Connect each core (x, y) to its local L1(x, y).
%core_to_L1 = df.mux %cores, %L1, {map = affine_map<(d0, d1) -> (d0, d1)>}
// On-chip NoC now connects L1 memories.
%noc_h = df.interconnects %L1, %L1, {map = affine_map<(d0, d1) -> ((d0 + 1) mod 8, d1)>, bandwidth = 28}
%noc_v = df.interconnects %L1, %L1, {map = affine_map<(d0, d1) -> (d0, (d1 + 1) mod 8)>, bandwidth = 28}
// Off-chip DRAM channels, indexed by a 1D spatial dimension.
%dram_idx = df.spatial_dim 4
%drams = df.memory {scaleout = %dram_idx, size = 12884901888, bandwidth = 267}
// Map each group of 4x4 edge cores to a DRAM channel.
%to_dram = df.interconnects %L1, %drams {map = affine_map<(d0, d1) -> (d0 ceildiv 4 + 2 * (d1 ceildiv 4))>, bandwidth = 30}
```

This representation now distinguishes the physical buffers that can hold tiles. For example, it specifies that each core `(x, y)` has an L1 scratchpad of around 1.5 MB, and that inter-core traffic flows between L1s rather than directly between cores. It also encodes DRAM channels are connected: every group of four adjacent cores along each edge shares the same DRAM bank, as in Figure 1. When *TileLoom* chooses where to buffer a tile and the costs of memory operations, it uses these `df.memory`, `df.mux`, and `df.interconnects` operators. As shown earlier in Listing 5, load instructions are annotated with bindings to these physical resources.

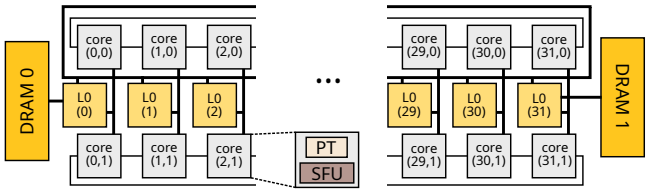

Figure 3: Example 1D triple-ring architecture modeled with the `df` dialect.

Intra-core compute model. To drive the performance model down to the level of individual cores, *TileLoom* needs a coarse description of the microarchitecture within each core. The `df` dialect provides operators for this purpose:

`df.mat(shape, throughput)` declares a matrix unit (for example, a tensor core) with a given input shape and sustained throughput.

`df.vec(shape, throughput)` declares a vector unit with the given vector width and throughput.

`df.scalar(latency)` declares a scalar unit with a given latency for scalar operations.

Each unit is assumed to accept operands of the specified shape and to produce results at the given throughput. These units are then attached to cores via the `scalein` argument of `df.core`, which describes the internal composition of each core. The lowest-level version of the 2D-mesh description therefore extends the previous listing with intra-core units:

Listing 8: Extra specifications of the intra-core architecture

```
%FPU = df.mat {shape=[32, 32, 32], throughput=98}
%SFPU = df.vec  {shape=[32], throughput=3}
%cores = df.core {scaleout = (%x, %y), scalein=(%FPU, %SFPU, [8, 1])}
```

With this information, the performance model can reason about the timing of both compute and memory. It can, for example, estimate how many cycles a particular tile-level matmul consumes on the matrix units and whether the NoC bandwidth and the L1 buffer are sufficient to keep them fed.

Expressiveness beyond 2D meshes. Although we have used the Tenstorrent-2D-mesh architecture as example, `df` can describe other spatial dataflow architectures. For instance, a 1D triple-ring topology similar to the IBM-Spyre accelerator as shown in Figure 3 can be described using `df` program as shown in Listing 9 .

Discussion We structure the hardware representation as a stack of layers of abstractions because each compiler pass should depend only on the level of detail it actually needs. Spatial–temporal mapping requires only the scale-out structure of cores and the topology and bandwidth of the interconnect. Data-movement planning additionally needs to know where memories are placed and how they are wired to compute and to DRAM. The fine-grain performance model, in

Listing 9: Example of the df dialect describing a 1D triple-ring architecture.

```
module {
    // functional units
    %PT = df.mat {shape = [128, 128, 128], throughput=16384}
    %SFP = df.vec {shape = [128], throughput=128}
    // scale-out
    %x = df.spatial_dim 32
    %y = df.spatial_dim 2
    %cores = df.core "cores" {scaleout=(%x, %y) , scalein=(%PT, %SFP, [1,1])}
    %L1 = df.memory {scaleout=(%x) , size = 2097152, bandwidth = 128}
    %core_to_mem = df.mux %cores, %L1, {map = affine_map<(d0, d1) -> (d0)>}
    %small_rings = df.interconnects %cores, %cores, {map = affine_map<(d0, d1)
        -> ((d0 + 1) mod 8, d1)>, bandwidth = 32}
    %big_ring = df.interconnects %L1, %L1, {map = affine_map<(d0) -> ((d0 + 1)
        mod 8)>, bandwidth = 258}
    // Global (DRAM/L2)
    %d = df.spatial_dim 2
    %dram = df.memory {scaleout=(%d) , size = 34359738368, bandwidth = 512}
    %to_dram = df.interconnects %dram, %L1, {map = affine_map<(d0)->(d0*31)>}
}
```

turn, needs a high-level view of intra-core compute units and their throughputs. This separation improves the reusability of the compiler. Changing the on-chip network, the memory hierarchy, or the per-core microarchitecture amounts to modifying the `df` description, without rewriting the optimization passes and the rest of hardware description. It also creates a bridge from software-level mapping decisions to hardware-level design trade-offs. Starting from the lowest abstraction level, the same representation can be refined further to include implementation-specific costs such as area and power, enabling combined design space exploration over both mappings and hardware configurations—an important capability for spatial dataflow architectures, where the architecture itself varies widely across generations and vendors.

2.5 Performance Modeling

After spatial–temporal mapping and data reuse / allocation decisions, *TileLoom* has a set of candidate dataflow schedules. Each candidate is represented as an MLIR program in which loop nests, memory operations, and data movements (global loads, broadcasts, buffered loads) are fully specified, and every memory or network operation is bound to concrete hardware resources described in the `df` dialect (Section 2.4). A simplified example is shown in Listing 5. The role of the performance model is to estimate the execution time of each candidate, using the compute units, memories, and interconnects defined in the `df` description, and then select the top-k candidates for downstream code generation and profiling.

Figure 4 illustrates how the performance model evaluates the overall execution time of the example in Listing 5. It evaluates from the innermost loop outward, aggregating compute, memory, and network costs hierarchically.

Compute cost per loop body. We first estimate the execution time of the innermost loop body, treating it as a block-level program running on a single core. For a given tile shape, every high-level operator (for example, a `linalg.matmul`) is decomposed into the core's low-level compute intrinsics. The available matrix, vector, and scalar units and their throughputs come from the `df.mat`, `df.vec`, and `df.scalar` units attached to that core via `df.core` (Section 2.4).

For each operator, *TileLoom* uses its `linalg` semantics to recover the parallel iteration space. This tells us, for each functional-unit type, how many intrinsic invocations of that type are independent and can, in principle, be issued in parallel. We then conceptually schedule these intrinsics onto the available parallel units of the same type: if there are N independent instances mapped to a unit type with U identical units, each capable of issuing r intrinsics per cycle, we approximate the operator's time contribution on that unit type as $N/(U \cdot r)$ cycles.

TileLoom then accounts for data dependencies and resource sharing among different unit types. Operators that are independent and target different unit types (for example, a matrix multiply on a matrix unit and a pointwise activation on a vector unit) can execute in parallel, whereas dependent operators or operators that compete for the same unit type must execute in sequence. The loop-body compute time is approximated as the sum over sequential segments, where each segment's time is the maximum over all operators that can run in parallel within that segment.

The potential parallelism exposed by this model is not necessarily fully achievable on a concrete microarchitecture, but the model does not attempt to exactly simulate the core's instruction scheduler. Instead, it is calibrated to be accurate enough to distinguish compute-bound from memory-bound mappings and to reason about overlap between compute and data movement. In our experiments, this coarse-grain modeling of compute is sufficient to discriminate between different dataflow schedules.

Compute–memory Overlap. Once we have an estimate for the loop body, we incorporate data movement. Let T_{load} be the time spent on all loads in one iteration of the loop body, T_{compute} the compute time (from the previous step), and T_{store} the time spent on all stores. We assume that each iteration executes as a pipelined load–compute–store sequence with double buffering: while iteration i is computing, the stores for iteration $i-1$ and the loads for iteration $i+1$ proceed in parallel whenever possible.

For an innermost loop with I iterations, the total execution time is approximated as:

$$T_{\text{loop}} \approx (I-2)\cdot \max\big(T_{\text{load}}+T_{\text{store}},\, T_{\text{compute}}\big) + \max\big(T_{\text{load}},\, T_{\text{compute}}\big) + \max\big(T_{\text{store}},\, T_{\text{compute}}\big) + T_{\text{load}} + T_{\text{store}}.$$

The first term accounts for the $I-2$ steady-state iterations, where load, compute, and store can overlap and the throughput is limited by the slower of T_{compute} and $T_{\text{load}}+T_{\text{store}}$. The remaining terms account for filling and draining the pipeline. This behavior is illustrated in Figure 4, where the k-body is executed in parallel with loading the next tile of B and storing the result tile of C from the previous iteration.

Concurrent data transfers and network traffic. Several

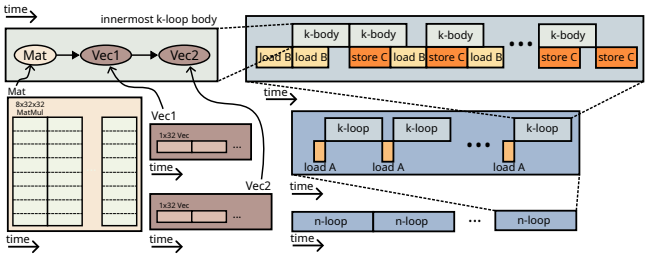

Figure 4: Example Evaluation of Pipelined execution.

memory operations may occur simultaneously and create traffic contention over the NoC. *TileLoom* estimates the effective bandwidth of each memory operation under this contention, using both the interconnect structure described in the hardware representation and the mapping annotations attached during memory operation mapping (Section 2.3). At that mapping step, each load or store is lowered either to a global load/-store or to a broadcast pattern, and the compiler records which subsets of the network it uses. For global loads, we assume accesses are sufficiently random that traffic is spread across the NoC links. For broadcasts, the resources used depend on the chosen pattern: on the 2D-mesh example, a broadcast that is performed independently along each row uses only the horizontal ring links (such as `%noc_h`), whereas a broadcast over the entire mesh may exercise both horizontal and vertical rings (both `%noc_h` and `%noc_v`). These choices are fixed during memory operation mapping and appear as annotations, as in Listings 3 and 5. Given these annotations, the performance model groups memory operations according to the network links and memory interfaces they occupy. For each group of operations that share a particular subset of links, it aggregates their offered traffic and derives an effective bandwidth per transfer by partitioning the nominal link bandwidth among them. Equivalently, the bandwidth seen by any one operation is reduced in proportion to the number of concurrent transfers using the same links or banks. The transfer time for each load or store is then computed from its tile size and effective bandwidth. The per-iteration load and store times, T_{load} and T_{store}, are obtained by combining these transfer times across operations, treating transfers on disjoint link sets as running in parallel and transfers on overlapping link sets as time-sharing the same resources. These T_{load} and T_{store} values are then plugged into the pipelined overlap model described above.

Candidate ranking through auto-profiling. *TileLoom*'s optimizations are highly dependent on the accuracy of the architectural models. When the architectural and micro-architecral information is not accurate enough, *TileLoom* supports a profiling-based autotuning step to maintain its performance. Concretely, for each candidate schedule, *TileLoom* combines the compute and data-movement estimates with the architectural model to obtain an approximate end-to-end execution time. This time reflects the balance between compute and communication, the benefit of spatial and temporal reuse, and the impact of NoC and memory contention on the concrete hardware described by `df`. *TileLoom* then ranks all candidates by this estimated time and keeps only the top-k dataflow mappings. Only these top-k candidates are handed to the back-end for full code generation and on-hardware profiling, where the final best-performing configuration (top-1) is selected. The choice of k controls the trade-off between compile time and the likelihood of including the true optimum: a larger k explores more mappings but costs more compilation and profiling time. We study this trade-off in Section 3.3.4.

3 Evaluation

3.1 Experimental Setup

Hardware platform. We conduct our experiments on Tenstorrent Wormhole and Blackhole cards. Table 1 summarizes the relevant hardware specifications. We compile *TileLoom* programs on a host machine equipped with dual 16-core Intel Xeon Gold 6326 CPUs and 512 GB of DRAM.

Table 1: Specifications of the Tenstorrent Wormhole and Blackhole used in our evaluation.

	TT-Wormhole	TT-Blackhole
Topology	8×8	12×10
On-chip SRAM	108 MB	180 MB
DRAM	12 GB GDDR6	32 GB GDDR6
Off-chip bw.	288 GB/s	512 GB/s
TFLOPS (FP16)	64	162
TBP	160 W	300 W
Technology Node	GF 12nm [52]	TSMC 6nm [53]

Architecture targets and modeling. Each Wormhole and Blackhole chip contains a 2D array of cores, with 8×8 cores on Wormhole and 12×10 cores on Blackhole, as shown in Figure 1. We model the Tenstorrent architecture in the `df` dialect, as described in Figure 1 and Section 2.4. Because the complete proprietary hardware specification is unavailable, we recover key parameters through isolated microbenchmarks, including matrix/vector-unit throughput and effective NoC and DRAM bandwidths. We instantiate these measured values in the `df` hardware representation used by *TileLoom*'s performance model.

Frontend. *TileLoom* currently supports Triton and Helion as kernel-development frontends. Although the core compiler is frontend-agnostic, our experiments use either Triton or Helion depending on kernel availability; the source code for all input kernels is available in our GitHub repository. For both frontends, we tune the tile, or block, shape using their existing Python-based autotuning stacks. For Triton, we use *triton-shared* [44] to lower kernels into MLIR, then apply a custom affinization pass that rewrites index arithmetic into affine expressions, followed by normalization into our dataflow-

agnostic MLIR format, as shown in Figure 2. For Helion, after Python-level tuning, we lower Helion Device IR into the same standard MLIR format using our custom lowering tool.

Backend. We lower our dataflow-aware MLIR to TT-Metalium, Tenstorrent's low-level C API, to generate the final executable, as shown in Figure 2. TT-Metalium exposes coarse-grained primitives for computation, synchronization, buffer allocation, and data movement, and handles most block- and core-level optimizations. *TileLoom* bridges the dataflow-level program and TT-Metalium by performing lifetime analysis over the block-level compute graph, using the resulting lifetimes to determine buffer allocation and synchronization among memory, compute, and data-movement operations. TT-Metalium then lowers these coarse-grained operations to hardware instructions.

3.2 End-to-End Performance

Table 2 reports the geometric mean of the relative performance of *TileLoom* over TTNN on four representative kernels: GEMM, FlashAttention, Flash Decode, and Mamba Chunk Scan linear attention. For each kernel, we evaluate a range of input shapes. The detailed shape-by-shape results are discussed in the corresponding subsections below. In this section, we report the performance of the top-ranked candidate selected by *TileLoom*'s performance model, without the final profiling-based tuning step. Therefore, the reported speedups come solely from *TileLoom*'s architectural modeling and dataflow-planning strategy.

Table 2: Relative performance of *TileLoom* over TTNN on GEMM, FlashAttention, Flash Decode, and Mamba Chunk Scan linear attention.

TileLoom vs. TTNN	Wormhole	Blackhole
vs. library implementation		
FlashAttention	1.94x	1.98x
Flash Decode	0.84x	0.87x
GEMM	0.95x	1.10x
vs. unfused implementation		
Mamba Chunk Scan	27.23x	16.27x

3.2.1 FlashAttention

We evaluate *TileLoom* on non-causal FlashAttention against the native TTNN implementation. The non-causal variant exposes more dataflow-optimization opportunities than the causal variant, making it a useful stress test for *TileLoom*'s spatial mapping strategy. We vary the number of attention heads between 64 and 128, sweep sequence length from 1024 to 16384, and adjust batch size to fit within DRAM capacity. As shown in Figure 5, *TileLoom* consistently achieves substantial speedups over TTNN, with 1.88–2.06× improvement in nearly every configuration. The gains come from exploiting reuse in the attention operands: *TileLoom* places tiles so that key tiles are reused on chip across multiple query and value tiles, reducing DRAM traffic compared with TTNN's default mapping, which repeatedly reloads these operands from DRAM.

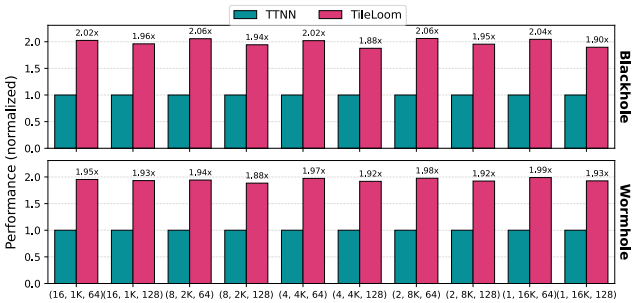

Figure 5: Relative Performance with *TileLoom* vs. TTNN on FlashAttention with parameters (batch size B, sequence length L, number of heads N).

3.2.2 FlashDecode

Flash Decode is algorithmically a special case of FlashAttention with query length one, but this changes the hardware mapping problem significantly. In full FlashAttention, *TileLoom* can exploit parallelism across query blocks and heads, while choosing mappings that improve key/value tile reuse. In Flash Decode, the query dimension no longer offers spatial parallelism, so parallelism mainly comes from the batch dimension and from splitting the key/value reduction across cores.

This yields a much smaller dataflow-planning space: there are fewer ways to distribute independent output tiles, and the main optimization is partitioning the key/value sequence and orchestrating the cross-core gather-reduce. Thus, this benchmark stresses *TileLoom*'s generated block-level code and reduction orchestration more than its ability to choose among diverse dataflow mappings.

As shown in Figure 6, *TileLoom* does not outperform the TTNN Flash Decode baseline, which is expected because TTNN uses scheduling and reduction optimizations specifically tuned for this operator. In contrast, *TileLoom* generates its implementation through a general compiler stack starting from tile-level kernel code. Even so, *TileLoom* achieves about 85% of TTNN performance on average, showing that it can produce competitive code even with limited dataflow optimization opportunity and a highly specialized vendor baseline.

3.2.3 Mamba Chunk Scan

Mamba Chunk Scan is a linear-attention kernel with substantial intra-block computation and nontrivial data movement.

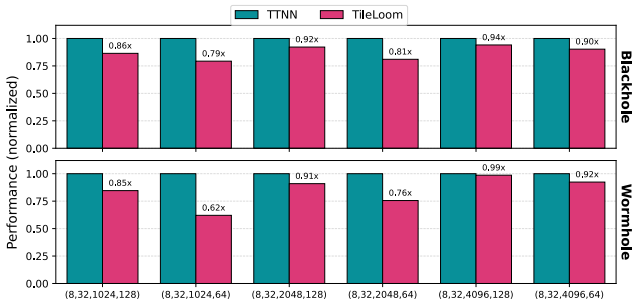

Figure 6: Relative performance of *TileLoom* compared with TTNN on Flash Decode with parameters (batch size B, head dimension H, sequence length L, hidden dimension D).

Since TTNN does not provide a fused implementation, we build the TTNN baseline by composing existing TTNN operations, yielding an unfused implementation. In contrast, *TileLoom* uses a fused tile-level Helion kernel.

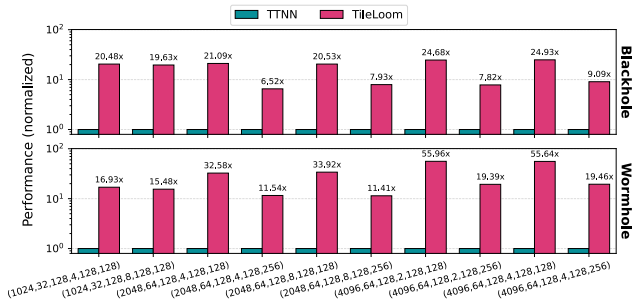

Figure 7: Relative performance of *TileLoom* vs. an unfused TTNN implementation on Mamba Chunk Scan with parameters sequence length L, number of heads N, head dimension H, number of groups G, hidden dimension D, and chunk size C.

This comparison shows a practical advantage of supporting tile-level kernel languages: fused kernels are often easier to obtain than highly optimized vendor-library implementations. Thus, *TileLoom* can generate efficient fused code even when the vendor library only exposes lower-level building blocks. As shown in Figure 7, *TileLoom* achieves 10x–55x speedup over the unfused TTNN baseline, reflecting both kernel fusion and *TileLoom*'s dataflow planning.

This large gap is typical between fused and unfused kernels, and similar trends appear in Tenstorrent's official technical reports. It is especially pronounced on dataflow architectures, which rely on on-chip NoC bandwidth for reuse and often have less off-chip bandwidth than HBM-based GPUs. Fusion and dataflow planning are therefore critical: without them, intermediate tensors are repeatedly written to and read from off-chip memory, causing severe slowdowns.

3.2.4 GEMM

We evaluate GEMM on over M, K, and N, ranging from 256 to 16384. GEMM is a key primitive, and the TTNN vendor implementation is already highly optimized, achieving about 70% of peak hardware throughput on average. Against this strong baseline, Table 2 shows that *TileLoom* delivers comparable performance using tile-level kernels while automatically generating low-level implementations.

For a more interpretable comparison, Figure 8 also reports two TTNN dataflow templates, TT-1D and TT-2D. TT-1D uses a 1D broadcast pattern: each core loads the smaller input matrix from global memory, while the other input is broadcast across the entire array. TT-2D uses a 2D broadcast pattern, streaming the two inputs across the mesh from the top and left. TTNN selects between these templates using a shape-dependent heuristic, with block size chosen by a separate strategy.

Figure 8 shows that *TileLoom* remains competitive with TTNN across the full GEMM sweep. This is notable because TTNN uses manually optimized library kernels, whereas *TileLoom* starts from tile-level kernels and searches the mapping space automatically. The TT-1D and TT-2D results show that fixed dataflows work well for regular GEMM shapes, where M, K, and N are similar, but can degrade on irregular shapes where the best mapping depends more sensitively on dimensions and hardware balance.

3.2.5 Shape Sensitivity on Irregular GEMM

To study shape sensitivity, we evaluate two irregular GEMM families. First, we fix $M = N = 32768$ and vary K from 256 to 2048. Second, we fix $M = K = 32768$ and vary N over the same range. Figure 9 shows the results.

When varying K (Figure 9a), *TileLoom* and TTNN follow trends similar to the 1D and 2D baselines. This is expected because K is mapped sequentially within each core, so changing it mainly affects intra-core compute cost and leaves limited room for inter-core dataflow optimization.

In contrast, varying N (Figure 9b) significantly changes the preferred dataflow. As N approaches M, the workload becomes more balanced across rows and columns, making 2D-like broadcast more attractive due to reuse along both mesh dimensions. When N is much smaller than M, 1D-like strategies are more effective, as reflected by the TT-1D and TT-2D results.

The transition between 1D- and 2D-favorable regimes depends on block size, compute-to-memory ratio, NoC overhead, and other hardware factors. This sensitivity motivates *TileLoom*'s cost-model-guided search, which accounts for spatial reuse, communication volume, and architectural constraints instead of relying on fixed heuristics.

These irregular-shape results also reveal a limitation of TTNN's heuristic selection: TTNN does not always choose

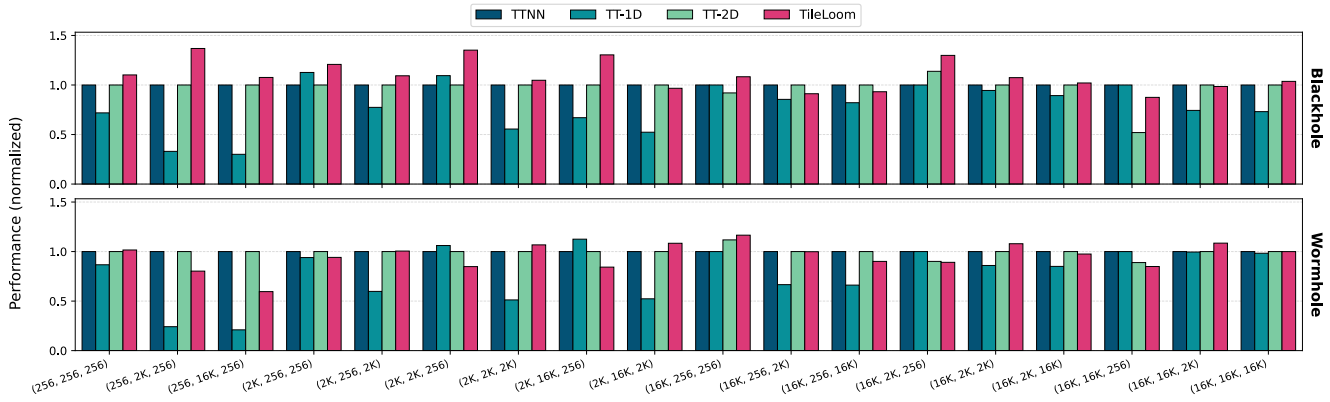

Figure 8: GEMM performance of *TileLoom* compared with TTNN. TT-1D and TT-2D are included as reference dataflow templates.

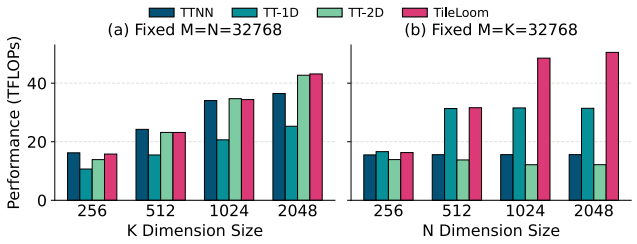

Figure 9: Performance comparison for GEMM under irregular input shapes.

the faster of its two templates. For example, in small-N, large-M cases, TTNN selects TT-2D even though TT-1D is faster, such as $M,K,N = 32K,32K,512/1024$. Our inspection suggests this comes from fixed thresholds over ratios such as M/N. Near these thresholds, the best strategy can also depend on tile size, bandwidth, and NoC cost, but the heuristic still makes a hard ratio-based decision.

In contrast, *TileLoom* searches beyond the two TTNN templates, exploring how logical dimensions map to spatial dimensions, where memory operations are hoisted in the loop nest, and which block sizes to use. This broader search allows *TileLoom* to find mappings that outperform both TTNN templates, as shown in Figure 8.

3.2.6 Wormhole vs. Blackhole

TileLoom generally achieves larger relative gains on Blackhole than on Wormhole. This is because Blackhole increases compute throughput more than off-chip bandwidth: peak FP16 throughput improves by 2.53×, while off-chip bandwidth improves by only 1.78× (Table 1). This shift makes kernels more likely to become memory-bound, increasing the value of *TileLoom*'s dataflow optimizations, which improve spatial reuse and reduce off-chip traffic.

GEMM shows this trend most clearly. On Wormhole, *TileLoom* reaches 0.95× TTNN performance. Profiling shows that GEMM is often compute-bound on Wormhole, so reducing off-chip traffic has limited end-to-end benefit. In addition, *TileLoom* starts from tile-level kernels and does not yet include all microarchitecture-specific optimizations used in TTNN's hand-tuned GEMM library, explaining the remaining 5% gap.

On Blackhole, the same GEMM evaluation improves to 1.10× over TTNN. Blackhole's higher compute-to-bandwidth ratio makes GEMM more sensitive to memory traffic and placement, allowing *TileLoom*'s dataflow planning to provide greater benefit. This shows that while *TileLoom* may not always beat a vendor GEMM library on a compute-limited device, its architectural modeling and spatial-reuse optimizations become more valuable as hardware shifts toward higher compute density.

3.3 Ablation Studies

3.3.1 Effect of Spatial Reuse

We quantify how much of *TileLoom*'s GEMM performance comes from spatial reuse by disabling the spatial-reuse pass and forcing all operands to be loaded from DRAM. Table 3 reports absolute performance with and without this optimization. Spatial reuse gives the largest gains on smaller GEMMs, where DRAM traffic is a major bottleneck. As size grows, the benefit decreases, consistent with the roofline model [69]: GEMM arithmetic intensity increases with matrix size, making larger problems more compute-bound. Once performance is limited by peak compute, reducing DRAM traffic has diminishing runtime impact.[3] Still, spatial reuse substantially reduces memory pressure: across these GEMM configurations, it cuts DRAM accesses by 70% on average. This does not

[3] Across all GEMM measurements, including configurations not shown here, effective throughput stabilizes around 45 TOP/s, indicating that many configurations operate near the compute roof.

always translate to proportional speedup in compute-bound regimes, but can improve memory headroom, reduce power, and leave more bandwidth for concurrent workloads.

Table 3: GEMM performance (TFLOP/s) on Wormhole with (*TileLoom*) and without (DRAM only) spatial reuse.

Configuration	DRAM only	*TileLoom*	Speedup
M=K=N=1024	11.15	23.70	2.12×
M=K=N=2048	16.77	33.96	2.03×
M=K=N=4096	22.96	40.44	1.76×
M=K=N=5120	29.19	41.61	1.42×
M=K=N=6144	28.22	42.47	1.51×

3.3.2 Effect of Temporal Reuse

Figure 10 shows the impact of temporal reuse across GEMM shapes. Temporal reuse buffers tiles locally so the same A or B tiles are reused across iterations instead of repeatedly loaded from DRAM.

We compare *TileLoom* with and without temporal reuse over different M and N values. As with spatial reuse, this optimization is most useful in memory-bound regimes, so we decrease K as M and N grow to keep the configurations memory-bound. In this setting, temporal reuse yields speedups up to 1.12×. The benefit increases with M and N, since larger dimensions create more opportunities to reuse the same A or B tiles. Thus, temporal reuse is most helpful when M or N is large and K is small. When it provides little benefit, *TileLoom*'s performance model deprioritizes those mappings, resulting in the same selected mapping and performance as the baseline without temporal reuse.

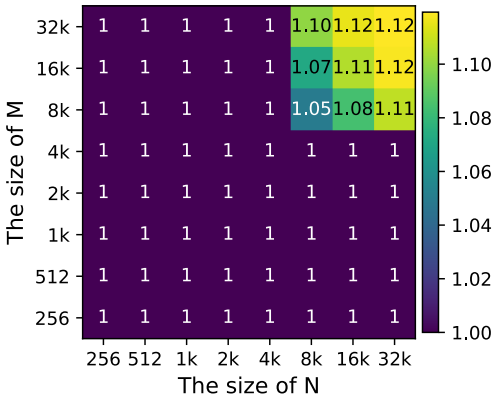

Figure 10: Normalized GEMM performance on Wormhole with and without temporal reuse.

3.3.3 Accuracy of *TileLoom*'s Performance Model Alone

We validate *TileLoom*'s performance model on Wormhole by comparing predicted throughput with measured GEMM performance across a wide range of (M,N,K) configurations. Figure 11 plots both estimates and measurements.

The predictions differ from measurements by 17% in geometric mean. However, the goal is not cycle accuracy, but reliable ranking and trend prediction, especially for transitions between memory- and compute-bound regimes as described by the roofline model [69]. As shown in Figure 11, the model captures these transitions well: it identifies when configurations become compute-bound and reflects the relative performance changes across shapes.

The end-to-end results in Table 2 and 4 further show that this error has limited impact on mapping selection. The model is accurate enough to rank candidates effectively, leaving the final optional profiling stage to choose among a small set of high-quality mappings.

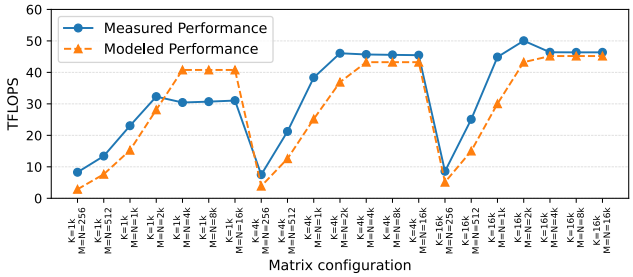

Figure 11: Validation of *TileLoom*'s performance model against measured GEMM performance.

3.3.4 Effect of top-k tuning and different topologies

As discussed in Section 2.5, *TileLoom* can optionally profile the top-k candidates generated by the compiler and select the best one. Thus, k trades compilation cost for final performance. We vary k from 1 to 5 and report geometric-mean normalized performance on Wormhole, along with compile time across hardware topologies, in Table 4. Here, top-1 means fully static compilation with only the best-predicted mapping, while larger k values add more profiled candidates.

We evaluate three topologies to test sensitivity to available parallelism and communication structure. The 8×8 mesh uses the full Wormhole core array, while the 4×8 mesh and 1×8 ring model smaller subsets. These reduced topologies change the balance between compute, NoC communication, and off-chip bandwidth, stressing whether mappings predicted for the full mesh remain effective under more constrained layouts.

Overall, k has a modest effect on performance. On the 8×8 mesh, top-5 outperforms top-1 by 7%, with most of the gain already achieved at top-2, which improves performance by 4.7%. The remaining gap mainly comes from occa-

sional model misrankings, where the predicted-best mapping is slightly worse than another candidate. In practice, a small k, such as 2 or 3, is usually enough to include the best mapping while keeping compile time moderate.

Similar trends hold on smaller topologies. The 1×8 ring is least sensitive to k because its restricted layout leaves fewer strong mappings to distinguish. The 4×8 and 8×8 meshes expose larger search spaces, so profiling a few extra candidates helps more. However, gains saturate quickly: beyond top-3, performance improves only marginally while compile time grows nearly linearly. This suggests that *TileLoom*'s static model effectively narrows the search to a small set of promising mappings, and a small profiling budget recovers most available performance across topology scales.

Table 4: Geometric-mean normalized performance (relative to TTNN) and compile time (seconds) of *TileLoom* under different top-k profiling settings. Top-1 corresponds to fully static compilation without additional profiling.

	1×8 Ring	4×8 Mesh	8×8 Mesh
top-1	-1.3% (6.36)	-5.4% (5.53)	-6.1% (5.75)
top-2	-1.3% (12.70)	-0.8% (11.29)	-1.4% (11.17)
top-3	-1.2% (19.07)	+0.5% (17.16)	-0.5% (16.65)
top-4	-0.4% (25.47)	+1.1% (23.03)	+0.4% (22.17)
top-5	-0.3% (31.82)	+1.3% (28.91)	+0.9% (27.66)

4 Related Works

Hardware modeling and co-design. There exist works on modeling and co-design of spatial accelerators: CGRAs, spatial FPGAs, and systolic arrays, where the computes and control are at a finer granularity than *TileLoom*. Languages and frameworks such as Spatial [31], Plasticine [56], T2S [59], Halide(-to-Hardware) [57], and HeteroCL [35] compile loop nests or functional pipelines into arrays of processing elements (PEs) and local memories, often co-designing the overlay itself. Polyhedral and tensor-centric systems such as AutoSA [65], TensorLib [24], and Rubick [39, 41] similarly start from affine loop nests or tensor expressions and derive space–time mappings that synthesize systolic or tensor arrays, buffers, and controllers. Co-design tools like Timeloop/Accelergy [51] and AMOS [74] explore dataflows, tilings, and memory hierarchies for DNN accelerators, while MAESTRO/-MAERI [32, 33] analytically model buffer and network usage for specialized systolic-style designs. In all of these systems, the modeling unit is a PE, buffer, or loop level in the memory hierarchy, and the goal is to search or synthesize hardware at that granularity. *TileLoom*, in contrast, assumes intra-core microarchitecture and local mapping are fixed, treats each core as the atomic unit, and models only the multi-level memory system and NoC *between* cores to decide how tile instances are distributed across space and time.

Software mapping and compilation for spatial architectures. On the software side, classical CGRA and FPGA flows treat mapping as a place-and-route problem on a PE-level dataflow graph: frameworks such as DSAGEN [67], ML-oriented CGRA compilers like ML-CGRA and MLIR-to-CGRA [40, 72], and architecture-agnostic mappers such as Morpher [68] and CaSMap [42] perform placement, routing, and modulo scheduling onto a fixed fabric. Loop- and polyhedral-based tools including Timeloop/Accelergy [51], and MAESTRO/MAERI [32, 33] reuse loop schedules or space–time mappings as the scheduling representation but are primarily design-space exploration tools: they evaluate mappings analytically. Research compilers for specific spatial architecture, such as AMOS [74], LISA [37], and system-level compilers for wafer-scale fabrics [20, 62], do generate per-core programs and communication schedules, but are typically tailored to a particular architecture family with baked-in mapping heuristics.

5 Conclusion

TileLoom demonstrates that compiler-driven mapping can deliver competitive performance on spatial dataflow accelerators while substantially reducing the need for hand-written, hardware-specific kernels. Starting from high-level tile-centric kernels, TileLoom automatically selects spatial and temporal mappings, data-reuse strategies, and communication patterns using a dataflow dialect that uniformly represents cores, memories, and interconnect.

Across Tenstorrent Wormhole and Blackhole, TileLoom achieves strong results on FlashAttention, Mamba Chunk Scan, GEMM, and Flash Decode. It outperforms TTNN when dataflow planning and fusion expose substantial opportunities, and remains competitive with highly optimized vendor implementations when the optimization space is more constrained. These results show that many decisions traditionally embedded in hand-engineered kernels can instead be handled by a reusable compiler stack, making optimized kernel development more accessible and providing a foundation for future spatial dataflow architectures.

Abstract

We introduce Mirage Persistent Kernel (MPK), the first compiler and runtime system that automatically transforms multi-GPU model inference into a single high-performance mega-kernel. MPK introduces an SM-level graph representation that captures data dependencies at the granularity of individual streaming multiprocessors (SMs), enabling cross-operator software pipelining, fine-grained overlap of computation and communication, and other optimizations that are infeasible under the conventional kernel-per-operator execution model. The MPK compiler lowers tensor programs into optimized SM-level task graphs and generates fast CUDA implementations for each task, while the MPK in-kernel parallel runtime executes these tasks within a single persistent mega-kernel using decentralized scheduling across SMs. Together, these components provide end-to-end kernel fusion with minimal developer effort, while preserving the flexibility of existing programming models. Our evaluation shows that MPK significantly outperforms existing kernel-per-operator LLM serving systems, achieving up to 1.7× lower end-to-end inference latency and pushing LLM inference performance close to the limits of the underlying hardware. MPK is publicly available at https://github.com/mirage-project/mirage.

1 Introduction

Enabling high-performance inference of ML models on GPUs is critical for modern AI applications, since inference latency directly affects both user experience and serving cost. Today's ML systems generally express model computation as a tensor program structured as a directed acyclic graph, whose nodes denote tensor algebra operators (e.g., matrix multiplication) and whose edges represent tensors, i.e., the n-dimensional arrays produced and consumed by these operators.

Most existing systems execute each operator using a dedicated GPU kernel, either hand-optimized by domain experts [18, 43] or generated automatically by ML compilers [15, 36, 41]. However, this *kernel-per-operator* execution model limits several key cross-operator GPU optimizations.

First, modern GPUs impose an implicit *kernel barrier* between consecutive launches on the same stream to ensure that all threads from the previous kernel complete before any thread from the next kernel begins. While this mechanism correctly enforces data dependencies, it prevents *cross-operator software pipelining* and forces dependent operators to execute strictly sequentially. NVIDIA recently introduced *programmatic dependent launch* (PDL) [11], which allows partial overlap between kernels on the same stream. However, adopting PDL requires significant engineering effort, as it fundamentally alters kernel structure and control flow.

Second, the kernel-per-operator execution model prevents fine-grained compute-communication overlap. Since dependencies are represented only at the coarse granularity of operators, the runtime must enforce full-operator completion before launching dependent communication or computation. For example, when a matrix multiplication is followed by an all-reduce in separate kernels, the all-reduce must wait for the entire matrix multiplication to complete, even though each fragment of the all-reduce depends only on a subset of the multiplication output. Exploiting such opportunities requires representing and enforcing dependencies at a granularity finer than individual kernels.

Finally, kernel-per-operator execution may require launching hundreds to thousands of kernels for each inference iteration. To reduce launch overhead, current systems rely heavily on *CUDA Graphs*, which capture a sequence of GPU operations and replay them with low overhead. However, CUDA Graphs are largely static: any changes to control flow, tensor shapes, or data dependencies require re-instantiating or modifying the captured graph, limiting their flexibility for the dynamic workloads commonly seen in model inference.

A promising approach to overcoming these limitations is to fuse all computation and communication of model inference into a single *mega-kernel*, also known as a *persistent kernel*. In this design, the system launches one GPU kernel to execute the entire model, including layer computations and inter-GPU

*Equal contribution.

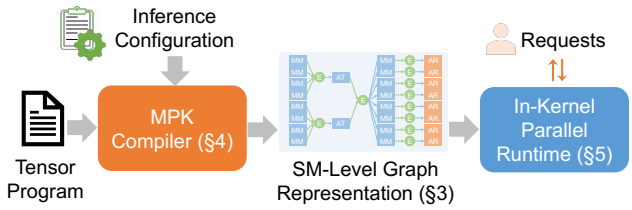

Figure 1: An overview of MPK.

communication, without interruption.

Mega-kernels address the limitations of kernel-per-operator execution in several ways. First, they eliminate repeated kernel launch overhead by replacing many operator-level launches with a single kernel invocation. Second, by fusing *all* operators into one kernel, they enable cross-operator software pipelining, allowing data for the next operator to be prefetched while computation for the current operator is still in progress. Third, they support fine-grained overlap of computation and inter-GPU communication, enabling concurrent execution that more effectively hides communication latency.

Despite these benefits, automatically transforming an ML model into a high-performance mega-kernel remains challenging. Existing ML systems—such as PyTorch [29], Triton [36], and TVM [15]—do not support end-to-end mega-kernel generation. Moreover, these systems rely on a fragmented ecosystem of specialized libraries: NCCL [4] or NVSHMEM [10] for communication, FlashInfer [43] or FlashAttention [18] for attention, and CUDA or Triton for custom computation. This fragmentation makes it difficult to unify the entire inference pipeline within a single kernel.

We present *Mirage Persistent Kernel* (MPK), the first compiler and runtime system that automatically transforms multi-GPU model inference into a high-performance mega-kernel. MPK enables end-to-end kernel fusion with minimal developer effort: users can mega-kernelize a PyTorch model with only a few lines of code while achieving significant performance improvements compared to running the model in vanilla PyTorch with CUDA Graphs and `torch.compile`. MPK combines the performance benefits of mega-kernels with the usability of existing ML frameworks.

A key idea in MPK is to represent computation and inter-GPU communication at the granularity of individual streaming multiprocessors (SMs), rather than at the granularity of an entire GPU. MPK introduces an *SM-level graph representation*, called *t*Graph, whose nodes denote *tasks* running on individual SMs and whose edges encode fine-grained dependencies between tasks. This representation exposes additional parallelism and enables optimizations such as cross-operator software pipelining and fine-grained kernel overlap, which are difficult to realize in conventional kernel-per-operator execution models. MPK realizes this idea using two key components shown in Figure 1.

The MPK compiler. The MPK compiler takes a tensor program and an inference configuration as input and automatically transforms the program's computation graph into an optimized SM-level *t*Graph tailored to the given inference configuration and GPU architecture. The compiler applies a range of optimizations, including event fusion, graph normalization, and graph linearization, to reduce synchronization overhead and improve the performance of generated *t*Graphs. In addition, MPK automatically generates fast CUDA implementations for individual tasks using existing superoptimization techniques [41], ensuring efficient SM-level execution.

In-kernel parallel runtime. MPK executes the SM-level *t*Graph using an in-kernel parallel runtime embedded entirely within a mega-kernel, enabling fine-grained control over task execution and scheduling *without* additional kernel launches during model execution. To achieve this goal, the runtime partitions a GPU's SMs into *workers* and *schedulers*. Each worker maintains a dedicated task queue and executes assigned tasks in a first-in-first-out order, while schedulers track dependencies across tasks and dispatch tasks once their prerequisites are satisfied. The MPK runtime uses an *event-driven, fully asynchronous* execution model to keep GPUs highly utilized. Finally, the runtime uses a *hybrid task-launch strategy* that combines just-in-time and ahead-of-time dispatch to minimize runtime overhead while preserving dynamic load balance across SMs.

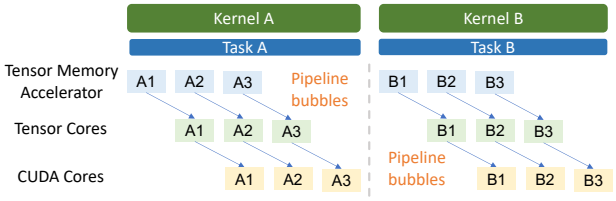
Evaluation results. We implement MPK as a PyTorch compiler backend: a PyTorch program can be compiled into an MPK mega-kernel with only a few lines of code changes. We evaluate MPK on five widely used models across three generations of NVIDIA GPUs: A100, H100, and B200. Even for workloads widely deployed and heavily optimized by existing kernel-per-operator systems, such as SGLang and vLLM for LLM serving, MPK outperforms current systems by 1.0–1.7× on both single- and multi-GPU deployments, pushing LLM inference performance close to hardware limits.

2 Background

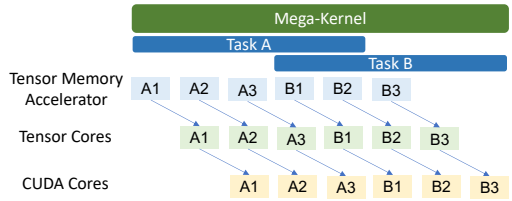
This section first reviews the kernel-oriented GPU programming model and its limitations (§ 2.1), and then presents kernel fusion and mega-kernel techniques (§ 2.2), which motivate the design of MPK.

2.1 GPU Programming Model

On GPUs, computations are organized as *kernels*, each representing a function executed concurrently across many cores in a single-program, multiple-data (SPMD) fashion. A kernel consists of a grid of *thread blocks*, where each block is scheduled on a streaming multiprocessor (SM) and contains mul-



(a) Kernel barriers prevent cross-task pipelining.



(b) MPK enables both intra- and cross-task pipelining.

Figure 2: Comparing how MPK and existing approaches support intra- and cross-task pipelining.

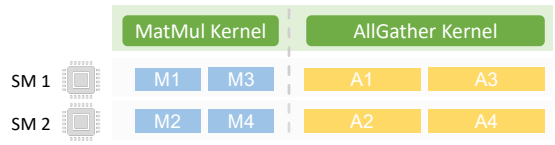
tiple *threads* that operate on individual data elements. Each thread has a private register file, while threads within the same block can cooperate through low-latency *shared memory* for data exchange and collective operations. All kernel inputs and outputs are stored in GPU *device memory*.

The conventional GPU programming model does not support direct synchronization across thread blocks within a kernel, because thread blocks are scheduled independently across SMs and may not all be resident simultaneously. As a result, cross-operator dependencies are enforced through *kernel barriers*, which are automatically inserted by the GPU runtime between consecutive kernels launched on the same stream.

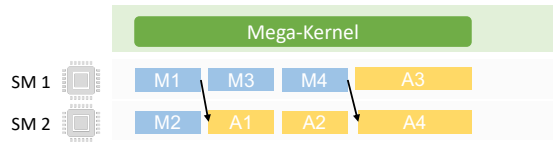
While kernel barriers simplify dependency management, they also prevent key GPU optimizations such as cross-kernel software pipelining and fine-grained operator overlap.

Software pipelining. GPU architectures are increasingly *heterogeneous*, integrating specialized accelerators such as tensor cores and tensor memory accelerators (TMAs). Since TMA load and store instructions execute asynchronously, data movement can proceed while tensor cores and CUDA cores perform computation. Fully exploiting these accelerators requires *software pipelining*—a technique that interleaves independent stages of computation and data movement across multiple iterations of tasks to maximize hardware utilization.

Existing systems implement *intra-task* pipelining, as shown in Figure 2a, where a single task is decomposed into multiple iterations. In this model, TMAs, tensor cores, and CUDA cores can simultaneously perform data transfer, matrix computation, and auxiliary operations for different iterations in a pipeline. However, kernel barriers restrict pipelining to within a single task, preventing *cross-task* pipelining and introducing pipeline bubbles that leave hardware resources underutilized.



(a) Kernel barriers prevent overlapping `MatMul` and `AllGather`.



(b) MPK enables fine-grained overlap of `MatMul` and `AllGather`.

Figure 3: Comparing how MPK and existing approaches support fine-grained kernel overlap between tasks. Data dependencies (black arrows in Figure 3b) ensure correctness.

Fine-grained kernel overlap. Kernel barriers also preclude opportunities to overlap kernels that utilize different hardware resources (e.g., compute and communication), as they enforce dependencies at the granularity of entire kernels rather than individual data units. Figure 3a illustrates a common pattern in large language models (LLMs), where a `MatMul` operator is followed by an `AllGather` operator. Existing systems generally launch these as two separate kernels, requiring all thread blocks of the `AllGather` kernel to wait until all thread blocks of the preceding `MatMul` kernel complete.

In practice, the data dependency between `MatMul` and `AllGather` is much finer-grained: since `AllGather` performs element-wise operations, each of its thread blocks only depends on the output of a single `MatMul` thread block. This dependency structure enables *fine-grained kernel overlap*, where different SMs can execute `MatMul` and `AllGather` in parallel, as long as fine-grained data dependencies are preserved. Such overlap allows the system to simultaneously utilize compute resources and communication bandwidth on modern GPUs, as identified in prior work [50]. Achieving this overlap, however, requires proper synchronization between SMs at sub-kernel granularity, as shown in Figure 3b, which is not supported by conventional kernel barriers.

2.2 Kernel Fusion

Kernel fusion eliminates kernel barriers by combining multiple GPU kernels that execute sequentially on the same data into a single, semantically equivalent kernel. Kernel fusion improves performance by avoiding materialization of intermediate results, reducing device memory accesses, and eliminating kernel launch overheads.

Kernel fusion has been widely adopted in tensor program compilers. Frameworks such as PyTorch, JAX, and TVM employ rule-based heuristics to fuse adjacent kernels [14, 15, 29], while systems such as Mirage and TASO automatically discover fusion rules through compiler super-

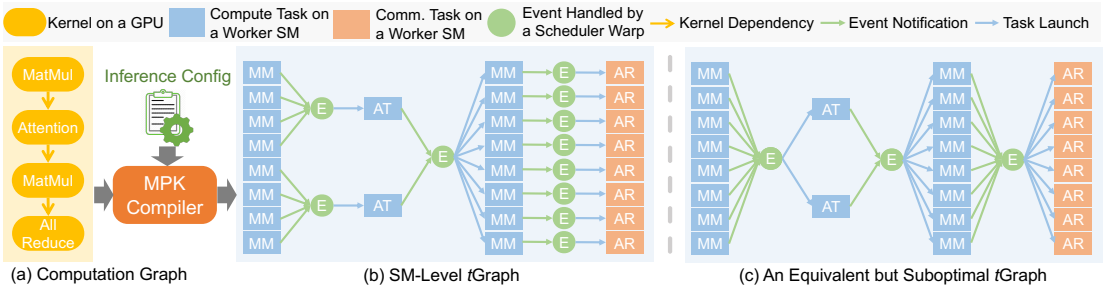


Figure 4: The MPK compiler transforms a kernel-level computation graph into an optimized SM-level *t*Graph. `MM`, `AT`, and `AR` denote `MatMul`, `Attention`, and `AllReduce` tasks, respectively.

optimization [26, 41]. However, existing compilers can only fuse small groups of local operators, as generating a single kernel that faithfully implements an entire complex tensor program is computationally difficult and often infeasible.

The *mega-kernel* paradigm pushes kernel fusion to the extreme by fusing all computation and communication of a tensor program into one persistent kernel, using device-memory synchronization primitives to coordinate execution across SMs. Despite its performance benefits, current ML compilers such as PyTorch, Triton, JAX, and TVM do not support mega-kernel compilation. Existing mega-kernels are instead handcrafted by GPU experts for specific models. For example, FlashDMoE fuses mixture-of-experts computation and inter-GPU communication into a single kernel [13], while Spector et al. manually designed and implemented a low-latency mega-kernel for LLAMA-1B [9, 37].

These manual approaches require substantial engineering effort and deep GPU expertise to mega-kernelize a tensor program. In contrast, MPK adopts a compiler-based approach that automatically transforms a tensor program into an optimized mega-kernel, eliminating the need for manual effort.

3 SM-Level Graph Representation

This section introduces *t*Graph, a representation that expresses the computation of a tensor program at the granularity of individual streaming multiprocessors (SMs). Unlike conventional computation graphs, which expose dependencies only between tensor operators, *t*Graph captures dependencies between SM-level units of work. This fine-grained representation exposes additional parallelism and enables optimizations such as cross-operator software pipelining and fine-grained kernel overlap, both of which are not supported by the existing kernel-per-operator execution model.

Figure 4 illustrates an example *t*Graph, where each node represents either a *task* or an *event*. Each task—shown as a blue (or orange) rectangle—denotes a unit of computation (or communication) executed on a single SM. Each event—shown as a green circle—represents synchronization across tasks. Tasks and events alternate in the graph: every task only has outgoing edges to *triggering events* and incoming edges from *dependent events*. A task is ready for execution when its dependent events are all *activated* and notifies its triggering event upon completion. An event is activated once it has received notifications from all tasks associated with it.

This structure captures dependencies at a much finer granularity than traditional computation graphs. For example, multi-GPU LLM serving often involves a `MatMul` operator followed by an `AllReduce` operator (Figure 4a). Existing systems generally execute these operators sequentially because coarse-grained kernel barriers synchronize entire kernels. In contrast, SM-level task graphs can represent precise task-level dependencies: since `AllReduce` performs element-wise communication and reduction, each of its tasks depends only on one corresponding `MatMul` task that produces its input tile. By inserting fine-grained events between dependent task pairs, MPK can overlap compute-intensive `MatMul` tasks with communication-intensive `AllReduce` tasks, improving overall GPU utilization.

Multiple *t*Graphs may represent the same computation graph. Figure 4c shows an alternative but suboptimal *t*Graph where events capture only operator-level dependencies, analogous to traditional kernel barriers. § 4 describes how MPK generates high-performance task graphs by inferring *precise* data dependencies to maximize concurrency and minimize synchronization overheads.

Comparison with CUDA Graphs. *t*Graphs can be viewed as a lower-level extension of CUDA Graphs, sharing several structural similarities. Like CUDA Graphs, *t*Graphs are statically instantiated and encode explicit dependencies among operations. However, while CUDA Graphs capture dependencies only at the kernel level, *t*Graphs operate at the granularity of individual SM tasks and sub-kernel events. CUDA Graphs primarily describe kernel launch order and rely on stream semantics for synchronization, which confines overlap and fusion to kernel boundaries. In contrast, *t*Graphs explicitly model both intra- and cross-operator dependencies, enabling fine-grained synchronization across SMs and overlap of computation and communication within a single kernel. This design allows MPK to exploit parallelism that is inaccessible to CUDA Graphs and other kernel-level execution models.

Figure 5: The MPK compiler workflow. In (b), Q, K, V, A, O, and R denote the sets of tasks produced by decomposing the query projection, key projection, value projection, attention, output projection, and RMSNorm, respectively. D_1 and D_2 in (e) are dummy tasks inserted during *t*Graph normalization to ensure that each task has a single triggering event. Finally, (f) shows how MPK linearizes the *t*Graph and stores the resulting structure, where tasks and events use a uniform, canonical representation.

4 The MPK Compiler

This section presents the MPK compiler, which takes a computation graph and an associated inference configuration as input and generates an optimized *t*Graph specialized for the target configuration and underlying GPU architecture. Figure 5 illustrates the end-to-end compilation workflow.

4.1 *t*Graph Generation

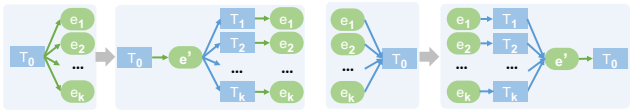
Operator decomposition. The MPK compiler decomposes each operator in the input computation graph into a set of tasks by *partitioning* the operator's output tensors. Each task computes a *disjoint* subset of the output, allowing tasks from the same operator to execute in parallel across SMs. Most tensor algebra operators can be partitioned along multiple output dimensions; for example, the output tensor of a matrix multiplication can be tiled along both the row and column dimensions to expose parallelism.

The performance of a partitioning strategy depends on both the problem shape and the target GPU architecture. To discover an effective strategy, MPK selects a partitioning strategy that minimizes data loading from device memory to shared memory, since device memory accesses are significantly more expensive than shared-memory accesses or computation on CUDA cores and tensor cores. By default, MPK generates a number of tasks proportional to the number of SMs to promote load balance across SMs during execution. MPK also provides an interface for users to specify custom partitioning strategies by setting the desired parallelization degree along each output dimension.

Dependency analysis. MPK uses *events* to capture dependencies between tasks. For any two operators sharing a tensor, MPK enumerates all pairs of tasks from the two operators and introduces an event e for a task pair (t_1, t_2) if and only if the output region produced by t_1 overlaps with the input region consumed by t_2. The event serves as a synchronization point indicating that t_2 cannot begin execution until t_1 has produced the required data. Accordingly, MPK inserts two edges, (t_1, e) and (e, t_2), into the resulting *t*Graph. This fine-grained dependency analysis preserves all producer-consumer dependencies while exposing parallelism across independent tasks.

Event fusion. MPK applies two complementary forms of event fusion—*successor-set fusion* and *predecessor-set fusion*—to eliminate redundant synchronization points and simplify the constructed *t*Graph. For an event e, we define two functions: $InTasks(e)$, the set of tasks that trigger e, and $OutTasks(e)$, the set of tasks that depend on e. These functions characterize when multiple events have identical dependency structure and can therefore be fused.

First, *successor-set fusion* merges events that serve as prerequisites for the same set of consumer tasks. Since these consumer tasks cannot begin execution until all such events are activated, representing the events separately provides no



(a) A transformation reducing fan-out of a task to one.

(b) A transformation reducing fan-in of a task to one.

Figure 6: MPK performs graph transformations to normalize an arbitrary *t*Graph, ensuring that every task has at most one dependent event and at most one triggering event.

additional scheduling flexibility.

Definition 4.1 (Successor-set fusion)**.** For any two events e_1 and e_2 in a *t*Graph, successor-set fusion applies if and only if $OutTasks(e_1) = OutTasks(e_2)$. MPK removes e_1 and e_2 from the *t*Graph and introduces a fused event e' with $InTasks(e') = InTasks(e_1) \cup InTasks(e_2)$ and $OutTasks(e') = OutTasks(e_1)$.

For example, successor-set fusion merges events e_{10} and e_{14} in Figure 5(b) into a new event, e_4 in Figure 5(c), because both events are prerequisites for task O_1.

Second, *predecessor-set fusion* merges events that depend on the same set of producer tasks. Since such events are triggered simultaneously, maintaining them as separate synchronization nodes introduces unnecessary graph complexity.

Definition 4.2 (Predecessor-set fusion)**.** For any two events e_1 and e_2 in a *t*Graph, predecessor-set fusion applies if and only if $InTasks(e_1) = InTasks(e_2)$. MPK removes e_1 and e_2 from the *t*Graph and introduces a fused event e' with $InTasks(e') = InTasks(e_1)$ and $OutTasks(e') = OutTasks(e_1) \cup OutTasks(e_2)$.

For example, predecessor-set fusion merges events e_4, e_5, e_6, and e_7 in Figure 5(c) into a single event, e_4 in the new *t*Graph, because all four events depend on tasks A_1 and A_2.

A core challenge MPK must address is representing dependencies between tasks and events efficiently. Because MPK executes tasks and updates events in parallel across SMs, the runtime requires a *uniform* and *cheap* representation that avoids costly indirect indexing. Two challenges arise. First, a task may depend on and trigger an arbitrary number of events. A straightforward approach to representing tasks is reserving space for the maximum number of dependent and triggering events per task. However, this approach leads to significant memory overhead. Second, after event fusion, an event may trigger an arbitrary number of tasks. Representing these outgoing edges by allocating space for the maximum fan-out per event is also expensive. MPK addresses these challenges using two techniques: *t*Graph normalization and *t*Graph linearization.

***t*Graph normalization.** Normalization bounds the dependency metadata stored for each task. When every task depends on and triggers at most one event, each task descriptor needs to store only one dependent-event identifier and one triggering-event identifier, rather than variable-length lists. MPK achieves this property through the two rewrites shown in Figure 6, which transform an input *t*Graph into a functionally equivalent form in which each task has at most one dependent event and at most one triggering event.

First, when a task T_0 triggers multiple events $e_1, \ldots, e_k$, MPK introduces a new event e' and k empty tasks $T_1, \ldots, T_k$, each of which performs no computation and depends on e'. After this transformation, T_0 triggers only e', and each newly introduced task T_i triggers exactly one of the original events e_i, as shown in Figure 6a. This transformation ensures that every task has at most one *triggering* event. Figure 5(e) shows how MPK applies this transformation to reduce the number of triggering events for A_1 and A_2 to one.

Second, when a task T_0 depends on multiple events $e_1, \ldots, e_k$, MPK introduces a new event e' and k empty tasks $T_1, \ldots, T_k$, each of which performs no computation and triggers e'. After this transformation, T_0 depends only on e', and each newly introduced task T_i depends on exactly one of the original events e_i, as shown in Figure 6b. This transformation ensures that every task has at most one *dependent* event.

*t*Graph normalization introduces additional tasks and events only when a *t*Graph contains tasks with multiple fan-in or fan-out events. This situation typically arises when the original computation graph contains operators that can execute in parallel. For example, tasks A_1 and A_2 in Figure 5(d) have two fan-out events because both the RMSNorm and output projection operators depend on attention and can therefore run in parallel. In practice, we observe negligible normalization overhead—always less than 1% in our evaluation—because real-world models are usually "deep" (with many sequential operators), rather than "wide" (with many parallel operators).

Algorithm 1 MPK's *t*Graph linearization algorithm. It is guaranteed that each task is enqueued into T once and that each event is enqueued into E once. Lines 5-7 ensure that all tasks depending on an event are consecutive in T.

Input: A normalized *t*Graph $\mathcal{G}$
Output: A list of tasks T such that for each event $e \in \mathcal{G}$, the tasks launched by e are consecutive in T.

```
1:  T ← ∅
2:  E ← {e ∈ G | e.counts = 0} ▷ Enqueue all events with no dependent tasks
3:  while E is not empty do
4:    e ← E.dequeue()
5:    for all task t ∈ G do
6:      if t.dependent_event = e then
7:        T.enqueue(t)
8:        e' ← t.trigger_event
9:        if all tasks triggering e' are in T then
10:         E.enqueue(e')
11:
12: return T
```

***t*Graph linearization.** Linearization complements normalization: while normalization bounds the number of events

associated with each task, linearization bounds the storage required to record the tasks associated with each event. *t*Graph normalization alone does not address the second representation challenge: after event fusion, an event may still need to trigger many tasks. For example, event e_5 in Figure 5(e) triggers four tasks, which would otherwise require explicit storage for all outgoing task indices.

MPK addresses this challenge using a breadth-first-search-based algorithm, shown in Algorithm 1, to linearize a *t*Graph. The algorithm assigns contiguous indices to all tasks triggered by the same event in the final task ordering. As a result, the fan-out of an event can be encoded compactly using only the first and last task indices, eliminating the need to store an explicit list of dependent tasks while preserving all dependencies.

Figure 5(f) illustrates how MPK stores the linearized *t*Graph in GPU device memory. For each task, MPK records only the indices of its dependent and triggering events. For each event, MPK stores the number of triggers required for activation; once activated, the runtime launches all tasks whose indices fall within the event's first and last task indices.

4.2 Task Implementation Generation

In addition to constructing a *t*Graph, MPK must generate a device function for each task to execute on a GPU SM. MPK leverages prior work and uses a *compiler superoptimization* approach to automatically generate a high-performance implementation for each task.

Specifically, MPK performs superoptimization at the thread block level instead of the kernel level. Each compute task is associated with a reference PyTorch implementation, and MPK uses the Mirage superoptimizer [41] to search for an optimized thread-block graph, which is sent to the Mirage compiler to generate a CUDA implementation. The CUDA implementation includes intra-SM optimizations such as software pipelining, register reuse, and layout optimizations to reduce shared-memory bank conflicts.

5 In-Kernel Parallel Runtime

MPK employs an *in-kernel parallel runtime* that executes the *t*Graph across all SMs within a single mega-kernel. This design eliminates repeated kernel launches and exposes fine-grained control over scheduling, synchronization, and execution order. Once launched, the mega-kernel continuously manages both computation and communication until the inference workload completes.

To support this execution model, MPK partitions a GPU's SMs into *workers* and *schedulers*. Each worker runs on one physical SM and maintains an independent *task queue*. Workers execute a lightweight loop that repeatedly dequeues tasks, performs the associated computation or communication, and signals task completion by notifying the task's triggering

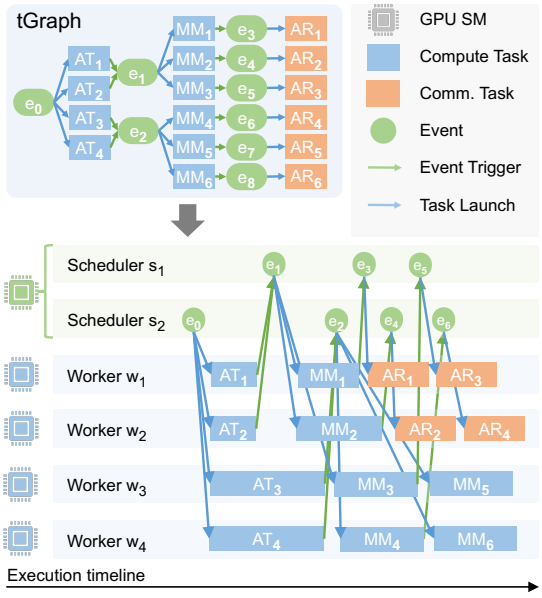


Figure 7: The MPK event-driven execution model. Circles denote events, and blue (or orange) rectangles denote compute (or communication) tasks, respectively. Edges from an event to a task correspond to task launches, while edges from a task to an event indicate that the task triggers the associated event upon completion. `AT`, `MM`, and `AR` refer to attention, matrix multiplication, and AllReduce, respectively.

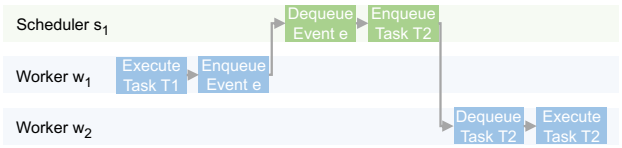
event. This design ensures that workers are fully utilized while enabling asynchronous execution across operators.

Schedulers are organized at *warp* granularity, with each SM hosting four scheduler warps. Each scheduler maintains an event queue and repeatedly polls for newly activated events, dispatching the corresponding tasks to workers. The allocation of workers and schedulers is fixed at kernel-launch time and matches the GPU's physical SM count, avoiding any dynamic role-switching overhead inside the kernel.

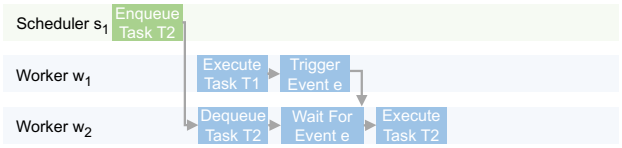
The remainder of this section details the in-kernel runtime architecture. § 5.1 describes MPK's event-driven execution model. § 5.2 introduces two complementary task-launch mechanisms, analyzes their trade-offs, and explains how MPK combines them to achieve low-latency and load-balanced execution. § 5.3 describes additional runtime optimizations that further reduce overhead and improve throughput.

5.1 Event-Driven Execution

MPK executes a *t*Graph using an *event-driven* model. Each *t*Graph begins with a designated *start* event (e.g., e_0 in Figure 7), which has no prerequisites. This event is initially enqueued into a scheduler's event queue. Upon dequeuing the event, the scheduler (e.g., s_1) launches all tasks that depend on it (e.g., $AT_1, \ldots, AT_4$). Each launched task is dispatched to a worker, which executes the task and, upon completion, notifies the triggering event associated with that task.



(a) Just-in-time task launch.



(b) Ahead-of-time task launch.

Figure 8: Comparing JIT and AOT task launches.

An event becomes *activated* once all of its prerequisites have completed and thus have collectively triggered the event the required number of times. When an event is activated, it is enqueued into a scheduler's event queue, allowing the runtime to continue propagating execution through the *t*Graph. In this way, events serve as the mechanism for driving task execution, enabling fine-grained, asynchronous scheduling.

This event-driven model also allows MPK to adapt to the underlying interconnect without requiring an explicit topology profile. Communication and computation are represented uniformly as tasks in the same *t*Graph and dispatched by the same scheduler. A dependent compute task launches as soon as the communication tasks producing its inputs trigger the relevant event, regardless of the latency of the links they traverse. A faster link triggers its event sooner and releases dependent work earlier, while a slower link delays only the tasks that depend on it. The scheduler therefore does not require explicit knowledge of link bandwidths or topology distances. The same *t*Graph and scheduler can thus handle heterogeneous interconnects, such as intra-node NVLink and inter-node networks, by reacting to data availability rather than relying on a static topology model.

5.2 Hybrid Task Launch

A task can be enqueued into a worker's task queue either *just-in-time* (JIT) or *ahead-of-time* (AOT). In JIT mode, a scheduler assigns a task to a worker only after its dependent event has been fully activated; the task can therefore begin execution immediately after assignment. In AOT mode, the runtime pre-enqueues the task into a worker's task queue before its predecessor event is activated. The worker cannot execute the task until the dependent event is fully activated, and thus waits locally for the dependency to be satisfied.

JIT and AOT approaches provide complementary advantages. On the one hand, JIT launch allows MPK to adapt to workload imbalance. For example, attention in LLMs involves highly variable execution times due to data-dependent sequence lengths—requests with long sequence lengths take longer to finish than those with short ones. This variance makes static assignment ineffective. Under JIT launch, MPK launches downstream tasks (e.g., `MatMul` or `AllReduce`) only after the attention tasks that trigger them have completed. Workers that finish their attention tasks earlier can execute more downstream tasks, improving end-to-end latency and balancing load across SMs, as illustrated in Figure 7.

On the other hand, JIT launch involves higher latency due to additional worker–scheduler communication. Figure 8 illustrates the difference when launching task T_2 after event e is triggered by task T_1. Under JIT launch (Figure 8a), the worker executing T_1 notifies a scheduler, which then dequeues event e, launches T_2, and enqueues it into a worker's task queue. The receiving worker must then dequeue T_2 before execution. This chain requires two synchronization steps (worker→scheduler and scheduler→worker). By contrast, under AOT launch (Figure 8b), T_2 has already been enqueued on a pre-assigned worker, which only needs to wait for event e to be activated. Thus, AOT launch requires only one synchronization step through the event trigger, reducing per-task launch latency.

MPK uses *hybrid task launch* to combine the advantages of both approaches. During *t*Graph construction, the compiler classifies each operator as JIT or AOT based on whether its execution time is data-dependent and likely to induce runtime imbalance. Operators with data-dependent durations (e.g., attention) are marked as JIT, and their downstream operators remain JIT until execution reaches a global barrier (i.e., an event that must be triggered by all upstream tasks). Such barriers eliminate accumulated imbalance, making subsequent operators suitable for AOT launch. All remaining operators are labeled AOT to minimize dispatch overhead. Labels apply at operator granularity: all tasks generated by the same operator share the same launch mode.

Workers maintain two queues, one for JIT tasks and one for AOT tasks. Workers always prioritize JIT tasks, as they are ready to execute immediately. When a worker exhausts its JIT queue, it checks whether the first AOT task's dependent event has been fully activated; if so, the worker executes that AOT task. This design ensures that a worker blocks only when no ready work is available.

Schedulers handle only events that launch JIT tasks. All AOT tasks are *pre-enqueued* before execution begins. Because operators typically produce a number of tasks proportional to the number of workers (§ 4), MPK distributes AOT tasks across workers in a round-robin fashion to maintain balanced load. Pre-enqueuing AOT tasks reduces scheduler load and amortizes dispatch overhead, while JIT launch dynamically balances work across SMs.

5.3 Runtime Optimizations

This subsection introduces runtime optimizations that minimize MPK's execution overhead.

Paged shared-memory abstraction. In conventional GPU programming models, shared memory is a fast on-chip memory private to each thread block. Shared memory exists only for the lifetime of a kernel: once the kernel finishes, its shared memory is automatically released. In the kernel-per-operator execution model, each kernel typically assumes *exclusive* access to the shared memory allocated to its thread block. However, this assumption prevents cross-task software pipelining (§ 2), which overlaps data loading for a subsequent task with computation in the current task, since both tasks may need shared memory at the same time.

To enable such pipelining, MPK introduces a *paged shared-memory* abstraction. Shared memory is partitioned into fixed-size pages, and task implementations are modified to operate on pages instead of assuming a monolithic allocation. A task may *acquire* one or more pages based on its shared-memory footprint and must *release* the pages when they are no longer needed. Once a task releases any page, it is no longer permitted to acquire additional shared-memory pages, enforcing a monotonic usage pattern that simplifies scheduling. When the current task releases pages, MPK can immediately allocate available pages for the next task and begin data prefetching. This design enables fine-grained, on-demand allocation of shared memory within the mega-kernel execution model.

Cross-task software pipelining. To enable software pipelining across tasks executed on the same worker (§ 2.1), MPK decomposes each task into a *pre-loading* phase and a *compute* phase. The pre-loading phase issues data transfer instructions to fetch a chunk of the required tensor from device memory into shared memory, initializing the intra-task software pipeline without performing computation.

MPK opportunistically overlaps the compute phase of the current task T_1 with the pre-loading phase of the subsequent task T_2 when two conditions hold: (1) T_1 has already issued all of its own data-transfer instructions, and (2) sufficient shared-memory pages are available for T_2's pre-loading phase. This pipeline does not interfere with T_1's execution because MPK inserts the necessary intra-SM synchronization barriers to ensure that T_2's memory transfers do not conflict with ongoing data transfers for T_1.

Pre-fetching task descriptions. Each worker maintains both JIT and AOT task queues in device memory. Every task is associated with a task description that encodes its input tensors, output tensors, and configuration parameters; in our current implementation, each description occupies 352 bytes (§ 6.1). To reduce enqueue/dequeue latency and hide device-memory access costs, MPK employs a lightweight prefetching mechanism that retrieves upcoming task descriptions into shared memory before they are needed.

6 Evaluation

This section evaluates MPK by answering four questions. First, § 6.3 compares MPK's mega-kernel execution model with state-of-the-art kernel-per-operator systems. Second, § 6.4 studies how MPK supports dynamic workloads. Third, § 6.5 evaluates the scalability and efficiency of MPK for multi-GPU execution. Finally, § 6.6 isolates the performance contributions of the main runtime optimizations in MPK.

We focus our evaluation on LLM serving for two reasons. First, LLM serving has several heavily optimized kernel-per-operator baselines, including SGLang and vLLM [27, 46]; comparing against them provides a stringent benchmark that highlights the benefits of MPK's mega-kernel approach. Second, LLM serving naturally exhibits dynamic execution behavior, as different serving iterations may vary in batch size, sequence length, and the mixture of prefill and decode work. This variability creates heterogeneous workloads that stress both the compiler and the runtime. Although our evaluation focuses on LLM serving, the MPK compiler and runtime are model-agnostic and can support general DNN architectures.

6.1 Implementation Details

We implement MPK as a PyTorch compiler backend. A PyTorch program can be compiled into an MPK mega-kernel via PyTorch's compilation interface by specifying MPK as the backend, i.e., `torch.compile(backend=MPK)`. This call invokes the MPK compiler, which generates a mega-kernel and returns it as a callable PyTorch function. Invoking this function issues a single launch of the generated mega-kernel.

The current MPK implementation consists of approximately 44K lines of C++, 42K lines of CUDA, and 10K lines of Python. The in-kernel parallel runtime is written in CUDA and uses semaphores in device memory to coordinate workers and schedulers. The MPK compiler, implemented in C++ and Python, automatically transforms an input tensor program into an optimized *t*Graph tailored to specific GPU types. For compute tasks, the compiler integrates the Mirage superoptimizer [41] to automatically generate optimized CUDA implementations and uses NVSHMEM [10] to support in-kernel inter-GPU communication.

Our implementation includes several optimizations to minimize runtime overhead and support dynamic workloads.

Task-launch overhead. Because MPK decomposes computation into tasks that are substantially finer-grained than traditional GPU kernels, minimizing per-task launch overhead is essential for performance. MPK uses several techniques to keep task-launch costs low. First, the runtime uses lightweight workers and schedulers: event queues and task queues are implemented as circular buffers in GPU device memory, and enqueue and dequeue operations rely only on

Table 1: MPK configuration in our evaluation.

GPU	# SMs	# Workers	# Schedulers
A100	108	104	16
H100	132	128	16
B200	148	144	16

low-cost `atomicAdd` instructions. Second, MPK uses decentralized scheduling, in which each scheduler assigns tasks using local state. This design avoids global coordination and eliminates the communication and synchronization overheads inherent to globally coordinated scheduling.

Although the current implementation uses decentralized scheduling, the runtime is designed to support alternative policies, including globally coordinated scheduling, with minor code changes. Exploring these policies and their performance trade-offs is an interesting direction for future work.

Supporting runtime dynamism. To demonstrate MPK's ability to support highly dynamic workloads, we extend the system with mechanisms required for LLM serving, including continuous batching [44] and paged attention [27]. When processing the start event of a *t*Graph, the scheduler prepares a new decoding iteration by (1) removing completed requests from the previous iteration, (2) admitting newly arrived requests, and (3) updating per-request KV-cache metadata. This logic executes as a single task, and the KV-cache metadata is stored in device memory for direct access by attention tasks.

To handle the dynamic batch sizes intrinsic to LLM serving, MPK generates multiple *t*Graphs specialized for representative batch sizes, using powers of two up to the maximum batch size. At runtime, the scheduler selects the appropriate *t*Graph based on the current batch size. This approach allows the compiler to generate *t*Graphs optimized for specific batch sizes while preserving flexibility for dynamic serving workloads.

6.2 Experimental Setup

We evaluate MPK on five widely deployed LLMs that span different parameter scales and architectural families, and on three generations of NVIDIA GPUs: A100, H100, and B200. Table 1 summarizes the MPK configuration for each GPU. In all experiments, MPK reserves four SMs for schedulers, allocating 16 scheduler warps in total because each SM can host up to four active scheduler warps. The remaining SMs are used as workers. We set the shared-memory page size to 32 KB on all GPUs, which yields 5, 7, and 7 shared-memory pages per SM on A100, H100, and B200, respectively. Figure 9 shows the evaluated LLMs, which include both dense and mixture-of-experts models across multiple model sizes.

To control for variability in request-arrival patterns, all experiments are conducted in an offline batched-inference setting while varying the maximum batch size. Each request uses a prompt length of 64 tokens and generates 1024 output tokens. This methodology eliminates server-side stalls caused by insufficient request concurrency and enables a controlled comparison of system-level performance.

6.3 End-to-end Results

We first compare the end-to-end serving performance of MPK with SGLang and vLLM, two state-of-the-art LLM serving systems. Both SGLang and vLLM use the kernel-per-operator approach and rely on specialized kernel libraries, including FlashInfer [43] and FlashAttention [7] for attention, cuBLAS and cuTLASS [2] for matrix multiplication, and CUDA or Triton [36] for other operators. All systems load model architectures from HuggingFace Transformers [6], use bfloat16 precision, and enable paged attention [27] and continuous batching [44]. The key architectural difference is that MPK integrates page allocation and request scheduling directly into the mega-kernel. In contrast, SGLang and vLLM perform these operations on the CPU, incurring additional host–device synchronization and dispatch overheads.

For each model, we evaluate all three systems on B200, H100, and A100 GPUs with maximum batch sizes from 1 to 16, and report serving throughput.

Figure 9 shows the end-to-end throughput results. For single-batch inference, MPK improves serving performance by 1.0–1.7× across models and hardware. The improvements are most significant for smaller models and newer GPU generations. This trend is expected because three overheads become more significant as the amount of computation per token decreases and GPU hardware becomes faster: (1) kernel-per-operator approaches incur kernel-switch overheads, even when using CUDA Graphs; (2) kernel boundaries introduce pipeline bubbles and prevent cross-task pipelining (Figure 2); and (3) SGLang and vLLM perform page allocation and request scheduling on the CPU, adding CPU–GPU synchronization delays. § 6.6 quantifies the impact of these optimizations.

These results show that MPK is well-suited for latency-sensitive serving scenarios, such as single-batch decoding, where reducing per-token latency is critical. For example, on Qwen3-8B running on an A100 GPU, MPK reduces per-token decoding latency from 14.5 ms, achieved by highly optimized systems such as vLLM and SGLang, to 12.5 ms. This approaches the approximate hardware lower bound of 10 ms, estimated by loading 16 GB of model parameters at 1.6 TB/s memory bandwidth.

Beyond performance, MPK also improves programmability. vLLM and SGLang require substantial engineering effort to optimize new models and integrate specialized kernels. In contrast, MPK takes a compiler-based approach that automatically mega-kernelizes a PyTorch model with only a few lines of code changes. As a result, MPK combines high performance with a familiar PyTorch development workflow, achieving more than 10× speedup over native PyTorch.

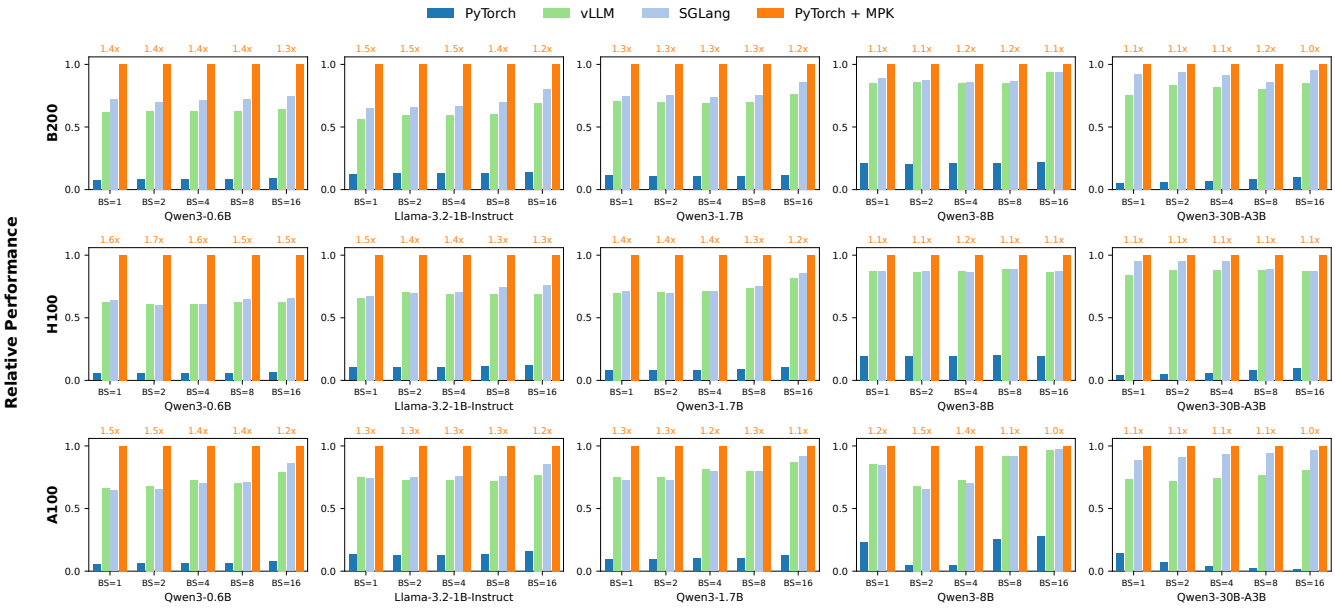


Figure 9: End-to-end comparison of MPK with existing systems across five models on A100, H100, and B200 GPUs. All results are normalized to MPK; higher is better. The value above each MPK bar reports its speedup over the best-performing baseline.

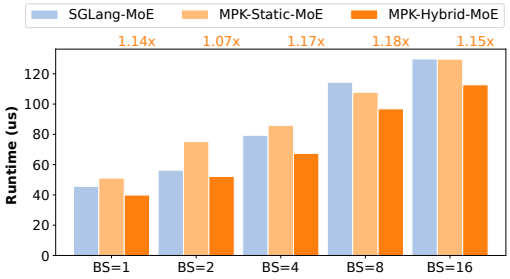

Figure 10: Comparing MPK with existing systems for Qwen3-30B-A3B on B200. Each value represents the actual MoE runtime in microseconds for each approach (lower is better), and the numbers above the bars indicate the speedup achieved by MPK-Hybrid-MoE over SGLang-MoE.

6.4 Case Study: Mixture-of-Experts

To efficiently serve dynamic workloads such as mixture-of-experts (MoE) models, MPK implements two MoE-specific optimizations: a hybrid workload balancer and a fused gather–GEMM implementation.

Representing expert parallelism. MPK represents expert parallelism using the same task abstraction used for other operators. An MoE block is lowered into a chain of SM-level tasks in the *t*Graph (§ 4), including routing, dispatch, expert computation, and combine. The dispatch and combine stages capture the all-to-all communication required by expert parallelism, and MPK lowers them into inter-GPU data-transfer tasks in the same way it lowers other collective operations (§ 6.5). Because communication tasks and expert-computation tasks reside in the same *t*Graph and are dispatched by the same event-driven scheduler, the runtime overlaps all-to-all communication with computation as soon as the relevant events are triggered, without relying on CUDA streams or host-side synchronization. The two MoE-specific optimizations described below operate within this task representation.

Hybrid workload balancer. Because the number of tokens routed to each expert is known only at runtime, choosing an effective workload partition statically is challenging. A naive static strategy assigns a fixed group of SMs to preassigned experts. However, under skewed routing distributions, this strategy can lead to severe load imbalance: some SM groups become oversubscribed while others remain underutilized. At the other extreme, a fully dynamic strategy based on persistent Grouped-GEMM [8] can balance work across SMs, but introduces fine-grained synchronization overheads.

MPK therefore uses a *hybrid* strategy that combines static structure with runtime adaptivity. At compile time, the compiler partitions the MoE computation into expert-specific tasks. At runtime, each task receives a meta-tensor produced by `topk-softmax` containing global MoE information, including the number of activated experts and tokens assigned to each expert. Using this metadata, tasks refine their workload allocation dynamically and split work more evenly while avoiding the overheads of fully dynamic scheduling. As shown in Figure 10, this hybrid strategy consistently outperforms purely static partitioning across all batch sizes.

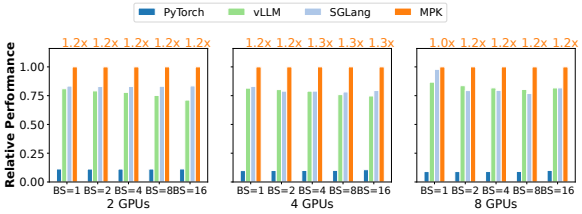

Figure 11: Multi-GPU comparison of MPK with existing systems for Qwen3-1.7B on H100 GPUs using tensor parallelism. All results are normalized to MPK; higher is better.

Fused gather-GEMM. To use tensor memory accelerators (TMAs) on Hopper and Blackwell GPUs, conventional MoE implementations first gather tokens routed to the same expert into a contiguous memory layout. For Qwen3-30B-A3B at batch size one on SGLang, this preprocessing step accounts for up to 11% of total MoE execution time. In MPK, implementing this step as a separate preprocessing task would also introduce additional scheduling overhead.

MPK addresses this issue by replacing the TMA-based gather with an asynchronous token-level copy integrated directly into the data-loading phase of the GEMM tasks. This fusion eliminates the standalone gather kernel and avoids additional scheduling points while preserving efficient memory movement. As a result, MPK with fused gather-GEMM achieves consistent speedups over SGLang's implementation.

6.5 Multi-GPU Results

We evaluate the scalability of MPK across multiple GPUs on an NVIDIA H100 DGX instance. As in the baseline systems, we use tensor model parallelism, following Megatron-LM [31]. Users specify tensor-parallel execution by inserting `AllReduce` after attention and gated MLP blocks. MPK then automatically compiles these collective operators into two types of tasks: inter-GPU data-transfer tasks, implemented using NVSHMEM's `nvshmem_signal_wait_until`, and local reduction tasks. This decomposition converts synchronous collective communication into asynchronous tasks that can be integrated into MPK's task-based, event-driven runtime.

Figure 11 shows the multi-GPU results. Compared with PyTorch, which uses a combination of hand-optimized kernels, CUDA Graphs, and `torch.compile`, MPK's mega-kernel execution improves throughput by up to 10×. Compared with highly optimized serving systems such as SGLang and vLLM, MPK achieves 1.1–1.4× speedups when scaling to 8 H100 GPUs. These gains come from three optimizations missing in kernel-per-operator baselines: (1) MPK integrates page allocation and request scheduling directly into the mega-kernel, eliminating CPU-side dispatch overheads; (2) MPK's asynchronous execution model overlaps compute tasks with collective communication; and (3) MPK eliminates kernel barriers and enables cross-task software pipelining. § 6.6 analyzes the latter two optimizations in detail.

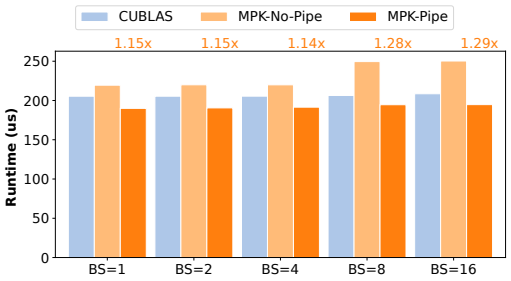

Figure 12: Ablation study of cross-task pipelining. We measure the runtime of the final linear layer in Qwen3-8B on an NVIDIA B200 GPU and report execution time in microseconds; lower is better. The value above each bar reports the speedup of MPK-Pipe over MPK-No-Pipe.

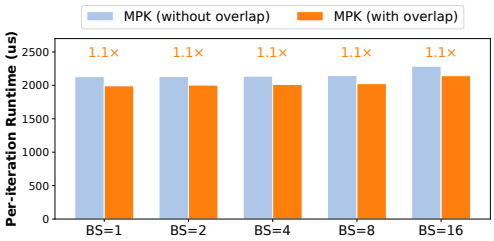

Figure 13: Ablation study on compute–communication overlap. We measure the runtime of Qwen3-1.7B on four H100 GPUs using tensor parallelism; lower is better. We compare MPK with compute–communication overlap enabled and disabled to quantify the benefit of fine-grained overlap.

6.6 Ablation Study

This section evaluates the impact of three runtime optimizations enabled by MPK: cross-task pipelining, compute–communication overlap, and kernel-launch reduction.

Cross-task pipelining. As described in § 5.3, MPK enables cross-task pipelining by preloading chunks of input tensors for the next task while the current task is executing. Figure 12 evaluates the impact of this optimization on the final linear layer in Qwen3-8B. Cross-task pipelining reduces task runtime by 1.2–1.3× and even outperforms cuBLAS-based compiled kernels.

Compute-communication overlap. MPK captures fine-grained dependencies between tasks (Figure 5), allowing the runtime to opportunistically overlap compute and communication. Figure 13 evaluates the impact of this optimization. To disable overlap, we restrict the *t*Graph to capture only coarse-grained dependencies between each collective operator, such as `AllReduce`, and its preceding computation using a single event, as illustrated in Figure 5c. Enabling fine-grained compute–communication overlap reduces per-iteration latency by 1.1×.

Kernel-launch reduction. MPK executes the entire model with a single kernel launch, whereas a kernel-per-operator execution of Qwen3-8B issues 293 kernel launches per token. On B200, each launch costs 3.8 μs in eager execution, totaling 1.1 ms per token, and 0.8 μs with CUDA Graphs, totaling 0.2 ms per token. MPK avoids this overhead; its in-kernel scheduler accounts for only 0.28% of total runtime (§ 6.1).

6.7 Compiler-Stage Ablation

The preceding ablations isolate two runtime mechanisms. We now isolate the contribution of each compiler stage described in § 4. Because these stages serve different purposes, we report the most appropriate metric for each stage rather than using a single common metric. Table 2 summarizes the results on three representative models.

Operator decomposition. Operator decomposition partitions each operator into independent SM-level tasks. As shown in Table 2, decomposition exposes substantial parallelism in real models: each operator is split into 32–47 tasks on average. For example, in Qwen3-8B, 293 operators are decomposed into 13,867 tasks. Compute-intensive operators, including linear layers, attention, and MoE experts, each expose tens of parallel tasks, while only a small number of pointwise operators, such as normalization at batch size one, map to a single task. This decomposition provides the runtime with sufficient independent work to keep all SMs busy.

Event fusion. Without fusion, dependency analysis emits a separate event for every overlapping producer–consumer task pair. Successor-set and predecessor-set fusion collapse events that share the same consumer set or producer set into a single synchronization point. This optimization is highly effective: across the evaluated models, the final *t*Graphs contain only 1,142–2,366 events, yet these events encode 69,000–162,000 producer–consumer task-pair dependencies. This corresponds to a 37–118× reduction in synchronization events (Table 2). The reduction is largest for the MoE model because expert routing creates many-to-many dependencies that are especially amenable to fusion.

***t*Graph normalization.** *t*Graph normalization inserts auxiliary tasks and events only when a task triggers or depends on more than one event, namely at forks and joins. The compiled LLM forward *t*Graphs in our evaluation are almost entirely sequential: we observe no fork/join groups in all three compiled *t*Graphs because operators that would otherwise fan out, such as the query/key/value projections, are emitted as fused operators. Normalization therefore leaves these *t*Graphs essentially unchanged, confirming the "deep, not wide" structure discussed in § 4. Nevertheless, normalization remains necessary for correctness when parallel branches do occur, such as in the unfused Q/K/V example in Figure 5. In those cases, normalization bounds each task's event fan-in and fan-out to one, preserving the fixed-size, indirection-free encoding.

Table 2: Per-compiler-stage statistics on B200. **Ops**: number of operators; **Tasks/op**: average number of tasks per operator after decomposition; **Events**: number of events in the final *t*Graph; **Fusion**: event-count reduction from event fusion; **Lin.**: device-memory footprint reduction from linearization.

Model	Ops	Tasks/op	Events	Fusion	Lin.
Qwen3-1.7B	229	35.6	1,870	37×	4.4×
Qwen3-8B	293	47.3	2,366	68×	5.9×
Qwen3-30B-A3B	533	32.2	1,142	118×	15.0×

***t*Graph linearization.** *t*Graph linearization encodes each event's successor tasks as a contiguous index range rather than an explicit task list. We measure the resulting on-device footprint as the size of the successor encoding with and without linearization. The contiguous-range encoding reduces this footprint by 4.4–5.9× on dense models, such as from 110,932 bytes to 18,928 bytes for Qwen3-8B, and by 15.0× on the MoE model. The MoE model benefits most because high-fan-out expert-routing events are particularly compact under the range-based encoding. Linearization achieves these reductions without losing dependency information.

7 Discussion

Resource footprint. A common concern with mega-kernels is that a single kernel must reserve, on every SM, the combined resources required by all fused operators. MPK avoids this issue: tasks are time-multiplexed across SMs rather than statically partitioned, so each SM uses only the resources required by the task it is currently executing (§ 5). Shared memory follows the same pattern: the paged abstraction (§ 5.3) acquires and releases pages at task granularity. The main exception is per-thread register usage, which is fixed for the mega-kernel at the maximum required across task types.

Integrating hand-tuned kernels and porting to new hardware. Each MPK task is a CUDA device function with a uniform calling convention defined by the *t*Graph. This interface gives MPK two forms of flexibility. First, a hand-tuned kernel can be incorporated into MPK by wrapping it as the device function for a task; the task then executes under the same event-driven schedule as compiler-generated tasks, without requiring changes to the runtime or the *t*Graph. MPK can thus reuse hand-optimized implementations when available while automatically generating the remaining tasks. Second, porting MPK to a new GPU architecture only requires updating the per-task code generators that emit these device

functions; the *t*Graph representation, the compiler's graph-level transformations, the runtime, and the scheduler remain unchanged. Therefore, per-task code generation is the only hardware-specific component of MPK (§ 4), while the rest of the system is shared across GPU architectures.

8 Related Work

Manually designed kernels. Existing ML frameworks such as TensorFlow XLA [1, 12], PyTorch [29], and TensorRT [34] adopt a kernel-per-operator approach and rely on GPU experts to manually design and implement kernels for individual operators. For attention alone, various specialized kernels have been developed, including FlashAttention [5, 18, 23], FasterTransformer [3], and FlashInfer [43], each targeting specific architectural features or deployment scenarios. Current systems rely on many specialized kernel libraries, making it hard to unify the entire inference pipeline into one mega-kernel.

ML compilers. A large body of work has explored *compiler-based* generation of high-performance kernels for tensor programs. Systems such as TVM [15, 16], Ansor [45], and Triton [36], alongside others [20, 22, 25, 49], build on the algorithm–schedule separation introduced by Halide [28, 30]. Another line of work employs *superoptimization* techniques to automatically search for efficient kernel implementations from high-level specifications [26, 38, 39, 42, 47]. However, these compilers are largely designed around operator- or graph-level optimization and do not support generating a unified mega-kernel or coordinating cross-operator execution.

Mega-kernels. Prior efforts on mega-kernels largely rely on manual design. For example, FlashDMoE fuses mixture-of-experts computation with inter-GPU communication into a single handcrafted mega-kernel [13]. Spector et al. manually developed a low-latency mega-kernel for LLaMA-1B [9, 37]. These approaches require extensive engineering effort and deep GPU expertise, and they do not generalize across models or GPUs. In contrast, MPK provides a compiler-based solution that automatically transforms a tensor program into a highly optimized mega-kernel, eliminating the need for manual fusion or hand-written mega-kernel implementations.

A related line of work simplifies the development of manually fused kernels. ThunderKittens [32] provides tile-based abstractions for high-performance kernels, and PipeThreader [17] exposes software-pipelined kernel execution to the programmer. These tools still require the developer to decide which operators to fuse, how to pipeline them, and how to coordinate their execution. MPK instead compiles an entire tensor program into SM-level tasks and executes them as one mega-kernel. These abstractions are therefore complementary to MPK: they could be used to implement individual task kernels within the MPK runtime.

TileRT [35] similarly decomposes operators into fine-grained tile-level tasks executed as a single persistent kernel, validating our core idea that persistent mega-kernel execution is key to low-latency inference.

Compute–communication overlap. A large body of work overlaps collective communication with computation to hide inter-GPU communication latency. DeepEP [19] provides expert-parallel all-to-all communication kernels for MoE models, and Triton-Distributed [48] extends the Triton compiler to express overlapping distributed kernels. TokenWeave [21], FlashOverlap [24], and ParallelKittens [33] fuse or co-schedule communication with dependent computation to reduce exposed communication latency. Earlier work from Google decomposes collective operators so that they overlap with dependent computation [40]. These systems realize overlap at the granularity of individual kernels or collective operators. In contrast, MPK represents communication and computation uniformly as tasks in one *t*Graph and schedules them using the same in-kernel runtime (§ 6.5). Compute–communication overlap therefore emerges from the global task schedule and applies uniformly to both tensor-parallel collectives and expert-parallel all-to-all communication.

9 Conclusion

This paper presents MPK, the first compiler and runtime system that automatically transforms multi-GPU model inference into a fully fused mega-kernel. By introducing SM-level task graphs and an in-kernel parallel runtime, MPK overcomes key limitations of the kernel-per-operator execution model, enabling inter-operator software pipelining, fine-grained overlap of computation and communication, and the elimination of kernel-launch and CPU-side scheduling overheads. Our evaluation shows that MPK brings LLM serving latency close to hardware limits and significantly improves throughput across models and GPU generations. By unifying execution within a single mega-kernel while preserving compatibility with existing ML frameworks, MPK opens a new path toward high-performance, compiler-driven inference systems.

Acknowledgment

We thank the anonymous OSDI reviewers and our shepherd for their valuable comments and suggestions. This work was partially supported by NSF awards CNS-2211882 and CNS-2239351, a Sloan Research Fellowship, and research awards from Amazon, Cisco, Google, Jane Street, Meta, NVIDIA, Oracle, Qualcomm, and Samsung. We also gratefully acknowledge NVIDIA for providing access to a DGX B200 system.

A Artifact Appendix

Abstract

The artifact is the MPK compiler and runtime together with scripts that reproduce the paper's end-to-end latency results. MPK transforms a PyTorch model into a single mega-kernel; the scripts measure per-token decoding latency for MPK, PyTorch, vLLM, and SGLang across five LLMs, five batch sizes, and three GPU generations.

Scope

The artifact validates the paper's main performance claims: (i) on single-batch serving, MPK reduces per-token latency by 1.0–1.7× over vLLM and SGLang, with the largest gains on smaller models and newer GPUs (Figure 9); (ii) under tensor parallelism, MPK improves throughput by up to 10× over PyTorch and 1.1–1.4× over vLLM/SGLang on 8 H100s (Figure 11); and (iii) cross-task pipelining and compute–communication overlap each contribute measurable speedups (Figures 12 and 13).

Contents

The repository holds the MPK compiler and in-kernel runtime, a runnable demo for each model under `demo/`, and one evaluation driver per GPU under `artifact_evaluation/`. A driver sweeps the five models over batch sizes 1 to 16 for all four systems and writes one result file per run, recording the system, GPU, model, batch size, and measured per-token latency. Collecting these files reproduces Figure 9 and the ablation figures. A `setup.sh` script installs the dependencies and builds MPK.

Hosting

The artifact is on the frozen branch `tgx-osdi26-ae` of https://github.com/mirage-project/mirage (commit `8b981a4`), archived on Zenodo at https://doi.org/10.5281/zenodo.20563064 (DOI: 10.5281/zenodo.20563064).

Requirements

Hardware. One NVIDIA A100, H100 (SXM), or B200 for the single-GPU sweeps, and a multi-GPU node (4–8 H100s) for the tensor-parallel experiments. The four smaller models fit on a 40 GB A100; Qwen3-30B-A3B needs at least 80 GB and runs on an 80 GB A100, an H100, or a B200.
Software. Linux with CUDA (12.8 in the paper), PyTorch 2.7, NVSHMEM and OpenMPI for the multi-GPU runs, and `transformers` 4.57.1. `setup.sh` installs these and builds MPK; vLLM and SGLang each run in a separate virtual environment.

Benchmarks. Qwen3-0.6B, Llama-3.2-1B-Instruct, Qwen3-1.7B, Qwen3-8B (dense), and Qwen3-30B-A3B (MoE), downloaded from HuggingFace (Llama-3.2 is gated; set `HF_TOKEN`).

Reproducing the results

```
git clone --recursive -b tgx-osdi26-ae \
   https://github.com/mirage-project/mirage
cd mirage && bash artifact_evaluation/setup.sh
bash artifact_evaluation/<gpu>/run_tgx.sh
bash artifact_evaluation/<gpu>/run_pytorch.sh
bash artifact_evaluation/<gpu>/run_vllm.sh
bash artifact_evaluation/<gpu>/run_sglang.sh
```

All runs use offline batched inference with a fixed prompt length of 64, 1024 decoded tokens, and greedy decoding; each reported number is the median of five runs after a four-iteration warmup. On a 40 GB A100 the sweep covers the four smaller models; reproducing the Qwen3-30B-A3B point additionally requires an 80 GB A100 (or an H100/B200).

GraCE: Unlocking CUDA Graphs with Compiler Support for ML Workloads

Abhishek Ghosh[†], Ajay Nayak[†], Ashish Panwar[‡], and Arkaprava Basu[†]
[†]*Indian Institute of Science* [‡]*Microsoft Research India*

Abstract

Machine learning (ML) workloads launch hundreds of short-running GPU kernels per iteration. With GPU compute throughput growing rapidly, CPU-side launch latency of kernels is emerging as a bottleneck. CUDA Graphs promise to address this by replaying a set of kernels with a single dispatch of the graph, removing per-kernel launch costs. However, CUDA Graphs remain surprisingly difficult to deploy correctly and efficiently.

We present GraCE — a compiler framework to maximize the coverage and benefits of CUDA Graphs for ML workloads. It introduces three novel optimizations: it applies automatic code transformations to make ML applications amenable for CUDA Graphs; it eliminates the parameter copy overheads for kernels executing in CUDA Graphs, and it selectively deploys CUDA Graphs guided by a cost–benefit analysis. For 25 ML workloads from TorchBench, HuggingFace and TIMM, GraCE more than doubles the benefit from deploying CUDA Graph compared to the most popular and widely used ML compiler PyTorch2. GraCE is built atop PyTorch2's compilation framework and requires no programmer intervention.

1 Introduction

The demand for GPU compute continues to skyrocket due to a surge in ML applications [2, 8, 9, 34, 37, 69–71, 95]. Catering to this growing demand through hardware enhancement *alone* is challenging in the post-Moore era of slowing transistor technology [14]. Consequently, hardware vendors increasingly rely on hardware-software co-design to improve efficiency. For example, NVIDIA continues to introduce new performance features in GPUs that need software enablement. Recent examples include scoped synchronization [29, 30, 39] that allow programmers to selectively enable faster synchronization, tensor cores for fast matrix multiplication [27], lower- and mixed-precision computation [38], and CUDA Graphs [20, 90] for improving GPU utilization.

Surprisingly, GPUs are often underutilized despite high demand. Several hyperscalers, including Alibaba and Azure, report GPU utilization typically below 50% [18, 26, 79, 80]. A major contributing factor is that CPUs cannot submit kernels fast enough to keep modern GPUs busy. An ML application typically invokes hundreds of GPU kernels per iteration, and each kernel launched from the CPU adds 5-10 microseconds of latency [13]. As a result, GPUs stall when they finish executing kernels faster than the CPU can dispatch subsequent ones. This problem is amplified by recent trends in distributed ML, particularly Tensor Parallelism (TP) [68]. TP shards model layers across GPUs, reducing the runtime of per-GPU compute kernels while introducing additional kernel launches for inter-GPU collective operations. Together, these effects push launch latency deeper into the critical path.

CUDA Graphs can mitigate the kernel launch bottleneck. It allows software to *capture* kernel launches in a directed acyclic graph – a CUDA Graph. The CPU then launches the graph instead of individual kernels. This can significantly speed up applications that repeatedly execute the same set of kernels (e.g., training and inference). While useful in theory, CUDA Graphs come with several constraints. For example, the parameters to a kernel are hardcoded during a graph's capture. The same parameter values are passed to kernels during replays, posing a challenge to applications that compute over different data (tensors) across invocations. A CUDA Graph is also prohibited from using GPU-synchronizing operations.

Effectively harnessing capabilities of CUDA Graph is further made challenging by the fact that most ML applications are written in high-level frameworks such as PyTorch [54] and TensorFlow [1], and are semantically distant from their execution on the hardware. A key challenge, thus, is to effectively bridge the gap between the high-level program semantics and the low-level idiosyncrasies of hardware features.

Our goal is to enable high-level programs, e.g., in PyTorch, to effectively harness CUDA Graphs in modern GPUs without needing programmer intervention. Upon qualitatively and quantitatively analyzing many tens of PyTorch programs, we observed three key shortcomings that either prevent the deployment of CUDA Graphs or fail to harness its benefits.

① **CUDA Graph-oblivious programs:** Many important

ML programs, e.g., in TorchBench [22], are *not* written with CUDA Graph in mind. For example, it is common for programs, such as the text-to-image generator model DALLE-2 [62], to allocate a tensor on the CPU's DRAM (say, address `x`) and then copy its content to GPU memory during computation, e.g., in the `forward` pass. A CUDA Graph captured for such computation would hardcode the address of the DRAM-resident tensor (`x`). Its content must then be copied to GPU memory during the graph's replay. However, the host program may de-allocate the CPU tensor (`x`) after the graph's capture, causing the application to crash intermittently during replays. Thus, CUDA Graph must be avoided in such programs. We notice similar pattern in other programs e.g., Vision Mask R-CNN [23], Torch Multi-modal Clip [31, 61].

Further, in many cases one or more kernel parameters are passed as *scalar* variables e.g., attention kernel in speech transformer [55]. A CUDA Graph captured with such kernels would record the value of the scalar as the kernel parameter. If the variable's value should change across kernel invocations, it will receive *stale* values during graph replays. Thus, CUDA Graph must be avoided in such cases.

While a single or a few lines of code changes can unlock hundreds of kernels being captured in CUDA Graphs, the challenge is to automatically find such opportunities and update the code accordingly. It is unrealistic to expect developers to continue evolving their programs to make them friendlier to new hardware features. Thus, we posit that frameworks, such as PyTorch2, JAX [5], must step up to effectively harness advanced hardware features without burdening developers.

② **Parameter copy overheads in replaying CUDA Graphs:** By design, CUDA Graphs capture GPU kernel parameters, including addresses of tensors *by value*. However, different invocations of the same kernel across a graph's repeated replays often need to operate on different data. A simple strategy to enable this is to replace mutable parameters with *placeholder* parameters. Before each replay, actual parameter values for a given invocation are copied onto its placeholders.

While this strategy allows correct replay of graphs and is employed by widely used PyTorch2 ML compiler, it adds the overhead of copying the parameter (data) into the placeholder in the critical path of every graph replay. We empirically found overheads of copying parameters constitute up to 24% of a CUDA Graph's execution time, particularly when operating on large tensors (§2). Thus, there is a need to correctly deploy CUDA Graph but without slowing down graph replays.

③ **CUDA Graphs may hurt performance:** While CUDA Graph is a performance feature, we discovered that the overhead of replaying them can sometimes outweigh the benefits. Besides the latency of copying kernel parameters (tensors), the overhead of reusing/garbage collecting CUDA Graph's memory after replay and reset of the GPU's random-number generator (RNG) state before each replay adds latency to the critical path. In our analysis, nearly a quarter of the total CUDA Graphs degrade performance (up to 397%). While a performance feature is not expected to speed up every application, it must not severely slow down many applications.

GraCE: Driven by these observations, we created a CUDA Graph-aware compilation framework for PyTorch programs. GraCE embodies three key optimizations.

① It employs CUDA Graph-aware code transformations such as hoisting memcopies, changing data placement for a wider deployment of CUDA Graphs. It analyzes the intermediate representation (IR) of programs to root cause the failures to capture kernel(s) in a graph (e.g., scalar variables). It then updates the IR to emulate changes in the source that would have enabled CUDA Graph. ② It introduces an additional level of indirection in kernel parameters to convert tensor copies for parameters to *pointer* copies. While a tensor can be thousands of bytes, a pointer is only 8 bytes. For JIT-compiled kernels, GraCE uses Triton compiler [52] to automatically update kernels to de-reference their indirected parameters. For vendor-supplied immutable kernels (e.g., from cuBLAS), it introduces prelude kernels in the graph that perform de-reference of indirect-ed parameters on behalf of immutable kernels. ③ Finally, it adds automated profiling during graph capture (slow path) to analyze the cost-benefit of deploying CUDA Graphs. This guides GraCE to *selectively* deploy CUDA Graph during replay (fast path) only when beneficial. The judicious deployment of CUDA Graphs not only enables better end-to-end performance but, crucially, ensures that no application slows down. GraCE is integrated into PyTorch2 and requires *no* program modifications.

On a diverse set of 25 ML applications, GraCE provides geomean speedup of 29% over PyTorch2's CUDA Graph feature (and up to 3.36×) on an H100 GPU. Further, we studied GraCE's efficacy under distributed ML workloads by spreading a subset of applications over four GPUs using tensor parallelism. There, GraCE speeds up applications up to 3.56× over PyTorch2's CUDA Graph and by 75% on average.

The key contributions of our work are as follows:

- We demonstrate subtle programming idiosyncrasies in popular PyTorch programs, coupled with the constraints of CUDA Graphs, limit wider deployment of CUDA Graphs.
- We show that overheads due to copying kernel parameters can be limited by introducing an additional layer of indirection in passing the parameters to kernels.
- We demonstrate the need to selectively deploy CUDA Graphs to achieve better end-to-end application performance.
- We create GraCE atop PyTorch2's compilation framework that achieves the above-mentioned optimizations without needing any manual modifications.

2 Background and Motivation

This section elaborates on how CUDA Graphs have become indispensable for modern GPU platforms, along with the challenges involved in maximizing their utilization. We use the terms CUDA Graph(s) and CG(s) interchangeably.

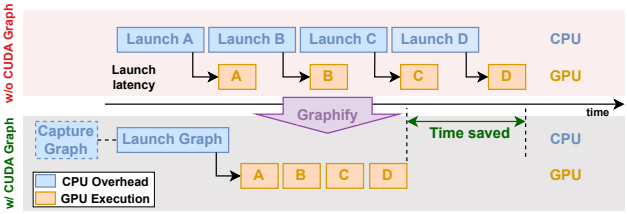

Figure 1: CUDA Graph reducing CPU launch overheads.

2.1 The need for CUDA Graphs

GPUs have become the workhorse accelerators for ML applications since they deliver massive compute throughput. NVIDIA's GPU compute scaling highlights this: peak FP16 tensor throughput jumped from 312 TFLOP/s on A100 [40] to ≈1 PFLOP/s on H100 [45], and ≈4 PFLOP/s on B200 [50]. In contrast, CPU frequency has stagnated, and the number of cores has only doubled during that period. At the same time, ML workloads have expanded dramatically, with each iteration often launching hundreds to thousands of kernels. Further, modern deployments increasingly shard a model across multiple GPUs. As GPU throughput improves and models scale out, kernels become smaller and faster.

A typical CUDA kernel launch takes ∼5-10 microseconds [13], while many kernels now run for only a few microseconds. This turns CPU launch overhead into a significant fraction of the total time. Reducing or amortizing this overhead is therefore critical to achieving high GPU utilization. For example, in DALLE2 [62] (inference, batch size 1), a segment of computation issues over 740 kernels whose combined GPU execution time is only 3.4 milliseconds on an H100 GPU, while the end-to-end time is 14 milliseconds—implying that 75% of the total latency is due to CPU launch delays.

A CG can address this bottleneck by obviating the need to individually launch each kernel from the CPU. The top part of Figure 1 shows traditional kernel launches, while the lower part shows steps involved in CG. Kernels are captured as part of a DAG (CG) once. The graph is launched from the CPU, and internally, the GPU hardware launches CG's constituent kernels without CPU intervention. Applications that repeatedly launch the same set of kernels, e.g., inference tasks, can benefit substantially by capturing the graph once and replaying it many times.

2.2 Deploying CUDA Graph and its challenges

CUDA supports automatic capture of CGs through *stream capture* mechanism. The developer designates a capture region. The runtime automatically records all GPU operations (e.g., kernel launch, memcopy) issued within the region, producing a computation DAG. Once capture completes, the developer instantiates the graph and launches it, causing the GPU to *replay* the recorded GPU operations. Owing to its simplicity, stream capture is the dominant way developers use CGs. However, even this approach requires care: the runtime records kernel parameters *by value*. If the application replays the CG without updating parameters that change across iterations, execution proceeds with stale arguments—leading to silent data corruption, incorrect results, or crashes. Developers must therefore identify which values remain stable across replays and update any mutable parameters in the graph before launching it. Furthermore, CUDA does not permit capturing synchronous copies (`cudaMemcpy`), memory allocation (`cudaMalloc`) or any other API that implicitly synchronizes the device [48]. These constraints force developers to rethink data movement and memory management, making it difficult to incorporate CGs—especially in legacy codebases.

```
1  import torch
2  import numpy as np
3
4  class ScaledDotProductAttention(nn.Module):
5    def __init__(self, temperature, attn_dropout):
6      ...
7      self.temperature = temperature
8      ...
9
10   def forward(self, q, k, v, mask=None):
11     attn = torch.bmm(q, k.transpose(1, 2))
12     # Divide operation below with a numpy scalar on CPU
13     attn = attn / self.temperature # offending line
14     ...
15
16 class MultiHeadAttention(nn.Module):
17   def __init__(self, n_head, d_model, d_k, d_v, dropout):
18     ...
19     temp = np.power(d_k, 0.5) # src of offending operand
20     self.attn = ScaledDotProductAttention(
21         temperature=temp, attn_dropout=dropout)
22     ...
23
24   def forward(self, q, k, v, mask=None):
25     ...
26     output, attn = self.attn(q, k, v, mask=mask)
27     ...
28
29 module = # Initialize the speech_tranformer model
30 module = torch.compile(module)
31 result = module(inputs)
```

Figure 2: Simplified code snippet from speech transformer model with CPU-resident scalar (marked red).

We posit that compilers and *not* the programmers should reason about program structure, automatically satisfy graph constraints and judiciously apply optimizations. This is the only way to harness advanced hardware features without burdening the developers. Unfortunately, existing compilers fall well short. To substantiate, we investigate PyTorch2 [3]—the most popular and widely used ML compiler.

2.3 CUDA Graphs are poorly harnessed

We analyze over 60 common ML and HPC workloads to identify key impediments to effective CG deployment. First, many programs fail to use CGs because their implementations are not aligned with CG requirements. Second, CG's deployment strategy today adds significant but avoidable overheads. Fur-

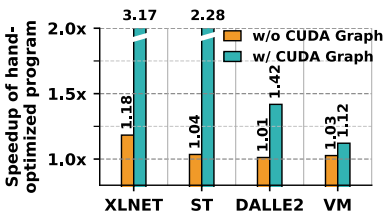

Figure 3: Performance impact of moving tensors from CPU (unoptimized programs) to GPU (optimized programs).

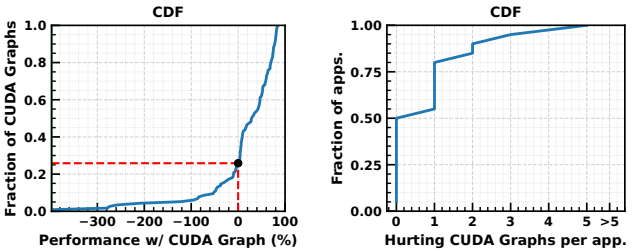


(a) 25% of the total CUDA Graphs hurt performance in TorchBench. **(b)** About 50% of the applications contain CUDA Graph(s) that hurt performance.

Figure 4: Cost-benefit analysis of CUDA Graphs.

ther, even when CGs can be deployed, their deployment is not always beneficial — yet current frameworks deploy them blindly. We present a detailed analysis below.

2.3.1 Obstacles in harnessing CUDA Graphs

We observe that CUDA Graphs are often not compatible with the way many ML workloads are written. For example, when a kernel is captured into a CG, all its arguments are recorded by value and baked into the graph. If those values change across iterations, replaying the captured graph would produce incorrect results. Consequently, a compiler would forgo CG deployment in these cases for correctness.

We highlight one such example with a simplified PyTorch code snippet of the speech transformer model [55] (Figure 2). In the constructor of `MultiheadAttention` (line 19), the variable `temperature` is assigned the value returned by a `numpy` method [74]. Note that `temperature` hosts a *scalar* value and is allocated on the CPU DRAM. This variable is passed to the constructor of `ScaledDotProductAttention` (line 21) and ultimately used to update `attn` in its forward method (line 13). This update of `attn` is performed by a GPU kernel whose parameters are `attn` and `temperature`. While the former is the address to a GPU tensor, the latter is a *scalar* variable. If this kernel is captured as part of a CUDA Graph, the scalar value of the parameter `temperature` will be hardcoded as a kernel parameter. Later, if the captured graph is replayed, the kernel would execute with a stale value of `temperature`.

We discovered other subtleties in PyTorch programs that limit CG deployment. A common case is when applications allocate a tensor on the DRAM (at address `x`) and copy its contents to GPU memory at the start of each iteration. A captured CG would hardcode the DRAM address `x`. However, CPU may de-allocate that tensor after capture, leaving the address invalid when the graph is replayed.

Quantifying the opportunity cost: The issues above stem from the fact that most ML programs are not written to meet CG constraints. Before the introduction of CG, the choice of where to allocate tensors had a limited impact. Tensors allocated on the CPU DRAM are copied to the GPU memory over PCIe for computation. If the tensor is large, the PCIe transfer time can dominate the kernel's execution time. Thus, a tensor placed in CPU DRAM can at most delay the execution of the corresponding kernel.

The same is not true in the context of CG. The choice of tensor placement for *one* kernel determines whether other surrounding kernels can be captured as part of a CG or not. This is because a single offending allocation for a kernel in an otherwise CG-amenable long chain of kernels can disallow any of the kernels from being captured in a CG. In short, how a tensor is allocated for a kernel can affect many *other* kernels in the context of CG.

To demonstrate this quantitatively, we manually rewrote small portions of several PyTorch models—XLNetLMHeadModel (XLNET) [85], Speech-Transformer (ST) [55], DALLE2 [62], and Vision Mask R-CNN (VM) [23]—specifically targeting code regions whose structure prevented CUDA Graph deployment. The edits were minor (e.g., relocating a CPU-allocated tensor to the GPU) but made the code CG-compatible. Figure 3 reports the results (all results use inference batch size 1). In the absence of CGs, optimizing tensor placement had a modest impact on performance, averaging 6.29% and reaching up to 18% for XLNET. However, the same code changes lead to a dramatic speedup when using CGs. For example, XLNET and ST sped up by 3.17× and 2.28×!

Furthermore, scaling out ML models to multiple GPUs makes CGs more critical for performance. For instance, in the XLNET model (inference at batch size 128), tensor-parallelism over four GPUs brings 48 additional collective kernels and reduces the runtime of more than 250 kernels by 50–75%. However, a few variable allocations in CPU DRAM render more than 450 kernels ineligible for capture in CGs, leaving significant performance on the table.

2.3.2 Cost-benefit analysis of CUDA Graphs

We also noticed that even when CGs can be deployed, they do not always improve performance. In fact, counterintuitively, we observed that CGs also hurt performance in many cases. This is unexpected; CGs are designed solely as a performance feature and should not slow down even a single application.

To understand this behavior, we quantitatively analyze 116 CGs drawn from 63 PyTorch applications in TorchBench [22].

We make two key observations. First, Figure 4a shows the CDF of performance changes when enabling CGs across all applications, capturing both cases where CGs help (right side of 0 on the x-axis) and where they hurt (left side of 0). Overall, 25% of the graphs (29 of 116) degrade performance. A deeper inspection reveals that the dominant source of this slowdown is the latency of copying kernel parameters (data) into the static placeholders (addresses) during a graph's replay.

The reason this copying is required is fundamental to how CGs operate: every kernel parameter is captured by value in a CUDA Graph, whereas different invocations of a kernel typically operate on different data. A simple strategy to manage this scenario is to replace mutable parameters with *place-holder* arguments. Before each replay, the runtime must overwrite these placeholders with the current input values of all mutable arguments. This copy happens on the critical path of every replay and scales with the number of kernels and the size of their argument lists, making it a nontrivial overhead. For instance, in CUDA Graphs of DALLE2 and NVIDIA Deep Recommender, parameter copying accounts for 24% and 17% of their end-to-end execution time, respectively. These overheads substantially erode the benefits of CG deployment and can even lead to net slowdowns.

Beyond parameter copy, replay of a CG suffers from other fundamental overheads. CGs cannot encode lifetimes of CPU-side objects. A language runtime that performs garbage collection, e.g., Python, must separate CG outputs from the host objects that originally produced them. The runtime snapshots only the GPU-side metadata of CG outputs (such as data pointers and layout) and discards the CPU-side tensor objects. This is necessary for the GPU memory to be safely reused across CG replays without memory bloat. However, on each replay, fresh CPU objects must be reconstructed from the saved metadata, adding further latency.

Our second insight is that many applications consist of both useful and harmful CGs. For example, Figure 4b shows the CDF of 20 applications that contain multiple CGs. Of these, nearly half of them exhibit a mix of performance-aiding and performance-hurting CGs. For a specific example, in DALLE2 (inference, batch size 1), one of the captured CG executes in 75 microseconds, while the kernel in it when run without CG takes 70 microseconds—implying an overhead of 7% in CG deployment. At the same time, a different CG in the same workload reduces the runtime of 743 kernels to 3.4 milliseconds, compared to 14 milliseconds without CGs, resulting in more than 75% performance gain. Unfortunately, CGs today are blindly deployed without a cost-benefit analysis.

In summary, these observations expose a deeper problem: today's ML software stack lacks both the semantic understanding needed to effectively harness CUDA Graphs and a cost model to decide when they are worthwhile. Applications often miss crucial opportunities to use CGs, or deploy them where they hurt performance. It begs for a compiler-driven approach to automatically enforce graph compatibility, reason about costs, and maximize the effective use of CGs.

3 GraCE: Goals and Optimizations

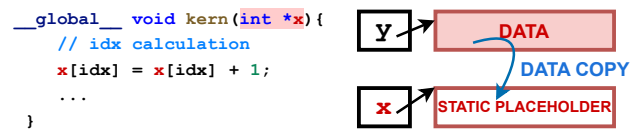
Motivated by the analysis, we present the goals of GraCE, a framework that enables effective use of CUDA Graphs in ML applications. We then outline the optimizations that help GraCE achieve the goals.

Goals: ① Expand the set of GPU kernels that can be captured in CGs. ② Minimize runtime overheads introduced during CG replay, especially those stemming from parameter copy. ③ Selectively deploy CGs only when they improve end-to-end performance. ④ Achieve all of the above without requiring program modifications or developers' intervention.

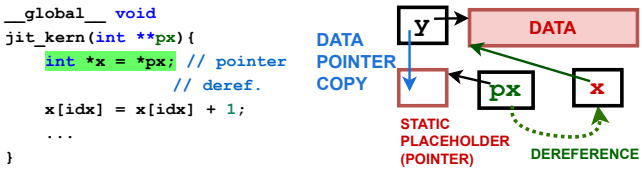
CUDA Graph-aware Code Transformation (CGCT): A large fraction of ML applications fail to utilize CUDA Graphs due to the presence of constructs—synchronous memory copies, CPU-resident scalars or tensors—that inhibit CG capture. These issues are often obscured by high-level frameworks and can easily escape a programmer's attention.

GraCE addresses this by restructuring the program such that large sequences of kernels become eligible for graph capture, without altering application semantics. It first analyzes the compiler's intermediate representation (IR) to identify code regions where CG capture fails and the root cause of the failure. It then performs targeted IR rewrites that make these regions compatible with CG capture. Conceptually, GraCE ensures that variables and operations in a candidate region satisfy the constraints imposed by CGs: computations and necessary inputs are placed on the GPU, and incompatible operations are hoisted prior to candidate graph regions. For example, if a scalar parameter prevents graph capture, GraCE alters the type of parameter as a GPU-resident tensor. During replays, the appropriate value of a parameter is copied into the tensor's placeholder, enabling safe capture of the surrounding kernels. Likewise, if a DRAM-to-GPU memory copy prevents CG deployment, GraCE hoists the copy above the sequence of kernels targeted for CG capture. This ensures that the copy is not captured as part of the CG and, thus, need not be replayed.

Parameter Indirection (PI): A dominant source of overhead in a CG replay is the copying of kernel parameters (data) into the placeholders that were recorded during graph capture. We eliminate this cost by removing data copies from the replay path entirely: instead of copying potentially large parameter data, we introduce a layer of indirection. Consequently, the replay updates only the corresponding pointers (eight bytes per parameter) rather than the data itself, which can be thousands of bytes. This optimization rests on a simple observation: with the input data changing on each replay, as long as a kernel can read from these new data tensors—different from those it



(a) Baseline behavior in current ML frameworks.



(b) After indirection.

Figure 5: Converting data (parameter value) copy to pointer copy through indirection in Parameter Indirection.

was captured with—the CG execution remains valid, without needing a parameter copy.

Figure 5 illustrates this mechanism with an example. Figure 5a shows the parameter (data) copy performed during the replay of a CG in the baseline. The kernel parameter recorded during graph capture (here, address x) is highlighted in red. During replay, the parameter for a given kernel invocation, residing at address y, must be copied into the memory location pointed to by x. Figure 5b shows how GraCE converts the kernel parameter to pointer-to-pointer via indirection. These pointer-to-pointers are then recorded during graph capture. Before each replay, the pointers to the parameter (y) for the given invocation of the kernel are copied onto the address (pointer-to-pointer, px) recorded during the graph capture. The modified kernel then de-references these pointer-to-pointers before performing any computation (green).

Our approach relies on the ability to rewrite kernels, which is feasible for JIT-compiled kernels (e.g., Triton [52]) but not for vendor-supplied libraries (e.g., CUTLASS [42], cuBLAS [41]) or pre-compiled kernels. In §4, we describe an alternative mechanism that extends PI to these kernels based on recently introduced CG management APIs [47], while meeting GraCE's goal of zero manual changes.

An additional benefit of our approach is that PI eliminates the need to keep static placeholders allocated for input tensors over a CG's lifetime. Instead, it requires a pointer-to-pointer whose contents are updated before each replay. This avoids duplicate storage, reducing the peak memory footprint by up to 15% during replay.

Selective CUDA Graphs (SCG): Since CGs can also hurt performance (§2), they should not be used blindly. GraCE employs automated profiling as part of the compilation and graph capture phase (slow path). Specifically, GraCE measures the aggregate time to execute individual kernels encapsulated in a CG. It also profiles the execution time of the corresponding CG with and without Parameter Indirection. The profiler then automatically chooses the best-performing configuration for the given set of kernels in an application. This decision is made independently for each of the CGs. Also, note that this profiling happens during compilation and CG capture phase (slow path) and not during the graph replay (fast path).

Taken together, these three optimizations push CUDA Graphs closer to their peak potential. CGCT broadens capture eligibility so that substantially more of the program can benefit from graph execution. PI removes a major replay bottleneck by eliminating parameter-copy overheads. SCG ensures that CGs are enabled only when they deliver end-to-end gains. The result is a system that captures larger kernel regions in graphs, executes them with lower overhead, and deploys CGs only where they improve performance.

4 Implementing GraCE

GraCE is built into PyTorch2's compilation workflow (slow path) that is responsible for CUDA Graph capture, enabling its optimizations to benefit fast-path execution (replay).

We chose PyTorch as the platform to build GraCE in order to seamlessly bring the benefits of CUDA Graph to a wide range of ML workloads. Arguably, PyTorch is the most popular framework for creating ML applications [6, 17, 35].

We begin with a brief discussion of the compilation workflow of the PyTorch2 compiler and then discuss how GraCE leverages it to apply its three optimizations.

Compilation workflow in GraCE: GraCE follows a structure commonly found in modern ML compilers—such as PyTorch2 [3], JAX/XLA [5]. The typical compilation pipeline consists of ① *Computation Graph Construction Layer (Frontend)*, where Python execution is symbolically traced, producing a computation graph in a high-level IR. ② *IR Lowering & Optimization Layer (Mid-Level Pass)*, where the graph is lowered into a more uniform IR, enriched with metadata such as tensor shapes, device placement, and debug mappings. ③ *Kernel Generation Layer (Backend)*, where primitive operations are either dispatched to optimized GPU libraries (cuBLAS [41], cuDNN [43], CUTLASS [42]) or implemented through just-in-time (JIT) kernel generators such as Triton [52]. ④ *Graph-Capture Layer*, where the final compiled module is executed, and if eligible, captured as a CG. This layer maintains parameter placeholders and bookkeeping logic required to replay CGs.

GraCE adds targeted extensions to each of these layers in PyTorch2. Figure 6 provides an overview of GraCE's implementation, depicting how it extends selected components of the PyTorch2's compilation workflow. The orange and purple background regions delimit the key components of the PyTorch2 compiler—its frontend (Torch Dynamo [57]) and backend (Torch Inductor [25]). Modifications for CGCT are shown in blue, while those for PI and SCG appear in yellow and green, respectively. GraCE's three optimizations —

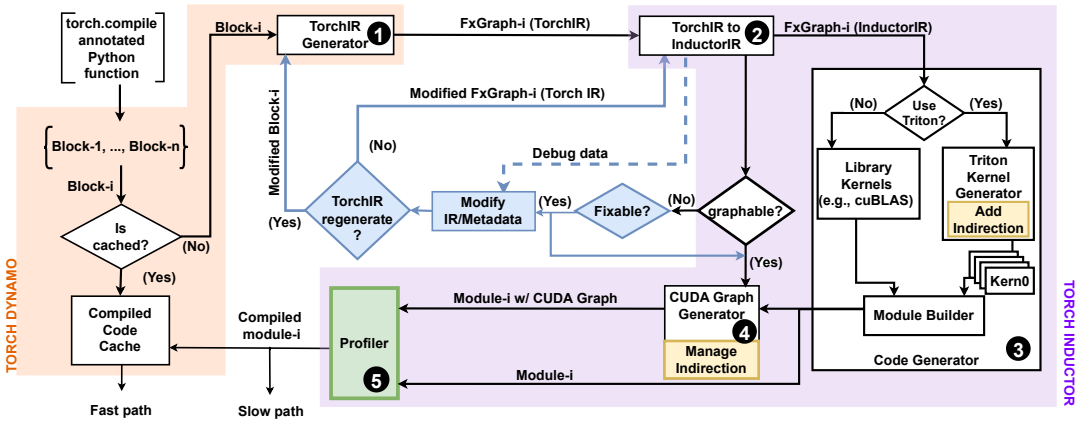


Figure 6: Implementation of GraCE within PyTorch2's compilation framework.

CGCT (blue), PI (yellow), and SCG (green) — extend different parts of the compilation workflow and are detailed in §4.1, §4.2, and §4.3, respectively.

4.1 CUDA Graph-aware Code Transformation

GraCE automatically finds and mitigates multiple factors that prevent deployment of CUDA Graphs. For ease of exposition, we describe the PyTorch2 components involved in deploying CGs first, and then GraCE's extensions to them.

4.1.1 Computation Graph Construction Layer

Torch Dynamo (Figure 6, orange block on the left) intercepts Python execution and constructs computation graphs (FxGraphs [63]) consisting of TorchIR — a simplified IR that exposes Python and PyTorch operations for optimization. Dynamo symbolically traces operations until it encounters one that cannot be safely traced (e.g., input-dependent control flow). It terminates the current FxGraph, compiles it, and splices the compiled result back into the source program via bytecode rewriting. It resumes tracing after the offending operation, effectively partitioning the program into blocks, each of which is lowered independently to TorchIR (① in Figure 6).

GraCE's extensions: Dynamo is extended to regenerate TorchIR from a modified code block (① in Figure 6), provided by the extensions to Torch Inductor described next.

4.1.2 IR-Lowering & Optimization Layer

Torch Inductor (Figure 6, purple region), lowers the TorchIR produced by Dynamo into a lower-level IR comprised of primitive Aten/Prim [56] operations. Inductor then augments this IR with operand metadata–including tensor shapes, device placement (CPU or GPU), and debug mappings from this lowered IR back to TorchIR–producing InductorIR (② in Figure 6). InductorIR serves as input to subsequent phases (§4.2) that apply further optimizations and code transformations.

Inductor also decides whether a FxGraph represented by an InductorIR instance can be captured as a CUDA Graph. If the metadata shows that an FxGraph's node has a CPU-resident scalar operand, performs a CPU–GPU memcopy, or involves an input mutation, Inductor avoids encapsulating it in a CG.

GraCE's extensions: To map more FxGraphs to CGs, GraCE enhances Inductor's decision routine for CG eligibility. When this routine determines that an FxGraph cannot be mapped to a CG, GraCE inspects the cause of failure. If the failure is due to the presence of one or more scalar variables (e.g., a NumPy scalar as discussed in §2), it uses bytecode rewrites to cast the variables as GPU tensors, effectively removing the CPU operand/operation from the graph capture path. Dynamo then regenerates TorchIR for the modified block, which is re-lowered to InductorIR, enabling the FxGraph to be mapped to a CG.

Figure 7 illustrates this transformation for the `temperature` scalar from the speech transformer example in Figure 2. Specifically, it shows the Dynamo-generated bytecode without (Figure 7a) and with CGCT (Figure 7b). GraCE analyzes the Inductor IR to notice that the scalar input

Without CGCT

```
graph_out_0 =
__compiled_fn_43(
 ..., torch.as_tensor(
  __import_torch.as_tensor(
   self.layer_stack[0]
    .slf_attn
    .attention
    .temperature
   )), ...)
```

(a) Original bytecode.

With CGCT

```
graph_out_0 =
__compiled_fn_43(
 ..., torch.as_tensor(
  __import_torch.as_tensor(
   self.layer_stack[0]
    .slf_attn
    .attention
    .temperature,
   device='cuda')), ...)
```

(b) Modified bytecode.

Figure 7: IR modification as part of CGCT.

to a kernel is resident on the CPU DRAM. It then uses debug metadata to backtrace the offending Dynamo-generated bytecode that creates a PyTorch tensor. GraCE then rewrites this bytecode to construct the tensor on the GPU (here, add `device='cuda'`). The rewritten IR then makes the surrounding FxGraph eligible for CG capture.

A CPU-to-GPU memcopy can also prevent Inductor from deploying a CG. Using debug metadata, GraCE backtraces the InductorIR node to the Python object owning the offending CPU tensor and copies it to the GPU. This effectively changes the variable's device placement, hoisting the memcopy into the object's constructor so that it precedes any computation. As a result, memcopy gets removed from the graph-capture path, and the corresponding module can be mapped to a CG. Similarly, a CG may not get deployed if the output of an InductorIR node is a CPU tensor. In such a case, GraCE updates the metadata of the corresponding TorchIR node to mark the output as a GPU tensor (i.e., setting `device='cuda'`). The updated TorchIR is then re-lowered to InductorIR (② in Figure 6), removing the CPU tensor from the graph-capture path and allowing the FxGraph to be mapped to a CG.

4.2 Parameter Indirection

We detail how GraCE achieves its goal of reducing parameter copy overheads through indirection. This needs modifying how kernels within CUDA Graphs obtain their parameters.

4.2.1 Kernel-Generation Layer

The code generator (③ in Figure 6) is responsible for generating an optimized executable (module) for an FxGraph. It uses different frameworks/libraries depending on the target hardware. Here, we focus on systems with NVIDIA GPUs.

The code generator either invokes kernels from vendor-supplied external libraries (e.g., cuBLAS [41]) or generates kernels just-in-time (JIT) using frameworks such as OpenAI's Triton [52]. It maintains a list of InductorIR ops (e.g., matmul, convolution) that use kernels from vendor-supplied libraries and emits direct calls to the relevant library routines. Remaining operations are implemented just-in-time using Triton. For such operations, the code generator constructs a Triton function in Triton's Python-based DSL, decorates it with `triton.jit` for JIT compilation. It then invokes the Triton compiler to generate CUDA binaries. A module created for an FxGraph may contain both Triton and vendor-supplied kernels. After resolving all operations, the module builder assembles these components into a single, optimized module.

GraCE's extensions: Recall that the goal of GraCE is to enable repeated replay of a captured CG with different parameter values, but without adding the overhead of copying the parameter. It makes two changes to kernels to turn parameter (data) copies into pointer copies. First, it replaces each pointer argument with a pointer-to-pointer that holds the address of the data the kernel will access. Second, before the kernel starts executing, it dereferences these pointers-to-pointers, allowing the rest of the kernel to access the actual data correctly.

GraCE employs two distinct implementation approaches to achieve the above objective, depending on whether the given kernel is generated just-in-time or is a vendor-supplied one. While the former can be updated during compilation, the latter *cannot* – requiring two different approaches.

Enabling PI in JIT-ed kernels: To apply indirection to eligible Triton-generated JIT kernels without manual intervention, GraCE identifies the parameters that must undergo indirection during the code generation phase [1] and attaches this information to the `torch.jit` decorator (yellow element in ④ in Figure 6). GraCE's custom LLVM [10] pass integrated into the Triton framework then retrieves this parameter list from the decorator and rewrites the PTX [46] code of the corresponding kernels. The pass updates the kernel signatures to use 'pointer-to-pointer' arguments for the designated parameters. Further, it inserts PTX instructions at the beginning of the kernel to de-reference these pointers before using them in computation. The rest of the kernel code remains unchanged.

Enabling PI in vendor-supplied kernels: The approach of rewriting kernels is not feasible for those from vendor-supplied external libraries. These kernels are often supplied as compiled binaries. To work around this fundamental limitation, GraCE introduces an additional *prelude* kernel in the CUDA Graph at the start of the graph. The prelude kernel updates the parameters of the vendor-supplied kernel to point to actual data for a given invocation on the fly during replays.

The prelude kernel is provided with pointer-to-pointers to the parameters of the vendor-supplied kernel, whose values change across graph replays. It is tasked with performing the dereferencing of the pointer-to-pointer argument for the immutable vendor-supplied kernel. GraCE compiles the prelude kernel on the fly using NVRTC [51], and re-records the CUDA Graph with this kernel inserted before any other nodes. To achieve the effect of dereferencing, the prelude kernel must be able to update parameters to the vendor-supplied kernel on the fly during replay.

Fortunately, CUDA runtime version 12.4 introduced new device-side APIs to update parameters of a node in CUDA Graph from within another kernel (`cudaGraphKernelNodeSetParam`) [47]. The prelude kernel uses this API to update the parameters of the vendor-supplied kernel during replay.

The device-side APIs to update kernel parameters take three arguments: ① the kernel-node handle, ② a device-memory address (pointer) that holds the replacement pointer value, and ③ the offset within the kernel node's parameter

[1] Not all kernels or parameters require copying parameter data into placeholders. Outputs produced by earlier kernels in a CG can be passed directly to later kernels. Only kernels whose parameters originate from external sources (e.g., application inputs) require indirection. GraCE selectively applies indirection only for such parameters.

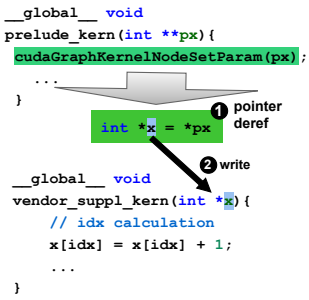

Figure 8: Indirection in vendor-supplied kernels.

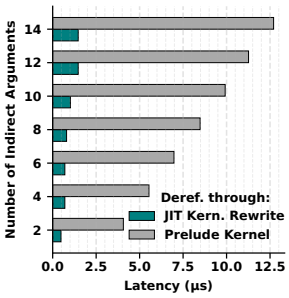

Figure 9: Latency comparison of PI approaches.

buffer. The API de-references the input pointer and writes the resulting value into the parameter buffer at the specified offset for the given kernel node. This operation performs a de-reference followed by a memory write.

The next challenge is to find the offset of the argument to be updated within the kernel's parameter buffer. For this purpose, GraCE uses another CUDA API `cuFuncGetParamInfo` to obtain a handle to the kernel's parameter buffer during compilation. Then, it performs a byte-pattern match with the known placeholder pointers (recorded during graph capture) within the buffer to identify the correct offsets. As with our earlier optimization, the transformation remains fully transparent to PyTorch programs and to the rest of the PyTorch2 compilation framework.

Figure 8 illustrates this technique. Recall GraCE's aim to convert a kernel parameter (pointer `x`) into a pointer-to-pointer (`px`). During graph capture (§4.2.2), these pointer-to-pointers are recorded as parameters of the prelude kernel. Before each replay of the captured CG, the invocation-specific pointers to parameters are written into the recorded pointer-to-pointer locations (`px`). During replay, the prelude kernel de-references these pointer-to-pointers (① in Figure 8) and writes the resulting values into the parameter fields of the vendor-supplied kernel node (②) using the aforementioned parameter update APIs.

A keen reader would note that this technique can also be used to achieve parameter indirection for JIT compiled kernels. While true, we empirically observed that it is noticeably slower than rewriting the kernel directly during compilation. Figure 9 compares the latency of de-reference through JIT kernel rewrite and through prelude kernel techniques as the number of indirected parameters increases. PI through the prelude kernel is substantially slower and scales poorly, exceeding 10 µs at higher parameter counts. Consequently, we employ JIT-based kernel update where possible, falling back to using prelude kernels only for vendor-supplied kernels.

4.2.2 Graph-Capture Layer

The CUDA Graph generator (④ in Figure 6) captures the compiled module as a CG whenever prior analysis on InductorIR determines that the entire FxGraph can be mapped to a CG. PyTorch2 captures CGs only at the granularity of a whole-FxGraph. Because a CG records kernel parameters (e.g., pointer addresses) by value, the generator creates static placeholders for these parameters and substitutes them for the original parameters before capture.

The graph generator must consider two types of kernel parameters: ① those supplied externally (e.g., application inputs), and ② those produced by preceding kernels within the CG. In the former, the placeholders do not initially contain the correct parameter value for each replay. It must be copied to the placeholders pointed to by the kernel parameters. In the second case, no copy is required, since the producer kernel writes directly into the placeholder. The CUDA Graph generator thus replaces the original parameters with static placeholders. It injects code that would perform the necessary parameter copies into the static placeholder before a kernel's invocation during replay. Finally, it uses the stream capture method (§2) to create a CG for the module.

GraCE's extensions: To take advantage of PI, GraCE enhances the CUDA Graph generator (yellow element in ④ in Figure 6). The enhanced generator receives the list of parameters that had undergone indirection by the code generator. For such parameters, GraCE: ① allocates static placeholders for *pointers* instead of data regions, and ② injects code to perform pointer copies for these parameters instead of parameter (data) copies. Note that these pointer copies are host-to-device (H2D) copies over the PCIe, as the list of pointers to parameters originally resides on the CPU. In contrast, original parameter copies are device-to-device within the GPU. The H2D pointer copy is issued on the same CUDA stream as the subsequent graph replay. Since operations queued in a stream are always executed sequentially, no additional host-device synchronization is needed for correctness. This extension also places the prelude kernel into the captured graph.

4.3 Selective CUDA Graphs

Recall that the overheads of a CUDA Graph can outweigh its benefits (§2). These overheads are due to parameter copies, as well as tasks such as garbage collection for graph replays (§2). While PI can reduce overheads due to parameter copies for kernels in a CG, the rest of the overheads remain.

GraCE introduces a profiler in the compilation phase (slow path) to judiciously decide whether to deploy a CG based on a cost-benefit analysis (colored green, ⑤ in Figure 6). The final outcome of the compilation is an optimized executable (module) corresponding to the given block of PyTorch code. It is then cached for use in the fast path.

PyTorch2 greedily deploys CGs wherever one can be

created. In contrast, GraCE considers up to three possible choices: ① A module *without* CG, ② a module with CG but *without* PI, and ③ a module with CG and PI. The profiler runs each of the available modules as part of the compilation phase, measures their execution time, and caches the module with the best performance.

One may wonder why GraCE distinguishes between ② and ③. The subtlety is that PI replaces device-to-device parameter (data) copies with host-to-device pointer copies. When working with many small objects, it is possible that the overhead of copying pointers over the PCIe outweighs that of copying parameters (data) within the GPU's memory. In addition, GPU memory bandwidth and PCIe transfer bandwidth vary across hardware. Consequently, the benefit from PI varies across hardware. This variability is captured by SCG through profiling conducted on the target hardware. GraCE selectively deploys CG only where it is beneficial.

Summary: GraCE extends Torch Dynamo and Torch Inductor to transparently update IRs for enabling more kernels to execute as part of CG (CGCT). It extends Triton's kernel generator and PyTorch2's CG generator to add indirections to convert data copies in CG to pointer copies (PI). Finally, it adds a profiler in the slow path that uses a cost-benefit analysis to decide when it is beneficial to deploy CG (SCG).

4.4 Applicability to other frameworks

GraCE addresses fundamental limitations arising from the CUDA Graph feature as defined by the hardware vendors. For example, the overhead of parameter copying exists because kernel parameters are recorded by value during graph capture – a constraint of NVIDIA's CUDA Graph feature. Such limitations affect not only PyTorch2 but also other frameworks that attempt to deploy CG. The optimizations proposed in this work, e.g., CUDA Graph-aware IR rewrite, parameter indirection, are also applicable to other frameworks such as JAX/XLA [5]. Importantly, these frameworks, like PyTorch2, embody features such as graph capture, JIT kernel generation, and metadata-rich IR, which enable GraCE's three optimizations to be implemented seamlessly.

Unlike PyTorch2 and JAX/XLA, which target general ML applications, specialized frameworks such as vLLM [33] and SGLang [11] are built atop PyTorch but are tailored for LLMs. For example, LLM's KV cache management is a primary focus of vLLM. In contrast, our goal is to bring the benefits of CG to any ML applications that rely on popular frameworks such as PyTorch. Importantly, vLLM is only partially compatible with PyTorch2's `torch.compile()`. Today, only parts of a model in vLLM can be compiled to benefit from PyTorch2. An ongoing community effort is actively working toward addressing this limitation [19]. In the meantime, vLLM employs a customized handwritten Torch's Inductor backend to leverage CG, albeit only partially [76, 77]. GraCE strives to avoid these custom and temporary fixes to individual frameworks. Once the community enables vLLM to fully use `torch.compile()`, we expect GraCE to benefit frameworks like vLLM automatically.

Suite	Application (Short Name, Type, Batch Size)
TorchBench	Equation of State (EOS, I 1048576), Speech Transformer (ST, I, 1), DALLE2_pytorch (DALLE2, I, 1), Multi-modal Clip (MMC, I, 1), Turbulent Kinetic Energy (TKE, I, 1048576), Deep Recommender (DR-T, T, 256), Deep Recommender (DR-I, I, 8192), Vision MaskRCNN (VM, I, 1), AlexNet (ALNET, I, 2), dlrm (DLRM, I, 2048), TIMM Efficientdet (TEFD, T, 1), dcgan (DCGAN, T, 32), BERT (BERT, T, 16), densenet121 (DNET, I, 64),

Table 1: Details of the workloads (T: Training, I: Inference).

5 Evaluation

Our evaluation seeks to answer the following questions:

- How well does GraCE exploit CUDA Graphs relative to the widely used PyTorch2 compiler?
- How much does each optimization in GraCE contribute to end-to-end performance?
- How robustly does GraCE generalize to distributed models and diverse GPUs?

Workloads and metric: We evaluate a broad mix of training and inference workloads from TorchBench [22], HuggingFace [24], and TIMM [81], spanning vision, NLP, and HPC. We focus on applications that are sensitive to CUDA Graph usage; Table 1 summarizes these workloads. Since ML workloads are inherently repetitive, we use per-iteration runtime as our primary performance metric for evaluation. An iteration consists of one forward pass for inference, while one forward and one backward pass for training. All reported numbers are averaged over 100 runs, each using a different input sample at the workload's configured batch size (Table 1).

Environment: We conduct experiments on an NVIDIA H100 NVL GPU with 94GB HBM3, paired with a 64-core Intel Xeon 8462Y+ CPU and 512 GB of DDR5 memory. The software stack includes PyTorch 2.4 [58], CUDA 12.8 [49], cuDNN 8.9.2 [44], and NVIDIA driver 575.57.08. For multi-GPU benchmarks, we use a system with four 80GB H100s connected via high-bandwidth NVLink, running CUDA 12.4.

Baselines: We compare GraCE against two baselines: PyTorch2 *without* CUDA Graphs, denoted PyTorch2-No-CG, and PyTorch2 with CUDA Graphs enabled, denoted

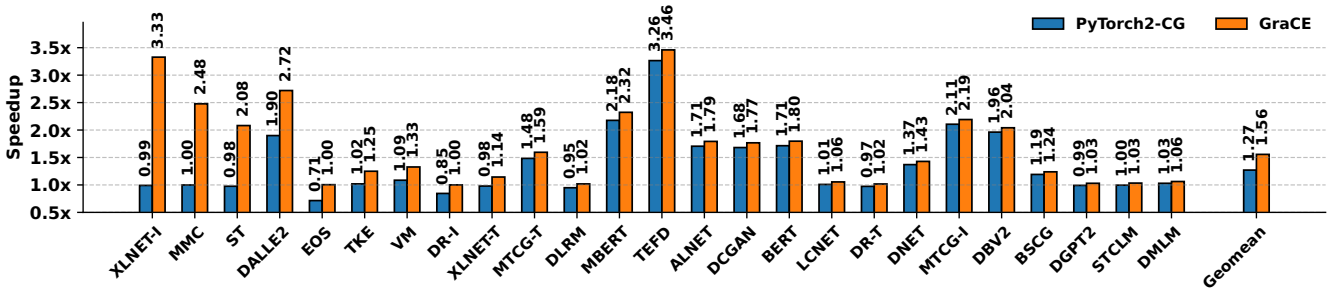

Figure 10: Performance improvement of PyTorch2-CG and GraCE against PyTorch2-No-CG.

PyTorch2-CG. All compilers are based on PyTorch v2.4.

We chose PyTorch2 as the baseline for two reasons: ① Our goal is to seamlessly bring the benefits of CG to a broad class of ML workloads. To the best of our knowledge, frameworks such as PyTorch2 and JAX/XLA are the only open-source ML programming frameworks that can automatically capture CG during compilation and deploy CG seamlessly in the fast path, and ② While it is possible to extend JAX/XLA to implement GraCE, we chose PyTorch2 because it is the most popular GPU backend [6, 17, 35]. In fact, popular LLM-specific frameworks such as vLLM [33] and SGlang [11] build on PyTorch2.

5.1 End-to-end performance

Figure 10 compares GraCE's performance against that of PyTorch2-No-CG and PyTorch2-CG. The figure displays two bars for each application, where the first bar indicates the speedup of PyTorch2-CG over PyTorch2-No-CG, and the second reports the speedup of GraCE over PyTorch2-No-CG.

First, we find that although CUDA Graph was introduced purely as a performance optimization, its current deployment in PyTorch2 can significantly hurt performance. PyTorch2-CG slows down 4 of the 25 applications by at least 3% compared to PyTorch2-No-CG (bars with height < 1), with worst-case regressions of 29% for EOS (HPC) and 15% for Deep Recommender (inference). These workloads consist of short kernels of tens of microseconds each for which the replay overhead (e.g., parameter copying and RNG management) dominates execution time (often around $\sim$ 50%). As a result, blindly deploying all CGs causes net slowdowns, and yet PyTorch2-CG deploys them anyway. In contrast, GraCE is at least as good as the best of PyTorch2-No-CG and PyTorch2-CG for every application. This is important as it absolves a user from having to decide whether to enable CG for each of their programs.

Second, even in cases where PyTorch2-CG improves performance over PyTorch2-No-CG, it still fails to effectively harness CUDA Graph as shown by the difference between bars for PyTorch2-CG and GraCE. GraCE improves performance over PyTorch2-CG by 29% on average and by up to 3.36× (XLNET-inference). While PyTorch2-CG fails to deploy any CUDA Graphs in XLNET-I, GraCE deployed 413 kernels through CGs, thanks to its CG-aware code transformation. In another example, PyTorch2-CG improves DALLE2 (inference) by 1.9× whereas GraCE improves it by 2.72×. In summary, GraCE effectively leverages CGs when there is an opportunity without hurting performance elsewhere.

5.2 Ablation of individual optimizations

Figure 11 quantifies individual contribution of each optimization in GraCE. Each application has three bars corresponding to three optimizations. The height of a bar is normalized to the performance of PyTorch2-No-CG. The total height of the first bar shows the speedup obtained by applying CUDA Graph-aware Code Transformation (CGCT) alone. The bottom stack (dark blue) of the first bar shows the speedup of PyTorch2-CG over PyTorch2-No-CG. The top stack captures the improvement due to CGCT over PyTorch2-CG. The second bar shows performance of PI in tandem with CGCT (+Parameter Indirection). The third bar shows the cumulative effect of three optimizations (+Selective CUDA Graphs).

CUDA Graph-aware Code Transformation. CGCT enables more kernels to be captured within CGs, amortizing the overhead associated with individual kernel launches. As a result, applications such as XLNET-I, MMC, and ST achieve speedups of 3.14×, 2.31×, 2× over PyTorch2-CG, while DALLE2, XLNET-T, and VM improve performance by 43%, 16%, and 11% over PyTorch2-CG, respectively.

Table 2 lists six applications that witness a significant increase in the percentage of their kernels launched as part of CG(s). For example, PyTorch2-CG fails to deploy any CUDA Graph for MMC and XLNET-I. In case of XLNET-I, its FxGraph with 413 kernels was not deployed via CG due to the presence of a *single* CPU tensor in the FxGraph. Similarly, one of the FxGraphs of DALLE2 with 314 kernels was not deployed as a CG due to a *single* memcopy operation from a CPU tensor to a GPU tensor. CGCT removes these constraints, deploying more than 99% of the kernels via CG(s). Even for ST and VM, CGCT increased CG coverage from 5.14% and 58.84% to 74.22% and 71.01%.

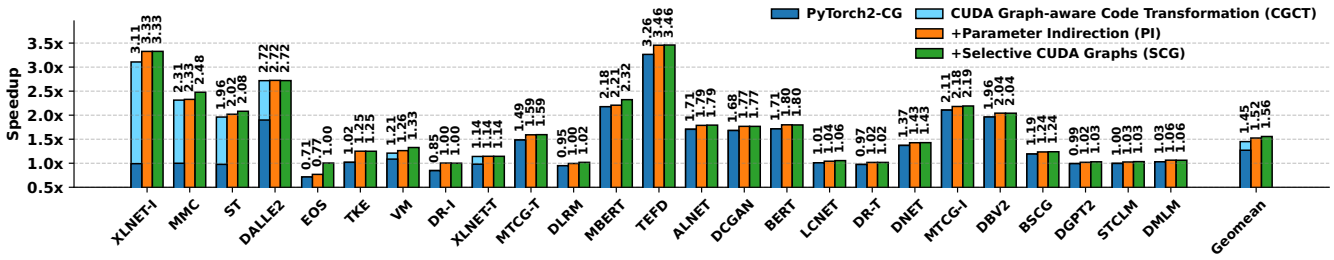

Figure 11: Ablation study on different optimizations of GraCE (performance normalized against PyTorch2-No-CG).

App.	% of Kernels in CUDA Graphs	
	PyTorch2-CG	w/ CUDA Graph-aware Code Transformation
ST	5.14	74.22
DALLE2	79.56	99.32
MMC	0	99.32
XLNET-T	1.53	98.06
XLNET-I	0	99.28
VM	58.84	71.01

Table 2: Enhanced coverage by CUDA Graphs due to CUDA Graph-aware Code Transformation.

App.	Bytes Copy Reduced (# CUDA Graphs)	App.	Bytes Copy Reduced (# CUDA Graphs)
XLNET-I	8.0 KB → 16.0 B (1)	MMC	314.0 KB → 16.0 B (1)
ST	1.3 MB → 336.0 B (3)	DALLE2	4.0 KB → 16.0 B (5)
EOS	4.1 MB → 24.0 B (0)	TKE	174.0 MB → 168.0 B (1)
VM	1.6 MB → 184.0 B (3)	DR-I	3.0 GB → 8.0 B (1)
XLNET-T	362.0 MB → 232.0 B (3)	MTCG-T	1.0 GB → 312.0 B (3)
DLRM	14.6 MB → 136.0 B (1)	MBERT	130.0 KB → 24.0 B (1)
TEFD	6.2 MB → 120.0 B (2)	ALNET	588.0 KB → 8.0 B (1)
DCGAN	1.5 MB → 16.0 B (1)	BERT	156.3 MB → 32.0 B (2)
LCNET	73.5 MB → 8.0 B (1)	DR-T	290.0 MB → 16.0 B (2)
DNET	18.4 MB → 8.0 B (1)	MTCG-I	32.0 KB → 16.0 B (1)
DBV2	4.0 KB → 24.0 B (1)	BSCG	1.6 GB → 56.0 B (30)
DGPT2	953.4 MB → 136.0 B (3)	STCLM	849.5 MB → 136.0 B (14)
DMLM	548.8 MB → 136.0 B (3)		

Table 3: Reduction in data copy and number of CUDA Graphs optimized by GraCE's parameter indirection.

Parameter Indirection. PI reduces overhead of copying kernel parameters while replaying CGs. This speeds up TKE by 23% and DR-I by 18%. Twelve others speed up by more than 4% (EOS, XLNET-I, MTCG-T, TEFD, DCGAN, DLRM, BERT, DR-T, ALNET, DNET, BSCG, VM).

Table 3 reports the reduction in bytes copied by PI. Most workloads see a drastic drop, with the maximum remaining copy size under GraCE at just 336 B. For example, it reduces the bytes copied in MTCG-T, DGPT2, STCLM, and DMLM from 1 GB, 953 MB, 850 MB, and 548 MB, respectively, to just 312 B, 136 B, 136 B, and 136 B, a reduction of over 99%. Table 3 also shows the number of CGs that GraCE optimizes via PI in parentheses.

Note that even after eliminating all data copy, PI may not always benefit the application. For example, for a small tensor, the PCIe transfer cost due to pointer copy may outweigh the benefit of avoiding a larger copy within GPU HBM. These are the cases where a CG does not benefit from PI. For instance, DALLE2 sees no benefit from PI. In contrast, the lone CG in TKE and DR-I gains significantly from reduced copy sizes, yielding speedups of 23% and 18%.

Selective CUDA Graphs. SCG judiciously deploys CGs driven by a cost-benefit analysis. It disables CGs where they could hurt performance, avoiding regression. This is particularly important for applications such as EOS, where blind deployment of CGs degrades performance by 29%.

In five applications, GraCE selectively disables CGs to achieve better overall performance. For instance, VM exposes 21 candidate CGs, but GraCE enables only four and disables the other 17 to improve end-to-end performance by 6%. Similarly, SCG disables the single CG in EOS to avoid performance loss. Overall, GraCE exercises selective deployment by enabling 97 of 123 possible CGs across the applications.

Overall, these results demonstrate that each of GraCE's optimizations makes a meaningful contribution across multiple applications, collectively enhancing overall performance.

5.3 Evaluating distributed ML models

We evaluated the efficacy of GraCE under tensor parallelism (TP) [68], a widely deployed strategy for distributing ML processing in a multi-GPU setting. We evaluated four workloads under TP on a server with 4×H100 GPUs connected over NVLink. Figure 12 summarizes the results: for each application, we report three groups of measurements corresponding to TP-1, TP-2, and TP-4. In each group, we compare the performance of PyTorch2-CG and GraCE against the PyTorch2-No-CG under the given TP setting. This allows us to observe the effectiveness of PyTorch2-CG and GraCE under TP.

Figure 12 demonstrates that GraCE significantly amplifies the benefits of CGs over PyTorch2-CG under TP. All results use an inference batch size of 1, except for XLNET and DALLE2, which use batch sizes of 128 and 2, respectively. As the degree of TP increases, GPU kernels finish faster, and CPU launch latency becomes a larger fraction of overall runtime. This, in turn, increases the importance of fully harnessing CUDA Graphs, which PyTorch2-CG fails to do. In contrast, GraCE yields substantially higher speedups for XLNET, DALLE2, and ST with progressively larger gains

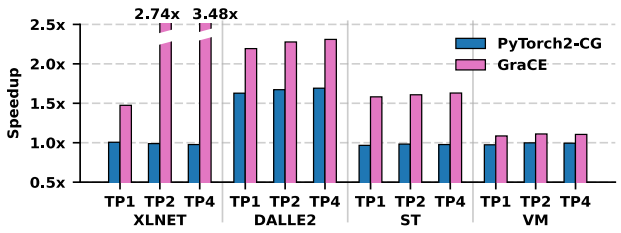

Figure 12: Speedup of PyTorch2-CG and GraCE over PyTorch2-No-CG across tensor parallel settings (TP=1,2,4).

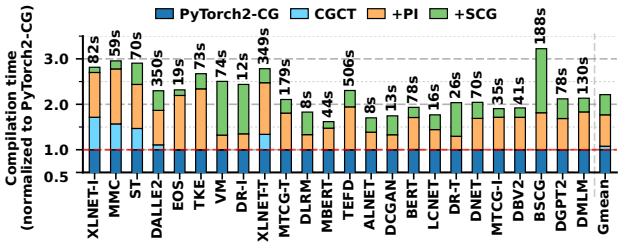

Figure 13: Breakdown of compilation time overheads of GraCE, normalized to PyTorch2-CG. The stacked bars show the cumulative contribution of CGCT, PI, and SCG. Numbers above the bars show absolute compilation time in seconds.

as parallelism increases, as it is able to deploy many kernels in CUDA Graphs. Its speedup reaches up to 3.48× over PyTorch2-No-CG at TP-4 for XLNET with 2.41× on average across different TP settings. This demonstrates that GraCE assumes further importance with increasingly wider deployment of distributed ML processing across multiple GPUs.

Evaluation on A6000 GPU. We also evaluated GraCE on a workstation-class A6000 GPU having less compute power than H100s. As the GPU becomes slower, the headroom for improvement with CGs reduces. Even then, GraCE more prudently utilizes CUDA Graph compared to PyTorch2-CG. For example, PyTorch2-CG degrades performance compared to PyTorch2-No-CG by up to 32% for EOS. In contrast, GraCE never degrades performance and achieves a maximum improvement of 3.25× over PyTorch2-No-CG with an average speedup of 1.18× compared to PyTorch2-CG's average speedup of 1.06 over PyTorch2-No-CG. This shows that GraCE's efficacy is not tied to a specific GPU architecture.

Analyzing overheads of GraCE. GraCE increases compilation time (slow path) for faster execution during graph replay (fast path). Note that PyTorch2 captures the CUDA Graph during compilation. Thus, GraCE's compilation overhead is incurred only once per application and hardware platform. This one-time cost is amortized over repeated execution of the application (fast path).

Figure 13 provides a breakdown of the compilation overhead of GraCE, normalized to PyTorch2-CG (y-axis; lower is better). Each application has a stacked bar. The number at the top of each bar reports the absolute compilation time. Each bar has four stacks. The bottom-most stack (PyTorch2-CG) represents the compilation time of PyTorch2-CG. The three stacks on top of it represent the overheads added by the three optimizations in GraCE, i.e., CGCT, PI, and SCG.

We observe that GraCE increases compilation time by 2.21× on average. In the worst case, the compilation time increased by 3.2× for the BSCG application. For BSCG, the increase comes from profiling a large number of candidate modules for CG deployment as part of SCG. On the other hand, applications such as TKE and MMC have many Triton-generated kernels that take longer to regenerate due to PI. Finally, CGCT contributes significantly to the compilation time of XLNET-I. It undergoes many TorchIR metadata updates and re-lowering to InductorIR to remove CPU-tensor outputs from InductorIR, enabling CG deployment. The remaining applications incur increased compilation time due to similar reasons. Overall, the compilation takes up to 506 seconds (highest for TEFD). For TEFD, PyTorch2 took 220 seconds to compile. In general, the increased time is a reasonable one-time cost for compilation and graph capture.

GraCE increases peak memory footprint during compilation by 12% on average. Like compilation time, this is also a one-time cost, though. The overhead arises from profiling multiple CG deployment choices in SCG. This temporarily retains captured tensors and allocation metadata in memory. However, GraCE does *not* introduce any memory overhead during replays (fast path). On the contrary, it actually reduces peak memory footprint during replays by up to 15% compared to PyTorch2-CG.

6 Related Work

ML compilers: Early ML compilers such as TensorFlow [1], Caffe [28], Theano [75], and CNTK [64] improve performance via graph-level optimizations, while later systems develop richer tensor-program IRs [4, 7, 12, 16, 21, 36, 52, 65, 78, 84, 89, 91–94] and target efficient code generation across diverse hardware and irregular workloads [15, 66, 73, 86]. Recent advances introduce whole-graph and memory-centric optimizations [67, 83], accelerate dynamic control flow [88], and perform multi-level super-optimization using unified IRs [82]. These efforts reduce kernel count and/or improve efficiency of kernels. GraCE complements them by mitigating CPU launch overhead and enhancing CUDA Graph's deployability.

PyTorch2 [3] showed that dynamic Python execution can coexist with graph compilation by using Torch Dynamo [57] to rewrite Python bytecode into FxGraphs [63] and Torch Inductor [25] to lower them into optimized GPU kernels. Earlier capture mechanisms–JIT tracing, TorchScript [60], lazy tensors [59, 72], and symbolic tracing [63]–were limited by unsoundness, incomplete Python coverage, or high recompilation overheads. GraCE is not tied to PyTorch2's

pipeline; it only assumes a compiler that produces a stable kernel-launch DAG and augments the backend that prepares and executes kernels. GraCE's approach can also be integrated with JAX [5] and XLA [53]. Source-level graph-repair techniques [32] are complementary to GraCE. They lengthen computation graphs, while GraCE ensures the resulting kernel DAGs are effectively captured as CUDA Graphs.

CUDA Graphs: Grape [90] is a close prior work, optimizing CUDA Graphs for DNNs through predication rewriting, metadata compression, and alias prediction, but these techniques require extensive manual kernel and CUDA-driver changes – e.g., over 400 lines of kernel edits for GPT beam search – and its alias predictor is incompatible with PyTorch2. In contrast, GraCE requires *no* manual modifications and works transparently for all PyTorch applications. The extensive manual changes required by Grape and its tight integration with PyTorch 1.12 make a quantitative comparison infeasible. Other systems use CUDA Graphs in specialized deployments, such as serverless LLM inference, by materializing and restoring pre-captured graphs [87]. These efforts focus on a graph's persistence, whereas GraCE enables broader and more efficient deployment of CUDA Graph and thus, is complementary.

7 Conclusion

We present GraCE — a compiler framework designed to enhance the deployment and performance of CUDA Graphs. GraCE addresses several key limitations of the PyTorch2 compiler, leading to substantial performance improvement across various ML benchmarks without requiring manual modifications to applications.

A Artifact Appendix

Abstract

The artifact contains the GraCE implementation, Docker environment, benchmark drivers, workload configurations, and analysis scripts for reproducing the main results in the paper. The recommended path is to use the prebuilt Docker image, run the smoke test, and then run the provided scripts to regenerate the figures and tables.

Scope

The artifact supports validation of the following claims:

- GraCE improves CUDA Graph coverage compared with the PyTorch2-CG baseline on selected deep learning workloads.
- GraCE reduces data-copy movement required by CUDA Graph execution.
- GraCE improves single-GPU performance on selected TorchBench, HuggingFace, and TIMM workloads.
- GraCE improves performance on selected tensor-parallel workloads.
- The reported figures and tables can be regenerated using the provided workload lists, scripts, Docker images, and analysis pipeline.

The artifact is intended for artifact evaluation and reproducibility. Exact performance values may vary across machines because CUDA Graph experiments are sensitive to CPU-side launch overheads, CPU frequency scaling, deep idle states, GPU clocks, NUMA placement, and background host activity. The artifact repository therefore includes optional host-tuning scripts for low-noise benchmarking.

Contents

The artifact repository is organized as follows:

`benchmark_runner/`	Benchmark launcher
`configs/`	Workload lists
`docker/`	Docker run/build scripts
`host_tuning/`	Optional low-noise host tuning
`scripts/`	Experiments and analysis
`third_party/`	GraCE source modules
`results/`	Raw and processed outputs
`figures/, tables/`	Generated paper artifacts

The main source submodules are:

- `third_party/pytorch`: modified PyTorch implementation used by GraCE. This submodule contains separate `osdi26/grace-*` branches corresponding to the incremental GraCE optimizations used in the artifact.
- `third_party/triton`: Triton changes needed by GraCE, primarily on the `osdi26/grace-indirection` branch.
- `third_party/torchbenchmark`: benchmark-suite used by the evaluation.

Generated results are written under `results/`, figures under `figures/`, and tables under `tables/`.

Hosting

The artifact is hosted on GitHub: https://github.com/csl-iisc/GraCE-OSDI26-Artifact on the `master` branch. The prebuilt Docker image is hosted on Docker Hub: `abhishekghosh1998/grace-osdi26:cuda128-prebuilt`. Detailed setup, experiments and analysis instructions are provided in the artifact repository README.

Requirements

The artifact is Docker-based. The host system must have:

- Docker Engine.
- NVIDIA GPU driver.
- NVIDIA Container Toolkit for Docker GPU passthrough.
- One CUDA-capable NVIDIA GPU for smoke tests and single-GPU experiments; four visible GPUs are needed to reproduce the tensor-parallel experiments.

A full CUDA Toolkit installation is not required on the host for the prebuilt Docker workflow. CUDA user-space libraries, Python packages, PyTorch, Triton, TorchBench dependencies, and analysis tools are included in the Docker image. The host only needs an NVIDIA driver compatible with the CUDA runtime used by the selected image.

The paper uses two hardware setups. Single-GPU experiments were collected on an NVIDIA H100 NVL GPU with 94GB HBM3 and CUDA 12.8, paired with a 64-core Intel Xeon Platinum 8462Y+ CPU, 128 logical CPUs with hyperthreading, and 512GB DDR5 memory. Tensor-parallel experiments were collected on a separate four-GPU H100 system with high-bandwidth NVLink and CUDA 12.4.

The artifact can run on other recent x86-64 Linux systems with NVIDIA GPUs, but performance is hardware- and system-dependent. H100-class GPUs and the optional host-tuning workflow are recommended for closest reproduction. Tensor-parallel runs require at least as many visible GPUs as the selected tensor-parallel degree.

The host system should have at least 150GB of free disk space for the prebuilt Docker image. Building the prebuilt image from source takes roughly 2–3 hours on an H100-class host; the full experiment workflow should be treated as a long-running job, with a safe end-to-end allocation of about 24 hours.

Getting Started

The 30-minute validation path checks that the repository, Docker image, CUDA stack, conda environments, benchmark runner, and result-file writing path are functional.

To obtain the artifact:

```
git clone \
https://github.com/csl-iisc/GraCE-OSDI26-Artifact \
    grace-osdi26-artifact
cd grace-osdi26-artifact
git submodule sync --recursive
git submodule update --init --recursive
```

To pull the default prebuilt Docker image:

```
docker pull \
    abhishekghosh1998/grace-osdi26:cuda128-prebuilt
docker tag \
    abhishekghosh1998/grace-osdi26:cuda128-prebuilt \
    grace-osdi26:cuda128-prebuilt
```

From the host:

```
docker/run_cuda128.sh
```

Inside the Docker container:

```
bash scripts/smoke_test.sh
```

The expected final smoke-test output is:

```
[OK] Workload run completed.
```

Experiment Workflow

All commands in this section are run inside the Docker container unless stated otherwise.

Activate a conda environment available in the container:

```
conda activate grace-full
```

For single-GPU experiments (Figures 10–11):

```
bash scripts/run_single_gpu_experiments.sh
bash scripts/generate_figure10.sh
bash scripts/generate_figure11.sh
```

Expected outputs:

```
figures/figure10.pdf
figures/figure11.pdf
```

For tensor-parallel experiments (Figure 12):

```
bash scripts/run_tp_experiments.sh
bash scripts/generate_tp_figure.sh
```

Expected output:

```
figures/figure12.pdf
```

For Table 2, CUDA Graph coverage:

```
bash scripts/run_table2_cgct_coverage_nsys.sh
bash scripts/generate_table2_cgct_coverage.sh
```

Expected output:

```
tables/table2_cgct_coverage.csv
```

This step requires Nsight Systems inside the Docker image.

For Table 3, data-copy movement:

```
bash scripts/run_table3_pi_copy_debug.sh
bash scripts/generate_table3_pi_copy_debug.sh
```

Expected output:

```
tables/table3_pi_copy_debug.csv
```

Host Tuning

Host tuning is optional for functional validation but recommended for paper-quality performance reproduction. GraCE evaluates CUDA Graph execution, where host-side CPU launch overhead and scheduling variability can affect measurements. The repository includes optional scripts for CPU/GPU frequency control, deep C-state control, hyperthreading control, and Docker-aware CPU-set isolation.

Before launching Docker, user may run:

```
sudo host_tuning/tune_host_intel_h100.sh
```

After tuning, launch Docker normally:

```
docker/run_cuda128.sh
```

After all experiments finish, restore the host:

```
sudo host_tuning/restore_host_intel_h100.sh
```

VTC: DNN Compilation with Virtual Tensors for Data Movement Elimination

Muyan Hu[1]* Ahan Gupta[1] Jiachen Yuan[1] Vima Gupta[2] Taeksang Kim[1] Xin Xu[1]
Janardhan Kulkarni[3] Ofer Dekel[3] Vikram Adve[1] Charith Mendis[1]

Abstract

With the widening gap between compute and memory operation latencies, data movement optimizations have become increasingly important for DNN compilation. Current optimizations such as layout transformations and operator fusion only target a subset of tensor operators and consequently miss important opportunities for reducing data movement in contemporary DNN workloads, including large language models.

We introduce VTC, a novel tensor compilation framework that for the first time eliminates all unnecessary data movement by targeting the full spectrum of data movement operators. VTC proposes the concept of *virtual tensors* to track data movement between compute operators via index mappings rather than expensive physical data transfers to and from global memory, which can seamlessly interoperate with existing computation kernels and handle arbitrary tensor operator compositions. We also introduce a novel data movement elimination algorithm to automatically identify a profitable virtual tensor creation strategy. Evaluation on a variety of DNNs shows that VTC can outperform existing ML compilers by up to 1.93× (1.28× on average) on NVIDIA GPUs with up to 60% (17.5% on average) inference memory savings.

1 Introduction

Deep neural network (DNN) workloads have gained popularity in recent years. Usually, DNN models are expressed as tensor (i.e. $n-$dimensional array) based computations. Consequently, DNN developers express these computations using tensor programming languages such as TensorFlow [3], JAX [7], and PyTorch [5], and then utilize tensor compilers like XLA [1], TorchInductor [5], and TVM [9] to generate highly performant executables targeting various hardware devices. These compilers use a multi-stage pipeline similar to general-purpose compilers [6]. During the *compiler frontend*, computations expressed in tensor programming languages are transformed into a compiler intermediate representation (IR), known as *computation graph*. Nodes of these graphs represent tensor operators (e.g. matrix multiplications, convolutions), and each edge represents a tensor flowing from the output of a producer node to the input of a consumer node. The *compiler middle-end* performs graph-level transformations (e.g. operator fusion, tiling) to optimize the computation graph. Finally, the *compiler backend* maps the computation graph onto a set of kernels, each of which is a program fragment written in single-program-multiple-data (SPMD) fashion on modern hardware accelerators.

To keep up with the computational demands of DNN models, specialized hardware accelerators, such as NVIDIA Tensor Cores, have been introduced. Each new generation of these accelerators has consistently improved the compute capacity to provide blazing speeds for compute instructions such as matrix multiplications (e.g., nearly 1 PFLOPS half precision on NVIDIA H100). Most tensor compilers already aim to maximize utilization on such hardware using dedicated compiler backends (e.g. Triton [30] for GPUs), achieving low latency and high throughput for compute operations.

However, memory technology in modern hardware has not kept pace with these advances in compute capabilities. Figure 1 illustrates the widening compute-to-memory ratio as newer accelerators are introduced, making memory instructions significantly more expensive than compute instructions. Moreover, an increasing number of DNN models are becoming memory bound, with performance dominated by memory access requests to and from the accelerator's global memory, which exacerbates the impact of slower memory. For example, in large language models (LLMs), the incremental decoding stage is memory-bound and can be the bottleneck of end-to-end inference [27]. Memory access requests are determined by the types and the composition of *data movement operations* in computation graphs. These operations only transfer data between global memory and the accelerator without performing any computation on tensor data with compute units. Critically, these inserted data movements between computational operators could introduce substantial extra latency. For example, Figure 2 demonstrates TensorRT's latency breakdown on a

*Part of the work done during an internship at Microsoft.

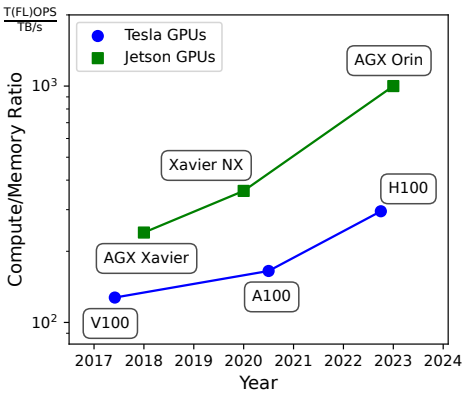

Figure 1: Trend of compute/memory ratio for NVIDIA GPUs over time. The ratio is calculated by dividing the computation power (half-precision performance in TFLOPS for Tesla GPUs and INT8 performance in TOPS for Jetson Edge GPUs) by the peak GPU memory bandwidth (in TB/s).

Llama 3 8B [14] decoder layer. Between the computation of QKV projection and FlashDecoding [11], the data movement operators take even more time than other computational operators. These findings underscore the critical importance of optimizing data movement operations in DNN compilers.

Prior works that propose optimizations for data movement operations in tensor compilers broadly fall under two categories: *layout optimizations* and *operator fusion*, both of which happen in the compiler middle end. These techniques are usually incomplete, targeting only a subset of the data movement operators and missing profitable data movement elimination opportunities that could lead to significant speedups, as detailed below.

Layout optimizations. The layout of a tensor determines in which order its dimensions are linearized into memory. When a producer operator generates an output tensor with a layout that differs from the expected input layout of the consumer operator, data layout conversion operators need to be inserted, resulting in excessive and avoidable data movement overhead. To find the optimal data layouts that minimize such overheads, previous work first identifies layout-sensitive tensor operators and optimally selects the adjacent layout operators (primarily `Reshape` and `Transpose` operators) to balance data movement overhead against computation efficiency [2, 16, 24]. However, the tensor operators considered in these works represent only a subset of data movement operations used in DNN models, overlooking optimization opportunities in other data movement operators (e.g., `ScatterND`) that are key for improved performance (see Section 3.1).

Operator fusion. During DNN execution, operators usually serve as boundaries of global memory data movement –

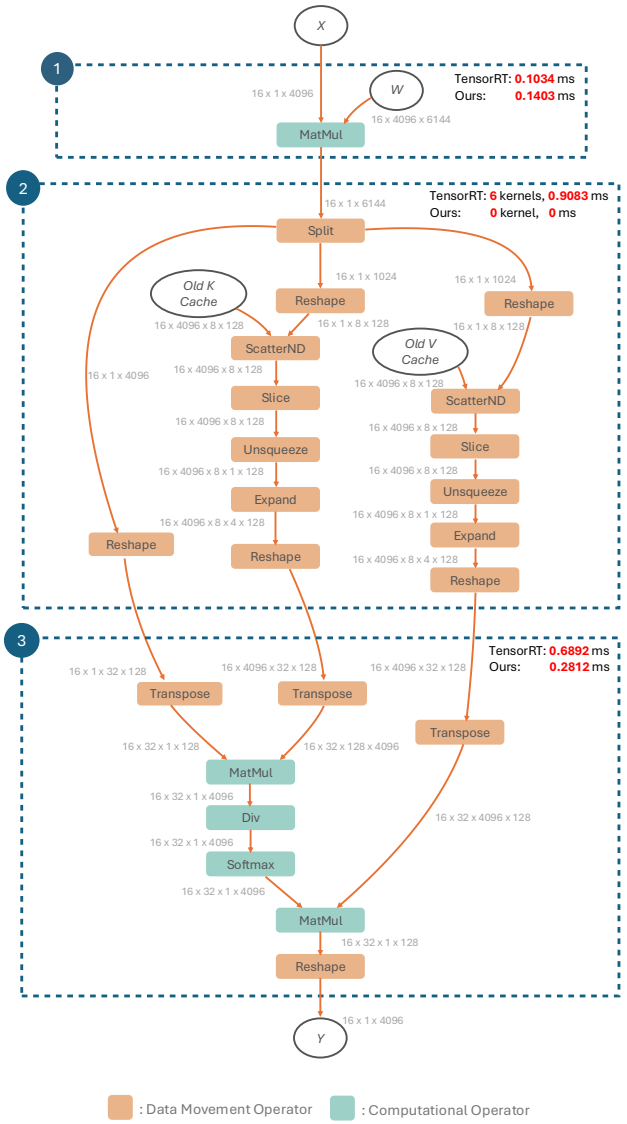

Figure 2: Motivating example: computation graph and latency breakdown for part of a Llama-3 decoder layer. The model size of Llama-3 is 8B, with batch size 16, context length 4096, query length 1 (decoding stage), `bfloat16` precision. Frame 3 denotes a single kernel fusing all the operators with FlashDecoding. VTC can eliminate all the data movement operators in frame 2 and achieve a 4× speed-up over TensorRT on this subgraph.

all input and output tensors are stored in global memory. For each operator, its corresponding kernel first loads inputs from global memory into on-chip buffers, performs computations, and then writes results back from on-chip buffers to global memory. To reduce this costly data movement, existing deep learning frameworks [2, 3, 5, 9] employ operator fusion, which enables intermediate results to be reused directly from fast on-chip buffers rather than being written to and read from

slower global memory. However, these systems perform fusion using hand-crafted rules that target specific data access patterns (e.g., [23]), making this optimization only available for operators that can be fused. As a result, similar to layout optimizations, operator fusion reduces data movement for only a subset of data movement operators, missing important optimization opportunities.

Our Solution. In contrast with these two popular techniques, in this paper, we introduce VTC, a compiler that eliminates unnecessary data movement across all data movement operators. For example, as shown in Figure 2, VTC can eliminate all the data movement operators between QKV projection and FlashDecoding. VTC is comprehensive and works for arbitrary composition of operators in computation graphs, making it generally applicable for all kinds of DNN models. Furthermore, it is complementary to both layout optimization and operator fusion.

The key idea of VTC is to eliminate data movement operators by using *virtual tensors* that store only a mapping function between physical tensors in global memory. This approach builds on the observation that modern hardware compute units require contiguity only in their local memory buffers, not in global memory. By relaxing the fully contiguous condition to partially contiguous without compromising memory coalescing, we can significantly eliminate data movement operators. Virtual tensors enable us to relax the contiguity condition by adding a level of indirection in the accesses to the tensors in global memory. However, realizing this virtual tensor representation requires addressing a few challenges to fully eliminate unnecessary data movement.

Challenge 1: Kernel creation that facilitates virtual tensors. With the introduction of virtual tensors, the current computational kernels cannot be used in their present form. First, these kernels assume contiguously laid out data in global memory, which is guaranteed by data movement operators. Second, virtual tensors can introduce extra overhead of mapping function and incontiguous memory access if used in current kernel implementations. We only modify the global memory I/O stages in existing computational kernels with block virtual tensor I/O (Section 4.2), resulting in minimal changes to the original kernel design and marginal runtime overhead.

Challenge 2: Determining a profitable virtual tensor construction strategy. Creating virtual tensors for all data movement operators is non-trivial. Different virtual tensor construction strategies lead to different profitabilities. We solve the problem of finding a profitable option in two parts. First, we introduce a *virtual tensor opportunity graph* to capture all virtual tensor creation options for a given computation graph (Section 5.1). Next, we design a global greedy algorithm that extracts a virtual tensor creation strategy with maximized latency savings (Section 5.2), which works empirically well in the evaluation.

In summary, we make the following contributions.

- We identify a new data movement optimization opportunity by allowing partially contiguous global memory storage in DNN compilation.
- We introduce the concept of *virtual tensors* for data movement elimination and efficiently support it in computational kernel generation.
- We propose *virtual tensor opportunity graph* and data elimination algorithm to automatically find an efficient strategy for creating virtual tensors.
- We implement these concepts in a compilation infrastructure, VTC. Our evaluations show up to 1.93× improvement (1.28× on average) over existing DNN compilers and up to 60% memory saving (17.5% on average) on NVIDIA GPUs.

2 Background

We first provide background about tensor stride, data movement operators at the graph-level, their necessity, and implementations of tensor operators at the kernel-level before explaining VTC.

2.1 Tensor Stride

To index an n-d tensor in the 1D memory, modern tensor compilers need to calculate an integer offset from the index vector $\vec{I} \in \mathbb{N}^n$. Tensor stride vector $\vec{S} \in \mathbb{N}^n$ indicates the number of elements we need to skip in memory to move from one element to the next in each dimension. For example, for a 3D tensor of shape (a,b,c), its stride vector $\vec{S} = (bc, c, 1)$. And the indexing will be simply the inner product of the stride vector and the index vector. In the same example, the offset of $\vec{I} = (i,j,k)$ is $\vec{I} \cdot \vec{S} = i \cdot bc + j \cdot c + k$.

2.2 Data Movement Operators

Data movement operators are a subset of tensor operators responsible for only moving data in global memory.[1] Examples include operators such as `Transpose`, `Split` and `ScatterND`.[2] As an example, the semantics of `Transpose` operator can be given as follows.

Definition 1 (`Transpose` Operator)**.** *`Transpose` operator takes a single input tensor and generates an output tensor by permuting the dimensions of the input with a given permutation `perm`:* $\forall i \in [0,n)$, output_dimensions[perm[i]] = input_dimensions[i].

[1] Conversely, computational operators are defined by their use of compute units to perform arithmetic operations on the data.

[2] In this paper, all mentioned operators are defined in ONNX (https://onnx.ai/onnx/operators/), a widely-used standard DNN format.

Figure 5 also shows a visualized example of `Split` operator. It is clear that `Transpose` and `Split` do not change values of individual elements, but rather reorganize their positions in the tensor. This property holds for any data movement operator and we formalize it as follows.

Definition 2 (Data Movement Operator)**.** *An operator with input tensors $I_1,\ldots,I_n$ and output tensors $O_1,\ldots,O_m$ is a data movement operator if and only if there exists a function $F(i,\vec{x}) = (j,\vec{y})$ such that $O_i[\vec{x}] = I_j[\vec{y}]$, for all $i \in [1,m], j \in [1,n]$, and $\vec{x},\vec{y}$ are subscripts of O_i, I_j, respectively.*

For the `Transpose` operator, $F(1,\vec{x}) = (1,\vec{y})$ where $y_i = perm[x_i]$. The mapping from outputs to inputs is one-to-one in data movement operators, ensuring that each output tensor element is derived from a unique input tensor element. Conversely, the mapping from inputs to outputs is one-to-many, indicating that an input tensor element may contribute to multiple output tensor elements.

2.3 Kernel Implementation of Operators

Graph-level tensor operators are typically implemented as hardware accelerator kernels with all the input and output data physically residing in global memory. The implementation can be divided into three distinct stages:

1. Transfer input data from global memory to on-chip buffers.
2. Perform computation with compute units, which read inputs from and write outputs to on-chip buffer (not present in data movement operators).
3. Transfer output from on-chip buffer to global memory.

For example, Listing 1 shows a matrix multiplication operator implemented in Triton [30] for GPU execution. In stage 1, two blocks of input matrices (2D-tensors) `a` and `b` are loaded as *contiguous* chunks from global memory into on-chip buffers. Stage 2 does the actual compute, in this case, it is an inner product of the loaded matrices. Stage 3 writes back the resultant `c` matrix from on-chip buffer to global memory also as contiguous chunks.

2.4 Necessity of Data Movement Operators

As seen in Section 2.3, tensor operators typically assume that the data is *contiguous* in memory during stages 1 and 3 of a kernel implementation. This serves two purposes: (1) satisfying the requirement of modern compute units for contiguous memory layout of inputs and outputs,[3] and (2) optimizing global memory access through memory coalescing and better locality. Due to the assumption of different kernel implementations, if a producer tensor operator uses a data layout or subsection that differs from its consumer tensor operator, data movement operators must be inserted to reconcile the difference. These data movement operators are necessary to maintain the correctness of the tensor computational graph, but they will introduce extra overhead.

[3]For example, NVIDIA tensor cores load two matrices of specific shapes from a contiguous memory fragment and then perform fused multiply-add (FMA) operations.

```
@triton.jit
def matmul_kernel(
    a_ptr, b_ptr, c_ptr, # Pointers to matrices
    ... # Elide some meta-parameters
):
    ... # Elide some pre-processing steps
    accumulator = tl.zeros(BLOCK_SIZE)
    for k in range(0, tl.cdiv(K, BLOCK_SIZE_K)):
        # Stage 1: global -> on-chip
        a = tl.load(a_ptrs, ...)
        b = tl.load(b_ptrs, ...)
        # Stage 2: computation
        accumulator = tl.dot(a, b, accumulator)
        # Advance the ptrs to the next K block
        a_ptrs += BLOCK_SIZE_K * stride_ak
        b_ptrs += BLOCK_SIZE_K * stride_bk
    ... # Elide some post-processing steps
    # Stage 3: on-chip -> global
    tl.store(c_ptrs, c, mask=c_mask)
```

Listing 1: An example of the three stages: a GPU matrix multiplication kernel written in Triton.

3 Motivation and Overview

3.1 Motivating Example: LLM Decoding

To illustrate the potential for data movement optimization in DNN inference, we examine the decoding stage of Llama 3 8B [14] as a motivating example. We profiled a single decoder layer using TensorRT [2], a state-of-the-art DNN compiler on NVIDIA GPUs. [4] TensorRT incorporates numerous expert-designed optimization rules and successfully identified the self-attention pattern in the decoder layer, triggering an ad hoc optimization for the entire layer. [5]

Figure 2 shows the computation graph and TensorRT's latency breakdown on an NVIDIA A100 GPU. TensorRT first applies graph-level transformations to merge the three query, key, and value (QKV) projections into a single matrix multiplication operation. It also employs the FlashDecoding algorithm [11] to fuse the computation of self-attention into one kernel. However, between these two computational kernels, there exists a large number of data movement operators, illustrated in frame 2 of Figure 2. The latency of these data movement operators in TensorRT even surpasses the combined latency of the two computational kernels.

[4]Similar latency distributions in this section were observed with other DNN compilers such as TorchInductor [5].

[5]This black-box optimization, called Myelin, fuses the entire transformer decoder layer into a single node and generates highly-optimized custom kernels for this node.

We now focus on the purpose of data movement operators and their role in the computation graph. TensorRT first executes a `Split` operator to extract the Q, K, V tensors from the result of merged QKV projection. Next, TensorRT uses `Reshape` and `ScatterND` operators to update the KV cache [25] with the new K and V tensors. Subsequently, TensorRT applies the `Slice` operator to keys and values to obtain a slice containing tokens up to the current sequence length. As Llama 3 8B employs grouped-query attention [14], TensorRT then uses `Unsqueeze` and `Expand` operators to align the number of KV heads with the number of query heads. Finally, TensorRT runs `Reshape` and `Transpose` operators to prepare the layout of keys and values for FlashDecoding. Although operator fusion is available for these data movement operators, TensorRT still requires 6 kernels to complete all the data movements above.

However, according to the analysis of layout requirements in Section 2, relaxing the fully contiguous condition of global memory storage may unlock opportunities for data movement operator elimination. For example, in stage 3 of the `MatMul` operator used for the merged QKV projection in frame 1, the `MatMul` kernel can directly write back the results to Q tensor and appropriate locations in KV cache, eliminating the need for `Split`, `Reshape` and `ScatterND` operators, as shown in Figure 3. Since the dimension per attention head (128) is larger than the GPU warp size (32), memory coalescing is not compromised, allowing for both good memory bandwidth in stage 3 and efficient utilization of tensor cores in stage 2. Similarly, by permitting stage 1 of FlashDecoding to read from not fully contiguous memory, the remaining data movement operators can be eliminated.

Based on these observations, VTC can eliminate *all* the data movement operators between QKV projection and FlashDecoding. For QKV projection, VTC writes to non-fully contiguous memory, resulting in a slightly slower `MatMul` kernel compared to TensorRT. However, VTC does not require any GPU kernel to explicitly execute the data movement operators shown in frame 2 of Figure 2, significantly reducing data movement overhead. Furthermore, after VTC's optimization, the FlashDecoding kernel can directly read from the KV cache instead of the duplicated data generated by the `Expand` operator. This optimization reduces global memory read overhead by a factor of 4 (the ratio of the `Expand` operator) and leads to a 2.5× speed-up of the FlashDecoding kernel.

3.2 Overview

Figure 4 shows VTC's overview. The input is a computation graph after operator fusion. To identify all the virtual tensor creation possibilities, VTC first runs an virtual tensor opportunity graph (VTOG) construction algorithm, based on VTC's virtual tensor definition and data movement optimization rules. Next, VTC runs a points-to graph construction algorithm to find a profitable virtual tensor strategy, represented by the resulting points-to graph. Finally, VTC generates an optimized executable according to this selected strategy.

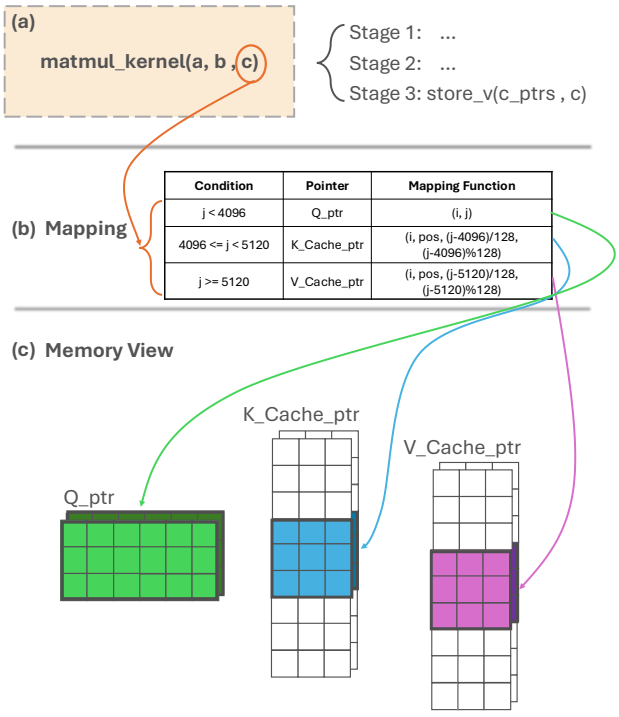

Figure 3: An example of data movement operator elimination with virtual tensors in QKV projection (frame 1 in Figure 2). The decoding stage is generating the *pos*-th token. Matrix $c[i, j]$ is a virtual tensor of shape (batch size, sum of QKV hidden dimensions), where Q has hidden dimension 4096, and K and V have hidden dimensions 1024 each. For the matrix multiplication kernel (Triton code is in Listing 1), we only need to modify stage 3, and the virtual tensor I/O function `store_v` will automatically write the data to proper physical tensor location according to the mapping function.

4 Virtual Tensor

Definition 2 reveals that it is possible to eliminate the need for actual data movement by storing only the mapping function F, which describes the relationship between the input and output tensors. By leveraging this insight, we can avoid the overhead associated with explicit data transfers in data movement operators. In this section, we introduce VTC's virtual tensor notation, which builds upon this observation to efficiently handle data movement operations. We will show how to handle virtual tensor I/O in Section 4.2 and analyze the profitability of the optimization in Section 4.3. Finally, we give several examples of how to use virtual tensors to eliminate data movement operators in Section 4.4.

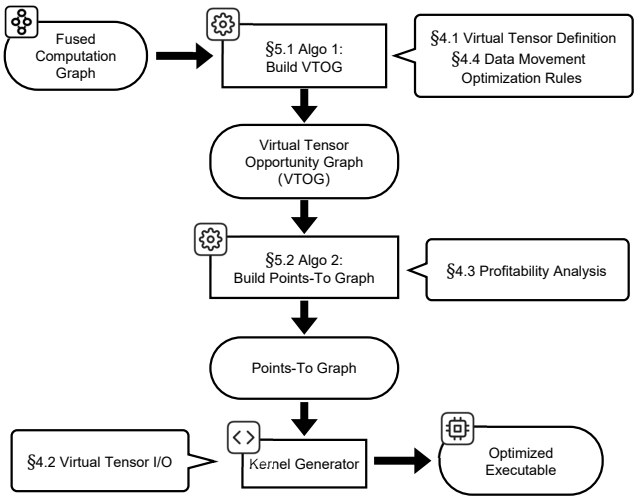

Figure 4: The overview of VTC.

4.1 Virtual Tensor Definition

The key idea behind the virtual tensor technique is to avoid redundant instantiation of tensor data in global memory. If a tensor is obtained by performing data movement operators on other tensors, we can directly represent it using a mapping function and a set of physical tensor pointers, instead of allocating global memory to store the tensor data.

Definition 3 (Virtual Tensor)**.** *A virtual tensor V is a tuple $(F, P_1, P_2, \ldots, P_n)$, where F is a mapping function and $P_1, P_2, \ldots, P_n$ is a set of physical tensor pointers. The mapping function $F : \vec{x} \rightarrow (j, \vec{y})$ describes the relationship between each virtual tensor index $\vec{x}$ of V and the corresponding physical tensor index $\vec{y}$ of P_j, where $j \in [1, n]$.*

Figure 3 shows an example of virtual tensor in QKV projection. Virtual tensor c has 3 physical tensor pointers Q_ptr, K_Cache_ptr, and V_Cache_ptr, with its mapping function illustrated in subfigure (b).

A virtual tensor provides a contiguous index space that references potentially non-contiguous locations within physical tensors. Mapping function F links each virtual tensor index to its corresponding physical tensor address. The virtual tensor technique eliminates data movement operators through two complementary approaches: (1) creating output virtual tensors for a producer data movement operation that map to input tensors of that operation, or (2) creating input virtual tensors for a consumer data movement operation that map to output tensors of that operation. While Definition 2 allows for one-to-many mappings, VTC restricts F to one-to-one mappings. This design choice simplifies implementation and avoids potentially expensive overhead of translating complex one-to-many mapping functions.

Mapping function composition. Virtual tensors can be nested: it is possible for a base tensor, which is used to create a virtual tensor, to be a virtual tensor itself. In such cases, the resulting virtual tensor's mapping function effectively applies the base tensor's mapping followed by the new mapping (e.g., $F_{\text{new}} = F_{\text{outer}} \circ F_{\text{base}}$), representing a chain of transformations.

4.2 Virtual Tensor I/O

VTC's virtual tensor interface seamlessly translates virtual tensor I/O operations into physical global memory I/O operations using the mapping function. In hardware kernels, global memory I/O is usually performed in a block-wise manner, where multiple threads simultaneously read a block of global memory data. For most real-world cases, the contiguity of mapping function conditions (e.g., 1024 in Figure 3) is larger than and a multiple of block size. Therefore, each block is likely to read from the same physical tensor, allowing us to directly apply a non-partitioned mapping function to a block of indices, which only introduces marginal overhead.

Virtual tensor provides a high-level abstraction that hides the underlying data movement complexities. Users can work with virtual tensors as if they were regular tensors, while VTC transparently manages the mapping and access to the physical tensor data behind the scenes. Since virtual tensors only impact the global memory I/O (stage 1 and 3 in Listing 1) of a hardware accelerator kernels, they leave the computation part (stage 2 in Listing 1) unchanged. This allows virtual tensors to be effortlessly integrated into existing optimized kernels with minimal modifications. For example, in Figure 3, we can directly pass a virtual tensor mapping to physical Q tensor and KV cache as the output parameter of the projection `MatMul` kernel. VTC then transforms the fully contiguous write to this virtual tensor into partially contiguous writes to the Q tensor and KV cache in `MatMul` kernel stage 3.

While virtual tensors have the potential to eliminate physical data transfers in data movement operators, the use of mapping functions and non-fully contiguous global memory access patterns still may introduce additional overhead. In the next subsection, we will delve into the profitability of this optimization technique, analyzing the trade-offs between the benefits of reduced data movement and potential extra costs.

4.3 Profitability Analysis

Since the indirect memory access patterns of virtual tensors are fully known at compile time, we can analyze the optimization profitability based on the characteristics of the mapping function. Similar to the classification of compiler optimizations into Type I (always profitable) and Type II (uncertain profitability) [22], we can categorize the profitability of virtual tensor optimizations by analyzing the mapping function. Without loss of generality, we assume each virtual tensor maps to a single base physical tensor here.

Remark 1. *In most DNNs, the final mapping function between the virtual tensor and a physical tensor can be expressed as*

$$f(\vec{I}) = \vec{S} \cdot \vec{I} + b(\vec{I}) \quad (1)$$

where $\vec{I}$ is the index vector, $\vec{S}$ is the stride vector (see Section 2.1) and $b : \mathbb{N}^n \to \mathbb{Z}$ is an index-dependent bias function.

Remark 2. *In ONNX operator set, most data movement operators preserve affine transformations on indexing, which can be achieved by adjusting stride and a* constant *bias. One exception is* `Expand`*. For instance, expanding a tensor from shape (a,b,c) to $(a,3b,c)$ and making the expanded tensor virtual yields the offset for index $\vec{I} = (i,j,k)$ as*

$$i \cdot bc + (j\%b) \cdot c + k = i \cdot bc + j \cdot c + k - \lfloor j/b \rfloor \cdot bc \quad (2)$$

Here for the mapping function in Equation (1), $\vec{S} = (bc, c, 1)$, $b(\vec{I}) = -\lfloor j/b \rfloor \cdot bc$.

Definition 4 (Contiguous dimension)**.** *For an n-d virtual tensor with shape $\vec{D} = (D_1, \ldots, D_n)$, dimension d is a* contiguous dimension *if its mapping function in Equation (1) satisfies*

1. *All strides from dimension d onward equal the suffix products of the shape vector: $\forall i \in [d,n]$, $S_i = \prod_{j=i+1}^{n} D_i$*
2. *Bias remains constant when the first $d-1$ dimensions are fixed: $\forall \vec{I_1} \in \mathbb{N}^{d-1}$, $\forall \vec{I_2} \in \mathbb{N}^{n-d+1}$, $b([\vec{I_1} \mid \vec{I_2}]) \equiv C$.*

Definition 5 (Partial contiguity and full contiguity)**.** *A virtual tensor with minimal contiguous dimension d and shape vector $\vec{D}$ retains* partially contiguous *memory access if $\prod_{i=d}^{n} D_i$ exceeds the minimal memory transfer unit size (e.g., memory coalescing size in GPUs). A virtual tensor maintains fully contiguous memory access if and only if its minimal contiguous dimension equals 1.*

Theorem 1. *Optimization is always profitable (Type I) for fully contiguous virtual tensors.*

Theorem 1 establishes the conditions for guaranteed profitability. When the mapping function preserves the original data access pattern with only a constant bias allowed, the virtual tensor optimization can be considered as Type I. Also, virtual tensors with partial contiguity are likely profitable since they do not break minimal memory transfer granularity and maintain high memory bandwidth. Otherwise, the profitability is uncertain. VTC will perform profiling (described in Section 5.2) to decide whether to proceed with the optimization according to actual latency impacts.

4.4 Virtual Tensor Optimization Rules for Data Movement Operators

The virtual tensor optimization is designed to eliminate data movement operators. In this subsection, we present several examples of data movement operators from ONNX, demonstrate how VTC eliminates them using virtual tensors, and discuss the profitability. All of the data movement operators presented in this subsection are outside the optimization space of previous layout optimizations.

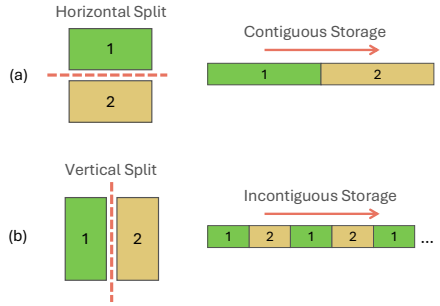

Figure 5: Comparison between contiguous `Split` (performed on the first axis) and incontiguous `Split` (performed on other axes) on a 2D matrix stored in row major.

Split When optimizing `Split` using virtual tensors, making input a virtual tensor of outputs is Type II, since the output tensors are stored separately and incontiguously in global memory. On the other hand, making outputs virtual tensors of input can be either a Type I or Type II optimization, depending on the contiguity of the split. If the split is performed along the first axis (axis 0), resulting in contiguous output tensors, it is a Type I optimization. Figure 5 shows an example of contiguous `Split` and incontiguous `Split`. When the incontiguous split size is large enough, all the two directions of virtual tensor optimizations have partial contiguity.

Expand The `Expand` operator broadcasts a single input tensor to a specified `shape`, producing a single output tensor with the same data as the input but with expanded dimensions. When optimizing `Expand` using virtual tensors, both directions are Type II. But if the number of duplicated elements exceeds memory coalescing size, it is almost always profitable.

ScatterND The `ScatterND` operator takes 3 inputs: `data`, `indices`, and `updates`. It generates a single output tensor by first initializing it as a clone of the `data` tensor and then updating the values at the specified indices in `indices` with the corresponding values from the `updates` tensor. There are two ways of virtual tensor optimization:

1. Making the output a virtual tensor of `data`. Since the output tensor is initially a clone of `data`, it is a Type I optimization.
2. Making `updates` a virtual tensor of the output tensor. This optimization is Type II because the `indices` can be incontiguous. In the LLM motivation example, `updates`

denotes all the locations in KV cache to be updated and is partially contiguous.

We can conduct analysis and define optimization rules similarly for all other data movement operators. As virtual tensor optimization rules are highly dependent on the operator semantics and the number of data movement operators is limited (e.g., 18 in the ONNX), VTC requires developers to specify the mapping function and possible virtual tensor optimization rules between inputs and outputs for each data movement operator. Then VTC can automatically analyze profitability and perform virtual tensor optimizations, which will be introduced in the next section.

5 Automatic Virtual Tensor Construction

This section introduces VTC's virtual tensor construction algorithm, which automatically makes intermediate tensors virtual to minimize unnecessary data transfers and improve overall performance. We first formalize the data movement elimination problem by building a virtual tensor opportunity graph (VTOG), and then introduce the global greedy algorithm to eliminate data movements.

5.1 Virtual Tensor Opportunity Graph

VTC's data movement eliminator takes a computation graph after operator fusion as input. In prior work, all the intermediate tensors, represented by edges in the computation graph, are physically stored in global memory. The data movement elimination problem aims to find a strategy to make certain intermediate tensors virtual and maximize the end-to-end latency savings.

VTC first builds a virtual tensor opportunity graph (VTOG) to analyze all the virtual tensor possibilities.

Definition 6 (Virtual Tensor Opportunity Graph)**.** *A virtual tensor opportunity graph (VTOG) is a directed graph* $G = (V, E)$*. Each node* $v \in V$ *represents a tensor in the computation graph. Each directed edge* $(u, v) \in E$ *represents a* direct *virtual tensor possibility, where tensor u can be made a virtual tensor of v by eliminating* only one *data movement operator.*

Figure 6 shows an example of a computation graph and its corresponding VTOG. `Split` determines the VTOG edges between `a` and `b`; `Reshape` determines the VTOG edges between `b` and `c`; and `ScatterND` determines the VTOG edges between `c`, `d` and `K Cache`.

For each node in the VTOG, some outgoing edges may conflict with each other, indicating mutually exclusive virtual tensor strategies. For example, in Figure 7, edges 1 and 3 conflict because designating `c` as a virtual tensor of both `a` and `d` simultaneously would map some indices of `c` to multiple physical memory locations, violating the one-to-one property

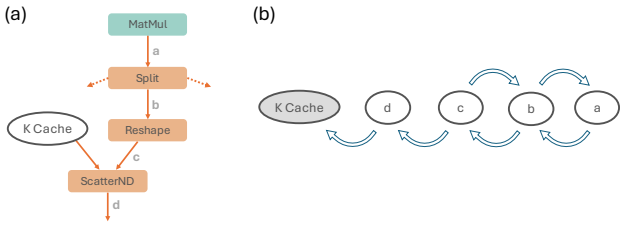

Figure 6: (a) The computation graph. (b) The corresponding virtual tensor opportunity graph. Other outputs of `Split` operator are ignored.

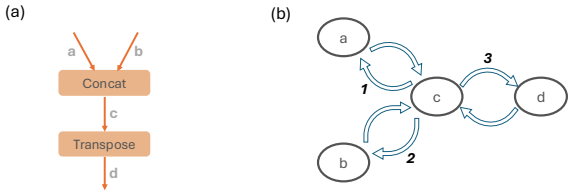

Figure 7: An example of a computation graph and conflicting edges in its VTOG. In (b), edge 1 and edge 3 conflict with each other. Edge 2 and edge 3 also conflict. However, edge 1 and edge 2 can be selected together.

of virtual tensor mapping functions. In contrast, edges 1 and 2 can coexist when preserving a one-to-one mapping. We capture all such conflicting edge pairs in a *conflict set*.

Algorithm 1 shows how to create a VTOG and the conflict sets from a computation graph. VTC constructs the VTOG by iterating through all data movement operators in the input computation graph, following the predefined virtual tensor rules for each operator (Section 4.4), and creating edges between operator inputs and outputs.

When all outgoing edges of each node in a VTOG are mutually compatible, the VTOG becomes a *points-to graph*, similar to that used in traditional compiler pointer analysis [4]. The points-to graph has one-to-one correspondence with a virtual tensor strategy for the entire computation graph. For example, Figure 8 shows several possible points-to graphs derived from the VTOG in Figure 6. Strategy 3 has no edges, indicating that all the tensors are physical. Strategy 2 has `b` and `K cache` as physical tensors, making `a` and `c` virtual tensors of `b`, and `d` a virtual tensor of `K cache`. Strategy 1 makes `a`, `b`, `c`, and `d` all virtual tensors of `K cache`. Note that `K cache` is an input tensor of the computation graph, so it must reside in physical memory.

Using an inductive argument, it is not hard to show the computational equivalence of the computation graph and the virtualization strategy corresponding to a points-to graph derived from the VTOG. As evident from the definition, a points-to graph can be derived from a VTOG by removing conflicting edges. However, different points-to graphs can lead to different end-to-end latency gains. The following subsection intro-

Algorithm 1 Build VTOG from a computation graph.

Input: A computation graph $G = (V, E)$
Output: The VTOG $= (V_{\text{VTOG}}, E_{\text{VTOG}})$ of G and a conflict set $S(v)\ \forall v \in V_{\text{VTOG}}$

$I = \{i \mid i \text{ is an input tensor of } G\}$
$O = \{o \mid o \text{ is an output tensor of } G\}$
$V_{\text{VTOG}} = I$
for $v \in V$ **do**
    $V_{\text{VTOG}} = V_{\text{VTOG}} \cup \{o \mid o \text{ is an output tensor of } v\}$
$E_{\text{VTOG}} = \{\}$
for $v \in V$ **do**
    if v is a data movement operator **then**
        for $(a, b) \in \text{VTRULES}(v)$ **do** ▷ a, b are input or output tensors of operator v and a can be made a virtual tensor of b
            if $a \notin I$ **and** $a \notin O$ **then** ▷ inputs and outputs of G must be physical tensors
                $E_{\text{VTOG}} = E_{\text{VTOG}} \cup \{(a, b)\}$
for $v \in V_{\text{VTOG}}$ **do**
    Construct $S(v)$ by enumerating outgoing edges of v
return $(V_{\text{VTOG}}, E_{\text{VTOG}})$, S

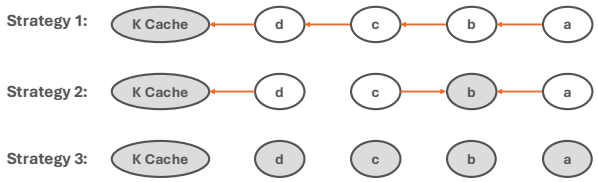

Figure 8: Several valid points-to graph of Figure 6, representing different virtual tensor strategies. Physical tensors are marked gray in each strategy.

duces VTC's points-to graph construction algorithm, which aims to obtain a points-to graph representing an efficient virtual tensor strategy.

5.2 Global Greedy Algorithm

The objective of our data movement elimination algorithm is to maximize the latency saving for each virtual tensor strategy, which can be formalized as follows. Let $(E_{\text{VTOG}}, \mathbb{F}, \ell)$ denote the virtual tensor search space corresponding to a VTOG. Here each edge in E_{VTOG} denotes a single virtualization opportunity, $\mathbb{F}$ denotes a set of all points-to graphs and $\ell : \mathbb{F} \to \mathbb{R}$ is the latency saving function that maps every points-to graph $C \in \mathbb{F}$ to the latency saving corresponding to virtual tensor strategy realized by C. Our goal is to find the optimal points-to graph

$$C^* = \arg\max_{\mathbb{F}} \{\ell(C)\} \tag{3}$$

Equation (3) is NP-hard as ℓ is a complex set function without any structure, which can only be measured through profiling on real hardware. In some situations we can expect that ℓ is a submodular function; for example, when all our operations are Type I (see Section 4.3). Unfortunately, it is not true for more general VTOGs.

Despite this, we take inspiration from the submodular function maximization literature, and design a global greedy algorithm to approximately solve our problem. It is well-known that the global greedy algorithm, which at each iteration adds the element that maximizes the discrete derivative of a submodular function ℓ, achieves a constant approximation to the optimal solution for a broad range of settings; we refer readers to [19] for an introductory survey.

Algorithm 2 shows VTC's points-to graph construction procedure. With all tensors stored in physical memory initially, it iteratively creates new virtual tensors. Specifically, the algorithm maintains an anchor node set A and a currently selected edge set C. In each iteration, it adds a new node v_c into the anchor node set by adding some non-conflicting edges between v_c and A into the currently selected edge set. For each edge $e \in E_{\text{VTOG}}$, we define its *discrete derivative with respect to* ℓ as

$$w(e) := \ell(C \cup \{e\}) - \ell(C), \tag{4}$$

which denotes the latency saving of merely adding edge e to C. The greedy strategy picks the node v_c that maximizes the sum of latency savings across its incident non-conflicting edges in the current iteration, then updates the sets A and C. Subsequently, since creating a new virtual tensor updates C, the algorithm recalculates $w(e)$ for each edge e pointing to v_c by profiling. If the maximum latency saving is negative or all the nodes are added to A, the algorithm terminates.

Complexity analysis. Algorithm 2 executes a maximum of $O(|V_{\text{VTOG}}|)$ iterations. In each iteration, it performs at most $O(|E_{\text{VTOG}}| + |V_{\text{VTOG}}|)$ calculations. Based on the VTOG definition 6 and its construction algorithm 1, $|E_{\text{VTOG}}|$ is linear with $|V|$ and $|V_{\text{VTOG}}| < |E|$. In typical DNN computation graphs, $O(|V|) = O(|E|)$, so $O(|V_{\text{VTOG}}|) = O(|E_{\text{VTOG}}|) = O(|V|)$. Consequently, the complexity of VTC's data movement elimination algorithm is the product of the maximum number of iterations and the cost per iteration, i.e. $O\left(|V|^2\right)$.

6 Implementation

We implemented VTC on top of Triton [30] and TorchInductor [5]. We first added virtual tensor support in Triton by overloading Triton's global memory I/O functions, `tl.load` and `tl.store`, enabling them to handle virtual tensor I/O operations. Mapping function is represented in the form of Equation (1). Our overloaded operators consume base physical tensor pointers along with mapping functions that determine how virtual tensors map to physical memory. Since all indirect memory access patterns through virtual tensors are fully known at compile time, we implemented overloaded `tl.load`

Algorithm 2 An iterative global greedy algorithm to build a points-to graph from a VTOG.

Input: VTOG $= (V_{\text{VTOG}}, E_{\text{VTOG}})$ and conflict set $S(v)$
Output: The points-to graph PTG $= (V_{\text{PTG}}, E_{\text{PTG}})$ of VTOG with maximized latency savings

1: $A = \{\}, C = \{\}$
2: **for** $v \in V_{\text{VTOG}}$ **do**
3: **if** v does not have outgoing edges **then**
4: $A = A \cup \{v\}$
5: **for** $e \in E_{\text{VTOG}}$ **do**
6: Profile and get $w(e)$
7: tot_saving $= 0$
8: **while** $A \neq V_{\text{VTOG}}$ **do**
9: max_saving $= -\infty$
10: **for** $v \in V_{\text{VTOG}} \setminus A$ **do**
11: $P, s =$ MaxEdges$(v, C(v), A)$ ▷ P is a set of non-conflicting edges between v and A with maximum sum of marginal latency savings s
12: **if** $s >$ max_saving **then**
13: max_saving $= s$, $P_c = P$, $v_c = v$
14: **if** max_saving < 0 **then**
15: **break**
16: $A = A \cup \{v_c\}$, $C = C \cup P_c$
17: tot_saving $=$ tot_saving $+$ max_saving
18: **for** $e = (t, v_c) \in E_{\text{VTOG}}$ **do**
19: Profile and update $w(e)$
return (V_{VTOG}, C), tot_saving

and `tl.store` by generating Python code specialized for each virtual tensor I/O, avoiding most of the indirection overheads.

We integrated VTC's data movement eliminator into TorchInductor through two passes: an analysis pass and a transformation pass. The analysis pass automatically generates a virtual tensor strategy with Algorithms 1 and 2. This entails identifying which physical tensors to promote to virtual tensors as well as computing mapping functions of promoted virtual tensors to their physical indices. The transformation pass then operates in two stages: (1) It mutates TorchInductor's IR nodes with virtual tensor awareness and removes any unnecessary data-movement operators. We modified TorchInductor's lowering strategy to correctly lower our overloaded `ops.load` and `ops.store` operators to Triton. (2) Once lowered to Triton, we generate the specialized Python code using the method mentioned earlier. The resulting Triton code is then compiled to produce an optimized hardware executable.

VTC's automatic virtual tensor construction employs a polynomial-time greedy algorithm rather than exhaustively searching in an exponential solution space. During compilation, profiling (lines 6 and 19 in Algorithm 2) dominates the time cost. Since VTC only modifies data movements in stages 1 and 3, no autotuning is needed for each kernel. The profiling overhead is less than 10 seconds per configuration, and the end-to-end compilation requires only a polynomial number of profiling runs, resulting in total compilation time under 10 minutes for all the models we have tested, which is on par with the compilation time of ML compilers [28, 37, 39].

As VTC focuses solely on optimizing data movement and does not alter the computation logic, it maintains end-to-end *numeric equivalence* with the original compiler, ensuring zero precision loss.

Table 1: Configurations of evaluated models.

Model	Component	Input Specification	Precision
Llama 3 8B Gemma 2 9B	Decoder Layer	Query Length: 1, Context Length: 4096	BF16
EfficientViT-Base YOLOv11n ShuffleNet	Attention Block C3K2 Block ShuffleUnit	Resolution: 4096 Resolution: 640 Resolution: 224	TF32

7 Evaluation

7.1 Experimental Setup

Platform. We conduct our evaluation on an A100 server and an H100 server. The A100 server is equipped with an Intel Xeon Platinum 8358 CPU and an NVIDIA A100 80GB PCIe GPU. The H100 server is equipped with an AMD EPYC 9454 Processor and an NVIDIA H100 NVL GPU. Both servers run Ubuntu 22.04, NVIDIA driver version 535.183.06 and CUDA version 12.1.

Workloads. We use five real-world DNNs from various domains to evaluate VTC. Llama 3 [14] and Gemma 2 [29] are transformer-based LLMs with grouped-query attention and local-global attention, respectively. EfficientViT [8] is a vision transformer backbone for high-resolution dense prediction with linear attention. YOLOv11 [18] is a powerful and efficient convolutional neural network (CNN) designed for a broad range of vision applications. ShuffleNet [38] is a CNN optimized for mobile devices. Table 1 provides detailed configurations for each model. We use PyTorch implementation for all the models. Except ShuffleNet, all the implementations are from official repositories. Following the common practice in previous ML compiler research [31, 40, 41], we evaluate all models with batch size 1 and 16.

7.2 End-to-end Performance

We first evaluate the end-to-end inference latency on a single A100 or H100 GPU and compare VTC with PyTorch 2.6.0 [5] (with `torch.compile` enabled), ONNX Runtime 1.21.1 [12], XLA[6] [1] and TensorRT 10 [2]. Figure 9 presents the end-to-end inference latency results with different batch sizes on A100 and H100, respectively. VTC achieves up to

[6] Since our benchmark workloads are implemented in PyTorch, we use `torch_xla` 2.6.0 package to run PyTorch models with XLA backend.

Table 2: Peak GPU memory consumption of PyTorch and VTC during end-to-end inference with batch size 1 and 16 on A100. All numbers are in Megabytes.

Model	Llama	Gemma	EfficientViT	YOLOv11	ShuffleNet
PyTorch (BS=1)	528.8	480.7	59.0	32.8	10.6
Ours (BS=1)	**461.8**	**436.1**	**55.6**	**26.7**	**10.4**
Savings (%)	**12.7%**	**9.3%**	**5.7%**	**18.5%**	**0.9%**
PyTorch (BS=16)	1787.3	1491.6	798.1	529.0	41.0
Ours (BS=16)	**714.5**	**776.4**	**773.9**	**450.9**	**39.9**
Savings (%)	**60.0%**	**48.0%**	**3.0%**	**14.8%**	**2.6%**

1.93× speed-up (1.28× on average) over the best of the four baselines (mostly TensorRT or PyTorch) in each benchmark.

During the evaluation, TensorRT successfully identifies the attention pattern for all Transformer-based models (Llama, Gemma and EfficientViT) and triggered highly optimized implementations for the entire model. [5] However, VTC still demonstrates an average speed-up of 1.36×. This is notably higher than the average speed-up of 1.15× observed for the CNN models (YOLOv11 and ShuffleNet), indicating that VTC effectively capitalizes on optimization opportunities inherent in newer model architectures like Transformers.

VTC achieves even greater speedup on H100 GPUs as compared to A100 GPUs for 7 cases out of the 10 benchmark cases (covering 5 models at 2 different batch sizes). This trend suggests that the optimization techniques employed by VTC are particularly effective on newer hardware accelerators, where the gap between compute power and memory bandwidth is getting larger (see Figure 1).

7.3 Memory Footprint

We also measure the inference GPU memory footprint after VTC's optimization compared to the PyTorch baseline (as VTC is built upon TorchInductor) using the PyTorch's built-in memory monitor. As shown in Table 2, even when optimizing for maximized latency reduction, VTC still achieves up to 60% peak memory saving (17.5% on average). This demonstrates that virtual tensor optimization inherently saves memory – it avoids storing full physical tensor data by representing virtual tensors with tensor pointers and mapping functions, and VTC handles virtual tensor I/O through code generation with no extra memory overhead. Analyzing the results in detail, we find that VTC successfully makes many large intermediate tensors virtual (e.g., the output of `ScatterND` in Figure 2), thereby reducing peak memory usage. Moreover, this highlights VTC's potential for more aggressive memory saving with relaxed latency constraints by reconfiguring the function ℓ in Section 5.2 to measure memory reduction, offering greater benefits for model training and deployment on memory-constrained hardware.

7.4 Latency Breakdown Analysis

Since TensorRT is the fastest baseline in most cases, we compare the latency breakdown of data movement operators and computational operators for VTC and TensorRT on A100. The results in Figure 10 reveal a substantial reduction in the latency proportion from data movement after VTC's optimization. In 7 out of 10 evaluated cases, VTC eliminates data movement operators entirely. Moreover, the analysis highlights that data movement operators account for a larger proportion of the overall latency in Transformer-based models compared to CNNs, enabling VTC to get better speed-ups.

However, in most of the benchmarks, VTC's latency on computational operators is higher than TensorRT's. There are two possible reasons: (1) VTC's computational kernels may perform virtual tensor I/O in non-contiguous physical addresses, introducing extra overhead in computational kernels (e.g., the `MatMul` kernel in frame 1 of Figure 2). (2) VTC is built upon Triton and TorchInductor, while TensorRT has more highly optimized implementations of computational kernels. This indicates that the performance gains from eliminating data movement significantly outweigh the slowdown incurred in computational operators.

7.5 Comparison with vLLM

As Figure 2 shows, VTC eliminates all data movement operators between QKV projection and attention in LLM decoder layer. Compared with existing compilers such as TensorRT and TorchInductor, the subsequent computational kernel FlashDecoding can launch directly after the previous computational kernel MatMul, improving the utilization rate of compute units without stalling on data movement operators.

To demonstrate the effectiveness of this optimization over a stronger LLM inference baseline beyond compilers, we compare VTC with a state-of-the-art LLM serving framework vLLM V1 [20] on Llama 3 8B inference. Since vLLM is PyTorch-based, we can seamlessly integrate VTC into it. We use similar settings (input sequence length 4096 and BF16 precision)[7] for evaluation on A100 and H100 GPUs.

Table 3 shows that vLLM has *manually* optimized many data movement operators from frame 2 of Figure 2 – the *KV Cache Update* row in Table 3 contributes to a small fraction of latency compared to compiler baselines. This poses a great challenge for VTC to compete, as vLLM is heavily optimized by domain experts on *specific* LLMs, while VTC is an *automated* compiler for *general* ML models. Nevertheless, VTC still identifies a redundant data movement involving the temporary tensor that stores QKV projection results, detailed in Table 4. This optimization yields a 1.043x speed-up on the

[7] vLLM V1 removes traditional notions of batch size and stage separation between prefill and decode through token-based iterative decoding. For our experiments, we construct an input batch of 4096 tokens and measure the corresponding attention latency.

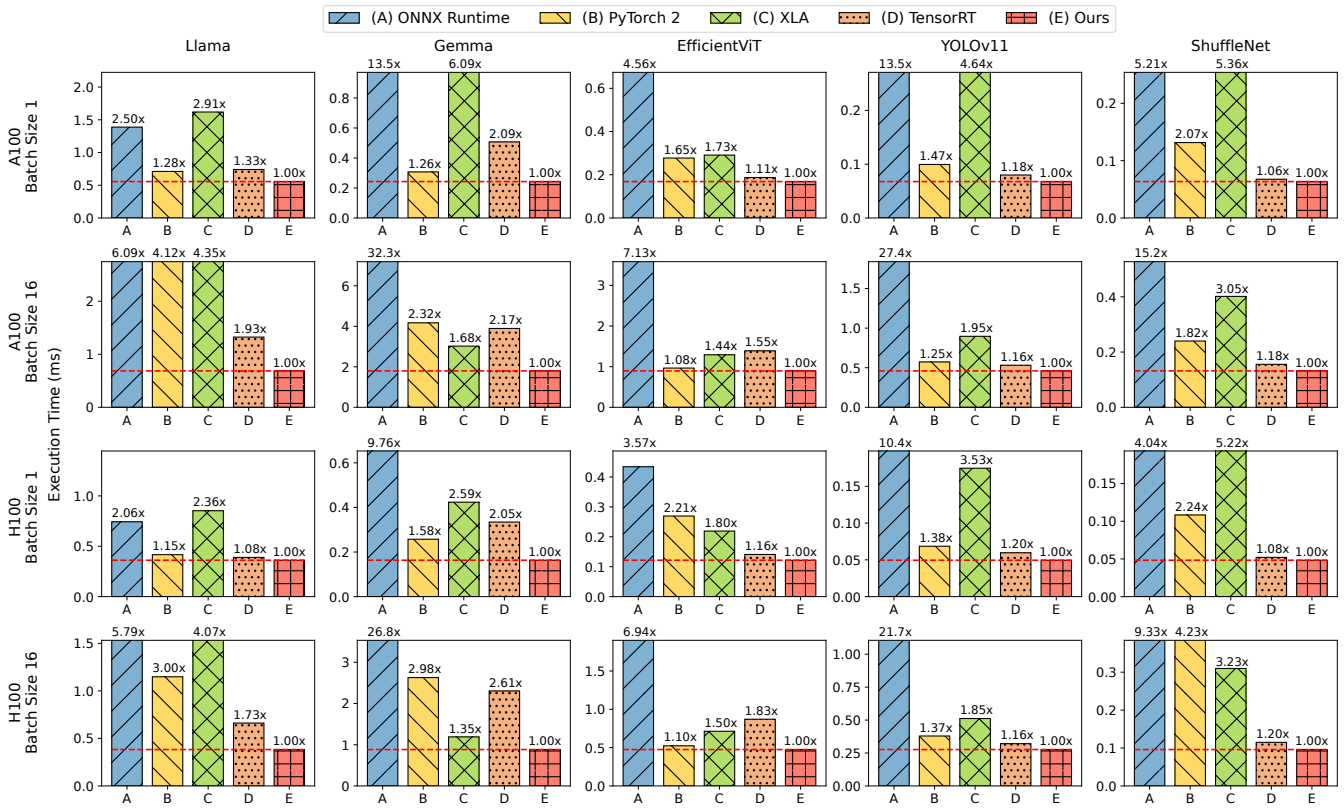

Figure 9: End-to-end inference latency comparison on a single NVIDIA A100 GPU and H100 GPU with batch sizes 1 and 16. Bars over 4× of VTC's latency are truncated.

Figure 2 computation graph and 1.011x end-to-end speed-up over vLLM on A100. However, no speed-up is observed on H100 since vLLM's cuBLAS MatMul kernel (QKV projection) significantly outperforms VTC's Triton kernel, and VTC's profile-guided virtual tensor construction automatically skips negative optimizations. Forcing the optimization from Table 4 on H100 causes an 8% performance degradation. We believe this gap could be bridged by integrating VTC into more optimized hardware-specific kernel libraries like CUTLASS in the future.

7.6 Case Studies

To gain a deeper understanding of how VTC eliminates data movement operators, we study some optimization cases found by VTC in detail.

EfficientViT. Figure 12 illustrates VTC's generated kernels and the points-to graph for EfficientViT attention block with batch size 16. All 5 kernels are computational kernels, and VTC eliminates data movement operators between these kernels by employing a virtual tensor strategy shown in the points-to graph. Among the tensors, only `a`, `e`, `f`, and `j` are physically stored. k_2 and k_3 directly read their inputs from the output tensor `a` of k_1. k_4 reads its inputs from the output tensor `f` of k_3 and writes to the input tensor `j` of k_5. VTC achieves only modest speed-up ($\sim 1.1\times$) and memory saving ($\sim 4.4\%$) on this model because most data movement elimination (e.g., optimizations related to `f`, `g`, `h`, `i` and `j`) can

Table 3: Comparison of Llama inference latency (ms) between VTC and vLLM. *QKV Projection*, *KV Cache Update* and *Attention* correspond to the 3 frames in Figure 2 in the same order. *Total* shows the latency on the Figure 2 subgraph. *End-to-end* shows latency for the entire decoder layer. *Speed-up* uses vLLM as the baseline. On H100, VTC defaults to identical behavior as vLLM, while enforcing optimization in Table 4 degrades performance.

	A100		H100		
	vLLM	VTC	vLLM	VTC	VTC w/ enforced opt.
QKV Projection	0.959	**0.914**	0.401	0.401	0.714
KV Cache Update	0.037	**0**	0.027	0.027	**0**
Attention	0.976	0.976	0.438	0.438	0.438

Speed-up	1.000x	**1.011x**	1.000x	1.000x	0.920x

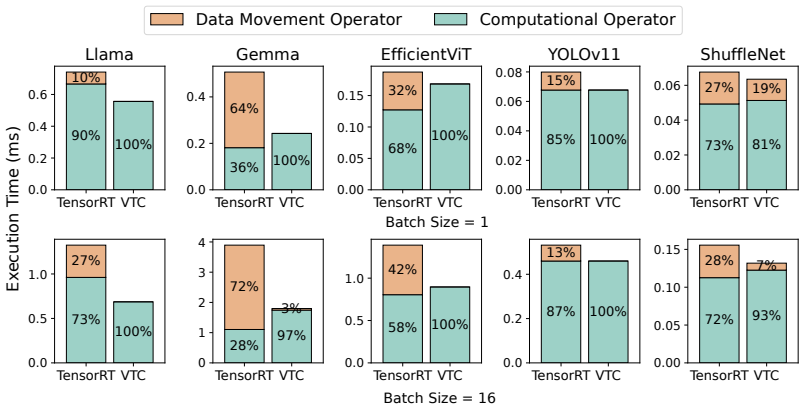

Figure 10: Breakdown of latency proportions for data movement and computational operators in VTC compared with TensorRT.

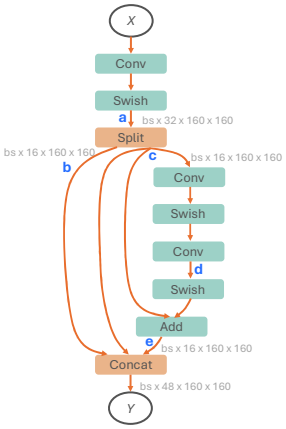

Figure 11: Computation graph of YOLOv11 C3K2 Block. VTC eliminates both data movement operators `Split` and `Concat` by making `a`, `b`, `c` and `e` virtual tensors of `Y`.

Table 4: Data movement optimization in VTC compared to vLLM. As defined in Section 2.3, *Stage 1 Input* and *Stage 3 Output* represent tensors stored in global memory that kernels read from and write to, respectively. vLLM allocates a temporary tensor to hold merged QKV projection values and splits it to update KV cache in an additional data movement kernel. VTC eliminates this overhead by making the temporary tensor virtual, directly writing results to Q tensor and KV cache.

vLLM	Stage 1 Input	Stage 2	Stage 3 Output
QKV Projection	Proj Input	MatMul	**Temporary Tensor**
KV Cache Update	**Temporary Tensor**	N/A	**Q, KV Cache**
Attention	Q, KV Cache	FlashAttn	Attn Output
VTC	**Stage 1 Input**	**Stage 2**	**Stage 3 Output**
QKV Projection	Proj Input	MatMul	**Q, KV Cache**
Attention	Q, KV Cache	FlashAttn	Attn Output

already be achieved by operator fusion in the baselines.

YOLOv11. Figure 11 shows the computation graph of C3K2 Block, a recurring component in YOLOv11. This block contains two data movement operators, `Split` and `Concat`. Traditional frameworks like TensorRT and PyTorch execute `Split` in an individual kernel and `Concat` in another kernel fused with `Swish` and `Add` (taking `b`, `c`, `d` as inputs and `Y` as the output). In contrast, VTC eliminates both data movement operators by making `a`, `b`, `c` and `e` virtual tensors of `Y`. Although `Split` and `Concat` are not fully contiguous at batch size 16 (Figure 5), each contiguous chunk ($16 \times 160 \times 160$ elements) is large enough to read and write in a coalesced manner, preserving high memory I/O bandwidth. Moreover, these two data movement operators constitute the primary memory footprint bottlenecks, as they operate on large tensors (`a`, `b`, `c`, `e` and `Y`). After VTC's optimization, all these tensors except `Y` become virtual, eliminating the need for physical memory allocation and reducing peak memory consumption.

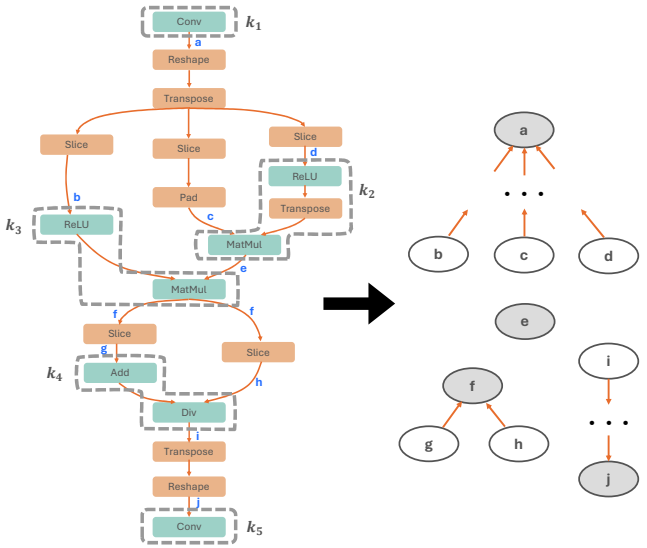

Figure 12: VTC generates 5 kernels (k_1–k_5) for EfficientViT attention block with batch size 16. All the unframed data movement operators are eliminated with virtual tensor. The figure on the right shows the virtual tensor strategy represented by a points-to graph.

8 Related Work

Virtual tensors. VTensor [34] is a programming framework which decouples tensor layouts from the programming interface, enabling developers to write layout-agnostic operations which significantly reduces lines of code. Separately, vLLM [20] and vTensor [33] are virtual memory management systems *specifically* designed for LLM serving. Unlike these systems, VTC optimizes *general* DNNs including LLMs with

a fundamentally different virtual tensor notation.

Layout optimizations. TensorRT [2] explores various layout options for 4D tensors and automatically applies the necessary layout transformations to determine the optimal layout. SmartMem [24] studies layout transformation elimination based on predefined rules and develops efficient memory layouts for 2.5D memory on mobile devices. In contrast to these layout optimizations, VTC proposes a more general optimization for data movements. Instead of focusing solely on layout operators (mostly `Reshape` and `Transpose`), VTC's optimization can be applied to all data movement operators. Furthermore, VTC's points-to graph construction algorithm automatically explores virtual tensor creation strategies, thereby expanding the optimization space beyond rule-based approaches.

Tensor graph optimizations. TensorFlow [3] and TensorRT [2] leverage manually designed rules to perform graph-level transformations. Recently, automated graph optimizers [17, 31, 35, 41] have emerged to automatically generate subgraph substitutions. VTC's optimization is orthogonal to these graph optimizations and can be used as an independent optimization pass after graph optimization in ML compilers.

Kernel orchestration is the process of mapping a computation graph to hardware-specific kernels [15]. This problem is commonly addressed by operator fusion [2, 3, 9, 23], which fuses multiple operators into a single kernel, thereby eliminating data movements of intermediate results. However, this type of work cannot optimize data movement operators that are hard to fuse with other operators. VTC takes a computation graph after operator fusion as input and further eliminates data movements between fused kernels.

Kernel generation. Numerous ML compilers [9, 40, 42] automatically generate hardware-specific kernels for DNN computation based on Halide's algorithm-schedule separation [26]. Rammer [21] and Hidet [13] approach kernel generation by utilizing a task abstraction of workloads. Mirage [32] employs superoptimization techniques on a multi-level compute hierarchy to generate efficient GPU kernels. As VTC only modifies the global memory I/O (stages 1 and 3) of a hardware-specific kernel, it can be easily integrated with virtual tensor support in these kernel generation frameworks.

Hand-optimized kernels crafted by domain experts can achieve state-of-the-art performance on specific DNN workloads. For instance, FlashAttention [10, 11] and FlashInfer [36] design highly optimized GPU kernels for self-attention calculation. VTC can also incorporate these manually optimized kernels by adding virtual tensor support.

9 Future Work

While our current virtual tensor construction algorithm provides performance guarantees through iterative profiling, this approach can incur substantial compilation overhead for time-sensitive applications. The VTOG formulation we present opens opportunities for developing more efficient algorithms that can compute high-quality virtual tensor strategies with reduced profiling requirements.

Our current implementation is based on Triton. However, Triton exhibits known performance limitations on newer GPU architectures, particularly NVIDIA Blackwell GPUs, where domain-specific languages such as CUTLASS demonstrate superior performance. Relatedly, the virtual tensor design does not explicitly consider emerging hardware-specific memory transfer mechanisms such as NVIDIA's Tensor Memory Accelerator (TMA), a hardware unit for asynchronous multi-dimensional memory transfers. While Triton handles some TMA patterns implicitly, explicit TMA awareness in the virtual tensor design could open additional optimization opportunities. Extending virtual tensor support to alternative DSLs and compilation frameworks, together with native handling of such bulk transfer mechanisms, is a promising direction for further performance gains on newer hardware architectures.

10 Conclusion

Data movement optimizations have become extremely important in tensor compilers to achieve good performance. VTC is the first compilation framework to eliminate all unnecessary data movement that spans across all data movement operators in a given tensor computational graph. We introduce the concept of a virtual tensor that allows VTC to track data movement between different physical tensors without instantiating intermediate tensors. VTC's data movement elimination algorithm allows us to achieve superior performance on a number of different DNN models including appreciable gains on large language model inference.

Abstract

High resource utilization is significant for cloud vendors. To achieve this, a common practice is to co-locate low-priority batch workloads (typically Spark-based analytics) with high-priority online services, while strictly maintaining Service Level Objectives (SLOs). This paper presents an empirical study of co-location and overcommitment in a production-scale datacenter. Specifically, within Ant Group, online services utilize only 22.0% of available CPU resources. By carefully overcommitting resources to deploy batch workloads, the system harvests an additional 26.8% of CPU capacity.

Despite this increased density, we observe that batch workloads remain inefficient, with a useful computation ratio of only 67%. We identify the root causes of this low "effective utilization" as four types of idleness: (1) *slot idle*, arising from coarse-grained resource management in Spark; (2) *gap idle*, caused by hardware heterogeneity and interference; and (3/4) *start/stop idles*, resulting from the high latency of launching and destroying analytic instances. To address these inefficiencies, we propose Quark, a novel framework that integrates serverless paradigms into batch analytics. Quark eliminates these idles through fine-grained resource allocation, heterogeneity and skew-aware scheduling, and rapid instance provisioning. Experimental results show that Quark increases cluster utilization by about 37.37% and reduces the proportion of long-tail jobs from 15% to 2%. Quark has been deployed at scale within Ant Group, processing 350,000 offline query jobs daily across a deployment footprint of 600,000 CPU cores, processing between 7,500 TB and 10,000 TB of data daily, and saving more than 100,000 CPU cores.

1 Introduction

Cloud providers strive to maximize resource utilization while strictly adhering to users' SLOs [56]. In modern cloud infrastructure, two primary strategies drive resource efficiency: *overcommitment* and *co-location*. Overcommitment enables providers to allocate aggregate resources exceeding a machine's physical capacity, leveraging the statistical probability that tenants will not reach peak usage simultaneously [13, 94, 100]. Complementing this, co-location schedules diverse workloads, combining latency-sensitive online services with resource-intensive offline analytics, onto the same physical nodes. This exploits complementary usage patterns to maximize utilization without a proportional increase in hardware, a common practice among major providers like Google [35, 78, 92], Alibaba [19, 40], and ByteDance [98].

	min	max	avg
total	48.6%	67.1%	61.2%
prod	9.59%	30.6%	22.0%
mid	1.92%	3.49%	2.72%
batch	21.2%	33.3%	26.8%
system	2.36%	4.59%	3.74%

Figure 1: **Co-location CPU Utilization in a Ant Group's Cloud Cluster.** Maintaining roughly 60% resource utilization achieves a practical trade-off between meeting online service SLOs and maximizing efficiency in clusters.

Ant Group also adopts these strategies to optimize its utilization. Our cloud overcommits resources such that total allocations exceed physical capacity, managing diverse workloads within a unified resource pool. As shown in Figure 1, a single node hosts a hierarchy of four distinct workload tiers. At the highest priority are *System* processes (cluster management daemonsets like etcd) and *Prod* services (latency-sensitive microservices or serverless functions [17, 39, 85]), which receive guaranteed resource allocations. Co-located alongside these are *Mid*-tier real-time tasks (not latency-critical but require stable and reserved resources, e.g., Flink [5]) and *Batch* workloads (opportunistic Spark jobs [12, 104]). *Mid* and *Batch* workloads run exclusively on overcommitted resources and are treated as best-effort; during contention, they are liable to

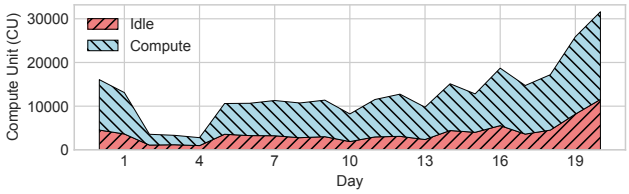

Figure 2: **Gap Between Allocated and Actual Compute Resources in Batch Workloads.** Light blue region represents utilization for actual compute tasks. Light coral region indicates idle time or non-effective computation. 1 CU indicates 1 CPU core and 4GB memory for a 1-hour period.

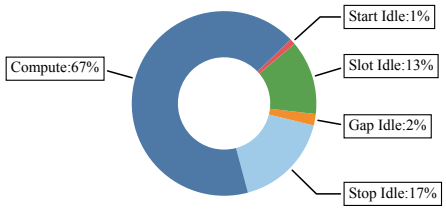

Figure 3: **Breakdown of Batch Workloads' Utilization.**

be throttled or evicted. Despite their lower priority, these workloads exhibit pronounced diurnal patterns, allowing effective co-location to significantly boost overall cluster utilization. However, based on large-scale production deployments and an in-depth analysis of existing solutions, we demonstrate that *the current coarse-grained job model [6, 8] for batch processing is structurally inefficient for co-location*.

Inefficiency in Batch Workloads. In Ant Group, the vast majority of batch workloads are processed using Apache Spark [104]. We execute over 350,000 Spark jobs daily, processing between 7,500 TB and 10,000 TB of data. This scale reflects a broader industry trend, where 80% of the Fortune 500 rely on Spark for large-scale data processing [11,26,29,97,102]. As shown in Figure 2, we analyze one month of resource usage in a production cluster, contrasting the resources requested by batch tasks against those effectively consumed (i.e., for computation). *Our analysis reveals that **33% of allocated resources were wasted** on non-effective states (e.g., waiting, initialization)*. Given the hyperscale of Ant Group, minimizing this hardware waste is critical.

We deconstruct this resource wastage into four types of idleness intrinsic to the current architecture. First, *Slot Idle* arises from Spark's coarse-grained allocation strategy, where an executor's resources remain fixed throughout its lifetime. This rigidity fails to adapt to the varying resource demands of different stages, leading to significant over-provisioning. Second, *Gap Idle* occurs when interference from high-priority workloads or hardware heterogeneity induces straggler tasks. Due to the bulk-synchronous nature of batch jobs, these stragglers delay the commit of entire stages, leaving other resources idle while waiting. Finally, *Start & Stop Idles* stem from the heavy initialization costs, such as JVM bootstrapping and SparkEnv [10] setup. To mitigate frequent startup overheads, the system retains executors for a timeout period before exiting, which inherently results in idle resource holding. Consequently, while overcommitment and co-location have improved cluster utilization in Ant Group, Figure 3 shows that a substantial portion of these resources is wasted.

Our Solution: Serverless Paradigm for Batch Workloads. We identify the root cause of the inefficiencies as a fundamental mismatch: traditional data analytics engines (like Spark) operate with long-running, pre-occupied, coarse-grained resource allocations, while co-located environments are dynamic, favoring fine-grained, on-demand provisioning. To bridge this gap, we advocate for ***applying serverless paradigms to batch workloads***. By transitioning from long-lived executors to task-level resource management, we align resource consumption with actual computational demand. While prior efforts have explored ephemeral executors [41, 43, 44, 95, 105], they often overlook the practical impediments to deploying such models at hyperscale, particularly regarding startup latency and scheduling overhead.

Realizing this vision in a production cluster presents three technical challenges. First, minimizing *slot idle* through task-level scheduling dramatically increases the pressure on the control plane; replacing thousands of coarse-grained executors with hundreds of thousands of individual tasks exacerbates scheduling complexity by orders of magnitude. Second, to address *gap idle*, the scheduler must account for the noise inherent in co-location. Online service interference and hardware heterogeneity create uneven computational power, causing stragglers that block stage completion. Finally, while on-demand provisioning resolves *stop idle*, it threatens to worsen *start idle*; without optimization, the cumulative latency of launching a fresh Java-based Spark instance for every task negates the efficiency gains.

We propose Quark, a novel analytics framework that fundamentally restructures batch processing by adopting a serverless paradigm where resources are provisioned and released at the granularity of individual tasks. Quark resolves the challenges through three key techniques. First, to ensure control plane scalability, we design a *scalable resource control* mechanism that regulates task parallelism via a *Slots Ring* and enforces global overcommitment limits through a *Quota Manager*, all orchestrated asynchronously to maximize throughput. Second, to mitigate hardware heterogeneity and interference, we introduce an *interference-aware scheduler* that converts raw node metrics into uniform capacity scores, enabling a variance-optimal placement algorithm that synchronizes task completion times. Finally, to resolve high cold start overheads, Quark employs *fast task provisioning*, which combines *state reuse* via `fork()` with *state pre-prepare* and *lazy-load* strategies, bypassing JVM initialization and removing non-critical dependencies (of Spark) from the critical path.

Deployment and Results. To the best of our knowledge,

Quark is the first reported commercial system to achieve near-zero resource waste for batch workloads in overcommitment and co-location scenarios. In the TPC-H benchmark, Quark reduced average resource consumption by 56.01%. In microbenchmark tests, the average task execution time decreased by 18% to 33%, the ratio of long-tail tasks dropped by 2.75×, and task startup overhead was reduced by 89.7%. In production environment tests, resource consumption decreased by 37.37%, the proportion of long-tail tasks fell from 15% to 2%, and the longest-to-shortest task time ratio dropped from 20× to 8×. The system has been deployed in a 600,000-core cluster, processing between 7,500 TB and 10,000 TB of data daily, and saving more than 100,000 CPU cores.

Research Contributions. First, it characterizes resource inefficiency in co-located batch workloads by identifying and quantifying distinct forms of idleness that prior work has not fully explored. Second, it proposes a serverless-based analytic framework that resolves critical challenges in scalability, heterogeneity, and latency through novel resource control and scheduling designs. Finally, it validates the system through a large-scale production deployment, offering practical optimizations and operational experiences that demonstrate its reliability and efficiency.

2 Demystifying the Reality of Cloud Utilization

We begin by profiling the overcommitment behavior and co-location workload characteristics in actual clusters. We then conduct an in-depth performance analysis of Spark, identifying critical bottlenecks that inform Quark's design.

2.1 Clusters and Resource Strategies

Clusters Characteristics. In Ant Group, millions of servers are deployed to host tens of thousands of services (different types), serving billions of users. To ensure data locality and stability, servers are distributed across 6 data center regions in different cities. As illustrated in Figure 4, the hardware within these clusters is highly heterogeneous, comprising multiple generations of servers from various hardware vendors. This diversity stems from staggered data center construction dates, the standard 4-year hardware warranty cycle, and the strategic need to ensure supply chain security. This practice of multi-generation server deployment is consistent with patterns reported in prior work [23, 25, 67].

Workload Placement. Ant Group supports a diverse ecosystem across finance, payments, and digital services. The applications of Ant Group include backend applications (microservices and serverless at 48.45%, AI agent at 3.95% and packages at 2.3%), web applications at 40.38%, big data at 4.43% (one platform supports all Spark SQL queries) and terminal applications. These applications are co-located in Ant Group and operate in accordance with a set of placement policies and specific allocate strategies.

(1) Placement Policy. As shown in Table 1, the placement policy follows a *hierarchical overcommitment* resource policy and *throttling and eviction* scheduling policies. Surplus capacity is allocated to lower-priority workloads when utilization of high-priority ones is low. Should their demand increase, lower-priority workloads may be throttled or evicted to guarantee Quality of Service (QoS) for higher-priority workloads.

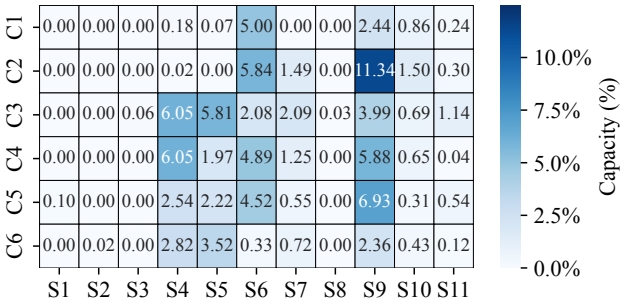

Figure 4: **Servers Distribution in Ant Group.** *C*1-*C*6 represents different clusters, and *S*1-*S*11 different types of servers.

Table 1: **Three-Layer Co-location of Workloads.**

Type	Resource Policy	Scheduling Policy
Prod	Strictly Guaranteed	Never throttled or evicted
Mid	Best-Effort	Can be throttled
Batch	No Guarantee	First to be throttled or evicted

(2) Allocation Strategies. When allocating resources, the scheduler determines the number and specifications of containers that can be deployed on each node based on the Placement Policy and a set of rules. Table 2 summarizes the allocation strategies for each workload. Intuitively, the ratio of prod and mid workloads is determined by pre-defined parameters, while batch is mainly determined by the remaining resources.

Table 2: **Allocation Strategies.**

Type	Allocate Ratio
Prod	min(NodeAllocatable * prodMaxCPUUsageRatio / prodCPUPredicatedUsage, HardLimit(Prod))
Mid	min(NodeAllocatable * midMaxCPUUsageRatio / midCPUPredicatedUsage, HardLimit(Mid))
Batch	min(NodeAllocatable * (1 - NodeUsageReserved) - NodeUsageExceptBatch, HardLimit(Batch))
NodeAllocatable: Total CPU cores in node. {prod, mid}MaxCPUUsageRatio: Max CPU utilization allowed. {prod, mid}CPUPredicatedUsage: Actual CPU usage. NodeUsageReserved: Reserved resources. *HardLimit*: Upper limit. NodeUsageExceptBatch: Per-node resource usage except batch.	

In Ant Group, the prodMaxCPUUsageRatio is 30%. Exceeding this threshold will incur two limitations: First, latency will increase and compromise the SLOs of online services. Second, it is essential to have capacity availability when needed during critical events such as cluster disaster recovery or unexpected workload spikes. There are few mid-type businesses, so the midMaxCPUUsageRatio is set to 10%.

According to these strategies, Figure 5 illustrates the CPU allocation ratios across different clusters. The ratios of *Prod* workload range from 94.6% to 121.3% and *Mid* workload

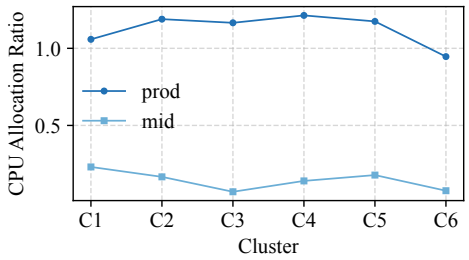

Figure 5: **CPU Allocation Ratios in Different Cluster.** Allocation ratio is defined as Allocated Cores/NodeAllocatable.

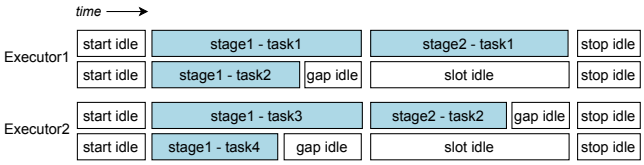

Figure 6: **A Spark Job's Execution Flow.** An example with two stages whose tasks are distributed across two executors.

range from 7% to 23.1%. *Batch* are not assigned a fixed allocation ratio; however, it is required that **the aggregate CPU utilization of all workloads on a node remain below 60% to avoid interference with *prod***. Figure 1 shows each type workload in Ant Group. In a co-located context with limited resource quotas, heterogeneity, and low priority, we need to consider how to efficiently run batch workloads.

2.2 Inefficient Co-location Job Model

We operate *batch* workloads on Spark [11], the de facto standard for big data processing. In Spark, each *job* is represented as a directed acyclic graph (DAG), and each DAG consists of multiple stages. A *stage* contains parallel *task*s that perform the same work, and those tasks are scheduled to run on *executor*s. In this paper, we will follow the same convention [8] to use the terms including *job*, *stage*, and *task*. Figure 6 illustrates an execution flow example across multiple nodes in the cluster. Through real-world deployments, we identify four types of idle or non-productive costs (uniformly referred to as *idle*) that significantly impact resource efficiency.

(1) Start Idle. Starting an executor is a complex, resource-intensive process in Spark. The startup procedure begins when the driver [8] requests executors from the cluster manager (e.g., Kubernetes), which launches pods on worker nodes. A pod is a basic scheduling unit in the cloud. After a pod is allocated, the JVM executor starts, initializes the RPC environment, and registers with the driver. It then creates SparkEnv [10], starts services such as the BlockManager and BlockTransferService, initializes memory and shuffle subsystems, and localizes driver-distributed jars and broadcast variables. Once BlockManager has registered, the driver marks the executor ready and begins sending LaunchTask RPCs.

(2) Slot Idle. An executor operates with fixed resource limits during its lifetime. When tasks at different stages require different resources, the executor must be provisioned to meet the peak demand for the entire job. This over-provisioning leads to resource wastage during less demanding stages. Adjusting resource allocation by replacing or restarting executors incurs significant performance penalties, primarily due to task rescheduling overhead and the potential loss of intermediate data. Previous work focuses mainly on predicting optimal resource configurations [18, 83] and reducing the granularity of resource allocation [97]. These approaches are hard to handle real-time resource requirement variation of different stages.

(3) Gap Idle. Spark adheres to the Bulk-Synchronous Parallel (BSP) model [46], requiring all tasks within a stage to complete before the next stage can commence. Consequently, slow tasks (stragglers) cause resource waste, with a few executors doing left work while others idle, delaying the entire job. Many studies have reported various straggler factors [2, 32, 53, 70]. In Ant Group, we focus on two cluster-related impacts. First is the *co-location*: batch workloads utilize overcommitted resources, and will be evicted when higher-priority workloads (e.g., system, production, mid-tier) contend for resources. Second, *hardware heterogeneity* within the cluster presents challenges. Servers in Ant Group follow 4-year replacement cycles and are sourced from multiple OEMs for supply-chain reasons. This heterogeneity results in uneven computing power across the cluster (Figure 4), causing unaligned tasks finish time within the same stage.

(4) Stop Idle. In Spark, an executor is a long-lived Java process, while a task runs as a thread within it. Executors do not terminate upon task completion. They persist until the driver requests their release from the cluster manager at application termination. When dynamic allocation feature is enabled, idle executors exceeding the configured executorIdleTimeout are decommissioned. Executor startup is slow (start idle), setting the executorIdleTimeout too low will increase latency and resource churn. The default executorIdleTimeout is 60 seconds, but it is often extended to several (or tens of) minutes in production environments.

2.3 Existing Approaches

Researchers have proposed a wide range of techniques, such as workload co-location and data analytics, to address performance and resource utilization issues in cloud infrastructures [3, 19, 23, 25, 29–31, 40, 41, 43, 44, 49, 66, 74, 75, 78, 84, 92, 97, 98, 105], as shown in Table 3. Some of these works are applicable and have inspired parts of Quark's design, which has been adopted in large-scale production environments. However, others neglect the critical issues discussed in §2.2 or rely on simplified assumptions that overlook the complexities of large-scale systems and cannot address the identified idles.

(1) Spark Optimizations. Apache Spark is the most widely used system for large-scale data processing and involves the coordinated work of many components. There are many efforts to improve its performance, including shuffle mechanisms [26, 59, 81], native compilation [29, 102], resource optimization [79], configuration tuning [50, 61, 99, 110] and so

Table 3: **Comparison of Existing Approaches and Quark.** (●is beneficial, ◐is partly beneficial, and ○is limited.)

Approaches	Related work	Slot Idle	Gap Idle	Start&Stop Idle
Spark Optimizations	Wu et al. [97], ResourceProfile [7]	◐	○	○
Cluster Management	Bubble-up [64], Quasar [25], Paragon [23], Gsight [109], Jiagu [54]	○	●	○
Serverless Analytics	Starling [74], Caerus [105], Ditto [41], Jiffy [44], MinFlow [49], MetaQ [95]	●	○	○
Quark(this paper)	-	●	●	●

on [22, 65, 72]. Some of the research efforts are orthogonal to, yet complementary with, the issues discussed in §2.2. Furthermore, prior work has also discovered that there is an urgent need to handle resource requirements variation of different stages (e.g., Wu et al. [97] and ResourceProfile [7]). However, these methods merely adjust resource configurations to align executors more closely with the average resource utilization. Although this yields certain improvements, the underlying two-layer *executor–tasks* job model remains unchanged, and the fundamental problem therefore persists.

(2) Cluster Management. Overcommitment and co-location may lead to performance degradation and QoS violation, it is a common practice to predict performance before scheduling an instance to avoid QoS violation. For example, previous works use modeling (e.g., Graph [33], Linear [60], RL [63], Random Forest Regression [54]) to determine optimal placement strategy [64, 73, 86, 101, 109]. Although this work offered valuable insights and inspirations that informed the design of Quark, there are still some issues that need to be addressed to optimize *gap idle*. First, existing works [54, 101, 109] focus on a single node, aiming to maximize instance deployment density without violating instances' QoS. However, batch workloads following the BSP model require that all tasks within the same stage have as uniform execution times as possible. Second, it fails to differentiate features among *prod*, *mid*, and *batch* workloads and the impact of heterogeneous hardware, prediction accuracy is limited [24, 25].

(3) Serverless Analytics. The elasticity, free-of management, and on-demand scalability of serverless have motivated the effort in deploying distributed data analytics applications to serverless platforms. We evaluate the potential of the existing work [41, 43–45, 49, 66, 74, 75, 84, 105] to provide fine-grained resource control and reduce slot idleness. Our analysis reveals two fundamental limitations in existing solutions: (1) *Coarse-grained resource allocation*. Some prior serverless analytic systems deploy function at executor scale [43, 45, 95], which cannot adapt to stage-level variations and leaves slot idle issues unresolved. (2) *Overlook the complexities of large-scale systems.* Ditto [41] allows each task to be assigned to a serverless function, but it neglects the task startup cost in real systems. MetaQ [95] reports that it takes $17.78s \sim 47.02s$ to start a Spark engine. When the granularity of serverless functions shifts from executor to task, the cumulative cold start penalty will increase enormously. Some systems [74, 105] remain in the prototype phase and are difficult to deploy at scale in practical scenarios, mainly due to challenges related to control plane scalability, heterogeneity, and cold starts.

3 Quark Overview

To address the inefficiencies of co-location (i.e., four idles), we propose Quark, a framework that re-architects batch workloads using a serverless paradigm. The core insight of Quark is to transition from a *coarse-grained and pre-allocated* resource model to a *fine-grained and on-demand* model. Specifically, a task could request one core (or sub-core) when it starts and release it immediately after completion. By utilizing the individual task, rather than the heavy-weight executor, as the basic unit of resource allocation, Quark allows the cluster to effectively harvest transient overcommitment resources.

3.1 Challenges

However, adapting a heavy-weight analytics engine like Spark to this fine-grained model introduces three challenges.

Challenge-1: Scheduling Scalability and Efficiency. The transition from coarse-grained executors to fine-grained tasks creates a massive surge in scheduling events, imposing severe pressure on the control plane. Figure 7 shows the CDF of task counts per stage; we observe that over 10% of stages exhibit parallelism exceeding 184, with peak parallelism reaching 52,383 tasks in a single stage. This explosion in scheduling introduces three specific issues. First, handling hundreds of thousands of individual task scheduling requests, as opposed to a few thousand executor requests, can saturate the cluster scheduler (e.g., Kubernetes), potentially disrupting the stability of co-located online services. Second, because native Spark lacks a global view of real-time overcommitted resources, it may aggressively issue scheduling requests that exceed available capacity, leading to a high volume of failed and wasteful invocations. Finally, the overhead of managing the lifecycle of short-lived tasks creates a throughput bottleneck in the control plane, increasing end-to-end latency.

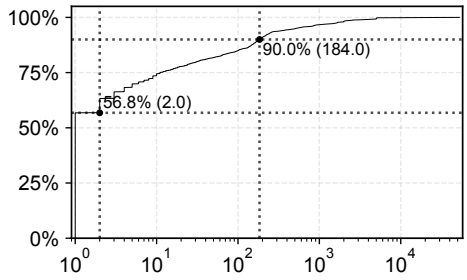

Figure 7: **Distribution of Tasks per Stage.**

Challenge-2: Hardware Heterogeneity and Interference. To effectively mitigate gap idle, the scheduler must ensure that

tasks within the same stage finish simultaneously. However, achieving this is difficult due to the significant variance in effective computing power across the cluster. As shown in Figure 4, servers in Ant Group follow a four-year replacement cycle and are sourced from multiple vendors, resulting in inherent hardware heterogeneity. Meanwhile, batch workloads run at low priority and are subject to being throttled or evicted by online service. Standard schedulers typically view resources nominally (e.g., CPU core counts) and overlook these performance variations. Without accounting for this heterogeneity and interference, tasks assigned to slower or noisier nodes become stragglers, delaying the completion of the entire stage and reducing cluster efficiency.

Challenge-3: Cold Start Overhead. The ephemeral nature of serverless tasks fundamentally clashes with the high cold start costs of the Spark runtime. While general-purpose serverless platforms utilize techniques like forking or checkpointing to optimize startup, Spark's initialization is uniquely complex, involving the setup of heavyweight components such as the JVM, RpcEnv, and RemoteDataManager. Currently, the startup latency for a standard Spark instance exceeds 6 seconds. In a coarse-grained model, this cost is amortized over the lifetime of a long-running executor. However, in a fine-grained model where instances are created and destroyed for specific tasks, this multi-second overhead becomes a dominant factor, potentially negating the benefits of on-demand allocation. Reducing this startup latency to a level compatible with short-lived tasks remains a critical open challenge.

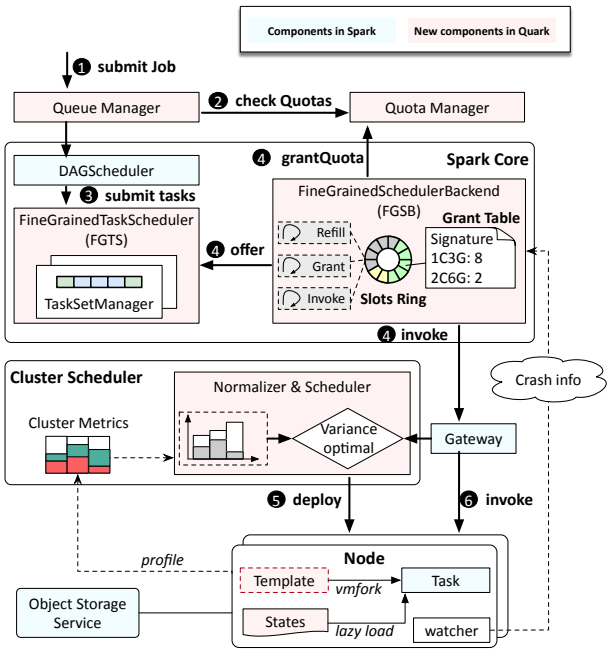

Figure 8: **Quark Overview.**

3.2 Design Overview

System Architecture. Figure 8 shows the overall architecture of Quark. Built atop the full Spark stack, Quark preserves complete compatibility with Spark-SQL while establishing a fine-grained resource model. The system operates across three logical layers. First, the **Spark Core** serves as the primary control plane; it receives analytic jobs and generates tasks via the *TaskScheduler*, which then coordinates with the *SchedulerBackend* to interact with the underlying infrastructure. Second, these components interface with the **Cluster Scheduler** within Ant Group's serverless platform, which handles the placement of individual tasks onto physical nodes. Finally, at the **Node Layer**, Quark utilizes lightweight, VM-based containers to execute these serverless instances, launching a fresh runtime for every scheduled task. These instances are stateless [74], driver/executor metadata objects that are traditionally pulled from executor memory (e.g., broadcast-related metadata) are stored in remote cloud object storage services and fetched on demand. Intermediate shuffle data are managed by vanilla Spark's ShuffleManager. This eliminates the need for rack-aware data locality during instance scheduling. Quark introduces three key techniques to address the challenges in §3.1.

Scalable Resource Control. To overcome the **Challenge-1**, we firstly design a *Slots Ring*-based mechanism within the Spark Core to regulate task parallelism and coordinate Spark scheduler components. Besides, we introduce a *quota-based resource management* to explicitly manage global overcommitment capacity, thereby reducing wasteful scheduling attempts. Finally, we adopt fully asynchronous principles in the control plane to decouple interdependent operations and maximize throughput.

Interference-aware Scheduler. To mitigate heterogeneity and interference (**Challenge-2**), Quark introduces a *Interference-aware Scheduler* situated within the serverless platform. Its primary goal is to normalize the effective computing power provided to tasks within the same stage. By monitoring real-time system metrics, the scheduler converts raw node resources into a uniform capacity score using a normalizer model. It then applies a variance-optimal placement algorithm to distribute tasks, significantly reducing the occurrence of stragglers and minimizing tail latency.When online services burst, a local agent detects contention signals (e.g., SLA degradation, LLC misses) and enforces an online-first policy by throttling batch resource entitlements and adjusting the node's reported available capacity.

Fast Task Provision. To resolve the high cold start overhead (**Challenge-3**), Quark optimizes the task initialization through three mechanisms. First, we employ *State Reuse*, where the system maintains pre-warmed template instances and creates new tasks via a fast *vmfork* operation, bypassing the initialization of JVM and parts Spark modules (e.g., executor-level state). Second, we use *State Pre-Prepare* to compute task-specific states (such as Codegen bytecode) in the driver and transfer them to the executor, avoiding redundant compilation. Last, we implement *State Lazy-Load* to remove non-critical components from the startup path, initializing them in parallel

only when needed.

4 Detailed Design

4.1 Scalable Resource Control

We first explain the techniques for scalable resource control.

Slots Ring-Based Task Management. In the traditional Spark architecture, a *TaskScheduler* decides which tasks should run, and a *SchedulerBackend* communicates with the underlying cluster manager (e.g., Kubernetes) to acquire and launch execution instances, as shown in Figure 8. To prevent the fine-grained model from leading to uncontrolled parallelism, Quark introduces the *Slots Ring* as a key data structure within the Spark Core. This ring buffer maintains the tasks currently allowed to be scheduled, helping to coordinate the *FineGrainedTaskScheduler (FGTS)* and the *FineGrainedSchedulerBackend (FGSB)*. The *FGTS* supplies new tasks (*refill*) to the ring only when idle slots are available, and the *FGSB* then attempts to acquire quotas and launch instances for these slotted tasks (*grant* and *invoke*). By configuring the size of this ring, Quark precisely controls the global parallelism of batch workloads, preventing scheduling pressure from overwhelming the cluster. Analogous to Spark's driver [9], *FGSB*/*FGTS* are centralized. They support HA via failover (restart/leader election depending on the deployment), but at any time only one instance is responsible for making scheduling decisions. Although centralized, the scheduler offer scalability because the slots-ring changes the critical path from O(M*N) tasks/executors match to O(1) enqueue/dequeue per scheduling event and avoids global contention.

Quota-Based Resource Control. Instead of relying on the cluster scheduler to reject scheduling requests due to lack of resources, which can lead to contention and wasted API calls, Quark introduces the *QuotaManager (QM)* to explicitly manage the global overcommitment capacity. *QM* is a distributed resource management service where a single leader instance is responsible for all allocation decisions, with follower nodes providing fault tolerance.When the leader fails, Quark enters a short failure-recovery window (<1 min) for failure detection and leader election. During this period, jobs that have already received a quota grant are not affected, and new submissions that require fresh quota decisions will be temporarily stalled until a new leader is ready. The leader maintains the current resource usage and schedulable tasks in an in-memory cache, which is periodically synchronized with a backend database. This design minimizes database load and accelerates scheduling decisions. Quota allocation is based on in-memory operations, so the leader will not suffer from scalability issues or performance bottlenecks.

As shown in Figure 9, operators define a total available quota for each *project* (representing a tenant or team). A submitted job registers its priority, and submission time within its project. Subsequently, the *FGSB* summarizes the resource needs of the tasks in the Slots Ring and requests a resource

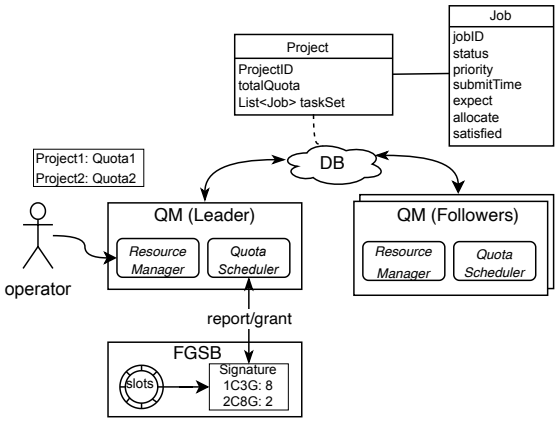

Figure 9: **Quota Manager.**

grant from the *QM*. Only upon receiving a successful grant does the *FGSB* proceed to invoke the underlying serverless platform. This explicit resource negotiation significantly reduces the number of failed and wasteful invocations.

Quota Allocation. The quota allocation procedure focuses on reclaiming under-utilized quota and prioritizing high-demand jobs. First, the *QM* reclaims resources by returning allocated quotas from completed jobs and adjusting the allocation of running jobs downward to their expected demand, recovering any surplus. Second, the reclaimed quota is re-distributed to jobs whose current allocation is below their expected level. Unfinished jobs are prioritized based on their explicit priority and submission time. The allocator first guarantees the required resource allocation for running jobs to minimize churn. If surplus resources remain, it allocates additional resources toward the job's expected demand on a best-effort basis, terminating the allocation cycle if the quota is exhausted. For jobs that receive a partial allocation, resources are preferentially assigned to smaller containers to maximize throughput.

Asynchronous Scheduling Framework. A key design to achieving control plane scalability is the full adoption of asynchronous principles. In a synchronous model, the three core operations of the SchedulerBackend: *refill*, *grant*, and *invoke*, are tightly coupled; a block in the *grant* operation, for instance, would stall the *invoke* of tasks that already possess granted quotas. To prevent this single point of blocking, Quark meticulously decouples these three operations into independent threads that communicate via the Slot Ring.

The *Refill* Thread generates available slots and presents them to the *FGTS*. It operates in a batched, asynchronous manner (e.g., every 500 ms), filling empty slots in the ring. The *FGTS* selects tasks based purely on priority, as the Slot Ring already controls parallelism (O(N) scheduling). The *Grant* Thread periodically (e.g., every 3 seconds) computes the aggregated resource demands of tasks in the Slot Ring and consults the *QM* for quota allocation. To reduce the load on the *QM*, it encodes the expected resource demand into a signature; if this signature remains unchanged from the previous

cycle, the expensive full allocation schedule is bypassed. Finally, the *Invoke* Thread handles the actual submission to the cluster gateway. It scans the Slot Ring every 500ms, identifies tasks that have received a valid quota grant, and dispatches the launch requests for parallel execution. This asynchronous design ensures that latency in one operation does not halt the entire task scheduling pipeline.

4.2 Interference-aware Scheduler

Quark introduces an interference-aware scheduler to overcome the heterogeneity and dynamic interference challenge, including two core techniques: the *Resource Normalizer* and the *Variance-Optimal Scheduler*.

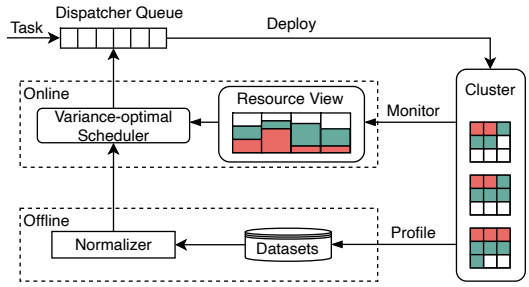

Figure 10: **Quark's Interference-aware Scheduler.**

Resource Normalizer. Since batch workloads have the lowest priority, they are susceptible to interference from both *prod* and *mid* workloads. The *Resource Normalizer* is designed to quantify the effective resource capacity available for batch on any given node. As shown in Figure 10, an agent continuously collects essential system metrics from kernel interfaces, including the CPU utilization of co-located workloads, NUMA topology, and the machine type. This data is fed into a linear model to calculate the effective capacity. Equation (1) quantifies the schedulable resource capacity on a node:

$$Batch_{\text{alloc}} = W_{\text{m}} \times \left(NodeAll - \sum_{i \in \{\text{sys,prod,mid,batch}\}} W_i \cdot Alloc_i \right) \quad (1)$$

Here, $NodeAll$ represents the total CPU cores of the node. W_{m} is a weight characterizing the intrinsic performance impact of the machine type (hardware heterogeneity). W_i is a weight representing the quantified impact of interference from workload type i (i.e., *sys*, *prod*, *mid*, and *batch*) on the batch execution, and $Alloc_i$ is the resources allocated to that workload. The weight-related parameters are determined offline through Bayesian optimization process, using a dataset built from comprehensive performance metrics collected across the cluster. The output, $Batch_{\text{alloc}}$ provides the scheduler with a unified metric of effective capacity. Cache contention is handled at the node via hardware QoS enforcement (e.g., Intel RDT, AMD QoS) with dynamically adjusted LLC quotas, which is orthogonal to scheduler-level interference model.

Variance-optimal Scheduler. After normalization, Quark then employs a variance optimization algorithm to make precise task placement decisions, ensuring optimal resource distribution across the cluster. Assume a cluster consists of N nodes, denoted as $node_1, node_2, \ldots, node_n$. The total resources of these nodes are $total_1, total_2, \ldots, total_n$, and at a given moment, their allocated resources are $alloc_1, alloc_2, \ldots, alloc_n$. The optimization goal is to minimize the variance of the nodes' allocation ratios after scheduling, The objective function is defined as:

$$Var = \frac{\sum_{i=1}^{n} \left(\frac{alloc_i}{total_i} - \overline{\frac{alloc}{total}} \right)^2}{N} \quad (2)$$

By minimizing this variance, the scheduler actively avoids creating load imbalances, ensuring that the workload is spread evenly relative to the effective capacity of each node.

4.3 Fast Task Provision

When a task is scheduled, the underlying execution platform must launch an instance to execute it, involving the startup of the *JVM*, the initialization of components within *SparkEnv*, and the preparation of the *ExecutorBackend*. In Spark's traditional model, the executor is a long-lived process, amortizing this multi-second startup cost across thousands of tasks. In contrast, when the execution granularity shifts to the task level, this startup delay must be incurred for every task, leading to a dramatic increase in cumulative cold-start overhead. To make the fine-grained model viable, Quark implements three mechanisms to achieve near-instantaneous task provisioning.

State Reuse via Forking. For states that are common across all tasks and independent of specific job logic, Quark employs a technique inspired by container optimization: it maintains a pre-initialized, paused template instance. This template instance completes the most expensive initializations in advance, including the JVM startup and the setup of core Spark components like RpcEnv and RemoteDataManager. When a new task instance is required, the system creates a live instance by forking from this template. Quark does not directly call fork() from an arbitrary multi-threaded JVM state. Instead, it leverages *sfork* (sandbox fork) design in previous work [17, 28], which introduces a transient single-thread mechanism: before forking, the template VM is brought into a controlled state where only one thread remains runnable and all other threads are quiesced. This avoids the well-known POSIX fork hazards in multi-threaded processes. After a new secure-container instance is forked, Quark will re-initialize the task-/application-specific Spark settings e.g., re-binding/re-initializing components such as RpcEnv endpoints and ShuffleManager connections. When new Spark versions are released, Quark periodically regenerates templates from the updated image. This mechanism allows the new instance to instantly inherit a initialized execution environment, eliminating seconds of overhead from the critical path, as detailed for the JVM and RemoteDataManager in Table 4.

State Pre-Prepare. The second mechanism addresses components that are task-specific but can be prepared outside

Table 4: **Cold Start Costs and Our Optimizations.**

Modules	Cost	Policy
WholeStageCodegen	70ms	Pre-Prepare
JVM	$2 \sim 3s$	Reuse
RemoteDataManager	600ms	Reuse
BlockManager	10ms	Reuse
RpcEnv	600ms	Reuse + Update
ShuffleManager	300ms	Reuse + Update
MetricsSystem	400ms	Lazy-Load
MapOutputTracker	300ms	Lazy-Load
SecurityManager	10ms	Lazy-Load
ExternalShuffleClient	100ms	Lazy-Load
NettyBlockTransferService	30ms	Lazy-Load

the critical launch path. A key target is Spark's Whole-Stage Code Generation (Codegen), which dynamically compiles optimized JVM bytecode at runtime to boost query performance. We leverage the insight that the code blocks generated by the driver for compilation are identical to those needed by the executor. The FGSB capitalizes on this by sending the compiled code from the driver directly to the executor instance via the serverless invocation payload. The task can then skip the costly process of code generation and compilation, directly loading the required classes, thereby reducing latency by an amount equivalent to the codegen time.

State Lazy-Load. Finally, Quark utilizes asynchronous loading and dependency removal for non-critical components. For states that can be initialized in parallel or are not immediately required for task execution, e.g., the security manager, Quark removes their initialization from the critical task startup path. As summarized in Table 4, this policy covers several heavyweight components like MetricsSystem, where initialization can be safely delayed, ensuring that task execution begins with minimal latency.

5 Implementation

Quark is implemented on top of Apache Spark. It remains fully compatible with Spark and requires no modifications to user code. To achieve Quark, there are approximately 10K lines of Java and Scala code for *FGTS* and *FGSB*, 5K lines for *QM*, 3K lines of Java for QueueManager, and 1500 lines of Go for cluster scheduler.

QueueManager. Beyond the design components, Quark introduces a *QueueManager (QMgr)* to control the maximum number of jobs that can be submitted. When a user submits a SparkSQL job, the system consults the *QM* to check whether the project's quota is sufficient. If the remaining quota is insufficient, the job is enqueued in the *QMgr*. Once enough quota becomes available, the *QMgr* dequeues and resubmits the job according to its priority and submission time.

Fault Tolerance. In Spark, when a task fails due to insufficient resources (e.g., out-of-memory), the Spark scheduler will retry it and reschedule it on another executor. However, because each executor has the same fixed resource configuration (e.g., CPU and memory), the retried task is likely to fail again. Quark's fine-grained job model can overcome the issues and enable precise fault-tolerance control: individual task failures do not affect other tasks, and the system can dynamically adjust resources and retry failed tasks as needed. As shown in Figure 11, Quark employs a three-level fault-tolerance mechanism tailored to the different stages at which failures may occur: (1) *Startup Monitor.* The *FGSB* monitors each task during startup. If a task fails to start within a predefined timeout, the *FGSB* marks the task as failed. (2) *Process Heartbeat.* While a task is running, it periodically sends heartbeat messages to the *FGSB*. If the *FGSB* does not receive a heartbeat within the expected interval, it treats the task as failed. (3) *Crash Callback.* If a task crashes, a node watcher detects the failure and reports the crash information to the *FGSB*, which then marks the task as failed.

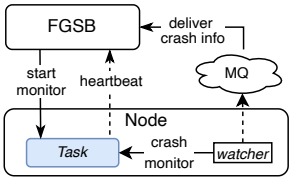

Figure 11: **Three Level Fault Tolerance.**

The *FGSB* then analyzes the failure context. If the failure is caused by insufficient resources (e.g., an out-of-memory error), it will apply an increased quota from the *QM*, and retries only the affected task, avoiding a full stage-wide retry.

6 Evaluation

6.1 End-to-end Performance

Testbeds. The evaluation is conducted on a 30-node cluster, with each node equipped with an Intel(R) Xeon(R) Platinum 8163 CPU (96 cores, 2.7 GHz). The operating system is Linux kernel 5.10. Each task instance gets 1 CPU core, 3 GB of memory, and 300 GB of storage. The evaluation takes the following systems as baselines.

1. **Spark** runs on Kubernetes (K8s) with a coarse-grained job model (version 3.2.0).
2. **Spark-F** represents an upgraded version of Spark; it adds a fine-grained resource model and runs in a serverless paradigm (include design in §4.1).
3. **Spark-S** adds the design of the interference-aware scheduler (§4.2) on the basis of Spark-F.
4. **Quark** is our final production platform that further optimizes task startup performance (§4.3) based on Spark-S.

Resource Efficiency. We first assess the resource utilization using the TPC-H benchmark [88], which includes 22 complex SQL queries covering a wide range of operations. Specifically, we measure the CU consumption of each SQL query over a 1 TB dataset (SF=1000) in four systems (1CU: 1CPU and 3GB memory for 1min in this context). As shown in Figure 12, Quark reduces resource consumption by 26.70%–87.86% compared to Spark across the 22 TPC-H queries, with an average reduction of 56.01% (20 trials, mean re-

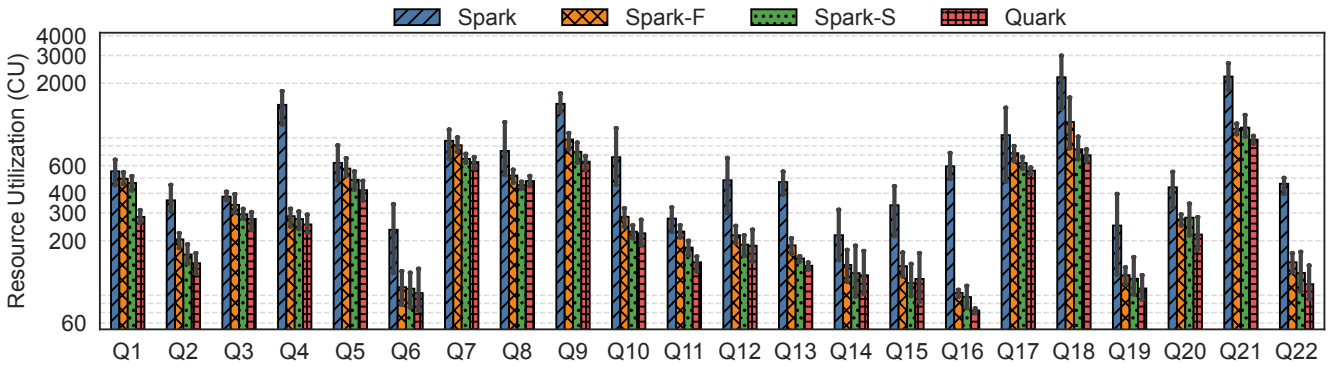

Figure 12: **Comparison of Resource Utilization in the TPC-H Benchmark.** Q1-Q22 are distinct TPC-H queries covering a broad range of SQL operations [89].

ported). This demonstrates the effectiveness of our approach. The smallest gain occurs in Q3, which involves joins and sorting on large tables (orders, lineitem) with heavy shuffle and memory use. Here, I/O is the main bottleneck, reducing the relative advantages of Quark's design. In contrast, Q16 shows the largest improvement, featuring filtering and group aggregation on small, highly parallelizable tables. For such workloads, Quark's scalable resource control, interference-aware scheduler, and fast task provisioning design are fully utilized, delivering significant gains.

Compared with Spark, Spark-F achieves a reduction in resource consumption ranging from 6.26% to 84.31%, with an average decrease of 42.68%. This improvement is attributed to fine-grained task scheduling, which minimizes resource waste caused by *Slot Idle* and *Stop Idle*. Similarly, Spark-S lowers resource consumption by 15.63% to 85.22%, averaging 50.26%, mainly through the adoption of an interference-aware scheduler that mitigates the *Gap Idle*.

Completion Time. To evaluate the job completion time, we design a compute-intensive job with no I/O operations. It consists of 800 tasks, each computing the Fibonacci sequence ($N = 50$) five times independently. Figure 13 compares the four systems in three aspects: resource utilization, job completion time, and task duration standard deviation.

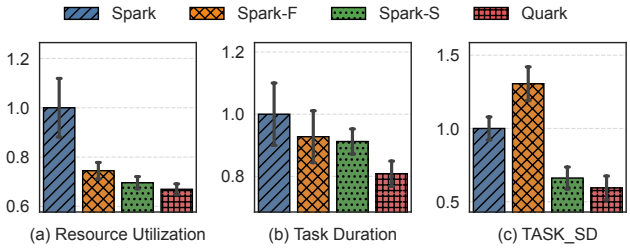

Figure 13: **Execution Time of Computation-Intensive Jobs.**

As shown in Figure 13(a), Spark-F, Spark-S, and Quark reduce resource consumption by 25.53%, 30.41%, and 33.06% compared to Spark. In terms of completion time, Figure 13(b) shows speedups of 7.24%, 8.78%, and 19.11%, respectively.

Notably, Figure 13(c) presents the standard deviation of task completion times for each system: native Spark exhibits an average standard deviation of 79.20s, while Spark-F, Spark-S, and Quark take 103.40s, 52.40s, and 47.07s, respectively. The slightly higher standard deviation of Spark-F compared to native Spark stems from its finer-grained scheduling, which operates at the task level rather than the executor level. In native Spark, each node allocates resources once at job startup. In contrast, Spark-F performs independent resource allocation for every task, increasing variability in startup overheads and thus leading to greater variation in task completion times. Spark-S and Quark substantially improve the consistency of task execution.

6.2 Micro-benchmarks

Interference-aware Scheduler. We construct a 21-node heterogeneous cluster, with machine models and counts listed in Table 5. To simulate realistic multi-service co-location, each node runs several online services: *Prod* services use 20%–30% of node resources, while *Mid* and *System* services each consume 5%–10%. To evaluate the effectiveness of interference-aware scheduler, a batch of computationally intensive tasks is submitted and their execution performance is assessed using two metrics: (1) *Average Task Time* and (2) *Tail Latency Ratio*, defined as the ratio of the longest to the shortest task run time within the same stage.

Table 5: **Cluster for Micro-benchmark.**

CPU Specifications	Number
Intel(R) Xeon(R) Platinum 8163 (24 cores, 2.5 GHz)	7
Intel(R) Xeon(R) Platinum 8269 CY (26 cores, 2.5 GHz)	7
AMD EPYC 7T83 (24 cores, 2.5 GHz)	7

Figure 14(a) presents the average task execution time within the cluster under varying load. After adopting an interference-aware scheduler, the average task execution time decreased from 250s to 191s (AR=70%) and from 306s to 286s (AR=100%), achieving a performance improvement of 18%–33%. Figure 14(b) illustrates the tail latency for the same stage of tasks. The tail duration ratio was reduced from 1.76× to 1.64× (AR=70%) and from 2.75× to 2.22×

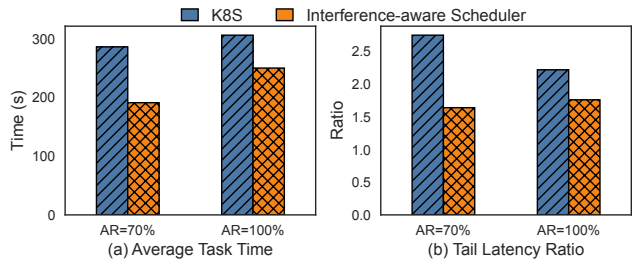

Figure 14: **Comparison of Task Execution Time and Tail Latency under Different Loads.** "AR" stands for allocation ratio. For example, a 100C cluster running 70 concurrent tasks (1C) has a 70% allocation ratio.

(AR=100%). This experiment demonstrates that interference-aware scheduler can significantly reduce both the average execution time and tail latency within a batch of tasks.

Fast Task Provision. Figure 15 compares the time to start an executor in Spark versus launching a task in Quark. Spark takes 6078*ms* to start an executor, while the corresponding task startup in Quark is only 626.53*ms* (100 trials, mean reported), attributed to the three startup optimization mechanisms in §4.3. Compared to SOTA results [17, 36, 37, 103], the remaining costs of Quark come from two aspects: first, the instance is launched under co-location with low-priority resources. In fact, Quark only takes around 100ms on a dedicated machine. Second, unlike typical simple serverless functions, Quark is monolithic and must initialize a lot of unique states, including driver/shuffle connection establishment, task-level code and plugin loading, and complicated structure initialization, which cannot be fully mitigated.

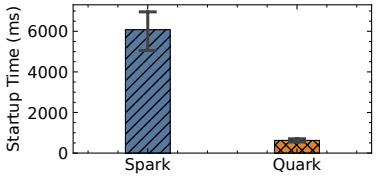

Figure 15: **Task Startup Performance.**

6.3 Production Workload Replay

To validate the effectiveness of Quark under real production workloads, we conduct a trace-driven replay experiment using 24-hour production traces captured from a project at Ant Group[1]. As shown in Figure 16, the traces comprise 22,532 Spark jobs exhibiting a typical diurnal pattern, with submissions peaking at 1,641 jobs/hour at 08:00 and declining to 630 jobs/hour at 21:00. The total I/O volume reaches 4,610 TB, dominated by warehouse reads (Tunnel I/O, 94.7%) with a 13.5:1 read-to-write ratio, while Shuffle I/O accounts for 5.3% with near-symmetric read/write.

To fairly compare Quark with unmodified Spark, we replay the same workloads on two equivalent-scale clusters, each

[1]The traces are available at https://github.com/antgroup/Quark

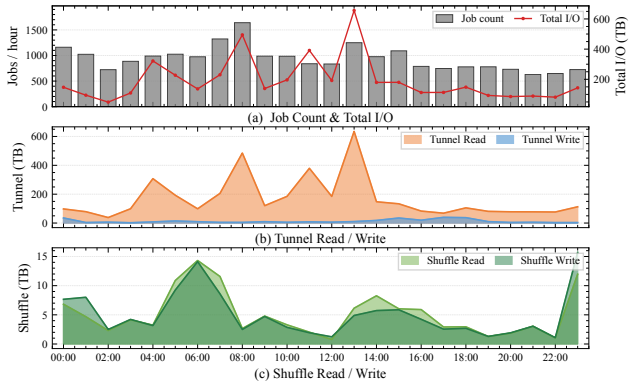

Figure 16: **24-hour Production Trace of Spark Workloads.** (a) Job count and total I/O volume. (b) Tunnel read/write throughput. (c) Shuffle read/write throughput.

consisting of 320 nodes equipped with Intel(R) Xeon(R) Platinum 8163 CPUs (96 cores, 2.7GHz), 512GB DRAM, and 3.52TB SSD. Figure 17(a) shows the CU distribution of each job, and Quark reduces the total CU consumption by 26.5% compared to Spark. Figure 17(b) further breaks down the total CU by cost tier. For jobs consuming 1K CU or above, Quark consistently achieves 22–29% savings across all tiers. A small fraction of jobs (3.4%) experience CU regression, primarily in the lightweight tier ($\leq$1K CU) due to the fixed overhead of function cold starts, which dominate the resource footprint for lightweight workloads. However, this tier accounts for only 1.0% of total CU, so its impact is negligible.

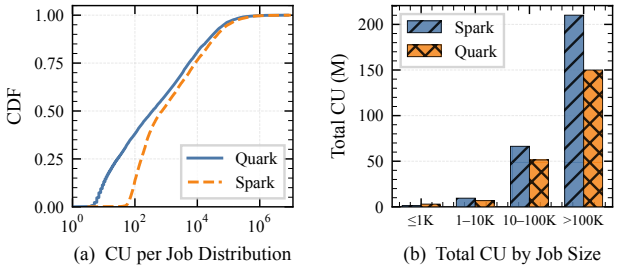

Figure 17: **Resource Consumption Comparison Between Spark and Quark.** (a) CDF of CU per job (log scale). (b) Total CU breakdown by job size.

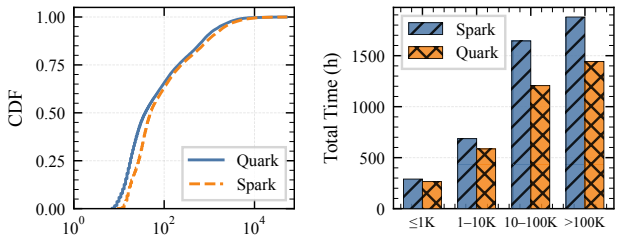
Figure 18 shows that Quark reduces total execution time by 22.4% (3,501h vs. 4,501h). The time distribution mirrors CU consumption, except that the $\leq$1K tier has shorter execution time. This improvement stems from Quark's on-demand scheduling model. Unlike Spark, which stages jobs through a centralized scheduler and incurs queuing delays before resource allocation, Quark dispatches function invocations directly to available nodes, reducing scheduling cost.

6.4 In-Production Migration

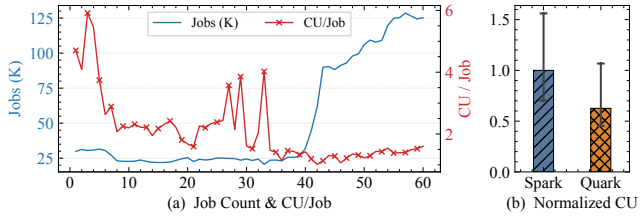
Following the successful replay experiment in §6.3, we proceed to migrate all production workloads from Spark to Quark.



(a) Execution Time per Job (s) (b) Total Time by Job Size

Figure 18: **Execution Time Comparison Between Spark and Quark.** (a) CDF of execution time per job (log scale). (b) Total execution time breakdown by job size.

This migration spans 57,000 tables and 350,000 jobs across 219 projects. This longitudinal deployment study captures real-world performance under actual user workloads, demonstrating Quark's operational effectiveness beyond controlled replay conditions.



(a) Job Count & CU/Job (b) Normalized CU

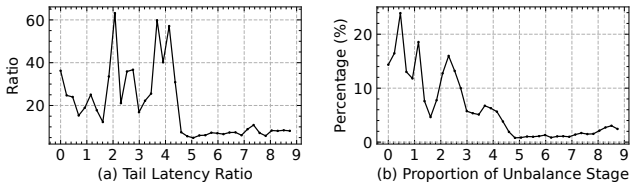
Figure 19: **Per-job Resource Consumption Trends During the Spark-to-Quark Migration.**

Per-job Resource Consumption. Figure 19(a) shows per-job resource consumption trends during this migration: Spark served production requests during days 0–40, followed by a complete cutover to Quark after day 40. The number of jobs increases (blue line) after migrating to Quark, while the average resource consumption per job (red line) declines throughout the migration. The normalized resource consumption in Figure 19(b) shows that Quark reduces resource idling during task execution, achieving 37.37% resource savings compared to Spark.

Job Tail Latency. We further evaluate the optimization effects in the production environment using two tail-performance metrics: (1) *Tail Latency Ratio*: within a stage, the ratio of the longest task runtime to the shortest; and (2) *Unbalanced Stage Proportion*: the fraction of stages where the longest task runtime exceeds 5× the average within that stage. As shown in Figure 20, compared to Spark, the average tail latency ratio was reduced from approximately 20× to 8× and the average unbalanced stage proportion decreased from approximately 15% to 2%. The interference-aware scheduler mitigates interference from co-located workloads and hardware heterogeneity, reducing latency variance and stage skew.

6.5 Operational Overview

Quark now operates as the batch workload processing engine at Ant Group. This section reports its operational metrics and

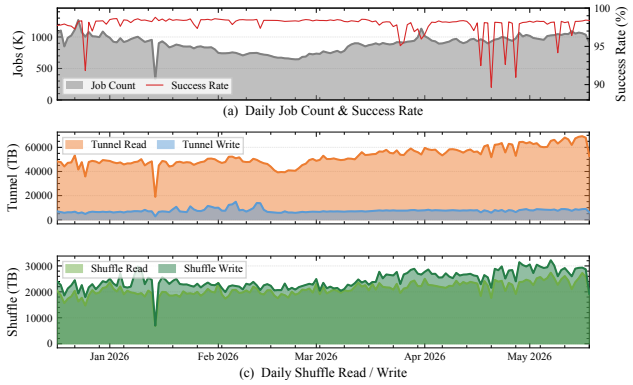


(a) Tail Latency Ratio (b) Proportion of Unbalance Stage

Figure 20: **Tail Latency Ratio and Unbalanced Stage Proportion Trends During the Spark-to-Quark Migration.**

production status over the past 6 months.

Scale and Reliability. As shown in Figure 21, Quark processes an average of 902K jobs per day (peaking at 1.27M) and achieves an overall success rate of 99.11%, meeting the strict SLA requirements of production batch workloads. The daily I/O volume averages 105.4 PB, dominated by tunnel reads (warehouse I/O) at 49.7% of total traffic (56.8 PB/day) and a 7.0:1 read-to-write ratio; shuffle I/O accounts for the remaining 43.2% (20.0% read, 23.2% write). These results demonstrate that Quark reliably meets production requirements at scale, sustaining high throughput and consistency over the entire 6-month period.



(a) Daily Job Count & Success Rate

(c) Daily Shuffle Read / Write

Figure 21: **Operational Overview of the Production Workload Over 6 Months.** (a) Daily job count and success rate. (b) Tunnel I/O. (c) Shuffle I/O.

Cluster Status. Quark is deployed on a production cluster comprising over 6,000 servers with approximately 600K CPU cores. The cluster employs resource overcommit with a ratio ranging from 1.592× to 1.803×, and achieves an overall utilization between 41.7% and 61.4%. Figure 22 shows the invocation rate over a representative 24-hour period. The system processes an average of 534 requests per second with a peak of 2,130 requests per second. The overall success rate (HTTP 200) is 98.55%. Error responses are dominated by rate limiting (HTTP 429), which spikes with traffic bursts.

We measure the overcommitted resource allocation ratio in the cluster to assess how evenly tasks are distributed across nodes. For example, if 100 cores are overcommitted in the cluster and 70 cores are in use, the allocation ratio is 70%. The black line in Figure 23(a) shows the mean overcommitted

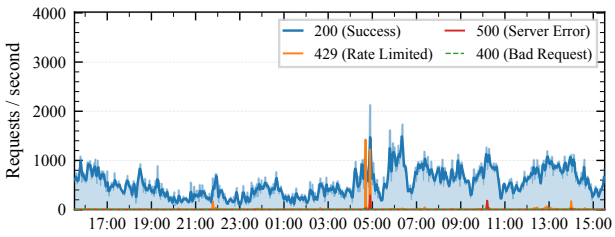


Figure 22: **Request Rate Over a 24-hour Period.**

resource allocation ratio over one day, with an average allocation ratio of 80.4%, red line shows the variance of allocation ratios across all nodes in the cluster, which remains stably low (the P95 is 22%), indicating good load balance. Figure 23(b) plots the CDF of the allocation ratio across all nodes at 00:00, showing that over 90% of nodes are higher than 69.2%.

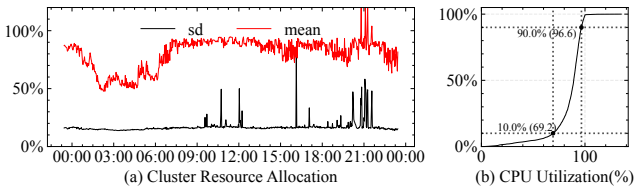

Figure 23: **Overcommitted Resource Allocation.**

7 Failure Analysis

In order to understand the operational situation and identify opportunities for improvement, we record 1.31 million failures over the past six months and classify these failures based on their root cause.

7.1 Failure Distribution

Table 6 summarizes the distribution of these failures. The most apparent is that the majority of recorded failures are user code, or permission issues rather than system-level problems.

Table 6: **Production Failures Distribution.**

Category	Count	%
User SQL / Query Errors	572K	44.0%
Permission / Access	163K	12.5%
Tunnel / Storage I/O	124K	9.5%
UDF / Environment	115K	8.9%
OOM / Resource Exhaustion	101K	7.8%
Driver / Coordinator	98K	7.5%
Shuffle / Compute Engine	78K	6.0%
Optimizer / Rule	47K	3.6%
Other / Unknown	3K	0.2%
Total	**1.31M**	**100%**

User-attributable Failures Dominate. User errors—including SQL mistakes, permission issues, UDF bugs, runtime environment mismatches, and Python worker failures—collectively account for 65.3% of all failures. SQL errors alone constitute 44.0%, making them the single largest category. Common sub-categories include: (1) references to non-existent tables or columns (the most frequent single error, with 296K occurrences); (2) user-initiated job cancellations (40K); (3) type mismatch and cast errors (25K); and (4) unsupported SQL syntax and features (e.g., `UNPIVOT`, `ALTER MATERIALIZED VIEW ... REBUILD`). Permission errors (12.5%) form the second-largest category, dominated by cross-project access restrictions (65K) and insufficient table-level permissions. UDF and environment errors (8.9%) encompass user-defined function loading and execution failures (23K), runtime environment incompatibilities (68K), and Python worker crashes (17K).

OOM Is the Leading System-Level Failure. Out-of-memory errors collectively account for 7.8% of failures. Table 7 breaks down OOM failures by type. Executor-level OOM (container crash or heartbeat timeout due to memory exhaustion) is the dominant sub-category at 47.9%. Sort and shuffle-write OOM (16.9%) and aggregate OOM (9.2%) follow. One benefit of Quark's fine-grained mode is that when a task fails with OOM error, it can be retried in-place with a larger resource footprint, rather than destabilizing a long-lived executor that may host many concurrent tasks. 94.7% of failed tasks succeed upon retry after Quark automatically increases the resource allocation. The remaining 5.3% are dominated by tasks with heavily skewed data partitions, which are inherently difficult to handle via online resource prediction alone. These failed retries also waste CUs, accounting for 35.2% of the total CUs consumed by retried tasks, but are negligible relative to the overall CU consumption of all tasks.

Table 7: **OOM Failure Sub-categories (101K total).**

OOM Type	%
Executor-level (crash / heartbeat timeout)	47.9%
Sort / Shuffle write	16.9%
Other (Java heap, spill disk full, unknown)	16.4%
Hash/Sort Aggregate	9.2%
Gluten/Velox native	9.1%
Join (Broadcast/SMJ/SHJ)	0.2%
Python-related	0.3%

I/O and Data Transfer Failures Are Transient but Frequent. Tunnel and storage-api errors account for 9.5% of failures. The most common sub-categories are quota/capacity limits (29.5% of tunnel errors, dominated by slot quota exceeded with 34K occurrences), schema and partition errors (18.1%), storage API timeouts (19.6%), and data read/write failures from the underlying distributed file system (10.4% and 9.9%). These failures are typically transient—caused by momentary network congestion, service restarts, or load spikes—and are well-served by Quark's built-in retry mechanism. However, the sheer volume highlights the importance of robust I/O error handling in production batch systems operating at scale.

Shuffle Reliability Remains a Concern. Shuffle-related failures (6.0%) include data-loss exceptions when shuffle services experience failures, Celeborn-related errors (connection timeouts, registration failures), and Velox native execution errors. Unlike I/O timeouts, shuffle data loss can cascade: a single lost shuffle partition may cause an entire stage to fail, requiring re-execution of all upstream tasks. Quark's task-level fault isolation limits the blast radius compared to Spark's executor-level model, but shuffle service reliability remains a critical dependency.

7.2 Operational Lessons

Use Secure Containers for Fault and Performance Isolation. Without proper isolation, these failures above (e.g., OOM crashes, transient I/O errors) can cascade across tasks. Morever, batch workloads are both CPU- and I/O-intensive, and their heavy use of kernel resources (e.g., scheduling and mutexes) can interfere with prod. Using secure containers to isolate both fault impact and performance impact is a good practice. We use SKernel [16] as the backbone of Quark, it provides comparable performance to runc (without virtualization-based isolation) [69].

Explore User-Provided Hints for Long-Tail OOM Reduction. Quark employs a history-based query optimizer that predicts memory requirements at submission time, resolving 94.7% of OOM-induced failures upon retry with increased resources. However, the remaining 5.3%—dominated by long-tail tasks with highly skewed data or non-stationary demands—remain difficult to predict purely from history. Prior work [50] on feedback-driven resource estimation shows that achieving stable prediction for such tasks may require many iterations (≈20) of adjustment. User-provided hints (e.g., expected data skew, memory-heavy operators) may help short-circuit this feedback loop where historical signal is insufficient.

Design for Transient I/O Failures at Scale. At the scale of 30K+ daily jobs processing petabytes of data, transient I/O errors are inevitable rather than exceptional. Systems must treat retries as a first-class mechanism: Quark's task-level model, where a failed task is independently retried without affecting other tasks, is well-suited to this environment. By contrast, in Spark's executor-level model, a transient I/O error may invalidate an entire executor's in-memory state.

8 Related Work

Cluster Resource Optimization. Cluster resource optimization focuses on maximizing resource utilization efficiency in clusters, including cluster management [21, 25, 35, 60, 63, 67, 78, 86, 91, 92, 98] and schedulers [14, 23, 33, 42, 47, 93, 107, 108]. Cluster platforms such as Azure [21, 80], Google [76, 87], Alibaba [20, 34, 55, 58] have published traces of their cluster management systems, workload characteristics and optimization strategies. Co-locate low-priority batch workloads with high-priority online services is a common practice to improve overall resource utilization [38, 52, 57, 64, 77, 106]. However, existing work mainly focuses on improving cluster resource utilization without violating SLOs and pays little attention to the *effectiveness* of resource usage because batch workloads are typically treated as "best-effort", and resources from overcommitment are often viewed as a free lunch. In this paper, we identify four types of idle or non-productive costs that significantly undermine effective utilization and propose a lift serverless paradigm for efficient co-location.

Serverless Analytics. In addition to the systems discussed in §2.3, many other works (e.g., PyWren [43], Flint [45],Locus [75], Lambada [66], Cloudburst [84]) also leverage serverless platforms for batch analytics. Existing work mainly focuses on demonstrating the feasibility of serverless for offline analytics, and on improving shuffle operation efficiency on serverless platforms. Notably, Ditto [41] can adjust the degree of parallelism of each stage to optimize job completion time. However, Quark differs from these efforts by introducing a fine-grained job model and targeting production co-location with practical, deployment-oriented optimizations to overcome challenges in §3.1. Quark has been validated for effectiveness in industrial deployments.

Optimizations for Cold Start. We observe encouraging advances in serverless cold-start optimization techniques [1, 4, 15, 27, 28, 37, 48, 51, 62, 68, 71, 82, 90]. E.g., recent research efforts [17, 28, 37, 51, 96, 103] have reduced function cold-start latency to within a 10-milliseconds. These works inspired the fast task provision design in Quark. However, compared with existing serverless platform, Spark is more complex and involves many operations whose state cannot be reused, such as additional plugin loading and establishing connections (e.g., with the Driver and ShuffleManager). The startup latency of a single task in Quark has not yet been optimized to within 10 ms, but it is sufficient for our needs.

9 Conclusion

This paper addresses the inefficiencies of co-location in modern cloud infrastructures, focusing on industrial-scale deployment. Through real-world deployments and in-depth analysis, we identify four types of idle or non-productive costs that significantly undermine effective utilization and leave clusters in a *pretending to be busy* state. This paper presents Quark, applying serverless paradigms to batch workloads for efficient co-location. Results show that Quark increases cluster resource utilization by 37.37%, and has been deployed in large-scale clusters, saving more than 100,000 CPU cores. We sincerely thank our shepherd and the anonymous reviewers, whose reviews and suggestions greatly strengthened our work. Continuation-Centric Computing with Arca

Akshay Srivatsan Yuhan Deng Katherine Mohr Emma Sudo
Sebastian Ingino Francis Chua Keith Winstein
Stanford University

Abstract

This paper presents *continuation-centric computing*, an operating system design paradigm for "serverless"-style workloads: short-lived tasks that spend a substantial fraction of time waiting on dependencies and other services. Under this paradigm, a running function can capture its current *continuation*—a lightweight snapshot of its state—as a distinct function that can be paused, migrated, or copied as needed.

This paper evaluates the continuation-centric computing model using Arca, an operating system providing continuation capture as a core service. Arca supports a process abstraction that is broadly similar to Unix processes in guarantees and isolation, but additionally provides efficient capture and resumption of serializable, portable continuations.

1 Introduction

Many cloud-computing operators offer function-as-a-service (FaaS) products, commonly as part of "serverless computing." These systems allow users to create functions to be invoked in response to external events, such as incoming HTTP requests or scheduled timers. The functions are run in provider-provisioned sandboxes with access to APIs for interacting with external services such as databases and object stores. In contrast to traditional cloud-computing products where a user must request and manage servers to run their functions, serverless providers manage the servers and only charge users based on the runtime of each function invocation. For appropriate workloads, this simplifies the developer experience and gives providers flexibility in scheduling and placing invocations.

To improve server utilization and reduce costs, commercial serverless systems break function invocations into slices as small as a few milliseconds [19] or 128 MiB of RAM [4]. Research has aimed to support even finer granularities in time and space [16,33,44,48], motivated partly by applications that use serverless systems for large-scale, highly parallel jobs, breaking up their workloads into fine-grained tasks with complex inter-task dependencies [20–22,26,28–30,45,55]. This has generally required software developers to break programs up ahead-of-time into subtasks, each a function of some identified input data. Doing so can expose available parallelism and let resource and data needs be matched more closely to the resources allocated and placed at runtime [16,31,43,44].

Isolation primitive	create/destroy (µs)	snapshot/resume (µs)
MicroVM [1]	✘ 742,000	✘ 217,000
Linux process	✘ 540,000	✘ 283,000
WebAssembly [2]	✓ 110	✘ n/a
Arca (our work)	✓ 32.2	✓ 2.55

Table 1: Performance of different isolation primitives (§2.2). Arca's create/destroy and snapshot/resume overheads are several orders of magnitude lower than other isolation primitives. Create/destroy time was measured with 128 parallel processes on a 128-core machine. Full results are in Section 6.

Is it useful to help applications break themselves up into smaller pieces? This paper argues that operating systems could benefit applications by adopting *continuation capture* as a core service. Continuations allow a running program to capture "the rest of this program" as a new program. Capturing a continuation on every I/O operation can transform a monolithic program into a composition of pure functions with delineated I/O. Current operating systems now include ways to capture a program's continuation by snapshotting running processes or VMs [9,13]; however, these methods take hundreds of milliseconds (Table 1). By designing a new OS with continuations as a core primitive, we found it is possible to capture a continuation of a running process in a few *microseconds*. This makes it more feasible to execute programs as a sequence of pure functions with I/O in between.

To explore the continuation-centric computing approach, we designed and implemented Arca, an OS designed for continuation-centric workloads. Arca's kernel provides continuation-capture as a syscall that processes may invoke; developers (or the compiler) do not need to explicitly express the state required by "the rest of the program from point x." Arca processes are broadly similar to Unix-style processes in

that the kernel isolates them via hardware memory protection, and they can do computations and return values. To perform an external side effect, which would traditionally involve system calls like `read` and `write`, an Arca process instead returns an "effect": a description of the desired I/O and a callback function, which may be a continuation of the same process.

Arca is a research prototype with many limitations. We have adapted musl libc to implement part of the POSIX API in terms of Arca effects, but it supports only the most common POSIX calls for file I/O (`open`, `close`, `read`, `write`, ...) and networking (`socket`, `connect`, `accept`, ...). There is no support for mutable shared memory between threads of execution (`mmap`, `shm_open`, `clone`). The most complicated program we've ported to run on Arca is FFmpeg (the video toolkit); most large applications would require considerable porting effort and a fuller libc. And Arca probably isn't very beneficial for long-lived programs with consistent resource demands.

Some of these are engineering limitations that could be overcome with further effort, but others are more fundamental to continuation-centric computing. Many APIs increase the footprint of a process in ways that frustrate clean continuation capture. Berkeley sockets create dependencies on IP addresses and TCP connection state. Shared mutable memory introduces dependencies on the internal state of other processes. A continuation-centric computing system that supports interfaces like these loses some of the benefits, but one that doesn't breaks compatibility.

What is Arca for? We designed Arca to fill a need we found we had ourselves. Many researchers, including us, have explored the use of serverless platforms for large jobs with complex inter-task dependencies: video processing [22], linear algebra [28,45], software compilation and testing [20], theorem proving [55], 3D rendering [21], ML training [26], data analysis [29,31], etc. This literature led to a principle of "I/O-compute separation" [15,30] and several general frameworks for describing and orchestrating the I/O relationships between individual functions to be executed [16, 20, 22, 28, 31, 34]. (Three of these [16,20,22] are from our research group.)

In all of this, what we've found missing is a practical way to *express* everyday programs as a set of pure functions connected by a dependency graph. Consider an ordinary program, perhaps written in Rust or C++, that creates a 1,000-element vector and wants to perform a parallel map-reduce, and, once that's complete, do more single-threaded computation with the result. At the places where the program transitions from 1-way to 1,000-way parallelism and back, Rust and C++ don't provide a tool to capture the state of the program in a way that can be resumed as a new serverless function invocation.

In past work, we and other researchers manually transformed our programs into continuation-passing style (CPS); separating them into smaller programs and tracking the intervening state explicitly. Arca makes this a lot easier, by providing the CPS transform as a core OS service.

Summary of results. For programs that would benefit from capturing their futures in a serializable continuation—generally speaking, programs that mix computation and I/O or that vary their working set over time—Arca's native continuation capture has lower overhead than some prior approaches. In a closed-loop test, Arca captured continuations five orders of magnitude faster than comparable existing systems (Fig. 3). Most of that benefit comes from Arca's ability to produce "zero-copy" continuations of an in-memory process. In tests of throughput, Arca can serve an order of magnitude more requests than existing process-based techniques, and performs comparably to in-process isolation techniques (Table 4).

In an evaluation of continuation-centric computing on a serverless image thumbnailing workload, we found that a continuation-centric approach implemented using Arca is able to achieve a 50–60× speedup over a non-continuation-centric approach. The captured continuation is much smaller than the image to be thumbnailed, and so the ability to send the continuation over the network instead of the image allows Arca to utilize the CPU more effectively (Figure 6).

This paper proceeds as follows: we first discuss the motivation and design goals of continuation-centric computing (§ 2) and the practical developer experience (§ 3). In Section 4, we provide an overview of Arca's design. We describe Arca's implementation in Section 5, and provide an evaluation of its performance and compatibility (§ 6). We then survey related work in Section 7. Finally, we discuss limitations and future work (§§ 8, 9) before concluding (§ 10).

2 Motivation

Continuation-centric computing is motivated by trends in recent work in serverless computing. Besides performance, there are two major selective pressures influencing the evolution of serverless platforms: *compatibility* with existing software and *granularity* of scheduling.

2.1 Compatibility

Serverless systems adopted in industry share a common focus on maintaining compatibility with existing software. Many current serverless providers run off-the-shelf Linux applications via containers or MicroVM; for example, this is the approach taken by AWS Lambda [1,4]. This approach maintains the widest compatibility. Some effort is still required to package an application for serverless execution—a developer must, for example, supply a wrapper that gathers necessary inputs from the provider's datastore, runs the target application, and writes outputs back to the datastore—but for the most part existing software can run unmodified.

However, full compatibility with Linux comes at a cost: shipping a full Linux userspace with every application leads to worse granularity and performance. This has led some

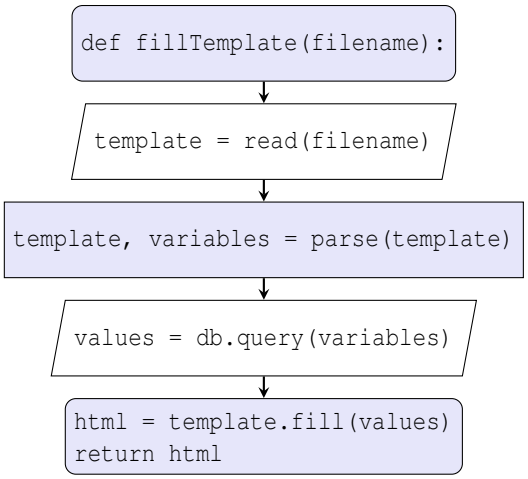

Figure 1: A logical function broken down into a sequence of funclets and I/O operations. Every shaded rectangular flow chart element is a separate funclet, while every unshaded trapezoid is an I/O operation.

providers to innovate on their isolation mechanism; Cloudflare Workers [10] relies on software isolation techniques like WebAssembly [23]. Providers taking this approach often expose traditional operating system primitives, such as file descriptors, so that applications can be ported without many source-level changes; in WebAssembly, this takes the form of the WebAssembly System Interface (WASI) [11]. These platforms are not as widely compatible with existing applications: in the case of WebAssembly, applications must be recompiled for a different architecture and must therefore be configured not to use features that WebAssembly lacks. WASI generally supports the subset of POSIX related to file I/O, but omits features like networking and/or multithreading; applications reliant on these features must use provider APIs to access equivalents instead. However, these platforms have seen adoption despite these incompatibilities, as they enable finer granularity scheduling.

2.2 Granularity

New serverless systems proposed in academia focus primarily on enabling fine-grained scheduling, with the goal of improving end-to-end performance. These works propose various approaches to decompose large monolithic applications into finer-grained functions [16, 31, 43, 44, 48]. While the details vary, all these systems have a notion of a small unit of pure computation (previously referred to as a "proclet") and a larger unit of mixed computation and I/O composed of the small unit (a "logical process"). Across most of these systems, the developer writes the small unit of computation in a traditional language, like C or C++.

The exact method of composing the small unit into the larger unit varies. Dandelion uses an external domain-specific language (DSL) [31], requiring logical processes to be written specifically for Dandelion. Fix uses a custom API exposed through WebAssembly, essentially providing an embedded domain-specific language (eDSL) in the form of a C library [16]. σOS similarly exposes a library interface to its primitives, akin to a reduced version of the Linux system call interface [48]. Likewise, Quicksand exposes its data structures and control flow using an API resembling the C++ standard template library [43].

The premise behind these works is that, when applications can express their data dependencies and resource requirements at a fine granularity, a provider can make better scheduling decisions. Every time the provider learns new information about an application's dependencies, they are able to use this information when scheduling the rest of the application. This same distinction appears in other contexts as well: *xsyncfs* uses this split to achieve the performance of asynchronous I/O while retaining the durability of synchronous I/O [37].

The situations where these systems are most useful share a common aspect: what developers logically think of as "one program" are actually sequences of smaller tasks with varied requirements. Nu [44] notes this by explicitly distinguishing larger "logical processes" from smaller "proclets."

We propose a similar distinction for continuation-centric computing, but with modifications to factor in the I/O-compute separation proposed by Fix [16] and Dandelion [31]. *Logical functions* are high-level programs which a developer would think of as one task; they are composed of I/O and computation. *Funclets* are the small computational steps that make up larger tasks; they run to completion and perform no I/O. Figure 1 shows how a logical function can be broken into funclets and I/O operations.

Existing systems essentially treat the granularity at which developers write functions as the granularity at which to schedule. In continuation-centric computing, these granularities are distinguished, so developers can write code in units natural for them, and the scheduler can schedule at finer granularities. When a logical function captures its continuation, it creates a new funclet that includes its current state. This new funclet is part of the same logical function, and control flow is not interrupted from the developer's perspective.

To a first-order approximation, a continuation is essentially a snapshot of a logical function's execution. In practice, however, capturing a snapshot of a container is incredibly expensive; in the best case it takes on the order of a millisecond, but in many cases is made slower than that by various kernel limitations [25]. Current JIT-based WebAssembly runtimes do not fully isolate the state of each sandbox from the state of the host and therefore do not generally support efficient snapshotting; while it's possible to work around this, doing so interferes with optimizations and impacts runtime performance [56]. In our experiments (Table 1, § 6.1) we observed snapshot/restore systems taking hundreds of milliseconds to capture and restore a snapshot.

2.3 Design Goals

Currently, these two pressures are at odds; the existing systems we have observed tend to specialize in one of compatibility or granularity. We propose Continuation-Centric Computing, exemplified in our serverless system Arca, as a middle ground with these concrete design goals:

Compatibility. We strive to maintain compatibility at a level comparable to a production system. Specifically, we aim to match the compatibility model provided by Cloudflare Workers [10]: programs may have to be recompiled or reconfigured, but can generally run without any internal control-flow changes. We evaluate this compatibility claim by showing a mechanical translation from WebAssembly with WASI, the same interface supported by Cloudflare Workers, to Arca.

Granularity. We strive to provide granularity at a level comparable to existing research systems such as Dandelion, Fix, and Quicksand [16, 31, 43]. As "granularity" is subjective, we evaluate it via its quantitative effect on performance, by comparing function execution latency across the isolation mechanisms used by these systems. We additionally add the restriction that we try to ensure isolation and security equivalent to production systems—once again, comparing to Cloudflare Workers/WebAssembly—as in practice isolation is a necessary property for a system to be adopted.

3 Developer Experience

As "continuations" are a concept many software developers are unfamiliar with, a reasonable concern is that continuation-centric computing will be difficult for developers to use. We introduce our continuation-centric system, Arca, by describing how it compares to more familiar systems from a developer's point of view. We also describe other factors relating to the developer experience, such as ease of debugging.

3.1 Existing WebAssembly Software

Serverless providers such as Cloudflare accept software in the form of WebAssembly binaries [10, 11, 23]. We ensure compatibility with existing WebAssembly binaries, as the restrictions imposed by WebAssembly are stricter than those imposed by Arca. Many existing software toolchains support compiling code to WebAssembly, using the WebAssembly System Interface (WASI) to provide side effects such as file I/O. Among other restrictions, software targeting WebAssembly is limited to a single thread and can only access a sandboxed virtual file system. Despite these limitations, WASI ports of many popular applications, including Python [51] and FFmpeg [49], already exist.

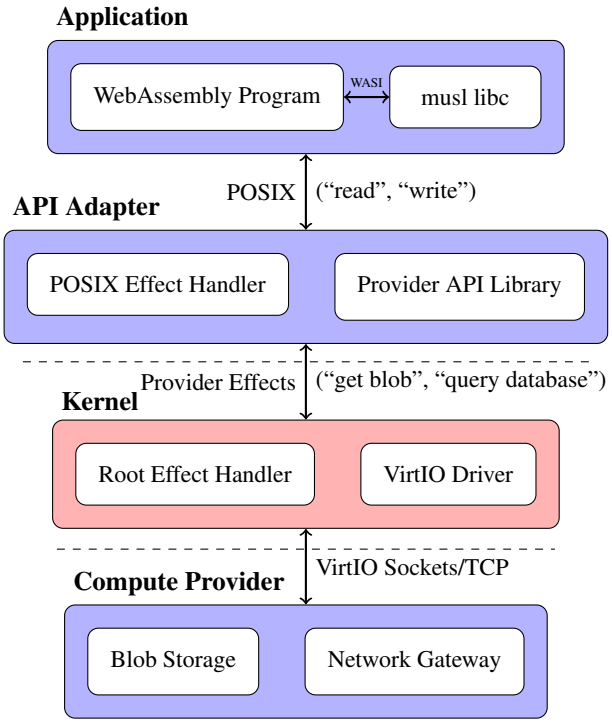

Figure 2: Arca's design allows programs written for traditional APIs, such as WASI, to be run in non-traditional environments with cloud-native APIs. A user provides their code in the form of a WebAssembly program using WASI; WASI I/O operations are translated into POSIX by musl libc, then propagated to the parent function as effects. A second userspace process translates the POSIX API into provider-specific effects. The kernel's root effect handler receives these effects and dispatches them to the outside world using VirtIO; the compute provider then performs the actual I/O. In this diagram, the dashed lines mark the boundaries between userspace and the kernel; since Arca is paravirtualized, the kernel communicates with both its own userspace and the userspace of the host machine.

The process of converting a WebAssembly binary to run on Arca is entirely mechanical; we provide a toolchain built on `wasm2c` [53] that takes an arbitrary WebAssembly/WASI binary, converts it to POSIX C, and links it against a custom implementation of WASI based on musl libc [36]. Section 6.5 describes our qualitative experience developing the WebAssembly compatibility toolchain and porting an existing WebAssembly binary to run on Arca.

The Arca implementation of WASI captures a continuation whenever a WASI I/O function is called. It then exits, returning to its parent a description of the necessary I/O along with the captured continuation—in our parlance, an "effect."

3.2 Effect Handlers

As described so far, however, there is still a missing piece: how does the I/O actually happen? If a WASI program returns an effect requesting a "read", *something* must perform the relevant I/O. In Linux this would be the kernel; in Arca we generalize this to be an "effect handler."

An effect handler is a piece of software that receives an abstract I/O request and a callback function. In the simplest case the provider supports WASI directly; then the kernel acts as the effect handler and performs the I/O itself. However, Arca also supports the case where a provider does not directly support WASI but rather supports some other provider-specific API. In this case, the raw effects produced by the application instead go to an "API Adapter," another userspace process which acts as the parent of the application. The API adapter parses the request, and reissues I/O effects in terms of the provider's native APIs. Figure 2 shows the different layers involved in this case. An API adapter only needs to be written once per cloud provider; the same adapter can run any WASI program against that provider's APIs.

We draw this distinction between the effect handler and the kernel because we have observed that developers tend to prefer familiar POSIX-like interfaces, but serverless systems provide higher-level abstractions. This is true across both the industrial and academic systems we have studied: for example, AWS Lambda uses S3 as long-term object storage rather than a traditional filesystem [4], and Dandelion exposes HTTP as a primitive communication operation [31]. By supporting user-level effect handlers, it's possible to implement a translation between WASI and a provider-native API.

3.3 Existing POSIX Software

Arca offers limited source-level compatibility with existing POSIX software. POSIX defines interfaces at the level of a C standard library (libc), to facilitate running the same application source code on different operating systems. We provide a basic implementation of a POSIX-compatible libc, based on musl [36]; this is the same libc we use for implementing WASI.

From a developer's point of view, they can write a program that looks like ordinary C or POSIX code (as in Listing 1). All the code dealing with continuations is contained within the libc, so the developer does not have to interact with or reason about continuations. Furthermore, the developer does not have to manually split a logical function into its constituent functions. Since a continuation snapshots the "rest of the function," capturing a continuation on every I/O boundary naturally breaks a logical function into funclets. When the continuation is resumed, control returns to the same point in the logical program; this allows the surrounding C code to remain unaware of the new control flow happening within libc.

```c
#include <stdio.h>

int main(int argc, char **argv) {
  FILE *in = fopen("input.txt", "r");
  fseek(in, 0L, SEEK_END);
  long sz = ftell(in);
  fclose(in);

  FILE *out = fopen("output.txt", "w");
  fprintf(out, "%ld\n", sz);
  fclose(out);
}
```

Listing 1: A trivial I/O-heavy function which counts the number of bytes in the file "input.txt", writing the result to "output.txt". Although this is a single logical function (and a single C program), the compute provider executes every line of `main` as a separate funclet (eight in total).

Arca currently supports file I/O and network I/O effects in a style similar to POSIX. Table 2 summarizes some common POSIX library calls and the status of their implementation in Arca. While Arca does support low-level network I/O, applications which use it lose the ability to capture complete continuations and must be resumed on the same machine.

Looking more generally at continuation-centric computing, there are some fundamental limitations on what POSIX APIs can be implemented. File I/O can be emulated, so it can be handled even if the provider's runtime doesn't support it natively. Pipe-based inter-process communication, `fork`, and other similar system calls can also be implemented or emulated with continuations. Network I/O comes with a tradeoff: since socket state cannot be cleanly captured in a continuation, a provider that supports it loses some of the benefits of continuation-centric computing. Many granularity-focused serverless systems explicitly do not support arbitrary network I/O for this reason [16, 31, 48]. Shared mutable memory between processes is not supported in continuation-centric computing at all, similar to WebAssembly, since it would become impossible to capture a continuation of any of the processes mapping a shared memory region independently of the others.

3.4 New Arca Software

While porting existing software to Arca provides continuation-centric computing "for free," it will nevertheless sometimes be necessary to write programs explicitly for Arca. One such case is when writing the aforementioned "API adapters"; these adapters must manipulate continuations directly using the Arca system call API (Table 3). Software which is cloud-native (i.e., new software written expressly to run on cloud platforms) may also use cloud-native APIs rather than POSIX abstractions. Developers who are already writing their applications against cloud-native APIs may be able to take advantage

POSIX Function	Status	Notes
`open`	✓	Translated to provider-native storage effects.
`close`	✓	
`read`	✓	
`write`	✓	
`lseek`	✓	
`socket`	✍	Provider must provide low-level access to networking, which makes continuation capture difficult.
`connect`	✍	
`send`	✍	
`recv`	✍	
`listen`	✍	
`accept`	✍	
`shm_open`	✘	No shared mutable memory support.
`mmap` (`MAP_SHARED`)	✘	

Table 2: Overview of common POSIX library calls and the status of their support on Arca. A status of "✓" means that a library call is always supported; "✍" means that a library call requires explicit provider support due to its impact on continuation capture; and "✘" means that a library call is not supported due to the restrictions of Arca's model. Our prototype implementation supports all the operations described as "✓" or "✍".

of this lower-level access to Arca primitives to achieve higher performance than the compatibility layers can provide.

Currently, such Arca-native code can be written as "free-standing" code in languages suitable for embedded or bare-metal development like C or Rust. So far, we have qualitatively found it easier to work with the raw Arca API in languages that support functional programming paradigms, like Rust; however, we are still exploring ways to effectively wrap the API and ease development of these "bare-metal" Arca programs. So far, we have not prioritized developing ergonomic Arca API wrappers, as we believe that in the short term most developers would prefer to use the compatibility layers to port their existing software, and in the long term developers should use cloud-native APIs like those provided by Fix, Dandelion, σOS, Nu, and Quicksand [16, 31, 43, 44, 48].

3.5 Debugging and Profiling

Since development for Arca is currently similar to embedded development, the debugging experience is also similar. Debugging logical functions is straightforward: a parent function enables single-stepping by changing the CPU flags associated with a child function, and can then inspect its state after every instruction as with `ptrace` under Linux. It can also insert breakpoint instructions by modifying the pages associated with the child function. Basic profiling is also straightforward: a parent function profiles a child function by executing it with a timeout and observing the state after the timeout. More advanced profiling, using performance counters, is possible but not currently implemented.

Debugging compositions of logical functions is more difficult, as the Arca kernel does not maintain any long-lived notion of a "call stack." However, since funclets are pure functions, it is generally possible to abstract logic into independent units to ease debugging.

4 Design

In this section, we describe the design of *Arca*, a continuation-centric operating system. We contrast the design of Arca with the design of traditional Unix-like operating systems such as Linux.

Unix is, at a high level, based on a model of processes communicating. Unix processes communicate using pipes or a shared filesystem; they perform computation in response to communication and communicate the results of their computation. Unix would therefore be classified as a message-oriented operating system [32]. As processes execute, they accumulate substantial implicit state, such as open file descriptors and socket buffers, which are difficult to capture, serialize, or restore elsewhere [25].

In order to enable continuation-centric computing, Arca is based on a model of functions consuming and producing data. Code executes in the form of short-lived funclets whose state consists primarily of their memory and registers, not ambient OS resources. Arca can therefore be classified as a procedure-oriented operating system [32]. Functional code can return requests to do I/O or gain access to more resources, which are interpreted and executed by external effect handlers; the handlers, as in Dandelion [31], then invoke separate callback funclets with the results of the I/O. Each Arca process has a limited amount of local state, forming an atomic unit which can be snapshotted, serialized, or migrated.

The duality and equivalence of message-oriented and procedure-oriented operating systems has been observed and studied. It has been demonstrated that any program written for one can be rewritten for the other as long as the appropriate primitives are present [32]. It is also well-known that the CPS transform is capable of transforming an imperative program into a functional one [7, 42]. We argue that, since serverless computing is a procedure-oriented environment but developers prefer to write message-oriented programs, integrating continuation capture into the operating system is the natural way to unite the two models efficiently.

4.1 Continuations

We have informally described a continuation as "the rest of a logical function." More concretely, a continuation in Arca is the snapshot of the execution state of an address space. This definition is consistent with prior work in distributed systems such as CIEL [34], except applied at the process level rather than the language level. Since Arca is procedure-oriented, this snapshot remains small and tightly-bounded even though the OS does not have insight into the internals of a process.

```
struct Process {
    page_table: PageTable,
    register_file: RegisterFile,
    descriptors: Vec<Value>,
}

enum Value {
    Null,
    Word(u64),
    Blob(Box<[u8]>),
    Tuple(Vec<Value>),
    Page(Page),
    Table(PageTable),
    Funclet(Funclet),
}

struct Funclet {
    defn: Definition,
    args: Vec<Value>,
}

enum Definition {
    Symbolic(Box<Value>),
    Procedural(Process),
}
```

Listing 2: The struct `Process` defines an Arca process, corresponding to Linux's `task_struct`. The other types define the primitive datatypes which Arca processes can manipulate.

The actual in-memory representation of a continuation in Arca is described by the structures in Listing 2. The structure `Process` is similar to Linux's `task_struct`, representing the state of a newly-created or suspended process. The enumeration `Value` gives the core data types which Arca programs have access to; specific abstractions like files and directories are instead replaced with these more generic abstractions. While the most common funclets are defined by a machine-code function definition, it is also possible to define a function that is merely "symbolic"; when it is invoked execution traps to the nearest effect handler instead.

4.2 System Calls

Arca processes provide a procedure-oriented set of system calls instead of the file- and message-oriented system calls available under Unix. In addition to an address space and a register file, every Arca process has a *value descriptor table* which replaces the Unix "file descriptor table." Running funclets use indices into this table to reference these values when making system calls. Instead of referring to files on disk, the entries in the value descriptor table are handles to data in kernel memory. These values include byte arrays (*blobs*), collections (*tuples*), integers, machine pages, page tables, and other Arca functions (*funclets*). Most of the system calls manipulate these values directly—they can be created, read, written, and destroyed. Several system calls instead manipulate the currently running funclet itself; they allow funclets to receive arguments, produce return values, and manipulate their address spaces. A final category of system calls allows a funclet to explicitly capture its continuation. A summary of the available raw system calls is provided in Table 3.

System Call	Description
`create_blob`	Construct a byte array from memory.
`create_tuple`	Construct a collection from other values.
`create_page`	Allocate a page of virtual memory.
`create_table`	Allocate a page table.
`create_fn`	Define a new funclet.
`read`	Read a value into program memory.
`write`	Update a value in kernel memory.
`clone`	Make a copy-on-write clone of a value.
`drop`	Delete a value.
`mmap`	Modify the current address space.
`get_arg`	Get the next argument to this funclet.
`exit`	Return a value from this funclet.
`call`	Call a funclet and get its return value.
`get_cc`	Capture the continuation of this logical function. This system call returns twice, once in the same logical function and once in the funclet described by its continuation, similar to `fork`.
`call_cc`	From the kernel's perspective, call a funclet f with the continuation k of the current logical function as an argument, and return that funclet's return value $f(k)$ as this funclet's return value. From the program's perspective, pause execution of this logical function until the specified funclet f completes.

Table 3: High-level summary of the system calls available within Arca. The first section describes system calls that manipulate values. The second section describes those that manipulate the current funclet. The third describes system calls that capture the logical function's continuation.

The biggest addition over previous procedure-oriented systems is Arca's `call_cc` system call. Since this is an OS primitive, the system call can be embedded within a library. Developers do not have to explicitly reason about, or even be aware of, continuations or effects.

4.3 Security Model

Since serverless providers run untrusted user-provided programs, it is important that programs are sandboxed.

Arca provides a security model similar to Cloudflare Workers, but without the requirement of WebAssembly [10]. Programs within an Arca process are denied access to high-precision timers such as the x86_64 timestamp counter. Since Arca processes have no shared-memory threads with which to emulate a timer and cannot perform I/O without going through

the runtime, programs cannot perform timing side-channel attacks.

The Arca kernel does not share state between different processes, reducing the surface area for attacks and data leaks. It enables standard kernel security CPU features, such as Supervisor Mode Access Prevention and Supervisor Mode Execution Prevention, to further reduce the attack surface. Further, the kernel code uses the Rust type system and memory safety model as an extra check to protect against certain classes of bugs that could leak information or privileges to userspace.

Arca does not give programs the ability to perform side effects directly. This does put some burden on the provider to choose an acceptable level of security—for example, providing arbitrary network access could allow a malicious function to access a high-precision timer over the internet. It is up to the compute provider to choose a list of explicit side effects which they deem acceptable.

4.4 Non-Goals

As a substrate for computation, Arca comes with notable limitations. Most significantly, Arca's model makes it impossible to represent parallel shared-memory threads. This restriction is imposed for both security and performance benefits on general programs, but may limit performance when porting programs that heavily rely on threads for parallelism. Programs which rely on threads only for concurrency, or which rely on processes for parallelism, can still operate as intended. We have experimented with adding support for monitors [24] as a limited form of shared state synchronization; our early results have been promising, but we have not fully fleshed out the design as it pertains to migrations and distributed state.

Arca also probably isn't immediately useful for long-lived programs with consistent resource demands and persistent state (database servers, daemons, etc.). These programs are more suited for microservice-style runtimes than serverless ones, and benefit from a different set of optimizations than those Arca provides.

Despite these limitations of Arca, we envision Arca as a useful substrate for functions that include large numbers of fine-grained funclets with complex inter-dependencies, mixing I/O and computation.

5 Implementation

In this section we describe our implementation of Arca. Our implementation is written in Rust targeting x86_64; however, we do not rely on architecture-specific features so porting to other architectures is dependent only on engineering effort.

5.1 Environment

The Arca kernel currently runs paravirtualized within Linux's Kernel-based Virtual Machine (KVM). A Linux userspace program acts as a virtual machine monitor, servicing the Arca kernel's requests for file and network I/O, and debug logging. The Arca kernel communicates with user-mode Linux programs, including but not limited to the monitor, using a VirtIO [50] Vsock device backed by the Linux kernel. Our kernel uses hypercalls to access the host's TCP stack via the monitor, and uses the Plan 9 Filesystem Protocol (9P) [39] over a Vsock for filesystem access.

5.2 System Calls

Arca's system call interface was previously described in Section 4.2; here, we focus on the kernel implementation thereof.

Values in Arca are conceptually immutable: it is not possible to *modify* a tuple, only to create a new tuple with changes. However, a literal implementation of immutability would require a prohibitive number of copies. We borrow the idea of "functional but in-place" programming from modern functional programming languages like Koka to resolve this issue [41]. System calls are linear by default, and consume their argument unless explicitly copied. System calls *appear* to mutate values; if a value is unique it is executed efficiently as a true mutation, and if a value is not unique it is executed as a less efficient copy-with-modified-contents.

A special case of "functional but in-place" which has proven to be performance-critical is the `call_cc` system call. In almost every circumstance where a continuation is captured, the program intends to use it as a callback. By implementing this operation as a single system call, the kernel avoids unnecessarily making a copy of the continuation. This means the cost of capturing a continuation is constant in this case, regardless of the memory footprint of the function.

5.3 Inter-Process Communication

As a procedure-oriented operating system, Arca does not have traditional inter-process communication constructs like pipes or shared memory. Instead, processes communicate by calling child processes with arguments and returning values to their parents. Arca processes can be thought of as coroutines, which can return values and still be resumed later.

The most frequent case of inter-process communication is in the case of the "API adapters." Instead of running "foreign" software directly, the Arca kernel runs the "native" API adapter within an Arca process and gives it the target function as an argument. The adapter does initial setup, then calls the target function in a second Arca process. The target function is then conceptually nested under the API adapter—when the target function produces an effect, the kernel sends that effect to the API adapter instead of handling it directly. The API adapter either emulates the I/O or translates it into provider-native effects that the kernel knows how to handle; either way, it eventually calls the callback with the result of the I/O.

At an implementation level, this is not inherently different from processes reading from and writing to pipes. In either case, the child process sends a request to its parent, then waits for a response. The API adapter can be thought of as a proxy that translates requests from one protocol to another. Conceptually Arca's approach closely resembles a call gate—the `call` system call allows one Arca process to invoke a function in another address space. Since sending messages on pipes and invoking functions are dual to one another, the underlying implementation remains similar despite the conceptual difference.

6 Evaluation

We test the feasibility of continuation-centric computing by evaluating the need for a new snapshotting technique, the practicality of Arca as an isolation mechanism, and the success of Arca in achieving the expected benefits of continuation-centric computing. We also discuss the process of converting existing code to run under continuation-centric computing.

6.1 Continuation Microbenchmark

The utility of continuation-centric computing is predicated on the assumption that it is possible to efficiently capture the continuation of a machine-code program. Furthermore, the need for continuations to be a core primitive depends on the relative performance of a continuation-centric approach when compared to existing snapshot/restore approaches. To evaluate the feasibility and necessity of continuation-centric computing, we compare Arca to two competitor systems.

This experiment was run on a machine with 2 AMD EPYC 7702 64-Core Processors (for a total of 128 physical cores and 256 hyperthreads) and 160 GiB of RAM, running Ubuntu 24.04.2 LTS (Linux 6.8.0-55-generic). Arca was run within a KVM virtual machine which was allocated 32 GiB of RAM; the other systems were run directly on Linux.

`Arca (snapshot+resume)` evaluates Arca in the case where a continuation is captured but not copied, e.g., when it is being used like a system call. Arca performs a functional-but-in-place optimization to make this case efficient, by keeping the continuation resident in memory. For this experiment, we assume that the effect handler is another Arca process, requiring a full context switch.

`Arca (snapshot+copy+resume)` evaluates Arca in the less-common case where a continuation is captured and copied. This would happen if a serverless runtime decides to swap a continuation to disk, send it over the network to resume on another machine, or is explicitly requested to make a copy of a continuation.

`Linux CRIU` evaluates the Checkpoint/Restore In Userspace (CRIU) system on Linux. This system is able to produce an on-disk snapshot of a process's state for later resumption. For our tests, we configure CRIU to write this snapshot to a tmpfs to avoid writing to disk.

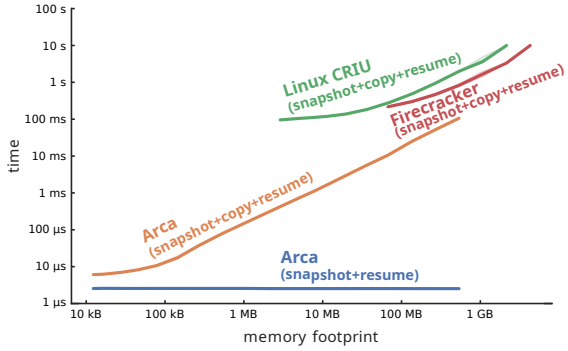

Figure 3: Time to snapshot and resume a process in Arca, Linux, and Firecracker, as process memory size varies. Measurements were averaged across 10 ten-second trials. Arca's ability to elide copies when a snapshot is resumed without migration gives it a significant advantage. Even when making a copy, Arca's elimination of global state lets it take snapshots faster than comparable techniques.

`Firecracker` evaluates the snapshot/resume system of Amazon's Firecracker MicroVM system. This system produces an on-disk snapshot of a MicroVM's state, which can be resumed later on any machine with matching hardware. We configure Firecracker to write the snapshot to a tmpfs.

All the systems run a single-threaded loop, where a parent program repeatedly snapshots and resumes a child program. We ran this loop for one second as a warm-up and then measured the number of iterations completed in the following ten seconds. We varied the memory footprint of the target program across the possible range of sizes. Arca can represent address spaces as small as 12 KiB; a Linux process by default occupies 2.75 MiB of RAM; and Firecracker needs 64 MiB of RAM and 512 KiB of disk to boot Linux. We ran 10 trials of each configuration and report averaged results in Figure 3.

In the case where a continuation is resumed without requiring a copy, `Arca (snapshot+resume)`'s performance is constant at 2.55 µs. In the case where a copy of a continuation is required, `Arca (snapshot+copy+resume)` exhibits performance that linearly scales with the size of the continuation. `Linux CRIU` and `Firecracker` similarly exhibit linear scaling performance; however, both systems entail an order-of-magnitude slowdown relative to `Arca (snapshot+copy+resume)` and have a larger baseline footprint. From these results, we conclude that Arca is feasible for continuation-centric computing as long as continuations are generally captured and resumed without being copied.

6.2 Sandbox Performance

For continuation-centric computing to be practical, it must be possible to use continuation-based sandboxes in places where traditional sandboxes are currently used. We evaluate this by comparing Arca's performance with other isolation systems.

- DKVM is a virtualization-based solution similar to Dandelion's KVM backend [31]. Dandelion supports multiple isolation backends; KVM performs the best of the backends compatible with x86_64. Dandelion's approach to KVM uses an optimization similar to Groundhog [3]: rather than creating and destroying virtual machines for every function invocation, each VM's state is reset in between function invocations.
- FCKVM is a virtualization-based solution similar to Firecracker [1]. FCKVM measures the overhead of creating a new virtual machine for every function invocation, similar to a cold start of Firecracker. To avoid the confounding factor of Linux boot times, we do not run Linux within the virtual machine, and instead run the workload bare-metal as a unikernel.
- PROC is an implementation of sandboxing using Linux processes. For every function invocation, a new process is forked to run the function (which is loaded from a shared object file). The function communicates its results with its parent by writing to a shared memory region. A true sandboxing system would additionally have to move the process to a new namespace.
- SHAREDOBJECT provides a baseline; it provides *no isolation*, and just calls a function from a shared object file. This represents the "ideal" performance if isolation had no overhead.
- WASMTIME uses the WebAssembly engine Wasmtime [2] to isolate WebAssembly functions. We configure Wasmtime to use its pooled allocation strategy to improve performance and parallelism. Functions transfer their inputs and outputs via WebAssembly memories.
- ARCA is our system, as described in the rest of this paper.

6.2.1 Sandbox Creation/Deletion

We first measured the raw sandbox creation/deletion times of the approaches, with a no-op workload. We ran this workload in a closed loop for 60 s, after providing 100 ms of warm-up time, and measured the overall request rate as we varied parallelism. We then calculate the effective time taken per request.

This experiment was run on a machine with 2 AMD EPYC 7702 64-Core Processors (for a total of 128 physical cores and 256 hyperthreads) and 512 GiB of RAM, running Ubuntu 25.04 (Linux 6.14.0-29-generic). Arca was run within a KVM virtual machine which was allocated 4 GiB of RAM; the other systems were run directly on Linux.

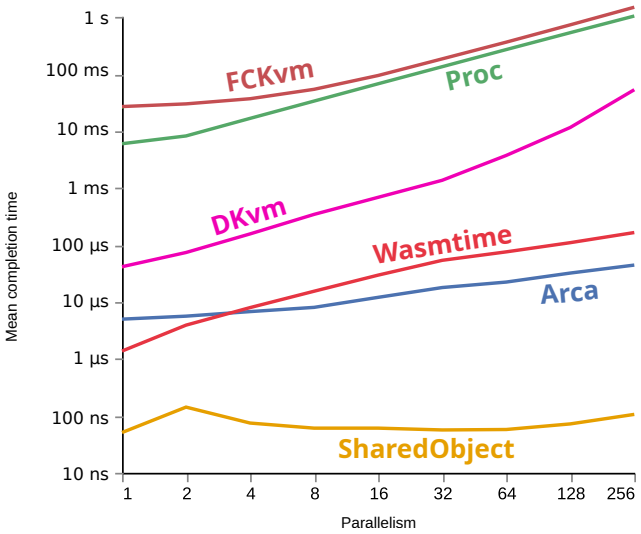

Figure 4: Performance of sandbox creation/deletion on a no-op workload. ARCA and WASMTIME are about an order of magnitude away from the theoretical limit (SHAREDOBJECT). In parallel settings, ARCA outperforms other isolation techniques.

The results of this experiment, averaged over 10 runs, are shown in Figure 4. SHAREDOBJECT provides a theoretical limit of about 100 ns per iteration, regardless of parallelism. In the single-threaded setting, WASMTIME follows at 1.5 µs per iteration, followed by ARCA at 5 µs per iteration. As parallelism increases, ARCA scales better than WASMTIME. At as low as 4-way parallelism, ARCA outperforms WASMTIME, and at 256-way parallelism, ARCA takes 30 µs per iteration (a slowdown of about 6x), while WASMTIME takes 200 µs per iteration (a slowdown of 133x). From our attempts to understand this, we believe that the slowdowns are due to contention on shared state internal to WASMTIME that effectively serializes its execution. DKVM trails about an order of magnitude behind ARCA when single-threaded, and actually scales *inversely* with increased parallelism—we believe this is because of allocator and page table contention within the kernel when changing the memory mappings of the VM. PROC operates on the order of 6 ms and FCKVM on the scale of 30 ms when single-threaded; both of these systems also scale poorly with added parallelism. We note that this microbenchmark is not a realistic measurement of the true scaling behavior under load, as longer-running functions reduce the amount of contention.

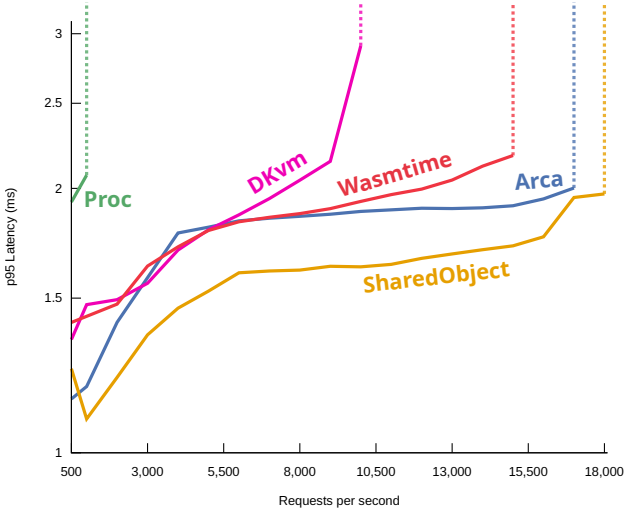

Figure 5: Request latency (95th percentile) of an open-loop 128×128 matrix-multiplication workload at various request rates. Vertical dotted lines indicate the highest request rate at which the system was able to reach a steady state. ARCA can sustain a higher request rate than other isolation methods, performing almost as well as no isolation (SHAREDOBJECT). FCKVM is omitted from this graph; it only reached 200 requests per second at a p95 latency of 42 ms.

6.2.2 Computational Workload

As a more realistic measure of the isolation mechanisms' performance under load, we perform an open-loop experiment in which we run a 128×128 32-bit integer matrix multiplication workload. For this experiment, we ran each system for 120 s, with requests isochronously generated at a range of request rates, and we measured the latency of each request. For every run of each system, we measure the p95 latency in the 10 s windows starting at the 30 s and the 100 s marks. We averaged this change in latency over all five runs of each system to determine how much each system slowed down over the course of 60 s. We declared the system unstable for a particular request rate if the slowdown exceeded 10% of the median latency; this indicates that the system would, if run long enough, exhaust its resources and crash. We only report latencies at request rates where each system remained stable.

This experiment was run on a machine with an AMD Ryzen 9 7950X 16-Core Processor (32 hyperthreads) and 64 GiB of RAM, running Fedora 42 (Linux 6.17.5-200.fc42.x86_64). Arca was run within a KVM virtual machine which was allocated 4 GiB of RAM; the other systems were run directly on Linux. All the systems were run with 32-way parallelism.

The results of this experiment are shown in Figure 5; solid lines indicate p95 latency, averaged across the five runs, and dotted lines indicate the maximum request rate for which the system remained stable. SHAREDOBJECT sets the theoretical maximum request rate for this workload at 18,000 requests per second. ARCA gets close to the theoretical limit, achieving 17,000 requests per second. WASMTIME achieves 15,000 requests per second; at most request rates, ARCA and WASMTIME have comparable response latencies. DKVM achieves 10,000 requests per second on this 32-hyperthread machine.[1] PROC trails behind, achieving 1,000 requests per second. While initially unintuitive that DKVM performs better than PROC, this is due to the implementation detail that DKVM does not actually create a new virtual machine for each request; it only has to reset the state of an already-created virtual machine. FCKVM, which does create a new virtual machine for each request, performs far worse than any of the other systems, sustaining only 200 requests per second with a p95 latency of 42 ms; we omit it from the graph.

Together, these benchmarks confirm that Arca is a viable isolation primitive for serverless computing. It slightly outperforms lightweight isolation through Wasmtime, and performs orders of magnitude better than heavyweight isolation like containers and MicroVMs: 2–3 orders of magnitude in computation-heavy tasks, and 4–5 orders of magnitude in sandbox creation/deletion. It is, however, more limited in the software it supports than the heavyweight isolation primitives.

6.3 Locality

To measure the benefits of continuation-centric computing on a serverless application, we ran an experiment on an image thumbnailing benchmark derived from SeBS [12]. For this experiment, we invoke the image thumbnailing function on one node, where the image data are located on a different node. The function takes a file path, `get`s the data, and then resizes the image. For this experiment, the image thumbnailing function invokes the "provider-native" API directly; we do not use POSIX compatibility helpers.

- CCC represents a continuation-centric computing approach to serverless, and implements `get` as a side effect. The effect handler captures, compresses, and then sends the continuation to the machine where the image data reside. The target machine decompresses and resumes the continuation.
- TRADITIONAL represents a status-quo serverless runtime where functions cannot be migrated once they have begun execution. Instead, `get` requests the image from the remote machine.

Both approaches use Arca as their isolation mechanism, but only CCC uses the continuation-capturing features of Arca.

This experiment was run on AWS `c6a.metal` instances running Ubuntu 24.04.3 LTS (Linux 6.14.0-1017-aws). Both CCC and TRADITIONAL were run within a KVM virtual

[1] This is consistent with the original measurement of 4,700 requests per second on a 16-core machine from the Dandelion paper [31].

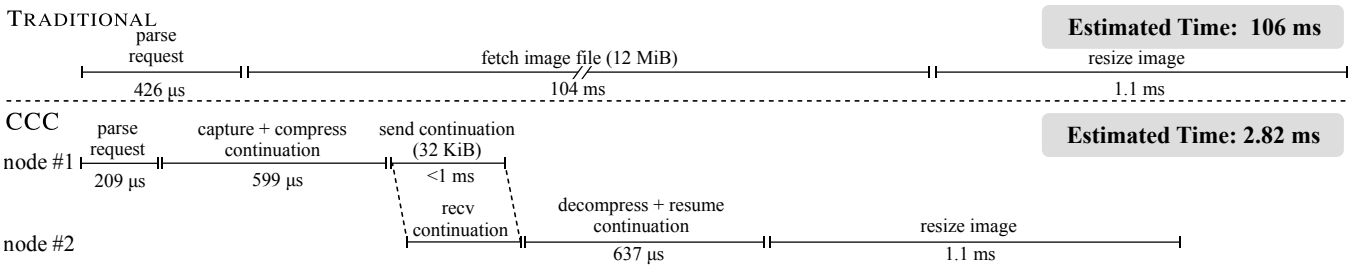

Figure 6: Time breakdown of an image thumbnailing function invoked on a different node than its input image. TRADITIONAL spends most of its runtime—98%—waiting for the image, bottlenecked by the speed of the network. CCC collocates computation and data by capturing and sending the continuation of the function. CCC spends comparatively little of its time—only 9%—doing data transfers, and is bottlenecked by computation time. TRADITIONAL achieves a throughput of 9.42 requests per second, while CCC achieves a throughput of 557.3 requests per second.

machine which was allocated 32 GiB of RAM, with networking support implemented using hypercalls to the Linux-side monitor. Both systems run a single-threaded loop on one node that launches the function locally. In CCC, the other machine receives and resumes continuations. In TRADITIONAL, the other machine serves image data to the first machine. We ran this loop for one second as a warm-up and then measured the number of functions completed in the following 60 seconds; we also measured the breakdown of where time was spent during a single function invocation. The results of the experiment are summarized in Figure 6. In CCC, 61% of a function invocation's runtime is spent resizing the image; on TRADITIONAL only 1% of the function's runtime is spent resizing, while 98% of the time is spent transferring data.

CCC achieves 557.3 requests per second, bottlenecked by decompressing and resuming the continuation and resizing the image on the target machine. In comparison, TRADITIONAL achieves 9.42 requests per second, bottlenecked by the network's speed in fetching the image. While this is an extreme case, these results confirm that continuation-centric computing can provide the benefits of collocating computation and data, similar to Fix [16], without make developers explicitly restructure programs in I/O-compute-separated style.

We also measured the throughput in the less extreme case where half of the functions can be completed with locally available data, while only half of the functions require data transfer to/from the other node. We still observe the benefit of continuation-centric computing in this case: CCC achieves 889.62 requests per second, while TRADITIONAL achieves 18.21 requests per second.

6.4 I/O Performance

We have described an automatic CPS transform based on capturing a continuation on every I/O operation. To measure the effects of this transformation on program performance, we evaluate an I/O-heavy application—a web server—implemented under Arca.

We implement this application two different ways: The first, which we call "pooled," resembles a microservice: many instances of a web server process are spawned in parallel (one per core), each incoming request is handled by the next available process from the pool, and processes return to the pool when they are done handling a request. We compare this approach against version 2.4.66 of the Apache HTTP Server [6] serving a static file from the filesystem.

The second way, which we refer to as "individual," more closely resembles serverless computing: every incoming request is handled by an invocation of a function, which runs to completion and terminates when it is done generating the response. We compare this against version 2.4.66 of the Apache HTTP Server using the Common Gateway Interface to launch a process on every request; our request handler is written in C to avoid the runtime startup penalties caused by managed languages like Python. While the request-per-function model approaches the *ideal* of serverless computing, it is not commonly used in practice due to performance concerns with spawning a process on every incoming request.

In all four cases, we generated load using ApacheBench, the Apache HTTP server benchmarking tool [5]. The four servers all returned the static string "hello, world" along with appropriate HTTP headers. This experiment was run on a machine with an AMD Ryzen 9 7950X 16-Core Processor (32 hyperthreads) and 64 GiB of RAM, running Fedora 43 (Linux 6.19.10-200.fc43.x86_64). Arca was run within a KVM virtual machine which was allocated 16 GiB of RAM; Apache was run directly on Linux. ApacheBench was configured to generate 65,536 requests with 32-way concurrency. For each system, we ran ApacheBench once as a warmup run, then measured request latency across the next 10 runs of 65,536 requests each. ApacheBench computed the CDF of request latencies for each run, and we averaged across the 10 runs. The results of this experiment are shown in Table 4.

These results show that capturing a continuation on every

Mode	System	p50	p90	p95	p99
Pooled	Arca	1.642	1.877	1.970	2.217
	Apache	1.737	1.904	1.959	2.067
Individual	Arca	3.665	4.381	4.677	5.390
	Apache	16.53	17.30	17.59	19.36

Table 4: Performance comparison of a web server implemented in Arca to the Apache HTTP Server; values are given in milliseconds. Both servers were measured under two modes of operation: in "Pooled" mode, the server spawns a thread/process for every core, each of which handles one request at a time; in "Individual" mode, the server spawns a new process for every request.

I/O operation does not noticeably affect the performance of a pooled web server; both Arca and Apache exhibit similar latencies. We believe the higher variance of Arca is due to a combination of performance tuning in Apache and the additional KVM entries and exits incurred by Arca. In a process-per-request web server, Arca outperforms Apache with CGI on Linux by a factor of four. This is likely due to the lower startup overhead of an Arca process relative to a Linux process, as previously measured in Section 6.2.1. With non-trivial workloads, we believe that computation time would dominate the workload—even on this workload, we see that the difference is much smaller than the pure startup time difference measured in Figure 4—so this measurement serves as a lower bound on the latency of each system.

6.5 Compatibility

To verify that continuation-centric computing is capable of handling existing applications, we qualitatively evaluate Arca's compatibility with existing software. We specifically consider the case described in Section 3.1, where we accept an unmodified WebAssembly binary using WASI and convert it into an Arca binary. For the purposes of this evaluation, we started with an off-the-shelf build of FFmpeg for WASI [49], based on a benchmark from SeBS [12]. This binary was compiled by a third party from the sources of FFmpeg version 5.1, using clang 14.0.4 from the official WASI SDK [52]. We first converted this binary to C code using `wasm2c` [53], a WebAssembly to C compiler. We then wrote a WASI shim, resolving WASI imports to equivalent calls into libc. Finally, we linked the converted C code, the WASI shim, and the Arca port of musl to produce a binary. We validated that the program successfully transcodes various audio files.

Developing the WASI shim layer to the level needed to support FFmpeg took one developer about two weeks of part-time effort. Since this work can be reused verbatim in the future, we expect that converting WASI programs to Arca will be fully automated. Providers can accept WASI programs and transparently run them under continuation-centric computing.

We see FFmpeg as a reasonable measure of the complexity of running unmodified WebAssembly applications: it uses a variety of WASI library functions which our conversion toolchain has to support. Since FFmpeg is compute-heavy, however, we don't see it as a difficult case performance-wise.

7 Related Work

This paper's primary contribution is providing continuation-centric computing, a new operating system design paradigm for serverless computing. This paradigm is realized in Arca, an operating system that provides lightweight hardware-isolated processes with efficient continuation capture. This section discusses prior work which relates to Arca and continuation-centric computing.

Low-Level OS Abstractions. Several prior systems provide new kernel abstractions in order to achieve better performance of userspace programs.

Exokernel [17] and Denali [54] provide abstractions that closely resemble the underlying hardware, and use a libOS to provide high-level abstractions. Spice [25] introduces new mechanisms to improve snapshot restoration time in existing OS designs. Similar to these works, Arca introduces new OS-level abstractions that more closely model the underlying serverless abstractions, using them to improve snapshot/restore performance. Lauer and Needham describe the duality between message-oriented operating systems and procedure-oriented operating systems [32]; while these prior systems fall into the former category, Arca falls into the latter.

Low-Latency Isolation. AWS Lambda is built on the Firecracker MicroVM system [1], which provides isolation using hardware virtualization. A lighter-weight approach is to use containers rather than full virtual machines; this is the approach adopted by σOS [48]. Containers share the host's kernel, but provide a new isolated namespace for global state. Previous work has tailored namespace creation for serverless workloads to achieve faster startup [38]. FAASM [46] uses WebAssembly [23] to provide software fault isolation, which outperforms containerized solutions. Arca provides hardware isolation at a level comparable to processes or containers, but by eliminating ambient OS state achieves performance similar to software isolation techniques.

High-Density Isolation. Various systems have proposed OS-backed abstractions to isolate specific components of applications. Shreds [8] provides threads with the ability to create multiple hardware-backed memory protection domains. Orbits [27] allows applications to move auxiliary tasks into separate lightweight process-like structures. These abstractions are primarily message-oriented, and Arca processes can be seen as the procedure-oriented dual to these abstractions.

Granular Scheduling. Nu [44] and Quicksand [43] advocate for resource fungibility: the ability to reassign resources quickly, even across machines. This line of work divides *logical processes* into fine-grained *proclets*. Dandelion and Fix [16, 31] perform a similar transformation, separating programs into I/O and computation. These systems use DSLs and/or eDSLs to capture dependencies. Previous systems like ExCamera and gg [20, 22] break large tasks into highly granular components to achieve burst parallelism with serverless computing. Together, this category of work provides motivation for continuation-centric computing; Arca would be a good fit as a substrate on which to implement them.

Continuations. There is a wide body of work regarding the use of continuations in programming languages [14, 18, 47], and their potential for integration in systems like WebAssembly [40]. Within distributed systems, CIEL [34, 35] explicitly uses continuations to execute programs with data-dependent control flow. These works can be seen as earlier realizations of continuation-centric computing; our contribution is to reify continuations as an operating system concept.

8 Limitations

While continuation-centric computing can improve the performance of serverless-style run-to-completion functional workloads, it is not a good fit for all use cases. We identify several categories of application which would be difficult to run under continuation-centric computing.

Shared-Memory Thread Pools. Arca does not support shared-memory threads, as shared memory increases the footprint of a continuation. An application which internally relies on a thread pool for parallelism would be limited to single-threaded performance in a direct port to Arca. Instead, a developer would need to modify the application to use a serverless provider's primitives for parallelism. We believe this limitation is true of continuation-centric computing in general.

I/O-Heavy Workloads. Applications that heavily mix I/O and computation (e.g., using `io_uring`) would be difficult to port to this model. Additionally, kernel bypass is incompatible with continuation-centric computing unless the hardware's state can be efficiently snapshotted and restored.

Databases and Daemons. Long-lived programs with consistent performance characteristics and large amounts of persistent state are probably a poor fit for "function-as-a-service" platforms, including continuation-centric computing. While Arca can transform such programs into continuation-based funclets, migrating a daemon with a large amount of persistent state will rarely be beneficial, and is generally dominated by the time required to transfer it to disk or over the network.

9 Future Work

Arca serves as a proof-of-concept of continuation-centric computing. A full system will require a runtime that schedules and places functions, akin to Fix, Dandelion, or CIEL [16, 31, 34], along with the other trappings of a serverless (or any) computing environment: access control, UIs, debuggers, metrics and monitoring, resource-allocation policies, billing, etc.

We also believe that continuation-centric computing can be extended to support microservice-style workloads, with long-running daemon processes. A possible step in this direction would be developing a continuation-centric version of a hybrid serverless/microservice system such as σOS [48]; this would require further work to efficiently represent persistent network connections in a continuation-centric style.

As we developed Arca and tested it against alternative systems, we observed that the limiting factor on the performance of sandboxing systems is often memory allocation, especially in highly parallel settings. We believe it would be worthwhile to explore whether kernel-level knowledge of the expected workload can be used to improve allocation performance.

10 Conclusion

This paper presents continuation-centric computing, a new operating system design paradigm, and evaluates it with Arca, a research OS that provides continuation capture as a core service. By designing Arca around this primitive, we found it is possible to capture a continuation of a running process in a few microseconds. This makes it more practical to automate a continuation-passing style transform of everyday programs, running them as sequences of pure funclets with I/O in between. For the right programs, this can yield substantial benefits—but much work remains to build a usable computing system around these abstractions.

Acknowledgments

We thank our shepherd Malte Schwarzkopf and our reviewers for their thoughtful feedback. We are grateful to M. Frans Kaashoek, Robert Morris, Dawson Engler, Ana Klimovic, Timothy Roscoe, Thea Rossman, Matthew Sotoudeh, Zachary Yedidia, Michael Paper, Haibib Kerim, Ariel Szekely, Hannah Gross, Benny Rubin, Ben Holmes, and Nicolaas Kaashoek for helpful conversations. Rethinking Process Snapshots for Near-Warm Serverless Cold Starts

Ben Holmes, Baltasar Dinis, Lana Honcharuk, Adam Belay, Joshua Fried†
MIT CSAIL †*University of Pennsylvania*

Abstract

Serverless computing promises effortless resource elasticity, yet this vision remains fundamentally limited by cold-start delays. Despite years of optimization, many function invocations still incur delays of tens to hundreds of milliseconds, often exceeding the function's actual execution time. Existing systems attempt to avoid redundant initialization by snapshotting functions after startup and restoring them on demand, but they still struggle to deliver consistently low-latency startup from disk.

We show that these limitations stem from a lack of OS support for snapshot restoration. Current memory primitives, tailored for incremental process startup, force a trade-off between efficient on-disk layout and cheap virtual address space reconstruction. Furthermore, the kernel lacks a bulk-restore mechanism for process metadata, forcing expensive, fine-grained reconstruction from userspace.

To address this, we introduce the Snapshot Hybrid ELF (SHELF) format and a co-designed kernel primitive, the *spliceVMA*, which decouple a snapshot's physical layout on storage from the process's virtual-memory layout. This enables the efficient overlay of sparse and reordered pages, reliable prefetching, and the elimination of unnecessary I/O, copies, and faults. In parallel, we build an efficient process-metadata restore path that reconstructs process state in bulk rather than using a large number of system calls from userspace.

We implement these mechanisms in Spice, restoring and running functions from disk within 0.6–18ms of warm-invocation latency (compared to 3.6–1197ms in existing systems). For representative Java, Python, and Node.js functions, Spice reduces end-to-end latency by 7.5× and 9.5× on average over state-of-the-art process- and VM-based systems, respectively.

1 Introduction

Serverless computing promises effortless elasticity: developers deploy lightweight functions, while the platform dynamically provisions resources in response to demand [17]. Freed from managing infrastructure, users benefit from fine-grained billing and scalability, while providers can, in theory, achieve high utilization by scheduling workloads just-in-time. In today's commercial platforms (e.g., AWS Lambda [1], Azure Functions [2]), these functions are typically packaged as containers that must be initialized before running user code. This initialization latency, known as a *cold start*, fundamentally limits the vision of effortless elasticity [7, 9, 13, 31, 34, 39, 43].

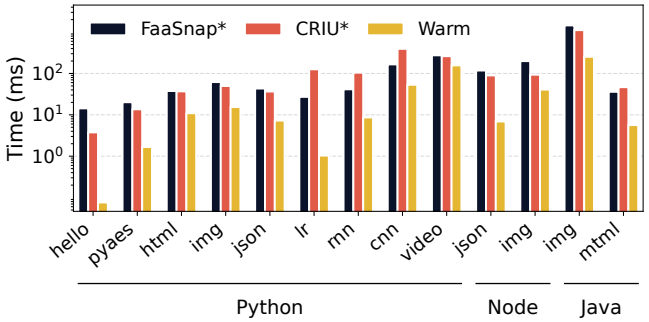

Figure 1: State-of-the-art restore-from-disk systems are still orders of magnitude slower than warm starts for serverless functions. Note the logarithmic y-axis.

Cold start delays stem from multiple sources, including container setup, language runtime initialization, library loading, and function-specific startup logic such as JIT compilation [22, 35, 42]. These steps often add tens to hundreds of milliseconds — frequently longer than the function's actual execution [10] — making them a major source of user-visible latency. Some mitigation strategies rely on *warm-state* approaches, such as keeping containers alive [4, 16] or leveraging *fork-based replication* [6, 10, 19, 43] to clone instances from a resident parent. While effective for scaling *active* workloads, these techniques only work when there is warm state already available in the cluster. However, maintaining warm state for the long tail of serverless functions is economically infeasible. Microsoft reports that 81% of applications are invoked at most once per minute [33], while Ant Financial observes that over 60% of functions experience cold starts more frequently than hot starts due to strict memory constraints [10]. Because rarely invoked functions cannot rely on a resident parent process, cold starts remain a major barrier to responsiveness in serverless systems.

The most effective existing approach to mitigating cold starts is to restore snapshots captured after a function has fully initialized [7, 23, 36, 39]. Over the last decade, work on fast snapshot restoration has focused on techniques such as lazy initialization [13, 44] (which populates process state

Table 1: Characterization of memory usage for various serverless functions. Delta intervals counts the number of contiguous sets of pages with modified/private application data. Values in parentheses refer to the working set, as opposed to the whole of the snapshot. For zero pages, only those in the working set are reported.

and memory on demand during execution) and working-set prefetching [7, 39] (which pre-loads only the pages that will be accessed into memory). However, even after applying these techniques, restore latencies are still significantly higher than warm starts. Figure 1 quantifies this gap and shows the end-to-end cold-start invocation times of two state-of-the-art snapshot/restore systems. They are 1.6×–188× slower than a warm start baseline.

In this paper, we show why this gap persists: current OS abstractions are a poor match for fast snapshot restoration in two ways: (1) the OS lacks an object format and interface for reloading memory efficiently, and (2) it provides no mechanism for reconstructing process metadata in bulk. We discuss each in more detail.

First, the OS provides poor support for reloading an application's memory during snapshot restoration. The state that actually needs to be recovered is a sparse, page-granular overlay: a relatively small set of modified pages scattered across large shared and anonymous mappings. To obtain good I/O performance, prior systems [7, 23, 39] reorder these pages on disk in predicted access order rather than virtual address order, producing a snapshot file that is effectively a jumble of pages laid out by predicted access time. However, neither standard binary formats nor the OS's mapping interface can efficiently express this sparse, reordered view of memory, forcing these systems to reconstruct the address space via thousands of tiny non-contiguous mappings or explicit page-wise copies, which scale poorly at restore time.

Second, the OS's lack of an interface to restore non-memory process state in bulk is responsible for large delays at restore time. To restore an application faithfully, a snapshot must recover not only its memory but also its file descriptors, signal handlers, timers, credentials, and other kernel-managed objects. However, today's OS interfaces assume incremental process startup, forcing restorers to recreate kernel objects through many serialized, fine-grained system calls rather than reinstating them in bulk. As a result, process-level tools must replay thousands of operations to rebuild this state (a process we refer to as *syscall replay*), substantially inflating restore latency. VM-level snapshotting sidesteps this replay, but only by capturing and restoring a much larger image, which increases the working set and adds delays due to guest OS processing at resume time.

To address these limitations, we introduce Spice, a system that co-designs an *object format* and *OS interfaces* for fast, elastic process restoration. Spice provides the **Snapshot Hybrid ELF** (SHELF) format, an ELF-inspired format that plays for snapshots the role ELF plays for program startup: it defines a compact contract between bytes on disk and the kernel's in-memory representation of a process. Whereas ELF assumes that a program can be described by a few large contiguous segments, SHELF generalizes this model with a page-granular indirection structure that can encode the sparse, reordered overlays produced by snapshotting. A single SHELF "segment" can thus contain arbitrary holes and page reorderings while still being presented to the kernel as a small number of contiguous virtual ranges.

On the kernel side, Spice introduces **spliceVMAs**, a new mapping mechanism that attaches SHELF's indirection structures directly to contiguous regions of a process's virtual address space and resolves page faults to disparate sources within a single VMA. spliceVMAs allow the kernel to retain a compact set of large mappings while loading pages from whatever on-disk layout SHELF chooses, rather than issuing thousands of tiny non-contiguous `mmap`s or performing page-wise copies. This decouples the snapshot's I/O-optimized representation from the address-space representation used by the kernel. Together, SHELF and spliceVMAs resolve the core tension between on-disk and in-kernel views of a process's memory: snapshots can freely reorder pages for high-throughput restore, while the kernel reconstructs the original address space without per-page mappings or metadata explosion.

For process metadata, Spice demonstrates that snapshots can remain at the process boundary without incurring the high costs of system-call replay. Using a library OS to prototype

bulk restoration of execution state, Spice reconstructs file descriptors, signal dispositions, threads, and other process state from compact serialized descriptions, reducing metadata reconstruction costs by 63–99% compared to replay-based restoration.

Together, these mechanisms show that high performance and memory elasticity need not be at odds. By removing both dominant bottlenecks—metadata replay and inefficient memory reconstruction—Spice reduces cold-restore latency from disk to within 0.6–18ms of a warm invocation (compared to 3.6–1197ms in existing systems), achieving up to orders-of-magnitude improvement over state-of-the-art. These results blur the line between cold storage and warm memory, enabling providers to more aggressively offload idle functions to disk without sacrificing the responsiveness required by user-facing workloads.

This paper makes the following contributions:

- We show experimentally that mismatches in OS interfaces for metadata restoration and memory-layout reconstruction are a central barrier to fast cold starts from disk.
- We introduce Snapshot Hybrid ELF (SHELF) and spliceVMAs, a co-designed snapshot format and kernel mapping abstraction that efficiently reconstruct sparse, reordered process address spaces.
- We present a compact metadata-restoration mechanism that recreates process OS state in bulk without system-call replay.
- We demonstrate that Spice significantly reduces cold-start latency from storage, outperforming state-of-the-art process-based systems by 7.5× and VM-based systems by 9.5× on average.

2 Background and Motivation

Snapshot-based cold-start mitigation requires choosing what state to capture and restore. Existing systems primarily choose one of two snapshot boundaries: the application process, represented by CRIU [3], or the entire virtual machine, represented by REAP [39] and FaaSnap [7]. This boundary determines both how much state must be restored and which operating-system mechanisms are available during restoration.

We first separate this snapshot-boundary choice from the deployment and isolation mechanisms used in serverless platforms. Serverless functions are commonly deployed either as code snippets assembled with a provider-managed runtime or as user-supplied container images. At invocation time, the provider materializes this package as an OS container containing the function process or processes, its language runtime, and its libraries. Depending on the platform's isolation model, this container may run directly using host OS mechanisms such as namespaces and cgroups, or inside a lightweight VM.

Thus, using a VM as the sandbox does not require using the VM as the snapshot boundary. A platform that relies on VMs for isolation can still snapshot the process or processes inside the container and later restore them inside a fresh VM; it need not snapshot the entire guest OS. We therefore treat process-level and VM-level restore as choices of snapshot boundary, rather than as consequences of the platform's sandboxing mechanism.

We evaluate these choices by measuring the end-to-end latency of cold serverless function invocations. To isolate the cost of restoring application state, we exclude non-function-specific container setup such as cgroups and namespaces, which can be prepared ahead of time and for which acceleration techniques are well explored [10, 19, 24, 26, 38].

2.1 The Snapshot Boundary: Processes vs. VMs

One foundational challenge for fast restoration is that modern operating systems lack a native interface to restore a process's kernel-managed state, or metadata. This state includes a wide array of resources: threads, file descriptors, timers, signal handlers, and more. Not only is there no single interface to reinstate this entire collection at once, but even restoring a single resource to its previous condition can require a complex sequence of operations.

Because there is no dedicated restore primitive, systems are forced into one of two suboptimal approaches: either (1) replaying the system calls that originally created the process, or (2) snapshotting and restoring the entire virtual machine it runs within. Both strategies push existing abstractions beyond their intended uses and are responsible for significant cold-start overheads.

Syscall replay. At one extreme, restore begins from an empty process and attempts to reconstruct every piece of kernel state — threads, file descriptors, memory mappings, and more — by reissuing the original system calls that created them. This strategy is expensive: there are often hundreds or thousands of such calls required, as most kernel objects lack dedicated import or restore interfaces to directly set them to their previous state. For example, restoring a single file descriptor may require a sequence of syscalls: `open` to create the file, `lseek` to set its offset, and `dup` to assign the correct descriptor number. Across complete function restores, this replay cost grows with function and runtime complexity. Figure 2 reports the initialization overhead of process-based restore for a range of serverless functions, along with the number of syscalls issued during restoration. Simple functions require hundreds of syscalls, while larger runtime environments require thousands, causing restore latency to rise accordingly. Because most of this state must be reconstructed before execution can resume, syscall replay directly inflates cold-start latency.

The userspace orchestration required for process restore adds further overhead. Rather than asking the kernel to in-

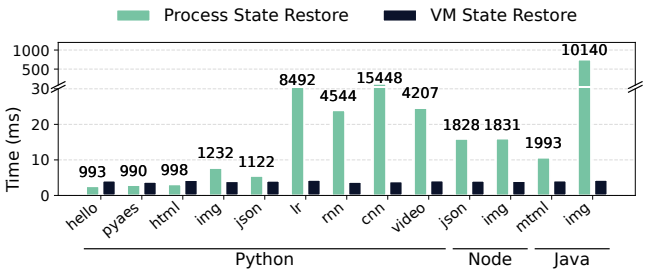

Figure 2: Initialization overheads for VM- and process-based restore; total syscall counts for process restore are shown above the bars. Process restore costs grow with process complexity due to syscall replay. VM restore costs are flat but still non-trivial, reflecting fixed-cost hypervisor setup operations.

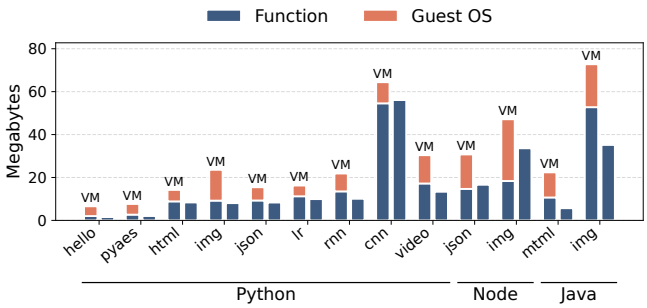

Figure 3: Working set composition for VM vs. process snapshots; the VM snapshot boundary increases the resulting active memory at restore time by 1.2–3.4×.

Python									Node		Java	
hello	pyaes	html	img	json	lr	rnn	cnn	video	json	img	mtml	img
50%	41%	22%	26%	23%	23%	40%	25%	40%	30%	25%	36%	19%

Table 2: Fraction of unmodified file-backed pages that, in a process-level snapshot model, can be reused and shared rather than reloaded from disk; VM snapshots cannot leverage this opportunity.

stantiate a saved process directly, CRIU runs as an ordinary userspace process and morphs its own address space into the restored one. This requires it to avoid collisions between its temporary restore state and the target layout: CRIU stages snapshot data in temporary regions, installs a small restorer binary into otherwise unused virtual address space, transfers control to it, unmaps CRIU's original code and data, and finally remaps the snapshot contents at their original virtual addresses. This elaborate dance avoids even more costly alternatives, such as reconstructing the target from a second process via `ptrace`.

Full-VM snapshots. At the other extreme, systems restore entire virtual machines from snapshots. Because the snapshot includes the guest kernel and its data structures, process metadata is already present when the VM resumes rather than being reconstructed through syscall replay. As shown in Figure 2, restore is reduced to a small, fixed set of hypervisor actions, such as reinitializing vCPU state, reattaching devices, and restoring other host-managed state. These operations complete in just a few milliseconds regardless of the complexity of the application running inside the guest.

The downside is that VM snapshots capture more than the function needs. Capturing the whole VM substantially increases both the stored snapshot image and the memory that must be present at restore time. Figure 3 compares the working-set composition of VM- and process-level snapshots, showing that VM working sets include substantial state from the guest OS at restore time.

Snapshotting at the VM boundary imposes additional memory efficiency costs. In Table 2, we show that 19–50% of the working set consists of pages that are *not function specific*, but are potentially shared with other processes, such as libc, a runtime interpreter, or other common libraries. In a process snapshot, any such pages that are already resident on the machine can be remapped from the page cache without any I/O; in a VM snapshot, these page reuse opportunities are not visible to the hypervisor and therefore it cannot make use of them.

Additionally, we found that after a prolonged pause, the guest kernel immediately experiences a "deferred housekeeping storm" due to the sudden clock jump. When the hypervisor restores the VM's virtual CPU, the guest kernel registers a sudden, massive jump in its system clock representing the time elapsed while paused. This clock jump immediately triggers all pending, timer-based background services and guest kernel housekeeping routines simultaneously, including periodic systemd daemons, guest memory reclamation passes, and critical kernel threads like RCU callback processing. Because these essential tasks are scheduled as soon as the VM becomes active, we found that even boosting the function process to a high-priority real-time scheduling class (`SCHED_FIFO`) offers only partial relief; critical guest kernel threads still preempt and delay the function's execution by up to 10ms, consuming 22–79% of the end-to-end response time.

Ultimately, capturing snapshots at the VM boundary reduces OS metadata restore costs but inflates resource consumption in many dimensions — larger stored snapshot images, more I/O and memory bandwidth consumed, and more duplicated memory on the host. Finally, the execution delays at restore time due to guest kernel interference waste compute and produce user-visible delays.

2.2 Repopulating memory

Even if metadata could be restored instantly, cold-start latency remains dominated by the work required to repopulate a process's address space. Existing snapshot/restore systems ultimately confront the same underlying limitation: the operating system provides only coarse-grained interfaces for constructing virtual address spaces. Interfaces such as `mmap`

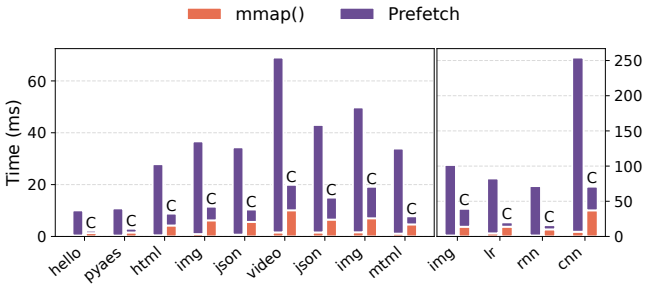

Figure 4: Time spent restoring memory and prefetching the working set under two snapshot file layouts. Storing working-set pages contiguously in the snapshot file (bars marked "C") greatly reduces prefetch time, but increases the cost of reconstructing virtual mappings. Leaving pages at their virtual-address offsets has the opposite trade-off: mapping reconstruction is cheaper, but prefetching is more expensive.

map contiguous file regions into contiguous virtual-memory regions, while restoring a snapshot demands fine-grained, page-level control. This mismatch forces restorers into an unavoidable trade-off between I/O efficiency and memory-management efficiency.

When an application starts, its address space is typically described by a small number of large virtual memory areas (VMAs). Each VMA corresponds to a contiguous region of virtual addresses backed by either a file or anonymous memory. During execution, however, this organization rapidly breaks down. Within a single VMA, page-level states diverge: some pages remain clean and continue to map to the backing file, others become private copy-on-write (CoW) pages due to writes, and still others are never touched. The kernel tracks these differences at page granularity through the page tables. However, address-space management interfaces such as `mmap()` remain segment-oriented: they create and manipulate contiguous virtual-memory regions with uniform backing and protection attributes rather than arbitrary collections of individual pages.

This segment-oriented model is highly effective for process startup. ELF, the standard executable format on Unix-like systems, describes a program image as a small number of large loadable segments. The kernel constructs an address space by mapping these segments and relies on demand paging to populate them lazily as execution proceeds. Because application memory is initially dense and contiguous, this approach requires only a small number of mappings and allows the kernel to rely heavily on demand paging, making ELF loading a highly optimized path in Linux.

A snapshotting system, however, seeks to reconstruct the memory of a running process rather than a freshly initialized one. At this point, the address space is no longer naturally organized as a small number of dense segments. Instead, the pages whose contents must be preserved form a sparse, page-level overlay on top of shared code and data. Moreover, the order in which those pages are accessed after restore is determined by application behavior rather than their virtual addresses. Consequently, the layout that is most efficient for storing and retrieving snapshot data need not mirror the layout of the virtual address space. Instead, arranging pages on disk according to their expected post-restore access order enables efficient prefetching and bulk retrieval through a small number of large sequential operations. Ideally, a snapshot representation would therefore store only pages whose contents cannot be reconstructed from their backing files and arrange those pages according to expected access order rather than virtual address order.

Realizing this design, however, requires a way to map a sparse collection of reordered pages back into their original virtual addresses. The kernel's mapping interface provides no way to directly map a sparse collection of pages, stored in arbitrary order within a file, onto the non-contiguous virtual addresses they originally occupied.

As a result, whenever pages that were adjacent in virtual memory are stored in different locations within the snapshot file, `mmap` requires a separate mapping operation to place each discontinuous region back into its original location. A snapshot for which pages have been clustered or reordered for sequential I/O can therefore expand into thousands of tiny VMAs, each mapping only a single page or a small range of pages. For the workloads in Table 1, we found that such reordering would increase the number of VMAs by up to 32×.

This proliferation of VMAs incurs two costs. First, each VMA creation requires kernel memory allocation and insertion into the process's VMA tree, operations that dominate CPU time during restore and scale poorly with tree size. Second, VMAs consume non-trivial kernel memory (approximately 300 bytes per VMA in Linux), so restoring thousands of page-sized VMAs per function introduces measurable overhead in the kernel's memory footprint.

Figure 4 illustrates this trade-off. Clustering working-set pages into a contiguous on-disk region allows snapshot data to be fetched with a small number of large sequential operations, minimizing both I/O overhead and CPU work in the loader and kernel. However, restoring those pages into their original scattered virtual addresses requires many independent mappings, resulting in a proliferation of VMAs. Conversely, preserving the original address-space layout keeps the number of mappings small, but forces the loader to retrieve snapshot data from many disjoint locations and can leave a long tail of page faults. Because current OS interfaces cannot decouple on-disk layout from virtual-memory layout, existing systems must choose between layout-efficient storage and mapping-efficient restoration.

Existing systems resolve this trade-off in different ways. CRIU [3] preserves the original VMA layout and saves only dirty modified pages in its snapshot, recreating VMAs and

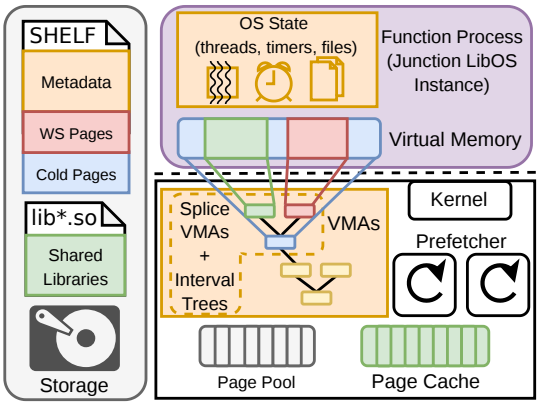

Figure 5: Overview of Spice's architecture.

copying dirty data back into place. This avoids VMA proliferation but requires scattered reads and explicit copying into the target address space. Replayable-Execution [42] reduces copying costs by mapping small modified segments directly from files and relying on demand paging, but doing so across many tiny regions amplifies VMA creation overhead.

REAP, Sabre, and FaaSnap [7, 23, 39] focus on prefetching optimizations and reorder working-set pages into contiguous regions for efficient prefetch. REAP and Sabre issue large sequential reads and then copy each page into its scattered virtual destination; execution cannot resume until this bulk copy completes. FaaSnap overlaps prefetch with execution by asynchronously `mmap`ing reordered segments into the process and warming the page cache. However, because file-backed writable memory in Linux employs CoW semantics, every write in the restored function induces a minor fault and a page allocation; in virtualized environments such as Firecracker, each fault induces a VM exit, adding hundreds of cycles before fault handling even begins.

Across all of these designs, the root cause is the same: the operating system lacks a page-granular mapping abstraction that decouples the layout of data on disk from its placement in virtual memory. Existing memory-management interfaces therefore force restorers to choose between I/O-efficient layouts and mapping-efficient address-space construction. In the next section, we show how Spice breaks this trade-off by extending the segment-based loading model embodied by ELF with support for sparse, reordered page-level overlays. The result retains the efficiency of ELF-style segment loading while enabling page-level reordering and sparsity.

3 Spice Design

We design Spice to address the challenges outlined in Section 2. Spice is a serverless execution engine that minimizes cold-start latency by restoring snapshots from storage at the *process-OS* boundary, rather than restoring an entire VM. This boundary reduces the amount of captured state while avoiding the restore-time overheads of VM-based approaches. As

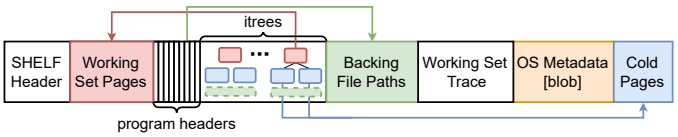

Figure 6: The layout of a SHELF file.

shown in Figure 5, Spice consists of several key components.

First, we introduce a new snapshot object format, Snapshot Hybrid ELF (SHELF), co-designed with a novel kernel memory abstraction: the spliceVMA. Together, these mechanisms enable the kernel to efficiently restore scattered and reordered memory pages directly from a snapshot file. Second, Spice includes a high-performance kernel memory engine that loads SHELF snapshots and performs both snapshot prefetching and page-table-entry (PTE) prefaulting to accelerate restoration.

Finally, user code in Spice executes within the Junction library operating system (LibOS), which serves as our container runtime. We selected Junction because it manages the vast majority of process metadata in userspace, making it well suited for prototyping a metadata restoration interface. We discuss this design choice in greater detail in Section 3.4. The remainder of this section describes each component of Spice in detail.

3.1 The SHELF File Format

We design the Snapshot-Hybrid ELF (SHELF) format, an evolution of the ELF object format that supports efficient loading of an already-running process's memory from disk. Figure 6 shows the layout of a SHELF file. SHELF is intentionally organized to promote access locality. Immediately following the initial header, SHELF stores the process's working-set pages in time-of-access order in a contiguous array. This allows the system to immediately execute an initial high-throughput sequential disk read to prefetch these pages at load time, before performing any additional parsing.

Like ELF, SHELF stores an array of program headers, one describing each VMA that existed in the process's address space at snapshot time. SHELF's program header diverges from ELF's in two key ways. First, each program header can describe backing memory that is primarily sourced from a different file, by referencing a pathname included in the subsequent file paths section. A program header that does not point to another file uses anonymous memory as its main backing source. Second, the program header describes non-contiguous memory regions within the SHELF file that are overlaid on the main backing source. Because these regions vary in size, each header points to a collection of memory intervals stored in a later section using a layout optimized for restoration by spliceVMAs (§3.2). Each interval describes a sub-range of the program header's address space and specifies the offset in the SHELF file containing the corresponding

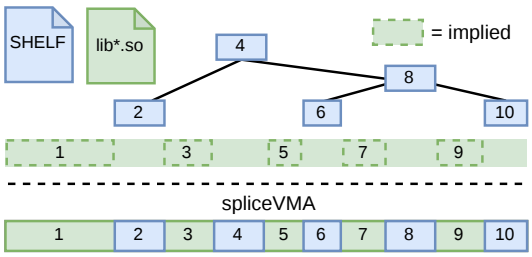

Figure 7: A spliceVMA and its interval tree. The interval tree lets a spliceVMA overlay sparse SHELF-backed ranges onto an existing file-backed (or anonymous) mapping.

data. The pages referenced by an interval reside either in the working-set section at the beginning of the file or in the cold-data section at the end. Any address range not covered by an interval is sourced from the backing memory (e.g., existing file-backed pages or anonymous zero pages).

Next, the SHELF file includes a trace of page accesses to guide prefetching. Each trace entry records the virtual address accessed, a timestamp, and a small amount of metadata about the access, such as whether the trace predicts a write. Our implementation includes records for pages already present in the working-set section, as well as records for accesses to zero pages and pages from other shared files. We discuss this design choice further in §3.3.

Finally, there is a section reserved for serialized OS metadata that is not memory-related. This section's structure is not specified by SHELF, and can be laid out as needed by the metadata restore implementation.

3.2 Splice VMAs & Interval Trees

SHELF's format alone is not sufficient to avoid the restore-time costs identified in §2.2; the kernel must also be able to *consume* the format without devolving into per-page work or VMA explosion. To this end, we introduce the *spliceVMA*, a new kernel VMA type co-designed with SHELF. A spliceVMA represents a mixed-source mapping: a single contiguous virtual address range whose pages may come either from a snapshot file or an underlying file-backed or anonymous mapping.

The design goal for spliceVMAs is to minimize compute work on the restore path. In particular, we want to (1) avoid per-page operations when reconstructing the address space, (2) avoid doing any work at all for pages that are never touched after restore, and yet (3) guarantee that when execution diverges from the predicted working set, any access still sees the exact bytes that were present at snapshot time. The key structure that enables this is the *interval tree* specified in the SHELF file for each program header. Figure 7 shows the representation of a spliceVMA and its interval tree.

For each VMA described in SHELF, the snapshot generator produces an interval tree that compactly encodes the page-granular overlay for that region. On disk, this tree is stored in a layout that can be used directly by the kernel without any deserialization. Concretely, each interval tree is a pre-balanced, cache-friendly B^+ tree stored as a contiguous array of nodes. Each node describes a range of virtual addresses and the corresponding offset in the SHELF file where the data for that range resides. At restore time, the loader maps this array into memory and attaches a pointer to it in the spliceVMA; no rebalancing, allocation, or pointer-fixup is required. On a page fault, the spliceVMA consults its interval tree to determine whether the faulting address falls within a snapshot interval. If so, the fault handler reads the page from the snapshot image at the recorded offset; otherwise, it falls back to the original backing source (the file named in the program header or zero-fill for anonymous memory). This guarantees correctness even when the function's execution path diverges from the original access trace.

Intuitively, the interval tree is a compacted, read-only representation of the application's original page tables for a particular region that enables lazy but correct restoration of that information. The kernel's VMA tree (implemented with maple trees [18]), must support frequent and likely concurrent insertions and deletions, so it is built from dynamically allocated, pointer-linked nodes. Conversely, the spliceVMA interval tree is static: it is constructed offline, never modified at runtime, and always perfectly balanced. This static, array-based layout makes lookups cheaper and more cache-efficient than traversals of the general-purpose VMA map, and it imposes no additional overhead on the restore path beyond wiring in the pointer from the spliceVMA to the already-constructed tree. Because interval trees are built offline and so cheap to query, SHELF can freely introduce arbitrary fractures and reordering of intervals to optimize the on-disk layout for I/O, without inflating the cost of address-space reconstruction. We evaluate the performance of querying an interval tree in §5.

Although the interval tree is immutable, spliceVMA-backed memory remains compatible with ordinary virtual-memory operations such as `munmap`, `mremap`, and `mprotect`. The interval tree describes the contents of the original snapshotted region; it is not the mutable representation of the process's current VMA layout. When an operation splits or moves a spliceVMA, the resulting VMAs continue to reference the same interval tree and record their position relative to the original snapshotted range. Once pages have been restored, subsequent changes are reflected in the process's page tables and VMA metadata, as in normal execution. Thus, runtime memory-management operations mutate the VMAs and PTEs around the interval tree, while the interval tree remains a read-only index for the snapshot contents.

3.3 SHELF Loading & Prefetching

The SHELF loader is a throughput- and latency-optimized kernel engine that ingests a SHELF file and recreates the snap-

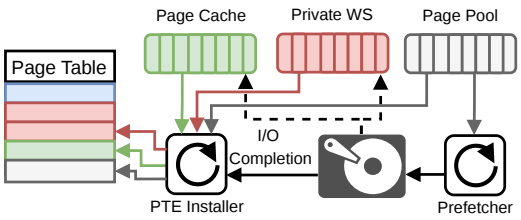

Figure 8: Spice's prefetching architecture.

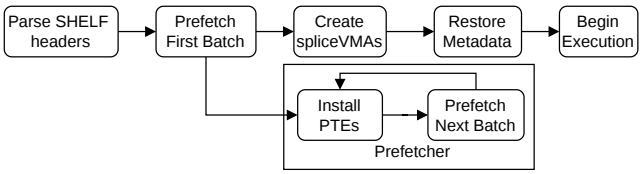

Figure 9: `reexec()` workflow

shotted memory layout. It is exposed through a new system call, `reexec()`, which augments the caller's address space with the contents of a SHELF snapshot. The loader is guided by SHELF's access trace, which records the pages expected to be touched after restore, whether those pages are private snapshot pages from the SHELF file, shared pages from other backing files, or anonymous zero pages, and whether each page was written during profiling. Figure 8 shows the components of the SHELF loader in the kernel, and Figure 9 shows the timeline of restore operations.

Synchronous restore path. `reexec()` is designed to minimize the synchronous time spent inside the system call. Its blocking path performs three steps. First, it initiates reads for the private working set. This is cheap because private working-set pages are packed contiguously in the SHELF file, reducing both file-system block-lookup overhead and the number of I/O submissions needed to fetch them. Internally, these reads are still split into independent I/O submissions so that completions arrive incrementally and can drive page-table installation before the entire private working set has been read.

Second, while the reads are in flight, `reexec()` constructs the process's spliceVMAs in bulk and wires each spliceVMA to its corresponding interval tree. This reconstructs the virtual address layout without per-page mapping operations and without touching pages that may never be accessed. Third, once the virtual address space exists, `reexec()` consults the access trace and installs an initial batch of PTEs for traced pages whose contents are already available, including zero pages, page-cache hits, and private pages whose reads have already completed. It then returns control to the restored process.

Asynchronous prefetching and PTE installation. After `reexec()` returns, kernel prefetch threads continue processing the trace concurrently with function execution. They initiate I/O for shared working-set pages, which come from the original backing files and are often scattered across many files in short intervals. They also install PTEs as page contents become available: for shared pages already resident in the page cache or fetched by the prefetcher, for zero pages that can be mapped immediately, and for private pages as the private-working-set reads complete.

A key design choice is that the loader aggressively installs page-table entries rather than relying on minor faults. In the serverless setting, accesses after restore are scattered across large regions, and minor faults can quickly dominate latency. The prefetcher therefore attempts to prefault traced accesses, including zero pages, so that the restored process rarely incurs even minor faults on its hot path.

Page-placement policy. The loader chooses where page contents should reside based on whether they are reusable and whether they are likely to be written. Shared pages from backing files are populated through the page cache, enabling reuse across functions. Private pages are loaded into newly allocated anonymous memory rather than inserted into the page cache, because they represent snapshot-specific anonymous state and would otherwise compete with broadly reusable file-backed pages for cache space.

This is a policy choice rather than a limitation of SHELF. For functions invoked frequently enough that repeated restores of the same snapshot are common, a future implementation could route read-mostly private pages through the page cache while directing pages likely to be dirtied into anonymous memory to avoid future CoW faults.

Zero pages and allocation policy. The write information in the trace is especially useful for zero pages. For zero pages that are unlikely to be written, Spice installs mappings to the shared CoW zero page. For zero pages predicted to be written, it instead installs private pre-zeroed pages so that the restored function can write without taking a fault.

Restoring a snapshot also puts substantial pressure on physical-page allocation. Both loading private working-set pages and installing writable zero pages require the loader to obtain large numbers of physical pages during a short restore window. Although Linux provides bulk page-allocation interfaces, we found that the per-page overhead still accumulates for snapshots containing tens of thousands of pages, making allocation a visible component of restore latency. To avoid placing this work on the invocation critical path, Spice maintains a reserved pool of preallocated pages that can absorb the allocation bursts caused by restore. The loader draws from this pool when populating private pages and writable zero pages, and falls back to ordinary allocation only when the pool is exhausted.

Together, the `reexec()` fast path, spliceVMA-based mappings, trace-guided prefetching, and proactive PTE installation allow Spice to reconstruct the snapshotted address space with minimal synchronous work, while overlapping I/O and page-table installation with resumed execution.

3.4 Metadata Restore

An effective snapshot/restore mechanism must choose a boundary that can be restored quickly without forcing the system to capture unnecessary state. The process boundary is attractive because it is much lighter weight than a full VM snapshot, while still containing the execution state relevant to the application. In principle, a production implementation could capture and restore this state directly in the Linux kernel by adding restore support for the relevant per-process kernel data structures. In this work, we instead use Junction's LibOS [15] as a practical substrate for prototyping the same process-boundary abstraction.

Junction uses a single-address-space LibOS model: the application and LibOS execute in the same virtual address space, and the LibOS virtualizes the Linux process and system-call interface seen by the application. This means that much of the process metadata that would otherwise be maintained as Linux kernel state is represented by LibOS-managed userspace objects. As a result, our prototype can restore most process metadata by reconstructing these LibOS objects, rather than modifying Linux to serialize and rebuild each corresponding kernel data structure.

Virtual memory remains the important exception. Even with a LibOS, the host kernel ultimately controls the hardware address space, including VMAs, page tables, and page-fault resolution. Spice therefore provides explicit kernel support for virtual-memory restore: the SHELF loader reconstructs the restored address space and installs page-table mappings, while the LibOS reconstructs the remaining process metadata. Open file descriptors are handled lazily, with the LibOS recording enough information to reopen or reconstruct descriptors when they are first used.

This use of a LibOS is primarily methodological. It lets us evaluate what a dedicated process-restore interface can provide without first re-engineering all of Linux's per-process metadata paths. A Linux-native implementation could provide analogous serialization and reconstruction logic inside the kernel. Our prototype instead demonstrates that, once the kernel exposes the right fast path for restoring virtual memory, the rest of process-boundary restore can be implemented efficiently enough to support very fast cold starts.

We considered two possible approaches to capturing the LibOS-managed metadata. One option was to ensure that all metadata objects were located in a dedicated, contiguous memory region that could be snapshotted and restored by bulk copying. The alternative was an object-wise serialization approach, where each process-related LibOS object implements a custom serializer and deserializer that is invoked per object at runtime. We chose the latter for several reasons. First, the LibOS uses C++ features such as dynamic heap allocation, slab allocators, RCU, and smart pointers, which make it impractical to constrain all metadata to a single layout-stable region. Second, not all in-memory state needs to be preserved: custom serializers can omit transient or quiescent structures such as locks, wait queues, and other synchronization artifacts that are guaranteed to be inactive at snapshot time. Third, per-object serializers enable space-efficient encodings tailored to the object type. For example, LibOS pipes are implemented as ring buffers; by serializing only the live portion of each buffer, we avoid copying unused capacity.

This design also circumvents a central limitation faced by userspace restorers such as CRIU. Because CRIU must perform restoration from within an already-running userspace process, it has limited control over the address-space layout of the process being restored. CRIU's restorer must map its own code and data while simultaneously injecting the restored process's memory mappings, and conflicts may require relocating regions at runtime. These relocation steps add CPU overhead. By contrast, our restore path executes from the LibOS's "kernel side," where we control the address space during restoration. This lets us arrange the LibOS and application mappings so that LibOS-internal mappings do not conflict with the restored application layout, avoiding the relocation overhead that CRIU can incur.

Metadata serialization starts from the root task object and emits a sequential, address-independent archive of the reachable LibOS state that must survive restore. Each object's serializer records the fields needed to reconstruct that object and invokes serialization for referenced objects that should also be preserved. Deserialization reverses this process, reading metadata from the SHELF file using a buffered reader to amortize I/O costs and reconstructing the LibOS object graph. In our measurements, metadata restore completes in as little as 0.9ms, compared to 2.6ms for CRIU, and no more than 7.5ms, compared to 749ms for CRIU. Despite the different techniques, we find that the metadata snapshots produced by Spice and CRIU are comparable in size across functions.

To ensure low invocation latency, we also avoid booting a LibOS instance on the restore critical path. Instead, we maintain a pool of freshly initialized LibOS instances that are ready to accept restored tasks. Each instance begins in a cleanly booted state, so restoring consists only of mapping the snapshot's memory image and reconstructing the object graph before execution resumes.

4 Implementation

We implement Spice on Linux 6.5.0 with three main components. First, we modify Junction's library OS [15] to support snapshotting and bulk metadata restore for unmodified Linux binaries running inside its `seccomp`+`chroot` sandbox. Second, we implement `shelftools`, a 7.4 KLoC Rust toolchain that constructs and rewrites SHELF files. Third, we add a 7.1KLoC kernel module that introduces the `reexec()` system call, spliceVMAs, and the SHELF loader and prefetcher. Our implementation is open source at https://github.com/JunctionOS/spice-ae.

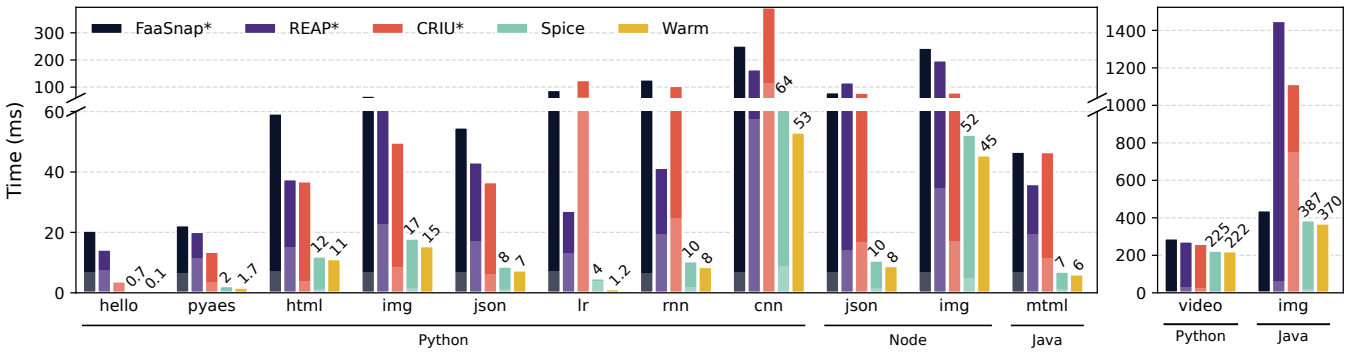

Figure 10: Spice achieves end-to-end cold-start latencies significantly closer to warm invocations than existing systems. The faded lower portion of each bar shows restore latency prior to executing the function.

User-level snapshot pipeline. We add a per-language shim to perform function invocations and prepare for snapshots. A snapshot proceeds in three steps. First, the LibOS pauses all function threads at a safe point and walks its internal object graph starting from the task root, and serializes them using the `cereal` C++ library. Second, the LibOS dumps the contents of each VMA in the process into temporary contiguous segments in a provisional SHELF file, without attempting to remove zero or shared pages. This keeps the in-process snapshot path simple and sequential. Third, `shelftools` runs offline to rewrite this file into the final SHELF layout: it removes unmodified file-backed pages and zero pages, deduplicates identical private ranges across snapshots, builds the balanced interval trees required by spliceVMAs, and emits the per-page access traces that guide prefetching.

Kernel loader and working-set profiling. We implement working-set estimation in the kernel, co-located with the loader, to avoid perturbing access patterns. In profiling runs, the module records the pages that fault after `reexec()`. The next run uses this trace to drive prefetching and prefaulting. We iterate profiling and replay until the trace stabilizes and then ship the resulting SHELF as the production snapshot for that function. SHELF files are agnostic to the working-set estimation mechanism; while we use a simple page-fault-based profiler, other working-set estimators could generate the same trace format.

Snapshot-size reductions. Our language shims cooperate with Spice by running garbage collection and dropping language-level caches when signaled before snapshotting. On the host side, we translate `MADV_FREE` into `MADV_DONTNEED` during snapshot preparation and trim each thread's stack by discarding unused stack regions above the current stack pointer. We found that optimizations like these were able to reduce snapshot sizes by several MB in some cases.

5 Evaluation

We aim to evaluate Spice by answering the following questions:

1. How well does Spice reduce end-to-end cold-start latency in the context of existing snapshot/restore systems (§5.1)?
2. How does each element of Spice's design contribute to its performance (§5.2)?
3. Does Spice's centralized prefetching design scale (§5.3)?
4. How sensitive is Spice to the speed of the device used for snapshot storage (§5.4)?

Experimental Setup All experiments are conducted on a machine with an Intel(R) Xeon(R) Gold 5420+ with 28 cores running at 2.8GHz and 128 GB of RAM. Our storage device is a Crucial T705 NVMe drive with a max sequential read bandwidth of 13,600MB/s and 1400K IOPS over PCIe 5.0. Unless otherwise stated, we run all experiments from this drive and use it to store all SHELF files and shared libraries used during function invocations. We use the commonly evaluated FunctionBench [21] test suite, based directly on the artifact from [39]. We also ported two workloads to Node.js and Java, runtimes that are popular in serverless functions and exhibit more complex behaviors than Python. Table 1 summarizes the functions used to evaluate Spice. For a fair comparison, we do not benchmark function-agnostic container setup costs, such as configuring isolation mechanisms, because this work can be pre-initialized and shifted off the invocation critical path.

5.1 End-to-End Latency

To understand how Spice performs in the context of existing systems, we compare to existing snapshot/restore systems that restore snapshots entirely from storage without relying on any warm state. As discussed in §2, this includes CRIU [3] which snapshots at the process boundary, and both FaaSnap [7] and REAP [39] which operate at the VM boundary. Both FaaSnap

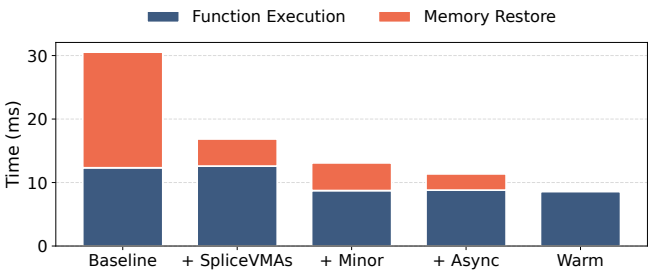

Figure 11: Ablation study of Spice's memory restore optimizations on the RNN serving Python function.

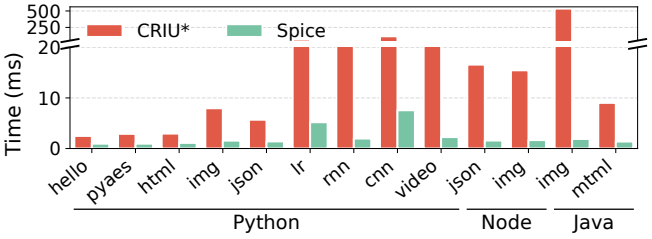

Figure 12: OS metadata restore time comparing CRIU to Spice. Spice lowers latency through a dedicated interface for restoring OS state and compact serialization.

and REAP employ working-set prefetching, while CRIU does not. We made every effort to tune existing systems to their peak performance, and our efforts yielded large performance gains for these systems relative to their out-of-the-box performance; therefore we refer to each of them with an asterisk in their name. In light of our observations regarding scheduler interference in VMs (§2.1), we modify the VM-based systems to use the `SCHED_FIFO` scheduling class for the function's process to minimize interference from other tasks running the guest. By default, CRIU copies every dirty page from the snapshot file back into memory. In-line with [42], we modified CRIU to use lazy mappings instead. While this results in slower execution time due to page faults, it provides a large win on end-to-end latency.

Figure 10 shows the end-to-end function invocation latency when restoring snapshots from storage with an entirely cold page cache. Spice is able to reduce latency significantly in all cases, by 17–96% compared to FaaSnap*, by 18–95% compared to REAP* and 14–96% compared to CRIU*. We show the latency of a warm invocation, which had been previously invoked several times but has cold micro-architectural state (e.g., CPU caches, TLB). This is a good approximation for an invocation on an otherwise busy system that is well utilized by many densely packed functions [4]. Spice is 1.01–6.34× slower than a warm invocation. We find the largest component of the remaining overhead comes from VMA creation, which cannot be parallelized with execution. Spice has the greatest impact on short-running functions, where restore latency can dominate execution time, but it also benefits longer-running functions by avoiding faults through prefetching and proactive PTE installation.

5.2 Microbenchmarks

Memory restore. We evaluate the impact of Spice's memory loading improvements in Figure 11, where we incrementally enable features of the SHELF loader and prefetcher for the RNN workload. In the baseline, the working set is packed contiguously in the snapshot file and prefetched from userspace. This necessitates creating 3212 VMA mappings to place the working-set pages in the proper location in the virtual address space. Adding spliceVMAs and batch creation of VMAs in the kernel dramatically lowers the time spent restoring virtual memory. Installing PTEs to prevent minor faults removes a significant portion of latency by avoiding thousands of kernel crossings during execution. Finally, asynchronous prefetching allows us to begin function execution sooner without incurring faults. With all optimizations, end-to-end function execution is within 2ms (23%) of a warm invocation, compared to 21ms (2.5× warm) added in the baseline case.

Cache State	# Intervals	Interval Trees	Maple Trees
Hot	10	4	41
	100	8	59
	1000	11	97
Cold	10	248	857
	100	278	874
	1000	284	1110

Table 3: Average lookup latency (cycles) for spliceVMA interval trees vs. Linux maple trees.

Metadata restore. Spice adds an interface to Junction for bulk restoring OS metadata, including threads, file descriptor state, signal handlers, and timers. Figure 12 compares the time spent on metadata restore for each workload to CRIU*, which reconstructs this state using thousands of syscalls. In all cases, Spice's metadata restore latency is significantly lower than that of CRIU*, demonstrating that snapshotting at the process boundary is a reasonable alternative to whole-VM snapshots.

Interval tree performance. Interval trees bridge Spice's file format and kernel abstraction, and are accessed on critical prefetching and fault handling paths. We compare their performance with that of the optimized B-Tree implementation used in Linux for VMA lookup (a step that typically precedes an interval tree lookup) in Table 3. Interval trees vastly outperform Linux's maple trees due to their contiguous, cache-friendly layout. In contrast, Linux's maple trees must handle concurrent updates and dynamic resizing.

Prefetcher performance. Figure 13 shows the rate at which Spice's prefetcher threads perform different restore operations. Prefetching shared pages is substantially more ex-

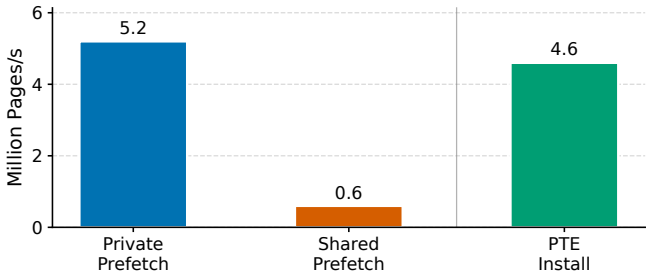

Figure 13: Peak operation rates for Spice prefetcher threads. Contiguous private pages can be prefetched at a much higher rate than scattered shared pages, which require more per-page lookup and I/O work. PTE installation also sustains a high rate, allowing it to keep pace with prefetching.

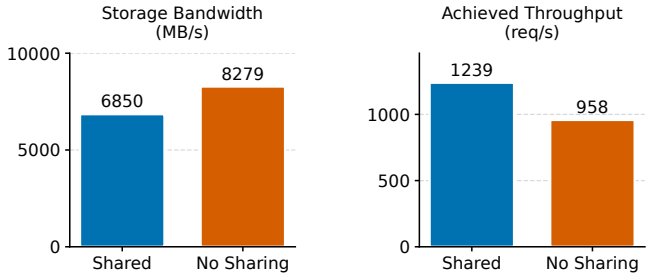

Figure 14: Storage bandwidth consumption and achieved throughput at 25 concurrent restores with and without page cache sharing. Sharing consumes less bandwidth and allows the system to achieve higher throughput.

	hello	pyaes	html	img	json	lr	rnn	cnn	video	node_json	node_img	mtml	java_img
Junction	.076	1.6	10.9	15.4	7.3	1.0	8.6	53.3	156.8	6.9	40.8	5.6	253.1
Linux	.001	1.3	10.2	14.3	5.9	.512	7.9	55.9	160.1	5.8	39.6	5.4	251.1

Table 4: Warm execution latencies (ms) for each function using Junction and Linux. Performance is largely similar between the two regimes.

pensive than prefetching private pages because shared pages are often scattered across many files and short extents, requiring per-page work to locate the backing file and issue the corresponding I/O. In contrast, SHELF stores private working-set pages contiguously, allowing Spice to issue larger, more efficient reads and prefetch at a much higher rate. Although PTE installation proceeds in observed access order rather than virtual-address order, Spice still sustains a high installation rate, allowing PTE installation to keep pace with prefetching.

Impact of sharing. Spice is designed to exploit the page cache to share pages from files (e.g., common libraries) when possible. Sharing in the page cache improves memory utilization, reduces storage bandwidth consumed, and can improve CPU cache efficiency [15]. We evaluate the benefit of this design by showing the storage bandwidth consumed and effective invocation throughput under a heavily concurrent function invocation workload (described in §5.3). We compare Spice with a version that doesn't allow sharing in the page cache, and instead stores the entirety of the snapshot in the SHELF image. Figure 14 shows that page-cache sharing reduces consumed I/O bandwidth by 20% and increases achievable invocation throughput by 30%. Without sharing, the system moves closer to storage saturation, causing prefetching to fall behind execution and exposing the restored functions to more page faults.

Impact of LibOS. Spice uses the Junction LibOS to implement fast OS metadata restore. Although Junction can accelerate kernel-intensive workloads through faster userspace implementations of standard OS services, our workloads are not kernel-intensive and therefore derive little benefit from these optimizations. To isolate the effect of Junction from the improvements shown relative to other systems, we report the warm execution latency of each function running in Junction and in Linux in Table 4.

5.3 Scaling

Spice relies on dedicated kernel threads to handle the asynchronous portions of prefetching and PTE installation for all restores. We evaluate Spice 's ability to scale in Figure 15, where we vary the number of concurrent restores and measure the achieved throughput. We construct this experiment using a mixed workload derived from the Azure public serverless traces [33]: we scale trace invocation durations to the execution time range of our workloads, map each invocation to the closest function in Table 1, and use the resulting distribution as the function mix. Our results show that Spice scales well, even under a mixed workload, achieving 76% of ideal throughput (extrapolated from the throughput at concurrency 1) at 25 concurrent restores.[1]

5.4 Sensitivity to Storage Device Performance

To understand how sensitive Spice is to storage performance, we evaluate it on a slower disk: a Micron 5400 PRO Series SSD rated for 540 MB/s and 95K IOPS. This experiment stresses the prefetcher by increasing I/O latency and reducing available bandwidth, allowing us to measure whether Spice can still hide restore work behind resumed execution when storage becomes a larger bottleneck.

Figure 16 compares performance on the fast and slow disks for three workloads with different execution latencies. We also compare this sensitivity against FaaSnap*. A single read

[1]There are 25 cores available on our machine for applications, after two are dedicated for prefetching and one for Junction's scheduler.

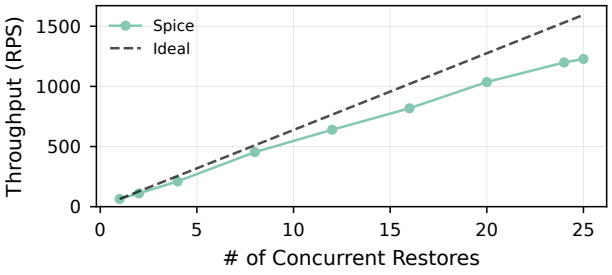

Figure 15: Aggregate throughput of function invocations with Spice as the number of concurrent restores increases, with a mix of all functions shown in Table 1.

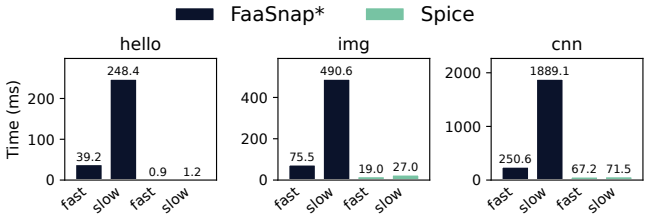

Figure 16: Impact of SSD speed on restore latency. The faster SSD has 2.8× lower read latency and 25× higher throughput than the slower SSD. Spice hides much of the additional latency of slower storage by prefetching asynchronously with execution, so restore latency is minimally affected as long as disk throughput is not the bottleneck.

takes 58 μs on the fast disk and 163 μs on the slow disk. Despite the increase in latency, Spice hides most of the difference by overlapping prefetching with resumed execution. This is possible because the slower disk still provides enough bandwidth to satisfy the demand of a single function restore.

FaaSnap*, by contrast, is much more sensitive to the slower disk. Because it already incurs many major faults during restore, increasing storage latency directly increases the cost of those faults and causes restore latency to grow by more than the proportional increase in single-read latency. We suspect this amplification is caused by the effects discussed in §2.1: delaying function completion gives other processes in the guest more opportunity to wake up, further polluting the working set and increasing interference.

6 Related Work

Working set estimation and prefetching. Working set estimation and prefetching have long been studied in serverless and other contexts [7, 39, 46]. Spice adds a dedicated kernel interface that accelerates prefetching and prefaulting; existing systems could benefit from this interface. Sabre [23] leverages a compression engine to improve effective I/O bandwidth from relatively slower SSDs; this is orthogonal to our approach. Faascale [47] and AFaas [10] both prefault EPT entries to reduce minor fault costs for VMs.

Fork scaling. Recent fork-like approaches [6, 10, 13, 19, 43] achieve low startup latency by cloning warm function instances. These systems are inspired by the kernel's `fork()` mechanism for cloning a process, and extend this concept to cloning containers [10, 13] or leveraging remote memory across RDMA or CXL [6, 19, 43] to create new function instances with demand paging. These techniques are effective for rapid horizontal scaling of functions — as long as a warm parent exists. As discussed in Section 1, the invocation patterns for most functions make retaining warm state for them economically infeasible. Spice targets this set of functions to enable fast cold starts from disk.

State reuse. Some systems aim to reuse partial state within a machine by creating stacks of increasingly specialized snapshot images [9, 10]. Because these stacks enforce a strict lineage of changes, they are effectively limited to sharing a single common base rather than the diverse mixtures of libraries used across functions. Medes [32] deduplicates memory across keep-alive containers so that more functions can remain warm, but still relies on long-lived sandboxes and existing OS restore interfaces. In contrast, Spice preserves large shared file-backed regions through spliceVMAs and focuses on making cold restores fast enough that platforms can rely less on aggressive keep-alive policies. VAS-CRIU [40] enables fast CRIU restores by keeping all pages in memory.

Sandboxing and the snapshot boundary. Existing systems use lightweight VMs [4, 7, 16, 23, 39], processes [22, 36, 40, 42], or containers [25, 32] as both their sandbox and snapshot boundary. As we discussed in Section 2, these approaches suffer from performance challenges. Some systems use alternative approaches for sandboxing. Faasm [34] relies on a Wasm runtime as the isolation mechanism, which offers low startup costs but higher end-to-end execution time compared to native Linux execution due to the cost of SFI [20]. SEUSS [9] implements a unikernel, tailoring its sandbox to executing a specific function. Unlike Spice, SEUSS requires backporting to support additional language runtimes, complicating deployment on existing FaaS platforms. AlloyStack [44] accelerates LibOS initialization via on-demand OS component loading. Spice could use similar techniques to avoid restoring some OS metadata, however, the time savings would be small.

Cold-start mitigation policies. Several systems try to reduce the impact of cold starts by increasing the fraction of requests that hit warm instances. They pre-warm sandboxes, tune keep-alive policies, or reuse containers to keep functions alive longer [5, 12, 16, 25, 27–30, 45]. Spice is complementary: instead of trying to avoid cold starts via longer warm lifetimes, it reduces the cost of the cold path itself, so platforms can rely less on aggressive keep-alive and prewarming. These approaches lower tail latency but consume memory and weaken elasticity, since resources must remain reserved for

functions that may be invoked rarely. Other work optimizes when to snapshot, so that captured state corresponds to a high-performance steady state [9, 48]. Spice benefits from these techniques.

Control-path optimization. Spice focuses on the data path of instance creation: reconstructing memory and process metadata from a snapshot. End-to-end latency also depends on the control path, including request scheduling, placement, and network setup. Dirigent [11], AFaaS [10], SigmaOS [38], and others [26, 37, 41] optimize these orchestration delays with smarter schedulers and resource managers. These efforts are orthogonal to ours. Achieving the lowest possible end-to-end latency requires a holistic approach, combining an efficient control path with the rapid restoration provided by Spice.

7 Discussion

Resource management and keep-alive policies. Spice's restore times in our prototype blur the line between warm and cold starts, potentially altering the economics of serverless resource management. The primary motivation for expensive keep-alive pools (avoiding the high latency of a cold start) is significantly diminished. This enables a new operational model where platforms can practice aggressive reclamation of idle instances to boost utilization, relying on just-in-time instantiation from disk to meet traffic demands without a major latency penalty.

This model also unlocks new strategies for cluster-level optimization. Because Spice leverages the host page cache for sharing, operators can create specialized node pools dedicated to functions with similar software stacks (e.g., a "Python+AI" pool). Co-locating these functions maximizes the page cache hit rate for common runtimes and libraries, which both accelerates restores and increases overall memory density through natural deduplication.

Integration with fork-based approaches. The snapshot/restore model of Spice is complementary to the cloning model of fork-based scaling mechanisms [6, 13, 43], which provide excellent latencies when scaling concurrent execution up from a warm instance. This relationship suggests a new, hybrid architecture for function instantiation. The principles of Spice's page-cache-aware design could be extended across the network to create a distributed page cache. Such a service would maintain a rack- or cluster-wide pool of frequently-accessed memory pages from common libraries and runtimes. During a restore, Spice could then source required pages from this low-latency remote memory fabric in addition to local storage, further reducing instantiation times and improving resource utilization across the cluster.

Limitations and future work. A key next step is extending our approach to virtualized environments. While our current techniques can already improve restore times inside a guest VM by reducing in-guest overheads, further potential can be unlocked with direct host-guest cooperation. This could be achieved with a custom hypercall interface that allows the guest to eagerly request EPT population for a dispersed working set. By enabling the guest to pass its predicted memory layout to the hypervisor in a single, batched operation, this approach would eliminate the thousands of costly VM exits typically caused by individual page faults during memory restoration.

Our prototype assumes that file-backed pages referenced by a SHELF snapshot can be resolved to the same file contents at restore time. We implement this by evaluating functions over a common static container image and recording static path names for file-backed mappings in the SHELF file. This simplifies the prototype, but a production implementation should use a more robust identity for file-backed pages, such as content hashes, image-layer identifiers, or another content-based naming scheme. Such an approach would avoid relying on path stability and would allow the loader to detect mismatches caused by image updates or configuration errors. More generally, SHELF only requires that shared file contents have stable identities across restores; this is compatible with existing approaches [8, 19] that use overlay file systems or image-layer deduplication to share common container contents across functions.

While Spice's `reexec()` mechanism is directly implemented in Linux, we chose to prototype metadata restore in Junction due to the simplicity of capturing C++ data structures in userspace with existing performant serialization libraries. We believe that implementing low-latency metadata restore on top of Linux is feasible but still requires significantly higher engineering effort. We hope that our efforts support the adoption of such a primitive by the kernel community.

8 Conclusion

By demonstrating that cold starts from persistent storage can achieve near-warm latency, this work redefines the fundamental trade-offs in serverless computing. The long-accepted compromise between performance and memory elasticity is not an inherent limitation, but an artifact of operating systems designed for an era before serverless. Our findings suggest that the focus of optimization should shift from userspace heuristics and keep-alive policies to first-class OS support for state restoration.

Spice serves as a blueprint for this new direction. By co-designing the execution engine with the kernel, we unlock a new operational model where functions can be aggressively offloaded to disk to maximize density and efficiency, yet instantiated in milliseconds on demand. This approach opens avenues for future platform architectures built around just-in-time, disk-based instantiation as the default, rather than the exception.

Acknowledgements

We thank our shepherd and anonymous reviewers, and many members of the PDOS group at MIT for their valuable feedback. We also thank CloudLab [14] for providing the testbeds for development and artifact evaluation. This research was supported by CNS-2212099, and by ACE, one of seven centers in JUMP 2.0, a Semiconductor Research Corporation (SRC) program sponsored by DARPA.

A Ablation Study

Table 5 shows the effect of Spice's memory-loading optimizations on the full suite of functions shown in Table 1.

B Artifact Appendix

Abstract

This artifact contains the source code of the Spice prototype, the benchmark harness used in our evaluation, and the source code for systems we compare to in our evaluation.

Scope

The artifact supports validation of the paper's primary performance claims: that Spice substantially reduces serverless cold-start latency relative to CRIU, REAP, and FaaSnap, and approaches the latency of a warm invocation. In particular, the provided experiment scripts reproduce end-to-end latency figure shown in Figure 10.

Contents

The artifact repository is organized as follows:

- `criu/`: a fork of CRIU with added benchmark timestamps and support for restoring an address space using `mmap()` only.
- `faasnap/`: a fork of the FaaSnap artifact, modified to support multiple functions and simplify the invocation path. This component is also used for the REAP experiments.
- `faasnap-kernel/`: the Linux 4.14 guest kernel used in the FaaSnap evaluation.
- `firecracker/`: FaaSnap's modified Firecracker VMM with support for detailed tracing of the guest kernel.
- `functions/`: serverless function workloads and input data, including Java, Node.js, and Python functions.
- `junction/`: the LibOS-based container system used by Spice to generate snapshots and invoke functions from snapshot images.
- `reexec/`: a Linux 6.5.0 kernel module that implements Spice's kernel-space SHELF snapshot loader.
- `shelftools/`: userspace tools for generating, editing, and reading snapshot images.
- `node/`: a modified Node.js runtime with support for freezing the garbage collector.
- `scripts/`: build, benchmark, utility, and plotting scripts used to run the artifact evaluation.

Hosting

The artifact is hosted on GitHub at:

`https://github.com/JunctionOS/spice-ae`

The repository contains several submodules. Evaluators should clone it recursively:

```
git clone https://github.com/JunctionOS/spice-ae
cd spice-ae
git submodule update --init --recursive
```

Requirements

The artifact has been developed and tested on a CloudLab [14] disk image running Ubuntu 24.04 with Linux 6.5.0. Building and running the artifact requires root privileges.

We have tested the artifact on a CloudLab `c6620` node with a Micron 7450 MAX NVMe SSD. The SSD used in the paper is rated for higher throughput/lower latency than the SSD in this CloudLab configuration, so absolute latency numbers may vary. The CloudLab configuration is located at `https://www.cloudlab.us/p/BlinkFaaS/Spice`.

Software and system requirements include:

- Ubuntu 24.04.
- Linux 6.5.0 for the host kernel module used by Spice.
- Root privileges.
- Sufficient disk space for building dependencies and storing snapshot files.
- Approximately 20 GB of disk space for the build, excluding snapshot files.
- A snapshot directory on an SSD-backed mount point, for example `/mnt/unused-nvme1n1/snapshots`.

B.1 Setup

The `README.md` in the GitHub repo contains detailed instructions on setting up and running the artifact.

Table 5: Results from ablation study in §5.2 for all functions, showing the importance of the loader's design elements. Values in each column reflect slowdowns relative to warm.

B.2 Expected Results

The main expected result is an end-to-end latency plot showing that Spice significantly reduces cold-start latency compared with FaaSnap, REAP, and CRIU, while approaching warm invocation performance. The exact numbers may vary with SSD performance.

Distributed Speculative Execution for Resilient Cloud Applications

Abstract

Fault-tolerance is critically important in highly distributed modern cloud applications. Solutions such as Temporal, Azure Durable Functions, and Beldi hide fault-tolerance complexity from developers by automatically persisting execution state and resuming seamlessly after failure. This pattern, often called *durable execution*, usually forces frequent and synchronous persistence, resulting in significant latency overheads. In this paper, we propose *distributed speculative execution* (DSE), a technique for implementing the durable execution abstraction without incurring this penalty. With DSE, developers write code assuming synchronous persistence, and a DSE *runtime* is responsible for transparently eliding persistence and reactively repairing application state on failure. We present libDSE, the first DSE application framework that achieves this vision. To hide speculation from application code, we design a novel programming model centered around message-passing, atomic code blocks, and lightweight threads, and show that it allows developers to build a variety of speculative services, including write-ahead logs, key-value stores, event brokers, and fault-tolerant workflows. Our evaluation shows that libDSE reduces end-to-end latency by up to an order of magnitude for persistence-bound applications compared to current durable execution systems with minimal runtime overhead and complexity.

1 Introduction

Modern cloud applications are more distributed than ever. Companies have long adopted microservice-oriented architectures, splitting their applications into hundreds of loosely coupled, independently deployed distributed components [2, 43]. Recent proposals, such as serverless and granular computing [49, 55], have pushed for even more distribution at a finer granularity. Benefits aside, this makes every modern cloud application inherently distributed and fault tolerance a key challenge, leading to a new class of *Durable Execution* [10] systems (e.g., Azure Durable Functions [8], Temporal [30]). These systems automatically persist application state where necessary and transparently recover from failures to resume execution. Today, they are widely used to orchestrate microservices or serverless workers [12–14, 16, 17, 20, 22, 27, 32, 48, 76, 78]. Despite growing popularity, however, durable execution engines often must perform frequent and synchronous state persistence for correctness, which results in high latency overhead (Section 2). Worse, this *persistence amplification* scales with the degree of distribution — as the application is split into more distributed components, synchronous persistence becomes more frequent and expensive.

In this paper, we propose *distributed speculative execution* (DSE), which decouples the abstraction of durable execution from its physical execution pattern. DSE bypasses synchronous persistence on the failure-free path, allowing services to communicate speculatively. To ensure correctness, the runtime acts as a speculation sandbox, buffering outputs to external systems (e.g., the user, legacy databases) until the underlying state is durable. This dramatically reduces perceived latency on the common path, in exchange for more complex failure recovery. This trade-off is worthwhile as long as the unit of speculation (e.g., an RPC request) is more likely to succeed than to be interrupted by a failure.

Speculation is not a new idea. Prior work in hardware [70], databases [39, 44], and file systems [35, 62, 63] used similar techniques to hide latency. However, applying speculation to modern cloud applications introduces new challenges.

Many previous systems assume a canonical shared state (e.g., main memory, distributed file system). Participants locally speculate on the outcome of operations on that shared state without committing speculative state. In contrast, many modern cloud applications adopt a shared-nothing, message-passing architecture (e.g., microservices, event-driven architecture). This requires speculation across multiple independent, failure-prone entities (i.e., on both sides of a message channel). Consequently, DSE must correctly orchestrate distributed rollbacks across multiple participants when failures occur. Additionally, such rollbacks can interleave and race with client logic unless the client rigorously protects itself by

synchronizing against possible rollbacks at any time, resulting in significant conceptual and engineering complexity.

To solve these challenges, we build libDSE, a speculative programming framework for message-passing applications. For the first challenge, orchestrating distributed rollbacks, libDSE adapts the *Distributed Prefix Recovery* (DPR) protocol [57], a distributed cache recovery scheme, to our message-passing setting. LibDSE automatically instruments messages (e.g., RPC calls) between services to build and maintain a recovery dependency graph. The graph is used to determine when results are safe to expose externally, and to compute a consistent snapshot for every affected component to roll back to after failure. Component services are required to expose hooks, enabling the libDSE runtime to force persistence/rollback when necessary and prevent unbounded growth of the dependency graph.

For the second challenge, synchronizing against possible rollbacks, libDSE provides a speculation-native programming model centered around two intuitive primitives, *actions* and *sthreads*. Actions are user-defined atomic blocks that are guaranteed by libDSE not to overlap with persist/recovery/rollback invocations. Sthreads are stateless and lightweight threads of execution that allow libDSE to guarantee correctness for long-running or asynchronous operations that cannot execute atomically. Advanced developers exercise fine-grained control over speculation behavior through *speculation barriers*, analogous to memory barriers [26], which allow libDSE services to co-exist with non-speculative components by only exposing non-speculative results.

Using libDSE, developers can build speculative message-passing services while relying on the framework to manage the complexities of distributed dependency tracking and concurrent rollback/recovery. We demonstrate the benefits and trade-offs of DSE by building three representative applications: a travel reservation workflow, a high-throughput event processor, and a transaction processing system. We evaluate our libDSE-based implementation against state-of-the-art production and research systems, including Temporal [30], DARQ [56], and Microsoft Orleans [29], showing that it can reduce end-to-end latency by up to an order of magnitude. We also quantify the engineering effort of adopting libDSE and discuss the practical implications of its programming model. In summary, our contributions are:

- We propose a new distributed speculative execution (DSE) scheme that dramatically reduces fault-tolerance overhead in durably executed applications.
- We present the design and implementation of libDSE, the first DSE programming framework for modern shared-nothing message-passing cloud applications.
- We present a detailed evaluation of libDSE on a diverse set of cloud applications, showing up to an order of magnitude latency savings compared to current, non-speculative implementations.

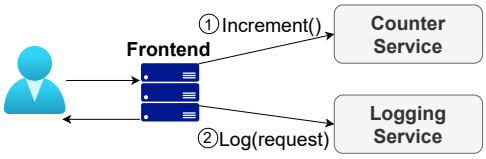

Figure 1: A Simple Running Example

2 Background and Motivation

Running Example. Consider a toy example of an application that consists of a frontend layer, a counter service, and a logging service. Users issue requests to the frontend to increment the counter. Each request and its result are then sent to the logging service for bookkeeping purposes. Failures can result in a number of anomalies even in this simple scenario. Each service can crash and lose data. The frontend server can crash after a successful increment but fail to log the incremented value. Naive attempts to solve this may retry the operation, and cause the services to increment or log too many times. While these anomalies appear innocuous in the toy example, they are highly undesirable in real-world scenarios. If an e-commerce company uses a similar architecture to connect their payment and fulfillment services, such anomalies can lead to double charging or unfulfilled orders. Developers often resort to principled solutions like durable execution to prevent such anomalies.

2.1 Current Solution

Durable execution creates an illusion of uninterrupted, failure-free execution by persisting application state at every step and automatically retrying execution after failure. The goal of durable execution is to ensure that users cannot distinguish between executions of the application with failures, and ones without (except perhaps through performance degradation) [4]. Today's cloud architect might achieve durable execution in our running example by first making each service durable (e.g., by persisting to a database before returning), and then using a resilient workflow engine (e.g., Temporal) to orchestrate the frontend calls.

To protect against frontend failure, the workflow engine automatically persists operation intents [69] and intermediate results, and retries on failure. Each stateful service must be programmed for *idempotency* – retried requests must have no visible effects beyond their first execution, e.g., by attaching a unique ID to each request and de-duplicating on the service side. In our running example, the workflow engine would execute an increment call by first persisting the intent to increment and generate a unique request ID, retry until successful, and persist the result. Under the hood, the workflow system maintains (sometimes implicitly) a directed acyclic graph

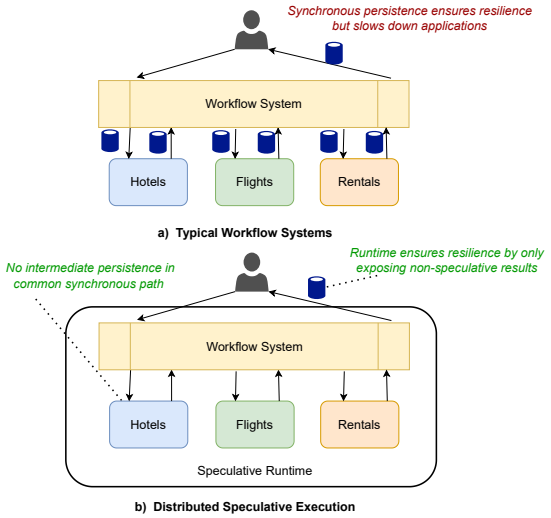

Figure 2: DSE optimizes durable execution by transparently eliding synchronous persistence and waiting in parallel

(DAG) of stateful tasks, and ensures at-least-once execution (which is equivalent to exactly-once if tasks are idempotent).

Most such systems today must synchronously persist each task's output before starting the next task. Otherwise, if tasks are non-deterministic, a replay may yield different outputs and spawn different downstream tasks. The divergent tasks may then conflict and cause anomalies. Consequently, almost all of today's durable execution systems have cumulative latency overheads that scale with the depth of the task graph.

Our Solution. In contrast, DSE forges ahead before operation intents, effects, or intermediate results are durable, greatly reducing latency. This inevitably leads to anomalies upon failures. To maintain the same durable execution guarantees, DSE applications must detect such inconsistencies, repair them, and prevent external users from observing them. In other words, the requirements of correct DSE are:

- *Recoverability.* Inconsistencies are eventually repaired.
- *Failure Transparency.* External entities (e.g., clients) never observe failure-induced inconsistencies.

Fundamentally, this means that DSE systems are rollback-based recovery systems [42]. Any solution must design protocols that correctly track recovery dependencies between participants, determine when state becomes recoverable, and roll back unrecoverable state on failure. On failure, the system determines the extent of failure based on collected dependencies and orchestrates rollback across participants to restore the application to a consistent state. Such schemes support non-determinism, as non-deterministic operations are either restored from persisted state and never replayed, or all their effects are rolled back. The key trade-off is that on failure, DSE systems lose speculative work and must coordinate rollback, which adds complexity.

2.2 System Model and Assumptions

Before we proceed, we discuss the system model and assumptions made for DSE that set it apart from earlier work.

Failure Model. Each component has *fail-restart* semantics [56], meaning it may fail at any point and lose its volatile in-memory state. However, it is guaranteed to restart in bounded time and recover from state that it has explicitly persisted before failure. Multiple incarnations of the same component may temporarily co-exist due to network partitions. We do not consider Byzantine failures.

Network. We assume reliable point-to-point communication channels (e.g., TCP/IP), meaning messages are not lost or corrupted. Network partitions can occur, temporarily preventing services from communicating.

Storage and Persistence. Each component has access to its own private durable storage that persists across failures, such as a local log, remote replicas, or a backend database. However, to enforce loose coupling between components, components cannot directly access each other's storage.

2.3 Targeted Workloads and Boundaries

DSE is broadly applicable to applications dominated by serial persistence overheads. Beyond microservice orchestration, DSE naturally targets:

Event-driven Processing. Many modern cloud systems use event-driven pipelines to process streams of data. While the initial ingestion may be durably logged upfront for reliability, the state of each processing operator in the pipeline must also be fault-tolerant. In conventional systems like Kafka Streams [73], this requires each operator to synchronously persist its intermediate state before passing results to the next stage, incurring a persistence penalty at each step. DSE can optimize this by allowing intermediate states to be managed speculatively, eliminating synchronous I/O between stages.

Distributed Transactions. Many applications require atomic updates across multiple microservices (e.g., orchestrating checkout between inventory, payment, and shipping). This is often achieved using distributed transaction protocols (e.g., two-phase commit [54, 60]), which rely on frequent, synchronous logging to a durable medium. DSE can transparently hide the latency of these synchronous log writes from the critical path without requiring changes to the core protocol logic.

Conversely, DSE's benefits diminish when applied to workloads where persistence is not the primary bottleneck. For *compute-heavy applications*, such as agentic exploration or a video transcoding pipeline, task execution time vastly overshadows persistence latency. In these scenarios, the latency saved by DSE can be negligible to the end-to-end execution time, as compute cost dominates. Similarly, for *shallow, CRUD-heavy applications*, the latency savings are proportionally smaller due to shorter execution chains. However, even for these simple applications, traditional durable execution

engines typically persist execution history (e.g., intent to execute, task start, and task completion) to guarantee deterministic replay. This turns single logical operations into multiple synchronous persistence operations. Consequently, DSE still provides measurable improvements for shallow workloads by bypassing these framework-injected persistence roundtrips, though the absolute savings are less dramatic than in deep workflows.

3 libDSE Design

DSE application developers build speculative services by encapsulating application state into `StateObject`s. Application developers define `StateObject`s by implementing a set of methods to persist or restore application state and using libDSE's primitives to protect state access. It is the responsibility of libDSE to manage the complexity of speculation and failure recovery; it 1) persists, recovers, or rolls back `StateObject`s when necessary by invoking developer-supplied methods, 2) instruments application messages to establish dependencies, drop rolled back messages, or delays speculative messages where necessary for safety, and 3) implements concurrency control primitives to protect application logic against rollbacks. Application developers do not need to implement the distributed recovery protocol logic or reason about speculation beyond specifying atomicity boundaries using libDSE. The rest of this section focuses on these primitives (Table 1). We discuss the details of how libDSE orchestrates speculative execution in Section 4.

3.1 StateObjects and Actions

Users create `StateObject`s by implementing the abstract `StateObject` API shown in Table 1. We show an example implementation of the counter service from our running example using cloud storage files in Figure 3. The framework ensures that `Persist` and `Restore` are not concurrently invoked. For performance, the `Persist` API is asynchronous; users may return from the call once the persistence operation is issued (e.g., flush the log at a specific offset), but before it is completed. While conceptually simple, `Restore` encapsulates two different use cases, one where the `StateObject` has failed and must reload state from persistent storage, and another where the `StateObject` responds to a rollback. For both cases, the example loads persistent state. This is correct for the latter, but potentially slow and inefficient. Developers are therefore encouraged to distinguish between these two cases (e.g., by checking if `value == default` in the example) and apply application-specific optimizations (e.g., by leveraging built-in multi-versioning [34, 65, 67]). If the `StateObject` crashes, the runtime uses `ListVersions` to identify unpruned `Persist` calls. This API easily allows for alternative implementations of persistence and recovery. For

```
1  class CounterStateObject : StateObject {
2    int value;
3
4    void Persist(long ver, byte[] m, Action c) {
5      var content = Marshall(ver, m);
6      // async write to cloud storage
7      Task.Run(() => {
8        WriteFile(GetName(v), content);
9        c();
10     });
11   }
12
13   byte[] Restore(long ver) {
14     content = ReadFile(GetName(ver));
15     var v, metadata = Unmarshall(content);
16     this.value = v;
17     return metadata;
18   }
19   ...
20 }
```

Figure 3: Example `StateObject` Implementation

```
1  class CounterService {
2    CounterStateObject so;
3
4    // Handler for RPC call to increment counter
5    IncrementResponse Increment(
6        IncrementRequest r) {
7      if (!so.StartAction(r.header)) throw;
8      response = new IncrementResponse();
9      response.result =
10         AtomicInc(so.value, r.incrementBy);
11     response.header = so.EndAction();
12     return response;
13   }
14   ...
15 }
```

Figure 4: Example CounterService Implementation

example, one can implement the counter service via either logging and replay or a replicated state machine.

libDSE organizes operations on `StateObject`s as a series of atomic execution units called actions. Each action's effects are either entirely persisted or entirely lost due to recovery or rollback. libDSE achieves this by ensuring actions never interleave with `Persist` or `Restore` operations. However, actions may execute concurrently with each other to allow for parallelism. Messages are consumed as part of actions or produced as a result of actions. libDSE provides users with flexibility on how best to deliver messages between `StateObject`s, relying on users to pass opaque headers rather than mandating a specific messaging implementation.

We present an example in Figure 4 that implements our counter service using gRPC [21]. Each message is instrumented with a `.header` field that holds metadata for libDSE (more on this later). If `StartAction` returns false, the message's sender was rolled back, and the message must be discarded. Otherwise, libDSE protects execution after line 7

StateObject API	**Semantics**
`StartAction(header) → bool`	Start an atomic action, (optionally) receive the given libDSE message header. If returned false, the message originates from rolled back state and should be discarded.
`EndAction() → header`	End an atomic action and (optionally) produce a header that encodes dependencies for any outgoing messages resulting from this action.
`Connect(config)`	Connect this `StateObject` to a libDSE Coordinator using the given configuration. Must be invoked exactly once before performing any other operation.
`Refresh()`	Refresh should be periodically called to perform libDSE background tasks and guarantee progress for the cluster.
`Detach() → sthread`	Temporarily suspend an action and produce a sthread that can be used for speculative operations independent of this `StateObject`.
`Merge(sthread) → bool`	Resume an action by merging the detached sthread back into this `StateObject` and update its dependencies. If false, the state leading to the creation of the sthread was rolled back and the sthread should be discarded.
sthread API	**Semantics**
`Receive(header) → bool`	Attempt to receive the given libDSE message header. If returned false, the message should be discarded. Throws exception if the sthread is rolled back.
`Send() → header`	Produce a header that encodes current dependencies of this sthread.
`Barrier()`	Blocks until all state observed by this sthread becomes non-speculative. Throws exception if the sthread is rolled back.
StateObject Callbacks	**Semantics**
`Persist(v, metadata, onPersist)`	Persist the current state and `metadata` as version `v` and then invoke `onPersist`.
`Restore(v) → metadata`	Recover (or roll back) to the given version and return associated metadata.
`Prune(v)`	Signal that a version (and all that precede it) can be pruned.
`ListVersions() → metadata[]`	List all unpruned versions and associated metadata.

Table 1: Summary of libDSE API

from libDSE-triggered persists and restores. Users still need to guard against multiple concurrent requests, and hence use the thread-safe version of increment in line 10. Finally, it ends the action, obtaining a header to pass back to the caller.

3.2 Handling Asynchrony

Long-running actions can block persistence until finished and halt persistence progress across the cluster. For example, the frontend server in our running example issues RPCs that may complete asynchronously and automatically retry in the background. In some settings, long running actions may even block each other and cause a deadlock. libDSE introduces *sthreads* to prevent this from happening. A sthread is essentially a lightweight thread of execution within a `StateObject` that encodes the speculative state of its parent `StateObject` at the time of sthread creation.

We show an example in Figure 5. Here, the frontend workflow orchestrator calls `Detach` after marking the start of workflow (line 7), but before executing the step (i.e., calling the service) (line 10). After line 8, application code no longer runs in an atomic block, and may go to sleep, retry, or otherwise perform long-running operations without blocking the `StateObject`. Thus, in the event of a rollback, the sthread may still temporarily continue to execute. It is therefore essential that sthreads are treated as *independent, standalone* participants of the system and interact with other participants, including their parent `StateObject`s, exclusively through libDSE-instrumented message passing. For example, on line

```
1  ...
2  WorkflowEngineStateObject so;
3  ...
4  // Handler for RPC call to execute workflow
5  async Task ExecWorkflow(WorkflowRequest r) {
6    if (!so.StartAction(r.header)) throw;
7    so.MarkWorkflowStart(r);
8    var  t = so.Detach();
9    // Request executes outside atomic block
10   cReq = ComposeRequest(r, t.Send());
11   var cRes =
12       await CallCounterServiceAsync(cReq);
13   if (!so.Merge(t)) throw;
14   // Back in an atomic block
15   so.UpdateWorkflow(cRes);
16   ...
17   // Finally, return after barrier to
18   // hide speculation from caller
19   await so.Detach().Barrier();
20   return response;
21 }
```

Figure 5: Example Workflow Implementation with libDSE

12, we obtain the result of an asynchronous action, but cannot yet consume its result; this must happen after the sthread is merged to start a new action (line 13), which logically sends a message from sthread that `StateObject` receives. If the system experiences a rollback while the asynchronous action runs, `StateObject` rejects the message and the sthread can simply terminate. The sthread represents state derived from its parent, which will recover independently and respawn the sthread if necessary.

Finally, sthreads support barriers, which provide fine-grained control over speculative behavior. Similar to a memory fence, a barrier blocks until everything the sthread received becomes non-speculative, thus preventing speculation across the barrier. Only sthreads are allowed to invoke barriers, as they are, by definition, blocking. Barriers are useful when interacting with external entities. For example, in line 19 of Figure 5, by detaching and calling barrier, execution of line 20 will be delayed until the response becomes non-speculative, thereby only sending non-speculative results to users. In many cases, barriers can be automatically inserted (e.g., at the end of an RPC handler processing an external user request), but advanced users may also use barriers to prevent speculative dependencies between parts of their applications. For example, inserting a barrier before line 7 prevents the system from logging workflow starts speculatively.

4 Speculative Protocol

4.1 Inspiration: DPR

Distributed Prefix Recovery (DPR) [57] is a recently proposed technique for causal consistency across sharded cache-stores – storage units spanning volatile memory and durable storage. For example, a shard within a partitioned database with an accompanying Redis caching layer can be considered a (logical) cache-store. Often in such an architecture, the caches are *write-through*: clients read from the cache, but write directly to the backend storage. In contrast, DPR is *write-back*: writes directly update the cache for increased throughput and immediate visibility, and cached entries are asynchronously flushed to storage. This leads to lost writes if caches fail, which may cause application anomalies as readers may have acted on lost updates. DPR presents a lightweight protocol for addressing this problem. First, operation completion and persistence are decoupled using two acknowledgements. Second, DPR clients interact with cache-stores explicitly through *sessions*. Each session is a (linearizable) sequence of operations and DPR guarantees that any surviving state corresponds to session *prefixes*. This ensures that no surviving operation depends on a lost operation when a cache node fails.

Our Insights. We identify two key mismatches between DPR and modern microservices. First, DPR has a rigid client-server formulation. DPR clients are first-class citizens but do not participate in rollbacks; they are responsible for discovering rollbacks and resuming (potentially replaying) operations. This complexity is compounded by possible client failures, as a recovered (amnesiac) client may lack the information needed to handle a rollback. libDSE eliminates this distinction by treating every component as a stateful, message-passing peer, correctly modeling that application control flow (e.g., in a workflow orchestrator) is itself state that must participate in rollbacks. Second, the original DPR relies on a stateful coordinator backed by an external database. Consequently, DPR requires an additional synchronous persist on the failure-free path before writes are recoverable. We improve upon this with a deterministic and stateless coordinator design where the ground truth is the collective persistent state of participants, thereby removing this overhead.

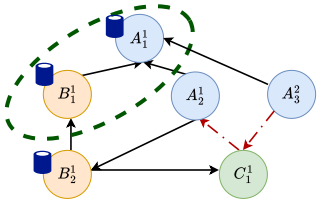

Figure 6: Example Dependency Graph

4.2 Protocol Details

The libDSE protocol centers on an explicit recovery dependency graph that all participants jointly maintain. We first define this graph, then describe the sub-protocols that operate on it: *instrumentation* populates the graph as the application runs, *boundary-finding* identifies regions of the graph that are safely committed and may be externally exposed, and *recovery* uses the graph to coordinate rollback on failure.

Dependency Graph. We show an example dependency graph in Figure 6. Each vertex of the graph is a recoverable point that can be loaded via `Restore`, and is uniquely identified by a combination of a `StateObject` id, a global failure counter (more details on this later), and a local persistence counter. For example, A_2^1 is the recoverable point from `StateObject` A with local persistence counter 2 and global failure counter 1. Vertices start off volatile, but become persistent as the underlying `StateObject` persists their state. In the example, A_1^1 is persistent, but A_2^1 is not yet. Edges of the dependency graph represent recovery dependencies – an edge from u to v iff u recovering without v results in an inconsistency. By definition of consistency [53], such a dependency is established either implicitly by precedence (i.e., u is later than v in the same `StateObject`), or if u received a message originating from state captured by v. Because each recoverable point captures multiple state transitions and messages, the dependency graph may have cycles. Because libDSE tracks dependencies at the granularity of recoverable points, rolling back a recoverable point wipes out all state updates and messages captured, even if only one was poisoned. This false sharing is a deliberate design choice. Per-message dependency tracking would impose substantial bookkeeping overhead on the failure-free path and require multi-round communication on failure to disambiguate causality. Another subtle but important property of this formulation is that recovery dependencies are established at *message consumption*, not at data read or write. This is what allows libDSE to handle indirect, control-flow dependencies uniformly with the data dependencies that prior work

focuses on. Consider a workflow orchestrator that receives a confirmation from service A and, based on the confirmation, conditionally invokes service B. The orchestrator never reads or writes A's state directly — but its decision to branch toward B causally depends on having consumed A's message. By tracking dependencies at message consumption, libDSE correctly classifies the invocation of B as recoverable only if A's confirmation is recoverable, even though the data flow between them is opaque.

Instrumentation Protocol. libDSE tags each message with its originating vertex on the dependency graph (the content of the aforementioned libDSE headers). If a `StateObject` receives a message from v when its current (not yet persisted) recoverable point is u, it adds an edge from u to v in the dependency graph. Each `StateObject` accumulates dependency graph updates and sends them periodically to the libDSE coordinator after persistence.

Boundary Protocol. A *Recoverable Boundary* is a cut of the graph where no future failure will cause vertices within the boundary to roll back. Messages originating from within the boundary are therefore not speculative and safe to expose externally. Recoverable boundaries manifest on the graph as closures, i.e., sets of vertices that 1) are all recoverable and 2) have no edge leading to non-recoverable vertices. For example, in Figure 6, A_1^1 and B_1^1 form a closure, but A_1^1, B_1^1, and B_2^1 do not because B_2^1 depends on C_1^1, which is not yet persistent. The coordinator finds boundaries by periodically searching the graph. However, a naïve implementation is susceptible to *the domino effect* [42], where frequent communications cause a node to always transitively depend on future, uncommitted versions, and there is no way to bound the blast radius of a rollback. To prevent this:

Definition 4.1. (Commit Ordering Rule) A_y^x is allowed to receive a message from B_n^m only if $y \geq n$.

For example, under this scheme, there cannot be an edge (red dotted arrow) from C_1^1 to A_2^1. The libDSE runtime would block an action from starting if the message it consumes has a larger persistence counter. Meanwhile, libDSE transparently issues `Persist`, which advances the local counter (e.g., from C_1^1 to C_2^1); the action can start immediately after the call without waiting for actual persistence. Intuitively, this scheme prevents the domino effect by guaranteeing that for any vertex A_y^x, the set of vertices with persistence number $\leq y$ is a closure that includes A_y^x. As a trade-off, participants that communicate frequently passively synchronize and will tend to issue persists on similar schedules.

Recovery Protocol. Failures lead to vertex loss on the dependency graph, and the system state is inconsistent iff any surviving vertex has an edge into a lost vertex. To recover, the system must roll back vertices until no such violations exist. The primary challenge here is that the system must achieve *consensus* on rollbacks; otherwise, overlapping failures or out-of-sync views of the dependency graph may result in different parts of the system recovering to different closures and creating inconsistency in the process. The global failure counter from before is how we encode consensus – upon failure, a leader assigns a monotonically increasing and unique failure sequence number to the rollback. Each participant of the rollback then recovers to the prescribed state at their own pace. In the example, A_3^2 signals that A has recovered from a failure and is now operating in the post-recovery world. Crucially, while every participant must eventually acknowledge recovery, they do not necessarily actively roll back if they are not impacted. A node like C_1^1 does not depend on any external nodes, and therefore can simply rename itself to C_2^1 without active recovery work. However, during recovery, there is a temporary divergence in the cluster between pre-recovery and post-recovery halves (or more if there are multiple concurrent failures). libDSE disallows communication across failure counters for safety:

Definition 4.2. (Recovery Partition Rule) A_y^x is allowed to receive a message from B_n^m only if $x = m$. If $m < x$, the message is discarded; otherwise, its receipt must be delayed.

In the example, if post-recovery A now receives a message from C_1^1, it again cannot receive the message (red dotted arrow), because otherwise, it would have potentially acted on a message from pre-recovery world that will be rolled back in the post-recovery world, polluting it. Instead, A would reply to C telling it about the failure and the action the cluster took to resolve it, allowing C to reconcile its view of the cluster state.

Supporting sthreads. Unlike `StateObject`s, sthreads are derived state and never appear as vertices in the dependency graph, but they do carry a dependency *set* that is updated as the sthread executes. On receiving a message tagged v, the sthread inserts v into its set. On send, the full set is attached to the header, so a sthread-originated message carries a set of triples rather than a single triple. The set is merged into the receiving `StateObject`'s in-memory vertex, producing the corresponding incoming edges as if the sthread's predecessors had sent directly. At every barrier or merge, the set is cleared, preventing unbounded growth. This is safe because a barrier is a quiescence point: any speculative work the sthread is carrying either commits past the barrier or is abandoned on rollback, and either way is no longer the sthread's dependency to track.

4.3 Coordinator Design

We now describe the design of our coordinator. Unlike DPR's, the libDSE coordinator is backed by a persistent log (either through distributed consensus like Raft [64] or reliable cloud storage) that encodes changes to the cluster state, such as membership changes and recoveries.

Finding Boundaries. LibDSE automatically persists fragments of the dependency graph as part of `StateObject`s us-

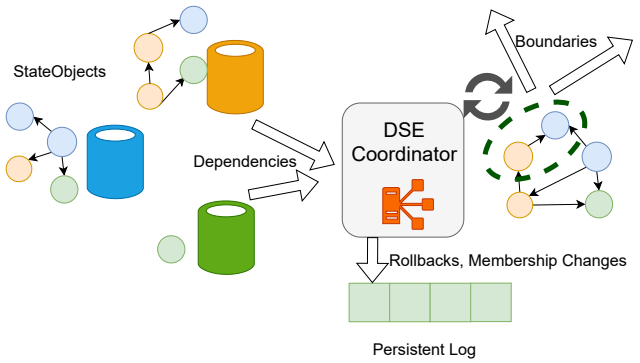

Figure 7: libDSE Coordinator Design

ing the metadata parameter on `Persist`. This establishes the distributed components as the ground truth; the coordinator maintains a (potentially stale) view of the actual graph. Newly persistent versions and in-flight operations may be missing from the coordinator's view. That said, the persistent part of the graph is *immutable*. Future operations may add vertices, but cannot change dependencies in the past. This makes it safe for the coordinator to declare recoverable boundaries on the coordinator's view, because any recoverable boundaries the coordinator finds on its present view must also be recoverable on a later view. Consequently, the coordinator does *not* persist its decisions on the failure-free path – restarted coordinators instead recompute the boundary on a more up-to-date view to find the same (or larger) recoverable boundary. To find recovery boundaries, the coordinator runs a standard graph BFS over its in-memory view of the graph and publishes its results immediately.

Orchestrating Rollback. A rollback is triggered when one of the `StateObject`s fails, and the coordinator computes the extent of data loss by removing any vertices on the dependency graph not reported as persistent by the restarting `StateObject`. Then, it iteratively removes vertices from the graph until no surviving vertex has a dangling edge. As discussed in Section 4.2, on failure, the coordinator must achieve *consensus* between `StateObject`s on what the final state of the graph is in response to the restart. This is achieved by synchronously persisting the failure (by assigning it a failure sequence number) and the rollback actions proposed, before releasing the decision to the rest of the cluster on the log.

Coordinator Recovery. Even though the coordinator is ephemeral, when a coordinator fails, the system must still perform some necessary steps to ensure correctness. On recovery, the new coordinator needs to reconstruct the cluster state, including previous rollback decisions and the list of active participants by replaying the persistent log. It then resends recent rollback decisions and asks for every participant to send locally stored dependency graph segments, which guarantees a view of the dependency graph that is more up-to-date than before the failure. The coordinator cannot answer queries about the current recovery boundary until every participant has responded to ensure a complete view of the graph.

4.4 Correctness Sketch

A full formal proof is out of scope for this paper. We sketch the informal argument here, addressing safety (the protocol never externally exposes inconsistent state), liveness (the protocol always makes progress), and the rollback bound.

Safety. Our libDSE protocol guarantees that external entities do not observe rollback-induced anomalies. Because the system exposes a message externally only after its originating vertex lies within a declared recoverable boundary $\mathcal{B}$. By definition, every out-edge of $u \in \mathcal{B}$ points to another vertex in $\mathcal{B}$, and every vertex in $\mathcal{B}$ has been reported persistent. A future failure can only invalidate vertices not yet persistent, which will not affect any vertex in $\mathcal{B}$. The Recovery Partition Rule additionally prevents participants from acting on or communicating across different pre/post-recovery splits for all failures, so recovery will not introduce additional anomalies.

Liveness. Given liveness of local persistence and recovery, libDSE guarantees to eventually declare every message non-speculative or rolled back. In the failure-free path, this is because 1) local persistence advances independently of each other and does not block on the progress of others (i.e., no deadlock), and 2) the Commit Ordering Rule guarantees finite closure for every recoverable point, which will eventually all become persistence given local liveness. On the failure path, each failure receives a strictly increasing sequence number on the coordinator's persistent log, and by assumption each induced rollback completes in finite time. A message m originating from u is therefore, in finite time, either (i) rolled back, if u lies in the lost set of some failure, or (ii) preserved across the failures u experiences, in which case the failure-free argument applies during any subsequent quiescent interval.

Bounded Rollback. As argued previously, the Commit Ordering Rule ensures $\{v : \text{counter}(v) \leq k\}$ is a closure for any k. Therefore, when a `StateObject` loses state past counter k, the rollback at every other participant is bounded by that participant's own persistence progress past k.

5 Implementation and Discussion

5.1 Putting it Together: libDSE Runtime

The libDSE runtime implements the aforementioned programming model, and connects each `StateObject` to the coordinator. The core libDSE and coordinator implementation consists of approximately 4000 lines of C# code.

gRPC Integrations. libDSE has built-in integration with gRPC [21] and ASP.NET [6]. To create a speculative service, users first write the service API using vanilla gRPC, encapsulate the state with a `StateObject`, and implement the generated gRPC stub using the libDSE API. During runtime, a

libDSE gRPC interceptor [23] automatically injects action boundaries before and after RPC handlers execute, and uses the HTTP headers to transparently pass libDSE headers. The presence of the special header is also used to infer whether the endpoint has speculation enabled (e.g., an external user would believe the speculative service is just another gRPC endpoint and send requests without libDSE headers), and automatically apply barriers to hide speculation. Advanced users can disable the interceptor and manually call libDSE APIs where necessary. Finally, all background logic of libDSE is packaged as an ASP.NET managed service, and users can start an ASP.NET-based speculative service simply by declaring these dependencies and leaving the rest to the ASP.NET framework.

Cluster Orchestrator Integrations. When starting an application, `StateObject`s first `Connect` to the coordinator to report its presence with a predetermined unique ID. If a `StateObject` that has already reported starting does so again, libDSE treats this as indicative of a failure. We observe that this model aligns well with current practices – for example, a user using Kubernetes to manage microservices expects Kubernetes to detect down services and replace them by relaunching in a new container. The relaunched service, upon its `Connect` call, will set off failure handling logic. When `Connect` returns, libDSE has registered the calling `StateObject` as the legitimate incarnation which may start sending and receiving messages. libDSE guarantees that any messages received from or sent to the previous incarnation will eventually be rolled back, but it is up to service implementers to ensure that two incarnations do not simultaneously update persistent state (e.g., with a Persistent Volume Claim in Kubernetes). It is not necessary for a service to explicitly disconnect from a libDSE coordinator, as long as it persists all of its outstanding state before becoming inactive. The coordinator sends periodic heartbeat/boundary update messages to participants, which includes instructions for garbage collecting dependency graphs and outdated recoverable points.

Action Synchronization. To guarantee atomicity of actions, each action executes under a shared lock while `Persist` and `Restore` execute under an exclusive lock. Because actions are far more common than `Persist` and `Restore`, we use biased locking [40, 58, 59, 68] to improve scalability.

5.1.1 Pattern: Speculative Log

A foundational pattern for stateful services is to treat a durable, append-only log as the source of truth, with the service's in-memory state acting as a materialized view over that log. Many systems, including databases, key-value stores, and workflow engines, fall under this model. This model is an excellent fit for libDSE, as it provides a principled way to adapt a wide range of applications to speculative execution by first building a speculative log. The most significant change required from a standard log implementation is attaching custom metadata with `Persist` calls. We achieve this by designing special commit records that hold metadata, and appending them to the end of a log at the beginning of `Persist`. To restore, we scan the log until the requested commit record and truncate the tail. When rolling back, we cache the offsets of speculative commit records in-memory to avoid the scan. On top of the log, service implementers are free to maintain arbitrary in-memory state that can be reconstructed by replaying the log's entries. While this model is powerful, reconstructing in-memory state from replaying can be prohibitively expensive. This is a well-studied problem in prior literature from database systems [60] addressed by periodic checkpointing of an in-memory state and log truncation.

5.1.2 Applying the Speculative Log Pattern

With the speculative log, implementing other complex stateful services is equivalent to maintaining different materialized views over it. This approach demonstrates the versatility of the pattern, allowing us to adapt libDSE to a wide range of common services. We describe three examples below.

Key-Value Store. We implement a speculative key-value store based on the open-source FASTER key-value store [18], which powers production systems such as Orleans [29], Durable Functions [8], and Garnet [24]. FASTER uses FasterLog as its backend and mostly maintains an in-memory hash index over the log to serve key-value workloads. To make FASTER speculative, we only need to make its underlying log speculative and access it using libDSE clients. We reuse most of FASTER's sophisticated storage and checkpointing schemes [36, 65] without modification.

Speculative Workflows. We base our speculative workflow orchestration system on the DARQ system [33, 56], which is itself a wrapper around a log. At a high-level, the DARQ log records the entire history of workflow events and commands, and relies on replay and deduplication to ensure exactly-once execution. Our implementation replaces DARQ's backend log with the speculative version, and triggers replay of the workflow system when the log is rolled back.

Event Broker. We implement a speculative event broker system similar to Kafka [52] and EventHubs [7], with a collection of producers and consumers interacting through disjoint topics. Each topic is fundamentally just a log, which we have replaced with a speculative log. We leave creation, deletion, and management of topics non-speculative, as they are usually not on the critical path.

Transactional Store. Lastly, we implement a transactional store with the standard two-phase commit protocol [60] and strict two-phase locking. Tuples are stored in main memory. We rely on a speculative log as write-ahead log for recoverability and persistence, and libDSE thread primitives for synchronization.

5.2 Limitations and Discussion

Developer Burden. LibDSE is not a transparent, drop-in solution for existing applications. It requires developers to adopt its programming model, encapsulating application state within the `StateObject` abstraction and using actions and sthreads for concurrency control. This may require significant refactoring for legacy applications lacking clear state management boundaries. That said, in our experience, most of these changes align with modern best practices for building correct and scalable microservices. Furthermore, libDSE naturally promotes the creation of highly reusable, foundational components, such as the services we discussed above, which can be implemented once and reused across many applications, amortizing the initial development cost. Adoption can be further simplified with integration with programming languages, but we leave this for future work.

Data Loss. From the external user's perspective, DSE does **not** introduce data loss, as speculative state is withheld from users, and only speculative state is lost on failure. However, our DSE recovery protocol is designed for simplicity and speed during failure, as it avoids complex, multi-round consensus protocols between participants. The trade-off is that this can lead to coarser-grained rollbacks than are strictly necessary, sacrificing speculative throughput (i.e., work loss instead of data loss) to minimize recovery latency. Because the coordinator's view of the dependency graph may be slightly stale, it must conservatively roll back all speculative work that could have depended on a failed component's lost state. We mitigate this in practice by allowing a service to skip a rollback if it can prove locally that it has no dependencies on the speculative state in question. We study the effects of rollback in more detail in Section 6.

Coordination Overhead. Relying on a centralized coordinator creates a potential bottleneck for scalability. libDSE mitigates this risk by decoupling coordination from the execution critical path. `StateObject`s communicate peer-to-peer and do not contact the coordinator during standard message processing. Dependency graph updates are batched and transmitted asynchronously only upon local persistence (e.g., every 10ms), independent of operations, resulting in control traffic that is proportional to the group commit frequency rather than application throughput. Furthermore, the coordinator finds recovery boundaries as a background process. A saturated coordinator may delay the visibility of results to external clients (by advancing the boundary less frequently), but it does not throttle the internal execution throughput of the speculative cluster. We observe that a single coordinator instance is usually enough to handle the metadata traffic of high-throughput workloads without saturation, but coordinator compute can also be parallelized if necessary.

Compatibility with Replicated Systems. The fail-restart semantics of a `StateObject` are a natural fit for services that use single-primary replication (e.g., State Machine Replication or Primary-Backup), where the volatile state exists on the primary node, and recovery is achieved by switching to a backup. However, the model is a poor fit for eventually consistent systems (e.g., Dynamo-style databases [38]). These systems lack a clear, linearizable notion of "restarting" from a single consistent point in time, making them difficult to model as a `StateObject`. That said, persistence is often cheaper in such systems, making speculation less critical and applicable.

Compatibility with External Infrastructure. libDSE assumes that participants in a speculative group are DSE-aware and implement the `StateObject` API. Real applications, however, frequently interact with infrastructure that is not, such as a shared SQL database or an external payment API. We support two strategies for these cases. When the external component is fully external to the speculative group (e.g., a payment API whose side effects cannot be rolled back), services interact with it through the `Barrier()` primitive, which blocks until all upstream speculative dependencies have committed. This forfeits speculation across the barrier but is always safe, and importantly allows libDSE to be adopted incrementally: speculation is enabled only between DSE-capable components, while legacy components continue to participate behind barriers. When the external component is a shared data store that all speculative participants access (e.g., a shared relational database used for coordination among speculative services), the external component can participate in speculation by internally tracking speculative dependencies—an arrangement equivalent to schemes like early lock release [46] on the shared store.

6 Evaluation

Our evaluation studies the following research questions:

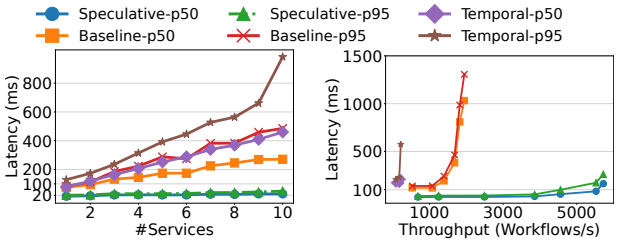
- Does DSE help applications reduce end-to-end latency?
- What overhead does libDSE impose on applications?
- Does libDSE scale to high throughput and/or concurrency?

Experimental Setup. We run all of our experiments on the Azure public cloud. For end-to-end experiments, we build the applications using the popular gRPC + ASP.NET stack and deploy them onto a managed Azure Kubernetes Service (AKS) cluster [28]; all workloads are scheduled onto a pool of 10 Standard_D8s_v3 machines [15] with attached premium locally redundant storage SSDs [9]. Unless otherwise specified, all libDSE services run with a group commit interval of 10ms. For microbenchmarks, we use a pair of D32s_v3 machines [15], each with 32 vCPUs and 128 GB of RAM.

Engineering Effort. Table 2 summarizes the engineering effort required to build the evaluated services. We implement the speculative log by modifying the open-source FasterLog project from Microsoft [19], which involved no modification of the log itself and only ∼200 lines of wrapper logic to expose it as a speculative service. Similarly, porting the

Table 2: Engineering effort for libDSE-based services.

Component	LOC	Base System
Speculative Log	∼200	FasterLog [19]
Key-Value Store	∼400	FASTER KV [18]
Workflow Engine	∼200	DARQ [56]
Event Broker	∼800	DARQ [56]
Transactions	∼2000	From scratch + FasterLog



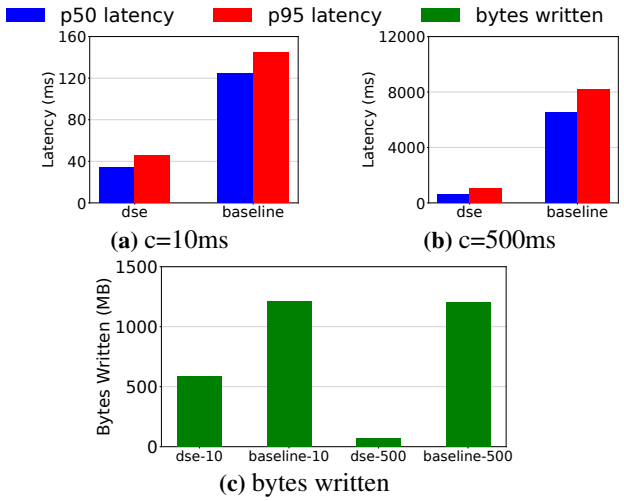
(a) Varying #Services **(b)** Varying Load

Figure 8: TravelReservations

FASTER Key-Value store [18] and the DARQ system (which is an event processing framework built on FasterLog) [56] required minimal code changes (∼400 and ∼200 LOC, respectively), primarily to wrap state objects and implement service-level logic. The Event Broker required slightly more glue code (∼800 LOC) for the gRPC streaming API. The Transactions benchmark is the largest component (∼2000 LOC) because it implements the 2PL + 2PC transaction processing and the TPC-C benchmark [72] as stored procedures from scratch on top of our speculative log, rather than modifying an existing codebase. However, this logic is largely orthogonal to speculative execution, and in our experience, is not further complicated by libDSE. These figures demonstrate that libDSE effectively abstracts the complexity of distributed dependency tracking, allowing developers to adopt speculative execution with minimal engineering overhead.

6.1 End-to-End Benchmarks

TravelReservations. We first assemble a travel reservation system based on DeathStarBench [43], where a workflow engine reserves a series of items, one from each service (e.g., hotel, flight, car-rental) backed by our speculative KV store using sagas [31]. We focus on the *write* portion of the workload. We exclude read operations as they are typically served from local cache in both baselines, exhibiting identical performance; focusing on writes allows us to isolate the overhead and latency benefits of libDSE's persistence mechanism. Note that this does not mean libDSE does not help read-only workloads: many durable execution engines log reads for correctness (e.g., to ensure deterministic replay during recovery), effectively turning reads into writes that libDSE also accelerates. We compare our implementation with the open-source version of Temporal [30], an industry-standard workflow-engine, deployed over an Azure-managed Cassandra cluster and using Azure CosmosDB for application logic. Additionally, we evaluate our system with speculation disabled to isolate the performance gains from speculative execution vs. implementation and tool stack. All benchmarks run for 120 seconds.



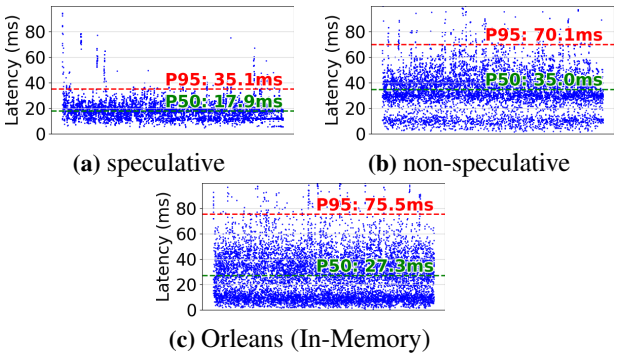
(a) c=10ms **(b)** c=500ms

(c) bytes written

Figure 9: EventProcessing

Figure 8 shows the result of our experiment. The left panel reports average and 95th-percentile latency as the number of participating services increases, using a steady rate of 10 workflows/s to avoid queuing delays. As the service chain grows, baseline latency increases linearly due to cumulative synchronous persistence costs. In contrast, libDSE incurs only minor latency increases due to RPC overhead, effectively bypassing persistence bottlenecks and achieving an order of magnitude lower latency for long workflows. We further demonstrate scalability by fixing the chain length to three services and varying the workflow arrival rate. As shown in the right panel of Figure 8, speculation significantly improves throughput capacity. Traditional workflow engines become CPU-bound under high load because they manage many concurrent workflow instances simultaneously blocked on synchronous persistence, each consuming non-trivial context-management overhead (thread state, stack frames, runtime bookkeeping, etc.). libDSE completes workflows rapidly, sharply reducing the number of in-flight blocked contexts and thus the associated CPU pressure—enabling higher sustained throughput on identical hardware.

Event Processing. We evaluate the search trend alert workload described in the DARQ paper [56] (available in open-source [33]) using our speculative event broker. The workload consists of three processing stages communicating via streaming events. We compare our implementation against the original, non-speculative version of DARQ. Figure 9 presents the results of processing a pre-generated event trace at a steady rate of 50k events/s for 120 seconds, while varying the group commit interval (c). Note that c governs the persistence of *intermediate* stream-processing state. While a larger c implies a wider window, meaning more intermediate results are lost



(a) speculative **(b)** non-speculative

(c) Orleans (In-Memory)

Figure 10: TwoPhaseCommit

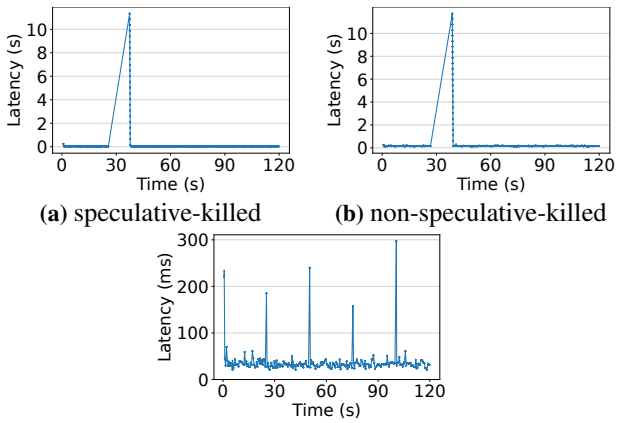
during cluster failures that must be replayed, it does not lead to additional loss of user data, which can be persisted eagerly at ingestion. The first two plots demonstrate that libDSE drastically reduces end-to-end latency compared to the baseline. The bottom graph illustrates the volume of bytes written to storage; libDSE achieves significant reductions in storage bandwidth because it prunes short-lived intermediate results that are generated and consumed entirely within the speculative window, preventing them from ever reaching storage. Consequently, these storage savings are more pronounced with larger group commit intervals, which increase the likelihood that intermediate state is pruned before disk I/O occurs.

Two-Phase Commit. Finally, we evaluate our transactional store. The benchmark cluster consists of four shared-nothing shards, each maintaining its own (speculative) log. We evaluate a modified TPC-C workload [72] consisting of 100% distributed transactions, comparing our implementation against Microsoft Orleans's optimized transactional framework [29, 41]. To ensure fair comparison, we manually place Orleans grains to have the same sharding with our system, and run Orleans purely in-memory to eliminate the throughput limitations of its standard Azure Table Storage backend.

Figure 10 illustrates the commit latency distribution. Non-speculative latencies cluster around multiples of the 10ms group commit interval, as most transactions must wait for the next persistence window. There are a few "lucky" transactions that complete the first round of messages at the end of the last group commit and therefore finish close to 10ms, but most transactions wait longer. In contrast, speculative execution eliminates sequential waiting between phases, allowing the protocol to overlap communication with I/O. The plots show most transactions finishing under 20 ms (essentially one round of group commit + RPC overheads). Consequently, our speculative implementation significantly outperforms both the non-speculative baseline and the in-memory Orleans setup.

6.2 Recovery

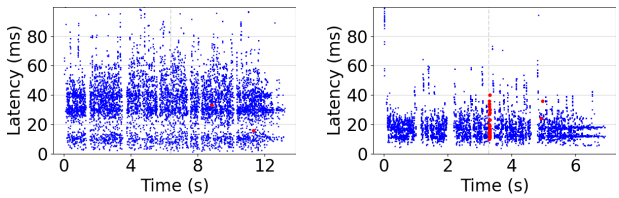
Event Processing. We evaluate realistic recovery scenarios using the EventProcessing workload by terminating a Kubernetes event handling node at the 30-second mark. Kubernetes



(a) speculative-killed **(b)** non-speculative-killed

(c) speculative-simulated

Figure 11: EventProcessing-recovery



(a) non-speculative **(b)** speculative

Figure 12: TwoPhaseCommit-recovery

automatically provisions a replacement container, triggering libDSE's recovery protocol upon startup. During this interval, gRPC requests to the affected node time out and are retried, temporarily halting processing for that partition. Figure 11 shows that recovery takes approximately 10 seconds for both speculative and non-speculative versions, a duration dominated by container orchestration latency rather than protocol overhead. To isolate the overhead of libDSE's rollback mechanism from orchestration delays, we also introduce simulated failures that trigger immediate rollback across all participants without container restarts. This configuration represents the theoretical best-case recovery performance, exposing only the latency induced by speculative state restoration. We inject four independent failures and observe that the system stabilizes rapidly, resulting in latency spikes of 100s of milliseconds.

Two Phase Commit. Similarly, we evaluate recovery in the transaction benchmark using simulated failures, comparing against a failure-free non-speculative baseline. Figure 12 plots the results, where red dots indicate aborted transactions. The primary trade-off of speculative execution is a temporary spike in user-visible aborts during rollback; to ensure safety, our implementation aggressively aborts all in-flight transactions that may depend on invalidated state. However, this effect is minimal in practice. Quantitatively, speculative recovery increases the overall abort rate by only 0.3% compared to the baseline. Because these transactions can be immediately retried, the aggregate impact on system throughput is negligible. Note that the measurement gaps visible in both

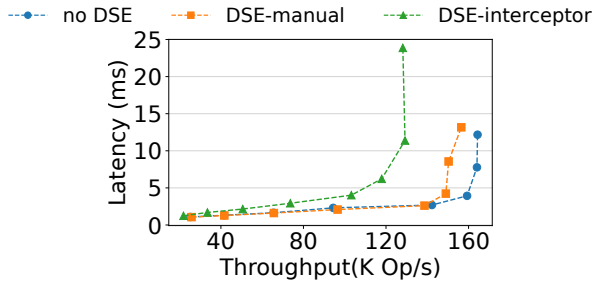


Figure 13: Overhead of libDSE instrumentation

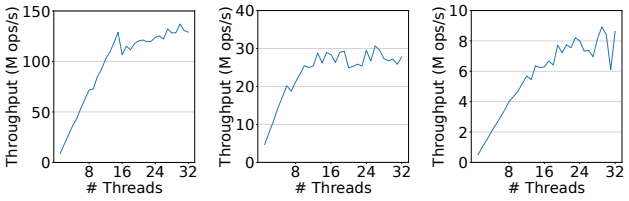

(a) local-action **(b)** send-receive **(c)** detach-merge

Figure 14: Thread scalability of libDSE Primitives

plots correspond to standard server GC pauses. The gaps in the speculative version appear longer because of the different scale on the x-axis (speculative baseline finishes the workload much faster due to higher throughput).

6.3 Microbenchmarks

Finally, we present a series of microbenchmarks to study the overhead of various libDSE mechanisms.

Overhead of libDSE Instrumentation. We first study the latency and throughput overhead of libDSE's message instrumentation protocol on a service. We study three versions of the FASTER-based key-value store from the hotel reservation benchmark, two with libDSE (DSE), and another as a thin RPC wrapper around the vanilla FASTER code (no DSE). To study the effects of the interceptor mechanisms vs. the instrumentation protocol itself, we also build one version that processes libDSE headers in user code (DSE-manual) and another that does so transparently with gRPC interceptors (DSE-interceptor). We vary the request issue rate for each configuration to investigate the resulting latency-throughput trade-off. Figure 13 shows that libDSE with interceptors has slightly higher latency when the system is not saturated and about 25% lower maximum throughput. This is mostly due to the additional work entailed by the gRPC interceptor mechanism (e.g., HTTP header manipulation). In contrast, the libDSE protocol itself causes a negligible increase in latency and a less than 5% reduction in throughput. This shows that the libDSE instrumentation adds only a small overhead to applications.

Thread Scalability of libDSE Primitives. Recall that libDSE users must protect their operations with libDSE threading primitives for correct speculative execution. It is therefore important that libDSE primitives be scalable and not introduce new bottlenecks in an application. To measure this, we design a simple microbenchmark where threads acquire protection under a tight-loop concurrently, reporting throughput as the number of concurrent threads increases. A background thread periodically performs (empty) checkpoints to advance versions. We measure three sets of primitives: local-action, where libDSE users mark blocks of code as atomic with respect to checkpointing and recovery; send-receive, where libDSE users start an action using a (randomly pre-populated) header and write the resulting dependencies to another header at the end of the action; and detach-merge, where libDSE users create a new sthread from the current dependencies and then merge it with the state object. As shown in Figure 14, our implementation of the action primitive (based on [58]) is scalable up to 16 threads with no performance degradation. As expected, send-receive is more expensive than local-action, and detach-merge is more expensive than send-receive, due to the amount of computation involved. However, all three primitives can sustain millions of operations per second on a single server, making them unlikely to be bottlenecks in typical RPC-oriented workloads that only see 100s of thousands of operations per second per node.

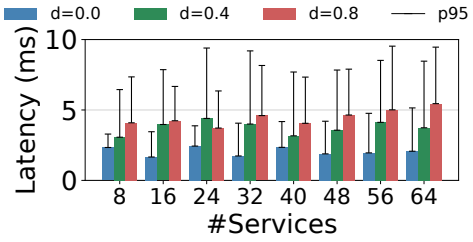

Figure 15: libDSE Coordinator Scalability

Coordinator Performance. Finally, we study the libDSE coordinator, which is responsible for identifying messages that are no longer speculative so their effects can be exposed externally. We design a microbenchmark in which simulated participants submit versions to a real coordinator on a predetermined schedule, and measure the latency between submission and commit. Each version depends on each other participant's current version independently with probability d. Participants run on a Kubernetes cluster, communicate with the coordinator over real intra-datacenter network connections, and refresh their cluster view every 5ms. Figure 15 reports median commit latency (bars) with the 95th-percentile tail as whiskers. A local-commit fast path lets versions with no speculative dependencies commit almost immediately, so the $d = 0.0$ bars sit near 2ms across the entire range and the corresponding p_{95} remains within one 5 ms refresh interval. In the general case, both median and p_{95} scale smoothly from 8 to 64 services: medians stay below a single refresh interval. Graph connectivity has only a modest impact, as in-memory traversal is cheap relative to network and refresh delays.

7 Related Work

Durable Execution and Workflows. Durable Execution, as a term, was first coined by Temporal [10], and is widely accepted in industry [8, 13, 14, 16, 17, 20, 22, 27, 32], although it is similar to earlier concepts of virtual resiliency [4, 45] and reliable workflows [5, 11, 25]. Most of these systems achieve resilience guarantees by modeling the application as a directed acyclic graph (DAG) of tasks and synchronously persisting execution state before starting new steps; external effects of execution are wrapped in special abstractions (e.g., activities in Temporal and DF, impulses in Ambrosia) and required to be idempotent for resilience. ExoFlow [78] is a recent workflow system that allows developers to take advantage of determinism and rollbacks within the workflow for better performance. Developers mark parts of their workflow as deterministic or rollback-capable, and ExoFlow will bypass synchronous persistence where possible, using replay and rollback to recover when necessary. In contrast, libDSE allows true inter-service speculation without relying on determinism.

Cross-Service Transactions. Other systems, such as Olive [69], co-locate service state and orchestration state onto one unified storage layer, providing exactly-once guarantees without requiring idempotency, but also forcing developers to migrate to their storage engine. While Olive used existing database services (e.g., Azure Tables), Boki [48] showed that a shared log abstraction can provide more performance and usability benefits, and Halfmoon [66] further optimizes Boki to reduce the amount of information logged. More recently, SpecLog [35] applies speculation within the shared-log setting itself: it introduces *fix-ante ordering*, which predetermines the global record order via per-shard quotas so that applications can begin processing records before the final global cut is committed. libDSE is complementary in that it speculates across the synchronous persistence of independent message-passing services (i.e., between independent logs) rather than inside the ordering layer of a single log. Other systems support distributed transactions in the unified storage layers [71, 76]. Orleans, of particular note, implemented early lock release [3, 39, 41, 44] to reduce latency. While conceptually similar to DSE, their implementation only applies to Orleans' transactional workers. In contrast, libDSE is designed to work for heterogeneous participants and *per-component private storage*. While some transactional protocols allow distributed transactions across heterogeneous storage engines [1, 51, 77], they are not widely used currently to our knowledge. Finally, DBOS [12, 50] proposes to build all services and runtime layers on top of a distributed transactional DBMS, but would require an even more radical rewrite of existing technology stacks than libDSE.

Other Related Work. Fault-tolerance in microservice-oriented cloud applications can be viewed as a modern instantiation of asynchronous recovery in message-passing systems, which was heavily studied in prior work [42]. Dataflow systems are conceptually similar to workflow systems and compose distributed components, but usually have the benefit of known application semantics (i.e., composed components are operators such as filter and map, rather than blackbox code). Consequently, dataflow systems predominantly use lineage-based techniques to reconstruct application state on failure [61, 74, 75]. libDSE is, at its core, a checkpoint-based recovery scheme, which assumes no such domain-specific knowledge. The DSE protocol bears similarity to classic distributed snapshot algorithms [37], but is redesigned for an online setting where checkpoints happen continuously. The idea of a performant distributed rollback system reliant on logical time is similar to the well-known time warp operating system [47], which employs speculative execution to handle out-of-order simulation actions (synchronization). In contrast, libDSE employs the algorithm to hide persistence latency (durability). Finally, Speculator [62] and xsyncfs [63] similarly use speculative execution to speed up file system operations transparently. However, they assume a shared state model and implement client-centric speculation, whereas libDSE specializes for message-passing scenarios.

8 Conclusion

We presented distributed speculative execution (DSE), a novel approach to reduce persistence overhead in durably executed cloud applications. Through our framework, libDSE, we demonstrate that DSE is both practical and beneficial for performance, and that its complexities can be effectively hidden from most developers through the use of abstractions. Our results show that DSE significantly reduces latency. We envision DSE to be a key technique in building future highly distributed cloud applications.

A Artifact Appendix

Abstract

The artifact provides libDSE, our distributed speculative execution (DSE) framework, together with the speculative services and end-to-end benchmarks used in the paper. It contains the core libDSE runtime and coordinator (the `StateObject`/sthread programming model, message instrumentation, and the rollback-recovery protocol), the four speculative services built on the speculative-log pattern (a key-value store, a workflow engine, an event broker, and a two-phase-commit transactional store), and the benchmark drivers for the TravelReservations, EventProcessing, and TwoPhaseCommit workloads. It also includes the plotting scripts and the raw experiment results needed to regenerate every figure and table in the evaluation (Section 6).

Scope

The artifact substantiates the paper's central claim that DSE reduces end-to-end latency for persistence-bound cloud applications by up to an order of magnitude relative to non-speculative durable execution, while adding only modest runtime overhead. Concretely, it allows one to reproduce: the latency and scalability results for the travel reservation workflow against Temporal and a non-speculative baseline (Figure 8); the latency and storage-bandwidth results for event processing against DARQ (Figure 9); the commit-latency distributions for distributed transactions against Microsoft Orleans (Figure 10); the recovery behavior under injected and real failures (Figure 11, Figure 12); the instrumentation, threading, and coordinator microbenchmarks (Figure 13, Figure 14, Figure 15); and the engineering-effort summary (Table 2).

Contents

The artifact is organized as follows:

- **libDSE runtime and coordinator** — the core library (approximately 4000 lines of C#) implementing actions, sthreads, speculation barriers, message instrumentation, the dependency-graph protocol, and the stateless coordinator, with built-in gRPC and ASP.NET integration.
- **Speculative services** — the speculative log and the four services layered on it: a key-value store (built on FASTER), a workflow engine (built on DARQ), an event broker, and a 2PL+2PC transactional store.
- **Benchmarks** — drivers and workload generators for TravelReservations (DeathStarBench-style sagas), EventProcessing (DARQ search-trend-alert), and TwoPhaseCommit (a modified TPC-C), plus the baseline deployments (Temporal, DARQ, Orleans).
- **Figure reproduction** — `plots.py` regenerates all figures from the raw measurement files under `data/`.

Hosting

The artifact is publicly available and permanently archived on Zenodo at `doi.org/10.5281/zenodo.20059348` (version v2), which provides a self-contained snapshot of the libDSE implementation, the speculative services and benchmarks, and the experiment data. The implementation builds on the open-source FASTER project [18], hosted on GitHub at `github.com/microsoft/FASTER`. The artifact's `README` documents the build and run procedure.

Requirements

The end-to-end experiments were developed and tested on Microsoft Azure.

- **Cluster.** A managed Azure Kubernetes Service (AKS) cluster with a pool of 10 Standard_D8s_v3 nodes, each with attached premium locally-redundant-storage SSDs.
- **Microbenchmarks.** A pair of Standard_D32s_v3 machines (32 vCPUs, 128 GB RAM each).
- **Software.** The .NET SDK and C# toolchain, gRPC, and ASP.NET for the services; Python 3.12 with `matplotlib` for `plots.py`; and the Azure CLI (`az`) for `download.sh`. Reproducing the baselines additionally requires Temporal (over Azure-managed Cassandra and Azure Cosmos DB), DARQ, and Microsoft Orleans.

Reproducing the exact numbers requires comparable Azure hardware; the framework and microbenchmarks themselves build and run on a single multi-core machine.

TrainMover: An Interruption-Resilient Runtime for ML Training

Abstract

Large-scale ML training jobs are frequently interrupted by hardware and software anomalies, failures, and management events. Existing solutions like checkpoint-restart or runtime reconfiguration suffer from long downtimes and degraded performance. We present TrainMover, a resilient LLM training runtime that leverages elastic and standby machines to handle interruptions with minimal downtime and zero memory overhead. To achieve these goals, TrainMover introduces three key techniques: two-phase, delta-based communication group setup; communication-free sandboxed warmup; and general standby design that enables failure recovery from any role. Our evaluation shows that TrainMover consistently achieves around 20 seconds of downtime when handling various interruptions at the 1024-GPU scale. TrainMover is projected to reduce wasted GPU hours by 55% compared to the best alternative, saving 1.4 million GPU-hours per week at the 64K-GPU scale.

1 Introduction

Large Language Models (LLMs) have gained significant attention in recent years [6, 8, 31, 35, 36, 45, 46]. Scaling laws continue to guide the design and training of increasingly large models. LLM training jobs are typically deployed on parallel training frameworks (*e.g.,* Megatron-LM [40] and NeMo [22]), require tight coordination across thousands of GPUs, and run for weeks to months. For example, training GPT-3 with 175 billion parameters on 1,024 GPUs required approximately 34 days [30], while Llama 3 with 405 billion parameters was trained over 54 days using up to 16,000 H100 GPUs [17]. Meta and xAI are further pushing the training scale to 100K+ GPUs [41, 54].

This large-scale, long-running, and tightly coupled distributed training frequently encounters *interruptions*, including hardware anomalies, software contentions, network failures, and various management events. First, failures and anomalies become common as scale increases, and even a single component fault can slow down or halt the entire job. Alibaba reports that 60% of large-scale training jobs experience slowness from such issues, causing a 35% increase in average JCT [51], and the Llama 3 training job observed a mean-time-to-failure (MTTF) of only 2.7 hours [17]. Second, because training runs for weeks to months, maintenance tasks (repairs, security upgrades, patches, etc.) cannot be deferred; they often require rebooting servers or switches and thus interrupt training [2, 21]. Third, in shared clusters, operators need to frequently reschedule jobs or rebalance resources when high-priority jobs arrive [12, 53] or when fragmented resources become consolidated [47].

To preserve high ETTR (Effective Training Time Ratio), operators always keep a small pool of backup or elastic GPU machines (e.g., 6% in Alibaba [34], Bytedance [49], Google [42], Meta [17]) to replace affected machines while preserving the original training layout. Large-scale training jobs are highly tailored for peak performance and GPU memory utilization. For example, Meta [17] and Deepseek [9] tailor their model layouts to balance memory, computation, and communication for peak throughput (see §2.2). Therefore, even small layout changes can degrade performance, trigger out-of-memory errors, or leave GPUs idle [14].

Existing solutions for replacing affected machines fall into two broad categories. The first, and the current industry best practice, is the *stop–reschedule–reinitialize* approach [13, 18, 20, 48]: the job is stopped, faulty nodes are replaced with healthy ones from a backup pool, and the training framework re-initializes from the latest checkpoint. For a 16,000-GPU LLM job, interruptions accumulate to over an hour of downtime each day, translating to $86K in wasted costs [4]. The second category is *reconfiguration systems*, such as ReCycle [14], Oobleck [19], and Parcae [12], which can be retargeted to replace a machine by tolerating interruption drop (–1) and adding back healthy machine (+1) elastically without halting the job. However, a fundamental limitation persists across both categories: bringing back a new machine (*joiner*) online after each interruption requires reinitialization, which remains slow and forces the entire job to stall until the joiner resumes, leaving the critical path unchanged (see §2.3).

In this paper, we introduce TrainMover, an **interruption-resilient** LLM training runtime that allows a new joiner to prepare initialization in advance and overlap it with ongoing training, minimizing the interruption impact to the rest. TrainMover is carefully designed to avoid interfering with ongoing training and to incur zero additional GPU memory overhead during handling.

Achieving this is nontrivial. Modern LLM training stacks tightly couple initialization with globally synchronized communication setup, making it impossible to prepare joiners

*Jiaqi Gao is the corresponding author.

in advance without dedicated handling. Decoupling joiner initialization from this global path is essential. TrainMover leverages the two-phase communication-group setup (§5) and sandboxed shadow iterations (§4) to prepare communication and computation state in the background. The general standby design (§6) further enables role-agnostic preparation, allowing recovery regardless of which machine fails.

Executing shadow iteration on sandbox (§4): TrainMover introduces a communication-free sandbox that allows joiners to trigger framework initialization independently by running shadow training iterations in isolation before entering the main training loop, replacing actual communication with pre-recorded tensors. This decouples joiners from existing machines and significantly reduces transitional downtime.

Two-phase delta-based communication group setup (§5): TrainMover extends a two-phase delta-based communication group setup to allow all non–critical-path steps to be performed upfront (the first phase) and overlapped with ongoing training. In the second phase, TrainMover applies the membership changes in a delta manner, minimizing disruption to users and reducing transition downtime.

General standby to handle unexpected failures (§6): TrainMover leverages a general standby that can be immediately promoted to a joiner when a failure occurs, exploiting the high symmetry of distributed training. This symmetry removes the need for any prior role knowledge, allowing a single pre-warmed standby to recover any failed machine. The resulting performance is nearly identical to handling interruptions at a known, specific role.

For expected interruptions, TrainMover prepares the joiners in a sandbox (§4) and two-phase communication setup (§5), allowing the ongoing training job to continue uninterrupted and preserving performance during migration. Once the joiners are ready, TrainMover replaces the affected communication group members and synchronizes the latest model state from the leavers to the joiners before resuming training. For unexpected interruptions, TrainMover uses the general standby design (§6) to pre-warm the standby machine with the same techniques in the background, enabling rapid replacement of the affected machine when a failure occurs.

Our experiments show that TrainMover achieves a consistent downtime of around 20 seconds at the 1,024-GPU scale and is projected to reduce wasted GPU hours by 55% compared to other systems at the 64K-GPU scale. It also enables other use cases, such as resource load balancing at 10-minute intervals, with less than 3% training throughput loss.

2 Background and Motivation

2.1 Interruptions Prevail in LLM Training

LLM training jobs commonly span tens to hundreds of thousands of GPUs and run for weeks to months. Such clusters are expected to operate at peak efficiency to amortize their substantial infrastructure cost. However, sustaining this performance at scale is difficult, as numerous infrastructure and operational events can hinder or slow progress. We refer to these events collectively as **interruptions**, which include:

- **Hardware anomalies** such as GPU failures or down-voltage from overheating or power limits [17]. Aegis [10] reports that GPU servers exhibit failure rates orders of magnitude higher than general cloud nodes, and even within accelerator families, the H100's MTTF is twice that of the A100.
- **Software contentions** such as co-located programs running on the same CPU [51], OS noise, or garbage collection in the Python training framework [27]. Falcon [51] shows that such contentions from background tasks and network anomalies can slow LLM training by 34.59% on average.
- **Network failures** including optical module or switch failures and network congestion. Although network architects provision sufficient redundancy to maintain connectivity [34], Falcon [51] reports that 40–50% of large-scale LLM training jobs still experience network-induced fail-slows, with average slowdowns of 15–35% due to congestion or switch failures.
- **Management events** including driver updates [17], GPU resource balancing, and power or thermal planning [28]. First, bespoke training hardware adopts the latest techniques and therefore requires frequent maintenance, including bug fixes, urgent security patches, and firmware or driver updates [2]; the Llama-3 training team reported at least one such interruption per day [17]. Second, in shared clusters, operators often reassign GPU servers to improve locality and avoid network congestion [17, 34]. Third, to reduce power and thermal fluctuations and better balance resources, operators regularly redistribute workloads across the cluster [1, 17, 28].

Depending on their impact on the training job, these interruptions can be classified into two types: (1) *expected/planned interruptions*, such as scheduled maintenance for which operators are notified in advance, and software contentions or network failures in which the training job is still alive but not performant and waits for the operator to intervene; and (2) *unexpected interruptions*, such as GPU and CPU failures that crash the training framework instantly without notice[1].

2.2 The Goal: Sustaining High ETTR

These interruptions severely impact existing LLM training frameworks (*e.g.*, Megatron-LM [40] and DeepSpeed [39]) that rely on tight synchronization across all GPUs. Since each GPU must exchange intermediate results before every iteration[2], any slowdown propagates to the entire cluster, and a single failure terminates the job [51]. Alibaba [51] reports that slowness can increase large-scale LLM training completion time by up to 90%. ByteDance reports that 42.5% of

[1] This paper does not consider failures resulting from user-level bugs; ensuring application correctness in long-running jobs lies with the user.

[2] We do not handle asynchronous training frameworks because, to the best of our knowledge, no such framework is deployed in production at scale yet.

Restart Stages	Avg. Time	Percentage
Job Stop & Cleanup	0.52 min	7.69%
Job Reschedule	1.5 min	23.08%
Job Initialization	4.45 min	69.23%
• Checkpoint time	1.56 min	35.1%
• NCCL instantiation	1.09 min	24.5%
• Cold warmup	1.80 min	40.4%
Total	6.47 min	100%

Table 1: Average restart time breakdown for 8192-GPU training jobs.

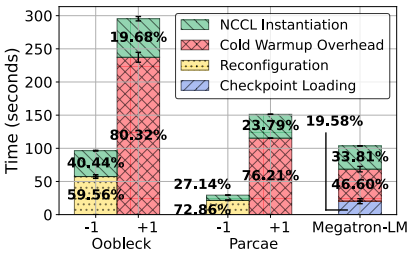

Figure 1: Reconfiguring and booting from scratch are both costly.

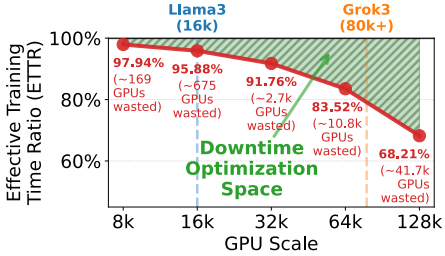

Figure 2: Impact of downtime on ETTR at different scales.

training jobs are at least 10% slower due to stragglers [27]. Meta reports that the ETTR drops to 0.6 when a job spans 8192 GPUs [21]. This wasted time stems from re-training lost progress since the last checkpoint, restart overhead, and checkpoint-saving overhead. Such longer training times translate directly into higher infrastructure costs. For example, based on AWS's public pricing, training with 16K GPUs costs $1.44M per day [4]. An ETTR of 0.6 translates to roughly $0.58M of wasted cost per day. Therefore, when an interruption happens, the highest priority is to restore the training job to its peak performance.

In practice, this goal translates to *quickly replacing interrupted GPUs with healthy ones while maintaining the training layout* (i.e., the parallelism configuration and model partitioning tuned for the job). The training layout is specially optimized from the ground up to achieve peak performance on the specific scale. For example, before training starts, Meta [17] manually fine-tunes the model partitions on each GPU to balance memory and computation load across different pipeline parallelism stages to achieve the highest throughput. Similarly, DeepSeek [9] carefully tunes the GPU SMs dedicated to computation and communication to achieve the optimal balance and trains DeepSeek-V3 at peak performance. Re-distributing the workload to the remaining machines can easily lead to inferior performance, job failures due to unexpected code behavior or out-of-memory errors, or idle GPUs in scenarios where an entire DP group is removed when the distributed optimizer is disabled.

Under such constraints, naively setting up the training cluster to match the job size is undesirable, as a single broken machine can undermine the entire training run. Instead, operators reserve a pool of healthy standby servers in the cluster for on-the-fly replacement to reduce downtime. For example, ByteDance [49] allocates warm-standby pools based on the 99th percentile of historical GPU failure rates. Alibaba's HPN [34] reserves 6% of its GPUs as backup in each segment. Google [42] maintains standby TPU cubes within each SuperPod to support rolling maintenance and recovery. Llama-3 [17] was trained on 16K GPUs within a 24K-GPU cluster. More discussion on the economic cost of standby machines can be found in §9.

2.3 Limitation on Existing Solutions

The industry has deployed automatic systems [10, 49] to reduce interruption downtime. Yet, as training scales grow, recovery in the training stack quickly becomes the bottleneck. We evaluate two representative interruption-handling solutions. Note that, across all experiments, we assume instant fault localization and isolation.

Solution 1: Restart. Restart refers to the standard stop–reschedule–reinitialize mechanism used in production to handle interruptions [10, 17, 21, 51]. When an interruption occurs, the system first *stops* the job by terminating the training framework and cleaning up active processes and connections. It then *reschedules* the cluster by offlining faulty nodes, selecting healthy replacements, and preparing their runtime environments. Finally, the training framework *re-initializes* from the most recent checkpoint before training can resume.

This process introduces substantial overhead. We consulted one of the largest cloud providers, and even with an automated recovery stack similar to that of Llama-3 [17], an 8,192-GPU production job still incurs 6.47 minutes of delay per interruption (Table 1). Excluding infrastructure overhead, framework initialization alone accounts for 4.45 minutes: (1) **Checkpoint loading** (35.1%), where model and optimizer states are restored from remote storage. This cost grows rapidly with model size [48, 50, 51]. (2) **NCCL instantiation** (24.5%), where each parallelism dimension (DP, PP, TP) must form its own NCCL group, requiring synchronized metadata exchange and connection setup. (3) **Cold warm-up** (40.4%), including CUDA context creation, GPU memory allocation, JIT compilation, and data-loader initialization. Since large-scale training is fully synchronized, an interruption affecting only a few nodes [10, 21] still forces *all* machines to restart, significantly amplifying downtime.

Solution 2: Runtime Reconfiguration. Recent works such as Oobleck [19], Parcae [12], and ReCycle [14] aim to avoid global restarts during interruptions by elastically scaling the training cluster up or down without halting the job. These systems adjust training configurations—such as batch sizes or parallelism schemes—to sustain reduced training throughput during failures. When an interruption happens, the system can remove the affected machine (`-1`) and continue training at reduced throughput, then later add a replacement machine once available (`+1`).

However, despite avoiding infrastructure overhead, the core restart *critical path* remains. Figure 1 shows the latency for Oobleck and Parcae when handling interruptions in a 6.7B GPT training job on 32 GPUs. Removing a machine (`-1`)

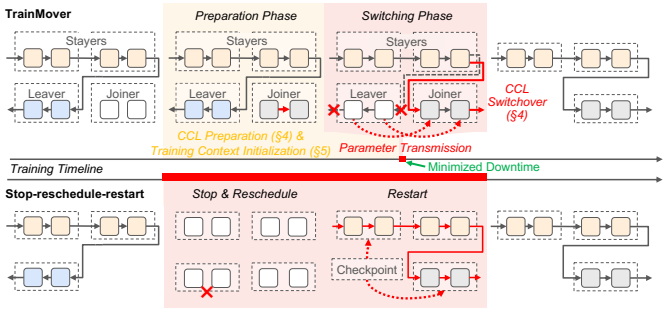

Figure 3: TrainMover Overview

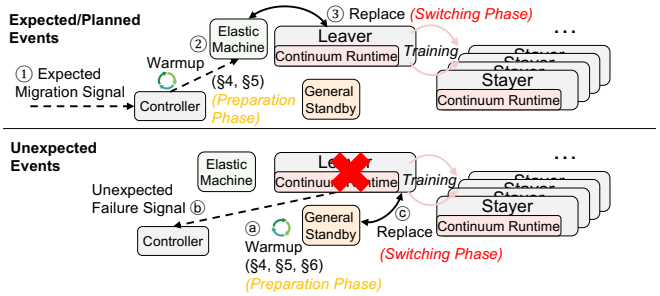

Figure 4: TrainMover Workflow

requires all nodes to redistribute parameters, re-instantiate model components, and reallocate GPU memory to support the new configuration—taking 57 seconds in Oobleck and 21 seconds in Parcae. Adding a machine (+1) is even more expensive: the joiner must initialize NCCL groups and reinitialize software and hardware components, taking over 100 seconds in Oobleck and more than 200 seconds in Parcae. The asymmetry arises because existing machines are already warm—their CUDA kernels are compiled and GPU memory is allocated—while a newly added joiner must complete a full cold warm-up from scratch. Oobleck is built atop ColossalAI [24], while Parcae is built atop DeepSpeed [39], leading to different framework warm-up times. Remarkably, this entire cost exceeds even the job initialization overhead in Megatron-LM at the same scale (rightmost bar, around 100 seconds).

In short, although infrastructure overhead can be reduced, *the heavy initialization required to bring a joiner online remains unavoidable*. While this downtime is tolerable at small scales, growing cluster sizes dramatically amplify its impact: higher interruption frequencies and larger numbers of affected GPUs cause downtime to quickly become the dominant bottleneck, substantially degrading ETTR.

This scaling effect is already evident in practical measurements. Although a 4.45-minute restart time appears modest, Figure 2 shows the resulting ETTR when this measurement is combined with the MTTFs reported by Meta [21] across increasing cluster sizes. As the figure illustrates, effective training throughput collapses at production-scale deployments (64K/128K GPUs) [41, 49, 54], resulting in 16.47% and 31.79% throughput losses, translating to $0.95M and $3.63M of daily monetary losses, respectively.

3 TrainMover Overview

To break through this scalability barrier, we design *TrainMover*, a resilient LLM training runtime for production-scale clusters that sustains high ETTR under frequent interruptions.

TrainMover migrates workloads only from interruption-affected *leavers* to healthy backup *joiners*, leaving the remaining *stayers* unchanged. By strategically leveraging readily available machines and overlapping all preparable work ahead of time, TrainMover moves most job-setup procedures off the critical path before the joiner participates in training.

This design enables a carefully orchestrated migration procedure that achieves 10× lower downtime for both expected and unexpected interruptions, without any additional GPU memory overhead, thereby avoiding the risk of out-of-memory crashes during migration.

As shown in Figure 3, instead of long restarting (bottom), TrainMover (top) splits the migration into two phases: in the *preparation phase*, TrainMover prepares the joiners' training stack in the background without affecting the foreground training job; once the *joiners* are ready and the foreground job finishes the current iteration, the system enters the *switching phase* and synchronizes each *joiner* to the latest training state before taking over the *leaver*. Each joiner takes over the leaver's role, keeping the training layout unchanged. Figure 4 illustrates TrainMover's workflow of handling both expected and unexpected interruptions as described below.

Expected Interruptions. Expected interruptions—such as scheduled maintenance—provide advance notice. When such an event is planned, the controller issues an expected-migration signal ①. TrainMover then selects elastic machines as *joiners* and immediately places them into a background *preparation phase* ②, while *stayers* and *leavers* continue training normally. Once preparation completes, TrainMover triggers a brief *switching phase* ③, during which the joiner receives the latest training state one-to-one from its paired leaver and takes over the leaver's role. This switching phase contributes to the total training pause downtime.

Unexpected Interruptions. Unexpected failures occur without prior notice, so a warmed standby machine must remain in the background *preparation phase* ⓐ. When an unexpected failure is detected ⓑ, the controller initiates recovery: TrainMover immediately promotes the standby machine to a joiner and transitions directly into the *switching phase* ⓒ, where the joiner retrieves the up-to-date state from a checkpoint, and the other machines roll back to the same checkpoint [13, 49, 50][3]. Once the switching phase completes, the *leavers* exit and the *joiners* replace their roles, resuming training seamlessly. Checkpoint loading only occurs as a fallback when no in-memory copy is available, in the switching phase.

TrainMover shifts as much work as possible off the critical

[3] If such a per-iteration checkpointing system is unavailable, other machines must restore their state from remote checkpoint storage.

path into the *preparation phase* while keeping the *switching phase* as lightweight as possible. However, several inherent properties of large-scale training fundamentally limit how much work can be shifted, creating key challenges for minimizing downtime.

(§4) Initialization is implicit and tightly coupled. A joiner must complete many initialization steps before starting training, yet modern frameworks trigger these steps implicitly across different levels (e.g., PyTorch, NCCL, and CUDA) and often require global coordination. These heavy behaviors prevent initialization from being invoked independently; performing them in advance requires untangling the tightly coupled procedures and understanding the implicit steps. TrainMover addresses this with a *communication-free sandbox* (§4): rather than untangling each implicit initialization path, the joiner simply runs a full shadow training iteration in isolation, so all computational initialization is triggered naturally—without blocking ongoing training or requiring assistance from active machines.

(§5) Communication groups assume static membership. Collective communication libraries are designed around fixed group membership. Replacing even a single machine typically requires globally tearing down and rebuilding all communication groups—a slow, synchronized procedure that dominates the interruption-handling critical path. TrainMover addresses this with a *two-phase delta-based CCL setup* (§5) that decouples CCL setup and performs all required setup during the preparation phase, applying only fast, delta connection-level changes when the membership switch actually occurs—with no additional GPU memory overhead.

(§6) Standby resources must cover unexpected failures. Unexpected failures can occur on any machine and in any training role, making advance preparation impossible. Warming up standbys for each role is wasteful at scale, while relying solely on elastic machines acquired after a failure introduces large critical path delays. Standby resources must therefore be role-agnostic and able to recover swiftly when failures occur. TrainMover solves this with a *general standby* design (§6) that exploits the structural symmetry of LLM training ranks: a single standby sequentially warms up for each pipeline role type, making it a universal recovery target without dedicating a separate standby per role.

These three techniques compose directly with the two-phase workflow above. At the start of training, hot standby machines are pre-deployed (§6) ⓐ to guard against unexpected interruptions; each runs the communication-free sandbox (§4) and Phase 1 CCL setup (§5) upfront, so upon a failure it enters the *switching phase* directly. For expected interruptions, upon receiving the migration signal ①, a new machine (no pre-deployed hot standby necessary) can serve as the joiner and undergo the same preparation (§4, §5), overlapping with ongoing training. In both cases, the *switching phase* ③/ⓒ enters CCL Phase 2 to switch only the delta inter-machine connections (§5) and transfer the state from the leavers to the joiners, keeping downtime to seconds.

4 Sandboxed Initialization

The joiner should initialize independently and in advance during the *preparation phase* to avoid global blocking; otherwise, all machines must pause until the joiner completes its setup. Yet, training initialization spans both cross-machine and intra-machine dependencies, making it difficult to identify and trigger initialization gracefully and independently (§4.1).

To address this, we propose a *communication-free sandbox* (§4.2 and §4.3) that allows joiners to execute shadow iterations in isolation to trigger initialization ahead of time. Afterward, the joiner enters the main loop and seamlessly continues training.

4.1 Prolonged and Complex Training Initialization

Training initialization, once overlooked as a one-time cost, has become a significant source of inefficiency as training scales grow and interruptions become more frequent. Each interruption must redo warm-up, wasting GPU time. In the GPT-10B experiment shown in Table 2, excluding NCCL instantiation, a single interruption triggers about 150 seconds of warm-up before reaching stable performance. The first iteration is also much slower—about 6× longer (around 44 seconds in our GPT-10B experiment)—due to just-in-time (JIT) compilation and cascading initialization dependencies—in pipeline-parallel training, for example, each stage depends on the completion of the P2P communication of the previous stage, so initialization proceeds sequentially across stages, further amplifying the startup overhead.

Initialization is complex and spans multiple layers of the training stack. While frameworks like JAX provide an eager mode to explicitly trigger initialization, mainstream training frameworks such as Megatron-LM, DeepSpeed, and NeMo rely on hardware-aware optimizations (e.g., memory-layout specialization and fused kernels) that are only activated when real data arrives (e.g., the first iteration). Furthermore, initialization is intertwined with communication, as exemplified by the pipeline-parallelism case discussed above. Addressing these behaviors would require uncovering and manually invoking many hidden initialization paths or thoroughly examining user training code. We need a mechanism that automatically triggers these complex initialization behaviors without requiring user intervention.

4.2 Shadow Iteration in Communication-free Sandbox

To pre-trigger initialization without any other machines' assistance, we create a *communication-free sandbox* that allows joiners to run a shadow iteration independently before joining the main training loop. This sandbox eliminates the need for case-by-case initialization handling: joiners can execute all implicit and framework-specific initialization routines in one shot, without relying on distributed communication or requiring any assumptions about user code or framework behavior.

This design introduces two key requirements: first, the shadow iteration must execute with valid state values and

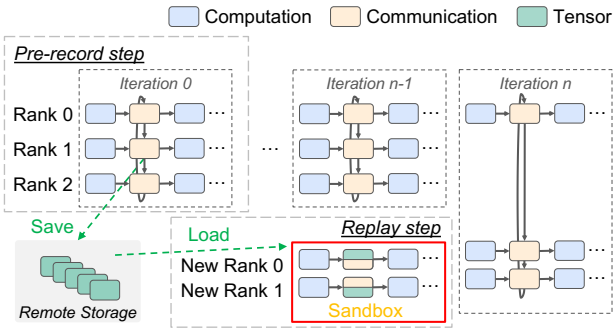

Figure 5: Sandbox initialization workflow

communication results to ensure the program does not crash and that initialization is correctly triggered—using dummy or zero values can easily cause NaNs or assertion errors. Second, communication operations must be handled locally without depending on communication responses from other machines. We address both requirements through valid tensor record–replay, as illustrated in Figure 5.

The sandbox warm-up has two steps: *pre-record* and *replay*. In the pre-record step, the designated recording machines capture one or more valid iterations and store the resulting communication outputs in advance. When a migration signal is received or a standby becomes available, the joiners enter the sandbox, where each joiner runs the replay step—reusing the recorded communication results to trigger its initialization.

Shield the Warmup — Pre-record step. We build a record hooking layer that sits between PyTorch and the CCL to intercept communication calls issued by the training framework. At the start of a new job as shown in Figure 5, designated machines—including Rank 0, Rank 1, and Rank 2—enter the pre-record step to prepare for potential migration. Our hook monitors and records the output tensors of all collective calls (e.g., all-reduce) to persistent storage once the collective completes. They are later replayed in the sandbox to ensure valid training states on the joiner.

This one-time pre-record step runs only during the first training iteration (or a few iterations) at the very beginning. After that, the interception hook is removed, and training proceeds as normal, introducing no additional overhead for the remainder of the training process regardless of the number of interruptions experienced or number of job restarts.

Run the Warmup — Replay step. When a migration signal is received or a standby is available (*the preparation phase*), all joiners (new Rank 0 and new Rank 1) enter the *replay step* and are placed into a sandbox, isolating them from the ongoing training in preparation for triggering initialization before joining the main training process. First, each sandboxed joiner pulls the initial state from the checkpoint. After loading the state, the joiner proceeds to a shadow iteration to trigger initialization. Our sandbox is designed to be *communication-free*, specifically to avoid any interaction with existing training machines. We deliberately prevent any assistance from active participants—such as responding to collective operations or sending state information—to ensure that the joiner triggers initialization entirely on its own.

We attach another hook to the PyTorch communication layer to intercept communication calls made during the replay step. Any communication call that attempts to reach outside the sandbox is intercepted and instead served with previously recorded tensors as responses. Certain operations—such as `barrier` and `send`—are safely bypassed, as invoking these operations does not affect the caller's state.

After the shadow iteration is complete, the joiners (e.g., New Rank 0 and New Rank 1) can replace the leavers (e.g., Rank 0 and Rank 1) at the end of iteration $n-1$ once they have received the up-to-date states in the *switching phase*, enabling a machine transition with no initialization downtime after migration.

Robustness and Correctness. The sandbox warm-up relies on a degree of determinism in the ML framework that modern LLM training frameworks satisfy. By design—fixed kernel schedules, static memory layouts, and deterministic collective ordering are maintained for reproducibility and peak performance. As a result, almost all initialization—including data-loader setup, CUDA context creation, and memory allocation—is correctly triggered during sandbox warm-up. Only in rare cases does a component depend on runtime data or require CUDA graph capture whose trigger may be missing. MoE routing is one such case: token routing is input-dependent and varies across iterations. However, in practice this has minimal impact—MoE frameworks (e.g., Megatron-LM) support preallocating fixed-size expert buffers regardless of the actual routing decision, so the underlying memory layout and communication structure remain static. Any initialization not triggered during sandbox warm-up simply completes during the *switching phase*, introducing only negligible overhead (*ms-level*).

Also, correctness is always guaranteed because the leaver's latest model and optimizer states will eventually overwrite all local states after sandbox warm-up in the *switching phase*.

4.3 Low Overhead Record and Replay

Recording and replaying tensors incur a one-time overhead in both storage and tensor loading time. However, not all communication needs to be recorded or replayed— each recording is essentially *a preparation for communication edges that might be temporarily missing during sandbox warmup*. We can reduce the recording scope by focusing only on what might be needed. For example, since migrations happen only at the machine level, intra-machine communication (where intensive TP traffic is always involved) can run natively inside the sandbox without record. We further eliminate redundant recordings for duplicated training roles, as discussed in §6. The storage overhead can be eventually reduced to under 300 GB in a GPT 5.12T MoE model setting.

During replay, as illustrated in the lower part of Figure 5, only the communication that touches the sandbox boundaries in the training graph relevant to the new joiner needs to be

NCCL Setup Components		
Network bootstrap		2.48s (4.92%)
Topology discovery and computation		9.40s (18.63%)
Connection Establishment	Intra-machine	21.49s (42.59%)
	Inter-machine	17.07s (33.86%)

Table 2: Time breakdown aggregated over all NCCL groups.

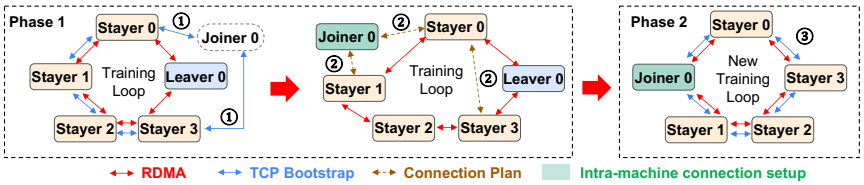

Figure 6: Two-phase CCL Migration workflow

loaded and replayed. When multiple machines are migrated together as a batch (e.g., an entire PP group), the joiners' internal communication can remain real, while only cross-boundary communication is loaded from storage. This boundary-aware record-and-replay design contributes to low I/O overhead.

5 Dynamic and Lightweight Communication group setup

Migrating one machine to another requires updating the membership of the existing CCL groups. However, CCL groups lack flexibility and are costly—they take time to create, and once created, their membership cannot be modified (§5.1). Existing approaches [12, 19] rely on globally destroying and recreating groups, which introduces unacceptable delays. An alternative strategy is to concurrently pre-allocate new groups in the background to avoid blocking, but this incurs additional GPU memory overhead. To solve this downtime–memory dilemma, we introduce a two-phase asynchronous CCL setup (§5.2) that enables dynamic group membership updates with minimal downtime and zero additional GPU memory overhead.

5.1 Today's Slow and Static CCL Setup

Communication setup is *slow*. The slowness stems from three main procedures: (1) *Network bootstrap* — participants form a TCP network through multi-round handshakes and consistency checks, which is expensive at scale due to the need for global coordination [41]; (2) *Topology discovery* — each node gathers local device metadata (e.g., NIC bandwidth) and exchanges it via ring all-gather to compute global topology and determine communication neighbors, incurring high synchronization overhead; and (3) *Connection establishment* — nodes allocate GPU buffers and set up inter- and intra-machine connections (e.g., GPU Direct RDMA, NVLink) based on the computed topology. These setup procedures can still be slow despite high parallelism, due to their inherent synchronization behaviors.

Table 2 shows the CCL setup overhead on an 8-machine cluster with 64×40GB A100 GPUs, training a GPT-10B model with TP=4, PP=2, and DP=8. The setup takes around 50 seconds due to the overhead of establishing and managing communication groups—a challenge that grows with scale. For example, training across 1,000 machines results in a connection count that scales with 1,000 × (# of CCL groups) × (# of channels inside each group). The number of CCL groups depends on the communication dimensions (e.g., DP, PP, TP); even in this modest 3D setup, each host participates in 7 groups. High-bandwidth links (e.g., 400 Gbps) further increase the number of required channels. Although many setup operations can run in parallel, the scalability of these massive numbers of connections is ultimately limited by global synchronization barriers, straggler effects from heterogeneous network latencies, and driver-level contention under high concurrency (e.g., CUDA and IB verbs serialization), causing setup time to grow with cluster size.

Communication setup is *static*. CCL connections are tightly coupled to hardware (e.g., NVLink, GPU Direct RDMA), requiring memory mappings (via CUDA IPC) and optimized connectivity topology computation—all constructed at initialization. These components are specific to the participating ranks and GPUs, so any group member change requires structural updates and may yield suboptimal performance if not carefully handled.

5.2 Two-phase Delta-based CCL Setup

We design a dynamic and lightweight CCL setup that minimizes transition overhead when a joiner migrates into an ongoing training job. Our two-phase design shifts most of the setup to Phase 1, where it is performed in advance and overlapped with training, deferring only minimal connection establishment to Phase 2 to reduce downtime. Additionally, we enable calculating and reestablishing only the delta connections between the old and new topology, avoiding the need to globally reconnect all links.

We demonstrate the migration workflow with four stayers (0–3), one joiner, and one leaver in Figure 6. Migration begins with a signal and role assignment from the controller. In Phase 1, Stayers 0–3 invoke `CCL_prepare_stayers(new_topology)` to incrementally modify their existing CCL group in preparation for the new setup with the joiner. This function also enables topology-aware configurations provided by users as input. Meanwhile, the joiner concurrently calls `CCL_prepare_joiners()`. During this process, the original group's communication remains functional ①. Stayers reuse existing TCP bootstrap connections and initiate the bootstrap process with Joiner 0. Since the additional TCP connections and topology state reside in CPU memory, this setup overlaps with training and incurs no GPU memory overhead. Once connected, the joiner and stayers exchange the necessary topology and state information.

After exchanging topology information, a recalculation of connectivity is required, as the original topology may no longer be optimal after migration ② (e.g., Joiner 0). Once the resilience runtime receives the new topology information, all participants locally compute a *delta topology*, identify the

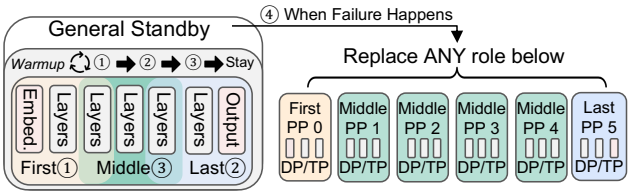

Figure 7: General Standby

minimal set of `channels` required for the updated configuration, and generate a delta reconfiguration plan that determines how to modify the necessary channels. Since all changes occur at the channel level, the design remains compatible with diverse topologies and communication techniques, such as hierarchical connectivity and SHARP [16].

The reconfiguration plan specifies which `channels` need to be updated. For `channels` that do not require replacement, they can be directly inherited and reused. Intra-machine channels (e.g., NVLink) are typically fully inherited, as they provide the fastest and highest-bandwidth paths and usually remain unchanged during migration, which operates at the granularity of entire machines. Meanwhile, the joiner (Joiner 0) begins setting up channels that can be initialized locally (e.g., intra-machine connections). If there are multiple joiners that need to connect with each other, their inter-connections are also established accordingly.

Delta `channel` connections in the reconfiguration plan—typically inter-connections—are intentionally deferred to the second phase. At this point, intra-machine communication is already available through inheritance, while inter-machine connections have not yet been established on the stayer machines—ensuring no additional GPU memory is consumed. Afterward, both the stayer and joiner CCL groups enter the *ready-to-switchout* state. Notably, the stayer and the leaver continue training without interruption during this phase.

Once both the joiners (e.g., Joiner 0) and impacted stayers (e.g., Stayer 0 and Stayer 3) complete Phase 1 and enter the *ready-to-switchout* state, they invoke the second API, `CCL_switchover()`, to switch delta inter-machine connections from stayer–leaver to stayer–joiner. For instance, the connection between Stayer 0 and Leaver 0 is replaced by one between Stayer 0 and Joiner 0; likewise, Stayer 3–Leaver 0 is switched to Stayer 3–Joiner 0. The replacement happens at the RDMA queue pair (QP) level, where it re-establishes the inter-machine peers, transitions the CCL group from *ready-to-switchout* to the normal state, and reclaims the resources tied to the old topology ③. This delta operation is the sole contributor to network downtime. The entire procedure incurs zero memory overhead; a detailed workflow can be found in §8.5.

6 General Standby

Failures can occur unexpectedly at any time. A key challenge in handling such events is that the standby machine does not know in advance which machine it should prepare for, as each machine holds different parallelism roles (e.g., TP and DP IDs). We design a *general standby* mechanism that prepares the standby for *any* rank by leveraging the symmetry of training ranks and the fact that warm-up requires only valid states, independent of role. This design enables both sandboxed initialization (§4) and two-phase CCL warm-up (§5) in unexpected failure cases and significantly reduces the number of standby machines needed.

6.1 Symmetry on Training Ranks

LLM architectures exhibit strong symmetry, as maintaining identical model partitions across all machines helps achieve peak synchronous training performance. Parallel methods such as tensor parallelism (TP), data parallelism (DP), expert parallelism (EP), and other structurally symmetric forms of parallelism maintain these identical partitions, which share the same parameter shapes and optimizer-state layouts; for example, running a DP+TP training job in Megatron-LM produces identical memory utilization across all ranks. Each rank executes the same set of computational operators and CUDA kernels[4], and participates in the same collective communication patterns. This strong, correctness-driven symmetry allows the standby to serve as a universal recovery target.

Pipeline parallelism (PP) is an exception to the model's inherent symmetry: each PP stage contains a subset of layers, while the first and last stages include additional layers such as the `word_embedding_layer` in the *first stage* and the `output_layer` in the *last stage*. Despite these variations, the first and last stages remain similar in structure: the `word_embedding_layer` and `output_layer` share the same shape (e.g., weight tying). The middle stages consist of repeated transformer blocks and are kept symmetric for optimal performance . In total, PP introduces at most three distinct role types—the first stage, the middle stages, and the last stage—yet the overall partitioning remains highly symmetric.

6.2 General Warm-Up Procedure

The symmetric design allows the standby machine to warm up and recover any role in the system. Figure 7 illustrates the warm-up procedure. To prepare it, the standby runs warm-up iterations for initialization (§4). Without pipeline parallelism (PP), a single iteration is sufficient because all machines share identical roles. When PP is enabled, the standby sequentially and independently runs up to three warm-up iterations ①②③, each corresponding to a different role—the *first stage*, *last stage*, and *middle stage*. Running each role during warm-up concretely initializes all role-specific components, such as JIT-compiled fused kernels.

At this stage, the general standby remains in Phase 1 of the CCL setup, where inter-machine connections are not yet established. Its overall GPU memory footprint stays hundreds of megabytes below peak usage (detailed measurements

[4]Although some techniques may introduce different execution orders due to scheduling patterns (e.g., VPP), the underlying set of operators remains the same.

in §8.5). This available headroom easily accommodates the GPU-resident artifacts produced during warm-up across all role types—including JIT-compiled kernels and other compiled GPU artifacts specific to each role's layers—which add at most a few hundred kilobytes per role, never exceeding the original memory budget.

After warm-up, we retain the middle-stage role because it represents the majority of pipeline instances. If a failure occurs on a middle stage, the standby can replace it directly. For failures in the first or last stage, TrainMover updates only the small delta of layers unique to those stages. This delta is negligible because only the memory for the optimizer states and parameters of the additional layers (e.g., embedding or output layers) needs to be allocated. Other artifacts, such as all precompiled kernels, are already initialized. Even at large scale, the standby needs to run only these three role types.

Two-phase CCL preparation (§5) is also enabled by symmetry, because each machine exposes an identical intra-node and inter-node topology. For example, if a CCL group contains two separate TP groups within a machine, the same configuration must exist on all other machines. This eliminates the need for dynamic topology specialization during recovery. The only exception arises with pipeline parallelism (PP): when PP spans multiple machines, the standby must additionally establish a few connections with its neighboring stages after recovery, according to its assigned role.

Leveraging this symmetry, we can prepare a general standby for unexpected failures at the beginning of the training job in parallel, with a deployment time no greater than that of a normal initialization. The general standby achieves downtime nearly identical to that of the switching phase in an expected event, as evaluated in §8.3. A discussion of the cost-effectiveness of the general standby can be found in §9.

The number of standbys needed is small in practice (§8.2): the probability of two machines failing simultaneously is the product of their individual failure rates ($\approx 1/\text{MTTF}$), making concurrent failures extremely unlikely [18, 49, 55]. TrainMover also supports the no-standby case and still recovers via its overlapped recovery path (§7). In practice, 1–2 standbys cover all distinct stage types (first, middle, last) for PP configurations; operators who wish to overprovision can assign dedicated standbys per stage proportion, e.g., with PP degree 8 and a 1:6:1 stage ratio, allocating more standbys to the dominant middle stages.

7 Implementation

TrainMover is implemented in Python and C/C++, comprising two main components: the training-node resilience runtime and the controller. TrainMover comprises about 12K lines of new code: 1.9K LoC of Python for the controller, 7.8K LoC of Python for the Megatron-LM runtime extensions, 1.1K LoC of C++/Python for the PyTorch `c10d` extensions, and 1.5K LoC of C/C++ for the NCCL extensions. The prototype is open-sourced on GitHub [43].

Training Node Resilience Runtime and Controller. The TrainMover runtime builds on Megatron-LM with focused modifications to Megatron-LM, PyTorch, and the CCL layer to support resilient training. In Megatron-LM, it manages interruption signals and preserves CCL ordering during overlapping training and migration. In PyTorch's `c10d`, we enable multiple global CCL groups, support the CCL layer's two-phase initialization API, and add an interception layer that records, replays, or bypasses tensors to facilitate sandbox warm-up. In the CCL layer, we implement the new APIs and demonstrate them in NCCL. The controller coordinates the system by assigning roles, initiating migrations, detecting failures, and distributing topology metadata; each node's runtime maintains a control channel with the controller to keep metadata synchronized and ensure joiners, leavers, and stayers correctly configure their CCL connections.

State Synchronization. Concurrently with CCL switchover, the joiner receives the up-to-date training state before resuming. For expected events, the *leavers* transmit the latest training states—such as model parameters and optimizer states—to their corresponding *joiners*, overwriting the sandbox-warmed state and bringing the joiner fully up to date with the current training progress. For unexpected failures, the *joiners* retrieve the required states based on the redundancy configuration. If a copy is available on other *stayers*—through DP group redundancy or remote CPU memory checkpointing [50]—TrainMover directly queries the states from a *stayer* machine that maintains a copy. Otherwise, in the absence of redundancy—such as with the distributed optimizer [3] or ZeRO optimizer [37, 38]—the *joiners* fetch the data from remote storage checkpoints [12, 48]. The *leaver–joiner* mappings are one-to-one, meaning that state transmission and connection establishment for different *joiners* occur independently and in parallel—the overhead does not grow with cluster size. The transfer is feasible within the ∼20-second recovery window because modern GPU memory is bounded (e.g., 80 GB per A100), and the state is transmitted via high-bandwidth RDMA directly from a neighboring stayer's GPU or CPU memory, achieving transfer rates of hundreds of GB/s, well within the recovery budget.

8 Evaluation

Our experiments show that TrainMover scales effectively, with about 20 seconds of downtime at 1024 GPUs and over 55% less wasted GPU time at 64K GPUs compared to the best baseline (§8.2). We further analyze event downtime (§8.3) and additional use cases (§8.4), where TrainMover sustains 97% training efficiency during periodic 10-minute load rebalancing at the 1024-GPU scale. A detailed breakdown of the designs and the *zero* memory overhead are shown in §8.5.

8.1 Experiment Setup

Testbed and Model Settings. We conduct our experiments on a 1024-GPU testbed and evaluate a range of models—including GPT-5.12T MoE, GPT-175B, GPT-39.1B [25],

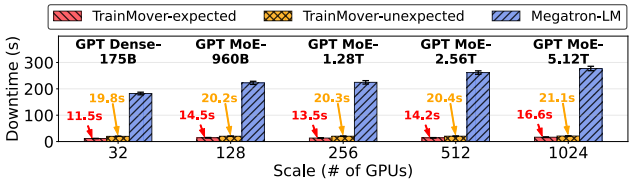

Figure 8: Downtime comparison across different GPU scales.

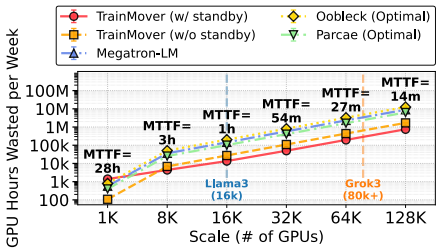

Figure 9: Projected GPU hour wasted in large scale deployment

GPT-20B [50], GPT-Medium [7], GPT-2.7B [7] and others—to cover diverse model sizes at different scales. Large-scale model configurations are summarized in Table 3. Detailed downtime analysis is additionally conducted at the 32-GPU scale to enable fair comparison with Oobleck and Parcae, which cannot scale beyond 32 GPUs (e.g., Oobleck's template construction time becomes prohibitively long at larger scales). For these experiments, models are tested with various TP, DP, and PP configurations including (TP1, PP8, DP3), (TP4, PP8, DP3), and (TP8, PP8, DP3). Default profiles are: GPT-Medium and GPT-2.7B use TP1, PP8, DP3 with a global batch size of 96 and microbatch size of 2; GPT-20B uses TP1, PP8, DP3 with the distributed optimizer, global batch size of 36, and microbatch size of 1; GPT-39.1B uses TP4, PP2, DP3 with the distributed optimizer, global batch size of 36, and microbatch size of 1. The Wikitext dataset [29] is used, following prior work [12, 19].

Baseline. Our primary baselines fall into two categories: the stop-and-restart approach, represented by Megatron-LM, and reconfiguration-based approaches, represented by Oobleck and Parcae. For expected events, since Oobleck and Parcae do not natively support live migration, we perform it by removing a node (-1) and adding a new one (+1). Parcae does not support tensor parallelism, and neither Oobleck nor Parcae supports distributed optimizers [37], as both rely on redundancy within data parallelism. We include various 32-GPU experiments because Oobleck cannot scale due to its prolonged template-generation overhead.

Metrics. We primarily use three metrics in our evaluation. The first is *downtime*, which measures the duration of interruption handling for both expected events and unexpected failures, reflecting the additional system time required to complete training per interruption. The second is *GPU hours wasted per week*, an end-to-end metric that quantifies the total GPU time lost during event handling—essentially overhead expressed as an absolute resource cost, which can be directly translated into training capital cost. The third one is *ETTR*.

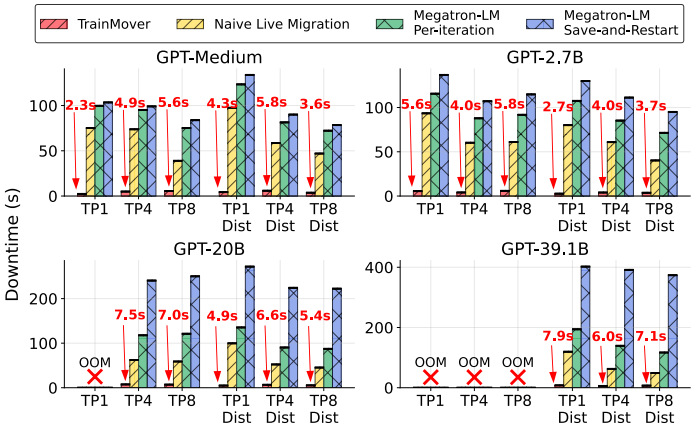

Figure 10: Migration downtime with different models and parallel settings

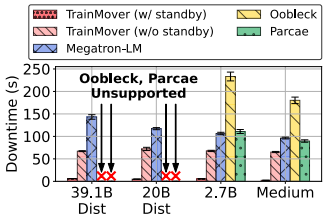

Figure 11: Unexpected failure downtime

8.2 End-to-end Experiments

TrainMover Performance at Scale. We evaluate downtime for both expected and unexpected interruptions on a large-scale testbed with up to 1024 GPUs, demonstrating TrainMover's scalability and low downtime in Figure 8. In TrainMover, migration downtime during expected events consistently remains below 20 seconds, while downtime for unexpected failures is also below 30 seconds even at the 1024-GPU scale. The downtime increases by no more than 10 seconds when scaling from 32 to 1024 GPUs, as TrainMover's design is fundamentally insensitive to job size.

The scalability benefit comes from our delta-based design. For expected events, during the switching phase, TrainMover only updates the connections between the leaver and joiner, while model states are transferred in parallel between corresponding leaver–joiner pairs. All other machines and connections remain unaffected. The small increase in downtime primarily results from the larger number of RDMA connection re-establishments required at higher scales. For unexpected failures, only TrainMover's general standby machine needs to retrieve its up-to-date state from a neighbor [49, 50]. If such a system is not present, the failed machine must recover its state from the remote checkpoint storage. Other procedures remain nearly identical to those for handling expected events, as the general standby machine performs CCL initialization and sandbox initialization in advance.

In contrast, Megatron-LM restarts the entire job during migration, requiring CCL group re-instantiation and other ini-

tialization steps across all machines, taking up to nearly 300 seconds at the 1024-GPU scale. We exclude the job rescheduling and cleanup overhead in Megatron-LM, as these depend heavily on the underlying cluster management system, and this procedure typically incurs minutes-level latency (Table 1). This is consistent with the restart cost breakdown in §2, where framework initialization dominates and scales proportionally with job size.

Projected GPU-Hour Savings at Production Scale. In practice, large-scale training jobs often run on tens of thousands of GPUs. We project GPU-hour waste per week by extrapolating from our 1K-GPU measurements to production scales of up to 128K GPUs [49, 54] (Figure 9), using MTTF values from Meta [21] and a 1:8.9 expected-to-unexpected failure ratio [17]. Each system's downtime is held constant at its measured value: TrainMover uses 1024-GPU measurements, while Oobleck and Parcae use 32-GPU measurements (§8.3) since they cannot scale beyond 32 GPUs. Using 32-GPU measurements gives Oobleck and Parcae an optimistic advantage, as downtime typically grows with scale; for TrainMover, holding the 1024-GPU downtime constant is justified by its delta-based design, which only updates leaver–joiner connections and is scale-insensitive. We also add a 2-minute infrastructure rescheduling cost to all systems from the 8192-GPU measurements (Table 1), which is conservative as this overhead also increases with scale.

Two versions of TrainMover are included for comparison. The first, TrainMover (w/ standby), pre-allocates a standby machine, which is counted as a reserved resource and considered wasted if unused. We use one standby machine as a backup because simultaneous multi-machine failures are rare [18, 49, 55]. The second, TrainMover (w/o standby), uses all GPUs without a dedicated standby. Without a standby machine, the handling downtime for unexpected failures increases, while expected events remain unaffected because their handling does not require standby resources. This configuration represents the case where all GPUs are dedicated to training with no reserved standby, and only TrainMover's recovery path optimizations are applied upon failure. It also characterizes the performance when the pool of reserved standby machines is exhausted.

At the 1K scale in Figure 9, where failures are infrequent, the wasted GPU hours across all systems are similar. In fact, TrainMover (w/ standby) incurs slightly higher waste than Oobleck and Parcae, as the standby GPU remains idle during training. However, as scale increases to production levels—for example, at 8K GPUs where interruptions become more frequent (MTTF = 3h)—TrainMover (w/ standby) achieves the lowest GPU-hour waste, reducing waste by 35.91% over TrainMover (w/o standby) and by 82.77% over Parcae. Beyond 8K GPUs, TrainMover (w/ standby) continues to deliver the highest overall efficiency, as the marginal benefit of adding more training GPUs diminishes while failures become more frequent and restarts take longer. At the 128K scale, TrainMover (w/ standby) further reduces weekly GPU-hour waste by 55% compared to TrainMover w/o standby and by 88% compared to Parcae.

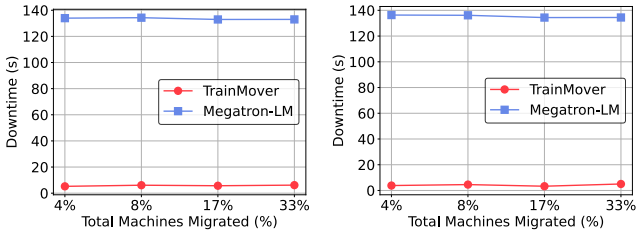
8.3 Downtime Analysis

Fast Recovery from Unexpected Failures. We evaluate TrainMover's downtime under unexpected failures in two settings: with a general standby machine and without one, as shown in Figure 11. Since Oobleck cannot scale to 1024 GPUs because of its prolonged template-generation time, we run other systems at the same 32-GPU scale for a fair comparison using the 32-GPU model settings (§8.1). For the GPT-Medium and GPT-2.7B models without the distributed optimizer enabled, TrainMover —despite having no standby—still outperforms all baselines. This is because TrainMover accelerates the initialization procedure by overlapping CCL instantiation, warm-up, framework initialization, and state transmission even when a general standby is not present. In contrast, Megatron-LM executes all components sequentially after rebooting, resulting in up to 3.48× longer downtime than TrainMover. Parcae and Oobleck, although enabling direct state transfer to reduce checkpoint loading time, still incur high restart overheads from initializing framework components, reinstantiating CCL groups, and performing warm-up. These steps lead to higher downtime than checkpoint-based approaches do.

For the GPT-39.1B and GPT-20B models, where the distributed optimizer (DO) must be enabled to fit the models into GPU memory, Oobleck and Parcae cannot be used because their redundancy assumption is eliminated. TrainMover (no standby) achieves 2.1× and 1.6× shorter downtime than Megatron-LM for the GPT-39.1B and GPT-20B models, respectively. This overlapping advantage becomes more significant as model sizes grow. In the case where a standby machine is available, TrainMover achieves performance nearly identical to live migration, with less than 10 seconds of downtime across all models.

Fast Migration on Expected Events. Migration occurs when an expected event takes place. We present the migration downtime comparison in Figure 10. In addition to the *Megatron-LM per-iteration* checkpoint baseline, which assumes that checkpoint saving is cost-free and can always be overlapped, we include two additional baselines for a comprehensive comparison of expected-event migrations. *Megatron-LM Save-and-Restart* is a more practical baseline. Before shutdown, training stops and waits for the checkpoint to be saved. *Naive live migration* directly transfers states from the leaver to the joiner without using the initialization warm-up design (§4) or the two-phase CCL setup (§5), and without requiring all machines to pull states from remote storage.

Megatron-LM Save-and-Restart performs the worst among all baselines due to significant checkpoint-saving overhead, which increases with model size, reaching approximately 400 seconds for the GPT-39.1B model. *Naive live migration* outperforms Megatron-LM Per-iteration by enabling direct trans-



(a) GPT-20B **(b)** GPT-39.1B

Figure 12: Downtime varying migration scale

fer of model states from migration leaver machines to migration joiner machines. This optimization achieves up to a 1.74× speedup on the GPT-39.1B model with TP4 and DO (distributed optimizer) enabled.

TrainMover delivers the best performance by overlapping CCL setup and warm-up processes with the non-critical path. This design consistently achieves second-level downtime and provides at least a 15× speedup compared to the *Megatron-LM Save-and-Restart* baseline across all models. Both TrainMover and the naive system maintain zero additional memory overhead during migration.

Migrating Multiple Machines at Once. Migrating multiple machines is essential for rapid large-scale operations like rebalancing and maintenance [2]. Figures 12a and 12b show the performance of GPT-20B and GPT-39.1B during migrations of 4% to 33% of the total GPUs.

Both models maintain stable downtime overhead of up to 6.15 seconds across both GPT-20B and GPT-39.1B. This consistency stems from TrainMover's design, where each migration leaver and joiner operates in parallel, performing one-to-one data transfers. This approach ensures constant overhead, preserving efficiency regardless of migration scale.

In contrast, checkpointing systems like Megatron-LM are highly inefficient. Even migrating just 4% of machines forces all machines to reboot and retrieve checkpoints from remote storage, causing 138 seconds of overhead.

8.4 Use Cases

We also present other use cases of TrainMover. Note that none of these use cases require hot standby machines.

Handling Stragglers. We evaluate the use case of handling stragglers, as shown in Figure 13. In this experiment, we inject a straggler by slowing down one GPU by 20% [51] at the 75th iteration of a 100-iteration, 1024-GPU job. Figure 13 reports the training efficiency and visualizes the training process. While this setup represents a specific case where the straggler appears at iteration 75, Figure 14 extends the analysis to all possible iterations (1st–100th), showing the full spectrum of when stragglers occur.

Alongside the previously evaluated *Per-iteration* and *Save-and-Restart* approaches, we include two additional strategies for broader comparison: deferred checkpointing and restart with progress loss. *Save-and-Restart* saves a checkpoint immediately and restarts training when a straggler occurs. *Defer-50/100* continues training and defers restarting

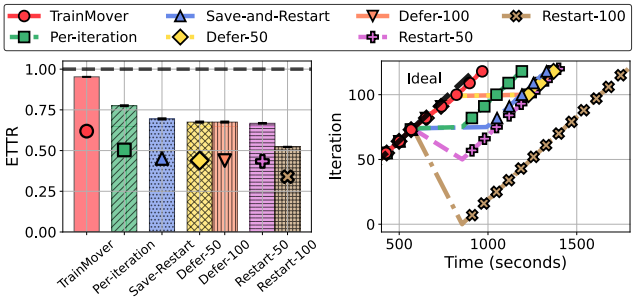


Figure 13: GPT 5.12T MoE model with 20% slowdown starting at the 75th iteration

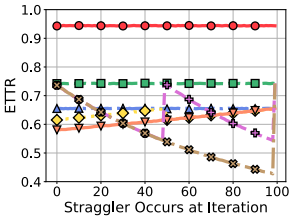

Figure 14: Straggler occurring at different iterations

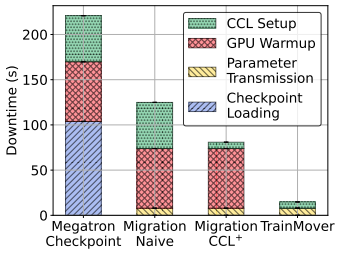

Figure 15: Design Breakdown

until the next scheduled checkpoint (e.g., every 50 or 100 iterations). *Restart-50/100* restarts training immediately, losing progress based on the most recent checkpoint at iteration 50 or 100.

As shown in Figure 13, TrainMover loses only 4.7% of training efficiency—the lowest among all approaches. During the slowdown period, TrainMover continues training while performing migration in parallel, minimizing downtime when switching from the straggler machine to a healthy one.

Defer-type baselines suffer reduced performance until the next checkpoint, restarting only afterward and thus causing delays. Restart-type baselines avoid checkpoint-saving overhead but lose progress proportional to the checkpoint interval, leading to up to 43% lower efficiency than TrainMover.

Figure 14 further illustrates the full performance spectrum across all possible straggler injection points. TrainMover consistently outperforms all baselines, maintaining high efficiency without relying on specific checkpointing frequencies. Remarkably, it even surpasses the ideal per-iteration checkpointing system, improving training efficiency by 22.8% in all cases. Restart-type methods peak immediately after a checkpoint when progress loss is minimal, but their performance deteriorates as the distance from the last checkpoint increases.

Rebalancing / Maintenance. TrainMover handles machine changes swiftly, making it suitable for rebalancing or maintenance that requires frequent GPU or network updates. The upper part of Table 16 compares the training efficiency of TrainMover and Megatron-LM per-iteration checkpointing across scales from 128 to 1024 GPUs. TrainMover consistently maintains an ETTR of above 0.97 across all scales, showing that rebalancing remains effective even as cluster size grows. In contrast, Megatron-LM's ETTR stays low under high rebalancing frequency, dropping to 0.42 at 1024

Scaling up to 1024 GPUs.

GPUs due to the increasing cost of repeated full-job restarts.

We also include comparisons with Parcae and Oobleck at the 32-GPU scale covering various model sizes and training parameters in the lower part of the table. During machine changes, online reconfiguration systems like Oobleck sometimes perform worse than the checkpointing-based Megatron-LM. This is because reconfiguration involves starting new machines, tearing down and reestablishing CCL groups, and performing warm-up procedures; collectively, these steps save little time compared to checkpoint-based systems and perform even worse when the system is not well-engineered. For instance, with the Oobleck 20B TP8 model, reconfiguration delays result in negligible training progress when rebalancing every 10 minutes. Additionally, Oobleck and Parcae lack support for distributed optimizers, and Parcae also does not support tensor parallelism, limiting their scalability for larger models.

TrainMover delivers the best performance among all approaches, maintaining a training efficiency of 0.99 across all models with and without the distributed optimizer. In comparison, the efficiency drops to 0.68 when using Megatron-LM per-iteration checkpointing. This table highlights that even in high-frequency (10-minute) rebalancing scenarios, TrainMover loses no more than 0.1% of performance, making it a robust and efficient solution.

8.5 TrainMover Key Designs

Design Breakdown. We break down our designs and evaluate their incremental impact on system performance in Figure 15 with the GPT-5.12T MoE model. In this setup, Megatron-LM's total downtime is approximately 221 seconds, with checkpoint loading, GPU warmup, and CCL setup times accounting for 47%, 30%, and 23% of the total, respectively.

Migration Naive represents a naive migration system that excludes the two-layer CCL designs and lazy initialization designs. Unlike Megatron-LM, which loads checkpoints from remote storage, it retrieves parameters directly from the leaver to the joiner. This approach eliminates checkpoint loading time, reducing the total downtime by a factor of 1.8×. The

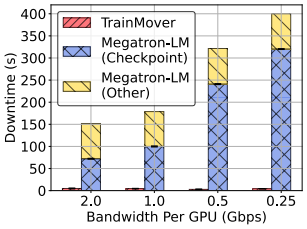

Figure 17: Downtime with different bandwidth (GPT-20B)

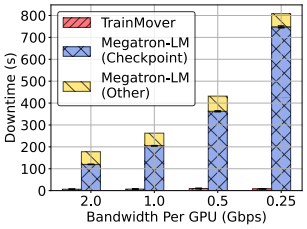

Figure 18: Downtime with different bandwidth per GPU (GPT-39.1B)

benefit becomes more pronounced as model sizes increase.

Migration CCL$^+$ builds on the naive migration baseline by introducing the CCL two-layer designs. This design shortens the critical path, leaving only the second stage of CCL initialization on it. CCL time decreases from 51 seconds to 7 seconds. This means Phase 1 absorbs ∼44 seconds off the critical path, leaving only Phase 2's 7 seconds as downtime—an 86% reduction in CCL-related recovery time.

The full system, *TrainMover*, further integrates the self-detached warmup design, effectively eliminating GPU warmup time. This enables training to resume immediately after migration, reducing downtime to 16 seconds.

TrainMover eliminates Network Bottleneck. TrainMover significantly alleviates network bandwidth bottlenecks during machine changes. The Llama-3 paper [17] reports a storage system bandwidth ranging from 2 TB/s to 7 TB/s while serving approximately 7,500 machines, translating to an effective bandwidth of 0.267 GB/s to 0.933 GB/s per machine. In this experiment, we evaluate checkpointing overhead under bandwidth ranging from 0.25 GB/s to 2 GB/s per GPU, encompassing the bandwidth range reported by Llama-3.

In both GPT-20B (Figure 17) and GPT-39.1B (Figure 18) setups, TrainMover maintains stable overhead of 6–9 seconds, due to parallel one-to-one state transfers between migration leaver and joiner. By contrast, Megatron-LM, which requires all GPUs to pull checkpoints from remote storage, incurs increasing overhead as bandwidth decreases and model size grows. Specifically, checkpoint loading overhead reaches 320 seconds for GPT-20B and 750 seconds for GPT-39.1B at 0.25 GB/s per GPU.

Zero Memory Overhead Workflow. Figure 19 illustrates the network (top) and memory (bottom) usage during a migration in TrainMover. A key step in the process is state transfer. As shown in the network breakdown, the leaver sends traffic to the joiner around the 530th second, resulting in high Rx bandwidth utilization on the joiner. However, model transfer is not without cost. Each leaver–joiner pair requires a new CCL group for state delivery, which consumes GPU memory. To achieve zero memory overhead, TrainMover implements specific optimizations during state transmission:

The migration leaver does not need to continue training after the migration is complete; around the 530th second, it can free up and repurpose the pre-allocated GPU gradient buffer for use as the CCL transmission channel. On the mi-

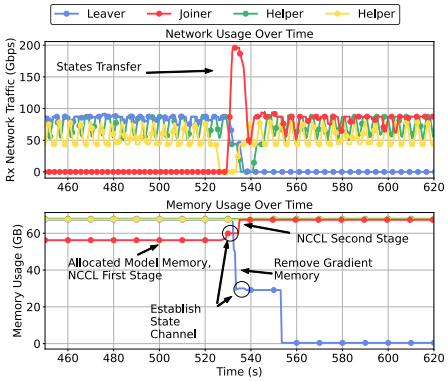

Figure 19: Network traffic and memory usage timeline during Migration

gration joiner, during the first stage of CCL initialization, inter-machine connections are not fully established, creating temporary memory headroom around the 530th second. This allows the state transfer channel to operate without exceeding memory limits. Once the transfer is complete, the channel is immediately destroyed, freeing memory before the second stage of CCL initialization. This process ensures zero memory overhead during migration.

A detailed analysis of CCL design choices is provided in Appendix A.

9 Related Work and Discussion

Economics of Standby. At massive scales, simply adding more GPUs yields marginal returns, whereas leveraging a standby machine can dramatically reduce downtime and provide far more cost-effective gains. For instance, at the 32K-GPU scale in Figure 2, using a single standby machine to shorten recovery from 4.45 minutes to 20 seconds delivers a benefit equivalent to adding roughly 2,400 GPUs (300 machines!) under ideal linear scaling. In other words, the acceleration provided by one or a few standby machines' fast recovery is comparable to provisioning thousands of additional GPUs—making standby resources vastly more economical.

CCL Reconfiguration and Generality. MCCS [52] enables runtime changes to CCL topologies but lacks dynamic membership. HotSpa [15] hides reconfiguration overhead by reusing CCL groups, at the cost of added GPU-memory overhead. NCCLX [41] speeds up CCL initialization by reducing bootstrap costs and adaptively configuring channels. In contrast, TrainMover supports dynamic CCL membership without GPU memory overhead and moves all non-critical initialization off the critical setup path. This two-stage setup is general and applies to systems that frequently reconfigure communication patterns, including reconfiguration frameworks and inference autoschedulers [12, 14, 15, 19, 23, 26, 41, 44, 52, 56].

Scalability. TrainMover scales to very large clusters. Transitional downtime comes from only two steps: inter-connection establishment and state transfer. State transfer is one-to-one—either from the leaver to the joiner during expected failures or from the joiner pulling from a checkpoint during unexpected failures—so its cost is effectively constant and the transfer size is bounded by the GPU size. Inter-connection establishment affects only the leaver's neighbors, which update their channels to the joiner. Neither step requires global coordination, enabling TrainMover to scale efficiently even in large production clusters.

GPU-granularity Migration. TrainMover's implementation supports GPU-granularity migration. The training framework can still benefit from minimal downtime and zero memory overhead. However, it forgoes the intra-machine optimizations introduced in §4.3 and pays extra storage overhead.

Heterogeneity and Warm-up Coverage. Heterogeneous or multimodal models may break symmetry assumptions or introduce non-static training paths. In practice, even if certain layer-specific or data-dependent execution paths are not fully covered, their impact is limited because the vast majority of initialization steps (e.g., data-loader setup, CUDA context creation, memory allocation, and runtime setup) remain shared across execution paths and are already covered by the warm-up procedure. These shared components dominate initialization time and are largely independent of specific layer behaviors. Extending TrainMover to fully support such dynamism remains future work.

Snapshot-based Warm Start. Recent advances such as CUDA checkpoint/restore (e.g., cuda-checkpoint [32] combined with CRIU [33]) provide an emerging mechanism for capturing and restoring GPU runtime state, offering a potential solution for warm-starting initialization—analogous to cold-start mitigation in serverless computing [5, 11]. These techniques enable preserving device memory and CUDA contexts, and are effective when the target role is known. TrainMover targets a different goal: supporting a *general standby* that can recover *any* role without prior knowledge. In large-scale training, different ranks (e.g., pipeline stages) may follow different execution paths. Supporting this with snapshots would require maintaining multiple role-specific snapshots or adapting them at runtime, increasing system complexity. In contrast, TrainMover uses record–replay to enable role-agnostic preparation without pre-defined artifacts.

10 Conclusion

We presented TrainMover, a resilient runtime that handles both expected and unexpected interruptions with minimal downtime and zero memory overhead. TrainMover leverages two-phase communication setup, communication-free sandboxed warmup, and general standby to enable rapid machine replacement. Our evaluation shows that TrainMover achieves a 20-second downtime at the 1K-GPU scale and wastes 55% fewer GPU-hours at 64K GPUs, enabling interruption-tolerant large-scale training.

Abstract

Modern GPU workloads increasingly rely on dynamic and fine-grained memory allocation, yet GPU memory management remains CPU-centric. In current GPU runtimes, allocation metadata updates, page-table construction, translation-state propagation, and TLB shootdowns are largely serialized through the host control path, introducing substantial latency. We present MOONBRIGHT, a GPU memory allocator that enables device-side page-table materialization and deferred TLB coherence on commodity GPUs. MOONBRIGHT keeps validation and allocation metadata on the host, but moves bulk page-table construction to the GPU, turning translation updates into data-parallel device-memory operations. To avoid costly TLB shootdowns on the common path, MOONBRIGHT assigns fresh virtual addresses to new mappings, ensuring that no stale same-address TLB entries can exist. Our evaluation shows that MOONBRIGHT reduces allocation latency, improves LLM inference performance, and mitigates allocator-level external fragmentation across diverse workloads. Unlike application-specific memory managers, MOONBRIGHT requires no GPU hardware modifications and runs on commodity NVIDIA and AMD GPUs with software-only changes. MOONBRIGHT is publicly available at https://github.com/MoonBright-project.

1 Introduction

Memory management has long been a core systems discipline, and decades of CPU hardware-software co-design have produced highly optimized virtual-memory systems and allocator designs, including PTMalloc [15], JEMalloc [14], TCMalloc [20], and others [21, 24, 27, 28].

Modern GPUs now host a diverse spectrum of workloads, spanning large-scale DL models [9, 13, 17, 63], data analytics [34, 42], scientific simulations [2, 3, 55, 69], graph processing [31, 38, 67, 75], and emerging general-purpose computations [54, 60]. GPUs such as NVIDIA B200 [40] have reached the thousand-TFLOPS scale, allowing many CUDA kernels to complete within only a few microseconds. As GPU execution becomes faster and more fine-grained, CPU-driven memory allocation increasingly falls on the critical path [23], turning frequent allocation into a major bottleneck.

Although modern GPUs include hardware MMUs for address translation, GPU memory management remains largely CPU-centric. The host maintains the authoritative page tables, and allocation, deallocation, and remapping requests are routed through the driver, which serializes translation updates and propagates them to the GPU. When mappings are changed or reused, the host is also responsible for enforcing device-side TLB coherence, often through costly TLB shootdowns. Consequently, allocation calls such as `cudaMalloc` incur high control-path latency.

Existing systems mitigate allocation overhead primarily through pool-based allocation. Framework allocators such as TensorFlow's BFC allocator [1] and PyTorch's caching allocator [43], as well as CUDA's stream-ordered allocator, reduce calls into the driver by caching and reusing previously allocated memory. While effective at reducing allocation latency, these designs still rely on reuse within pre-allocated memory regions rather than addressing the CPU-centric control path itself. As a result, they inherit the central weakness of pool-based allocation: fragmentation can accumulate when allocation lifetimes and sizes do not match the allocator's layout and reuse policies.
